Anaerobic infections are uncommon and most likely result from penetrating or necrotizing wounds of the skull bones. Such infections in horses should be treated with metronidazole (15 to 25 mg/kg PO q6h)[1]; penicillin or ampicillin would be appropriate therapy in food-producing animals. Treatment of meningitis caused by *Chlamydophila* or *Mycoplasma* spp. has not been critically investigated in large animals, but administration of oxytetracycline, doxycycline, fluoroquinolones, or florfenicol can be considered. In general, treatment for 2 weeks is considered to be an empiric standard[3]; however, if aminoglycosides are included in the treatment regimen, careful patient monitoring for nephrotoxicosis is recommended.

Adjunct therapy for bacterial meningitis includes analgesics/antiinflammatory/antipyretic agents, fluid therapy, anticonvulsant therapy for seizures, protection against self-induced trauma (including corneal trauma), and nutritional support. Maintenance of euvolemia and euglycemia is considered vital to success.[10] Hypoxemia and hypercapnea are deleterious and should be avoided whenever possible; mechanical ventilation of severely affected patients may be necessary. Osmotic diuretics such as mannitol or glycerol should be administered if CSF pressure, neurologic examination, and/or fundic examination are suggestive of cerebral edema. Use of narcotic agents for analgesia should be weighed against their potential to increase cerebral blood flow and therefore intracranial pressure. Although outcomes vary according to the causative organism, concurrent administration of dexamethasone may improve clinical outcome, although this remains controversial.[10] Nonsteroidal anti-inflammatory agents may be a preferred choice if avoidance of dexamethasone-related complications (e.g., laminitis) is a concern. Owing to limited food intake and the pain associated with this condition, the potential for gastric ulceration is real and prophylactic anti-ulcer medication should be considered. Treatments for seizures, cerebral edema, and inflammation are listed in Table 35-3.[13-17] The maximum desirable trough phenobarbital concentration is 40 μg/mL, and the minimum therapeutic level is 15 μg/mL.[14,15] After initial sedation, long-term control of convulsions in horses can be maintained by oral phenytoin (2.8 to 16 mg/kg three times daily) or IV phenobarbital (11 mg/kg once daily).[15-17] The trough plasma concentration of diphenylhydantoin should also be measured repeatedly during continuous drug therapy; the maximum desirable trough level is 10 to 20 μg/mL,[16] and optimum plasma concentration is 5 to 10 μg/kg. In critical care settings, constant rate infusions of selected anticonvulsive drugs and drug combinations can be considered. The concentration of plasma immunoglobulins should be measured in neonatal patients with bacterial meningitis, and plasma should be administered if those values are subnormal for the species.

Prognosis A guarded prognosis at best is warranted for most cases of bacterial meningitis. In a retrospective study of 32 calves with septic meningitis, only 5 (16%) survived until discharge and all 5 animals subsequently died or were euthanized.[2] In a recent case series from Spain, two of seven treated foals survived to discharge.[18] The survival rate may be higher for adult horses.[9] Early detection is considered pivotal for successful treatment; therefore a poor prognosis is warranted for animals with severe neurologic impairment. However, because concurrent metabolic derangements (e.g., hypoglycemia) may cloud the clinical picture, aggressive antimicrobial treatment including achievement of euvolemia, euglycemia, control of convulsions (if present), and normalization of acid-base, blood gas, and electrolyte status may be attempted for valuable animals, with the prognosis refined on the basis of response to therapy.

Pituitary Abscesses

Pituitary abscesses occur sporadically in ruminants and are rare in horses. *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) is the most frequently isolated bacterium, but *Corynebacterium pseudotuberculosis,* as well as *Streptococcus, Staphylococcus, Actinomyces, Bacteroides, Fusobacterium, Acinetobacter, Pasteurella, Pseudomonas,* and *Actinobacillus* spp. have occasionally been isolated.[1]

The clinical signs of pituitary abscess occur suddenly and progress for 7 to 10 days before the affected animal dies.[1] The initial signs are ataxia, head-neck extension, basewide stance, inappetence, depression, head pressing, and recumbency.[1-3] Most affected animals have asymmetric deficits of one or more cranial nerves, resulting in dysphagia, blindness, anisocoria, absent pupillary light reflexes, mydriasis, and/or a flaccid tongue. Nystagmus, facial paralysis, facial hypalgesia, ventrolateral strabismus, or head tilt may also be seen.[1,4] Approximately half of the affected animals have bradycardia (pulse rate < 60 beats/min).

The CSF protein concentration in affected cattle ranges from 70 to 502 mg/dL, and nucleated cell counts range from 6 to 12,640/μL (6% to 84% neutrophils).[1] The antemortem diagnosis is based on the observation of bradycardia, blindness, and nonresponsive pupils in conjunction with evidence of pyogenic inflammation in the CSF.

Some authors have postulated that the infectious agent gains entry to the sella turcica hematogenously and then localizes in the rete mirabile, which is the complex of blood vessels encircling the pituitary gland.[1] A direct relationship exists between the complexity of the rete mirabile and the incidence of pituitary abscessation in different mammals. The horse and dog lack a well-defined rete and correspondingly have a low risk for developing a pituitary abscess, whereas the situation is reversed in cattle. One study reported that 55% of cattle with a pituitary abscess had pyogenic foci in other organ systems or in the sinuses, teeth, or soft tissues of the face,[1] indicating that the abscesses may result from a retrograde bacterial embolization through branches of the facial veins.

Ataxia is caused by interruption of extrapyramidal motor nuclei in the brainstem by the expanding abscess. Extension of the abscess into the communicating retroorbital rete may result in exophthalmos. Extradural extension of the abscess along the brainstem causes loss of the cranial nerve function. Bradycardia may be caused by interference with diencephalic cardioacceleratory centers.

Animals ranging in age from 9 months to 12 years have been affected, but most cases occur between 2 and 5 years of age.[5] Pituitary abscess appears to have a slightly increased prevalence in castrated and intact males.[1] Pituitary abscess has been related to infections that develop in bulls after insertion of a nose ring.[3] Prophylactic administration of penicillin and attention to aseptic procedure during insertion of the ring can reduce disease incidence. Because of the high mortality rate associated with pituitary abscesses, treatment is not usually attempted.

Brain Abscesses

Streptococcus equi is the most common cause of brain abscesses in horses, likely owing to the occurrence of strangles in this species.[1] *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) is a common cause of brain abscesses in cattle by means of extension of a sinus infection through the calvarium. Brain infections of cattle with *Bacteroides* species have also been reported.[2] The neurologic dysfunction caused by brain abscesses typically has a slower onset and is more commonly asymmetric than that caused by meningitis. However, acute onset of signs can also occur.[1] Forebrain abscesses

VetBooks.ir

compress the cerebral cortex, causing a caudal displacement of the brain and functional loss of one or both occipital lobes, which may result in cortical blindness in one or both eyes. Because of the high proportion of crossed fibers in the optic nerve decussation, unilateral cortical abscesses may result in vision loss in the contralateral eye. Increased CNS compression by the mass may induce ipsilateral mydriasis caused by interference with the oculomotor nerve. Further increases in the size of the lesion cause more generalized cortical signs including blindness, propulsive walking, circling, head tilt (toward the lesion side), depression, coma, head pressing, or sudden unexplained mania (Fig. 35-8). Abscesses at the base of the brain may cause additional abnormalities of cranial nerve function including vestibular disease (Fig. 35-9). Ophthalmoscopic examination may reveal papilledema in the ipsilateral eye.[2] Advanced imaging studies such as CT and MRI may be helpful for antemortem diagnosis when these modalities are available.[3-5]

In later stages, animals may assume lateral recumbency and display a decerebrate posture characterized by hypertonicity, hyperreflexia, opisthotonos, coma, and convulsions. At this stage the disease is difficult to differentiate from septic meningitis. CSF findings in animals with brain abscesses are variable, ranging from normal to very abnormal, with high protein concentration and marked pleiocytosis.[1,6,5] Treatment of brain abscess includes antibiotics and supportive care (see Meningitis earlier in this chapter). In one clinical report a brain abscess in a horse was localized with CT scanning and successfully drained through a craniotomy.[7]

FIG. 35-8 Head pressing in a pony caused an abscess in the right cerebral hemisphere. *(Courtesy Dr. R.H. Whitlock.)*

FIG. 35-9 Severely obtunded bull that developed a brain abscess from extension of a frontal sinusitis. The abscess extended to the base of the brainstem and affected cranial nerves V and XII, resulting in dropped jaw and tongue paralysis. The bull was also severely depressed, blind, and ataxic and had facial analgesia.

Nervous Coccidiosis

Definition and Etiology Nervous coccidiosis is a neurologic syndrome of calves and yearling cattle, sheep, and goats that is associated with enteric infections by *Eimeria* spp. The condition is most often seen in western Canada and the northwestern United States and is particularly prevalent in feedlots. The incidence of nervous coccidiosis is highest in the winter months. In contrast to enteric coccidiosis, mortality from nervous coccidiosis is relatively high, approximately 70%.[1] The pathogenesis of the encephalopathy may be related to the elaboration of a labile neurotoxin by the parasite.[2] The clinical signs and history of nervous coccidiosis are similar to those of other neurologic diseases that affect the function of the cerebral cortex.

Clinical Signs The onset of the nervous system signs is usually preceded by diarrhea, tenesmus, and hematochezia. Some calves with severe diarrhea develop prolapsed rectums. Initial signs of CNS dysfunction include depression, incoordination, twitching, and hyperesthesia. As the clinical signs worsen, the animal becomes recumbent and develops numerous cerebrocortical signs including opisthotonos, periodic tremors, horizontal nystagmus, frothing at the mouth, bellowing, snapping eyelids, and muscular fasciculations.[3-6] Blindness is rarely seen. Stimulation of the patient may precipitate a tonic-clonic seizure.[3-6] The animal may die after 1 to 5 days of encephalopathy. Convulsive calves may regain consciousness but relapse days later.[7]

Clinical Pathology Fecal flotations from the patient and herdmates show a large burden of coccidial oocysts. Fecal egg counts of affected animals may range from 5000 to 4 million/g. To exclude the possibility of other neurologic diseases, blood should be collected for measurement of electrolytes (calcium, magnesium, potassium). The acid-base status, plasma glucose, and blood lead concentrations should be measured. Acute meningitis and salt poisoning may be ruled out by CSF analysis. The plasma vitamin A concentration should be measured in any animal that has not had exposure to green forage. Polioencephalomalacia, ethylene glycol poisoning, lead poisoning, rabies, pseudorabies, petroleum distillate poisoning, and clostridial enterotoxemia should be considered as possible differential diagnoses.

Pathophysiology The pathogenesis of the encephalopathy is unknown. The nervous form of coccidiosis cannot be transmitted to mice by injection of CSF from infected calves; however, a heat-labile neurotoxin has been identified in the serum of calves with nervous coccidiosis.[2] The coccidia do not directly invade the CNS.

Epidemiology Nervous coccidiosis occurs most frequently in feeder cattle, but dairy and pastured beef calves, lambs, and kids may also be affected on occasion. In one survey, the prevalence of nervous coccidiosis was 0.3% of the calves that were affected with the intestinal form of the disease. Nevertheless, outbreaks with a large percentage of calves developing CNS disease have been reported.[3] In western Canada, nervous system signs have been reported in 21% of

herd outbreaks of intestinal coccidiosis.[8] Most cases occur in mid to late winter.

Necropsy Findings No macroscopic lesions are seen in the CNS of calves with nervous coccidiosis. The microscopic lesions of the brain are mild and nonspecific and include edema, congestion, and occasional shrunken neurons. Parasitic invasion of the ileum, cecum, and colon results in lesions in these organs.

Treatment and Prevention Treatment should include supportive fluid, macromineral, and electrolyte therapy. The coccidial infection should be treated with sulfadimethoxine (55 mg/kg PO or IV, followed by 27.5 mg/kg PO or IV q24h). Alternatively, sulfamethazine (110 mg/kg PO q24h for 5 days, or 1 lb/100 gallons of drinking water) or amprolium (50 mg/kg/day PO for 7 days) can be administered. Treatment administered via drinking water will only be effective if animals are willing and able to drink. Diazepam, sodium pentobarbital, or phenobarbital may be used to control tonic-clonic convulsions (see Table 35-3). The response to treatment is poor, and the case-fatality rate can be high in calves that develop tonic-clonic seizures. Specific chemotherapeutic regimens and methods of preventing intestinal coccidiosis are described in Chapter 49.

Sporozoan Infections of Ruminants (*Sarcocystis* Infection)

Definition and Etiology The three recognized species of *Sarcocystis* that infect cattle—*S. cruzi, S. hominis,* and *S. hirsuta*—are sporozoan parasites with definitive hosts of dogs, primates, and cats, respectively.[1,2] Three other *Sarcocystis* species—*S. capricanus, S. ovicanus,* and *S. tenella*—have definitive hosts in dogs and secondary hosts in goats and sheep.[3]

When a carnivore ingests flesh from infected cattle, *Sarcocystis* cysts in muscle are broken down by digestive enzymes and motile bradyzoites are released. The bradyzoites infect the intestinal mucosal cell and differentiate into sexual stages. The gametes fuse to form an oocyst, which is shed onto pastures as sporocysts. When eaten by a ruminant, the sporocysts hatch in the proximal small bowel and penetrate into the medium-sized mesenteric arteries, where they enter endothelial cells and form sporozoites. The sporozoites then mature in three successive waves. Each wave of development spreads downstream. The third-generation merozoites finally enter the soft tissues and encyst as sarcocysts. The total period of development in the ruminant requires 10 weeks. The life cycle is completed whenever a carnivore ingests uncooked meat containing viable sarcocysts. Disease may develop in cattle during the maturation of the cyst in the muscles, at approximately 9 to 11 weeks after infection.

Clinical Signs Most cases of *Sarcocystis* infestation are asymptomatic in both definitive and secondary hosts. However, if a large number of sporocysts are ingested by a nonimmune ruminant, clinical illness may develop. Clinical signs include fever (>39.5° C [103.5° F]), anorexia, weight loss, symmetric lameness, and diarrhea. Neurologic signs include ataxia, muscular weakness, tremors, hyperexcitability, hypersalivation, recumbency, tonic-clonic seizures, leg biting, blindness, opisthotonos, and nystagmus.[4,5] Cattle may lose the hair of the tail switch ("rat tail"). Sheep may show a wool break.[1-5] Animals with chronic infections may develop edema of the limbs, poor weight gain, muscular atrophy, and pallor.[1-5] Second-trimester abortions may occur in cattle and small ruminants beginning 28 days after ingestion of infectious sporocysts.[6] The fetuses may appear either normal or autolyzed.

Clinical Pathology and Pathogenesis Serum activity of liver enzymes is increased. The packed cell volume (PCV) and the serum protein concentration are often decreased. During early infection there is a marked normocytic, normochromic anemia. The anemia is thought to be caused by extravascular hemolysis.[7]

Antibodies to solubilized freeze-dried *Sarcocystis* antigens have been detected by indirect hemagglutination, ELISA, and an agar gel immunodiffusion (AGID) test.[8-10] Immunoglobulin M (IgM) responses first occur by 3 to 4 weeks after infection and peak by 11 to 15 weeks.[8-10] The concentrations of *Sarcocystis*-specific IgG begin to rise by 5 to 6 weeks postinfection. Background titers of normal cattle range from 1:54 to 1:486, and titers of infected cattle often exceed 1:10,000.

Pathophysiology The pathogenesis of *Sarcocystis* is poorly understood. Pathologic changes in the skin and muscle and in serum chemistry are speculated to result from a combination of parasite-directed immunologic responses and diffuse vasculitis. Abortions probably occur because of luteolysis that results from the increased concentrations of prostaglandin $F_{2\alpha}$, caused by vascular infection by the parasite.[11]

Epidemiology Estimates of infection rates range from 70% to 98% in cattle in the United States.[1] When infected flesh is eaten by carnivores, the encysted sporozoites complete their life cycle.[1] The prepatent period of the parasite in the carnivore (primary host) ranges from 9 to 45 days. The primary host may shed the sporulated oocysts in the stool for as long as 2 months after a single infection. The oocysts withstand freezing but are rapidly killed by sunlight and drying.[1] Reexposure of previously infected canids results in a large fecal output of sporocysts. Ingestion of approximately 250 g of infected meat by a dog can result in an output of 100 to 6000 sporocysts per gram of feces. Wild canids are even more susceptible than domestic dogs and may serve as a major mechanism for propagation of *Sarcocystis* in range cattle in the western United States.

Pathologic Lesions The pathologic lesions of the CNS are similar for all species of sporozoans; they include granulomatous meningoencephalomyelitis, focal malacia, perivascular cuffing, neuronal degeneration, and gliosis. The changes are generally most severe in the cerebellum and midbrain but can occur anywhere in the CNS including the spinal cord. The pathologic diagnosis is based on finding meronts and merozoites in the affected sections of neural tissue.[12,13]

Pathologic lesions elsewhere include hemorrhages on the sclera, serous surfaces, and muscles; fluid in the body cavities; and lymphadenopathy. The muscles have alternating light and dark stripes. Macroscopic changes may not be evident in animals with chronic sarcocystosis. If changes are not evident, postmortem diagnosis is based on the finding of intravascular schizonts or intramuscular hemorrhages without significant inflammation. Ultrastructural examination of affected areas of CNS shows an intracellular colony with rosette orientation of agents in the cytoplasm of infected astrocytes.

Treatment Feeding monensin (100 mg/kg daily for 30 days) during the incubation period is prophylactic; however, the efficacy of the drug in symptomatic cattle is unknown. For maximum effectiveness, monensin should be administered continuously for 2 to 5 weeks after exposure. Treatment of infected sheep with salinomycin (1 to 2 mg/kg) has also been recommended.[14] Administration of amprolium (100 mg/kg once daily for 30 days) may reduce the severity of *Sarcocystis* infection[15] but may not completely eliminate the clinical disease.

Control The best method of controlling *Sarcocystis* infection is to protect the food supply of ruminants. Scavenging of carcasses by carnivores should also be prevented by deep burial or incineration. Feed bunks should be kept clean and raised approximately 1 to 3 feet (30 to 90 cm) off the ground. All carnivorous pets that have access to the feed or pastures should be fed cooked meat or processed dry food. In range pasture situations, prophylactic feeding of monensin or elimination of predatory or scavenging carnivores may be necessary.

Neospora Infection of Cattle (Protozoal Abortion)

Definition and Etiology A cyst-forming protozoal parasite that closely resembles *Neospora caninum* has been identified in aborted fetuses from cattle in California. The condition is predominantly a disease of dairy cattle; however, sporadic abortions can occur in beef cows.[1-3] The predominant clinical sign of a *Neospora*-like agent is a midterm to late-term abortion (3 to 8 months of gestation). Fetal lesions consist of a focal nonsuppurative necrotizing encephalitis, nonsuppurative myocarditis and myositis, and mononuclear cell infiltrates disseminated in other tissues. Occasionally, calves are mummified. (See Chapter 43 for more on abortion).

Nonfatal infection in the fetus results in neurologic dysfunction of the newborn. The clinical signs of neurologic disease vary because of the randomly widespread distribution of the parasite within the CNS. Affected calves are often unable to stand and suckle and have abnormal spinal reflexes. Flexural contractions of the forelimbs, domed skull, and torticollis have also been reported in spontaneously occurring cases.[4,5] The calves are usually born with the CNS signs, which initially are mild but then progress after birth. Pathologic lesions associated with the fetal infection include focal areas of brain discoloration, focal cavitation with cyst formation, and reduction of gray matter. Microscopic changes in the CNS of affected calves include nonsuppurative inflammation of the gray and white matter, focal lymphocytic meningitis, and neuronal necrosis. Changes in other tissues include nonsuppurative myocarditis, myositis, and hepatitis. Protozoa can be seen in microscopic sections of the stained tissues.

Neospora organisms have been isolated in pure form using cultured cells.[6] Antibodies have been produced by intubation of laboratory animals, and the agent can be identified microscopically using immunoperoxidase staining on the fixed tissues. The CSF changes in affected calves range from normal to mild pleocytosis.[7] Similar conditions have been described in sheep[8,9] and goats.[10,11]

Babesia Encephalitis (Babesiosis; Piroplasmosis; Texas Cattle Fever; Tick Fever; Redwater)

Parasitemia of cattle caused by the protozoans *Babesia bovis, Babesia argentina,* and *Babesia bigemina* is usually subclinical but results in devastating economic losses worldwide.[1] The disease is transmitted to cattle by the cattle fever ticks *Boophilus annulatus, Boophilus microplus,* and *Boophilus decoloratus.* Babesiosis occurs in the Americas, Europe, Africa, Asia, and Australia. Ticks acquire *Babesia* infection from an infected animal and then pass the agent to their offspring through the ovaries. The protozoan is passed to susceptible cattle by adult ticks and nymphs. Most infections result in intravascular and extravascular hemolysis and kidney and liver failure. See Chapter 37 for more detail.

A small proportion of *Babesia* infections cause acute encephalitis.[2,3] CNS signs begin suddenly and include fever (41.7° C [107° F]), anorexia, depression, ataxia, conscious proprioceptive deficits, mania, convulsions, and coma. Sudden death is occasionally observed. The nervous system signs are accompanied by engorgement of the scleral vessels, icterus, proteinuria, and hemoglobinuria. Encephalopathic diseases that closely resemble babesiosis include rabies, nervous coccidiosis, polioencephalomalacia, lead poisoning, bovine herpesvirus encephalitis, theileriasis, heartwater disease, salt poisoning, and chlorinated hydrocarbon toxicity.

The pathogenesis of the CNS signs is unclear; however, possible causes include capillary thrombosis and infarction, disseminated intravascular coagulation (DIC), anoxic encephalopathy, and direct invasion of the CNS by the parasite. Thrombi are disseminated throughout the CNS. Expression of parasite proteins on the surface of infected RBCs facilitates binding of RBCs to capillary endothelial cells.[4] The proclivity of *Babesia*-infected RBCs for binding to brain capillaries, particularly those in the cerebellum, is supported by the high incidence of parasite-positive RBCs found in the brains of infected cattle.[5] These findings and the observation of increased prothrombin and partial thromboplastin times, thrombocytopenia, and decreased fibrinogen concentrations suggest that DIC may play a role in the pathogenesis of the CNS disease.[6-8] Vascular blockage in the CNS, caused by severe sludging of RBCs within brain capillaries, appears to be central to the pathogenesis of neurologic disease in infected animals.[9] Studies of *Babesia ovis* in sheep, in which neurologic disease did not occur, failed to demonstrate RBC blockage of brain capillaries.[10] This further supports the belief that CNS vascular pathology is key to the development of neurologic signs in bovine babesiosis.

Babesia encephalitis is a reportable disease in the United States. Suspect cases should be referred to the appropriate state and federal authorities.

Ehrlichia (Cowdria, Rickettsia) ruminantium Infection (Heartwater Disease)

Definition and Etiology *Ehrlichia ruminantium* is a rickettsial parasite that causes a fatal encephalitis in goats, sheep, and cattle.[1] The disease originated in sub-Saharan Africa and has spread to cattle in the West Indies (Guadeloupe, Antigua, and Marie Galante).[2] *E. ruminantium* is transmitted by *Amblyomma* ticks.[3,4] Although a number of *Amblyomma* species have been implicated in the transmission of heartwater disease, the most important agents are *Amblyomma hebraeum* and *Amblyomma variegatum.* The intermittent feeding behavior of the tick makes it particularly difficult to control. *Amblyomma* ticks require three separate blood meals to complete their life cycle. The gravid females fall from the host and lay the eggs in rotting vegetation, particularly in areas where the hosts are bedded for the evening. Recently hatched larvae crawl onto foliage and await a host. After their first feed the larvae detach, molt into nymphs, and await a second host. After refeeding, the nymphs detach and molt into adults. The adults remain under rotting vegetation until they are activated by carbon dioxide exhaled by a large mammal. They are further attracted to the host by pheromones from male ticks that remain permanently attached to the host. Animals that do not have male tick infestations are poor attractants for nongravid females. Once attached to the proper host, the females seek the male, breed, feed, and fall from the host when it lies down for the evening. Ticks that feed from *Ehrlichia*-infected hosts develop ovarian infections and transmit the agent to their offspring. This serves to perpetuate the agent over successive seasons.[5]

Many species of vertebrates including snakes, iguanas, lizards, and birds are reservoirs for *E. ruminantium* because these animals may serve as the first two hosts for the *Amblyomma* tick.[6] A vector-wildlife cycle facilitates the survival of *E. ruminantium* even when domestic livestock are absent from the environment.[7]

Clinical Signs Animals with the peracute form of *E. ruminantium* infection die suddenly without premonitory signs. The acute form of the disease is characterized initially by fever, anorexia, depression, and respiratory distress. Cyanosis may also be noted. Nervous system signs, which may appear within a few days, include hyperesthesia, snapping closure of the eyelids, rapid extension of the tongue, behavioral changes, muscular fasciculations, hypermetria, ataxia, conscious proprioceptive deficits, and head pressing. As the disease progresses, the animals become recumbent and comatose. Convulsions may occur terminally. These episodes are characterized by opisthotonos, nystagmus, chewing movements, and frothing at the mouth. Mild forms of the disease are characterized by transient diarrhea, malaise, and fever, with no CNS involvement. The mortality rate in sheep ranges from 6% to 80%. Animals that recover are immune to reinfection for at least 58 months.[8] Losses may reach 60% of susceptible cattle and 40% of goats. The mortality rate among

VetBooks.ir

Angora goats may exceed 90%. Enterotoxemia caused by *Clostridium perfringens* type D is an important differential diagnosis in small ruminants.

Pathophysiology After inoculation into a ruminant, the rickettsial agent infects reticuloendothelial cells and proliferates by binary fission within membrane-bound vacuoles.[9,10] Release of the parasite from degenerating macrophages and neutrophils causes successive waves of parasitemia that infect endothelial cells and cause vasculitis.[10,11] Nervous system lesions may be caused by permeability changes in the cerebral capillaries. Changes in the other soft tissues include hydropericardium, hydrothorax, and subcutaneous edema.[1]

Except for Angora goats, which are highly susceptible to *Ehrlichia* infection, animals reared in indigenous areas usually have a high level of immunity and do not succumb to the infection.[12] Animals that survive the initial infection become asymptomatic but remain rickettsemic for as long as 223 days (sheep), 246 days (cattle), and 8 days (goats). Calves younger than 3 weeks of age, lambs younger than 8 days of age, and kids younger than 6 weeks of age are inherently resistant to *E. ruminantium* infection, regardless of the amount of colostral protection they have received.[13,14]

Necropsy Findings Pathologic changes of heartwater disease include hydropericardium, hydroperitoneum, hydrothorax, pulmonary edema, perirenal edema, hemorrhages in the pleura and peritoneum, and hemorrhagic enteritis. Microscopic changes include microgliosis, necrotizing vasculitis in the brain, hemorrhage, edema of the neuropil, microcavitation, and focal necrosis of the granular layer of the cerebellum. In clinical cases the parasite can only be definitively diagnosed by biopsy of the cerebral cortex or by collection of the cortical tissues at postmortem examination.[15] Simple techniques for collection of such biopsy specimens have been described.[16-18] Squash preparations of the biopsied material should be stained with either methyl green pyronine or Giemsa stain before microscopic examination of the tissues.[19,20]

Diagnostic tests developed to identify infected livestock include an indirect fluorescent antibody (IFA) test using infected bovine aortic endothelial cells for indicators, several ELISAs, and tests using PCR methodology.[21-24] Of these, PCR is the most accurate.

Treatment The administration of oxytetracycline (6 to 10 mg/kg IV twice daily for 3 or 4 days) may be beneficial for treatment of the early stages of the disease. The long-acting formulation of oxytetracycline is also effective, but for best results it should be administered as soon as the animal becomes febrile. Treatment is usually futile if the first dose of oxytetracycline is administered after the onset of neurologic symptoms.[25] Despite the depository nature of the long-acting formulation, two or more doses 48 hours apart are necessary to achieve a good clinical response. Cattle should be retreated if they develop a fever after the first dose has been administered.[26] Animals with nervous system signs frequently die despite intensive antibiotic therapy. Angora goats are highly susceptible to heartwater disease. In South Africa, Angora producers routinely treat all animals every 14 days during the summer with oxytetracycline. Animals that remain essentially tick free never develop adequate immunity to the *Ehrlichia* organism.

A small degree of tick infestation and exposure of the animals to low numbers of the agent, combined with judicious oxytetracycline therapy, would seem to favor the development of immunity over time.[27] One method of immunization uses a controlled infection of a virulent strain (Onderstepoort Ball 3 strain) of the *Ehrlichia* organism and treatment with long-acting oxytetracycline (800 mg per adult goat) at the beginning of clinical disease and 10 days later.[28] Vaccination with this isolate produces immunity against exposure to homologous but not heterologous strains of *Ehrlichia*.[29-31] More recent strategies have included vaccines using inactivated organisms, live attenuated organisms, and fragments of *E. ruminantium* nucleic acid, but none has had great success.[32-36]

Prevention and Control Control of ticks on cattle pastures is the most desirable means of controlling heartwater disease. Complete eradication of the ticks in most regions of sub-Saharan Africa is neither possible nor desirable. Cattle that are reared in areas where *Ehrlichia* infection is endemic develop acquired immunity over time. In these areas the ticks should be sufficiently abundant to permit a low level of heartwater infections in most cattle yet not so populous as to introduce severe, overwhelming infections. Integrated methods for tick control have been recommended. These include exclusion of wildlife from paddocks, artificial induction of host resistance to ticks, application of insecticidal ear tags, and conventional acaricide application. Application of insecticides as the sole method of tick control has not proved highly effective. Resistance to the acaricides may develop with prolonged use.

Cerebral Theileriasis (Turning Sickness; Draaisiekte; East Coast Fever; Corridor Disease; January Disease; Tropical Fever)

Definition and Etiology Cerebral theileriasis is an encephalitic disease of cattle caused by the piroplasma parasites *Theileria annulata* and *Theileria parva*.[1,2] Theileriasis is seen mainly in Africa (Kenya and Tanganyika) and India, where it is characterized by a high mortality rate and is known as East Coast Fever. *Theileria sergenti* is found in Korea and Japan. *Theileria mutans,* a parasite of cattle in the southwestern United States, is relatively nonpathogenic.[3] A mild form of theileriasis, locally called "January disease," occurs in cattle in Mozambique. This condition is caused by the subspecies *T. parva bovis.* Corridor disease is caused by *T. parva Lawrence,* and *Theileria annulata* is the cause of Mediterranean Coast fever or tropical theileriasis.

European breeds of cattle *(Bos taurus)* develop a more severe disease than do comparably infected Indian breeds *(Bos indicus).* Both types of cattle appear to be equally susceptible to infection but differ in their ability to control the course of disease.[4] *Theileria* organisms are transmitted to susceptible cattle by the ticks *Hyalomma anatolicum, Hyalomma lusitanicum,* and *Amblyomma hebraeum.*[5]

Trypanosoma spp. manipulate the immune system both to evade destruction and to promulgate infection. Organisms escape the host immune response by altering immune system activation so that infected cells avoid recognition and destruction.[6-8] Clonal expansion of infected lymphocytes is promoted, and these cells disseminate throughout the body.[9]

Clinical Signs The clinical signs of *Theileria* infections include lymphadenopathy, nasal discharge, lacrimation, tachycardia, fever, subcutaneous edema of the face, gangrenous dermatitis, sloughing of facial skin, dyspnea, pallor, CNS disease, and emaciation.[10] The neurologic syndrome is characterized by ataxia, hypermetria, conscious proprioceptive deficits, depression, head pressing, hyperesthesia, blindness, nystagmus, circling, and aggressiveness. Terminally the animals become recumbent and develop opisthotonos, tonic-clonic seizures, and coma. In rare cases the parasite may localize in the spinal cord. The CNS signs result from vasculitis and lymphocytic inflammation of the brain.[11-13] Clinically recovered animals become persistently infected.

Necropsy Findings The postmortem lesions of theileriasis include capillary engorgement, scattered punctate hemorrhages on the surface of the brain, thrombosis of the meningeal vessels, hemorrhage in the cerebral ventricles, pulmonary edema, peripheral lymphadenopathy, and infarctions of the kidney and spleen. The brain of affected animals appears to have a yellow hue.[13] Microscopically, blue cytoplasmic inclusion bodies (Koch blue bodies) are seen in the lymphocytes adjacent to the hemorrhagic areas.

The nervous form of theileriasis is difficult to diagnose definitively because the parasite is only sporadically visible in sections of nervous tissue from the infected animals. Occasionally, parasitemia can be

VetBooks.ir

detected by microscopic examination of blood smears from infected calves. Reliable blood tests are not currently available. Biopsy of the cerebral cortex has been recommended as a confirmatory test for the disease. The CSF of affected animals is normal or has an increased protein concentration ranging from 1400 to 12,452 mg/dL, with normal numbers of WBCs.[12]

Treatment Parvaquone 10 to 20 mg/kg IM in two injections 48 hours apart and buparvaquone at a single dose of 2.5 mg/kg are approximately 90% effective for the treatment of theileriasis.[14] Some studies have found buparvaquone to be the most effective treatment.[15,16] Parvaquone can be combined with furosemide, which improves survival of cattle that develop pulmonary edema, a common consequence of theileriasis.[17] Menoctone (10 mg/kg IV or IM) is also curative. Single doses were effective, but repeating the treatment daily for 5 days eliminated posttherapeutic recrudescence.[18]

Prevention Prevention of *Theileria* infection has largely been based on the use of live attenuated vaccines, which produce a solid, cell-mediated immunity.[19] These vaccines are used in an "infection and treatment" manner, whereby vaccination must be combined with administration of long-acting tetracyclines.[20] Recent efforts at vaccine development have focused on the creation of subunit vaccines, using a variety of *Theileria* antigens.

The naphthoquinones are the preferred chemotherapeutic agents in vaccinated animals and include parvaquone, halofunginone lactate, and buparvaquone (see Treatment).

Tick control is vital for prevention. Weekly spraying with coumaphos and insertion of ear tags impregnated with cypermethrin (have been effective for controlling ticks and preventing *Theileria* infections in calves in Tanzania. The calves became infected with *T. parva* by 3 months after the tags were removed. Woodford[21] suggested that the intensive tick control could minimize the incidence of theileriasis until the calves could be successfully vaccinated. However, inadequate or incorrect application of products and tick resistance to chemicals present challenges to effective tick control. The disease is exotic to North America.

Cerebral Trypanosomiasis (Sleeping Sickness)

Definition, Etiology, and Clinical Signs Trypanosomiasis is a hemoprotozoan disease of African cattle that also infects the CNS. The disease is transmitted to cattle by the bite of the tsetse fly (*Glossina* spp.). The agents that infect cattle include *Trypanosoma vivax, Trypanosoma congolense,* and *Trypanosoma brucei.* An especially severe neurologic form of the disease has been caused by the inoculation of cattle with *T. congolense,* followed 1 year later by infection with *T. brucei,* or by simultaneous inoculation with the two agents.[1] The encephalitic signs develop 2½ to 5 months after infection and include ataxia, conscious proprioceptive deficits, knuckling, depression, circling, and head pressing. Some animals may show signs of behavioral change, lose the herd instinct, and develop hyperesthesia and constant repetitive movements. Other signs associated with progression of trypanosomiasis are semicoma, coma, recumbency, opisthotonos, and intermittent tonic-clonic convulsions, which occur 2 to 3 days before death. Affected animals are emaciated, anemic, and icteric at death.[2]

Experimental infection with trypanosomes causes a marked fever (as high as 40.5°C [105°F]). Other common nonneurologic signs are anemia, petechiation of the mucous membranes, occult fecal blood, melena, and epistaxis. Chronic weight loss without other clinical signs may be seen in some animals. Hematologic abnormalities include anemia, hypoalbuminemia, hyperbilirubinemia, and increased plasma concentrations of aspartate transaminase and urea nitrogen.

Acutely infected animals may develop a thrombocytopenia and prolongation of the prothrombin and partial thromboplastin times, indicating that disseminated intravascular coagulation (DIC) may be responsible for the vascular changes that occur before death. The anemia is characterized by increased mean corpuscular volume and mean corpuscular hemoglobin, with increased serum iron concentrations early in the infection.[3,4] One study did not demonstrate a change in the concentration of WBCs or protein in the CSF of animals with the encephalitic form of trypanosomiasis.[1] However, another study showed significant alterations in cattle infected with *Trypanosoma brucei*i.[5] These included an increase in total protein (range, 37 to 44 mg/dL) and pleocytosis (range, 0 to 3060 mononuclear cells/μL). The abnormalities in the CSF may be present in infected cattle not currently displaying clinical neurologic signs. Antitrypanosomal antibody may be found in the CSF of affected cattle using indirect fluorescent antibody (IFA) tests.

Pathology The pathologic lesions of trypanosomiasis are a nonsuppurative encephalomyelitis, serosanguineous pericardial fluid, serosal hemorrhages, pulmonary edema, centrilobular coagulative necrosis, splenomegaly, necrotizing myocarditis, and glomerulonephritis.[6] Macroscopic lesions of the CNS include subtle thickening and grayish discoloration of the meninges. The meningeal vessels are congested. Microscopic lesions of the CNS reflect moderate diffuse meningoencephalitis. The pathogenesis of the encephalitis is not understood.

Trypanosomes may be cultured from the blood and CSF of infected cattle. The number of hematogenous parasites is highest in animals with a dual infection by *T. congolense* and *T. brucei.* The clinical diagnosis of trypanosomiasis may be confirmed by inoculating blood or CSF specimens into laboratory mice and observing the recipients for parasitemia with direct darkfield examination of the patient's blood. Identification of motile trypanosomes in the buffy coat zone of a microhematocrit capillary tube using darkfield illumination is apparently the most accurate of all diagnostic methods. Trypanosomes can be differentiated by their morphologic features, manner of attachment to erythrocytes, and type of motility.[7] Species-specific antibodies can be detected in serum using either an antigen-capture ELISA or an IFA test. Infected cattle develop acquired resistance to homologous but not heterologous isolates of trypanosomes.

Treatment and Control Of the drugs available for the treatment of trypanosomiasis, isometamidium chloride is most often used. The recommended dosage ranges from 0.25 to 1 mg/kg IM; a single dose of 1 mg/kg exerts a protective effect for up to 6 months.[8] The higher dosage (1 mg/kg) was required to obtain increased weight gain and prevent recurrent infection. The treatment was particularly effective when combined with weekly surveillance, followed by treatment of confirmed infected animals.[9] Side effects of isometamidium include tachycardia, salivation, lacrimation, pollakiuria, muscle fasciculations, convulsions, diarrhea, and in rare cases, death. The drug apparently does not cause abortion in pregnant cows or otherwise affect the calf.[10]

Other drugs used include suramin sodium, diminazene aceturate (7 mg/kg), quinapyramine sulfate, and homidium chloride (1 mg/kg). These drugs provide residual protection from reinfection for approximately 2 months; however, recurrent infection and resistance, especially to diminazene, have been reported.[11-14] Combinations of these drugs (e.g., diminazene followed by isometamidium) reduce the number of resistance-related therapeutic failures. Relapses also undoubtedly occur because many of the chemoprophylactic drugs are unable to penetrate the blood-brain barrier in sufficient concentrations to eliminate the parasite in the CNS tissues.

Because of the variable responses to treatment and the ability of *Trypanosoma* organisms to develop drug resistance, all control programs must include methods of controlling the tsetse fly.[13] Because the tsetse fly prefers to feed from the ventral torso or the legs, insecticide-impregnated ear tags have been ineffective for preventing infection; other means of application of insecticide are necessary.[15] Other fly control methods include aerial spraying with endosulfan, ground-based spraying with 4% dichlorodiphenyltrichloroethane

VetBooks.ir

(DDT), or use of scented insecticidal traps.[14] However, cost and environmental concerns have limited the usefulness of these techniques.

Selection of resistant lines of cattle is possible. The taurine N'Dama and West African shorthorn breeds have innate resistance to trypanosomiasis and are the sole breeds of cattle in areas of tsetse fly range.[16] Resistant breeds of small ruminants include the Djallonke, Red Maasai, Blackhead Persian, and East African sheep and goats.[17] Imported breeds of livestock usually cannot be maintained, even in areas of low tsetse fly risk, without intensive drug therapy.[18]

Polioencephalomalacia (Cerebrocortical Necrosis)

Christopher Cebra • Guy H. Loneragan • Daniel H. Gould

Definition and Etiology Polioencephalomalacia (PEM) is a common and important neurologic disease of ruminants[1,2] with a worldwide distribution. An animal with clinical manifestations of PEM is often referred to as having "polio" or being a "sleeper" or "brainer." "

Polioencephalomalacia is a descriptive term for histologic lesions[1,3] that may arise from a variety of etiologies. Literally, the name means softening or necrosis (malacia) of regions of the gray matter (polio) of the brain (encephalo). Thus a definitive diagnosis of PEM requires appropriate histologic examination of brain tissue. The possible etiologies of PEM include (but are not limited to) excessive sulfur consumption,[4-6] presumably manifested through elevated ruminal sulfide production[7,8]; altered thiamine metabolism[9]; salt poisoning or water deprivation[10]; amprolium administration[11-13]; rations composed of molasses and urea[14]; and lead intoxication.[15] When an etiology can be established, most PEM cases involve excessive sulfur consumption and/or altered thiamine metabolism.

Clinical Signs PEM appears to manifest both subacutely and acutely.[1,8] In the subacute form, signs may develop within hours or over several days. In the early stages of the disease, the affected animals detach from the herd or flock, become anorectic, and stagger. Neurologic signs are symmetric. Affected animals are blind, walk with the head held erect, and demonstrate a slight hypermetric gait. Progression of the condition is associated with bilateral cortical blindness, head pressing, opisthotonos, bilateral dorsomedial strabismus, miosis, repetitive chewing, profuse ptyalism, and odontoprisis.[1,5,16-18] Despite the defective menace response, the animals usually have normal palpebral reflexes. Affected animals may also develop a variable nystagmus. The rectal temperature is normal unless excessive muscular fasciculations have developed. The pulse and respiratory rates are usually increased. An odor of hydrogen sulfide may be detected on the breath if the PEM is associated with excessive sulfur consumption.

Although most of these animals respond favorably to aggressive therapeutic intervention, clinical signs may progress to recumbency, tonic-clonic convulsions, and death. In facilities with certain types of fencing, such as cables, affected animals may push or press with such force that they die of asphyxiation.

In the acute form of PEM, animals are found recumbent and comatose.[1,8] These animals often experience episodic tonic-clonic convulsions, and they remain recumbent and hypertonic between seizures. The prognosis is poor for acutely affected animals or those with advanced subacute manifestations. Survivors may remain irreversibly decorticated and are culled because of poor performance, chronic anorexia and ataxia, or blindness. However, mildly affected animals may remain as productive members of the herd.

Because the clinical manifestations of PEM may be subtle and nonspecific, they can be confused with other disorders. PEM is often confused with lactic acidosis that develops after consumption of excessive amounts of readily fermentable carbohydrates. Animals with lactic acidosis may appear ataxic and obtunded in addition to having a foul-smelling, watery stool and a distended, fluid-filled rumen. Concurrent PEM may not be diagnosed, or producers may confuse PEM for lactic acidosis or primary ruminal tympany in acutely affected animals that have remained laterally recumbent for some time.

The major differential diagnoses for PEM include enterotoxemia type D (focal symmetric encephalomalacia in small ruminants), head trauma, bacterial meningoencephalitis, coccidiosis with nervous system involvement, vitamin A deficiency, ethylene glycol poisoning, locoism, rabies, and infectious bovine rhinotracheitis encephalitis.

Clinical Pathology Although a definitive diagnosis depends on histologic confirmation, a presumptive diagnosis may be made antemortem on the basis of the history and clinical signs or response to therapy. If a diagnosis of PEM is made, the investigation should proceed at the animal, herd, and environmental level to identify evidence supportive of sulfide toxicity, thiamine deficiency, lead toxicity, or water deprivation (salt toxicosis).

Sulfide concentrations in the ruminal fluid and gas cap in experimentally induced sulfur-associated PEM have been shown to be high.[19,20] However, unpublished data supported a finding of a decrease in gas cap sulfide concentrations in naturally developing PEM associated with increased sulfur consumption.[21] This is most likely caused by the rapid metabolism of sulfate to sulfide in the rumen and resultant absorption or eructation of hydrogen sulfide (H_2S). Animals with naturally developing PEM are likely to have been anorectic for some time, resulting in a decrease in oxidized and reduced forms of ruminal sulfur.

Estimation of the rumen gas cap H_2S concentration in clinically healthy penmates of affected cattle is an effective chute-side diagnostic procedure that can indicate excessive sulfur consumption.[8] This method provides real-time results that may aid direction of further animal and environmental investigations. In short, an area in the left paralumbar fossa is prepared for ruminocentesis. An 18-gauge, 3½-inch spinal needle is inserted through the body wall and into the rumen gas cap. A modified gas sampler is attached to the spinal needle by means of an extension set, and a known amount of gas is drawn through an H_2S detector tube.[20] It is important to adjust the values to account for any dead space of the sampling instrument, such as the extension set and other modifications. H_2S concentrations greater than 1000 ppm are indicative of excessive sulfur consumption.[22]

Appropriate blood samples may be analyzed for lead concentration and possibly estimation of thiamine status. Thiamine status is generally evaluated using one of several available methods including determining the total blood thiamine concentration using a thiamine-dependent *Lactobacillus* bioassay.[23] The erythrocyte thiamine pyrophosphate concentration may be measured by high-performance liquid chromatography (HPLC).[24]

Another method of evaluating thiamine status is determining erythrocyte transketolase activity.[25] This test compares the specific activity in the active (holoenzyme) and inactive (apoenzyme) forms with the activity of the two forms after addition of thiamine to the homogenates. A large increase in specific transketolase activity after addition of the thiamine pyrophosphate suggests thiamine deficiency. Theoretically, in animals with thiamine-associated PEM, the concentration of holoenzyme is decreased, and that of the apoenzyme is increased. If thiamine deficiency is identified in an affected animal, caution should be used in interpreting the results because a period of anorexia may result in a decrease in ruminal de novo synthesis.[26,27]

Changes in CSF of affected animals are usually vague. They include mild pleocytosis (5 to 50 WBCs/dL) with vacuolation and increased protein concentrations (>50 mg/dL).[9,28] Electrophysiologic studies of affected animals show a normal latency and decreased amplitude of the late peaks of the visual evoked potentials. These changes reflect a decreased population of neurons capable of responding to the photic stimulation.[29]

VetBooks.ir

Environmental investigations should include evaluation of all feed and water sources for sulfur concentrations or the possibility of lead contamination. The diet should also be checked for molasses, salt, and urea content.

Pathogenesis The fundamental lesion with PEM appears to be neuronal edema with necrosis. In most cases the edema is postulated to result from adenosine triphosphate (ATP) depletion and insufficient function of the sodium-potassium pump in cortical cells. The bony calvarium limits expansion and neuronal swelling leads to pressure necrosis.

The brain is susceptible to PEM because of its high energy and oxygen requirements. Brain tissue is only about 2% of body weight but accounts for 20% to 30% of body glucose utilization and 20% of oxygen utilization in adults.[30] More than 85% of glucose used by the brain is energy substrate, and the blood-brain barrier prohibits the switching to many alternate energy substrates. Compared with liver or muscle, the brain has relatively small glycogen stores, only about a 10-minute supply. It is entirely dependent on circulating oxygen, and under normal conditions, the extracellular fluid contains approximately 100 times as much glucose as the oxygen required for complete aerobic glycolysis. Thus oxygen delivery or utilization is much more rate limiting for ATP production under most circumstances than glucose availability,[31] and factors that inhibit oxygen utilization (e.g., H_2S, lead) could have profound effects on neuronal ATP production.

Much of the early work on PEM focused on the importance of thiamine (vitamin B_1, thiamin, aneurin). In adult ruminants, thiamine is produced by rumen microbes at a rate that is marginally faster than the rate of consumption; very little is stored.[32] Preruminants depend on dietary thiamine. Thiamine compounds play several important roles in the glycolytic pathways. Thiamine pyrophosphate (thiamine diphosphate) is an important coenzyme for transketolase, the rate-limiting enzyme in the hexose monophosphate pathway (pentose phosphate shunt) of glycolysis, and the α-ketoacid dehydrogenases of the Krebs cycle. The role of thiamine in the hexose monophosphate pathway was long thought to be key in the development of PEM, but this pathway actually accounts for less than 3% of cerebral glycolysis.[33] It is unlikely that impairment of this pathway alone could lead to such severe disease. However, decreased function of the Krebs acid cycle through inactivity of the α-ketoacid dehydrogenases could cause the necessary reduction in ATP production. Thiamine triphosphate may also play a role in neuronal function independent of its enzymatic function.

The dependence of ruminants on microbial thiamine production has led to investigation of factors that might decrease production, absorption, or function. The mechanisms proposed include ruminal production of bacterial thiaminases, production or ingestion of inactive thiamine analogs, ingestion of preformed plant thiaminases, decreased intake of preformed thiamine by preruminants, impaired absorption or phosphorylation of thiamine by rumen bacteria, increased fecal excretion of thiamine, and decreased ruminal production of thiamine diphosphate. The most frequently reported inactive thiamine analog is amprolium.[11-13] Two types of bacterial thiaminases have been described. Thiaminase I, which is produced by *Bacillus thiaminolyticus* or *Clostridium sporogenes,*[34] catalyzes the cleavage of thiamine at the methylene bridge between the pyrimidinyl and the thiazole ring. A basic cosubstrate is required to combine with the pyrimidinyl derivative to form a new compound[35] (any common feedlot medications, including benzimidazoles, levamisole, and promazines, appear to be able to serve as this cosubstrate). Several plants also appear to make a thiaminase similar to thiaminase I. These include bracken fern *(Pteridium aquilinum),*[36,37] horsetail *(Equisetum arvense),*[37] and Nardoo fern *(Marsilea drummondii).*[38] Of these, only the Australian Nardoo fern has been strongly linked to outbreaks of PEM.

Thiaminase II is produced by *Bacillus aneurinolyticus,* which proliferates in response to excessive grain intake.[39] The enzyme catalyzes the hydrolysis of the methylene bridge between the two ring structures of the thiamine molecule. The specific relationship of this thiaminase to the clinical syndrome of PEM as seen in the field is unclear.

Complete correlation has not been established among production of ruminal and fecal thiaminase, tissue and plasma concentration of thiamine, and development of clinical encephalopathy.[40,41] Some affected animals may show normal amounts of thiamine in the plasma but have greatly decreased levels in the erythrocytes and other tissues, supporting the diversity of causes of PEM.[42]

Dietary sulfur and sulfates are an important factor in the development of many cases of ruminant PEM. Beef cattle require 0.15% to 0.20% sulfur on a dry matter basis.[43] Sources of sulfur include elemental sulfur,[4] feed additives such as gypsum and ammonium sulfate,[5,44] feedstuffs such as corn-processing by-products,[43] cruciferous crops,[45,46] molasses,[14] and fertilizers. Water can be an important contributor to sulfur intake, usually in the form of sulfates.[7,47,48]

There are two primary metabolic pathways of sulfur in the rumen.[48-53] The *assimilatory pathway* involves reduction of sulfate to sulfides and incorporation into sulfur-containing organic compounds such as cysteine and methionine.[51] These are ultimately incorporated into microbial crude protein. The *dissimilatory pathway* is an energy-producing pathway in which microorganisms use sulfate as a terminal electron acceptor, similar to how mammals use oxygen.[54] The end product is liberated sulfide ion. At a ruminal pH of 5.2, 97.2% of sulfide ions are in the form of H_2S and move freely to the rumen gas cap.[50,55] H_2S is readily absorbed and transported to the liver and oxidized to sulfate.[55,56] Some H_2S may be lost through eructation,[19,56] but the significance of this route has been questioned.[57] Excess sulfur is excreted in the urine and large intestine[58,59] or recycled to the rumen.[60,61] A period of adaptation is required for maximum H_2S production after exposure to sulfur.[52,58,61-63]

Because sulfur and sulfate demonstrate low cellular toxicity, it is unlikely that sulfur-associated PEM results from a sulfate or sulfur toxicity. However, sulfides are highly toxic.[64-66] Sulfur-associated PEM is more likely to occur secondary to a sulfide toxicity.[6,8,19] It has been proposed that the pathogenesis of sulfur-induced PEM involves inhibition of cytochrome-*c* oxidase, an enzyme in the electron transport chain; this chain is important for regenerating the intermediaries of aerobic glycolysis and the final round of ATP production. With oxygen availability already limiting aerobic glycolysis in the brain, inhibiting the electron transport chain could have a profound effect on neuronal ATP production.

For highly toxic sulfide to reach the brain, it must escape hepatic oxidation. This might be achieved by two mechanisms. A surge in ruminal sulfide generation usually follows a period of adaptation to high-sulfur diets. This may overwhelm the hepatic detoxification capacity. As an alternative possibility, cattle inhale the majority of eructated ruminal gas.[67] These inhaled gases can contain high amounts of H_2S, and if absorbed via the pulmonary route, the H_2S would completely bypass the hepatic circulation. However, this concept has been questioned.[68]

In feedlot cattle, a summer peak in PEM cases was associated with consumption of water containing 2500 mg/L of sulfate.[7] The total sulfur intake of these steers was estimated to be 0.6% on a dry matter basis during the hottest days of the year. Most PEM cases occurred between 15 and 35 days after arrival in this feedlot. In another investigation, 11% of weaned calves consuming a diet containing 0.9% sulfur on a dry matter basis developed clinical manifestations of PEM.[8] Lesions were confirmed in one steer that died. Addition of gypsum (calcium sulfate) to feeder steer rations at a final concentration more than 2% organic sulfate results in a significantly greater risk of developing PEM. The addition of sodium sulfate (0.6% to 0.8%) to diets may induce PEM within 11 days.[19,62,69,70] High sulfur concentrations in well water in combination with accumulation in forage has been traced to an outbreak of PEM in Canada.[8] One survey described an outbreak of cerebrocortical necrosis in cattle eating diets containing 7200 mg/kg of sodium sulfate.[48]

The recommended maximum tolerance level of sulfur is 0.4% of dry matter intake.[43] Other effects of excessive sulfur intake are

VetBooks.ir

decreases in feed intake and weight gain. Accurate diagnosis of sulfur toxicity requires measurement of sulfur in all food and water sources. Sulfur from water must be included when calculating total sulfur intake. One third of the molecular weight of sulfate is sulfur. Accordingly, if an animal drinks 30 L of water a day containing 2000 mg/L of sulfate, this contributes 60,000 mg of sulfate, or 20 g of sulfur. Further, if this animal consumes an average of 10 kg of dry matter daily at 0.15% sulfur, the feed or forage contributes 15 g of sulfur, making the total sulfur intake 35 g, or 0.35% on a dry matter basis. Therefore water may be a substantial source of sulfur.

Some have suggested that sulfides result in thiamine destruction, thereby directly implicating a thiamine deficiency in the pathogenesis of sulfur-associated PEM. Rumen thiamine production was slightly reduced by the inclusion of excessive sulfur in the ration.[71] However, the authors deemed the reduction clinically insignificant. Apparently, sulfur-associated PEM occurs independent of thiamine status.

PEM induced by feeding of molasses and urea is thought to be related to the high sulfur content of the molasses and to the depletion of propionate and other glucogenic precursors induced by the foodstuff.[14] It is not considered to be caused by an underlying thiamine destruction. The tissue thiamine concentrations of animals with molasses-related PEM are normal,[72] and signs are preventable by concomitant feeding of glycerol, which is converted to glucose in the rumen. Outbreaks of PEM in range cattle have been associated with ingestion of the plant *Kochia scoparia*.[73,74] The pathogenesis of this condition is unknown; however, some have suggested that the plant has the capacity to accumulate sulfur.[48]

Some cases of PEM cannot be linked to either problems with thiamine or sulfur toxicosis. Other compounds, such as lead, affect electron transport in a manner similar to sulfides and therefore also impair ATP production. Water intoxication creates a similar histologic lesion, but the pathogenesis of edema relates more to the generation of osmotic compounds and fluid shifts with rapid fluctuations of blood and neuronal osmolality (see section in this chapter titled Salt Poisoning [With or Without Concurrent Water Deprivation]).

Epidemiology PEM has a worldwide distribution. The condition is seen both in individuals and as herd outbreaks. In one instance, approximately 2000 of 2200 sheep grazing were clinically affected with PEM.[4] No predilection by gender or breed is seen. The condition affects cattle, sheep, goats, deer, camels, and camelids.[5,11,75-78] Although PEM is seen predominantly in animals that eat a high-concentrate supplement, the condition can also occur in unsupplemented animals on pasture.

The age range for susceptibility to PEM has been reported as 3 weeks to 5 years in sheep, 3 weeks to 8 years in cattle, and 2 months to 2½ years in goats. The peak age of incidence is 18 months or younger in cattle and sheep, but this depends on the production system.[1,8,79] The incidence of PEM has been reported as high as 90% in some sheep flocks, with mortality of 1% to 10%.[4] The incidence of PEM can be high in sheep exported by sea from Australia to the Middle East. In these cases the underlying disturbance was thought to be associated with a thiamine deficiency caused by a lack of rumen synthesis secondary to the shipboard conditions.[80]

Necropsy Findings In cases of sulfur-associated PEM, rumen contents may have an odor of H_2S. In other cases there may be evidence of grain overload, coccidiosis, or respiratory disease. Some of these lesions relate to management conditions but may also relate directly or indirectly to PEM. The macroscopic pathologic brain lesions of PEM include cortical swelling, softening, flattening, and yellowish discoloration of the gyri. Necrotic areas of the cerebral cortex autofluoresce under ultraviolet light (365 nm).[81,82] Severe cases show herniation of the cerebellum through the foramen magnum or the occipital cortex under the tentorium cerebelli. Animals necropsied months after recovery may show cerebral atrophy and submeningeal cortical cysts. The major microscopic lesion is a diffuse laminar necrosis. Other changes include intracellular and intercellular edema, neuronal necrosis, and neuronophagia.[3,17]

Treatment and Prognosis Regardless of the underlying cause, animals with the subacute form of PEM often respond favorably to parenteral administration of thiamine hydrochloride. These animals may remain blind and may have depressed sensorium for weeks or months.[83] Thiamine should be administered at 10 to 20 mg/kg IM or SC three times daily. In severe cases, IV administration of the first dose might be warranted. If given intravenously, thiamine should be administered slowly to avoid adverse reactions. If no improvement occurs initially, the treatment should be continued for at least 3 days. In some patients, recovery may take as long as 7 days, but most patients show improvement by 24 hours. A single administration of sodium dexamethasone at 0.1 to 0.2 mg/kg IM or IV or 1 g/kg of mannitol in a 20% solution IV may be beneficial in reducing cerebral edema. Anecdotal reports indicate that feedlot animals that have recovered from PEM are at increased risk of respiratory disease; therefore prophylactic antimicrobial administration may be indicated. Convulsions may be controlled with phenobarbital, pentobarbital, or diazepam (see Table 35-2). Animals with the acute form of PEM usually have more severe cortical and deep gray matter lesions than animals with the subacute form.[8] These animals generally do not respond to therapeutic regimens. Ruminants with PEM secondary to the molasses-urea diet do not appear to respond to treatment with thiamine. They may respond more favorably to parenteral administration of glucose or enteral or parenteral administration of a glucose precursor.

Prevention and Control Ultimately, the best way to prevent outbreaks is to manage the dietary intakes of susceptible animals appropriately. Ruminants should be allowed an adequate period of adaptation to high-concentrate rations. All feedstuffs and water sources should be carefully analyzed on a routine basis with an estimate of total sulfur intake. If excess sulfur consumption is a factor, steps should be taken to remove sources such as high-sulfur hay, ammonium sulfate, and molasses. If the excess sulfur intake is unavoidable, steps can be taken to limit its effects. Older members of the cow herd could be used to graze the high-sulfur pastures, and younger, more susceptible animals could be kept to lower-sulfur pastures or given hay supplementation. Personnel should be trained so that animals with PEM can be identified early in the disease and treated appropriately.

Thiamine may be supplemented (3 to 10 mg/kg of feed) in rations in which the concentrate/fiber ratio is high, but this has little or no effect in preventing PEM. Other recommendations for preventing PEM include addition of brewer's yeast to the ration and gradual adaptation of ruminants (at least 2 weeks) to high-concentrate diets. If present as a feed-limiting additive, gypsum should be removed from the diet. Elimination of supplementation and rotation of pastures have been sufficient for controlling some outbreaks.[79] Supplementation with cobalt in trace-mineral salt mixes may be necessary in deficient areas.

Salt Poisoning (With or Without Concurrent Water Deprivation)

Lisle W. George • David C. Van Metre

Definition and Etiology Salt poisoning is a common CNS disease of livestock. Salt-rich solutions ingested over time can cause production-related losses and even death. Ingestion of water containing more than 7000 mg/L of total dissolved salts is likely to result in acute salt poisoning.[1,2] Water that contains less than 3000 mg/L of total dissolved salts is considered safe for consumption. Salt poisoning can be associated with water deprivation.[1,3,4] Provided that access to free water is constantly available, animals may tolerate up to 13% dietary salt intake.[5]

VetBooks.ir

The acute toxic dose of oral sodium chloride (NaCl) for cattle and horses has been reported as approximately 2.2 g/kg body weight and for sheep about 6 g/kg.[5] With water restriction, the toxic dose of salt is considerably less, and poisonings have resulted from ingestion of 0.9% NaCl in water-restricted cattle.[6] Chronic toxicity can occur at lower dietary salt levels than acute toxicity. Ingestion of water with salt concentrations above 1% uniformly results in toxicosis if no other source of ion-free water is provided.[7,8]

Ingestion of water containing 0.7% salt lowers the fertility of females,[8] and water containing 0.25% salt suppresses milk production in cattle.[9] Dairy calves have been poisoned by daily feeding of 4 L of milk replacer containing 2.6% NaCl.[10] Animals are most susceptible to salt poisoning during the summer because of the increased insensitive loss of water at that time. Salt poisoning in ruminants is most frequently a syndrome of concurrent "water intoxication": a period of restricted access to water, followed by unrestricted access to water.[1,3,4] In such cases, the dietary intake of sodium can be relatively modest, yet disease occurs once water enters the extracellular fluid and moves into the brain tissue.

Clinical Signs

Acute ingestion of large amounts of salt causes gastrointestinal and neurologic signs.[7,10-15] These include mucohemorrhagic diarrhea and colic, head-neck extension ("star gazing"), blindness, aggressiveness, hyperexcitability, psychomotor seizures (paddling and loss of consciousness), vocalization, ataxia, proprioceptive deficits, head pressing, constant chewing movements, nystagmus, muscle twitching, and coma. Death occurs as a result of respiratory failure. Before the onset of neurologic signs, cattle with chronic salt toxicosis may appear to be depressed and dehydrated. Table 35-4 summarizes the spectrum of clinical effects associated with different levels of salt intake.

Excessive salt intake may also interfere with productivity in the absence of acute neurologic signs. In one study, cattle were given either tap water (196 ppm of dissolved salts) or saline (2500 ppm NaCl), and their milk production was measured.[9] Cows given tap water had a greater fluid intake and a significantly greater lactational persistence and daily milk production than did cows given saline, despite the fact that the latter group showed normonatremia and normokalemia. This study illustrates the importance of provision of high-quality water for optimization of milk production.

The clinical diagnosis of salt poisoning depends on the demonstration of exposure to toxic concentrations (>7000 ppm or 0.7% of sodium), the presence of water deprivation, or the determination of serum or CSF sodium concentrations greater than 160 mEq/L (occasionally exceeding 200 mEq/L).[11] CSF/serum sodium ratios greater than 1 also suggest salt poisoning. The serum sodium concentration may vary, depending on whether the patient had recently been given ion-free water before measurement. Some animals with acute neurologic lesions may be normonatremic if they have recently drunk to repletion with ion-free water, whereas others that have not had ion-free water may be hypernatremic.

Ruminal sodium concentrations above 0.36% to 0.5% or brain sodium concentrations above 150 mEq/g or 1800 ppm[16] also suggest salt poisoning in cattle.[11,12,17] Rapid intake of low-sodium water during the rehydration phase of the disease may cause intravascular hemolysis with resultant hemoglobinuria; such findings raise the index of suspicion of salt poisoning.[2]

TABLE 35-4

Effects of Different Salt Concentrations in Drinking Water on Performance in Cattle[8]

Salt Concentration (mg/L or ppm)	Clinical Effect
<1000	No effect
1000-3000	Temporary diarrhea; reduced milk production
3000-5000	May reduce milk production and feed intake; may produce reproductive failures (failure to conceive)
5000-7000	Conception failures (abortion, infertility), reduced appetite
>7000	Unsafe, especially in hot weather; may produce encephalopathic signs, abdominal pain, mucoid diarrhea, thirst, salivation, polyuria, central nervous system signs; include knuckling, blindness, convulsions, coma, and abdominal pain

Pathophysiology

The pathogenesis of salt poisoning involves the deposition of sodium ions in the CNS parenchyma and the CSF, which occurs either acutely from ingestion of a large quantity of salt or chronically after long periods of reduced water consumption with low to moderate sodium intake. The ionic sodium accumulates in the brain cells by passive diffusion. The resulting hyperosmolality reduces energy-dependent sodium transport mechanisms and glycolysis.[18] These mechanisms normally provide energy by which the sodium ion is removed from the cell cytoplasm.[14] The thirst receptors are triggered in response to the hyperosmolality of the extracellular fluid (ECF). The animal is permitted to drink ion-free water to repletion, and the fluid is absorbed from the gastrointestinal tract, resulting in expansion of the extracellular fluid and an abrupt reduction in the ECF osmolality. Water then diffuses down its osmolar gradient from the ECF into the relatively hyperosmolar CSF and neurons, resulting in CNS edema, increased intracranial pressure, and acute encephalopathy.

Gastrointestinal signs may also be seen when animals ingest large quantities of salt over short periods of time. The hyperosmolality in the intestinal lumen results in saline catharsis and osmotic diarrhea.

Epidemiology

Animals are tolerant of high dietary salt levels if they have concomitant access to fresh drinking water. Feedstuffs that are common sources of excessive salt include whey, saline-preserved fish or fish meals, bakery by-products, and certain milk replacers.[19] Confined calves may be poisoned by improperly formulated milk replacers or oral electrolyte replacements.[11,19] Cattle eagerly ingest large amounts of oil well sludge, which is a potential source of salt for cattle in the western and southwestern United States.[15,20,21] Brine is used extensively as a flush during the drilling of oil wells. Effluents from drilling rigs may contain as many as 100,000 ppm of salt. The effluents are also contaminated by heavy metals and magnesium salts, which complicate the clinical syndrome of salt poisoning. Concurrent neurologic disease may predispose animals to reduced water intake, as occurred in a group of goats with locoweed (*Oxytropis* spp.) poisoning who became water deprived because of reluctance to move to a water source. They developed clinical and pathologic evidence of salt poisoning when moved subsequently to an area where water was easily available.[3] Salt poisoning caused by water restriction may occur either inadvertently from freezing of water sources in northern climates or from intentional water restriction of veal calves.[11] Ingestion of brackish or tidal water is a cause of salt poisoning in cattle pastured on the coastal regions of the world.

Necropsy Findings

The pathologic changes of salt poisoning include cerebral edema and softening and flattening of the cortical gyri. Microscopic lesions include laminar cortical necrosis, poliomalacia, and occasionally, meningeal or perivascular infiltration of eosinophils and/or mononuclear cells.

Treatment

Treatment of animals affected by salt poisoning is difficult. Many animals die even after intensive medical treatment. Prognosis depends on severity of clinical signs at the start of treatment: Animals that already have significant cerebral edema have a guarded prognosis. Therapy should be aimed at limiting the ingestion of nonionic water and attempting to remove intracellular solutes

VetBooks.ir

slowly from the brain while simultaneously controlling cerebral edema and attendant CNS signs. To prevent brain swelling and herniation of the brain through the foramen magnum or the tentorium cerebelli, slow reduction of the CSF and plasma sodium is imperative. Slow intravenous administration of normal or hypertonic saline is the mainstay of treatment.

Adult cattle should receive normal (0.9%) saline intravenously at maintenance rate (7% body weight in adult cattle, 10% in neonates).[2] Slight underestimation of fluids is preferable to excess fluid administration. Serum sodium should be monitored regularly and correction effected over 24 hours or longer. Oral fluids can be introduced gradually toward the end of the first day of treatment; salt should initially be added to oral fluids to make them isotonic to blood. When IV replacement is not feasible, isotonic to hypertonic oral fluids should be administered at a maintenance level divided into four to six feedings daily. Access to low-salt water is gradually allowed after 3 to 4 days. Any worsening of clinical signs is an indication to increase the salt level in fluids and may require IV mannitol (0.5 to 2.0 g/kg as a 20% solution) or oral glycerin (1 mL/kg diluted 50:50 with water) to reduce cerebral edema.[2]

High-sodium crystalloid solutions (HSCS) have been used for individual treatment of severe hypernatremia, as might develop in salt poisoning.[22] Sodium (as dry salt, or, if metabolic acidosis is present, as sodium bicarbonate) is added to normal (0.9%) saline to create a final sodium concentration in the HSCS that is 10-15 mEq/L less than the patient's serum sodium concentration. Dry table salt (17 mEq Na^+ and Cl/gram) is added to 0.9% saline to achieve the desired sodium concentration in the HSCS. The HSCS is administered at 1-3 mL/kg/h while the patient's neurologic status and serum sodium concentration are monitored carefully over the first 1-2 days of treatment; reduction of serum sodium concentration by 0.5-1 mEq/L/h is considered optimal.[23] Small volumes of water are subsequently offered to aid in gradual reduction of the ECF sodium concentration; this gradual decline in ECF sodium is thought to prevent development of an abrupt osmolar gradient favoring water entry into brain cells.

The use of solutions containing 5% glucose is dangerous and probably contraindicated because this represents ion-free extracellular fluid, which can exacerbate brain edema. Administration of corticosteroids (dexamethasone, 0.04 to 0.08 mg/kg by slow IV injection twice daily for 2 to 3 days) may be helpful in animals with acute cerebral edema. If the neurologic signs diminish and the plasma sodium level returns to normal, the animal may be given fresh drinking water. Thiamine (10 mg/kg SC) may be a useful adjunctive therapy.

Control Cattle should be fenced away from polluted ponds and oil wells. Cattle on coastal pastures should have access to fresh well water. The total daily dietary salt intake should not exceed 4% of dry matter intake. Drinking water must contain less than 7000 ppm of sodium unless the dietary sodium load is reduced correspondingly. Oral rehydrating fluids for calves should be dissolved in strict accordance with the manufacturer's recommendations. Assessment of water cleanliness and availability should be a component of a daily animal husbandry plan.

Vitamin A Deficiency

Definition and Etiology Vitamin A (retinol) is found in green plants and can be synthesized from plant carotenoid precursors in the liver and intestinal mucosa. Precursors of vitamin A are usually fed in cattle rations as β-carotene or as retinoids. Vitamin A deficiency occurs primarily in growing ruminants in feedlots. Deficiency develops under these conditions because the growing animal has a higher requirement for the vitamin, and feedlot-reared animals may have limited access to succulent plants. The vitamin is labile in foodstuffs and is depleted after several years of storage. Diets that are naturally low in vitamin A include cereal grains, beet pulp, and cottonseed hulls. Conditions in which the immune system is challenged, as when exposure to pathogens is high, also increase the requirement for vitamin A. Other scenarios conducive to vitamin A deficiency include prolonged grazing on dry pastures or cereal grains other than corn, exclusive feeding of cereal grains that have been stored at high temperature and humidity, or prolonged feeding of mineral oil as a preventive for frothy bloat.

Clinical Signs Signs in deficient calves include anorexia, illthrift, blindness, diarrhea, and pneumonia. The syndrome in adults is characterized by "star-gazing" posture, blindness, diarrhea, anasarca, nystagmus, strabismus, exophthalmos, loss of pupillary light reflexes, and intermittent tonic-clonic convulsions. The seizures may last for only a few minutes and can be followed by partial recovery.[1-3] Animals may die during seizures. Stimulation of the animals frequently precipitates seizures.[4,5] Death is often preceded by hyperesthesia and coma.[1,2,6] Inadequate vitamin A supplementation of calves is associated with unthriftiness, intermittent fevers, and a higher incidence of diarrhea.[7] Vitamin A–deficient adults appear to be in good body condition unless parasitism or some other nutritional deficiency is superimposed on the low vitamin A intake.[1,8] Secondary factors that can influence the appearance of the animals include concomitant nutritional deficiencies, parasitism, and pneumonia.

The ocular changes of vitamin A deficiency are characteristic. The pupils become dilated and unresponsive. As papilledema develops, the optic disc becomes pale and its borders become indistinct, particularly in the upper quadrants,[1,3,9] giving the appearance of an inverted heart. The swollen disc may cast a shadow on the adjacent retina. The color of the disc becomes faded. In advanced cases the disc may become atrophic and appear dull, gray, flattened, and smaller than normal.[10] The retinal blood vessels become tortuous or appear to be occluded as they course over the disc. Retinal detachment and subretinal hemorrhages are possible.[1]

Reproductive disturbances can occur, including malformed fetuses, abortions, loss of libido, testicular degeneration, and decreased sperm counts. Calves born to vitamin A–deficient dams are blind, have domed foreheads and thickened carpal joints, and are weak at birth.[11]

Vitamin A deficiency can be clinically differentiated from polioencephalomalacia (PEM) and salt poisoning by comparing the menace response with the pupillary light reflex. Calves with lead poisoning and PEM generally have intact pupillary light reflexes because of the proper functioning of the mesencephalon and optic nerves, whereas vitamin A–deficient cattle have absent pupillary light responses because of retinal degeneration and constriction of cranial nerve II at the level of the optic foramen.

Clinical Pathology Assay of vitamin A and carotene concentrations in the plasma and feed is the most direct method of diagnosing the dietary deficiency. The concentration of plasma vitamin A and β-carotene in normal animals ranges from 25 to 85 μg/dL and 150 and 397 μg/dL, respectively.[2] Plasma concentrations of vitamin A–deficient and β-carotene–deficient animals usually are less than 7 and 70 μg/dL, respectively. The hepatic concentration of vitamin A and carotene in normal calves ranges from 60 to 200 and from 4 to 800 μg/g of tissue, respectively. In deficient calves the hepatic concentrations of the vitamin A and carotene nutrients range from 2 to 14 and from 0.5 to 32 μg/g, respectively.[8] There are no consistent changes in the blood chemistry analysis or the hemogram of deficient animals. Changes in the CSF of vitamin A–deficient animals include a mononuclear cell pleocytosis (40 to 50 nucleated cells/dL) and an increased protein concentration (140 mg/dL)[12]; increased CSF pressure (>200 mm Hg) may also occur.[13]

Pathophysiology Vitamin A is responsible for the regeneration of rhodopsin in the retina and in normal function of osteoblasts and osteoclasts, epithelial tissues, the choroid plexus, and reproductive tissues. Vitamin A deficiency causes a thickening of the dura mater, resulting in diminished CSF absorption from the arachnoid

granulations and the nerve rootlets. Narrowing of all the bony foramina of the skull occurs in immature animals, although bone remodeling does not occur in adults. The combined effects cause an increase in CSF pressure.[8] Closure of the optic foramen may lead to transection of the optic nerve. The high CSF pressure is transmitted into the optic nerves and results in papilledema.

Three causes of blindness have been associated with vitamin A deficiency. Nyctalopia (night blindness) is presumably caused by the decreased formation of vitamin A aldehyde in the regeneration of the visual pigment rhodopsin; this type of blindness is usually reversible. Second, degenerative changes in the outer retinal layers also cause blindness; this is reversible if treated in the early stages. The third cause is associated with stenosis of the optic foramen and compression of the optic nerve; this condition is irreversible.[14]

Epidemiology The vitamin A requirement of all species ranges from 40 to 110 IU/kg daily.[15-17] The minimum recommended daily dose of vitamin A for growing calves up to 1 year of age, for pregnant sheep, and for growing horses is 40 IU/kg. Pregnant cattle and pregnant or lactating horses require 40 to 50 IU (13.76 to 17.2 µg/kg) of vitamin A daily.[16] Lactating cattle require 80 IU (27.5 µg/kg) of vitamin A daily. Horses are susceptible to vitamin A deficiency, but the condition is rarely seen in that species. This is thought to be the result of differing conditions of management rather than an inherent resistance to the deficiency. The daily dietary requirement for carotene is 0.12 mg/kg.[16] Pasture forage, silage, and properly cured hay (<1 year old) contain large amounts of carotene. Common constituents that have low concentrations of vitamin A are sorghum, brewer's grain, and wheat straw.

Livestock are protected from short-term deprivation of vitamin A by their ability to accumulate the vitamin in the liver; however, it is estimated that the intake required to initiate storage is at least three times the minimum daily intake.[16] Vitamin A–replete cattle fed a diet devoid of vitamin A require approximately 180 days before they begin to show clinical signs. During that time the cattle grow and fatten normally and show no adverse effects. Offspring born to these animals may show severe deficiencies. Papilledema and blindness develop rapidly after the hepatic stores are depleted.[16]

Vitamin A deficiency may be categorized as a primary or secondary condition. Primary deficiencies of vitamin A develop in cattle confined in drylot corrals or pasture on dry grass forage for prolonged periods or when cattle are kept indoors and fed unsupplemented, vitamin-depleted cereals and dry forage in which the activity of carotene has been destroyed. Also, there is a seasonal difference in the concentration of vitamin A in feedstuffs. For example, cattle grazed on green pastures are consistently replete with the vitamin, whereas those grazed on dry pastures at the end of summer may become marginally deficient. Approximately 80% of the vitamin A concentration of hay is lost during field curing.[18]

Destruction of carotene is hastened by many environmental and physical factors, including heat, sunlight, trace mineral supplements, and humidity.[19] Other factors that affect the stability of vitamin A in feedstuff include pelleting and exposure to rancid fat in the feed.

Secondary deficiencies of vitamin A result from interference with vitamin absorption, inhibition of the conversion of β-carotene to retinol (vitamin A) in the small intestine, or an increased requirement in the face of limited vitamin intake. The conversion of carotene to retinol is impaired in vitamin A–deficient patients.[6] Sheep may be more resistant to vitamin A deficiency because they convert β-carotene more efficiently than cattle.[6] Fever, lactation, high ambient temperatures, and inadequate dietary energy may increase the daily requirement for vitamin A.[19] Other factors that can affect availability of vitamin A or the requirement for the vitamin include diets with low forage content, high proportion of corn silage to hay in the diet, increased exposure of animals to pathogens, and periods where immunocompetence is reduced (e.g., the peripartum period).[17] Secondary deficiencies of vitamin A may be caused by impaired vitamin absorption, which may occur from long-term feeding of mineral oil.

Necropsy Findings The major pathologic changes in the fundus of vitamin A–deficient calves include papilledema, small flame-shaped hemorrhages around the optic disc, venous congestion in the area of the swollen optic disc, degeneration of the retinal ganglion cells, focal retinal thinning, and fusion of parts of the retina to the choroid plexus.[9] Other changes associated with vitamin A deficiency include doming of the frontal bones, enlargement of the carpi, cerebellar and cerebral compression, partial transtentorial herniation of the cerebellum, cystic dilation of the hypophyseal cleft, focal ruminal hyperkeratosis, and increased keratinization of the squamous epithelium of the penile and the preputial mucous membrane. Corneal ulceration and clouding have been observed in the eyes of calves with naturally occurring deficiencies.[12] Vitamin A deficiency also can cause anasarca, squamous metaplasia of the salivary ducts, degeneration of the germinal testicular epithelium, degenerative changes in the intestinal epithelium in lambs, and reduction in intramuscular fat in cattle.[20-22]

Microscopic changes in the CNS include attenuation of the optic nerve with necrosis and demyelination. Focal accumulations of phagocytic cells containing lipofuscin and hemosiderin are present in the necrotic area. The optic nerve is attenuated along its entire length. The meninges are thickened by fibrosis and mononuclear cell inflammation. The microscopic changes in the bones include wider than normal spacing of the central canals and reduction of osteoclastic lacunae.

Treatment and Control Cattle with severe blindness caused by damage to the retina or optic nerves do not regain their vision when treated with vitamin A; however, cattle with acute encephalopathy and simple papilledema may respond favorably after a short period of vitamin supplementation.[16] Affected cattle should receive 440 IU/kg (1 IU = 0.4 µg) of vitamin A parenterally and then 6000 IU/kg parenterally every 50 to 60 days until the diet has been enriched. High-dose oral therapy is important because carotene and oil suspensions of vitamin A are not efficiently utilized when administered by parenteral injection.[23] Administration of large doses orally is important because conversion of β-carotene to vitamin A is inhibited in deficient calves. The recommended concentration of vitamin A in milk replacers for preruminant calves is 11,000 IU/kg dry matter.[7]

Prophylactic dietary supplementation of vitamin A should be considered in all cattle that lack access to green feed. Dietary supplements could include leafy, freshly cured hay, green pasture, or alfalfa meal. Concentrate feeds formulated with exogenous, stabilized vitamin A are commercially available. Recommended concentrations (IU/kg dry matter) of vitamin A in feed are 2200 IU for feedlot cattle, 2800 IU for pregnant cows, and 3900 IU for lactating cows.[18]

Hydrocephalus and Hydranencephaly of Ruminants

Definition and Etiology Hydrocephalus/hydranencephaly is a common occurrence in large ruminants. It is underdiagnosed because many of the affected animals die of complications, and the primary condition is overlooked during clinical and pathologic examinations. One study reported that 97 of 155 calves with CNS lesions had hydrocephalus.[1] Hydrocephalus may be classified as hypertensive or normotensive.[2]

NORMOTENSIVE HYDROCEPHALUS (HYDRANENCEPHALY). Normotensive hydrocephalus that develops as a result of a failure of cell growth or cellular necrosis is called *hydranencephaly.*[2] Most cases of hydranencephaly in domestic livestock are caused by in utero infection of the fetus by viral pathogens such as bluetongue, bovine viral diarrhea (BVD), akabane, Cache Valley, aino, border disease, and the Schmallenberg virus.[1,3-13] The pathogenesis and epizootiology of the multisystemic virus infections bluetongue and BVD are discussed in detail in Chapter 32. The neurologic effects of border disease virus infection are discussed earlier in this chapter.

VetBooks.ir

VetBooks.ir

The loss of fetal neurons in utero results in flexural contractions of the limbs (arthrogryposis), which may manifest as dystocia. Affected neonates may be stillborn or born alive but weak, blind, unable to stand, and unable to nurse. They may exhibit a dysphonia, which resembles a bark. Neonates that are unable to nurse are deprived of colostrum and often die from septicemia.

Akabane Virus Infection. The akabane virus is a member of the Sindbis serologic subgroup of the Bunyaviridae family.[3] It has been isolated from cattle in Africa, Japan, Israel, Korea, and Australia.[4-9] The host range of akabane virus includes sheep, cattle, and goats. Infection of pregnant, nonimmune dams results in hydranencephaly or arthrogryposis of the fetus.[14] The disease is thought to be transmitted to the cow by various *Culicoides* spp. Experimentally infected calves develop porencephaly and encephalitis when exposed to the akabane virus between gestational days 62 and 96.[15] Studies in naturally infected cattle showed that infection of calves between days 76 and 104 of gestation resulted in hydranencephaly or porencephaly, whereas infection between days 103 and 174 of gestation resulted in arthrogryposis.[16] Lambs are susceptible when exposed to the virus on gestational days 30 to 36.[9] The CNS lesions are apparently the result of a direct necrotizing effect of the virus on the developing neurons. The pathologic changes of the CNS in experimentally infected calves and lambs are similar to those of naturally acquired infections.[6,9] Adults occasionally abort when infected by the virus but do not develop clinical disease.

A syndrome of arthrogryposis, facial deformities, kyphoscoliosis, hydranencephaly, and hypoplasia of multiple regions of the brain and spinal cord has been described in Corriedale sheep in Australia. Although resembling the disorder caused by congenital akabane virus infection, breeding trials supported an autosomal recessive inheritance for the disease.[17]

Aino Virus Infection. The aino virus causes stillbirths, premature calving, and congenital malformations including arthrogryposis, cerebellar hypoplasia, and hydranencephaly in calves of Japan and Australia.[18-20] Aino virus is antigenically and biologically distinct from akabane virus, but the clinical syndromes of fetal infection by the two viruses are indistinguishable.

Chuzan Virus Infection. Hydrocephalus, hydranencephaly, and cerebellar hypoplasia have been attributed to infection of pregnant cattle with the Chuzan virus.[21-23] This virus is a relative of the akabane and aino viruses and is classified as a new member of the Palyam subgroup of the genus *Orbivirus*. The virus has been isolated from *Culicoides oxystoma,* which may serve as the major vector. The clinical signs are characteristic of hydrocephalus.

Cache Valley Virus Infection. A flock outbreak of arthrogryposis, myositis, hydranencephaly, and a variety of other brain malformations (micrencephaly, cerebellar hypoplasia, porencephaly) in newborn lambs in the southwestern United States was attributed to in utero infection with the Cache Valley virus (family Bunyaviridae).[24,25] Cache Valley virus was first isolated from mosquitoes from Utah and has since been isolated from caribou, horses, sheep, and cattle elsewhere. Antibodies have been found in white-tailed deer in the southwestern United States, but the role of this mammal in the survival of the virus and the transmission of the disease to livestock is unknown.[26] In one survey of sheep in the western United States, the seroprevalence for the Cache Valley virus was 19.1%.[24] Vectors for the virus include *Anopheles, Aedes, Culex,* and *Coquellettidia* mosquitoes.[27] Infection before 30 days of gestation may cause embryonic death, whereas infection between days 30 and 52 causes fetal malformations.[27]

Bluetongue Virus Infection. Hydranencephaly and/or arthrogryposis may occur in ruminants when the dam is infected at specific vulnerable windows during gestation; abortions or fetal resorption can also occur. Serotype 11 or serotype 17 of the virus is most frequently isolated from calf and lamb neonates in field epizootics.[28,29] Recently, bluetongue virus serotype 8 has caused devastating disease in ruminants in Central and Northern Europe; importantly, neonates infected in utero may be born viremic, thereby providing *Culicoides* spp. with more abundant viremic hosts during the subsequent spring.[30] Calves, lambs, and kids infected in utero may be born normal or develop one or more associated birth defects including hydranencephaly, arthrogryposis, brachygnathia, prognathia, and excessive gingival tissue (see Chapter 32 for additional information).

Bovine Viral Diarrhea Virus Infection. Hydranencephaly, hydrocephalus, and cerebellar hypoplasia have been associated with fetal infection of cattle with the BVD virus.[31-34] Precolostral serum antibody titers for the virus in affected calves vary; some titers range from 1:32 to 1:256, but other calves may have persistent viremias yet no demonstrable antibody.

Schmallenberg Virus Infection. The Schmallenberg virus (SBV) is an enveloped RNA virus belonging to the genus *Orthobunyavirus* in the family Bunyaviridae.[10] The Schmallenberg virus is a member of the Simbu serogroup, which includes the well-known teratogenic Akabane virus. It is named after a town in west-central Germany where, in the autumn of 2011, signs of this viral disease first emerged in local cattle. Diagnosticians at the Friedrich-Loeffler Institute (the Federal Research Institute for Animal Health Investigation) subsequently identified this virus as a cause of transient fever, depression, reduced milk production, and occasional diarrhea in cattle. The virus was subsequently detected in ruminants in France, Belgium, the Netherlands, Luxembourg, the United Kingdom, Italy, and Spain.[11] During the fall of 2011, infections in small ruminants in the region were predominantly asymptomatic; however, once ruminant birthing commenced in late 2011 and early 2012, it became apparent that the virus had induced significant fetal morbidity and mortality—primarily in sheep—but in goats and cattle as well.

Fetal infection with SBV may result in abortion, stillbirth, weak newborns, newborns with significant neurologic deficits, or normal, healthy neonates; on the basis of the pathophysiology of Akabane viral infections, the outcome of fetal infection with SBV is considered likely to depend on the timing of viral infection relative to the stage of fetal development.[10,11] Infection early in pregnancy, within the first trimester, appears to result in the most significant fetal deformities, with arthrogryposis of one or more limbs, torticollis, spinal malformations (scoliosis, kyphosis, and/or lordosis), brachygnathia inferior, and a multitude of CNS malformations.[10,11] Hydranencephaly, porencephaly, and hydrocephalus are among the more common neurologic malformations. According to the Office International des Epizooties (OIE, or World Organization for Animal Health) the clinical disease in ruminants can best be categorized as an *arthrogryposis/hydranencephaly syndrome.*[12] Fetal limb, neck, and spinal skeletal anomalies can result in dystocia. To date, there have been no reports of SBV causing human infections, and the virus is not presently considered to be a zoonotic threat.

As is the case with other members of the *Orthobunyavirus* genus, SBV is an arthropod-borne virus, with Culicoid midges (specifically, *Culicoides obsoletus*) currently considered to be the most likely vector in Europe.[13] Other vectors, however, may also be involved. Vertical transmission of the virus from infected ruminant dam to ruminant fetus is considered to be the primary means of spread within animals. Horizontal transmission is a possible but less likely means of transmission. The cause of SBV emergence in Europe remains undetermined. Current research efforts are aimed at screening banked sera for evidence of previous exposure to the virus in European livestock, characterizing the vector(s) that may transmit the virus, investigating potential means of animal-to-animal spread, and vaccine development.

Other Infectious Agents. A single case of hydrocephalus in a calf aborted at 7 months of gestation was associated with necrotizing encephalitis caused by *Neospora caninum.*[35]

HYPERTENSIVE HYDROCEPHALUS. An increase in CSF volume that results from compressive or obstructive lesions in the ventricular system or from decreased CSF absorption is called *hypertensive hydrocephalus.*[2] Obstructive lesions of the ventricular system trap the CSF in the ventricles, causing an increase in CSF volume and pressure. Ischemia and CNS degeneration result from the high CSF

VetBooks.ir

pressure. The sites of obstruction most often include the lateral apertures, mesencephalic aqueduct, lateral ventricles, interventricular foramina, and fourth ventricle. The obstructions may be either congenital or acquired. Causes of acquired obstructive hydrocephalus include cerebral abscess, cholesteatoma (equines), equine infectious anemia, *Coenurus cerebralis* infestation, meningitis, and lymphosarcoma. Hypertensive hydrocephalus may also be caused by acute inflammatory disease such as meningitis and vitamin A deficiency. In these diseases the increased pressure is the result of impaired CSF resorption.

CONGENITAL HYPERTENSIVE HYDROCEPHALUS. Congenital hypertensive hydrocephalus is a hereditary condition seen in Hereford, Charolais, Ayrshire, Dexter, Holstein, and Jersey calves.[36-38] The condition has also been recognized in Arabian foals.[39]

Clinical Signs Hydrocephalic animals are often born dead or are weak and die shortly after birth. The most obvious signs in animals that survive include failure to bond to the dam, depression, diminished learning ability, partial failure of suckling, droopy head and ears, muscular fasciculations, head tremor, conscious proprioceptive deficits, blindness, ventrolateral strabismus, nystagmus, dysphonia, tongue flaccidity or paralysis, retention of food material in the cheeks and lips, limb spasticity, hyperreflexia, psychomotor seizures, recumbency, and coma. Occasionally, doming of the calvarium or protrusion of fluid-filled cystic structures through an open fontanelle is seen. Affected neonates often do not ingest sufficient amounts of colostrum and frequently die of septicemia.

In virally induced cases of hydranencephaly, associated skeletal deformities including abnormally curved ribs, kyphoscoliosis, flexural deformities of the limbs, domed skulls, and brachygnathia may be observed. Patients with hydrocephalus caused by compressive lesions around the ventricular system may show unilateral or bilateral signs of increased intracranial pressure. The clinical signs of unilateral lesions include head tilt (toward the lesion side), ipsilateral mydriasis, and contralateral menace deficit. Signs of hydrocephalus in foals are similar to those in calves. The cause of the condition in horses is unknown.

Antemortem diagnosis of brain malformations has been facilitated by CT and MRI. However, these techniques are rarely warranted or available for use in large animal species. A more practical technique for using ultrasonographic imaging, transorbital echoencephalography, has recently been described and has proved effective for the diagnosis of hydranencephaly.[40]

Clinical Pathology The diagnosis of hydrocephalus in calves and lambs is typically based on the presence of characteristic clinical signs and a domed skull. Whenever hydranencephaly is suspected, blood should be collected for virus isolation, serologic testing, and quantitative immunoglobulin determination. Presuckle serum samples from neonates that have been infected by the akabane or bluetongue virus in the latter part of gestation may be seropositive.[26]

Necropsy Findings The pathologic lesions of hydranencephaly are similar regardless of the etiologic agent. They include microcephaly, cerebellar hypoplasia, hydrocephalus, hydranencephaly, and porencephaly of the cerebral and the cerebellar cortex. Microscopic lesions of hydranencephaly include segmental loss of dorsolateral ventricular ependyma, thinning of the periventricular white matter, porencephalic cysts, and nonsuppurative meningoencephalitis. Lesions in other parts of the CNS may include loss of ventral horn cells in the spinal cord and demyelination in the spinal cord. Nonsuppurative inflammatory changes may be seen in cases caused by viral infections. Polymyositis has been described in affected calves; however, it is unclear if these lesions are caused by viral infection or occur secondary to the denervation. The skeletal deformities associated with virally induced hydranencephalies include rigid extension or contraction of one or more limbs (arthrogryposis), abnormally curved ribs, domed skull, thickening of the calvarium, kyphoscoliosis, and brachygnathia. Important differential diagnoses include causes of normotensive hydrocephalus, vitamin A deficiency, and congenital infection with bovine viral diarrhea virus in cattle.

Treatment Except for one report of successful surgical intervention in a calf with a meningocele, no satisfactory therapy is available for the treatment of hydrocephalus or hydranencephaly in large animals.

Ammoniated Forage Toxicosis (Cow Bonkers)

Exposure of poor-quality forage to anhydrous ammonia improves the nutritional density of the material and reduces certain toxic fungal metabolites, specifically the prolactin-like toxins of the endophytic fungus *Acremonium coenophialum* in fescue hay.[1] Ammoniation increases dry matter intake, enhances digestibility, and increases the relative value of the protein content of the feed. However, overammoniation of the forage, at a rate exceeding 3% of the forage on a dry matter basis, may result in toxicosis. Studies now suggest that several dialkylimidazoles may be responsible for the neurotoxic effects of ammoniated feedstuffs, superseding previous theories that 4-methylimidazole is the primary neurotoxin.[2,3] Ammoniated foodstuffs containing high levels of molasses are more toxic than similarly treated grass hay. The toxin may be concentrated in milk; consequently, calves suckling from normal-appearing dams may show clinical signs of intoxication.

Affected animals are hyperesthetic and ataxic. At rest the animals assume a sawhorse stance, but when excited, they become hyperactive, appear to be blind, and circle propulsively. Other clinical signs include vocalization, dysphonia, and walking or running into objects. The periods of frenzy may result in recumbency and convulsions. The spasmodic episodes last for 15 to 20 minutes. Afterward the animals rest quietly, with occasional muscle tremors. Repeated occurrences of the mania may be precipitated by loud noises or other frightening experiences. The concentrations of ammonia in the blood and CSF may be increased. Although specific treatments have not been identified, one report indicated that affected calves benefited from acepromazine (0.045 mg/kg IV) and thiamine (1.14 mg/kg IM). Thiamine dosages higher than described in this report[4] (such as 10-20 mg/kg SC q12h) have been used for treatment of other neurologic diseases and may be considered for use in this disease.

Lead Poisoning

Definition and Etiology Lead poisoning in ruminants is characterized by an acute encephalopathy. In contrast, lead poisoning in horses is characterized by chronic polyneuritis. Blindness, ataxia, and depressed sensorium are significant clinical signs in cattle, sheep, and goats, whereas in horses the poisoning is associated with weight loss, dysphagia, and secondary aspiration pneumonia. Cattle are most often poisoned because of their tendency to lick or chew on foreign objects, their access to lead-containing materials, and their propensity to drink contaminated petroleum distillates.[1]

Clinical Signs The signs of lead poisoning in ruminants are characteristic of CNS derangement. During the first stages of lead poisoning, affected cattle stand alone and are depressed.[2] They may show hyperesthesia, muscular fasciculations, and rapid, spastic twitching of the eyelids or other facial muscles. Progression of the disease is associated with ataxia, conscious proprioceptive deficits, cortical blindness, head pressing, odontoprisis, coma, and convulsions.[3,4] Some animals may display episodic running, hyperesthesia, and bellowing. Others may die suddenly without premonitory signs. The more acute and severe the toxicity, the more acute, severe, and excitatory are the clinical signs.[5] Affected cattle may accumulate frothy saliva at the commissures of the lips. GI signs of bloat, diarrhea, rumen atony, and colic occur in about 60% of lead-poisoned

VetBooks.ir

cattle, and the presence of such signs increases the index of suspicion for lead toxicity versus other causes of cerebral dysfunction.[6] Infertility, abortions, and fetal malformations may result from exposure to lead.[5]

The clinical signs of lead poisoning in horses include weight loss, lack of coordination, laryngeal or pharyngeal paralysis, dysphonia, roaring, conscious proprioceptive deficits, loss of anal tone, facial paralysis, and difficulty with mastication.[7] Aspiration of pharyngeal debris caused by dysphagia may result in pneumonia. Fine muscular tremors occur intermittently. The poisoned animals die in psychomotor seizures. Horses with lead poisoning are emaciated at death.[8]

Clinical Pathology Diagnosis of lead poisoning is based on measurement of increased blood and tissue concentrations of lead. Tissue levels of lead in naturally poisoned cattle can reach 20 to 100 ppm in the liver, 30 ppm in the kidneys, and 5000 ppm in bone. When interpreting the results of a lead measurement, consideration of the reference ranges obtained with similar methodology is essential. Heparin is the anticoagulant of choice when collecting blood for lead measurement because it does not chelate the lead. The lead concentration of ruminal fluid from acutely poisoned cattle ranges from 0 to 11,875 ppm.[3]

Livestock that are chronically poisoned with low concentrations of lead may have a normal blood lead concentration but a high concentration in the bone. In these cases the poisoning can be diagnosed by administration of calcium disodium ethylenediamine tetraacetic acid (EDTA), which solubilizes the bone lead stores and increases the concentration of lead in the plasma. The soluble lead-EDTA complexes are excreted in the urine. The urinary lead concentration may rise by 40-fold over pretreatment levels within a few hours. In cases of chronic lead poisoning, radiographs of the abdomens of smaller patients may reveal lead-containing radiodense foreign material in the GI tract.[9] "Lead lines" may also be present in the long bones of young animals chronically exposed to lead.

When blood lead concentrations are normal in chronically poisoned animals, measurement of free erythrocyte porphyrins and erythrocyte concentrations of α-aminolevulinic acid (ALA) are the preferred methods of diagnoses. The concentration of porphyrins is increased in the blood, urine, and feces of animals with lead poisoning. The reference range of blood porphyrin concentrations in normal calves is 21.6 ± 11.6 to 45.6 ± 10.3 μg/dL for whole blood and 113 and 142.8 ± 32.4 μg/dL for erythrocytes.[4,10,11] In chronically exposed, asymptomatic cattle, the free erythrocyte porphyrin concentrations are frequently greater than 2000 μg/dL.

Reference ranges for ALA dehydrase are 45.8 ± 20.6 U, whereas activities ranging from 28 to 33 U have been reported in naturally exposed calves.[8] The urinary concentration of δ-ALA is increased and ranges above 500 μg/mL.[12,13] Measurement of ALA in the erythrocytes is more reliable than measurement in urine.[14]

Environmental sources of lead can be detected by direct measurement of the lead concentration of the soil or pasture forage. Forage from toxic pastures contains more than 30 ppm of lead, and in some cases the level may exceed 300 ppm.[13,15]

The hematologic abnormalities of lead poisoning are subtle. Most poisoned livestock have a normal hemogram. If present, lead-related changes are characteristic of a hemolytic anemia with an inappropriately robust regenerative response. The morphologic abnormalities of erythrocytes include anisocytosis, poikilocytosis, polychromasia, hypochromia, Howell-Jolly bodies, metarubricytes, and basophilic stippling.[3,16] The shape changes begin within hours after ingestion of the lead and peak by 100 days.[3,16] Blood changes do not occur in all cases of the disease and are not necessarily specific indicators of lead poisoning in cattle, in which elevated blood lead may be present without hematologic abnormalities.[17] However, hematologic abnormalities tend to be more consistent in chronic lead toxicity and in lead-poisoned horses.

Lead toxicity has a variety of effects on endocrine function in cattle. Elevated levels of serum T_3, T_4, estradiol, and cortisol have been demonstrated in cattle with elevated blood lead levels.[18] Parameters of liver function are also affected; serum alanine and aspartate transaminase (ALT and AST) levels are increased, whereas serum lipids, total protein, and albumin are decreased.

In poisoned animals the concentrations of protein and WBCs in CSF are increased, ranging from 50 to 100 mg/μL of protein and 5 to 50 mononuclear cells/mL, respectively. Such changes are relatively nonspecific and found with other causes of cerebral cortical necrosis.

Pathophysiology Lead enters the body through the GI tract or less often through the respiratory tract. Metallic lead and the sulfide form are less well absorbed than the acetate, phosphate, carbonate oxide, and hydroxide salts. Metallic lead is poorly absorbed and causes toxicity only when a lead foreign body becomes entrapped in the stomach for prolonged periods. Interaction between lead and other minerals may occur. For example, high levels of dietary calcium reduce the GI absorption of lead. Concomitant exposure to lead and cadmium results in a worsening of the clinical signs of lead poisoning.[19]

Acute toxic single doses of lead range from 200 to 600 mg/kg for calves and 600 to 800 mg/kg for adults.[20,21] Although intestinal absorption of lead is relatively inefficient, significant amounts can cross into the blood if sufficient quantities are ingested. Approximately 1% to 2% of the total oral dose of lead is absorbed by 24 hours.[3] Most of the lead absorbed from the digestive tract (90%) is bound to erythrocyte proteins, resulting in a low lead concentration in the plasma but higher concentrations in whole-blood specimens.[22] At the end of the erythrocytes' lifespan, the cell-bound lead is metabolized from the erythrocyte proteins and deposited in the bone as the triphosphate salt. The half-life of blood lead in adult cattle is extremely variable and unpredictable, ranging from 48 to 2507 days in one study.[23] Phenotypic or genotypic factors may affect metabolism and storage of lead. The variable time for clearance of lead has an obvious implication for public health because all carcasses of animals suspected or known to be exposed to lead must be tested before being cleared for human consumption.[24]

Lead also crosses the placental barrier and accumulates in fetal bone, liver, and kidneys but does not substantially accumulate in milk. However, cattle with higher blood lead levels may have greater concentrations in milk.[25]

The toxic effects of lead include inhibition of free sulfhydryl groups found in many enzymes, interference with zinc-containing metalloproteins, and steric inhibition of enzyme activity.[16] Enzymes of heme synthesis are particularly susceptible to injury. These include δ-ALA dehydratase and ferrochelatase. Interference with ferrochelatase inhibits the formation of heme from protoporphyrin, resulting in a buildup of unmetabolized porphyrins.

Because of the interference with heme metabolism and the altered function of other erythrocyte proteins, the erythrocyte half-life is shortened, which may result in a normochromic, normocytic anemia in a small proportion of chronically poisoned animals.[26] Iron is not adequately used and is stored in sideroblasts in the bone marrow.[11] Lead also interferes with the activity of pyrimidine-specific 5′-nucleotidase, resulting in basophilic stippling of red cells.[27]

After absorption, lead rapidly enters the brain at a dose-dependent rate. The lead deposition in the CNS results in acute cerebellar hemorrhage and edema from capillary dysfunction.[22] The pathogenesis of lead encephalopathy is multifactorial. Encephalitic signs probably originate from a combination of microvascular damage, cellular necrosis, brain swelling, neurotransmitter dysfunction, and decreased glucose uptake by the brain.[26]

Ingestion of lead also results in competitive inhibition of selenium uptake, thereby diminishing the absorption of selenium by up to 26%.[21] If selenium intake is marginal, lead toxicosis could manifest as overt selenium deficiency.

Epidemiology Sources of lead are legion including lead arsenate defoliants, batteries, used motor oil, linoleum, roofing felt, paint,

VetBooks.ir

machinery grease, caulking compounds, improperly compounded mineral supplements, and foliage near lead smelters and battery-recycling plants.[2,8,13,28-33] High lead levels have been reported in grasses growing near busy roadways, but the clinical significance of these findings is unclear.[30,34,35] Factors that can increase the likelihood of ingestion of lead-contaminated foodstuffs include lack of alternative feed, hunger, and phosphorus deficiency.[5] The single lethal dose of lead for cattle is estimated to range from 220 to 600 mg/kg for calves, 600 to 800 mg/kg for adult cattle, and 400 mg/kg for goats.[5,20] Lead poisoning has been reported in cattle exposed naturally to 6 to 7 mg/kg/day of lead on foliage and in calves given oral lead acetate at 2.7 to 20 mg/kg/day.[36] The interval for development of clinical signs ranges from 5 to 20 days and is related to the dose and ionic form of lead administered.[36] Ensiling of contaminated forage results in percolation and concentration of lead at the bottom of the silo.[37]

The toxicity of lead is apparently influenced by dietary factors. Calves on a milk diet are more susceptible to lead poisoning than calves fed hay and grain.[38] There appears to be a direct correlation between high levels of vitamin D and enhanced lead absorption, which may explain the greater occurrence of poisoning during the summer. Elevated copper concentrations in forage, such as may be found in pastures fertilized using pig slurry, may potentiate accumulation of lead in animals consuming it.[39]

The estimated cumulative toxic dose of lead for horses is 2.9 mg/kg/day.[40] Poisonings have been reported in horses grazing pastures contaminated with 320 to 440 ppm of lead from a metal smelter; this amounted to a daily intake of 2 g (≈6.4 mg/kg). Metallic lead and the "galena" (insoluble sulfide salt) are less toxic than the acetate and carbonate lead salts.[41]

Necropsy Findings The macroscopic brain lesions of lead poisoning are mild and include brain edema, congestion of vessels of the cerebral cortex, and yellowish discoloration and flattening of the cortical gyri. Lesions tend to be most severe in the occipital lobes. Microscopic changes in the brain include capillary prominence, endothelial cell swelling, edema of the Purkinje cell layer of the cerebral cortex, laminar cortical neuronal necrosis, and edema of the white matter.[42]

Treatment Therapy for lead poisoning should include removal of the lead from the digestive tract, chelation therapy with calcium disodium EDTA, and fluid and nutritional support of the patient. Treatment with calcium disodium EDTA (calcium versenate) has been shown to be superior to treatment with penicillamine or dimercaprol (BAL). The EDTA chelates osseous but not soft tissue–bound lead. After chelation, the unsaturated bone stores reequilibrate with the lead remaining in the soft tissues. In cases of acute lead poisoning, several days are required before reequilibration results in a decreased blood lead concentration. The dose of calcium disodium EDTA is 66 mg/kg/day, divided into several doses daily for 3 to 5 days.[43] After five daily treatments, a 2-day nontreatment period is recommended to reequilibrate the soft tissue and bone lead. After the 2 days' rest, daily treatments are given for another 5 days. The decision to continue therapy with EDTA should be based on the results of post-treatment blood lead analyses and renal function tests. Another recommendation is for administration of two IV injections of calcium disodium EDTA (110 mg/kg per dose) given 12 hours apart for 2 days.[44] Therapy is then withheld for 2 days, after which the EDTA treatments are reinstituted for 2 more days. The comparative efficacy of this regimen is unknown.

The EDTA also chelates other divalent cations. Consequently, prolonged administration of the drug results in trace-mineral deficiencies, especially of zinc. For this reason, after prolonged EDTA therapy, oral supplementation with zinc should be considered to prevent the development of parakeratosis.

Reports have indicated that thiamine therapy is an effective adjunctive treatment with EDTA in cases of acute lead poisoning of cattle.[20,45,46] Administration of 2 mg/kg thiamine daily was more effective than treatment with disodium EDTA (62 mg/kg twice daily for 4 days) or thiamine plus disodium EDTA in inducing remission of clinical signs of experimentally induced lead poisoning.[47] For clinical treatment of lead poisoning, thiamine dosages of 500 mg for small ruminants and 1 g for cattle weighing 300 kg have been recommended,[45] and alternatively, a dosage of 10-20 mg/kg SC q12h can be used. Administration of daily doses of thiamine (100 mg/calf/day or 5 mg/kg) has protected experimentally exposed calves from clinical signs of lead poisoning and reduced lead deposition in the soft tissues.[46,48,49] The nature of the protective effects of thiamine is unclear. Apparently, either lead interferes with thiamine synthesis or the tissue distribution and deposition of lead are reduced by the formation of rapidly excreted lead-thiamine complexes.

In ruminants, ingested lead is best removed from the digestive tract by means of a rumenotomy.[20] Magnesium sulfate laxatives are administered concomitantly to form insoluble lead sulfides. Patients that respond slowly to chelation and thiamine therapy should be given supportive care. These measures should include provision of 40 to 80 mL free water/kg/day for maintenance, oral hyperalimentation, and administration of diazepam or phenobarbital for convulsions (as discussed in the section on bacterial meningitis).

Prevention and Control Toxic pastures can be made safe by removing contaminated forage. This is best done by cutting, baling, and burying native grasses, then burning the stubble. The source of the lead should be established, and the affected animals should be carefully documented. In the United States, insurance liability responsibilities may be covered under homeowner or farm insurance.

Helichrysum argyrosphaerum (Golden Guinea Everlasting, Vaalsewejaartjie) Poisoning

Both naturally occurring and experimental poisoning of sheep and cattle in South Africa by plants of the genus *Helichrysum* results in blindness and a variety of CNS signs.[1,2] The clinical signs of intoxication include progressive tetraparesis, depression, nystagmus, mydriasis, blindness, intentional head tremor, and star-gazing attitude. Older sheep may develop lens cataracts 2 to 3 months after eating the plants. The case-attack rate ranges from 1% to 29%. Plants are toxic only in the flowering stage. *Helichrysum* spp. have been shown to contain substances that bind at the γ-aminobutyric acid (GABA)–benzodiazepine receptor, suggesting a mechanism for toxic effects on the nervous system.[3]

Pathologic findings include widespread status spongiosus of brain white matter, particularly in subependymal areas and in the cerebellar peduncles and brainstem.[2] Myelin edema is present in some cases. Edematous swelling of the optic nerve causes compression of the nerve in the optic canal, with secondary damage to nerve axons and myelin. The toxic principle in *Helichrysum* plants also causes a primary retinopathy in some animals.

Flatpea (*Lathyrus sylvestris, Lathyrus collis*) Poisoning

Ingestion of flatpea *(Lathyrus sylvestris, Lathyrus collis)* results in a CNS disorder. The condition may be seen by 5 days after consumption of a diet composed of 50% flatpea vines. Toxicosis has been induced in sheep ingesting forage of 35% flatpea vines.[1] Livestock can develop a tolerance for the plant through rumen microbial detoxification. Nevertheless, acclimatized animals can be rendered susceptible by treatment with monensin or by a change in rumen microflora.[2]

The toxic constituent of the plant, 2,4-diaminobutyric acid, is known to inhibit ornithine transcarbamylase, an enzyme responsible for urea detoxification. Consequently, the blood ammonia concentration in clinically affected animals is increased.

VetBooks.ir

The clinical signs of flatpea intoxication are depression, muscular tremors, and spasmodic torticollis. Affected animals become recumbent and are reluctant to rise. When stimulated to move, they display circling, head pressing, and odontoprisis. The urine may appear dark brown. The clinical disorder often culminates fatally in a seizure. During the interictal periods the animals may rest, rise, and resume normal behavior and gait. Treatment is empiric and supportive and could include 1 to 2 L of vinegar PO, IV diazepam, and removal from the offending forage.

L. sylvestris is a leguminous plant with a high protein content that might be an adequate substitute for alfalfa in areas where the latter grows poorly.[3] *L. sylvestris* harvested in the vegetative state has been fed to lambs in combination with alfalfa and as a sole diet without ill effect.[4] Similarly, when fed as part of a mixed silage in which the concentration of diaminobutyric acid was approximately 1%, *L. sylvestris* produced an acceptable weight gain in cattle without signs of toxicity.[5]

Nitrofurazone Toxicosis

Nitrofurazone is an antimicrobial that has been fed to cattle for the treatment and control of respiratory or gastrointestinal diseases. Treatment of food-producing animals with the nitrofurans is currently prohibited by the U.S. Food and Drug Administration. Nervous system signs of nitrofurazone toxicosis occur after 1 to 3 weeks of continuous feeding at dosages exceeding 15 to 30 mg/kg.[1,2] Lower dosages (7.1 mg/kg) reduce feed intake but do not result in neurologic signs. The nitrofurans inhibit enzymes of the oxidative glycolytic pathways and are thought to interfere with brain metabolism of carbohydrates.

Clinical signs of nitrofurazone toxicosis include hyperirritability, propulsive running, muscular tremors, blindness, convulsions, and death. At lower doses the convulsions may appear intermittently, but as the condition progresses, the signs become continuous.

Coenurosis (Sheep Gid; *Coenurus cerebralis* Infestation; *Taenia multiceps* Infestation)

Definition and Etiology Coenurosis is caused by invasion of the CNS by *Coenurus cerebralis,* the intermediate stage of the tapeworm *Taenia multiceps.* The adult worms live in the intestine of domestic dogs and some wild carnivores, where they shed eggs into the feces. Ruminants eat the eggs from contaminated pastures. The eggs hatch in the small intestine of the ruminant, and the larval stages travel through the blood to the CNS, where they mature into *C. cerebralis.* The life cycle is completed when the ruminant dies and the brain is eaten by a scavenging carnivore. *Coenurus* cysts then develop into sexually mature adults in the bowel of the carnivore host.

Many animals including sheep, goats, cattle, horses, wild ruminants, and humans are susceptible to *C. cerebralis* infestation.[1-3] Outbreaks of coenurosis may occur in previously uninfected sheep that are suddenly exposed to contaminated fecal matter from carnivores. Cases initially occur as early as 2 weeks after the sheep are exposed and continue for as long as 4 months.

Clinical Signs Signs can occur acutely, during the migratory phase of the larval stage in the intermediate host. Lambs 6 to 8 weeks old are most often affected by this form and develop fever, dullness, and mild neurologic deficits.[4] Occasionally, acute encephalitis occurs, leading to sudden onset of severe neurologic signs and death within a few days. More frequently, the clinical presentation of coenurosis is that of a space-occupying brain lesion; signs include depression, anorexia, ataxia, unilateral or asymmetric loss of vision, facial hemiplegia, head tilt, circling, high-stepping forelimb gait, and hyperesthesia. When the spinal cord is the site of cyst development, hindlimb ataxia and paresis to paralysis is the main clinical sign.[5] As the disease progresses, the sheep assume lateral recumbency and become comatose.[6,7] In advanced cases the calvarium directly over the parasite enlarges and softens.[3]

Pathophysiology Lesions of the CNS may result from three separate pathogenic mechanisms. These include encephalitis from invasion of the CNS by large numbers of larvae, hypertensive hydrocephalus resulting from interference with CSF drainage, and development of large cerebral cysts that increase intracranial pressure.

Necropsy Findings In the acute form of coenurosis, the main finding is coagulation necrosis and inflammation associated with the pathway of the larval form as it migrates through the CNS.[8] This may be visible grossly as yellow to red tracks through the brain parenchyma. Coagulation necrosis and surrounding inflammatory cells such as degenerate granulocytes, macrophages, and histiocytes are found microscopically. The mature cysts, up to 7 cm in diameter, are thin walled and contain clear fluid or, occasionally, purulent fluid. Protoscolices, up to many hundreds, can be visualized microscopically within the cysts, which are surrounded by severe and mainly nonsuppurative inflammation. The cysts deform and compress the underlying brain tissue.

Diagnosis The combination of a characteristic clinical syndrome and location in an endemic area supports a presumptive diagnosis. Radiographs in the lateral and posteroanterior planes may detect radiolucent areas in the calvarium. The optimum diagnostic views in the posteroanterior projection occur whenever the base of the nose is level with the upper margin of the orbit. When possible, CT effectively demonstrates the presence of cysts.[9]

Treatment Praziquantel (50 to 100 mg/kg PO q24h for 3 to 5 days) is effective for the treatment of coenurosis in sheep that do not yet have neurologic signs.[5,10] Concomitant administration of an NSAID or dexamethasone may enhance the posttreatment survival rate. The cyst can also be removed surgically by craniotomy.[11-15]

Prevention In endemic areas the carcasses of affected animals should not be fed to dogs, and dogs in endemic areas should be treated repeatedly with a vermifuge to minimize the possibility of pasture contamination. Appropriate management practices have virtually eliminated this disease from North American sheep flocks.

Ceroid Lipofuscinosis

Definition and Etiology Ceroid lipofuscinosis is a lysosomal storage disease that has been reported in South Hampshire, Swedish Landrace, and Rambouillet sheep; Nubian goats; Devon cattle; and horses.[1-5] The disease is known to be inherited as an autosomal recessive trait in many cases[7] and is believed to be so in others.[6] It is characterized by the intracellular accumulation of abnormal autofluorescent lipopigments in lysosomes of neurons and other cells throughout the body. The storage material has been shown to consist predominantly of the subunit *c* of mitochondrial *c* synthase.[8,9] Affected animals display progressive ataxia and postural abnormalities, blindness due to retinal involvement in many cases, sensory depression, and terminally, coma. Lesions seen on CT scans include enlargement of the lateral ventricles and reduced thickness of the cerebral cortex.[10]

Gross pathologic lesions in the CNS may include moderate enlargement of the lateral ventricles, flattening of cerebral gyri, and a yellow to brown discoloration of the brain parenchyma. Accumulation of protein storage material in neuronal lysosomes is evident on microscopic examination and is accompanied by neuronal necrosis and astrocytosis, which may be severe. The lesions sometimes have a lamellar appearance.[11] The disease is ultimately fatal, and no practical method of treatment is currently available.

Diseases Presenting Principally with Brainstem and Cranial Nerve Dysfunction

Peripheral Vestibular Disease of Horses

Robert J. MacKay • Mary O. Smith

Definition and Etiology Vestibular disease of horses is an acute, usually asymmetric, condition with several major causes: bacterial or mycotic infection of the middle/inner ear, polyneuritis equi, viral/idiopathic labyrinthitis, remodeling and/or fractures of the petrous temporal bone associated with temporohyoid osteoarthropathy (THO), and external trauma to the skull with or without fracture of the petrous temporal bone.[1] Idiopathic labyrinthitis is probably an acute viral inflammation of the vestibular system that is severe, but complete recovery is common. Lightning strike is also an uncommon cause of vestibular signs in horses.[2,3] Staphylococci, streptococci, *Actinobacillus, Aspergillus, Enterobacter, Pseudomonas, Salmonella* spp., and *Corynebacterium pseudotuberculosis* have been isolated from cases of otitis media/interna in horses.[1,4] There has been speculation that THO results from extension of chronic low-grade bacterial otitis media to the adjacent temporohyoid joint[5]; however, remodeling and fusion of the temporohyoid joint is more likely the result of repeated trauma and/or chronic degenerative processes.[6,7] Primary otitis media/interna in horses is probably rare and, by contrast to ruminants, young age does not appear to be a risk factor. It is presumed that the middle ear is infected via the eustachian tube or hematogenously. With the exception of viral/idiopathic labyrinthitis, the proximity of the facial canal to the vestibular system means that the facial nerve (VII) is frequently involved in conditions causing vestibular signs.

Clinical Signs There is rotation of the poll (i.e., head tilt) toward the affected side, abnormal physiologic nystagmus, spontaneous horizontal or rotatory nystagmus with the fast phase away from the affected side, and vestibular strabismus with downward rotation (infraduction) of the eye ipsilateral to the lesion that can be exaggerated by elevating the horse's chin. There is usually a staggering, dysmetric gait, with a tendency, because of increased extension of the contralateral limbs, to lean or circle toward the affected side. Horses with any acute peripheral vestibular disease sometimes fall or even roll to the side of the lesion and may panic and thrash wildly in an effort to stand. Bilateral vestibular disease causes severe dysmetria and ataxia, and complete absence of normal vestibular nystagmus. The horse may have wide swinging movements of the head.

Signs of vestibular disease are markedly exacerbated by blindfolding. Deafness is also apparent with bilateral involvement of the cochlear division of cranial nerve VIII. With unilateral vestibular disease, visual accommodation often occurs over a period of weeks and affected animals may even return to racing. Signs of vestibular disease may still be elicited by blindfolding, however.

Concomitant ipsilateral facial paralysis is evident as deviation of the nose toward the normal side, reduced flaring of the ipsilateral nostril during inspiration, and ipsilateral drooping of the lip, eyelid, and ear. Reflexes involving cranial nerve VII such as the lip, eyelid, menace, and ear reflexes are reduced or absent. Inability to close the eyelid causes exposure keratitis, which is particularly severe and usually involves deep horizontal corneal ulceration when there is damage to the secretomotor fibers of the facial nerve at or proximal to the geniculate ganglion. With chronic facial paralysis, there is visible atrophy of the parotidoauricularis caudal to the vertical ramus of the mandible.

Horses with bacterial otitis media/interna may have other sites of infection including paranasal sinuses, guttural pouches, and the lower respiratory tract. Extension of infection along a fracture defect or from otitis media/interna into the meninges is associated with development of additional neurologic signs including obtundation, limb ataxia and weakness, and cranial nerve deficits, along with systemic signs of sepsis including fever, tachycardia, and tachypnea.

Diagnosis and Treatment A complete blood cell count (CBC) should reveal leukocytosis and increased fibrinogen concentration in cases of chronic otitis media/interna, whereas neutrophilic pleocytosis in CSF samples is evidence of secondary meningitis. Diagnostic procedures for horses with peripheral vestibular disease include skull radiography, CT, and endoscopic examination of the guttural pouch. Otoscopic examination in the horse is difficult,[5,8] and general anesthesia is required for transtympanic centesis of the middle ear, although this procedure can rarely be justified. The rate of tear secretion may be tested with a Schirmer tear test strip and should be greater than 17 mm/min. Brainstem auditory-evoked response testing may help to establish the location of vestibular pathology as peripheral versus central.[9]

Antibiotic treatment of peripheral vestibular disease due to otitis media/interna should, if possible, be guided by antimicrobial susceptibility testing of bacteria cultured from the middle ear or from related processes such as sinusitis, guttural pouch empyema, or pneumonia. In the absence of such information, coverage should be provided against gram-positive bacteria by penicillin G (22,000 units/kg bid IM as procaine penicillin or IV qid as potassium penicillin) or ceftiofur sodium (2.2 to 5 mg/kg IM sid to bid). Additional coverage (including for staphylococci) can be provided by the addition of enrofloxacin (5 mg/kg IV, or 8 mg/kg PO sid). Oral continuation of treatment can be conveniently provided by trimethoprim-sulfonamide drugs (30 mg/kg PO bid) or chloramphenicol (50 mg/kg PO qid). Treatment should continue for at least 30 days and ideally should be guided by results of repeated imaging of the affected petrous temporal bone.

Affected horses should be kept in a quiet, heavily bedded stall with good footing. Exposure keratitis may be treated or prevented under a partial tarsorrhaphy.

Equine Nigropallidal Encephalomalacia (Star Thistle Poisoning, Knapweed Poisoning)

Robert J. MacKay

Nigropallidal encephalomalacia (NPE) is a disease of adult horses characterized by facial and lingual dystonia, mild obtundation, behavioral signs, and ataxia. NPE is caused by ingestion of large quantities of the plants *Centaurea solstitialis* (yellow star thistle) or *Rhaponticum repens* (Russian knapweed; syn. *Acroptilon repens, Centaurea repens*).[1-4]

Clinical Signs The signs appear suddenly but always after long-term ingestion of large quantities of the plants. Characteristic signs of NPE include weight loss, mild to moderate obtundation, ataxia, yawning, lowered head, protruding tongue, tremor of the tongue and lips, and facial grimacing when feed is offered. The facial hypertonicity causes a retraction of the lips, resulting in a fixed grimace with the mouth and lips held half open. Although affected horses can grasp food between the incisors, prehension, chewing, and swallowing of food are uncoordinated and inefficient. There may be constant chewing movements and food retained in the mouth, and cheek pouches may protrude from the commissures of the lips. Affected animals may attempt to drink by immersing their muzzles deeply into the bucket to force the water into the back of the pharynx. There also may be a transient tendency to walk compulsively, often in circles. Occasionally, horses with NPE are hyperexcitable.

After several days of progression, signs stabilize and do not then progress. Affected animals usually do not recover and are euthanized or die of starvation or dehydration.

Diagnosis The CSF of affected horses may have high nucleated cell counts.[3] There are no characteristic changes in the CBC or the

VetBooks.ir

serum chemistries. MRI was used to make an antemortem diagnosis in one horse with NPE.[5]

Pathophysiology A toxic principle in yellow star thistle and Russian knapweed has been isolated and chemically characterized and named *repin*. Repin is a sesquiterpene lactone with high affinity for neural tissue.[6-8] Studies in rats suggest that repin exerts its neurotoxic effects by inhibiting dopamine release.[8] A role for neurotoxic amino acids, including aspartic and glutamic acids, has been proposed, but recent work could not confirm their presence in yellow star thistle.[9] Immunohistochemical staining of affected brains show that NPE is similar to environmentally acquired toxic parkinsonism of humans, with clinical findings attributable to lesions in the globus pallidus and substantia nigra pars reticulata rather than to destruction of dopaminergic neurons.[10]

Necropsy Findings At necropsy, sharply demarcated areas of yellowish malacia are visible grossly in the substantia nigra and globus pallidus (extrapyramidal system). Lesions are symmetric in most but not all cases. Lesions in other brainstem nuclei are found in a small number of animals.[2,9] Microscopic lesions include neuronal necrosis, vacuolation with gliosis, liquefactive necrosis, and cavitation in well-developed lesions.[11]

Epidemiology NPE has been reported in horses of the United States, Australia, and South America. Yellow star thistle is a common plant in unirrigated pastures in the arid regions of the western United States. The plant is resistant to the effects of saline or alkaline soil conditions and has a minimal moisture requirement. Russian knapweed belongs to the sunflower family and grows predominantly on flood plains, where it can extract deep subterranean moisture. In the United States the plants tend to remain green during the dry months, so most poisonings occur during the summer or late autumn. Most horses are reluctant to eat *Centaurea* and *Rhaponticum* plants unless other vegetation is unavailable, but some develop a craving and selectively seek it out. Horses that develop NPE are usually being fed a poor-quality, high-roughage diet. Affected horses range from 4 months to 10 years of age (median, 2 years).[11] The case-attack rates of yellow star thistle poisoning range from 3% to 31% of horses on infested pastures.[11] Feeding studies have reported that as much as 59% to 200% of the body weight of yellow star thistle and 59% to 63% of Russian knapweed must be eaten over 3 to 11 weeks to cause clinical disease.[2,11] Continuous protracted exposure to the weeds seems to be important for expression of clinical disease. The dried plants retain their toxicity.

Treatment and Prevention There is no known treatment for the poisoning. Prevention is best aimed at correcting the nutritional problem by daily supplementation with 10 to 15 lb of alfalfa hay and by not pasturing horses in areas where either of the responsible plants grows.

Temporohyoid Osteoarthropathy

Robert J. MacKay • Lisle W. George

Temporohyoid osteoarthropathy (THO) is a progressive syndrome involving periosteal reaction, enlargement and sclerosis of the stylohyoid bone, tympanic bulla, and petrous portion of the temporal bone (Fig. 35-10).[1] Ultimately, there is fusion between the skull and hyoid apparatus, stricture of the external ear canal, and obliteration of the lumen of the tympanic bulla. These changes are thought to represent a primary degenerative process in the temporohyoid joint (THJ), although it is conceivable that some cases are secondary to chronic otitis media.[1-3] The tympanic membranes of horses with this condition are usually not inflamed, and ruptures and associated discharges from the external ear are uncommon.[1] Horses from 6 months to older than 20 years of age have been affected with a mean or median age of 10 to 12 years reported in all studies.[1,4-8] Quarter Horse and Quarter Horse–type breeds accounted for more than 50% of cases in several but not all series.[4-7] Both joints are affected, albeit asymmetrically, in most horses with clinical THO.[4] In rare instances, there are associated clinical signs on both sides.[5,6] Fusion of the THJ causes interference with the interdependent coordinated movements of the tongue, hyoid apparatus, and larynx. Particular stress is placed on the fused joint(s) during chewing, swallowing, vocalizing, and combined head and neck movements. Veterinary procedures such as dental work and passage of a nasogastric tube also put unaccustomed pressure on the THJ. Any of these mechanical forces applied to the immobilized THJ may result in fractures through the petrous temporal bone or proximal stylohyoid bone. THO is also likely a risk factor for fracture of the petrous temporal bone during head trauma, especially in horses that flip over backward and strike the poll. The facial nerve (cranial nerve VII) and vestibulocochlear nerve (VIII) and apparatus are within the petrous temporal bone and can be impinged on by bony proliferation or lacerated by fracture. After fracture of the petrous temporal bone, there may also be extension of middle/inner ear infection around the brainstem with signs of meningitis or extradural abscess.

FIG. 35-10 Rostral view of left and right tylohyoid bones from a horse with left-sided temporohyoid osteoarthropathy. Note fusion of the temporohyoid joint on the affected side and extensive remodeling and enlargement of the stylohyoid.

Clinical Signs Two sets of clinical signs are associated with the evolution of this disease process.[1] Early in the syndrome, including the period before ankylosis of the temporohyoid joint, reluctance to chew, dysphagia, headshaking, ear rubbing, sensitivity to pressure at the base of the ear, facial hyperesthesia, wild tossing of the head and neck under tack, reluctance to take a bit, dropping of feed, or even weight loss may be seen, although most THOs are probably subclinical until development of neurologic signs. Fracture of the proximal stylohyoid bone increases the likelihood of pain-associated clinical signs. Because of bony proliferation around the ear canal, the external ear may be unusually narrow and difficult to examine by otoscope.

After fusion of the THJ, the disease may manifest as sudden onset of asymmetric signs of cranial nerve VII and/or VIII dysfunction. Almost all affected horses have degrees of facial paresis, with drooping of the ear, upper eyelid, and lower lip on the affected side and deviation of the muzzle to the contralateral side.[1,6,7] Buccinator weakness results in "quidding" (retention of feed material in the denervated cheek) and dropping of feed. Facial denervation may be

VetBooks.ir

evident as fine fasciculations of facial muscles and, after 2 weeks, obvious atrophy of the parotidoauricularis muscle behind the vertical ramus of the mandible. Facial paralysis may occasionally be bilateral.[5] Schirmer tear tests commonly disclose reduced tear production (i.e., values of 5 to 20 mm, normal >20 mm),[5] indicative of injury to the parasympathetic lacrimal branch of the facial nerve. By the time of presentation, most such horses already have a deep horizontal corneal ulcer with corneal edema and miosis. Because of facial weakness, affected horses cannot mount the typical response to corneal ulceration—namely, blepharospasm and epiphora, so ulcers often go undetected by horse owners. Signs of vestibular dysfunction accompany facial paresis in the majority of cases. Of 29 horses with THO that had involvement of VII, 23 (≈80%) had vestibular signs.[6] Typically, there is a sudden onset of head tilt, neck turn, body lean, and tight circling, all toward the affected side, and a staggering ataxic gait with preservation of limb strength. These signs may be revealed or exacerbated by blindfolding the horse. In the acute stages, there may be conjugate horizontal nystagmus, with the fast phase away from the side of the lesion. In a study of 11 horses with THO and neurologic signs, all had electrodiagnostic evidence of partial to complete hearing loss on the affected side; 5 also had partial hearing loss on the contralateral side.[5] Although it is unusual, vestibular signs can occur without concurrent involvement of the facial nerve. Rarely, horses may also have difficulty eating and swallowing due to either pain (e.g., because of acute stylohyoid fracture) or involvement of cranial nerves IX and X. A few horses have seizure-like convulsions at the onset of neurologic signs. Bacterial abscess adjacent to the brainstem or meningitis may be sequels to fracture of the petrous temporal bone and result in the death of the horse.

Diagnosis Endoscopic examination of the inside of the guttural pouches is the diagnostic imaging test of choice because of its convenience in standing horses and its high sensitivity for detection of THO.[6] Evaluation of the external contour of the THJ from within the guttural pouch can detect asymmetric enlargement and discoloration of the stylohyoid bone and THJ and, in some cases, hyperemia, edema, and/or hemorrhage in the guttural pouch lining surrounding the joint. Previously healed fractures of the stylohyoid bone may be evident as angulation and distortion of the bone close to the THJ. CT imaging of the THJ allows appreciation of changes not always evident by endoscopy (or plain radiographs) including involvement of both sides, enlargement of the ceratohyoid bone, fractures of the petrous temporal and stylohyoid bones, and the presence of fluid in the tympanic bullae.[4,9] A system has been developed to quantify the remodeling changes found in THO cases.[4] The main disadvantage of CT is the expense and requirement for general anesthesia. In Europe, where standing CT units are available in some referral practices, this is less of a concern, although adequate positioning can be difficult in horses with severe vestibular dysfunction.[8] Radiographic examination of the skull using ventrodorsal, lateral, and lateral oblique views detects those cases in which the bony proliferation has progressed to cause osteitis and fusion of the temporohyoid joint. Optimal images are obtained with the horse under general anesthesia and in dorsal recumbency; however, adequate views can be taken using a dorsoventral projection with the horse standing but heavily sedated. Sensitivity for detection of THO by plain radiography in one series was 20/24 (83%).[6] MRI and nuclear scintigraphy are imaging techniques that have been applied successfully to THO diagnosis but have not found wide application.[6,8,10]

Brainstem auditory-evoked response (BAER) testing of vestibulocochlear nerve function has been described for horses with THO and is the only way of evaluating auditory function in these horses.[5] It is also a sensitive method for detecting involvement of the contralateral side.

In horses with neurologic signs other than dysfunction of CNN VII and VIII, CSF tap, analysis, and possible culture are recommended. Two of four horses tested in one report had increased nucleated cell counts or protein concentrations suggestive of septic or nonseptic meningitis.[6] Xanthochromia and increased RBC counts are also expected in acute cases.[3]

Treatment and Prognosis Medical and surgical approaches to THO have been described.[1,3,11] Conservative medical therapy involves prolonged rest and treatment with an NSAID (e.g., 2 mg/kg phenylbutazone PO, or 1.1 mg/kg flunixin IV or PO twice daily for 3 days, then once daily for 1 to 2 weeks more) and broad-spectrum antibiotics (e.g., trimethoprim-sulfa, 30 mg/kg PO twice daily for 30 days). The lever action of the hyoid apparatus on the petrous temporal bone can be removed surgically by complete removal of the ipsilateral ceratohyoid bone or removal of a 1- to 2-cm section from the middle of the stylohyoid bone.[3,11,12] Because midbody stylohyoid ostectomies tend to heal,[12] the ceratohyoid procedure is now favored. If necessary, this surgery can be done bilaterally and the procedure can be performed in the standing sedated horse. With facial nerve paralysis and keratitis sicca, corneal ulcers are a medical emergency and must be treated or prevented with topical antibiotics, artificial tears, and, preferably, a multifocal partial split-thickness tarsorrhaphy.[3] For this purpose, shallow 3- to 5-mm-long incisions are made in the tensed lid margins of each eyelid immediately posterior to the line of tarsal gland openings. Using 5-0 absorbable suture, a bite is taken in each eyelid deep in the incision, in the plane of the eyelid, and then the suture is carefully tied so that margins evert away from the corneal surface.[3] One or two shallow horizontal mattress sutures are then placed in the everted lid margin. The eyelids are joined in this manner at two or more sites, leaving open the nasal third of the palpebral fissure. The tarsorrhaphy is maintained permanently or until resumption of lacrimal and eyelid function, which may take up to 18 months.

Both medical and surgical approaches reportedly have returned most treated horses to athletic activity after a period of weeks to months, so there is not yet clear evidence to support the need for surgery in all cases.[1,6,7] On theoretical grounds, however, it is clear that a horse with THO will remain at risk for catastrophic relapse of neurologic signs as long as the hyoid apparatus and skull remain connected through a fused THJ. Relapse is particularly likely if there is a temporal bone fracture. In one series 20 of 30 horses treated medically (18) or surgically (2) survived, with 19 of 20 returning to athletic function albeit with persistent mild residual facial and/or vestibular dysfunction in most cases.[6] Four horses in this series died or were euthanized because of fractures along the base of the skull, complications that should be preventable by ceratohyoidectomy.

If possible, the management of convalescent horses should be adjusted to minimize stress on the remaining THJ(s). Cribbing collars can be tried for crib biting, bitless bridles can be used for riding, and dental work and other professional procedures can be minimized and done cautiously.

Horner Syndrome

Robert J. MacKay • Lisle W. George

Definition and Etiology Horner syndrome results from interruption of ocular sympathetic pathways. Sympathetic pathways to the head originate as first-order neurons (upper motor neurons) in the tectum of the midbrain. Axons descend to the first to third thoracic (T1 to T3) segments of the spinal cord, where they enter the gray matter of the dorsal horn, synapse on second-order (preganglionic) sympathetic motor neurons, and exit in the ventral spinal nerve roots. From there the nerves pass through the cervicothoracic and middle cervical ganglia (combined as the stellate ganglion) and ascend in the cervical sympathetic trunk (part of the vagosympathetic trunk) to the cranial cervical ganglion (CCG), where they synapse on the third-order (postganglionic) sympathetic nerve. In the horse, the CCG is part of a neurovascular bundle in the caudodorsal aspect of the guttural pouch; in ruminants the CCG is located under the petrous temporal bone. The third-order fibers are distributed with the blood supply via canals through the petrous

VetBooks.ir

temporal bone to the sweat glands of the head, ciliary muscles, and periorbital smooth muscles including the eyelid levator, Mueller muscle, and periarteriolar musculature. The sympathetic supply of the head thus can be damaged within the brainstem or spinal cord (first order), cranial thoracic nerve roots or spinal nerves or cervical sympathetic trunk (second order), or the CCG, the skull, or behind the eye (third order).

Specific causes of Horner syndrome include mycotic guttural pouch infections; traumatic lesions of the basisphenoid area; otitis media; cervical trauma; abscesses, tumors, or space-occupying lesions in the anterior aspect of the thorax; periorbital abscesses or tumors; parotid duct obstruction and inflammation; esophageal rupture; and complications associated with surgical ligation of the carotid artery.[1-7] Lesions involving first-order sympathetic neurons in the ipsilateral brainstem are rare but have been reported as a consequence of metastatic neoplasia or with equine protozoal myeloencephalitis in horses.[8,9] Horner syndrome has also occurred after intravenous injection of certain drugs including xylazine, vitamin E or selenium, and phenylbutazone.[10-12] The sympathetic supply to the eye may rarely be involved in the inflammatory polyneuropathy characterizing horses with polyneuritis equi (cauda equina neuritis) syndrome.[13,14] Tumors that have resulted in Horner syndrome include sclerosing respiratory epithelial carcinoma, squamous cell carcinoma, lymphoma, mesothelioma, and melanoma.[2,4-6,10,15,16]

Clinical Signs The clinical signs of Horner syndrome in horses vary but include miosis, ptosis, regional hyperthermia, excessive sweating on the ipsilateral side of the face, congested mucous membranes, inspiratory stridor, and dermatitis caused by chronic sweating. Although enophthalmos is reported to be a reliable sign of equine Horner syndrome, many (most?) affected horses do not prolapse the nictitans and thus are probably not enophthalmic. The presence of this sign is apparently variable among species: Enophthalmos is not part of Horner syndrome in humans and ruminants[17] but is so in cats and dogs.[9] Ptosis is caused by the combined effects of loss of the eyelid levator function of Mueller muscle and variable enophthalmos. It is most reliably detected by comparison of the eyelash angles on each side. On the affected side the eyelashes slope at a relatively downward angle. The palpebral reflex and the menace response are normal. Facial sweating may begin to decrease 6 to 14 days after sympathectomy.[10] If there is concomitant damage to the vertebral nerve or its cervical sympathetic branches, sweating of the skin of the neck may also be seen. Regional hyperthermia results from cutaneous and mucosal vasodilation, which results from removal of sympathetic vasomotor tone. Sweating is thought to be caused by vasodilation and increased delivery of epinephrine to sweat glands.[18,19]

In cattle, there is *dryness* of the ipsilateral planum nasale. This can be explained by the mediation of normal sweat gland secretion by postganglionic sympathetic fibers and α-adrenergic receptors in cattle.[19] The other signs seen in cattle are similar to those in horses. The clinical signs of experimentally induced Horner syndrome in sheep and goats are limited to mild ptosis.[19] Retrobulbar tumors may cause both exophthalmos and Horner syndrome.[15] On cold days, while exhaled breath from the external nares of cattle normally contains a mist of condensed water vapor, breath from the relatively warm nostril on the affected side may be mist free.[9]

Diagnosis The level of sympathetic interruption can be determined by pharmacologic testing.[9] Hydroxyamphetamine (1% solution) instilled into the eye will result in release of norepinephrine from intact postganglionic sympathetic neurons, causing pupillary dilation, but no response when the postganglionic neurons are damaged. A positive response to this test indicates a preganglionic sympathetic lesion, and a lack of response indicates a postganglionic lesion. In animals with a postganglionic lesion, topical administration of 0.1 mL of 1:1000 epinephrine solution directly activates the iris musculature and produces mydriasis by 20 minutes, whereas the onset of dilation occurs at about 40 minutes in animals with preganglionic lesions. Similarly, 2.5% to 10% phenylephrine solution will produce pupillary dilation in an eye with a postganglionic sympathetic lesion, but not in a normal eye. The increased sensitivity to these direct-acting sympathomimetics in animals with postganglionic sympathetic lesions results from the phenomenon of denervation hypersensitivity, with numbers and sensitivity of norepinephrine receptors in the iris muscle increasing over days to weeks after postganglionic nerve injury. A positive response therefore is not seen until several days after the injury. Parenteral administration of 1 mL of 1:1000 epinephrine solution causes affected horses to sweat profusely over the affected side of the face.[10] However, this test does not differentiate between preganglionic and postganglionic lesions.

The guttural pouches of horses and the pharynx of all patients should be examined endoscopically to exclude the possibility of pharyngeal or laryngeal paralysis or guttural pouch disease. The jugular furrows should be palpated for swellings. Insertion of a nasogastric tube during palpation may be helpful for detecting subtle lesions on the left side of the neck. The thorax should be examined using auscultation and ultrasound and, if indicated, radiographs should be taken. Cranial ribs can be evaluated for lesions by scintigraphy.[20] A neurologic examination should be performed to evaluate the function of the spinal cord. The skin temperature may be measured using thermography[1,6,21]; on the affected side it is 1° C to 3.5° C higher than normal.

Treatment The treatment for Horner syndrome depends on the underlying cause of the denervation. Except for Horner syndrome related to IV injection of xylazine, the signs are often irreversible, even if the primary cause of the condition has been eliminated. With xylazine-associated Horner syndrome, the condition disappears spontaneously. The necrotizing effects of perivascular drug injections can be minimized by immediate dilution and/or irrigation with large volumes of saline infiltrated into the perivascular tissues. Antiinflammatory doses of flunixin and dexamethasone can be given systemically. Abscesses should be drained, and fungal infections of the guttural pouch should be treated as described in Chapter 31.

Guttural Pouch Mycosis

Robert J. MacKay

Definition and Etiology The clinical signs occur because fungal infections invade vital vascular and neural structures in the roof of one, or occasionally both, guttural pouches. There is no apparent age, sex, breed, or geographic predisposition to this disease.[1] Foals as young as 3 months of age have been affected.[2] *Aspergillus fumigatus* and *Emericella nidulans* (also known incorrectly as *Aspergillus nidulans*) are the fungi most commonly identified in pure or mixed culture.[3,4] Lesions are typically diphtheritic membranes of variable size, composed of necrotic tissue, cell debris, a variety of bacteria, and fungal mycelium (Fig. 35-11).[1]

The guttural pouch is partially separated into two compartments by the stylohyoid bone and occipitohyoideus muscle. Cranial nerves IX through XII, the cranial cervical ganglion and postganglionic sympathetic nerve, and the internal carotid artery are located in a fold that traverses the dorsomedial aspect of the medial compartment. For unknown reasons, this site is susceptible to colonization and destruction by invasive mycotic infections.[5] In about one third of cases, the fungal lesion is located in the lateral compartment, sometimes after extension from a primary site in the medial compartment.[1] At this location, the fungal mycelium may invade the wall of the external carotid artery or any of its branches and affect the facial nerve (VII). Facial nerve paralysis has also been observed as a result of direct invasion by a fungal guttural pouch infection into the overlying parotid lymph node and salivary gland.[6] Fungal plaques may also spread from one guttural pouch to the other by eroding through the apposed medial walls of the pouches.

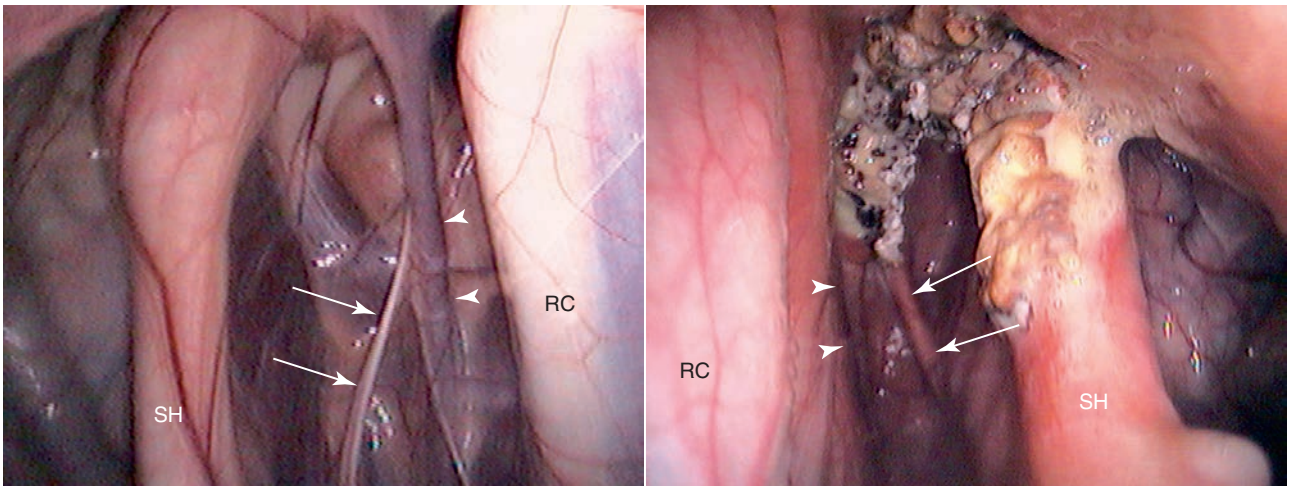

FIG. 35-11 Endoscopic views of the caudal aspects of the left guttural pouch with a mycotic plaque over the neurovascular structures of the medial compartment of left guttural pouch (right) and normal right guttural pouch (left). There is also thickening of the left stylohyoid bone secondary to temporohyoid osteoarthropathy. *Arrows* point to the glossopharyngeal nerves and arrowheads are pointing to the internal carotid arteries. *RC,* Rectus capitis ventralis major muscle; *SH,* stylohyoid bone.

Clinical Signs Initial signs are headshaking and unilateral nasal discharge. There is a tendency to hold the head in extension or lower to the ground than normal. Additional clinical signs are nasal discharge, dysphagia with nasal return of feed-stained saliva, head shyness, stridor, dysphonia, protrusion of the tongue from the mouth, and epistaxis.[6,7] Epistaxis may be bright red, high volume, and life threatening. Other clinical signs include sensitivity to pressure over the parotid salivary gland; Horner syndrome (sweating, miosis, and ptosis on the side of the lesion); paralysis of the tongue on the affected side; and facial paralysis.[6-10] Atrophy of the brachiocephalicus and trapezius muscles has been described in a few cases secondary to denervation of the spinal accessory nerve (XI). Horner syndrome occurs secondary to damage of the cranial cervical ganglion and postganglionic fibers. The sensorium is intact unless aspiration pneumonia develops or the fungus spreads into the brain.[11,12] Affected horses may die peracutely as a result of exsanguination from ruptured internal or external carotid arteries or their branches. Endoscopic examination of the larynx of affected horses may reveal dorsal displacement of the soft palate, inability to swallow, and laryngeal hemiplegia. Mycotic guttural pouch infection can be diagnosed definitively endoscopically by identifying the characteristic fungal mass in the caudodorsal aspect, usually of the medial compartment. Radiographic examination of the pouches shows a poorly defined border of the pouch in the abnormal area.

Treatment Before the onset of neurologic signs, the affected artery or arteries may be occluded on each side of the lesion(s) by ligation/balloon-tipped catheter, embolization coils, or nitinol plugs.[1] Arterial occlusion prevents fatal epistaxis, but it is not clear whether or not it affects fungal growth. Some studies have shown excellent, albeit delayed, rates of resolution of mycotic lesions in horses that underwent the procedure with or without additional antifungal therapy,[13,14] but in other animals the lesion may progress despite complete arterial occlusion.[8] Because a proportion of such lesions resolve spontaneously over time, the role of surgery in their resolution remains controversial.[1] Optic neuropathy and blindness of the ipsilateral eye are occasional sequelae of occlusion of the external carotid artery and its branches.[1] Lesions may be treated topically through an endoscope with povidine-iodine or triazole antifungal agents such as enilconazole, voriconazole, and itraconazole. Itraconazole is also affordable and safe when used systemically. Nystatin, natamycin, miconazole, and fluconazole have little activity against *Aspergillus/Emericella* spp. Amphotericin is effective, although systemic administration is limited by its toxicity. Topical treatment may be repeated daily (or as frequently as is practicable) for up to several weeks. As the fungal mass degenerates, pieces can be carefully removed endoscopically with biopsy forceps in horses that have previously undergone arterial occlusion. Dysphagic horses may be fed via an indwelling esophagostomy tube while lesions are being treated.[15] Neurologic signs may be permanent, although improvement or recovery over many months has been reported in some horses.[14] Affected horses are often euthanized for humane reasons. (See Chapter 31 for more on treatment of guttural pouch mycosis.)

Listeriosis (Circling Disease; Silage Disease; *Listeria monocytogenes* Infection)

Lisle W. George

Definition and Etiology Listeriosis is an acute meningoencephalitis caused by the gram-positive bacterium *Listeria monocytogenes.* The disease has a worldwide distribution but occurs most often in temperate climates. Listeriosis typically affects ruminants, fowl, and humans but is rare in horses. The prevalence of listeric meningoencephalitis in infected herds does not usually exceed 1% of the adult animals at risk.[1]

Clinical forms of listeriosis include septicemia of neonates, abortion, neonatal death, ophthalmitis, uveitis, septicemia and diarrhea of ewes, and neurologic disease.[2] Neurologic listeriosis may manifest as a multifocal brainstem disorder, diffuse meningoencephalitis, or myelitis. The condition usually affects individual animals but occasionally can affect several members of a herd.[3] Asymptomatic intramammary infections apparently occur and may be responsible for outbreaks of listeriosis in humans. Repeated intramammary inoculation of 10^6 to 10^7 colony-forming units (CFUs) of *L. monocytogenes* into cattle resulted in 500 to 50,000 CFUs of *Listeria* in the milk for as long as 12 months.[4]

Clinical Signs The neurologic signs of listeriosis in adults reflect dysfunction of the caudal brainstem, cerebellar peduncles, or spinal cord.[5] Fever may be present early in the clinical course, and poor appetite and depression are common. Central nervous system signs are usually asymmetric and include conscious proprioceptive deficits, head pressing, and cranial nerve deficits. Depressed consciousness is the result of lesions of the reticular activating system. Conscious proprioceptive deficits are caused by interference with the descending motor pathways and the ascending proprioceptive fibers in the brainstem and may precede or accompany cranial nerve

VetBooks.ir

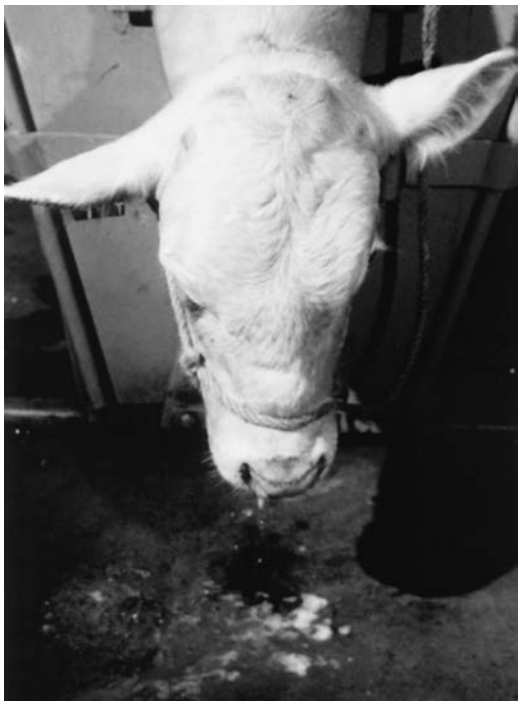

FIG. 35-12 Clinical appearance of the neurologic form of listeriosis in a Charolais bull. Note the dropped right eye and ear and the drooling of saliva from the right side of the mouth. *(Courtesy Dr. W.D. Wilson.)*

dysfunction. Head pressing and propulsive walking or compulsive circling are caused by lesions of the basal ganglia. Severely affected animals may be recumbent and may display torticollis, head tilt, or other unilateral vestibular signs.

Cranial nerves (CNs) V through XII are usually dysfunctional in listeric animals. Patients with loss of the trigeminal nerve (CN V) show dropped jaw or asymmetric jaw closure and facial analgesia or anesthesia. Facial analgesia is best detected by stimulation of the nasal septum with a pencil or piece of straw. Animals with lesions of CN VI exhibit a medial strabismus on the ipsilateral side of the lesion. Animals with lesions of CN VII have ptosis, loss of menace response, absent palpebral reflex, drooped ear, loss of levator nasolabialis muscle function, and decreased lip tone (Fig. 35-12). Small ruminants with CN VII loss have a deviated philtrum. The paralysis of the orbicularis oculi muscle results in exposure keratitis.[6] The loss of levator nasolabialis function is best detected by observation of the muscular contraction on the dorsum of the nose during inspiration. Loss of lip and cheek muscle tone is best detected by observation of drooling of saliva from the ipsilateral side of the mouth and by palpation of the lips and nostrils.

Animals with CN VIII lesions display a nystagmus that changes as the position of the head is altered. Other signs include a head tilt toward the side of the lesion and a tendency to circle or fall to the lesion side. The nystagmus may be horizontal, vertical, or rotatory and is usually inconstant. If the spinal reflexes can be tested, the affected animals show a mild to moderate hypertonia and hyperreflexia in the limbs opposite the side of the lesion. Animals with acute loss of CNs IX, X, and XII develop stertorous breathing and dysphagia. Animals with dysfunctional CN XII have paresis or paralysis of the tongue. With unilateral lesions the tongue protrudes from the side of the mouth ipsilateral to the lesion. Progression of listeriosis is associated with decreased consciousness, coma, and convulsions.

Lambs may selectively develop spinal myelitis without brainstem disease. This condition results in flaccid paraparesis or hemiparesis without attendant signs of brainstem dysfunction.[7] The clinical signs of myelitis include tetraparesis, tetraplegia, paraparesis, paraplegia, conscious proprioceptive deficits, and recumbency. The sensorium and appetite are normal in some affected animals and greatly depressed in others.[8] Primary ocular disease caused by *L. monocytogenes,* manifesting as keratitis, conjunctivitis, or uveitis, may occur in cattle or horses with no signs of neurologic disease.[9]

Clinical Pathology The clinical signs of multifocal, particularly unilateral, brainstem disease with inconsistent fever in a ruminant are suggestive of listeriosis, head trauma, or aberrant parasite migration. Examination of the CSF should be helpful for confirming a diagnosis of listeriosis, but the cell and protein concentrations of the specimens do not correlate with the severity of the clinical signs or prognosis. The protein concentration in the CSF may be more than 40 µg/dL, and the CSF WBC counts may be more than 12 mononuclear cells/µL.[1,10,11] Many cattle with advanced signs of listeriosis develop metabolic acidosis as a result of salivary bicarbonate loss.

Pathology Pathologic confirmation of listeriosis is based on identification of multifocal microabscesses in the brainstem and isolation of *L. monocytogenes* from infected brain tissue. The agent is only rarely isolated from CSF and is best recovered from refrigerated nervous tissues. Enrichment of the *Listeria* organisms may be accomplished by refrigerating slices of brain at 4°C (39.1°F) for 3 months while culturing the tissues weekly. In contrast to septicemic listeriosis of monogastric animals, peripheral monocytosis is not observed in infected ruminants.

Pathophysiology *Listeria* organisms produce a hemolysin, listeriolysin-O, a thiol-activated toxin (molecular weight, 58 kD) that is correlated with pathogenicity. The molecular role of the toxin in dissemination of the infection and in cell death is not known.

It is unclear whether infection of the brain by *L. monocytogenes* occurs hematogenously or by ascent from the cranial nerve rootlets.[12] Morphologic studies of naturally occurring cases of encephalitic listeriosis have demonstrated the bacterium in the axons of the trigeminal nerve rootlets, indicating a possible centripetal migration.[12,13] Similar findings have been reported in animals infected experimentally.[14] Younger animals may be susceptible because eruption of the permanent teeth may expose trigeminal nerve rootlets. A model for experimental induction of listeriosis by inoculation of the bacterium into the pulp cavity of sheep has been described.[15] Infection of the CNS without bacteremia has been detected, indicating that centripetal migration of the bacterium is possible.[16] Some investigators consider axonal migration as an unlikely mode of pathogenesis because of a lack of nutritional dependency of *L. monocytogenes* for nervous tissue and the ready ability to produce multifocal brain microabscesses by intravenous inoculation of the bacteria into susceptible hosts.[12,17]

Epidemiology In untreated cases the fatality rate is almost 100%.[5] The survival rate in treated animals is considerably higher than in untreated patients. The disease in sheep and goats tends to be more acute and results in a higher case-fatality rate than in cattle. Occasional outbreaks of listeriosis may occur in sheep without access to silage.[5,18] In these cases the source may be the feces of carrier animals or rotting vegetation on the pastures or feed bunks. During an outbreak of listeriosis, the bacterium can be isolated from the feces of a large percentage of normal animals.[19] It is unclear whether this high rate of asymptomatic infections represents a true carrier state or is simply the result of a high environmental contamination by nonpathogenic isolates.[19] The agent infects the udder but rarely causes clinical mastitis. In sheep, excretion of the bacterium in the milk is greatest during the immediate postlambing period.[20,21]

L. monocytogenes can survive for long periods in the environment and in asymptomatic carriers. The bacterium can multiply at low environmental temperatures and is resistant to environmental influences. *L. monocytogenes* is shed in the feces of asymptomatic carriers, especially at the end of pregnancy and at lambing. Once in the environment, the bacterium can survive for 2 years in dry soil. It is

VetBooks.ir

resistant to freezing and thawing in the soil but does not survive for more than 1 to 2 weeks in properly preserved silage. The bacterium proliferates in rotting vegetation in which aerobic conditions exist and the pH is above 5.4.[22-24] Common sources of contaminated forage include spoiled silage at the ends of trench silos, decaying forage at the bottom of feed bunks, or rotting hay at the periphery of hay stacks.[22,25] The incidence of listeriosis may be increasing because of the greater use of trench silos and bulk handling methods that result in a greater amount of spoilage than in conventional upright silos. Although *L. monocytogenes* can be isolated from silage with a pH below 4, fewer bacteria are found in well-preserved forage.[26]

A selective enrichment medium has been developed for identifying and enumerating the *Listeria* organisms in silage. This medium permits semiquantitative enumeration of *Listeria* bacteria in 10 g of silage. Hemolysin production is measured by overlaying the colonies with bovine blood agar and reincubating the plates. Using this method, outbreaks of listeriosis have been correlated with silage containing 1 million *Listeria* organisms and more than 1 million enterobacteria per gram of silage. The pH of such silage is characteristically above 7.8.[27]

There is a significant public health concern about *Listeria* contamination of milk products. The 4b serotype of *L. monocytogenes* is most often responsible for infections in humans.[28] Outbreaks have been traced to ingestion of pasteurized milk, cole slaw, and soft, ripened cheese. Recent foodborne listeriosis outbreaks have also been linked to contaminated fruit and vegetables.

Pathologic Lesions The lesions of listeric meningoencephalitis are most common in the pons and trapezoid bodies, but they can be located anywhere in the brainstem. Neurologic structures most often affected include the reticular formation and CNs V and VII to X. Macroscopic lesions are limited to mild meningeal congestion and clouding of the CSF. Microscopic lesions include perivascular cuffing with mononuclear cells, multifocal asymmetric brainstem microabscesses, and mononuclear cell meningoencephalitis.[28] The microabscesses are composed predominantly of neutrophils. Other microscopic changes include degeneration of the neuropil and neuronophagia.

Treatment The recovery rate is best if treatment is administered early in the disease course. Animals that are recumbent, comatose, or convulsive rarely survive despite intensive antibiotic and supportive therapy. In most cases, treatment must be administered for a prolonged period because recovery may take as long as 1 month. *L. monocytogenes* is susceptible to most of the common antimicrobial drugs. Recommended treatment is either oxytetracycline, 10 mg/kg IV twice daily, or penicillin G.[6] Specific recommendations for penicillin therapy include an initial dosage of 40,000 IU/kg (IV potassium penicillin G) three or four times daily for 7 days and then 22,000 IU/kg (procaine penicillin) IM once daily for 14 to 21 additional days.[6]

The plasma concentrations of bicarbonate and potassium should be measured, and specific corrective fluid therapy should be administered as indicated by acid-base and electrolyte assays. Good footing and nursing care are also beneficial.

Prevention Serologic responses to flagellin and listeriolysin-O develop after oral administration of virulent *L. monocytogenes* and correlate with protection against listerial bacteremia.[16] Vaccines of attenuated or killed bacteria have been used successfully to protect sheep and goats. Although these vaccines reduce the incidence of listeriosis in vaccinated flocks, they are not commercially available in the United States.

Although the case-attack rate of listeriosis is low, occasional epizootics may occur in cattle, sheep, or goat herds, invariably associated with high rates of environmental contamination. In such cases the hay and silage should be cultured for *L. monocytogenes*. Rotten vegetation should be discarded, and cattle should be fenced from contaminated areas.

Thromboembolic Meningoencephalitis (*Histophilus somni* [formerly *Haemophilus somnus*] Infection; Sleeper Calves)

Definition and Etiology Thromboembolic meningoencephalitis (TEME) is a fulminant neurologic disease of cattle that arises from septicemia caused by the pleomorphic, nonencapsulated, gram-negative bacterium *Histophilus somni* (formerly *Haemophilus somnus*).[1] Owing to its capacity to disseminate via the bloodstream, this organism can incite infection in multiple organs. In addition to TEME, *H. somni* can cause pleuropneumonia, myocarditis, laryngeal abscesses, polyarthritis, polyserositis, and infections of the ear, eye, udder and urogenital tract.[1-6]

Clinical Signs Only the neurologic syndrome (TEME) is discussed here. Descriptions of other clinical syndromes of *H. somni* infection are discussed in Chapters 31, 39, and 43. The initial signs of TEME are fever (40° C to 41.6° C; 104° F to 107° F), anorexia, depression, and ataxia.[7-9] In addition to depression, affected animals show a number of conscious proprioceptive deficits including knuckling, circumduction, crossing over, and interference. Affected animals may fall while attempting to walk. Signs specifically associated with lesions of the cerebellum and caudal brainstem include head tilt, nystagmus, strabismus, blindness, muscular tremors, opisthotonos, coma, and convulsions.[10] Signs of infection in other organ systems (e.g., pneumonia, arthritis) may be present in the affected animal or in cohorts. Death may occur within 36 hours after the onset of neurologic signs.

Clinical Pathology Examination of CSF may be helpful in substantiating a clinical diagnosis of TEME. Specific CSF changes characteristic of hemorrhage include high erythrocyte counts, xanthochromia, and increased concentrations of protein (>100 mg/dL) and neutrophils (>500 WBCs/μL). In untreated cases of TEME, the bacterium may be isolated from the brain, kidney, pleural fluid, lung sections, aspirated tracheal exudate, urine, blood, and preputial washings. Standard transport swabs containing Amies media are appropriate for culturing of clinical samples. Isolation of *H. somnus* from joint fluid and CSF is usually unsuccessful.[11] The kidneys and brain should be collected at postmortem examination because these tissues contain the highest concentrations of *H. somni*.[11]

Initial changes in the peripheral WBC count include neutropenia, left shift, and toxic changes in the neutrophils. Cattle that develop acute TEME invariably have agglutinating antibody titers greater than 1:400 and show a fourfold increase by 2 to 4 days after infection.[12] Serum agglutination titers greater than 1:1024 are seen in convalescent cattle; lower titers may be seen with inapparent infection or vaccination.[13]

Pathophysiology Infection of cattle by *H. somni* probably occurs through the respiratory tract. Bacterial proliferation in the lungs and other soft tissues by serum-resistant isolates results in bacteremia. *Histophilus* possesses multiple virulence factors including the capability to induce apoptosis of endothelial cells.[6] Exposure of subendothelial collagen occurs subsequently, resulting in microthrombus formation and organ damage through hypoxia and inflammation. The sites of the body most affected by the thrombosis are the brainstem, spinal cord, synovial membranes, pleura, and lungs. Although the name *thromboembolic meningoencephalitis* implies the passage of solid material in the vasculature to a downstream occlusion site (embolism), thrombus formation likely occurs directly at the site of the vascular lesion.

Epidemiology Although TEME occurs most frequently in feedlot cattle,[9] outbreaks in the western United States and Canada have been reported in both pasture and dry-lot environments.[7,14] In a serologic study of feedlot cattle, seroconversion to *H. somni* occurred early in the feeding period (soon after placement).[15] This may be reflective of the role of stressors (e.g., comingling of animals

VetBooks.ir

from different sources, transport, changes in feed) in the pathogenesis of this disease. Chapter 31 includes further details on the epidemiology of *H. somni* infections in cattle.

Necropsy Findings Macroscopic pathologic lesions of the CNS include disseminated multifocal hemorrhages and infarctions in the spinal cord, brainstem, and cerebral cortex. Bacterial colonies are frequently observed in thrombosed blood vessels and the surrounding infarcted tissues. Ocular lesions are characterized by conjunctivitis, multifocal retinal hemorrhages, and areas of retinal edema. The CSF is cloudy and xanthochromic. A focal fibrinous meningitis is seen, and suppurative otitis may be seen in some cases.

The earliest microscopic lesion of TEME is a vasculitis that progresses to septic infarction and abscess formation. The lesions are usually found in the CNS but in severe cases may be disseminated throughout the body.

Non-neurologic lesions of *H. somni* infection include suppurative arthritis, synovitis, myocarditis, suppurative pleuritis, urogenital infections, and bronchopneumonia. Changes associated with the bronchopneumonia include infarction, cranioventral pulmonary consolidation, and hemorrhagic interstitial pneumonia. Other lesions include ecchymotic to petechial hemorrhages over the serous surfaces, purulent exudate in the joints, and ulceration of the laryngeal and tracheal mucosa with diphtheritic membrane formation.[16]

Treatment and Prognosis During an outbreak, cattle must be examined frequently and should be treated when the neurologic signs first appear. *H. somni* is susceptible to many antibiotics and antimicrobial drugs. Drugs that have been reported to be effective for the treatment of TEME include tetracyclines, penicillin, aminoglycosides, and ampicillin. Parenteral oxytetracycline is regarded as the most cost-effective treatment for infected commercial cattle; dosage is 10 mg/kg of a conventional formulation given IV twice daily for 3 days or 20 mg/kg of a long-acting formulation given SC. Some advocate the addition of chlortetracycline (2.2 mg/kg) to the feed for 10 successive days.[17]

Prevention and Control Antibody responses protective against respiratory challenge have been generated by vaccinating cattle with anionic, heat-stable proteins derived from the bacterial cell wall.[18] Vaccination of cattle with commercial products affords substantial protection from experimentally induced *H. somni* septicemia and neurologic disease for more than 3 months.[18-20] (See Chapter 48 for more information about vaccines.) Mass prophylactic treatment of affected cattle with a parenterally administered, long-acting oxytetracycline formulation may be efficacious for preventing TEME in high-risk cattle.[21]

Otitis Media/Interna of Ruminants

Otitis media/interna is a common bacterial disease of cattle and sheep; it is less commonly observed in goats. The condition usually occurs as a sequela to upper or lower respiratory infections caused by *Mannheimia haemolytica, Pasteurella multocida, Corynebacterium pseudotuberculosis, Histophilus somni,* or *Mycoplasma* spp.[1-5] Subclinical otitis media/interna is common in feedlot-reared animals, particularly early in the feeding period.[1,3] Although viral infections are the cause of a large proportion of otitis media/interna cases in children,[5] the role of viral infections in ruminant otitis media/interna remains speculative; it is possible that viruses play a similar role in facilitating otitis media interna as they do in facilitating lower respiratory tract disease. Recently, the detection of *Mycoplasma* spp. in clusters or outbreaks of otitis media/interna on dairies has justified the consideration of contaminated milk as an important potential source of this organism to young stock.[4,6] Chapter 31 includes more detailed discussion on the role of *Mycoplasma* in the bovine respiratory disease complex.

Otitis media/interna is considered to most commonly result from ascending infection of the middle ear from the nasopharynx via the eustachian (auditory) tube.[5] Infection that progresses from the external ear into the middle ear is less common but may occur secondary to aural infestation by ectoparasites. Once infection is established in the middle ear, extension into the inner ear may occur as a result of erosion of bone or extension of the infection through the round and/or oval windows. The constellation of clinical signs of otitis media/interna results from damage to the peripheral vestibular apparatus residing in the tympanic bulla and petrous temporal bone. In chronic cases, the peripheral vestibular apparatus can be damaged beyond repair and neurologic deficits may be permanent. Rarely, extension of infection into the central nervous system can occur, resulting in subdural abscess formation, meningoencephalitis, or brain abscess formation.[5] The vast majority of cases shows clinical signs of unilateral peripheral vestibular disease; however, subclinical inflammatory lesions may be present in the contralateral, clinically normal side. Bilateral, clinically apparent peripheral vestibular disease is rare. Additional signs of multisystemic disease caused by *Mycoplasma bovis, Pasteurella multocida,* or *Histophilus somni* may be present (e.g., pneumonia, polyarthritis).

Clinical Signs Headshaking (possibly producing an aural hematoma), an ear droop, and reduction in appetite may precede the clinical vestibular signs. Fever is inconsistent.[6] Patients with vestibular signs display unilateral head tilt (toward the side of the lesion), continuous horizontal nystagmus (fast phase away from the side of the lesion), and imbalance, manifested as a tendency to stumble, fall, or circle tightly (walk in a tight circle) toward the side of the lesion. If the tympanic membrane ruptures, or in the rare case of otitis externa as a preceding condition, purulent exudate may be evident in one or both ears.

Animals may become recumbent and lie with the lesion side toward the ground; if turned, they return to the same position. Many animals with otitis media also develop ipsilateral facial nerve dysfunction, which results in ptosis, drooped ear, and flaccid lips and nostrils. In small ruminants, facial nerve paralysis results in deviation of the philtrum toward the normal side. Deviation of the philtrum does not occur in cattle because of the large amount of connective tissue surrounding the planum nasale. Occasionally, affected animals develop subtle or pronounced signs of cortical or brainstem disease as a result of extension of infection from the middle ear into the meninges. Cerebrospinal fluid analysis may reveal increased leukocyte counts in such cases.[6]

Although the clinical signs of peripheral vestibular disease are characteristic, it is important to differentiate this condition from that of central vestibular disturbance. Animals with peripheral vestibular disease are usually appetent, alert, and aware of their surroundings and do not have a significant deficit of postural placement. The nystagmus of these animals is constantly horizontal. In comparison, animals with central vestibular disturbances are depressed, have a nystagmus that varies in direction, and show marked conscious proprioceptive abnormalities.

Treatment Treatment of bacterial otitis with procaine penicillin (44,000 IU/kg IM or SC daily) may be effective. Importantly, however, given the potential for involvement of bacteria that do not have a cell wall (*Mycoplasma* spp.), initial treatment with an antibiotic other than a member of the β-lactam class might be warranted (e.g., tetracyclines, florfenicol, macrolides, and where legal, fluoroquinolones), unless bacterial culture and sensitivity results or clinical response directs the veterinarian to treat with a β-lactam class antimicrobial drug.[6] Relapses may occur, warranting prolonged treatment (3-6 weeks). Treatment is effective in obtaining a complete cure in animals with acute otitis but is less so in the chronic form. In chronic cases, infection may irreversibly damage middle or inner ear tissues, causing neurologic deficits that can persist despite resolution of infection with antimicrobial therapy. Osteomyelitis of the petrous temporal bone, abscess formation in the tympanic bulla, or a noninfectious etiology (e.g., neoplasia) are other considerations for affected animals that do not respond to antimicrobial therapy.

Ear Mite Infestations of Ruminants

The ear mite of cattle is *Raillietia auris,* and that of small ruminants is *Psoroptes cuniculi.* Severe infestations perforate the tympanum and result in vestibular disease, facial paralysis, and ataxia.[1-4] Infestation can be recognized by observation of ulceration and purulent debris in the auditory canal next to the tympanum. Mites may or may not be visible during otoscopic examination. Malodorous discharge on the side of the face under the ear canal may be seen in some affected animals.

The accumulation of purulent debris and swelling of auricular tissues block the transmission of sound to the tympanum.

Ear mite infestations in cattle are common and in some herds may affect most of the adults. The biologic importance of the infestation may be related to changes in the herding or mothering behavior of range cattle. The economic significance of the infestation is unknown.

Ear mites have been successfully treated in goats using eardrops containing rotenone once daily for 5 to 10 days. Good clinical responses can be obtained in cattle with the same treatment. Fenthion drops have also been used successfully. In cases of parasitic otitis in which the discharge has been inspissated, lateral resection of the ear canal should be considered to establish adequate ventral drainage.[5] A single subcutaneous injection of ivermectin at 0.2 mg/kg has been shown to be an effective treatment for *P. cuniculi* otitis in both sheep and goats.[6,7]

The life cycle of the mite involves two free-living stages, the protonymphs and deutonymphs. These forms molt in the vegetation and reinfest cattle as they graze or bed during the evening.[8] Therefore tilling the soil of the infested pastures or retreating cattle every 14 to 21 days with insecticide should be considered as part of an eradication scheme.

Diseases Producing Tremors and Ataxia; Cerebellar Diseases

Cerebellar Abiotrophy of Arabian Foals

Robert J. MacKay

The most commonly reported cerebellar neurodegenerative conditions of horses are inherited abiotrophies. A distinct apparently inherited cerebellar condition of Oldenberger foals is characterized by multifocal cerebellar degeneration and an invariably fatal outcome.[1] A syndrome of progressive ataxia associated with cerebellar degeneration was identified in one American Miniature Horse foal, and anecdotal evidence for an additional two cases was cited.[2] An unusual case of neuroaxonal dystrophy with cerebellar signs was reported in a Pony of the Americas foal.[3] Cerebellar degeneration and lipofuscin accumulation associated with presumed toxicosis has been described in Gomen disease of horses in New Caledonia.[4] Induced mannosidosis with neurovisceral degeneration involving the cerebellum has been reported for poisoning by swainsonine-containing plants in the United States, Australia, and Brazil.[5-7]

Cerebellar Abiotrophy

The term *abiotrophy* refers to spontaneous premature degeneration resulting from an inborn error of development.[8] Syndromes of cerebellar abiotrophy (CA) have been described for Arabian[9] and Gotland Pony[10] foals. In Arabians with CA, degeneration only begins after formation of the cerebellum and is characterized by apoptosis of Purkinje cells.[11] The likely genetic basis for CA in Arabians was recently identified as a single-nucleotide polymorphism (SNP) upstream of the *mutY* homolog gene (MUTYH), in a region involved in transcriptional upregulation of the gene.[12] MUTYH encodes for a DNA glycosylase involved in repair of oxidative damage to genomic DNA during organogenesis and mitochondrial DNA during postnatal life. This gene is abundantly expressed in the cerebellums of normal horses; expression is significantly reduced in CA foals.[12]

The mode of inheritance of CA is simple autosomal recessive.[9,12,13] The CA allele was found in 19.7% of approximately 4200 Arabian horses and is well represented in Egyptian, Spanish, and Polish lineages.[12,13] Among tested horses, 1.4% of were homozygous for the allele. Nine of these were clinically normal, which, taken together with the observed range of ages of onset, is evidence for variable expression of the CA trait. The allele was also present at low frequency in the Bahkir Curly Horse, a breed that used Arabians as foundation stock, and in Welsh Ponies and Trakehners, breeds that allow out-crossing with Arabians.[14]

Signs of CA typically begin in foals between 6 weeks and 4 months of age; however, foals may be affected at or shortly after birth. Among 18 confirmed or suspected cases, signs were present at birth in 4 (22%) and began at 3 months of age or younger in 10 (56%), 3 to 6 months in 2 (11%), and older than 6 months in 2 (11%).[1,15-17] The first signs noticed are incoordination, basewide posturing in the thoracic limbs, and head tremors. The head tremor is usually a coarse bobbing in either the horizontal or vertical plane. When the head is extended (e.g., toward the dam's udder or toward offered food), the head tremor becomes more pronounced. Although CA foals can see normally, the menace response cannot be elicited in most cases. Foals walk with a swaying, lurching gait and may even wobble side to side or back and forth while standing still. Thoracic limbs may appear stiff, or there may be exaggerated flexion ("paddling") during the protraction phase. Gait abnormalities are most obvious when movement is initiated and during turns. Normal strength is preserved even in severely ataxic foals, and blindfolding does not exacerbate clinical signs. All clinical signs are exaggerated by stimulation of affected foals. Such hyperresponsiveness means CA foals are difficult to halter-train and lead; even normal handling often causes an affected foal to pull away or even flip over backward. Severely affected foals that fall often panic and struggle for some time before standing.

The diagnosis in an Arabian foal with compatible clinical signs is strongly supported by demonstration of homozygosity for the CA allele. This test requires submission of 20 to 30 hairs with roots and is submitted to the Veterinary Genetics Laboratory at the University of California, Davis (http://www.vgl.ucdavis.edu/services/horse.php). Hematologic and serum chemistry findings are usually normal. Some foals have high CSF protein concentration and creatine kinase activity, consistent with active neurodegeneration at the time of CSF collection.[16] Magnetic resonance, and possibly CT, imaging of affected foals reveal atrophy of the cerebellum in foals with CA.[18]

Signs may be stable after onset or get worse for up to several months. It is rare, however, for CA foals to become persistently recumbent. Modest improvement has been noted in some mildly affected horses once they become adults.[1] Foals with CA seldom succumb to direct effects of the condition but most are euthanized because of severe clinical signs and poor prognosis.

Gross appearance of the affected brain is usually described as normal; however, the ratio of cerebellar to whole brain weight is usually less than 8%, whereas normal ratios are 8% or higher. The characteristic histologic lesion is thinning of the cerebellar cortex affecting both granular and molecular layers.[1,9,15-17] There is marked reduction in the number of Purkinje cells in the granular layer, and some of those remaining show degenerative changes (swelling, shrinkage, and hyperchromasia of the perikaryon). There is relative sparing of the Purkinje cells of the nodulus and flocculi.[16] Vacuolation may be noted in the olivary nuclei.[15] Mineralized neuronal cell bodies may be found in the thalamus adjacent to the third ventricle.

Cerebellar Hypoplasia Caused by Congenital Bovine Viral Diarrhea Virus Infection

Lisle W. George • David C. Van Metre

A complete discussion of bovine viral diarrhea–mucosal disease (BVD-MD) can be found in Chapter 32. BVD virus infection of

VetBooks.ir

FIG. 35-13 Characteristic head position and basewide stance of a calf with cerebellar hypoplasia.

susceptible pregnant cattle from 90 to 170 days' gestation results in abortion or stillbirth, hydranencephaly, or cerebellar hypoplasia in the fetus.[1,2] The BVD virus infects the developing germinal cells of the cerebellum and kills Purkinje cells in the granular layer, resulting in necrosis and inflammation.[3] The microscopic lesions include necrosis of the external germinal cells, focal parenchymal hemorrhages, and folial edema.

The signs of cerebellar dysfunction are usually present at birth and include truncal ataxia, falling backward, opisthotonos, basewide stance, coarse intentional head tremors, hypermetria, hyperreflexia, and nystagmus or strabismus (Fig. 35-13).[4,5] If severely affected, the animal may be unable to stand or lie in sternal recumbency. Excitatory stimuli in these animals precipitate wild oscillations and side-to-side movements of the head, which can be mistaken for convulsions. The affected calves may have a deficient menace response and appear to be blind, especially with concomitant hydranencephaly or microphthalmia. The neurologic condition rarely improves after birth. Other fetal changes that may be induced by the BVD virus include thymic atrophy, retinal degeneration, corneal opacity, failure to grow, and abortion.[1,4] The diagnosis of cerebellar hypoplasia is based on identification of the specific clinical signs and the recognition of BVD antibodies in precolostral blood specimens. The virus may be cultured from the blood of some affected calves, but this appears to be dependent on whether or not an immune response to the virus has developed in the affected calf.

Storage Diseases and Inborn Errors of Metabolism

Inherited Myoclonus of Peruvian Paso Foals

Robert J. MacKay

Inherited myoclonus is a disorder described in two Peruvian Paso foals that is characterized by myoclonic contractions of the musculature in response to auditory or tactile stimuli.[1] These contractions are sustained with repeated stimulation. One foal could not stand without assistance, and the other had a "bunny-hopping" gait in the pelvic limbs. Analeptic drugs and tranquilizers are ineffective for controlling this condition. Inherited myoclonus is associated with a specific deficiency of spinal glycine receptors, which are responsible for synaptic inhibition in the CNS. Glycine is a major inhibitory transmitter providing reciprocal inhibition via Ia afferents and interneurons, as well as recurrent inhibition on motor neurons via Renshaw cells.

Congenital Encephalomyelopathy in Quarter Horses

Robert J. MacKay

Congenital encephalomyelopathy has been described in Quarter Horse foals.[2] The condition occurred in three foals born to two different mares and three unrelated stallions. Signs were present at birth and included recumbency and coarse tremors of the pelvic limbs. When foals were assisted to stand, the hindquarters bounced off the ground. Thoracic limb function appeared normal; however, patellar reflexes were exaggerated. Affected foals are bright, alert, and responsive and have intact pain perception. There are no gross CNS lesions. Microscopic lesions include spongiform degeneration and axonal swelling of the spinocerebellar spinothalamic tracts within the medulla and spinal cord.

Lavender Foal Disease (Coat Color Dilution Lethal)

Robert J. MacKay

Lavender foal syndrome (LFS), also known as coat color dilution lethal (CCDL), is an autosomal recessive disorder of Arabian foals that has been recognized for many years but only recently reported.[3,4] LFS is characterized by a dilute coat color, episodes of opisthotonos, hyperresponsiveness to touch, limb paddling, and rapid, uncontrolled eye movements. Affected foals are unable to assume sternal recumbency or stand. Despite the incapacitating neurologic signs, LFS foals are able to vocalize and usually have a strong suckle response. The important feature of this condition that distinguishes it from neonatal encephalopathy and other causes of neonatal neurological dysfunction is the dilute hair color. In a few cases, the color is the striking iridescent silver to pale lavender hue suggested by the name. *Coat color dilution lethal* may be a more appropriate name, however, because many affected foals exhibit other dilute coat colors including pewter (pale slate gray) and pale chestnut (pink). Complications from neurologic abnormalities invariably lead to death or euthanasia by around 72 hours. Abnormal findings at necropsy are nonspecific and minimal. A single base pair deletion in the *MYO5A* gene is responsible for LFS.[5,6] This deletion results in a frame shift and truncation of the protein at a premature stop codon 12 amino acids beyond the deletion. Loss of *MYO5A* disrupts melanosome trafficking and endoplasmic reticulum transport in cerebellar Purkinje cells, thus leading to the clinical signs of cerebellar seizures. Reported allelic frequencies are 5.2% among Egyptian Arabians in the United States[6] and 1.62% among European Arabians and 0% among European Thoroughbreds and Standardbreds. Testing for the *MYO5A* gene mutation is available commercially and is performed on plucked mane and tail hairs.

Overo Lethal White Syndrome

Robert J. MacKay

Overo lethal white syndrome (OLWS) is an inherited syndrome of American Paint foals from parents with the frame overo coat pattern.[7,8] Affected foals are totally or almost totally white and die within days from complications due to intestinal aganglionosis.[7] Aganglionosis is characterized by a complete lack of submucosal and myenteric ganglia from the distal small to large intestine. Foals with OLWS are homozygous (designated OO) for a dinucleotide mutation, which causes an isoleucine to lysine substitution at codon 118 in the gene for endothelin receptor B.[9,10] Although heterozygotes for the

VetBooks.ir

lys118 mutation (nO) are mostly frame overos, the mutation is also found at lower frequency in other white patterned horses including tobianos and solid pattern breeding stock.[11] The mutation should not be found in breeds without white pattern variants, although OLWS was reported in the offspring of a registered Quarter Horse. Genetic testing is the only reliable method for detecting carriers. Plucked mane or tail hairs are submitted to commercial laboratories for testing.

Locoism (Swainsonine Toxicity)

Robert J. MacKay • Lisle W. George

Definition and Etiology Chronic ingestion of a variety of plants worldwide can result in an acquired neurovisceral storage disease. Plants incriminated so far include members of *Astragalus* and *Oxytropis* genera (locoweeds) in the western United States (Table 35-5), Canada, Africa, Asia, and Australia; *Ipomoea carnea* in Mozambique; the darling pea in Australia (*Swainsona* spp.); and *Ipomoea* spp., *Turbina cordata,* and *Sida acuta (carpinifolia)* in Brazil.[1-8] The disease was also diagnosed in a horse in Belgium; however, the causative plant was not identified.[9] Horses are most susceptible, but cattle, sheep, goats, and deer can also be affected.[10]

Conditions that promote locoweed poisoning are hot, dry weather and a scarcity of alternative forage. Horses may be more prone to graze on locoweed than cattle, particularly when other green forage is scarce, and may increase their consumption over a single season.[10] Chronically exposed livestock become addicted to locoweeds and feed selectively on the plant over successive grazing seasons.[11]

Locoweeds represent only a small proportion of the species in the *Astragalus* or *Oxytropis* genera; many *Astragalus* spp. contain nitrotoxins or are selenium-accumulators, and many other members of both genera are nontoxic. The indolizidine alkaloid *swainsonine* (also known as locoine) has been identified as the cause of locoism. Swainsonine acts by potent inhibition of mammalian α-D-mannosidase and of Golgi mannosidase II.[5,12] The source of swainsonine in *Astragalus* and *Oxytropis* plants is the fungal endophyte *Undifilum oxytropis* or closely related *Undifilum* spp.[13,14] Swainsonine, along with slaframine (slobber toxin), is also produced by *Rhizoctonia leguminicola,* a fungus that causes black patch disease of red clover.[15] Whether or not plants other than *Astragalus* and *Oxytropis* spp. are also colonized by swainsonine-producing fungus has not yet been clarified. Other toxins identified in locoweeds have included β-galactosidase and β-glucosidase; aminonitrile, a toxin that causes abortion and teratogenesis; and miserotoxin, a cause of respiratory disease.

Oxytropis and *Astragalus* plants are legumes that have herbaceous stems and alternate pinnately compound leaves.[16] The fruits are characteristic leguminous pods that contain kidney-shaped seeds with pods marked by characteristic longitudinal grooves. The plant is eaten because it is the first vegetation available in the spring. Neurologic signs do not usually develop in cattle until 3 weeks after the animals first begin grazing the plant and may not occur until long after ingestion of the plant has stopped. In parallel with changes in the concentration of endophyte in locoweeds, toxicity may vary from year to year and even within one season.[17]

TABLE 35-5

Species of *Astragalus* and *Oxytropis* Found in the Western United States[16]

Scientific Name	Common Name
Oxytropis sericea	White locoweed, point locoweed
Oxytropis lambertii	Purple locoweed
Oxytropis campestris	Yellow locoweed
Astragalus argillophilus	Half-moon locoweed
Astragalus bisculatus	Two-grooved milk vetch
Astragalus earlei	Earles locoweed
Astragalus lentiginosus	Speckled, spotted locoweed
Astragalus mollissimus	Wooly locoweed
Astragalus mothoxys	Sheep locoweed
Astragalus wootnii	Wooton locoweed

Clinical Signs Experimentally and naturally poisoned horses show clinical signs by 2 to 3 weeks after continuous ingestion of locoweed.[10,18] The clinical signs include ataxia and obtundation alternating with periods of frenzied or manic activity.[7] There is sometimes a high-stepping gait suggestive of cerebellar dysfunction.[7] At rest, there is intention tremor of the head; flaccidity of the nose and lips; repetitive, dystonic movements of the lips and tongue; and dysphagia. The clinical signs worsen when affected horses are handled or transported. Signs in goats are similar including ataxia, hypermetria, hyperesthesia, and muscle tremors.[1,2] When the chin is raised for 30 seconds and then suddenly released, even mildly affected goats fell into recumbency with additional signs of nystagmus, opisthotonos, tetanic spasms, and seizures. Sedation is usually ineffective for controlling the hyperexcitability of locoism. Horses that survive locoweed poisoning retain altered behavior and an irregular gait. Abortions, stillbirths, and neonatal deaths can occur in all species exposed to these toxic plants, regardless of whether the dams have clinical signs of neurologic disease.[2,3,19]

Neurologic signs in adult cattle include ataxia, limb hypermetria and weakness, obtundation, dull staring eyes, and loss of herding instinct. Heavy losses from abortions or malformed calves have also been described. The indolizidine alkaloids are secreted in the milk and may cause unthriftiness and weak suckling behavior in calves. Calves that have been exposed to the toxin in utero are weak and fail to thrive. Some may have flexural contractions of the limbs and lateral rotation of the carpus.[8,20,21] Ingestion of locoweed by certain cattle at high altitudes may result in the development of cor pulmonale.[22] Many cattle with mild signs of locoweed poisoning recover completely by 60 days after removal from the offending pastures. Poisoned sheep have a star-gazing attitude and appear to be blind, nervous, and stiff. The normal flocking behavior is absent.[12] Affected sheep may salivate excessively. Testicular atrophy has been reported in rams.[23] The immunosuppressive actions of swainsonine predispose affected animals to pyogenic infections such as pneumonia, keratoconjunctivitis, and foot rot.

Clinical Pathology Microscopic examination of stained blood smears may reveal cytoplasmic vacuolation of lymphocytes. These changes are found in the majority of lysosomal storage disorders but might be considered diagnostic of locoweed poisoning in animals with characteristic clinical signs and historical evidence of exposure. Serum activities of alkaline phosphatase (ALP) and aspartate transaminase (AST) are high; elevated concentrations reflect liver dysfunction associated with prominent vacuolation of hepatocytes.[24] Definitive diagnosis can be established by assaying blood from affected animals for α-D-mannosidase activity and swainsonine concentration. The half-life of swainsonine in the serum is 16 to 20 hours.[25] This means that an animal suspected of locoweed poisoning must have a blood sample taken within 2 days of eating locoweed for swainsonine to be detected.

Pathology The microscopic abnormalities of the soft tissues of acutely poisoned animals are similar to those of the inherited lysosomal storage diseases of cattle including cytoplasmic vacuolation of neurons, particularly cerebellar Purkinje cells, and cells in various other tissues.[7,18,26] Paraffin-embedded tissues can be examined using lectin photochemistry to characterize the stored material within the vacuoles.[27] Vacuolation of renal tubular epithelial cells may occur as early as 4 days after the start of daily feeding of 0.34 kg of locoweed to horses and may be present in animals exposed to toxic plants but clinically normal.[28] Pulmonary lesions associated with chronic ingestion of locoweed that may predispose to high-altitude disease (brisket disease) in cattle include alveolar emphysema, bronchiolar constriction and hypertrophy, and interlobular edema and fibrosis. Pyloric or gastric ulcers have been reported in affected cattle.[8,28] Placental

VetBooks.ir

edema, fetal ascites, and hydrops allantois have been described in exposed pregnant cattle.

Treatment There is no known effective long-term therapy for locoweed poisoning. Animals remain affected for a prolonged period or even permanently after removal from the plants. One author recommends tranylcypromine (60 mg PO), a monoamine oxidase inhibitor, and protryptyline (60 mg PO) or reserpine (1.25 mg PO per animal once daily) for treatment of chronically affected animals.[29] The efficacy of these treatments is unknown. Addition of a mineral supplement and a natural clay (clinoptilolite) to the diet of cattle ingesting locoweed did not prevent toxicity.[30]

Prevention Nonaddicted livestock normally do not eat locoweed if other forage is available. The condition may be prevented by supplemental feeding during the early spring and late summer. One report has described conditioning aversion to locoweed in horses using lithium chloride administered simultaneously with grazing of *Oxytropis sericea*.[31] Whether this is a practical management tool in large numbers of animals has yet to be determined.

Staggers Syndromes (Grass Staggers)

Robert J. MacKay

Forage-associated staggers syndromes are common and have been associated with protective fungal secondary metabolites, bacterial antibiotic corynetoxins, or neurotoxic chemicals produced by the forage itself. Some associated plant or fungal toxins also induce other physiologic effects including agalactia, fever, and low productivity because of a prolactin-like effect.

Tremorgenic Mycotoxicoses

There are at least 20 known tremorgenic mycotoxins, produced by several different fungi, that have the same biologically active moiety and give rise to similar clinical manifestations.[1,2] Indole-diterpenoid tremorgens are secondary fungal metabolites that act by blocking potassium outflow from cells via inhibition of cell membrane large-conductance Ca-activated potassium (BK) channels.[3,4] The most important classes of tremorgens are the *lolitrems* (perennial ryegrass staggers) and *paspalitrems* (*Paspalum* staggers, Bermudagrass staggers). Other indole-diterpene tremorgens that may be elaborated on moldy feeds by saprophytic fungi and occasionally cause staggers in livestock include penitrems, janthitrems, aflatrems, and verruculogen. The major tremorgenic mycotoxicoses are similar or identical clinically; therefore clinical signs are only discussed in detail in the Perennial Ryegrass Staggers section.

Perennial Ryegrass Staggers

Perennial ryegrass staggers (PRS) is a syndrome of tremors and ataxia resulting from ingestion of endophyte-infected perennial ryegrass *(Lolium perenne)* by horses, cattle, sheep, deer, goats, and alpacas.[5] PRS is an important condition of livestock in New Zealand and Australia and occurs occasionally as outbreaks in Northern Europe, the northwestern United States, South America, and Europe.[6-9] The case-attack rate may reach 100%, but mortality is generally low and attributable only to accidents. Substantial economic losses may be incurred, however, when production animals with PRS cannot be safely moved. For example, herd- or flock-wide outbreaks have prevented milking of dairy cows and mustering of sheep for necessary procedures such as anthelmintic treatment, shearing, or breeding.[5] Conditions that increase toxicity of perennial ryegrass pastures include high proportion of endophyte-infected plants; late seasonal growth; hot, dry summer and fall after wet spring; ryegrass domination of pastures; ambient temperatures over 23°C; ryegrass that is allowed to flower before consumption; and close grazing.[9] Endophyte is most abundant in the leaf sheath and florets and lowest in the blades. The disease is seen from June to September in the northern hemisphere and December to June in the southern hemisphere.

PRS typically appears acutely 5 to 10 days after introduction of livestock onto endophyte-rich pastures; onsets as early as 48 hours and as late as 2 weeks after exposure have been recorded. The source of tremorgenic toxins is the symbiotic endophytic fungus *Neotyphodium lolii*.[5] The fungal infection confers resistance to predation of grass by insects including the Argentine stem weevil, so there is selective pressure for expansion of toxigenic cultivars. *N. lolii* produces three classes of alkaloids with approximately parallel profiles of production, namely *tremorgens, ergopeptides,* and *peramine*. The most abundant and active indole-diterpene tremorgen produced by endophyte-infected plants is lolitrem B.[10] Concentrations of more than about 2 mg/kg (ppm) dry matter of lolitrem B in forage reliably cause staggers in sheep, cattle, and horses.[11] The concentration of lolitrem B in pasture increases from spring through fall. Plant infection rates below 25% (typical in northern hemisphere pastures) are associated with sporadic cases, whereas plots with 90% infection rates are common in Australasian pastures and are associated with outbreaks of PRS.

Ergovaline and other ergopeptide alkaloids (also see Chapter 54) produced by endophytes cause signs comparable to heat stress syndrome, a condition seen in cattle in the U.S. Southwest that are grazing tall fescue infected with the endophyte *Neotyphodium coenophialum*.[9] The resulting clinical signs are diarrhea, hyperthermia, high heart and respiratory rates, poor weight gain, and reduced milk production. The high mortality rates (up to 30% of affected sheep) reported during PRS outbreaks in Australia in 1986, 1993, and 2002 have been attributed to heightened susceptibility to heat stress caused by ergopeptides in endophyte-infected perennial ryegrass.[9] Horses experimentally fed endophyte-infected *L. perenne* seeds during cool conditions in New Zealand developed limb edema and exudative heel lesions, signs that reflected the vasoconstrictive fescue footlike effects of ingested ergopeptides.[11] Peramine, a pyrrolopyrazine alkaloid, is a potent insect-feeding deterrent with substantial protective effects against the destructive Argentine stem weevil. Strains of endophyte-free perennial ryegrass have been propagated but are difficult to maintain without extensive insecticide use. Cultivars of *L. perenne* that are infected with strains of *N. lolii* have been produced that contain peramine but not tremorgen or ergopeptide. These cultivars (e.g., AR1, AR37) therefore have multiple advantages, compared with traditional endophyte-infected strains, in that they do not cause staggers or ergopeptide-associated production loss and substantially protect against stem weevil predation.[12] AR1 is not as broadly insect resistant as wild-type *N. lolii,* however, and root aphid infestation is notably unaffected.

Clinical signs first occur about 5 to 10 days after introduction of livestock to infected pasture (or after eating infected ryegrass seeds or straw[7,11]) and become progressively more severe until animals are removed from the endophyte source. It is useful to review the carefully observed signs recently reported for experimentally induced PRS in horses because these are typical of mild to moderate signs shown by animals of all affected species during natural PRS outbreaks.[11] Initially, there were fine, then coarse, fasciculations and tremors of skeletal muscles, particularly those of the shoulders, chest, and thoracic limbs. Tremors were particularly apparent during eating, after exercise, or in a thoracic limb that was offloaded by the horse and rested. Fine tremors of the eyeballs were evident during ophthalmoscopic examinations but otherwise difficult to appreciate.[11] Other early clinical signs included a basewide gait, truncal sway, both at rest and during walking, and rapid, stumbling, corrective foot placements. Blindfolding or elevation of the chin exaggerated these signs, consistent with bilateral vestibular dysfunction. Horses were hyperresponsive to the withers slap used to test the laryngeal adductor ("slap") reflex. With progression, signs of general proprioceptive ataxia became apparent including delayed limb protraction, interference between pairs of limbs, and circumduction of pelvic limbs on the outside of circles. The gait also became jerky and more interrupted, but hypermetria, a characteristic cerebellar sign, was not seen

VetBooks.ir

in these mildly and moderately affected horses. The authors speculated that signs reported in severely affected livestock—namely, limb stiffness and unpredictable, inconsistent limb movements, hypermetria, head tremor, falling, and generalized tetanic convulsions[6,13]—are consistent with cerebellar involvement.[11] They therefore propose a time- and dose-related progression through the three "qualities" of ataxia (vestibular, general proprioceptive, then cerebellar) during the course of PRS in an individual animal.[11] Note that normal muscle strength is preserved in affected animals and they remain bright and alert.

In all cases, signs are exacerbated by handling. Attempts to force affected animals through gates or onto trailers may precipitate recumbency. While down, animals have rigid extension of the legs with occasional flailing with opisthotonus and tonic-clonic convulsions. Frothy exudate from the mouth has also been described. After approximately 10 to 20 minutes, the animal recovers if left undisturbed, stands, and walks back to the herd or flock.

Recovery occurs over days to weeks with longer recoveries typical of severely affected animals. Most animals are normal within a week of removal from toxic pasture. Treatment is not usually necessary, but it is important not to disturb or frighten tremoring animals and to handle them as infrequently and carefully as possible. If practicable, they should be kept on level ground in an area free of potential hazards, especially water hazards. If handling is necessary, hyperresponsiveness can be controlled by sedation. Tremors can temporarily be suppressed by diazepam (0.02 to 0.1 mg/kg IV for horses or 0.1 to 0.2 mg/kg IV for small ruminants).

Paspalum Staggers

Claviceps paspali ergots parasitize *Paspalum* spp. grasses and produce paspalitrems, indole-diterpene tremorgens that cause staggers syndromes in livestock similar or identical to that described earlier for perennial ryegrass staggers. Susceptible grasses include dallisgrass *(P. dilitatum),* bahiagrass *(P. notatum),* water couchgrass *(P. distichum),* and knotgrass *(P. paspaloides).*[14-16] *Paspalum* staggers has been recognized in the United States, South Africa, Great Britain, Australia, and New Zealand.[15,17-19] Natural outbreaks occur most commonly in cattle, but *Paspalum* staggers has been reported in three foals and two adult horses grazing dallisgrass in Australia[20] and sporadic cases are seen regularly by the author in horses on bahiagrass pastures in Florida.

C. paspali first attacks the pistil of the grass flower and replaces the ovary with a sclerotium (ergot). The fungus secretes a sticky fluid, the "honeydew," which contains a large number of spores but little toxin. The fluid hardens into a mature sclerotium containing high concentration of tremorgenic metabolites. Toxic stands of dallisgrass or other *Paspalum* grasses can be recognized by the presence of numerous small, reddish brown or black sclerotia measuring 3 to 5 mm in diameter on the seed head of the plant. The most abundant indole-diterpene metabolite in sclerotia is paspalitrem B, but paspalitrems A and C, paspaline, and paxalline are also produced.[15,21] *C. paspali* sclerotia also produce ergot alkaloids, albeit at low concentrations (on the order of 10 µg/kg dry weight compared with 150 mg/kg for paspalitrem B in one report[22]). Notable ergot alkaloids are ergonovine and ergine (lysergic acid amide). Particular animals apparently develop a craving for the infested seed heads and graze them selectively. Toxin production is greatest when there is a wet period after formation of the seed heads. The toxin remains active in cured hay. Mowing the toxic pastures and removing or burning the infested seed heads is effective for preventing further exposure to the tremorgen.

Clinical diagnosis is made by observation of clinical signs, visible detection of the toxic agent in the feed, or detection of indole-diterpenes by thin-layer chromatography (TLC). Animals recover spontaneously within days to several weeks after being removed from the pasture.

Bermudagrass Staggers

Bermudagrass *(Cynodon dactylon)* occasionally may become toxic for livestock.[19] Cattle are considered most susceptible, followed by sheep, goats, and horses. As is the case for *Paspalum* staggers, bermudagrass staggers results from ingestion of paspalitrems in grass parasitized by fungal ergots, in this case *Claviceps cynodontis*. *C. cynodontis* is closely related to *C. paspali,* and the profiles of indole-diterpenoid and ergot alkaloids produced by the sclerotia of these two fungi are similar. The clinical and epidemiologic aspects of bermudagrass staggers and *Paspalum* staggers are likewise similar.[22]

Animals may develop clinical signs as early as 36 hours after consuming toxic forage. Experimentally poisoned goats have developed clinical signs 8 days after being fed 772 g/head/day of toxic hay.[23] The toxin survives drying, and hay that is cut from offending pastures may remain toxic for as long as 9 years.[24] Pastures that are toxic remain so for successive seasons unless the vegetation is burned off and the ground is tilled and reseeded. The clinical signs occur suddenly, usually simultaneously, in several animals in the herd. In some cases, most of the animals on a single pasture may be affected, whereas animals on an adjacent pasture remain normal. The mortality rate is low, and deaths usually occur from self-inflicted trauma. Affected animals recover 2 days to 2 months after removal from the affected pasture or hay. Management is as for perennial ryegrass staggers.

Tremorgenic Mycotoxicoses Associated with Saprophytic Fungi

Most tremorgenic mycotoxins are synthesized by common saprophytic fungi of the genera *Penicillium* and *Aspergillus* that elaborate mycotoxins onto improperly harvested or stored livestock feeds. Some *Penicillium* spp. can also act as opportunistic plant pathogens, most notably as a cause of ear rot in corn. Ingestion of moldy cornstalks is probably the most common source of fungal tremors in livestock. The fungi proliferate in the corn but do not produce tremorgens until the stalks touch the ground. After production at or near the soil surface, the toxins translocate in plants through root absorption.[25] Cases associated with *Aspergillus* molds (usually *A. clavatus*) have occurred worldwide, linked to feeding sprouted grains and the by-products of beer production, both of which provide an environment for growth of the mold.[26,27] Clinical signs are indistinguishable from those of *Paspalum,* perennial ryegrass, and bermudagrass staggers.[16,25,28,29] Indole-diterpenoid tremorgens produced by *Penicillium* and *Aspergillus* spp. can be classified into four major groups: the aflatrem-paxilline group, verruculogen-fumotremogen group, territrem group, and tryptoquivaline group. Of these, the most important fungal tremorgens are aflatrem, penitrem A, fumotremogen B, and verruculogen. In some cases, additional non-indole-diterpenoid mycotoxins elaborated by these fungi cause a wider spectrum of clinical signs. For example, *A. clavatus* caused a highly fatal mycotoxicosis of cattle in South Africa, associated with widespread degeneration and necrosis of skeletal muscle and CNS motor neurons.[15]

Diagnosis is by demonstration of indole-diterpenoid tremorgens by thin-layer chromatography (sometimes in combination with a mouse tremorgen assay). Mycelial elements of *Penicillium* and *Aspergillus* molds may survive degradative conditions in the gastrointestinal tract and can be identified and cultured from the feces of affected animals.

Corynetoxicoses (Annual Ryegrass Toxicity, Flood-Plain Staggers, Blown Grass Staggers)

Corynetoxicoses are severe, often fatal neurologic disorders of livestock in Australia and South Africa.[30] A related syndrome was seen in Oregon from the 1940s through the 1960s but apparently has not been seen since.[31,32] Corynetoxins are produced by plants of several genera including *Lolium rigidum* (annual ryegrass), *Polypogon monspeliensis* (annual beard grass), and *Lacnagrostis filiformis* (blown grass) that are colonized by a nematode (*Anguina* sp.) and a bacterium *(Rathayibacter toxicus).*[33-35] Affected sheep and cattle with the same clinical syndrome in Oregon had been fed a fescue *(Festuca negrescens)* infected with a grass seed nematode and a *Rathayibacter*-like organism.[31,32] Corynetoxin-producing *R. toxicus* is transported

VetBooks.ir

into host plants by nematode L2 larvae and ingested by sheep, cattle, and occasionally horses.[30] The colonized plant forms a hollow gall in response to larval invasion of the seed. Bacteria are thus carried into the galls, where they proliferate into a distinctive yellow to orange mass.[30] *R. toxicus* organisms produce a series of closely related corynetoxins that are glycolipids in the tunicaminyluracil class of antibiotics. Corynetoxins potently inhibit lipid-linked *N*-glycosylation of glycoprotein, and their toxicity in animals probably results from the depletion of essential *N*-glycosylated proteins. It takes up to 15 years after introduction of the nematode-bacterial complex to a pasture before clinically significant amounts of toxin are produced.[36] A method of evaluating toxic pastures based on both enumeration of contaminated seedheads and ELISA to quantify *R. toxicus* has been developed.[37]

Although the serum half-life of corynetoxins in livestock is only about 4 hours, repeated exposure leads to an accumulation of the toxin and onset of clinical disease may take up to 12 weeks of continued ingestion.[30] Also, the concentration of the toxin increases in the seedheads during the summer and is greatest as the plant dries and the seeds ripen. Outbreaks associated with the feeding of hay made from toxic pasture may occur at any time. Stock losses are highest in sheep, although cattle deaths can be substantial. Outbreaks in horses occur occasionally and generally involve only a few horses.[38,39] Clinical signs appear to reflect the cerebellar and thalamic lesions that are evident histologically.[39] All ages are affected, and morbidity and mortality are usually high. When an affected flock is driven or cattle rounded up or otherwise stressed, some animals collapse in sternal or lateral recumbency. They often have muscle tremors, opisthotonos, head nodding, tetanic and clonic convulsions, limb extension, hypermetria, teeth-grinding, nystagmus, and ptyalism. Animals may regain their feet after several minutes and stagger away with a stiff-legged, jumping, or swaying gait. These animals often wander aimlessly, exhibiting stupor and ataxia. In mildly and moderately affected animals, clinical signs usually resolve within a week of removal from affected pasture, although relapses may occur in animals that appear to have recovered and it may take several months for severely affected animals to recover. Treatment with magnesium sulfate solution (50 to 100 mg/kg, IV in horses, SC in ruminants, repeated as needed) is reportedly effective in some cases.[38,40] The most practical strategy for controlling annual ryegrass toxicity is to break the nematode's life cycle by killing the ryegrass for two or three growing seasons. Otherwise, pastures remain perpetually toxic. Integrated control measures that have been recommended for prevention of annual ryegrass toxicity include applying herbicides in the spring, seeding the pastures with legumes, burning the infected pasture grasses during early autumn, and applying ryegrass-selective herbicides in the summer months, combined with heavy winter grazing.

Pathologic changes associated with corynetoxin poisoning include widespread petechial hemorrhages and a yellow, friable liver. Histologically, CNS changes are surprisingly mild and nonspecific. Most lesions are cerebellar with proteinaceous fluid around vessels, especially in the meninges. There is diffuse vacuolation of hepatocytes and bile duct proliferation.

Kikuyu Grass Poisoning

A multiorgan disease characterized by peracute onset obtundation, ataxia, drooling of saliva, sham drinking, ruminal distention, and colic occurs in cattle and, to a much lesser extent, sheep and goats of New Zealand and Australia that are grazing kikuyu grass *(Pennisetum clandestinum).*[41] A review of 9 reports involving 2719 cattle at risk reported a 23% morbidity rate and 70% case-fatality rate.[41] The cause and pathogenesis are poorly understood.

Canarygrass Staggers (*Phalaris* Staggers)

Phalaris poisoning has been reported in Australia, New Zealand, South Africa, Norway, Argentina, and the United States, in association with the ingestion of *Phalaris* spp. grasses by sheep and cattle, most notably *P. aquatica* (bulbous canarygrass or hardinggrass) and *P. arundinacea* (reed canarygrass).[42] These outbreaks have involved either sudden death due to peracute brain dysfunction (termed *polioencephalomalacia-like sudden death*) or myocardial dysfunction (termed *cardiac sudden death*).[43,44] Sheep are considered to be the most susceptible species, but cattle are also affected.[45] Only the cardiac sudden death syndrome has been reported in horses.[46,47] In the United States, outbreaks of canarygrass staggers have been reported in sheep and feedlot lambs in California *(P. aquatica),*[48,49] as well as sheep and cows in Louisiana *(P. caroliniana)*[50] and cows in West Virginia *(P. arundinacea).*[45]

It has been suggested that phenylethylamines or derivatives of tyramine are involved in sudden death syndromes.[42,51] Staggers occurs as either an acute and reversible or a chronic, irreversible, and typically lethal form. The latter, more common, presentation usually occurs as outbreaks. Delayed or chronic *Phalaris* staggers is associated with tryptamine alkaloids produced by the plant that structurally resembles serotonin.[42,51] These alkaloids act as serotonergic receptor agonists, and accumulation within serotonergic tracts of the CNS eventually results in staggers signs. Rapid growth of canarygrass favors the formation and accumulation of toxin. Other factors that enhance the toxicity of canarygrass pasture include fog, humidity, or rain, followed by sunny, warm weather or sunshine on nitrogen-fertilized pastures.[52] Grazing animals are not usually affected until *Phalaris* spp. grasses comprise more than 50% of the diet.[53] The concentration of tryptamine alkaloids may be reduced by curing the forage as hay. By contrast, ensiling canarygrass does not reduce the amount of toxin.[54]

Staggers occurs after exposures of from 5 days to 33 weeks. Signs may be delayed for as long as 4 months after removal from the toxic grass.[50] Characteristic early clinical signs in sheep are constant anxious observation of handlers and continuous twitching ear movements. Signs progress to include hyperexcitability, exaggerated responses to auditory or tactile stimuli, fine muscular fasciculations (particularly of masseter muscles), licking of the lips, wrinkling of the facial muscles, repetitive chewing, inability to swallow, flaring of the nostrils, ptyalism, nystagmus, intention tremor of the head, ear and tail twitching, basewide stance, reduced menace response, and deficient pupillary reflexes.[55] The gait of affected sheep is described as stiff legged, with both hindlimbs moving in unison at gaits above the trot ("bunny-hopping"). Affected sheep and cattle may buckle at the knees and assume sternal recumbency with the hindquarters elevated.[45,53] They then fall into lateral recumbency and flail wildly while attempting to stand. Poisoned cattle also become uncoordinated and may have distinctive stabbing movements of the tongue and inability to prehend forage.[56] They salivate profusely and drop feed from the mouth. Eventually the animals die from starvation. There may be increased protein concentration (40 to 100 mg/dL) and nucleated cell count (up to 50 mononuclear cells/μL) in CSF of affected animals.[48] Animals may survive the initial signs but have neurologic signs that wax and wane for up to 10 months. For confirmation of a diagnosis, tryptamine alkaloids in suspect grasses can be quantified by ELISA.[57] Concentrations greater than 30 to 50 mg/100 g dry weight of forage are considered toxic for sheep.[52,55]

The pathologic lesions in the CNS of affected animals are characteristic and include focal, demarcated, blue-green or slate-gray discoloration in the brainstem and corticomedullary junction of the kidney; intracytoplasmic accumulations of yellow-brown pigment in the dorsal root ganglia, brainstem nuclei, and ventral horns of the gray matter of the spinal cord; neuronal loss; focal gliosis; and swelling of axonal sheaths in the ventromedial aspect of the spinal cord.[45,48,53] The pigment is thought to originate from deamination of the toxic alkylamines, but their presence does not correlate well with the development of neurologic deficits.[55]

Administration of cobalt to animals on toxic grass pastures is protective. In the presence of cobalt, rumen microflora inactivate toxic alkaloids. Weekly administration of 28 mg of cobalt to each animal was required experimentally to prevent clinical signs in

VetBooks.ir

exposed sheep.[58,59] Additional recommendations include removal of affected animals from the offending pasture, sedation with a phenothiazine tranquilizer, and administration of sodium pentobarbital or diazepam to convulsive animals. *Phalaris* plants may also contain potentially toxic concentrations of nitrate or cyanide. In any outbreak of suspected *Phalaris* toxicosis with acute signs of sudden death, cyanide and nitrate poisonings should also be considered.[43]

Differential Diagnoses for Staggers Syndromes

Grass staggers is easily recognized by clinical signs. The specific plant involved must be identified by examination of the pasture forage. Tremorgenic diseases of adult cattle are common throughout most of the world. In addition to the syndromes discussed earlier, plants that may cause staggers syndromes include toxic storage syndromes including locoism induced by the swainsonine-containing plants *Swainsona luteola, Swainsona galegifolia, Astragalus,* and *Sida* spp. and the tremor syndrome induced by *Solanum dimidiatum, Solanum fastigiatum,* and *Solanum viarum*. Hypomagnesemia causes grass staggers and has been reported to cause cerebellar degeneration under some circumstances. The genetic storage diseases α- and β-mannosidosis, generalized glycogenosis, globoid cell leukodystrophy, and neuronal lipodystrophy may also be important differential diagnoses for ataxic animals with tremor and cerebellar signs.

Multiple Congenital Central Nervous System Defects

Multiple congenital defects that are suspected or documented to have a heritable (genetic) basis have been described in large animals. Many, but not all, of these disorders involve signs referable to cerebellar dysfunction; others may have signs referable to spinal cord dysfunction. These defects along with others are presented at this point in the textbook in Table 35-6.

Diseases Presenting Principally with Spinal Cord or Peripheral Nerve Signs

Equine Herpesvirus Myeloencephalopathy

Robert J. MacKay

Equine herpesvirus 1 is a member of the Alphaherpesvirinae subfamily of Herpesviridae. Along with another alpha herpesvirus EHV-4, it is a common cause of upper respiratory disease in horses (see Chapter 31); more importantly, because of a predilection for cell-associated viremia and vasculitis, EHV-1 infection is associated with late-term abortion, death of neonatal foals, and spinal cord disease. There is a strong perception that outbreaks of the last of these syndromes, known as *equine herpesvirus myeloencephalopathy* (EHM), have over the past 20 years become more frequent and severe. The U.S. Department of Agriculture has suggested that EHM is an emerging disease on the basis of the following criterion: "A disease changes in severity, type of animal that can be infected, or other changes in pathogen behavior."[1]

Clinical Signs Acute onset of ataxia and tetraparesis of variable severity most often characterizes the neurologic form of EHV-1.[2,3] Signs usually appear between 6 and 10 days after infection. The severity of clinical signs can range from subtle pelvic limb ataxia and weakness to complete recumbency without limb or head movement. Nonneurologic signs including nasal and ocular discharge, limb edema, colic, ocular lesions, and anorexia may also be seen.[2-7] Horses may be febrile at presentation, but most are normothermic. Fever, often biphasic in profile, is the most consistent premonitory sign of neurologic disease, although not all febrile horses develop myeloencephalopathy. Coughing and nasal discharge or abortion sometimes accompany the neurologic signs or may have occurred during the preceding 2 weeks.[5,8,9]

The neurologic signs reflect injury to the white and gray matter of the spinal cord and include limb and truncal ataxia and paresis, bladder distention, urinary incontinence, weakness of the tail and anus, and reduced perineal sensation. There may be either penile paresis or persistent erection (priapism) during the first several days of clinical signs. Pelvic limbs are more severely affected than thoracic limbs, and signs are usually symmetric. In mild and moderately affected horses with EHM, there is often bladder distention with spastic detrusor tone without urethral relaxation (dyssynergia). Bladder atony and incontinence also occur, particularly in recumbent horses, and the associated dribbling of urine leads to secondary perineal scalding. Bladder rupture has occurred in such horses. Anal sphincter and caudal rectal tone may also be reduced, with consequent obstipation and gaping of the anus.

Signs of brain dysfunction including seizures, blindness, and cranial nerve dysfunction have been reported in a few cases of EHM.[10] Ocular lesions such as mydriasis, hypopyon, uveitis, and optic neuritis may also be present. The occurrence of multifocal chorioretinopathy, visible several weeks after onset of neurologic signs as foci of depigmentation, appears to be a particularly sensitive indicator of previous EHV-1 viremia.[11]

The clinical signs typically stabilize within 48 hours, and in most instances recumbency, if it occurs, begins during this period. Some horses continue to deteriorate and eventually die or are euthanized. In survivors, improvement begins within the first 5 to 7 days and may continue for weeks or even months. Many horses make a full clinical recovery; however, an unknown proportion still have residual signs of limb weakness or ataxia. Obviously, a horse that does not become recumbent during the first 2 days has a much better prognosis for survival.

Diagnosis A tentative diagnosis of EHM can be made on the basis of characteristic neurologic signs, history, and supporting findings on physical examination. A CSF analysis that shows a xanthochromic fluid with high protein concentration and normal or slightly high nucleated cell count (albuminocytologic dissociation) is typical and almost pathognomonic for EHM,[10,12] although cases with normal protein concentration and/or mononuclear pleocytosis occur occasionally.

Conventional, nested, or quantitative PCR amplification of EHV-1–specific gene sequences (usually glycoprotein B) in nasal swabs and EDTA-anticoagulated blood is the diagnostic technique of choice for horses with suspected EHM.[12] Both nasal swab and blood should be submitted at the acute stage of disease; nasal swabs alone are sufficient to monitor for release from quarantine in some jurisdictions. Nasal swabs are more likely to collect virus than are nasopharyngeal swabs.[13] Swabs for this purpose should be about 6 inches long with a synthetic shaft. After collection, the swab should be placed in viral transport medium and sent to the diagnostic laboratory. If transport media are not available, the swab can be broken into a sterile tube and transported. Positive samples can separately or simultaneously be analyzed for a single nucleotide variant in the viral DNA polymerase gene, DNA_{pol} D_{572}, that defines the best known and most important neuropathogenic strain of EHV-1. Real-time PCR provides quantification of viral DNA load and allows additional interpretation of the relevance of positive results.[12] It should be noted that these molecular diagnostic tests confirm active EHV-1 infection (and viremia when blood is positive) but do not per se confirm the diagnosis of EHM.

Additional aliquots of nasal swabs and anticoagulated blood should also be submitted for traditional virus isolation in tissue culture. Virus isolation is important to allow full characterization of outbreak viruses including susceptibility to candidate antiviral drugs.[14]

A fourfold or greater increase between acute and convalescent serum virus neutralizing (VN) or complement-fixation (CF) antibody titers in samples taken 7 to 21 days apart is presumptive

VetBooks.ir

TABLE 35-6

Congenital Diseases of Large Animals with CNS Signs and Mode of Inheritance, Where Known

Diseases with Predominant Intracranial Signs	Species and Breed(s) Affected	Clinical Signs/Ancillary Tests	Age of Onset	Mode of Inheritance	References
Ceroid lipofuscinosis	Ovine: South Hampshire, Swedish Landrace, Rambouillet Caprine: Nubian Cattle: Devon Horses: breeds not described	Progressive ataxia, blindness, depression, coma	Variable	Autosomal recessive	1-10
Citrullinemia	Cattle: Holstein	Progressive depression, bellowing, abnormal tongue and facial movements, convulsions, death Increased blood ammonia and citrulline concentrations	Newborns	Autosomal recessive	11-19
Exophthalmos and strabismus	Cattle: Jersey, Holstein, Brown Swiss, Shorthorn	Protrusion and crossing of the eyes	>6 mo	Unknown	20, 21
Cerebellar abiotrophy	Cattle: Holstein, Angus, Limousin	Intention tremors, hypermetria, basewide stance; may or may not progress	Variable	Suspected autosomal recessive	22-26
Bovine familial convulsions and ataxia	Cattle: Angus, Charolais, Polled Hereford, Angus Cross	Stillbirth/abortion with occasional dorsiflexion of the spine Intermittent cerebellar signs and convulsions	Variable, may improve with age	Autosomal dominant with incomplete penetrance	27-33
Cerebellar abiotrophy/ hypoplasia	Horses: Arabians, Arabian cross	Head tremor, ataxia, hypermetria	>2 mo	Autosomal recessive	34-39
Familial ataxia	Cattle: Hereford	Ataxia, abnormal head posture, pupillary dilatation	Newborns	Unknown	40
Micrognathia/cerebellar hypoplasia	Cattle: Angus	Stillbirth, brachygnathia, cerebellar hypoplasia	Stillborn	Suspected autosomal recessive	41
Alpha mannosidosis	Cattle: Angus, Murray Grey, Simmental, Galloway, Holstein	Stunted growth, ataxia, head tremor, hypermetria	1 wk-15 mo	Autosomal recessive	42-49
Beta mannosidosis	Cattle: Salers Goats: Anglo-Nubian	Recumbency, deafness, narrow palpebral fissures, intentional head tremor, rotatory head movements, ocular defects, joint abnormalities, domed skull	Newborns	Autosomal recessive	50-71
Generalized glycogenolysis (beta-galactosidase deficiency, GM1 gangliosidosis)	Sheep: multiple breeds Cattle: Holsteins	Lethargy, anorexia; head carried low and extended; blind, collapse when head moved	>1 mo	Suspected autosomal recessive	72-83
Bovine generalized glycogenosis (type II glycogenosis, Pompe disease)	Cattle: Shorthorn, Brahman	Weakness, tremors, ataxia, right-sided heart failure	2-3 mo	Autosomal recessive	84-93
Globoid cell leukodystrophy (Krabbe disease)	Sheep: Polled Dorset	Depression, head tremor, ataxia, hyperesthesia	>4 mo	Unknown	94, 95
Neuronal lipodystrophy	Cattle: Angus, Beefmaster Sheep: Breeds not described	Depression, blindness, circling, seizures, coma	>10 mo	Unknown	96-98
Shaker calf syndrome	Cattle: Horned Hereford	Recumbency, hypermetria, hypertonia, hyperesthesia, muscle tremors	Newborns	Unknown	99
Maple syrup urine disease	Cattle: Hereford, Polled Shorthorn	Viscous, dark, malodorous urine; fever, depression, opisthotonos, myoclonus, convulsions; spongiform changes in brain	Newborns	Autosomal recessive	100-116

TABLE 35-6

Congenital Diseases of Large Animals with CNS Signs and Mode of Inheritance, Where Known—cont'd

Diseases with Predominant Intracranial Signs	Species and Breed(s) Affected	Clinical Signs/Ancillary Tests	Age of Onset	Mode of Inheritance	References
Hereditary neuraxial edema	Cattle: Polled and Horned Herefords, Hereford × Friesian	Inability to rise; hyperesthesia, myoclonus, extensor rigidity, and apnea/dyspnea when stimulated	Newborns (may be stillborn)	Suspected autosomal recessive	117-125
Epilepsy	Cattle, horses	See text			
Narcolepsy/cataplexy	Horses, cattle, sheep	See text			
Diseases with Predominant Spinal/Motor Nerve/Muscle Signs					
Inherited myoclonus	Horses: Peruvian Paso	Myoclonus in response to stimuli, bunny-hopping gait; may not be able to stand without assistance	Newborns	Unknown; deficiency of receptors for the inhibitory neurotransmitter GABA	126
Congenital encephalomyelopathy	Horses: Quarter Horse	Inability to stand; when assisted to stand, hindlimb tremors cause the hindlimbs to bounce off the ground; increased patellar reflexes		Unknown	127
Systemic neuraxonal dystrophy	Sheep: Suffolk	Progressive hindlimb ataxia leading to recumbency	>1 mo	Suspected autosomal recessive	128-129
Weaver syndrome (bovine progressive degenerative myeloencephalopathy)	Cattle: Brown Swiss, Angler	Progressive paraparesis, hindlimb ataxia with proprioceptive deficits, muscle tremors, recumbency	>5 mo	Autosomal recessive	130-146
Progressive spinal myelinopathy	Cattle: Murray Grey	Unable to stand; progressive hindlimb hypertonia and proprioceptive deficits	Newborns	Autosomal recessive	147-148
Bovine spinal muscular atrophy	Cattle: Brown Swiss, Red Swiss, Braunvieh, Holstein	Progressive muscle atrophy leading to recumbency	>2 wk	Autosomal recessive	149-157
Spinal dysmyelination	Cattle: Braunveih, Braunvieh Cross	Unable to stand, generalized tremors, muscle atrophy	Newborns	Autosomal recessive	158-160
Neuropathy/myopathy/glomerulopathy	Cattle: Gelbveih	Progressive hindlimb ataxia and paraparesis, muscle atrophy, reduced anal tone; proteinuria	Few weeks-1 yr	Unknown	161-162
Progressive ataxia	Cattle: Charolais, Charolais Cross	Progressive paraparesis and hindlimb ataxia, proprioceptive deficits; muscle/tail tremors on rising	>6 mo	Suspected autosomal recessive	163-172
Spastic paresis (Elso heel)	Cattle: multiple breeds	Intermittent extensor spasticity and hypertonia of one or both hindlimbs; hyperextension of hock during weight bearing	>3 wk	Unknown	173-195
Inherited periodic spasticity (crampy syndrome, barn cramps, Krampfigkeit)	Cattle: dairy breeds	Intermittent muscular spasms of hip and upper hindlimb muscles, simultaneous kyphosis	>3 yr	Suspected autosomal dominant with incomplete penetrance	196-200
Hereditary lethal spasms (Doddler syndrome)	Cattle: Jersey	Unable to stand, head and neck spasms when stimulated, convulsions, death	Newborns	Suspected autosomal recessive	201-202
Congenital abnormalities of the vertebrae and/or spinal cord	Multiple species	See text			

evidence of EHV-1 infection.[12] These tests are of limited value, however, because they do not distinguish between EHV-1 and EHV-4 responses and results are delayed several weeks. An ELISA that distinguishes between infections with these two viruses is available commercially outside the United States[15] and is the serologic diagnostic of choice. A practical approach to an outbreak that may involve many horses is to submit serum from both clinical and in-contact/cohoused horses for serology and samples for PCR only from horses with clinical signs of fever and/or EHM. Such an approach provides additional support for the diagnosis and defines the extent of exposure to the virus during the outbreak.

Pathophysiology After initial colonization of the epithelia of the upper respiratory tract, EHV-1 spreads to and amplifies in regional lymph nodes before circulating in the blood within leukocytes. The magnitude and duration of the leukocyte-associated

VetBooks.ir

viremia are positively related to the risk for EHM.[12,16] Virus is presumed to enter endothelial cells of small arterioles of CNS after binding to its surface MHC-1 receptor. Endothelial infection incites destructive innate and specific immune inflammatory responses, which in turn initiate coagulation and widespread arterial microthrombosis and hemorrhage. Viral replication within neurons has not been demonstrated in EHM; rather, neuronal injury is secondary to ischemia secondary to vasculitis and thrombosis.

Epidemiology Herpesvirus infection is enzootic in the horse population. Infection usually occurs through the respiratory epithelium when the animal comes in contact with the virus in aerosolized droplets or via fomites contaminated with fluids from an abortion or in ocular, nasal, or other respiratory tract secretions.[3,10] Foals likely become infected with virus shed from their dams during recrudescence of latent infections.[12] Most horses first become infected before 1 year of age and remain infected with latent virus in the trigeminal ganglia or in lymphoid tissues around the head.[12,14] Surveys of necropsied adult horses indicate that more than 50% of normal horses are latently infected by EHV-1 in one or both of these sites.[12]

EHM is rare, but cases have been reported worldwide. Outbreaks occur more commonly in Europe and the United States than they do in Australia and New Zealand.[12] Viral polymorphism undoubtedly accounts for differences in neurovirulence. Viruses with one allele of a single nucleotide polymorphism in the viral DNA polymerase gene, D_{752},[17] were found to be 162 times more likely to cause EHM than were viruses with the alternative allele N_{752}.[18] The mechanism for enhanced neuropathogenicity of D_{752} partly relates to higher-order viremia in infected horses compared with that in horses infected with N_{752} but is not due to greater neurotropism. It is common for horses to be latently infected with both variants (D_{752} and N_{752}), and there is no evidence that horses latently infected with the neuropathogenic strain pose a higher risk of being the source of future EHM outbreaks.[12] Polymorphism elsewhere in the genome likely also modulates neurovirulence.[9] During outbreaks, the virus appears to be spread readily and both morbidity and mortality can be high.

Horses of any age, gender, or breed are susceptible. In some studies females in general, or mature pregnant or lactating mares, are most often affected.[7,16,19] The principal risk factor for development of EHM is fever, especially the second peak of a biphasic fever.[6] The onset of neurologic signs often follows closely the decline from peak temperature. Additional purported risk factors in at least some outbreaks were older age,[6,7] cooler seasons (all but summer), introduction of horses to a herd,[7,8] and inconsistent outbreak-specific breed susceptibilities.[7,8,12] Foals are rarely affected. Mules and donkeys are infected and shed virus but apparently do not develop EHM.[20] Frequent (up to four times annually[6,19]) and recent[19] vaccination against EHV-1 have been reported as risk factors; however, age was an important covariable in the former study and confounded interpretation of any role of vaccination.[12] Stress-associated recrudescence of latent infections and subsequent shedding without clinical signs has been difficult to confirm experimentally but undoubtedly is important in the initiation of some outbreaks, especially those occurring after long-distance transportation or in closed herds. Experimentally infected horses may nasally shed virus for 3 weeks or longer after infection; however, viral shedding was not found after 9 days after onset of clinical signs in 20 horses with EHM.[21]

Primary attack rates, as judged by occurrence of fever (usually defined as rectal temperature >101.5° F) among at-risk horses may be up to 90%; an average of 10% of these infected horses develop EHM, and mortality rates for horses with EHM are typically between 20% and 80%, with 50% a typical rate.[3,12] There is no report of EHM caused by modified live virus vaccines currently approved for use in horses.

Necropsy Findings Gross and histologic lesions are not always limited to the CNS. Ocular lesions including hypopyon, iritis, and chorioretinitis have been reported. Cystitis and scrotal edema may be present. Focal areas of hemorrhage may be found throughout the brain and spinal cord parenchyma and meninges. Vasculitis and thrombosis of the small arteries and veins of the spinal cord and brain results in ischemic lesions in the CNS.[22,23] Equine herpesvirus is infrequently cultured from the CNS, but PCR, in situ hybridization, and immunohistochemistry can be performed on CNS tissues obtained postmortem to confirm the presence of the virus.[12]

Treatment Acyclovir is guanosine analog with in vitro activity against EHV-1 that has been used successfully for treatment of herpes simplex encephalitis in humans. Adequate blood levels of acyclovir can be achieved in horses by oral dosing of valacyclovir (30 mg/kg q8h for 2 days and then 20 mg/kg q12h) or IV administration of acyclovir (10 mg/kg q12h) but not by oral acyclovir.[24] Valacyclovir is now available as a generic but still costs $150 to $300 daily to treat a 500-kg horse. Unfortunately, on the basis of limited experimental and anecdotal clinical reports, valacyclovir, although safe, is not effective in horses with EHM.[25] In light of the scant evidence available, however, valacyclovir treatment is still worthwhile when economic circumstances permit. Ganciclovir may be more effective than valacyclovir in preventing clinical signs in horses experimentally infected with EHV-1 (see Prevention section later),[25] but its efficacy in treating horses with EHM has not been evaluated.

Supportive care is the most important aspect of treatment for equine herpes myeloencephalopathy. Measures include bladder decompression by sterile catheterization at least twice daily for horses with bladder distention and/or incontinence, evacuation of the rectum, administration of intravenous or oral fluids, and enteral or parenteral nutritional support. Recumbent horses must be appropriately padded, and decubital lesions must be prevented or treated. Horses that are recumbent but able to support their weight when lifted should be managed with an abdominal sling.

Administration of antiinflammatory drugs soon after the onset of neurologic signs may be beneficial. NSAIDs (e.g., flunixin meglumine 1.1 mg/kg IV q12-24h) should be used if the horse is febrile or there is clinical suspicion of a painful condition, but there is no evidence that NSAIDs affect the course of neurologic signs. Corticosteroids are often used because of presumed suppression of vasculitis, and although no objective data for their efficacy are available, there is a solid theoretical basis for their use.[12] Dexamethasone (0.05 to 0.1 mg/kg IV or IM) can be given q12-24h for 3 to 5 days, with the dosage then tapered for 1 to 3 days. There are unquantifiable risks related to steroid-induced immunosuppression including increased susceptibility to bacterial infection of the urinary tract and reactivation of latent virus. Because of uncertainties as to its benefits and risks, steroid treatment should be reserved for horses that are recumbent or in imminent danger of becoming so. Dimethyl sulfoxide (DMSO; 1 g/kg as a 10% solution in polyionic fluids by slow IV infusion) every 12 to 24 hours is often used, although its efficacy has not been documented.

Use of antibiotics should be considered if the horse is recumbent or has urinary tract or respiratory tract involvement. Chronic cystitis, sometimes associated with bacteria resistant to common antimicrobials, is a common complication of urinary incontinence and bladder catheterization in horses with EHM. Management of such cases is discussed in Chapter 34.

The lesions of EHM are characterized by both microvascular thrombosis and hemorrhage, so there is as of yet no compelling rationale for the use of anticoagulant therapy in horses with EHM.

Control and Prevention Vaccines currently used to prevent EHV-1 respiratory and abortion syndromes do not claim to prevent EHM, and there is no reliable evidence that they do. A small study concluded that modified live virus vaccine provided modest albeit significantly better protection against experimentally induced EHM than did a killed low-antigen vaccine,[26] although the duration and robustness of such protection, if any, are not yet clear. Vaccination with inactivated "high-antigen" vaccines (i.e., those with a label claim

VetBooks.ir

for prevention of herpesvirus abortion), enhanced adjuvant vaccines, or modified live vaccine does have the important effect of reducing nasal shedding and thus potentially limiting the spread of infection during an outbreak. This rationale has also been used to justify booster vaccination of at-risk horses during an outbreak. Because of persistent evidence-based concerns about inducing or exacerbating EHM by excessive and recent vaccination, however,[6,19] this practice remains controversial.

Immunostimulants are sometimes administered to horses at risk for EHM on the basis of the theory that immune system activation will prevent viral reactivation or replication,[12] but supportive evidence is lacking. Provision of nutritional supplements containing zinc protected horses exposed during an EHM outbreak from developing the disease according to a retrospective study of horses involved in the 2011 Ogden, Utah, outbreak.[19]

Valacyclovir and valganciclovir are prodrugs of the antiviral agents acyclovir and ganciclovir that have adequate bioavailability in horses when given orally.[24] Although these agents have in vitro activity against EHV-1, valacyclovir and ganciclovir were not effective at preventing EHM when either one was 4 to 6 days after viral inoculation (i.e., at the onset of the second temperature rise).[25] Ganciclovir, but not valacyclovir, reduced the severity of ataxia. Therefore if these drugs are tried as preventatives, they should be used no later than the onset of the initial febrile period with the understanding that there are no data for preventive efficacy in this setting.

Protocols for management of premises with EHM cases are now well established and tested. The reader is referred to the comprehensive and regularly updated guidelines available from the American Association of Equine Practitioners (AAEP; http://www.aaep.org/). In addition, the British Horserace Betting Levy Board publishes Codes of Practice on Equine Diseases (http://codes.hblb.org.uk/). In brief, the essentials of these protocols are (1) isolate affected horses; (2) monitor temperatures twice daily on all quarantined horses; (3) submit diagnostic samples; and (4) implement robust biosecurity procedures.[12] There is still uncertainty about the length of quarantine required after the last occurrence of fever in any horse. AAEP guidelines currently call for 28 days. A workable but expensive alternative is to require 14 days after the last fever in any quarantined horse, then test all horses for nasal shedding by PCR on swabs taken on 2 to 4 successive days.[12] It is essential that all guidelines are followed meticulously; each new fever resets the quarantine clock for another month. Biosecurity procedures for EHM caused by neuropathogenic and nonneuropathogenic strains should be the same.[11] Additional guidelines are available for measures designed to prevent or reduce the likelihood of outbreaks and to lessen the impact of those outbreaks that do occur.[12]

Equine Protozoal Myeloencephalitis

Robert J. MacKay

Equine protozoal myeloencephalitis (EPM) is the most common infectious neurologic disease of horses in the United States, and *Sarcocystis neurona* is the usual cause, with sporadic cases caused by *Neospora hughesi*.[1,2] Species of *Sarcocystis* have an obligatory definitive host such as a dog, cat, opossum, skunk, or raccoon, which passes the oocysts (sporocysts) to the herbivore via fecal contamination.[3] Sexual reproduction occurs in the lining of the small intestine of the definitive host, the opossum (*Didelphis virginiana* in North America and *Didelphis albiventris* in South America), while asexual proliferation occurs in the intermediate host and culminates in the formation of sarcocysts in muscle. The nine-banded armadillo, striped skunk, raccoon, and domestic cat are natural intermediate hosts that cover the geographic range in which EPM occurs.[4-7] The hosts for *N. hughesi* are not known. The horse usually functions as an aberrant dead-end intermediate host. With the exception of a single foal with *S. neurona* muscle sarcocysts,[8] only precystic stages (i.e., merozoites and schizonts) have been found in the CNS of horses with EPM.

Pathogenesis

The pathophysiology and immunology of *S. neurona* infection in horses is not completely understood. Horses ingest the infective sporocyst stage of *S. neurona* in food and water that has been contaminated by opossum feces. The mechanism of entry into the CNS of the horse is likely related to leukocyte-associated parasitemia. Once in the CNS, *S. neurona* can localize and replicate in any region, from cerebrum to spinal cord. Peripheral nerves and nerve roots are not infected. The location and extent of the lesions determine the character and severity of clinical signs. Histologically, protozoa are usually associated with mixed inflammatory cellular responses and neuronal destruction. Schizonts (multicellular proliferative bodies) or free merozoites are seen commonly in the cytoplasm of neurons or mononuclear phagocytes and in capillary endothelial cells or rarely in other inflammatory or CNS cells.[3]

Both cellular and humoral immunity are thought to be important for control of infection by *S. neurona*. Because of the intracellular location of the parasite, competent cell-mediated adaptive immune responses are considered essential for its elimination.

Epidemiology

Equine protozoal myeloencephalitis is a disease of horses that have spent time in North or South America. There are isolated reports of horses diagnosed with EPM elsewhere that have no travel history to the Americas, and the nature of infection in these cases remains unclear. [9,10] Horses of all breeds can be affected by EPM and there is no gender bias. There is only one report of EPM in a pony and one describing *N. hughesi* in a mule, suggesting that these equids may be less susceptible to EPM than are horses. Ages at onset have ranged from 2 months to at least 30 years, although it is rare in horses younger than 2 years old. One study identified an increased risk of EPM in horses aged 1 to 4 years and older than 14 years.[11] EPM typically occurs as individual cases, but clusters of cases have occasionally been reported.[12]

The reported prevalence of *S. neurona* infection as evidenced by *S. neurona* antibodies in horses in various locations throughout the U.S. varies from 0% to 89.2%.[13,14] Generally high rates are found in areas with dense human populations, abundant water sources, and moderate rainfalls; low seropositivity rates are found in arid, sparsely populated regions. The geographic variation in prevalence is accounted for by the still-expanding range of the definitive host, the opossum. Despite the high rate of infection by *S. neurona,* there is probably only about a 1% lifetime risk of a horse developing EPM in these areas (estimated from the mean 0.14% one-year incidence reported in the *National Animal Health Monitoring System 1996* survey[11]).

The factors that influence the relationship between infection with *S. neurona* and development of EPM are not well understood. Although *S. neurona* lacks the genetic diversity found among *Toxoplasma gondii* isolates, it may still be capable of *T. gondii*–like clonal expansion of virulent strains,[15] although conclusive evidence for this has not yet been found. Results of risk factor analysis for EPM vary by study, but factors likely to increase exposure to opossums, their environment, and their feces are consistently identified.[11,16-18] Other risk factors include previous diagnosis of EPM on the premises; primary use of the horse, with showhorses and racehorses at increased risk; recent transport; and recent adverse health events including medical problems, parturition, and management changes. Collectively, these risk factors indicate that physiologic stress may play an important role in the onset of EPM.

Diagnosis

Antemortem diagnosis of EPM remains challenging. Criteria for diagnosis include finding clinical signs consistent with EPM, ruling out other differential diagnoses, and finding *S. neurona*–specific antibodies through immunodiagnostic testing. Proof of diagnosis postmortem is demonstration of protozoa in CNS lesions, often done with immunohistochemical staining or polymerase chain reaction. Even when the organism is not seen, the diagnosis is frequently made presumptively if characteristic inflammatory changes are found.[19,20]

VetBooks.ir

Two types of immunodiagnostic tests are available for EPM: those that rely on threshold values of serum anti–*S. neurona* antibody (indirect fluorescent antibody test, ELISAs for antibody against various *S. neurona* surface antigens) and those that purport to detect specific antibody made within the CNS (Western blot, serum-to-CSF antibody ratios, *C* values). Blood samples for serum tests are easily obtained, but the diagnostic assays are based on the yet-to-be validated principle that horses with EPM have distinctly higher serum antibody concentrations than do exposed/subclinically infected horses.[21] The rationale for tests of the second type, each of which requires a clean CSF sample, is that identification of CNS-origin antibody is the only way to discriminate EPM cases from exposed horses. The most popular test of each type—namely, serum IFAT and snSAG2,4/3 ratio, both have reported good (i.e., >80%) sensitivity and specificity for diagnosis of EPM among horses with solid postmortem diagnoses.[22,23] One drawback of the IFAT is that it is unable to differentiate between antibodies against *S. neurona* and *S. fayeri* (a nonpathogenic species),[24] but an advantage is that submitted samples are tested for both *S. neurona* and *N. hughesi* antibodies. A recent study used samples from necropsy-confirmed EPM positive and negative cases to specifically compare results of serum IFAT and snSAG2,4/3 serum-to-CSF ratio tests. Sensitivity, specificity, and accuracy values were 59%, 71%, and 68% for the serum IFAT and 88%, 100%, and 97% for the snSAG2,4/3 ratio test.[20] Further large comparative clinical studies are necessary to determine clearly the relative utilities of these two approaches, although the lack of a gold standard for diagnosis in horses that are not subjected to necropsy makes this challenging. What is clear, on the basis of both flawed concepts and unsupportive clinical data, is that neither CSF Western blot nor serum SAG-1 ELISA is a robust diagnostic test for EPM.[25-27] In contrast to the situation with Western blots, snSAG ratio test results are relatively robust in the presence of a small amount of contaminating blood; however, false positives do occur in cases of moderate or severe blood-brain barrier (BBB) injury. For samples from horses with BBB injury (as detected by high CSF albumin concentrations or high albumin quotient values[28]), additional total IgG testing is performed on the serum/CSF sample and a C value is calculated.[29] CNS antibody production is indicated by C values greater than 1.

At the time it was last investigated more than a decade ago, PCR testing of CSF had high specificity but low sensitivity for the diagnosis of EPM.[30] False negatives are common because free parasitic DNA is destroyed by enzymes in the CSF and merozoites rarely enter the CSF. Testing by PCR of tissue samples is useful for postmortem diagnosis.

Ancillary procedures including survey cervical radiographs, lameness examination, and serology may be required to rule out competing differential diagnoses. In horses with signs of brain involvement, suggestive lesions may be seen with advanced imaging techniques.[31] Consistent abnormalities are not found in complete and differential WBC counts and serum chemistry panels in horses with EPM. Abnormal CSF values occur in some horses with EPM. It has been reported that up to 35% of horses at a referral hospital have increased protein concentration (>65 mg/dL) or nucleated cell count (>6 cells/μL).[32] In the author's experience, in horses with mild clinical signs of EPM (i.e., those that typically are encountered in practice), a low percentage have any abnormality on routine CSF analysis. Creatine kinase (CK) activity may be high in CSF, reflecting diffusion of the BB isoenzyme from damaged CNS gray matter.[33] Unfortunately, inadvertent inclusion of a small plug of epidural fat or dura during CSF collection can dramatically elevate CK activity, thus reducing the specificity of the test.

Clinical Signs Protozoa may infect any part of the CNS, making almost any neurologic sign possible. The disease usually begins insidiously but also may present acutely and be severe at onset. Signs of spinal cord involvement are seen much more commonly than signs of brain disease. Horses with EPM involving the spinal cord have asymmetric (usual) or symmetric truncal and limb weakness and ataxia. If all lesions are behind the second thoracic spinal cord segment (T2), only the pelvic limbs are affected. If a lesion (or lesions) is located in front of T3, all four limbs may be affected. In the rare instance when the spinal cord behind the second sacral spinal cord segment (S2) is involved, there are signs of cauda equina syndrome, which may include degrees of rectal, anal, bladder and penile paralysis, and reduced sensation of the skin of the tail and perineum. When gray matter of the ventral horn of the spinal cord is damaged for more than 1 to 2 weeks, there may be obvious focal muscle atrophy and electromyographic changes in denervated muscle. Common locations for atrophy in horses with EPM are the gluteal, biceps femoris, and infraspinatus/supraspinatus and serratus ventralis muscles. Lesions in the spinal cord may also result in demarcated areas of spontaneous sweating or loss of reflexes and cutaneous sensation.

FIG. 35-14 Obtundation, right-sided head tilt neck turn and body lean in a 3-year-old Thoroughbred colt with peracute-onset equine protozoal myeloencephalitis.

Neurologic signs noticed at the walk or during neurologic examination include any to all of the following: asymmetric stride length, toe dragging, circumduction of pelvic limbs, and hypometria (also described as floating or marching) of thoracic limbs. Other signs are noted only when the horse is ridden. There may be difficulty maintaining a specific lead, cross-cantering or cross-galloping, and difficulty negotiating turns. Some signs that are usually attributed to primary musculoskeletal disease, such as back soreness or upward fixation of the patella(s), can be caused by weak or asymmetric use of muscle groups in horses with EPM that are in training.

The most common manifestation of brain disease in horses with EPM is a brainstem syndrome with signs of obtundation and asymmetric vestibular (VIII) nerve dysfunction (Fig. 35-14). There may also be facial paralysis (VII); dysphagia (X); tongue paralysis (XII); laryngeal paralysis (X); strabismus (III, IV, IV); failure of globe retraction (VI); and deviation of the mandible (Vm). With involvement of the rostral brainstem or cerebrum, EPM may manifest as seizures, visual deficit/abnormal menace response, reduced perception of touch on the opposite side of the face, or behavioral abnormality.

Without treatment, EPM usually progresses. Progression to recumbency occurs over hours to years and may occur steadily or in a stop-start manner.

Treatment Since 2000, the folate inhibitor combination sulfadiazine/pyrimethamine (SDZ/PYR), the triazine coccidiostats

VetBooks.ir

ponazuril (PNZ) and diclazuril (DCZ), and the nitrothiazole nitazoxanide (NTZ) have all been licensed by the U.S. Food and Drug Administration (FDA) for the treatment of EPM and commercial products have been launched.[34] NTZ was withdrawn in 2009. Multicenter studies of SDZ/PYR, PNZ, NTZ, and DCZ reported improvement rates of 57.1% to 61.5%.[34]

Many dosage permutations and combinations of these products and the use of pharmacologically similar products occur in clinical practice, although efficacies have not been investigated. A loading dose of 15 mg/kg PNZ (three times the normal dose) achieves steady-state concentrations of PNZ several days earlier than is the case with conventional dosing.[35] A sodium salt formulation of diclazuril has been shown to have good oral bioavailability and may have potential as a feed additive.[36] Some veterinarians use a compounded form of diclazuril IV, although there are no published data for its safety or efficacy. There is experimental support for the enhanced antiprotozoal effect of combinations of PYR with either DCZ or PNZ in treatment of other coccidian infections,[37] so the author routinely combines PNZ and SDZ/PYR when treating horses for clients with the necessary financial resources. Such treatments constitute unapproved and/or extra-label use, albeit of FDA-approved products.

Another drug used commonly as an anticoccidial in calves, decoquinate, was evaluated in horses with presumptive EPM, at dosage of 0.5 mg/kg daily for 10 days, in combination with the immunomodulator levamisole, 1 mg/kg daily.[38] Success rates of 93.6% and 89.3% were reported on the basis of improved neurologic gait score at the end of treatment and reversion of serum snSAG1,5,6 titers, respectively. Decoquinate was also shown to have potent inhibitory and cidal activity in vitro against two different isolates of *S. neurona*.[39] If this drug combination continues to perform well in wider use, it will obviously become an important treatment option.

Horses may relapse soon after the initial course of treatment is discontinued, or up to several years after improvement or apparent resolution of signs. Although there is no consensus on how to treat relapses, the authors prefer to change or add antiprotozoal drugs. If a horse relapses twice, the author usually recommends indefinite intermittent therapy with SDZ/PYR, 2 days/week at double the standard dose. A similar rationale can be used to treat horses only around stressful events that may predispose to relapses.

Of the available drugs, only PYR has significant adverse side effects. Toxicity reflects inhibition of mammalian dihydrofolate reductase by PYR, inducing folate deficiency. Signs include reproductive and neonatal disorders, glossitis, and bone marrow suppression including anemia, leukopenia, neutropenia, and thrombocytopenia in decreasing frequency.[40,41] Horses treated with SDZ/PYR should be kept on good-quality green forage (e.g., alfalfa hay or pasture), which is likely to be rich in folate. There is no advantage to supplementation with folic acid during treatment, and some evidence from other species indicates that this practice could increase the possibility of toxicity.[41] Most cases of bone marrow suppression resolve if treatment is suspended for 1 to 2 weeks. Folic acid (100 mg daily) is appropriate for treatment of folate deficiency once PYR is discontinued. If signs are severe, treatment with folinic acid (100 mg PO daily for 1 month, then every other day for 1 month) is indicated.

In mild acute cases of EPM (grade 1), additional therapy is unnecessary. In horses with moderate or severe disease, antiinflammatory and antioxidant treatment is usually provided for the first 1 to 2 weeks. If the horse is grade 3 or worse, a corticosteroid may be added. Vitamin E is often given empirically throughout the period of antiprotozoal treatment for additional antioxidant effect. Oral administration of vitamin E has been shown to result in increased concentrations of alpha-tocopherol in serum and CSF. As a relatively crude way to address putative immunodeficiency and "boost" cellular immunity, immune stimulants are sometimes given to horses with EPM.

Prognosis On the basis of drug efficacy studies and clinical experience, it is reasonable to expect that about 60% of moderately or severely affected horses will improve at least one grade after treatment. Only 10% to 20% of such horses will completely recover, and 10% to 20% of successfully treated horses will suffer at least one relapse. The outlook for mildly affected horses (grade 1) is considerably better, particularly if treatment is begun promptly. Although there are no published data for the latter, more common class of treated horse, at least 80% of such cases can be expected to improve and at least 50% should recover completely, with low possibility of recurrence.

Prevention An inactivated vaccine was marketed under conditional approval by the U.S. Department of Agriculture. The conditional license lapsed in March 2008, and the vaccine is no longer available. There was no published evidence for or against preventative efficacy for this product.

Prevention of EPM by antiprotozoal agents is probably effective but probably cost prohibitive. Prevention of infection by *S. neurona* may be possible by daily administration of a drug such as DCZ or PNZ.[42] The disadvantage of this approach is that normal immune responses to the organism may be prevented. An alternative approach is metaphylaxis, wherein intermittent doses of drug are given to allow an initial round of protozoal proliferation and normal immune responses to take place but prevent invasion of the CNS. Ponazuril given at 20 mg/kg every 7 days but not every 14 days significantly reduced *S. neurona* antibody in the CSF of *S. neurona*–challenged horses, suggesting the potential utility of such an approach.[43]

Common-sense measures can be instituted to prevent contamination of feed with *S. neurona* sporocysts. Opossums can be trapped and removed or kept away by free-ranging dogs. Spilled grain, fallen fruit, and animal or bird feed should be removed, and horse food sources should be monitored and secured. The utility of controlling intermediate hosts in an effort to reduce environmental sporocyst load is doubtful; however, if there are heavy populations of host animals on a problem premise, then such animals should be trapped and removed. Products useful for cleaning of areas potentially contaminated with sporocysts have been described.[44]

Cervical Vertebral Stenotic Myelopathy

Robert J. MacKay

The term *wobbler* (also wobbler syndrome) describes horses with ataxia caused by any of a group of developmental anomalies and degenerative conditions involving the cervical vertebrae.[1] Several more or less descriptive abbreviations are used in wobbler terminology. The most important of these are CVM (cervical vertebral malformation and malarticulation), CSM (cervical stenotic myelopathy), and the inelegant but descriptive CVSM (cervical vertebral stenotic myelopathy). CVSM is the most common noninfectious neurologic disease of horses. The prevalence of CVSM among 1289 Thoroughbred horses born on four breeding operations was 1.3%.[2]

Two overlapping CVSM syndromes are recognized, differing greatly in developmental histories. *Type I:* There is focal or multifocal stenosis of the vertebral canal, principally between C1 and C6, that is worse on flexion (*dynamic* stenosis). Affected horses are typically younger than 2 years of age. *Type II:* There is bony and soft tissue impingement into the vertebral canal resulting from remodeling of the articular facets of the caudal cervical vertebrae (usually C5 to T1) and stenosis of the cranial vertebral orifice. This impingement is present in all positions of the neck (*static* stenosis) but may also have a dynamic component with worsening during hyperextension. Horses with static stenosis are usually young to middle aged at the onset of wobbler signs.

Both syndromes likely involve some combination of aberrations in cartilage and bone development and external trauma that may precede clinical ataxia by many months (perhaps even in utero in the case of type I CVSM[1]).

Pathogenesis Type 1 CVSM is another manifestation of the group of disorders of endochondral ossification (i.e., osteochondroses) that occur in young, growing horses and include physitis,

VetBooks.ir

contracted tendons, osteochondritis dissecans (OCD), subchondral bone cysts, and malformation of the cuboidal bones of the carpus and tarsus.[3] Study of wobbler matings has indicated a propensity for rapid growth and superior performance among offspring but no clear evidence that CVSM was genetically predetermined.[4] Interestingly, other developmental orthopedic diseases were overrepresented. There is clearly a genetic predisposition to development of CVSM, but because it is probably genetically and environmentally multifactorial, pure genetic influences have been difficult to discern. Because rapid growth and large size appear to be risk factors for foal osteochondrosis,[5] it is not surprising that studies have tentatively implicated high protein and caloric intake in the development of CVSM.[1] Marginally low levels of trace minerals such as copper may come into play during rapid growth.

As a result of presumed genetic, physical, and dietary factors, there is early osteochondrosis of the articular facets and metaphyseal growth plates of foals. Genetic predisposition, rapid growth, maternal nutrition, calcium/phosphorus imbalance, low dietary copper, and high dietary zinc all have been implicated as developmental orthopedic diseases in foals, but their roles as risk factors for CVSM are not clear.[6-9] Osteochondrosis of the vertebral physes of rapidly growing foals and weanlings results in multiple vertebral abnormalities including flaring and enlargement of the caudal metaphyses and epiphyses of the vertebral bodies (equivalent to physitis of the limbs) and disparity of longitudinal growth of the vertebral bodies and dorsal laminae. These deformities cause focal stenosis (narrowing) of the vertebral canal and susceptibility to dynamic compression, respectively. In severe form, the latter abnormality forces pairs of vertebrae into a permanently flexed, malarticulated, kyphotic position in which severe vertebral canal stenosis (both static and dynamic) is likely. Flaring of the caudal metaphyseal-epiphyseal unit contributes to the narrow caudal orifice of the canal within an affected vertebra that is commonly seen in horses with CVSM.

Osteochondrosis of the articular facets may result in joint instability and later osteoarthritis and remodeling of the dorsal intervertebral joints. Associated with degenerative joint disease of the dorsal intervertebral joints are gross enlargements due to osteophyte development. Affected facet pedicles may be relatively brittle and susceptible to trauma. Fractured facets are found quite frequently in diseased intervertebral joints at postmortem, although the fractures often cannot be seen in lateral radiographs. Pedicle fractures caused by trauma likely contribute to the massive asymmetric remodeling and enlargement seen in some of these joints. The canals within affected vertebrae may deform to a funnel shape with a small stenotic cranial orifice. There may also be hypertrophy and fibrosis of the synovial membrane and joint capsules of the dorsal intervertebral joints, and fibrovascular proliferation of the ligamentum flavum. These soft tissue structures or fluid-filled cysts associated with them may cause static stenosis and compression of the spinal cord and spinal nerves. Synovial and epidural cysts are prone to cause dramatic waxing and waning of clinical signs of spinal cord compression.[1]

Necropsy Findings

Horses with CVSM have one or more focal compression–type lesions in the cervical spinal cord.[10] Grossly, such lesions may appear as flattening and palpable softening of the cord. Histologically, they are characterized by swollen and disrupted axons and phagocytosis of myelin in white matter. Mild hemorrhages are sometimes seen in acute lesions. In the white matter of chronically affected animals, there is continued degeneration of neuronal fibers, proliferation of capillaries with prominent fibrous coats, and astrofibrosis. More severely affected horses also have neuronal necrosis, loss of cell bodies, and sometimes astrofibrosis in the gray matter. Massive focal lesions also occur with cavitating necrosis of white matter, particularly in lateral funiculi and occasionally in gray matter. Markedly asymmetric lesions are found in horses with prominently asymmetric clinical signs. Cranial to the focal lesions, there is secondary degeneration of neuronal fibers (axons and myelin) in ascending (proprioceptive) tracts for variable distances, depending on the extent and age of the focal lesion. Caudal to the lesion, there is secondary fiber degeneration in descending (motor) tracts. This fiber degeneration is the result of neuronal fibers being severed from their cell bodies by the focal lesion. It is most prominent in dorsolateral funiculi cranial to the lesion and deep lateral and ventromedial funiculi caudal to the lesion.

Clinical Signs

Most animals with type I CVSM are 6 to 18 months old, whereas those developing type II CVSM are typically 18 months to 5 years, although there are many exceptions to these ranges and both conditions can occur in a single animal. In four large breeding farms, the onset of type I CVSM occurred in horses aged 202 to 986 days (average 434 days), whereas type II CVSM cases began at 1085 to 1299 days (average 1188 days).[2] A recent study of 811 horses in the United States indicated that horses of the Thoroughbred, warmblood, and Tennessee Walking Horse breeds were significantly more likely to have CVSM than were Quarter Horses; Standardbreds and Arabians were significantly less likely to have CVSM.[11] Large warmblood breeds are notably affected by type II CVSM.[12] Males are over-represented among horses with CVSM.[12,13] Affected horses are often well grown, and some have a history or signs of other developmental orthopedic diseases such as osteochondritis dissecans or physitis.

Clinical signs of ataxia and paresis typically begin insidiously but may present suddenly. In the latter case, there is often a history of some minor fall or training incident that confuses the diagnosis (was the fall a precipitating cause or a result of the disease?). After they have been recognized, signs typically progressively worsen for a period of months and then may stabilize or even regress. Spontaneous complete recovery is rare, although it does occur[1]; waxing and waning signs are frequent. In general, horses with CVSM appear physically normal; however, enlarged intervertebral joints in the caudal cervical spine and severe flexion angulations, particularly at C2-C3 and C3-C4, are occasionally externally visible and palpable. Pain in response to pressure over the transverse processes, or reluctance of the horse to flex its neck laterally are common findings in horses with type II CVSM. Rarely, impingement on caudal cervical spinal sensory nerves by enlarged intervertebral joints in type II horses is sufficient to cause signs of thoracic limb lameness.

The principal neurologic signs are ataxia, weakness, and spasticity of the limbs. These signs reflect involvement of axons of upper motor neurons and general proprioceptive tracts in the white matter of the spinal cord underlying the site(s) of compression. Because of the more superficial location of general proprioceptive tracts from the pelvic limbs, the pelvic limbs are generally more affected than the thoracic limbs.[1] Dynamic stenosis is usually associated with symmetric signs, whereas static stenosis may cause asymmetric signs. Occasionally, severe arthrosis of the joints between C6-7 or C7-T1 causes signs more severe in the thoracic than in the pelvic limbs. The first sign noticed may be stumbling or clumsiness when the horse is moving into or out of a box stall. During exercise gallops, the rider may comment on a feeling of looseness or "losing the back end" around turns. Reluctance to change leads, cross-cantering or cross-galloping, or even falls after stumbling are other early signs in horses being ridden. With progression, affected horses may have an obviously stiff uncoordinated gait at the walk; the prominent truncal sway; or "wobble" explains the common name for horses with CVSM. Because of pelvic limb extensor weakness, some wobblers catch their patellas or have persistent upward patella fixation.

In addition to the signs already mentioned, careful neurologic examination usually discloses some to all of the following: (1) Abnormal pelvic movements during walking best observed from behind including excessive swiveling of an imaginary line on the median plane from between the tuber sacrale to the tailhead, excessive rotation of the pelvis around its long axis (seen as exaggerated amplitude of the rise and fall of the tuber coxae), and side-to-side truncal sway; (2) decreased resistance to lateral pressure exerted by pulling the tail while the horse is walking; (3) apparent stiffness of the limbs during the swing phase of the stride in the thoracic and/or pelvic limbs. This may be associated with scuffing of the toes. When the horse's head is

VetBooks.ir

raised during walking, especially down a gentle slope, the stiff hypometric gait in the thoracic limbs may be exaggerated and is sometimes described colloquially as a "marching," "floating," or "tin-soldier" gait; (4) circumduction of each outside pelvic limb when the horse is walked in small circles; (5) interference between the thoracic limbs and pivoting around the pelvic limbs when the horse is moved in tight circles; and (6) absence of the thoracolaryngeal ("slap") reflex. In horses with markedly asymmetric compression (usually horses with asymmetric caudal intervertebral arthritis), there also may be marked asymmetry of stride length between the pelvic limbs.

Diagnosis

Radiography of the cervical spine is the most important diagnostic tool. A presumptive diagnosis of CVSM can usually be obtained from plain laterolateral radiographs of the cervical spine by finding focal narrowing (stenosis) of the vertebral canal. The diagnosis is buttressed by additional demonstration of malformation, osteochondrosis dissecans, or degenerative joint disease of the facet joints, metaphyseal and epiphyseal flaring of the caudal aspect of vertebral bodies, relative elongation caudally of the dorsal laminae, or angulation between pairs of vertebrae.

Intravertebral sagittal ratios for vertebrae behind C2 are calculated as the ratio [minimal sagittal diameter of the vertebral canal] ÷ [maximal sagittal diameter of the cranial half of the vertebral body].[14] Both measurements are made perpendicular to the long axis of the vertebral canal. The denominator normalizes for variations in horse size and object-film distance. A value for sagittal ratio (SR) of less than 0.52 from C4 to C6 and less than 0.54 at C7 predicts spinal cord compression with 89% sensitivity and specificity for diagnosis of spinal cord compression according to the original description.[14] In practice, cutoff values of 0.50 for C3-C6 and 0.52 for C7 are typically used.[1] Even horses with static stenosis, which may have predominantly transverse compression from large joints, usually have at least one abnormal intravertebral SR.[14]

Intervertebral sagittal ratio measurements are made between pairs of vertebrae in order to capture the effect of *fixed* flexion or extension angles on the diameter of the vertebral canal.[15] For a pair of vertebrae fixed in a kyphotic angle, the primary measurement (numerator) is the shortest distance between the caudal aspect of the dorsal lamina and the craniodorsal aspect of the vertebral body of the caudal-adjacent vertebra. For a fixed lordotic intervertebral joint, the corresponding measurement is the shortest distance between the caudodorsal aspect of the vertebral body and the most cranial point on the dorsal lamina of the caudal-adjacent vertebra. The intervertebral SR is calculated by dividing this measurement by the maximal sagittal diameter of the cranial half of the vertebral body of the cranial-adjacent vertebra.[15] Normal values for means and lower bounds of the 95% confidence intervals for intravertebral and intervertebral SR from C3 to C7 have been published.[1,15] Any value below these lower bounds is highly predictive of spinal cord compression.

A semiquantitative scoring system has been developed for use in foals 3 to 7 months of age to predict the risk of developing CVSM.[16] Intravertebral and intervertebral sagittal diameters are recorded as described earlier but rendered as ratios by using vertebral body length (rather than sagittal diameter) as denominator.[16] Up to 10 points are assigned for decreased sagittal ratios and up to 5 points for each of the following signs of cervical vertebral malformation: dorsal flaring of the caudal vertebral body, caudal extension of the dorsal lamina, angulation between adjacent vertebral bodies, delayed ossification, and enlargement of articular processes. A score of 12 or higher (maximum, 35) predicts the development of CVSM. Interestingly, this study revealed a strong tendency for the diameter of the vertebral canal to be greater in female foals than it was in males.[16] A multi-component and detailed system of measurements in plain and myelographic studies has been devised by Japanese workers[17,18] This system accurately identifies foals and yearlings with CVSM but has not been widely adopted in other countries.

When plain radiographs are abnormal, contrast myelography may be used to support the diagnosis, establish the number and locations of sites involved, and the severity of lesions in each, and to define the soft tissue contribution to spinal cord compression. These factors are especially important if surgical stabilization is contemplated because a different site may be revealed by myelography than was suspected in plain films. Under general anesthesia, 30 to 50 mL iohexol (Omnipaque) or iopamidol (Isovue) radiocontrast solution are injected slowly into the atlantooccipital subarachnoid cistern after a similar volume of CSF has been removed. After injection has been completed, the head is raised for 5 minutes to encourage caudal flow of dye and then the head is lowered and radiographs are taken.

Laterolateral views of the cervical spine are taken in neutral, flexed, and extended positions. Spinal cord impingement due to dynamic compression is clearly defined in lateral views if the dorsal and ventral dye columns are completely extinguished at diametrically opposed sites in flexed views. When there is less than complete compression of the dorsal column, several different diagnostic criteria have been used, none of which is completely satisfactory.[19,20] The traditional standard of complete compression of the ventral dye column and greater than or equal to 50% compression of the dorsal column at diametrically opposed sites is sensitive but has poor specificity (i.e., there are many false positives). Other likely, more accurate alternatives are (1) comparison with reference ranges for minimal dural diameters and minimal flexed dural diameters for horses either above or below 320 kg and (2) 20% or greater reduction in dural diameter in neutral views at the site of interest (usually intervertebral) compared with the midbody dural diameter in the cranial-adjacent vertebra. Sites affected in order of frequency are C3-C4, C4-C5, and C5-C6. Multiple sites may be affected in a single horse. The typical myelographic feature of *static* stenosis is focal spinal cord compression throughout the full range of vertebral motion. Any dynamic component at these caudal sites is relieved by flexion of the spine. The C6-C7 articulation is most frequently involved, and C5-C6 and C7-T1 to a lesser extent. At these sites, absolute narrowing of the minimal dural diameter or 20% reduction in comparison with the cranial-adjacent midbody measurement are the best diagnostic criteria.[1] In those cases in which the plane of compression is transverse rather than dorsoventral, the dural diameter is usually abnormal; however, less objective criteria may have to be considered when measurements are normal. These include widening of the spinal cord diameter and fading of the dye columns over the area of lateral compression. Unfortunately, the diagnostic accuracy of plain radiographic or myelographic diagnoses of CVSM has been unimpressive when compared against the gold standard of postmortem spinal cord histopathology.[13]

Advanced imaging by CT[21] or MRI[22] techniques have been described but in mature horses are limited by gantry dimensions to vertebrae in front of C4, so currently these techniques have little application to the workup and diagnosis of horses with CVSM.

A technique has been described for endoscopic evaluation of the epidural and subarachnoid spaces of the cervical spinal cord, and this procedure was applied to a horse with CVSM.[23,24] Although the technique may have application in selected cases, it has no place in the routine diagnosis of CVSM.

Because needle electromyography is most useful for investigation of muscles deprived of lower motor neuron activity, it has little application to the diagnosis of CVSM. The most promising electrodiagnostic testing application in this setting is transcranial magnetic stimulation.[25,26] Descending motor tracts are stimulated by current pulsation from a coil placed on the scalp. The onset latency of electromyographic responses in limb muscles is related to the integrity of spinal motor pathways. Latencies for horses with CVSM were significantly longer than those for normal horses.[27]

CSF analysis is generally normal. At most there are xanthochromia and elevated protein (70 to 130 mg/dL).

Treatment

MEDICAL. Corticosteroids and NSAIDs may provide transient improvement of the signs of CVSM but do not treat the underlying problem.

VetBooks.ir

Large degenerative intervertebral joints can be seen ultrasonographically, and corticosteroid (e.g., triamcinolone or methylprednisolone acetate) can be injected intraarticularly under ultrasound guidance, as has been described.[28] The theoretical applications for this procedure include relief from pain of arthritis and reduction in the soft tissue components of arthritic joints so as to provide at least temporary reversal of their impingement on the spinal cord and spinal nerves in the case of CVSM and thoracic limb lameness, respectively. Although descriptive support for all of these possibilities was provided in a recent observational series,[29] no fully objective evidence has been provided for reversal of the signs of CVSM, and it is inconceivable that permanent relief could be provided.

Some mildly affected horses can stabilize and even improve both radiographically and clinically if confined and placed on restricted but nutritionally complete feed.[1] There are reports of complete recoveries with this conservative approach.[30] Horses younger than a year of age (and preferably younger than 6 months of age) can be tried on a restrictive "paced-growth" diet in order to retard growth rate and prevent CVSM in clinically normal foals with radiographic evidence of stenosis of the vertebral canal or to treat foals with mild clinical signs of CVSM.[31] This diet reduces energy intake to 65% to 75% of National Research Council recommendations and increases trace minerals. The essential elements are as follows: (1) immediately wean if still suckling; (2) feed free-choice grass hay (e.g., coastal Bermuda hay) plus 3.5 lb daily of a ration balancer that is high in micronutrients and low in calories (e.g., Buckeye's Gro 'n Win). At 1 year of age (based on birth date), the supplement is reduced over 1 week to 1 lb daily. Foals should be confined in a stall except for limited round-pen or equivalent turnout time, certainly without access to pasture. Good results are claimed for slightly affected foals, although breaking, training, and racing are set back several months and the foals look poor as yearlings.[31]

SURGICAL. Ventral interbody vertebral fusion is the principal procedure. In this surgery, pairs of vertebrae are fused in extension by implantation of a cylindrical stainless steel or titanium basket (Cloward Bagby basket) filled with autogenous cortical bone fragments.[32,33] Osseous union of the vertebral bodies and stabilization of the dorsal intervertebral joints occurs after this surgery, although nonunion is an occasional postoperative problem. A recent modification uses a threaded titanium implant that screws into a prepared circular, threaded kerf around an isthmus of preserved bone. By leaving the isthmus and its blood supply intact, it is expected that complete bony fusion occurs more quickly. A plate may be secured over the implant, but this does not prevent retrograde migration of the implant.

The surgery provides immediate relief from dynamic stenosis and may improve static stenosis over months by causing atrophy of arthritic intervertebral joints. In the latter case intraarticular administration of corticosteroid may hasten atrophy of the enlarged joint. The surgery results in improvement in neurologic status in 44% to 90% of horses with dynamic compression, and 12% to 62% of treated horses return to athletic function.[32-35] Overall, the success rate offered by most surgeons is about 60% with normal myelographic columns expected by 2 months after surgery and complete osseous union by 1 year postoperatively. On average an improvement of 1 to 2 grades is expected.[34] Results of surgery for dynamic compression were significantly better than those for static compression in one published series.[36] Although there is a general impression that increasing time since onset of signs, higher neurologic grade, and multiple surgical sites are negative indicators for response to stabilization surgery, published results are not consistent on any of these issues.[32] Even three-site surgeries can be successful, although neck mobility is diminished.[37] The use of a locking compression plate has been described with initial promising results.[32] If the results of locking plate surgeries continue to be positive, such surgeries may become more widely available, obviating the need for the specialized equipment needed for implant surgery.[32]

Dorsal subtotal decompressive laminectomy is described[38] and provides immediate relief for static compression but technically is extremely difficult and fraught with severe postoperative complications.

Equine Degenerative Myeloencephalopathy

Robert J. MacKay

History and Epidemiology Since the original description in 1976,[1] equine degenerative myeloencephalopathy (EDM) and the related condition neuroaxonal dystrophy (NAD)[2] have been reported throughout the world in horses and ponies of many different breeds and in other equids including a donkey, Przewalski's Horses, and zebras.[3,4] The clinical signs of EDM and NAD are identical, and the associated CNS lesions are thought to be on a continuum with EDM lesions more widely distributed than are those of NAD.[3,4] For the rest of this section, both conditions will be referred to as EDM.

Clinical signs usually begin within the first year of life and, with only a few reported exceptions, have begun by 3 years of age.[5] A hereditary basis for the condition has been strongly suggested by the results of breeding studies or pedigree analyses in Morgan, Appaloosa, and Lusitano horses.[4,6,7] The mode of inheritance was suspected to be polygenic or dominant with variable expression.[4,6] A familial basis has also been suspected because of clustering of cases among the progeny of particular Standardbreds, Paso Finos, Norwegian Fjord horses, Arabians, Welsh ponies, Haflingers, and Quarter Horses.[8,9]

Overcrowding, lack of access to fresh green forage, pelleted feed, and poor-quality hay were thought to be risk factors on two affected premises.[10] In another study, significant risk factors were exposure to insecticides/repellents, exposure to wood preservatives such as creosote, and time spent on dirt lots.[5] Time spent on green pasture was a protective factor. By contrast, several clusters of cases in Oregon and California occurred in horses on pasture.[7,9] In the latter case, the pasture was growing on volcanic soil that was deficient in selenium and vitamin E.[9]

With rare exceptions,[5,11] there has been a consistent association reported between EDM and marginal or low serum/plasma vitamin E concentration. Published normal ranges for α-tocopherol vary with age, location, season, diet, and use; however, a commonly accepted scheme classifies results greater than 2 μg/mL as normal, 1.5 to 2 μg/mL as marginal, and less than 1.5 μg/mL as deficient.[10,12] Healthy horses sharing feedstuffs and environment with affected horses usually also have low vitamin E, although foals in an Appaloosa family with hereditary EDM had significantly lower plasma vitamin E than did age-matched normal pasturemates.[13] This effect was continuous from 6 weeks to 10 months of age. During the approximately 15 years after it was first recognized, EDM was one of the most prevalent causes of spinal cord disease in horses presented to teaching hospitals in the United States.[5] Although no statistics on prevalence have been published in recent years, prevalence of EDM in the United States may have declined over the past 20 years.

Cause and Pathogenesis EDM most closely resembles vitamin E deficiency of humans and other animals.[4,9,12] The neuroprotective effects of vitamin E relate to inhibition of oxidation of CNS membrane lipids and facilitation of axonal transport of macromolecules.[12] Although familial isolated vitamin E deficiency of humans is caused by mutations in the α-tocopherol transfer protein (α-TTP) gene, expression of α-TTP mRNA was similar between one unaffected horse and two horses with EDM from a group of related Quarter Horse weanlings and yearlings.[9] Low serum vitamin E in horses with EDM is not explained by impaired intestinal absorption: oral vitamin E tolerance tests were normal in affected horses.[13] It is reasonable to speculate that a defect in some component of vitamin E metabolism such as a lipoprotein carrier, hepatic transfer protein, or vitamin E receptor site may be involved in the pathogenesis of EDM.[12,13]

VetBooks.ir

Clinical Signs EDM is an acute to occasionally insidious-onset symmetric ataxia and paresis of the trunk and limbs. The onset of clinical signs typically occurs between 1 and 12 months of age but has been seen in neonates and mature horses.[3,4] Posture and gait are wide based. There is notable hypometria (spasticity) in affected limbs. Signs are typically considerably more severe in the pelvic limbs, and the thoracic limbs may be clinically normal. In two recent reports, it was noted that limb weakness was only seen in horses with moderate or severe ataxia and was not recognized in many horses that were mildly ataxic.[4,9] Some horses with EDM adopt a two-beat lateral ("pacing") gait at walking speed. Long spinal reflexes such as the cervicofacial, laryngeal adductor (slap), and cutaneous trunci may be reduced or absent, especially in long-standing cases. Neurogenic muscle atrophy is not seen in horses with EDM, and recently reported cases occurred in horses with body condition scores of 5 to 6 out of 9.[4,9] Signs of brain dysfunction were not reported until recently. Among a group of Quarter Horses with EDM (NAD), 77/88 were described as dull or obtunded and minimally responsive to light flashes, sudden movement, or loud noises.[9] An electroencephalogram performed on one affected horse revealed dominant states of drowsiness to slow-wave sleep. Reduced or absent menace responses were noted in 33/88 Quarter Horses and 4/6 Lusitanos with EDM.[4,9] Vision, pupillary light reflexes, ophthalmologic examinations, and electroretinograms were normal.

Signs may not worsen after initial onset; others progress for days to months before stabilizing. Only rarely does the condition progress to recumbency.

Laboratory Findings There is no antemortem diagnostic test for EDM. Plasma/serum vitamin E concentrations of EDM horses and pasturemates are often marginal or low. Because vitamin E concentrations within individual horses vary considerably over time (especially if they are low), it is recommended that three blood samples be taken over the course of 24 hours.[12,13] Samples must not be visibly hemolyzed and should be stored so that the blood is not in contact with the rubber stopper. Plasma CK and AST activities may be slightly to moderately high because of increased recumbency.[7]

Diagnosis Diagnosis antemortem is presumptive only and is made primarily by suggestive signalment and clinical signs with exclusion of competing diagnoses. EDM should be suspected in horses with symmetric limb ataxia that began within the first year of life and for which results of standard neurologic workups (cervical vertebral radiographs, CSF analysis, immunoassay for *S. neurona* antibody) have not implicated another diagnosis. Low or marginal serum/plasma vitamin E concentration (≤2 μg/mL) is supportive of the diagnosis.

Necropsy Findings There are no abnormal gross necropsy findings. Histologic changes develop in the spinal cord and brainstem.[4,7,9,11] In horses with NAD there are lesions in the lateral and medical cuneate, gracilis, and thoracic nuclei characterized by spheroid formation with vacuolation, loss of somata, astrogliosis, and lipofuscin pigment accumulation. Additionally, in horses with EDM, axonal necrosis and demyelination involve the dorsal and ventral spinocerebellar tracts and ventromedial funiculi of the cervicothoracic spinal cord. No histologic lesions were found to explain observations of dull mentation[14] and abnormal menace responses[4,9] in recently reported case series.

Treatment and Prevention It is unlikely that EDM can be cured even if treated early. Slight to no improvement was seen in affected horses supplemented with 2000 to 8000 IU vitamin E daily.[7,10] The type of vitamin E and the method of supplementation have important effects on its bioavailability. Natural vitamin E (RRR-α-tocopherol) is up to twofold more active than synthetic vitamin E (d,l-α-tocopherol or all-rac-α-tocopherol). Absorption requires fat, so bioavailability of vitamin E is negligible or low unless given with feed or vegetable oil.

Consistent with the notion that EDM is associated with some interaction between metabolic defect and vitamin E deficiency, vitamin E supplementation appears to be at least partially effective prophylaxis and is recommended in circumstances in which there are familial predisposition, processed feed, lack of access to pasture, and exposure to insecticides or wood preservatives. In one study, the incidence of EDM was reduced from 36% over 3 years to 9% in the following year by supplementation of foals with 1500 IU vitamin E daily.[10] Similar results were seen in two other outbreaks.[9,10] Obviously, sensible genetic, nutritional, and other management practices alone could greatly reduce or eliminate the risk of EDM.

Spinal Cord Trauma

Robert J. MacKay • Lisle W. George

Vertebral trauma is a relatively common cause of spinal cord dysfunction in both ruminants and horses. The spinal cord is normally protected by a complex of bones and ligaments that can be conceptualized in biomechanical terms as two columns: dorsal and ventral.[1] The ventral column consists of the vertebral bodies, intervertebral disks, and dorsal and ventral longitudinal ligaments, whereas the dorsal column consists of alternating bony (arches, dorsal articular processes, and dorsal spinous processes) and ligamentous (supraspinous ligament, interspinous ligaments, ligamenta flava, and joint capsules) complexes. According to biomechanical models that have been used for assessment of spinal trauma in humans and small animals, acute spinal instability occurs when there is disruption of *both* of these columns by external mechanical forces. The corollary is that a single intact column provides stability. This two-column system has not been validated for large animals. Fractures of vertebral transverse processes and dorsal and ventral spinous processes and partial fractures of vertebral bodies or arches (i.e., stress fractures) do not cause spinal instability or neurologic signs.[2]

Most, but not all, traumatic spinal cord injuries are accompanied by vertebral fracture, subluxation, or dislocation.[3] Conversely, many spinal injuries are associated with pain, reduced mobility, and abnormal neck position but do not cause acute neurologic signs. In large animals, cervical spinal cord trauma is usually caused by hyperextension or hyperflexion of the spine in the sagittal plane with superimposed vectors of compression, distraction, rotation, and/or shear. With vertebral hyperextension, compressive force is applied to the dorsal column and distractive force to the ventral column, whereas the reciprocal forces apply to hyperflexion injuries. In all cases, the likelihood of associated spinal cord compression is higher in animals with abnormally narrow vertebral canals. Disk prolapse and fibrocartilaginous embolization of the spinal cord are rare in large animals, and when they occur are usually associated with degenerative changes rather than with acute trauma, as may occur in dogs.[4-6] Young animals are subject to fractures involving epiphyseal or growth plates (i.e., Salter-Harris fractures). Vertebral infections may be seeded hematogenously along these cartilaginous plates or by direct traumatic implantation, and osteomyelitis may progress to the point of pathologic vertebral fracture. Poorly balanced nutrition or undernutrition decreases bone density and increases susceptibility to vertebral fractures.

Horses

In racehorses, cranial or vertebral fractures have accounted for 2.5% to 3% of deaths at flat races and 16% to 23% of deaths at chase and hurdle starts.[7] In a 3-year study of fatal fractures/dislocations in the spine of 125 horses at racing events in Britain, 23% involved the cervical vertebrae, whereas the remainder involved the thoracolumbar vertebrae.[8] Of 60 horses with vertebral trauma that were necropsied in Australia, 33 involved cervical, 10 thoracic, 10 lumbar, and 2 sacral vertebrae.[9] In general, cervical vertebrae are more prone to fractures during accidents at jumping events (e.g., cross-country, showjumping, foxhunting, steeplechasing, and hurdling). The occipitoatlantoaxial region is most often involved in the following

VetBooks.ir

situations: (1) when there is broad forehead impact as in collisions with the ground, other horses, or fixed objects; (2) when a horse rears and flips over backward; or (3) when major traction forces are applied to the head as occurs in tied horses jerking backward on a halter. The atlantal ring or body of the axis may be fractured, the dens may fracture transversely anywhere along its length (including at physes in young horses), and/or the dens may subluxate or dislocate from its usual position in the fovea dentis of the atlas. Fracture of a single articular process is the most common fracture from C3 to C7. In young horses (especially those younger than 2 years), a characteristic and spectacular hyperextension fracture results in severe extension angulation of the intervertebral joint.[10,11] On the more cranial of the affected vertebrae, the dorsal lamina and caudal articular processes are fractured and lifted dorsally. It is thought that this "deroofing" lesion provides natural decompression of the spinal cord while the surprisingly sturdy dorsal half of the intervertebral disk provides residual stability of the ventral column of the cervical spine.

In the thoracolumbar spine, T1 to T3, T10 to TI6, and T18 to L6 appear to be relatively susceptible. Foals and young horses at pasture are prone to collide with fixed objects or other horses, get kicked by adult horses, or pitch forward headfirst into the ground, all while running at high speed. Such accidents often occur at night. Typical hyperflexion and hyperextension injuries of the cervical spine result from these falls, and cranial thoracic and midback fractures result from striking solid objects or being kicked. Horses may suffer contiguous or noncontiguous injuries of multiple vertebrae after high-speed impacts. Any horse that falls backward or struggles violently against a caudal barrier (e.g., in a trailer) may sustain sacrococcygeal fractures with damage to the cauda equina. There are reports that avulsion of the cauda equina can be caused by lifting or dragging a recumbent horse by its tail. It is worth noting that horses may have serious spinal injuries while alone in a stall, without observed or external evidence of an accident, so trauma should always be considered in cases of acute onset of spinal cord signs, regardless of the environment.

Ruminants

The common sites of spinal fractures in calves are C2 to C4, T10 to T13, and L3 to L6 vertebrae. Vertebral fractures (particularly compression fractures) are especially common in 3- to 6-month-old ruminants as a result of nutritional problems including vitamin D, calcium, and copper deficiency or low calcium-to-phosphorus ratio.[12] Nutrition-related fractures usually involve several animals and may also involve the ribs and long bones. Traumatic cervical vertebral fractures of cattle and small ruminants may be caused by injuries sustained in falls, roadway accidents, butting of other animals, collisions with moving farm machinery, predation, or accidents in tie-stalls, stanchions, or squeeze chutes.[12-14] Spinal injury is especially likely if the head is restrained in the chute or stanchion when the animal falls. Fractures or dislocations of the lumbar or sacrococcygeal spine frequently occur in cattle that slip in wet cemented areas.[13] Many of these fractures occur during mounting by herdmates exhibiting estral behavior. Spontaneous fractures of vertebrae weakened by congenital defects (e.g., hemivertebrae) or osteomyelitis also are common problems in calves.[15] Traumatic dislocations, subluxations, or fractures of the atlantooccipital and atlantoaxial joints of pygmy goats may occur when the horns are held during restraint. Thoracolumbar fractures, particularly with epiphyseal separation of the middle to caudal thoracic vertebrae, may occur in calves transiting the birth canal during correction of a dystocia.[16-18] These fractures are mainly related to excessive traction and rotational force.[19] Luxation of a sacroiliac joint in the dam may occur with the use of extreme force during manual extraction of a calf. Mature Holstein bulls and rams may have a fused thoracolumbar spine and stenotic vertebral canal because of ankylosing spondylitis. This condition results in progressive pelvic limb paresis and ataxia.[20] These animals are at risk for traumatic lumbar vertebral fracture, spinal cord injury, and recumbency if they are required to mount for semen collection or breeding.[21] As was described for horses, vigorous traction on the tail (e.g., when trying to assist a downer cow to stand) has the potential to cause stretching or avulsion of the cauda nerve roots and signs of cauda equina syndrome.

Pathophysiology

The primary phase of spinal cord injury is the direct effect of the mechanical events of the original trauma.[22] The primary phase is irreversible, but additional rounds of primary injury can be prevented or minimized by surgery and external stabilization of the spine. The principal mechanical forces that are involved in acute traumatic injury are concussion, compression, shear, laceration, distraction, and contusion of the spinal cord. The secondary phase of spinal cord damage refers to the injurious molecular and biochemical events that are set in motion by the primary injury and occur in the first few hours after initial injury. The goal of medical therapy is to limit the damage that occurs from secondary injury. The most important events during this phase of injury are vascular damage with hemorrhage and microthrombosis, loss of autoregulation of blood flow, excessive release of the excitotoxic neurotransmitters aspartate and glutamate, increased neuronal intracellular calcium concentration, cellular damage from reactive oxygen species, and acute neutrophilic inflammation.

Clinical Signs

The most common sign of vertebral trauma in all large animal species is localized pain and limited mobility of the affected part. The atlantoaxial vertebral canal of horses is subject to fractures, subluxations, and dislocations, many of which do not cause signs of neurologic dysfunction, presumably because of the large cross-sectional area of the vertebral canal at this level of the spine.[23] There are two quite rare disorders that result from spinal cord trauma and confound the rules of neuroanatomic localization: spinal shock and Schiff-Sherrington syndrome. *Spinal shock* refers to loss of muscle tone and segmental spinal reflexes caudal to a focal severe transverse spinal cord injury, usually between T3 and L3.[24] Although seldom described in the veterinary literature, it does occur in large animals but, in contrast to the situation in humans, areflexia usually lasts less than 30 minutes after which there is progressive recovery of segmental reflexes with persistence of signs referable to a focal spinal cord lesion. With such a lesion, the thoracic limbs may be hypertonic, reflecting release from the inhibitory effect of tracts originating in the lumbar segments. This combination of paraplegia and thoracic limb stiffness is known as *Schiff-Sherrington syndrome*.[25] At least in small animals, signs regress by about 10 days. Spinal shock and Schiff-Sherrington syndrome may occur together or separately.

Diagnosis and Treatment

The first priority is the safety of attending personnel, which means that large thrashing disoriented patients may need to be heavily sedated or anesthetized to allow for initial assessment, IV catheter placement, and treatment of any life-threatening conditions. Small ruminants theoretically can be taped to a backboard to immobilize them in lateral recumbency during initial procedures. Handlers must be careful not to exacerbate cervical vertebral trauma when restraining injured animals via lead rope and halter.

An indwelling IV catheter should be inserted and secured and IV fluids and initial treatment provided as needed. Volume support and maintenance of normal arterial pressure and hematocrit are essential in all forms of CNS injury.[26] Any animal with spinal injury and neurologic signs should be provided with full doses of analgesics. Nonsteroidal antiinflammatory drugs (e.g., flunixin meglumine 1.1 mg/kg IV or PO) have the dual advantages of analgesic effect and inhibition of potentially injurious cyclooxygenase activity.[22] Additional analgesia can be provided if necessary by doses of butorphanol, morphine, or lidocaine or ketamine constant-rate infusions. The use of methylprednisone sodium succinate in this setting in human medicine remains highly controversial, although slight long-term benefits have been reported for a regimen of 30 mg/kg, followed by 5.4 mg/kg/h for 23 hours.[27,28] Patients are at an increased risk for pneumonia, sepsis, and hyperglycemia. Because more recent data indicate a trend away from the routine use of methylprednisolone because the risks

VetBooks.ir

of complications outweigh the potential benefits,[29] high-dose MPSS is not recommended in large animals with acute spinal cord injury. As is the case for brain injuries, the use of routine antiinflammatory doses of dexamethasone (0.05 mg/kg IV or IM once or twice daily) is reasonable.

As soon as possible, a careful neurologic examination should be performed to localize the lesion. It is important that this examination be complete even if the site of injury seems obvious because multiple discontinuous spinal cord segments and/or the brain may be injured in a single traumatic incident.[30]

When technically possible, it is prudent to radiograph the entire vertebral column. In large animals under field conditions, views are generally restricted to lateral projections of the cervical vertebrae. Remember that radiographs show the amount of spinal displacement at the time they are taken, not the amount of displacement that occurred at the time of injury. The two-column model can be used to assess spinal instability.[1] Myelography is usually not necessary if it is determined that the spinal injury can be treated conservatively or if there is a substantially displaced fracture or luxation that is an obvious candidate for surgery. Myelography should be performed in animals with marked neurologic deficits and normal or equivocal radiographs. Additional information can be obtained from oblique and ventrodorsal radiographic views, C-arm fluoroscopy, CT, MRI, and osseous-phase nuclear scintigraphy. Techniques that require general anesthesia in a large animal with spinal instability generally should be avoided unless there is an immediate surgical option.[10]

After these initial evaluations, the clinician has sufficient information to make recommendations for euthanasia, conservative treatment, or surgical management. Obviously, economic considerations and the intended use of the patient are driving considerations in this situation. In all cases, if there is quadriplegia and loss of deep pain and/or radiographic evidence of likely spinal cord transection, early euthanasia is appropriate. Otherwise, keeping paramount the issues of handler safety and humane treatment, it is reasonable to wait 12 to 24 hours to allow time for recovery of function before delivering a hopeless prognosis and euthanasia recommendation. Once the decision has been made to continue treatment, most large animals are still managed conservatively with surgery an option in selected cases.

Conservative Management

For large animals with vertebral column injury, 1 to 2 months of each of the following is recommended: full-time stall confinement; stall confinement with daily hand-walking; turnout into a small paddock or roundpen during the day with stall confinement at night. Pain control and sedation should be provided as needed. In horses that have difficulty getting to their feet, frequent use of an abdominal sling is essential. Such horses must be able to support their own weight once in the standing position. In cattle, a flotation tank can be used for the same purpose.

Surgery

In the absence of evidence-based guidelines for surgical intervention in large animals, it is worth considering the potential adverse consequences of *not* doing surgery. Although conservative management has often been successful, the following negative outcomes have been observed in horses with spinal injuries managed conservatively: (1) sudden recumbency days to weeks after dens fracture, subluxation, or dislocation[2,31]; (2) limb ataxia and weakness after callus formation and joint remodeling around a fractured articular process[11]; (3) progressive torticollis and/or head tilt after articular process and vertebral body fractures in the midcervical region; (4) limb ataxia and weakness after fibrous proliferation at the site of previous atlantoaxial subluxation; (5) abnormal head position and stiffness of the upper neck after upper cervical injury; and (6) a domino effect wherein there is progressive stenosis of the vertebral canal at the intervertebral joint(s) immediately caudal or cranial to a traumatized intervertebral joint that has healed with a marked flexed or extended angle.[11,18] In light of the foregoing, reasonable indications for surgical intervention in horses are (1) prevention of neck stiffness or deformity; (2) prevention of callus formation or joint remodeling that may impinge on the spinal cord; (3) decompression and/or stabilization of the atlantoaxial joint after dens fracture, subluxation, or dislocation[23,31,32]; and (4) decompression or reduction and stabilization of vertebral fractures/subluxations in response to deteriorating neurologic signs. Techniques have been described for each of these surgical procedures (generally with successful outcomes) in the cervical spine of horses.[10,33,34] Canine surgical techniques can be adapted for use in the lumbosacral spine of valuable small ruminants, calves, and foals. In particular, the use of polymethylmethacrylate and Steinmann pins and plating of the dorsal spinous processes have wide potential application to thoracolumbar injuries in animals less than 70 kg.[35] Surgical decompression of the cauda equina by dorsal laminectomy of the sacrum has been described. In adult horses, the tuber sacrale of the pelvis interferes with the approach to the first and possibly the second sacral vertebra, but decompression of the caudal part of the sacrum is possible.[36] In foals and heifers, sacral fractures may be reduced and stabilized with plates and screws.[37]

Prognosis For horses with spinal trauma without neurologic dysfunction that are treated conservatively, there is a fair to good likelihood that neurologic signs will not develop; however, there is also a fair chance that the neck will remain stiff and/or become deviated or rotated. The prognosis for horses with spinal cord trauma associated with luxations or fractures of the vertebral body, arch, or articular processes must remain guarded to poor for return to use. Healing of such fractures frequently results in some degree of vertebral malalignment, sometimes with lordosis, kyphosis, scoliosis, or torticollis. Even after apparent healing and resolution of neurologic signs, delayed callus formation and degenerative changes in adjacent articulations can result in delayed spinal cord compression. When the injured spine is appropriately stabilized, improvement may continue for up to a year. It is estimated that even 10% survival of axons across a lesion site in the spinal cord may be compatible with walking in a small quadruped. The limbs behind a permanent spinal cord lesion will be ataxic and weak to lateral pressure but spastic and stiff during walking and able to resist dorsal pressure.

Ankylosing Spondylitis of Holstein Bulls

Lisle W. George

Ankylosing spondylitis is an inflammatory disease of joint tissue associated with fusion of lumbar vertebrae in Holstein bulls. Approximately 4% of all Holstein bulls used for artificial insemination are culled each year because of spondylitis.[1] The clinical onset of the condition is insidious. The first signs of the disorder are a stilted gait, reluctance to move, and dragging of the toes of the rear limbs. Affected bulls are slow to mount teaser dummies for collection. The condition is progressive, and over several months the animals develop paraparesis and ataxia. With mounting, the ankylosed area of the spine may fracture, leading to acute recumbency. Pathologic changes associated with the condition include calcification of the ventral vertebral ligaments between the T11 and L3 vertebrae. The condition appears to be hereditary. All bulls with the condition possess the class I major histocompatibility complex (MHC) BoLA A8 phenotype. In comparison, the phenotypic frequency of BoLA A8 in the general population of normal Holstein bulls is only 44%.[2]

Spinal Tumors

Robert J. MacKay • Lisle W. George • Mary O. Smith

With the exception of lymphosarcoma in cattle, tumors involving the spinal cords of domestic animals are rare. In the horse, tumors within the spinal cord or dura (i.e., intramedullary or extramedullary-intradural) have included meningioma, ependymoblastoma, angioma, angioblastoma, ganglioglioma, schwannoma, and neurofibroma.[1] Reported extradural tumors are lymphosarcoma, plasma cell

VetBooks.ir

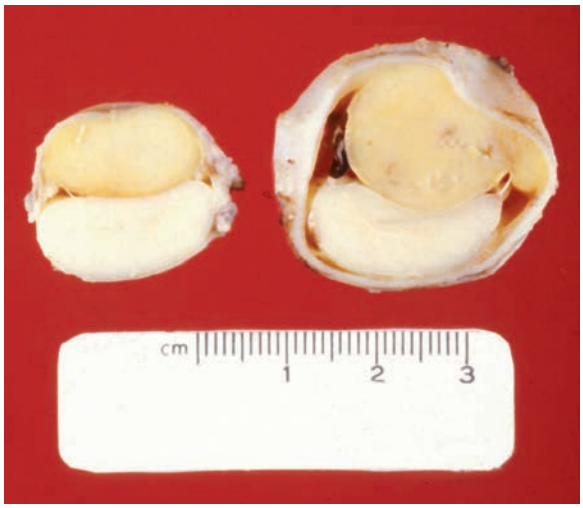

FIG. 35-15 Epidural lymphosarcoma in a 5-year-old Holstein dairy cow. The tumor had spread from neoplastic periaortic lymph nodes and had expanded to compress the caudal lumbar and cranial sacral spinal cord segments, resulting in signs that resembled bilateral sciatic paresis. Tumorous masses are above the compressed spinal cord in the two transverse sections shown.

myeloma, neurofibroma, fibrosarcoma, melanoma, hemangiosarcoma, and carcinoma.[1-4] The most common tumor affecting the spinal cord of ruminants is lymphosarcoma, but others such as histiocytic sarcoma, glioma, neuroblastoma, and embryonal neuroectodermal tumors have been reported.[5-9]

Clinical Signs The clinical signs of tumorous invasion are usually referable to a single-site spinal cord lesion, although extradural tumors such as lymphoma can extend over multiple spinal cord segements.[9] The rate of onset of the neurologic dysfunction varies. Some neurofibromas, melanomas, and lymphosarcomas invade centripetally along the peripheral nerve rootlets. These patients develop slowly progressive limb ataxia and weakness caudal to the location of the lesion, leading eventually to tetraplegia or paraplegia. In rare cases the onset of tetraplegia may be peracute and unaccompanied by prodromal neurologic signs. Lymphosarcoma has a predilection for the lumbar segments of the spinal cord and the cauda equina in cattle older than 5 years of age (Fig. 35-15). A diagnosis of spinal cord tumor should be considered in cases of progressive neurologic disease characterized by flaccid tail and anus, dysuria, urine scalding, distended bladder, perineal analgesia or anesthesia, and paraparesis. Although most animals with spinal tumors are mature to older adults, immature animals can be affected rarely, mainly by embryonal tumors.[8-11]

Clinical Pathology Examination of CSF may be useful when the tumor has infiltrated the cauda equina and is located in the lumbosacral cistern. In these cases, tumor cells may be biopsied as the needle is inserted into the lumbosacral space. In other cases the CSF may be normal, or albuminocytologic dissociation can be expected (elevated CSF protein with normal to mildly elevated nucleated cell count) with or without variable degrees of hemorrhage and xanthochromia. After necropsy, various immunohistochemical techniques can be used to identify the tumor type when routine histologic examination is insufficient.

Treatment There is currently no treatment for most spinal cord–associated tumors of large animals; however, protocols could be adapted from those used for other forms of lymphoma in horses or for other solid tumors in small animals. One study reported survival of a cow for 57 days after three treatments with L-asparaginase at 10,000 IU/m^2 surface area. The nearly 2-month period of survival allowed the investigators to successfully superovulate the cow. When treating food animals with L-asparaginase, the benefits of the antimetabolite drug must be weighed against the potential for teratogenicity of the fetus, toxicity for humans, and the certainty of relapse in the patient.[12]

Verminous Meningoencephalomyelitis

Robert J. MacKay

Verminous meningoencephalomyelitis is caused by the meanderings of one or more parasites through the CNS and is, therefore, an extremely variable clinical entity. Depending on the number, size, and location of the parasites and the duration of their migration through the brain or spinal cord, a spectrum of signs is possible, ranging from a nonprogressive localizing neurologic deficit to rapidly fatal, diffuse encephalitis. Verminous meningoencephalomyelitis usually occurs sporadically and has been associated with strongylid *(Strongylus vulgaris),* metastrongylid *(Angiostrongylus cantonensis, Parelaphostrongylus tenuis),* filarid (*Setaria* spp.), tylenchid (formerly rhabditid) *(Halicephalobus gingivalis),* and spirurid *(Draschia megastoma)* nematodes, as well as warble fly larvae (*Hypoderma* spp.).

Strongylus vulgaris

Verminous myeloencephalitis due to *S. vulgaris* in the CNS is a rare aberrant event resulting from embolization to the CNS of L4 or L5 larvae from verminous thrombi in the left ventricle, proximal aorta, or any of the aortic branches that supply the CNS.[1,2] Upstream subintimal migration of *S. vulgaris* larvae in the aorta occurs from locations in the proximal cranial mesenteric artery.[2] Disintegration of thrombi in these aberrant locations sends clot fragments and larvae to the CNS. Three differing outcomes are possible: (1) acute massive infarction, ischemia, and edema of the brain; severe neurologic dysfunction; and death after a brief clinical course; (2) nonlethal or even subclinical embolization of the CNS is followed by entry of a larva (or larvae) into the CNS parenchyma and wanderings therein for up to several months with associated neurologic signs; or (3) subclinical embolization and parasite migration. Subclinical larval migration occurs in relatively forgiving parts of the cerebral hemispheres and ends when the parasite dies or migrates out of the CNS. A single larva can migrate through many levels of the CNS; in one case an L5 *S. vulgaris* larva was estimated to have traveled 8 cm per day for several days along the spinal cord of a donkey.[3] Virtually any clinical sign is possible, and signs are likely to change dramatically over time or even stop and then restart or spontaneously resolve. A larva may exit the CNS only to reenter at a different location and continue its migration. The donkey mentioned earlier was paraparetic and dog-sitting because of larval damage through the midlumbar spinal cord; signs improved for a few days when the larva migrated out of the spinal cord, then the animal collapsed into recumbency when the larva reentered and migrated within the cervical spinal cord.[3] Thrombosis, infarction, and serpiginous hemorrhagic or discolored tracts may be evident grossly. Microscopic findings include linear tracts of hemorrhage lined by neutrophils, macrophages, occasional eosinophils, and reactive glial cells. CSF changes associated with *S. vulgaris* migration include xanthochromia, protein concentration ranging from 32 to 550 mg/dL, and increased nucleated cell count (42 to 10,000/μL).[1-4] The differential counts range from 70% to 80% neutrophils, 12% to 19% mononuclear cells, and 1% to 2% eosinophils. Verminous myeloencephalitis due to *S. vulgaris* virtually disappeared after the introduction of the macrocyclic lactone anthelmintics in the 1980s; however, the increasing practice of selective deworming may allow the reemergence of large strongyles.[5]

Hypoderma lineatum and *Hypoderma bovis* (Cattle Grubs)

Hypoderma lineatum (common cattle grub) and *Hypoderma bovis* (northern cattle grub) are parasites of cattle that occasionally migrate in the horse (also in goats and deer). In the late spring or early summer, adult *Hypoderma* spp. flies (known as warble flies or heel

VetBooks.ir

flies) deposit eggs on hairs on the limbs or lower body. First-stage larvae hatch in 5 to 7 days, penetrate the skin, and migrate in a dorsal direction along fascial planes, often following the paths of blood vessels or nerves.[6] Over about a year migrating larvae moult once or twice and arrive in subcutaneous tissues along the back. Their dorsally directed path may sporadically take larvae through the foramen magnum or other foraminae of the skull to penetrate and meander in the brainstem. Because of the large size of *Hypoderma* spp. larvae and their propensity for migration within the caudal fossa of the skull, resulting neurologic signs are usually severe, progressive, and fatal.[6,7] Typically, there is profound obtundation and signs of asymmetric cranial nerve dysfunction (e.g., head tilt and circling) that worsen quickly and lead to recumbency and death. Since the advent of pour-on and injectable systemic organophosphate insecticides in the 1950s and macrocyclic lactones in the 1980s for systematic treatment of cattle, *Hypoderma* populations have decreased dramatically in the United States and have been eradicated in several European countries, so intracranial myiasis is now unlikely in developed countries. *Hypoderma diana,* a parasite of deer, has also infested horses and presumably has the potential for CNS invasion.[8]

Halicephalobus gingivalis

Halicephalobus gingivalis (previously *Halicephalobus deletrix, Micronema deletrix*) is a free-living microbivorous tylenchid nematode that feeds on bacteria in rich organic environments such as decaying vegetation, compost, or manure.[9,10] Cases of meningoencephalomyelitis caused by *H. gingivalis* occur sporadically worldwide in equids (including zebras) and occasionally humans.[11-16] The nematode opportunistically enters the body through breaks in the mucous membranes (and possibly skin) of the nose, mouth, prepuce and mammary gland of horses and invades and proliferates locally to cause clinically apparent granulomas.[17-22] Such masses can be locally invasive and destructive, particularly in the jaws, nasal cavity, and paranasal sinuses.[17,23] In one case a foal was apparently infected by suckling from its dam who had *H. gingivalis* mastitis.[24] From these superficial sites larvae or adults may enter lymphatic or venous drainage and be distributed hematogenously to various organs and tissues. *H. gingivalis* has a propensity to invade and proliferate in the kidneys (Fig. 35-16), CNS, and eyes, although lesions have also been found in long bones, heart, lungs, liver, uterus, testes, lymph nodes, and the walls of the aorta and pulmonary arteries.[22,25-27] The brain is the usual site of CNS infection with lesser involvement of the spinal cord or, in one instance, the cauda equina.[28] The typical severe progressive neurologic signs are due to massive proliferation of nematodes adjacent to blood vessels and the associated florid perivascular granulomatous inflammation.[9] Only female nematodes are present in lesions, and reproduction is by parthenogenesis.[9] Clinical signs of *H. gingivalis* infection of the CNS depend on the location of the lesions and include asymmetric ataxia, hypermetria in the thoracic limbs, obtundation, behavioral changes, compulsive walking, head pressing, head tilt, circling, nystagmus, recumbency, convulsions, and coma.[11-16,29-31] *H. gingivalis* meningoencephalitis is invariably fatal, regardless of treatment; affected horses die or are euthanized within several days of onset.[25,32] CSF analysis in affected horses ranges from normal to xanthochromic appearance with increased protein and mild to moderate pleocytosis of nucleated cells. Differential analyses reveal mostly mononuclear cells with lesser numbers of neutrophils and occasional eosinophils. In many (most?) cases of *H. gingivalis* meningoencephalitis there are also characteristic renal lesions.[25] The latter are usually multifocal large nodules in the renal parenchyma of one or both kidneys.[25,33] Of potential diagnostic significance in such cases, there may be a history of weight loss, hematuria, and/or polyuria and findings at initial examination of nematodes in the urinary sediment, high serum creatinine and calcium concentrations, and ultrasonographically evident renal masses.[34-37] Severe progressive, usually unilateral verminous chorioretinitis or panophthalmitis may precede or coincide with the onset of signs of encephalitis.[36,38,39] Efforts to eliminate subcutaneous or renal *H. gingivalis* infections by surgery and anthelmintics are occasionally successful[20] but, unfortunately and unpredictably, are often followed within several days to weeks by the onset of encephalitis.[18,38,40-42]

FIG. 35-16 Kidneys from a horse with disseminated *Halicephalobus gingivalis* infection including fatal meningoencephalomyelitis.

Parelaphostrongylus tenuis

Parelaphostrongylus tenuis (the meningeal worm) is a ubiquitous parasite of white-tailed deer in the eastern United States (north of a line through the middle of the states along the Gulf of Mexico[43]). Infective larvae are ingested within infected snails and slugs, exit through the abomasum, and then migrate to the dorsal horn of the gray matter of the spinal cord, where they mature to adults before traveling along the dorsal nerve roots to the venous sinuses and subarachnoid spaces over the cerebral hemispheres.[44] *P. tenuis* is increasingly a cause of verminous meningoencephalomyelitis due to aberrant larval migration in the CNS of other cervids, goats, sheep, and New World camelids within the same geographic range. In 2003 a series of six equine cases with cervical scoliosis were described.[45] In each case, there was a unilateral multisegment contiguous lesion involving the dorsal horn of the gray matter on the convex side of the neck. In one case, cross-sections of a metastrongylid nematode were seen associated with the characteristic lesion and the presumption is that all cases were caused by aberrant migration of *P. tenuis*. Five of the horses were younger than 1 year of age and, in each case, there was acute onset of severe scoliosis after a variable prodrome with degrees of hypalgesia of the neck and cranial thorax and limb weakness and ataxia, all on the side of the cervical convexity. Treatment with anthelmintics and antiinflammatories had no effect, and affected animals were all euthanized for humane reasons. An additional case, also in a young horse, was reported in 2007, this time with signs of obtundation, head tilt, circling, quadriparesis, and ataxia in all four limbs.[46] There were numerous larval stages, eggs, and occasional adults of both sexes associated with granulomatous eosinophilic inflammation in the cerebellum and adjacent brainstem. These nematodes were shown by PCR of specific DNA sequences to be *Parelaphostrongylus* species.[44] A *P. tenuis* nematode was extracted from the anterior chamber of a horse with signs of anterior uveitis.[47]

Angiostrongylus cantonensis

Angiostrongylus cantonensis is a neurotropic metastrongylid parasite with a life cycle in rats closely analogous to that of *P. tenuis* in white-tailed deer.[48] It has long been endemic in the Pacific islands and Southeast Asia but has spread its range into Australia, the United States, and the Caribbean. It is now well established among the wildlife of Louisiana.[49] The definitive hosts are species of wild rat that become infected by ingesting the infective larva in slugs or snails. The larvae migrate to the CNS to continue development before finishing the life cycle via the pulmonary vasculature. Inadvertent ingestion of infective larvae by atypical hosts such as humans, dogs, and horses may lead to aberrant migration in the CNS and signs of verminous meningomyeloencephalitis similar to those described earlier for

VetBooks.ir

S. vulgaris. Equine cases have been reported for two foals in Australia and an American Miniature Horse foal in Louisiana.[50,51] Larvae migrated in the gray and white matter of the spinal cord and brainstem. CSF analysis revealed mild pleocytosis with small numbers of neutrophils and eosinophils. Specific ELISA tests are available for testing of CSF in humans and dogs.[48]

Draschia megastoma

Draschia (Habronema) megastoma is a spirurid nematode that has been found in the brainstem of a horse from the southern United States.[52] The adult worm is normally embedded in benign pyogranulomatous masses in the equine stomach, but larvae can invade wounds to cause granulating summer sores and have been reported to cause pulmonary nodules. The two unusual features of the solitary report of encephalitis are, first, the parasite found at necropsy was an adult gravid female and, second, there was a quiescent period of 6 weeks during the clinical course when clinical signs improved before again progressing.

Setaria spp.

Setaria spp. are long threadlike filarid nematodes that live without adverse effect in the peritoneal cavities of animals worldwide.[53] Microfilariae are released into the blood of the host and acquired by feeding mosquitoes in which they undergo development to infectious larvae. Bovids outside the Americas are hosts to several setarial nematodes including *Setaria digitata, Setaria labiatopapillosa,* and *Setaria marshalli*.[54-56] When inserted by mosquitoes into atypical hosts such as horses, goats, and sheep, immature *S. digitata* may migrate aberrantly through the CNS and other organs of atypical hosts.[55,57] This parasite has also migrated aberrantly in the CNS of cattle.[58] Outbreaks of so-called epizootic cerebrospinal nematodiasis, lumbar paralysis, or kumri occur during the summer or autumn when mosquito intermediate hosts are active. Outbreaks have been reported in Japan, Taiwan, China, Korea, Sri Lanka, Burma, India, Nepal, Iran, Israel, and Saudi Arabia.[57,59,60] Cases in horses are sporadic and often involve older horses; in goats, young animals are usually affected and morbidity and mortality is up to 100%.[55] *S. digitata* apparently does not occur in the United States[54]; however, a single case of verminous encephalomyelitis due to *S. labiatopapillosa* has been reported in this country.[61]

Clinical signs are variable and are related to mechanical and inflammatory destruction along the tracks left in the brain or spinal cord by one or more larvae.[57,62] In this respect, the pathology of setarial meningoencephalomyelitis is identical to that described earlier for *Strongylus vulgaris*. Changes in the CSF associated with *Setaria* infestation include xanthochromia, pleocytosis (25 to 84 cells/dL), and a slightly increased protein concentration. The cells of one horse contained a small proportion of eosinophils and basophils, but this finding was inconsistent with other reports.

Treatment and Prevention When single or a few migrating larvae are involved, there have been successful outcomes using combinations of anthelmintics and vigorous antiinflammatory treatment. The latter component is likely important to prevent the effects of strong inflammatory responses against killed parasites.[48] Because penetration of the blood-brain barrier by anthelmintics is limited, high-dose benzimidazoles are often used for this purpose. Typical protocols are 10 to 60 mg/kg fenbendazole one to five times daily by mouth or nasogastric tube with 0.05 mg/kg dexamethasone (or equivalent) IV or IM, once or twice daily for 3 days. Ivermectin was effective in goats with early signs of setarial myeloencephalitis[55] but has not been effective in treatment of *P. tenuis* or *H. gingivalis* cases in horses, even when used against *H. gingivalis* at a potentially toxic dose of 1.2 mg/kg (6× the recommended dose).[34] Diethyl carbamazine citrate at 40 to 100 mg/kg daily was effective in natural and experimental setarial cases in horses.[63] Most types of verminous encephalitis are unlikely in horses on a regular deworming program; however, *H. gingivalis* cases regularly occur in horses on any of a variety of regular anthelmintic regimens.

Postanesthetic Myelopathy and Encephalopathy

Mary O. Smith • Robert J. MacKay

A sudden-onset myelopathy has been described in horses and in a single calf after anesthesia.[1-6] Most of the horses were large, young, and in dorsal recumbency under halothane anesthesia. There is a tendency for affected animals to be hypotensive during anesthesia. Paraparesis, ataxia, recumbency, or paraplegia is usually apparent during recovery from anesthesia but may be delayed as long as several days. Other reported signs include cutaneous hypalgesia and areflexia of the hindquarters and occasionally the thoracic limbs. Lesions occur mainly in the lumbosacral spinal cord, although cervicothoracic segments also may be involved. There is malacia predominantly within gray matter (poliomyelomalacia), with associated mild to severe hemorrhage in most cases.

Rare cases of postanesthetic encephalopathy have been described in horses.[5,7] Clinical signs included dementia, pacing and circling, cortical ("central") blindness, ataxia, hypermetria, and recumbency. In mild signs, blindness may be the only clinical sign. The onset of signs ranged from a few hours after recovery to several weeks later. The major pathologic finding in affected horses that did not survive was cerebrocortical necrosis, particularly in regions of the cortex supplied by terminal arterial branches ("watershed zones").

Although the pathogenesis of postanesthetic myelopathy is incompletely understood, it is proposed that compromise to the blood supply to the spinal cord is caused by hypotension or pressure from the abdominal viscera on the great veins (caudal vena cava, azygos vein). Systemic hypoxia, hypovolemia, and hypercapnia may underlie postanesthetic encephalopathy.[7] Factors suspected to increase the risk of postanesthetic encephalopathy include positioning in dorsal recumbency during anesthesia, multiple anesthesias, use of halothane anesthesia, endotoxemia, and shock. Differential diagnoses for myelopathy include orthopedic conditions such as limb fractures, spinal fracture, myopathy, and peripheral neuropathy secondary to recumbency. Differentials for encephalopathy include numerous metabolic, infectious, and toxic disorders. Prognosis for recovery in cases of myelopathy is poor or hopeless. By contrast, most horses with encephalopathy recover completely. The risk of these complications probably can be reduced by supporting adequate blood pressure and ventilation in patients under anesthesia, minimizing anesthesia duration, and avoiding dorsal recumbency whenever possible.

Occipitoatlantoaxial Malformation

Robert J. MacKay • Mary O. Smith

Occipitoatlantoaxial malformations are a heterogeneous group of cranial cervical spinal abnormalities.[1] They occur in cattle, sheep, goats, and horses.[2-5] At least five different types of defects have been reported in horses, as follows[6-12]:

1. A heritable condition in Arabians characterized by symmetric atlantooccipital fusion, atlantalization of the axis, and hypoplasia of the atlantal wings.[1,11,12] A similar disorder has been reported in an Arabian-cross colt.[13]
2. A nonfamilial disease of Quarter Horses with spinal lesions similar to those in Arabians.[6,14]
3. Asymmetric malformations of the occipitoatlantoaxial area in Morgan horses and Standardbred foals.[1]
4. Atlantal duplication in Arabian and Arabian crossbred horses.[8,15]
5. Asymmetric occipitalization of the atlas and symmetric atlantalization of the axis.[1]

Malformations common to the five forms include loss or flattening of the occipital condyles, asymmetric flattening of the articular surfaces of the axis, and shortened dens. The pathogenesis of the vertebral defects is unknown, but a familial form has been demonstrated in the Arabian horse.[11]

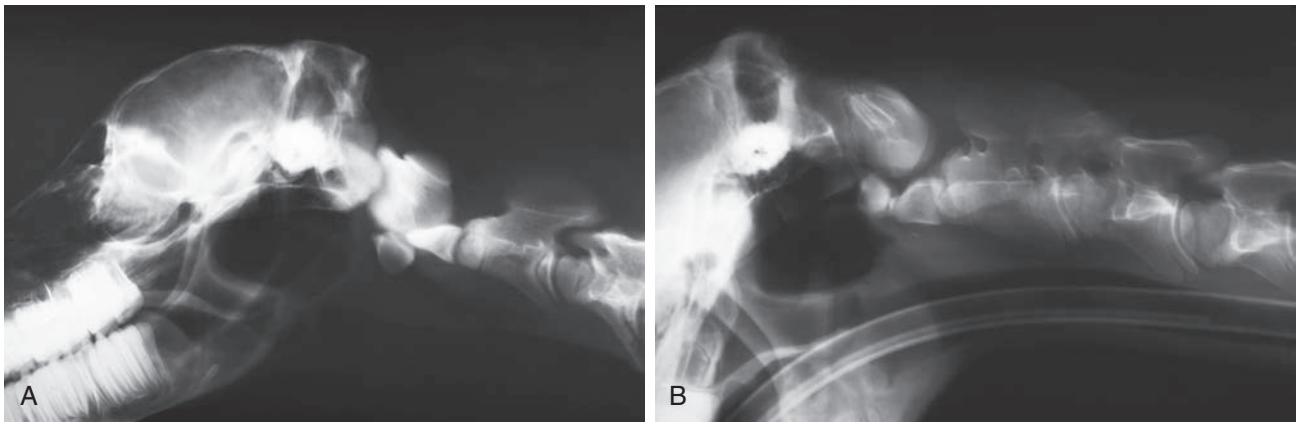

FIG. 35-17 Occipitoatlantoaxial malformation (OAAM). Radiographs of the craniocervical region of a normal neonatal foal **(A)** and a 3-week-old Arabian foal with OAAM **(B).** Note slightly shortened dens, ventral luxation of the dens, cranioventral movement of the body of the atlas to encroach on the guttural pouch, and fusion of the atlas to the occiput with occipitalization of its caudal surface, in the foal with OAAM. *(Images courtesy Dr. I.G. Mayhew, Massey University.)*

The clinical signs range from normal with or without torticollis to brainstem compression, sudden unexpected death, and stillbirth.[1] In typical cases, signs of tetraplegia or tetraparesis begin at or shortly after birth and progress at variable rates. Foals may become suddenly tetraplegic, appear to stabilize for several days, but then die suddenly.[16] In rare cases, horses may not show nervous system signs until 3 years of age.[10]

The signs are symmetric in most affected animals and include hyperreflexia, hypertonia, weakness, and ataxia in all 4 limbs. There may be reluctance to move the neck and head and resistance to manipulation of the area. A click or crepitation may be palpated over the cranial cervical spine when the head is moved.[1,4] With asymmetric bone lesions there often is torticollis, whereas patients with symmetric lesions hold their heads in extension and frequently display the "weather vane" attitude. Neurologic deficits may not be seen despite moderate torticollis.

The malformations are readily apparent radiographically (Fig. 35-17) and by CT can further elucidate the anatomic abnormalities.[14] There may be subluxation of the atlantoaxial joint, ventral displacement of C2 relative to C1, nonunited ossification center of the dens, shortened or elongated dens, shortened transverse process of the atlas, fusion of C1 with the occipital condyles, atlantal duplication, and deviation of the basioccipital bone.[1,17] In sheep, additional malformations of the cervical vertebrae have been seen concomitantly.

Suggested approaches to treatment are surgical fusion of the atlantoaxial joints, with or without a laminectomy.[10,18] Laminectomy alone has been used to alleviate spinal cord compression and clinical signs caused by occipitoatlantoaxial malformation.[19] However, long-term results of surgical intervention have been poor, with neurologic deficits persisting. Closed reduction of the luxated atlantoaxial joint has been similarly unsatisfactory.[14,20] If treated, Arabian horses must not be bred because of the hereditary nature of the disease in that breed.

Congenital Vertebral Anomalies

Mary O. Smith • Robert J. MacKay

A large number of spinal deformities have been reported in domestic livestock including the following:

- *Spina bifida.* Failure of closure of a vertebral neural arch; spina bifida usually occurs together with myelodysplasia.[1]
- *Spina bifida cystica.* Spina bifida associated with a cerebrospinal fluid-filled cyst at the site of the bony defect.
- *Hemivertebra.* A unilaterally incomplete vertebral segment; spina bifida and hemivertebrae have been described in calves, and spina bifida has also been reported in sheep and foals.[1-4]
- *Arnold-Chiari syndrome.* A complex disorder that has been reported in lambs, calves, and a foal[4-6] and is characterized by a group of changes including herniation of cerebellum through the foramen magnum, caudal overgrowth and displacement of the brainstem, internal hydrocephalus, polymicrogyria of the cerebral cortex, malformation of the base of the skull, and enlargement of the foramen magnum. The strong correlation between the occurrence of spina bifida and Arnold-Chiari syndrome of calves indicates that the pathogenesis of the two conditions may be interrelated.[1,4,6]

Animals with spina bifida may be asymptomatic or, in reverse order of frequency, may have signs involving only the hindquarters, pelvic limbs, and hindquarters or all four limbs and the hindquarters. Affected animals that are ambulatory often have a peculiar "bunny-hopping" gait and some or all of the elements of cauda equina syndrome (tail paralysis, perineal and tail analgia, and anal, bladder, and penile paralysis). The clinical signs are often present at birth or develop during the first 2 months of life and are nonprogressive.[7,8] Kyphoscoliosis and abnormalities of the rib cage may be seen at birth in some animals.[8] The skin over the abnormal vertebrae may be smooth and hairless.[9] When examined microscopically, this tissue resembles leptomeninges or ependyma.[2]

Spina bifida and hemivertebrae are easily diagnosed by examination of plain radiographs or CT images. The specific site of central nervous system stenosis can be detected by performing a myelogram, CT, or MRI. The etiology of spina bifida is unknown; genetic and toxic etiologies have been suggested.[10-12]

Arthrogryposis occurs secondary to the spinal cord changes. Spina bifida and myelodysplasias are not the only causes of arthrogryposis, however, and clinicians should attempt to differentiate between these and other diseases that interfere in utero with motor neuron development in the spinal cord. Nongenetic arthrogrypotic conditions of cattle include perosomus elumbis, hydranencephaly, manganese deficiency, and ingestion of lupines or *Nicotiana glauca* (40 to 60 days of gestation).[12,13]

See also Chapters 51 and 52.

Myelodysplasias (Syringomyelia; Spinal Dysraphism; Hydromyelia)

Mary O. Smith • Robert J. MacKay

The following types of myelodysplasia occur in livestock[1-13]:

1. *Spinal dysraphism.* A general term denoting arrested development of the spinal cord before complete differentiation of gray and white matter; the areas of agenesis form longitudinal cystic

VetBooks.ir

structures instead of differentiated nervous tissue. Most of these anomalies are neural tube defects.
2. *Syringomyelia.* Longitudinal cavitations of the spinal cord.
3. *Hydromyelia.* Abnormal dilation of the central canal.
4. *Diastematomyelia.* Duplication of the gray matter at one or more segments.
5. *Rachischisis.* Complete failure to close the neural tube; the central canal remains open and communicates with the integument.
6. *Meningocele.* Herniation of the dura mater through a vertebral defect (usually spina bifida).
7. *Meningomyelocele.* Herniation of the meninges and spinal cord through a spinal column defect.

Associated abnormal neurologic signs are as described earlier for spina bifida.[14]

Myelodysplasia has been related to genetic factors in Charolais and Hereford calves, although the mode of inheritance is unknown.[3,15] The condition has also been recognized in foals of several breeds.[16-18] In addition to genetic factors are intrauterine BVD infection, hypovitaminosis A or copper deficiency, maternal fever, or exposure to teratogens including substances in species of *Solanum* and *Veratrum*.[19]

The neurologic deficits of myelodysplasia are difficult to differentiate from other spinal diseases unless the disorder is accompanied by spina bifida. Clinical recognition of myelodysplasia is usually based on the historical findings of paraplegia in a newborn calf without radiographic evidence of spinal fractures and with no myelographic evidence of spinal cord compression.

Acquired Torticollis

Robert J. MacKay • Mary O. Smith

Primary acquired torticollis with or without neurologic disease occurs in all species of domestic livestock. Causes include fracture or subluxation of the cervical vertebrae, basilar skull fractures, dystrophic muscle degeneration, unilateral cicatricial muscular contracture from injections, lupinosis, traumatic rupture of the cervical muscles, parasitic migration through the cervical spinal cord, hydranencephaly, asymmetric neurodegeneration, and congenital vertebral deformity.[1-6] One study hypothesized that physical constraint within the narrow tips of uterine horns caused acquired torticollis and a variety of other deformities such as head scoliosis and limb malformations in more than 200 foals.[7] Draft horses may be predisposed to this problem, which frequently results in severe dystocia in horses. Provided the spinal cord is intact, no neurologic deficits result. The current epizootic of fetal Schmallenberg virus infections has caused torticollis with other malformations in calves, kids, and lambs.[8]

Treatment of traumatic torticollis should be directed at reducing the edema, relieving pain, and immobilizing the damaged structures. Muscular tears may be treated by incorporating the head, neck, and proximal thorax in a fiberglass cast. Ancillary supportive treatment may include dexamethasone (0.04 to 0.08 mg/kg IM or IV daily for 2 to 3 days), methocarbamol (8 mg/kg IV daily for 5 days), and NSAIDs (e.g., phenylbutazone PO or IV or flunixin meglumine IV for 3 to 5 days after injury). A method of surgical correction of cervical muscle contractures using a muscle-splitting procedure has been described[9]; however, this seems unnecessary because most animals recover with only medical treatment. When torticollis is the cause of equine dystocia, delivery of the foal by cesarean section is often followed by rapid and complete anatomic and functional recovery.[7]

Tetanus

Robert J. MacKay

Tetanus is characterized by muscular rigidity and spasms. Death is common and results from respiratory compromise or tetanic convulsions. Clinical signs are caused by tetanospasmin (TeNT), an exotoxin produced by the anaerobic, spore-forming, gram-positive bacterium *Clostridium tetani*. Horses are exceptionally sensitive to TeNT; cattle are relatively resistant, and small ruminants have intermediate sensitivity to the toxin. Spores are long-lived and resistant to most disinfectants and environmental extremes. They are not completely destroyed by boiling but can be eliminated by autoclaving at 115° C (239° F) for 20 minutes.[1] *C. tetani* is a ubiquitous soil inhabitant and can be isolated from feces of herbivorous domestic animals, with highest frequency in horses.[2,3] Tetanus is usually a disease of individual animals, but herd outbreaks of tetanus in livestock have been described.[4-8]

Pathogenesis

The most common route of infection is inoculation of wounds with *C. tetani* spores. Deep puncture wounds contaminated by manure, soil, or rusty metal are especially likely to cause tetanus. In horses, such wounds are typically in the lower limb, although contaminated surgical sites, the postpartum uterus, injection abscesses, and infected umbilical structures are also potential sites for *C. tetani* infection.[9-11] Causative wounds are not found or reported in up to 50% of equine cases. Dairy cattle are infected most frequently after bacterial contamination of the uterus postpartum. Reestablishment of anaerobic conditions in the involuting uterus favors germination and proliferation of *C. tetani* spores. Other sites for growth of *C. tetani* in livestock include lesions caused by elastrator bands, sharp castration or tail docking, dehorning or disbudding, insertion of bull rings or ear tags, shearing, fly strike, intramuscular injection of anthelmintics or vaccines, and umbilical infections.[4,5,7,8] Outbreaks of "idiopathic tetanus" occur occasionally in young cattle, usually in association with the grazing of rough, fibrous feed, and it is likely that this is analogous to the pathogenesis of toxicoinfectious and forage poisoning forms of botulism wherein toxin is produced in wounds in the mouth or gastrointestinal tract or ingested preformed in contaminated feed.[12,13]

The crucial event in development of tetanus is germination of *C. tetani* spores followed by vegetative growth and elaboration of exotoxins. Factors that enhance the germination and growth of *C. tetani* include necrotic tissue, pus, concomitant bacterial infection, and foreign bodies. Spores inoculated into the tissues are highly resistant to normal host defenses and may remain dormant for months or years before germinating. *C. tetani* produces at least two exotoxins: *tetanospasmin* and *tetanolysin*.[14] *Tetanolysin* damages viable tissue, thereby lowering the redox potential and creating favorable conditions for expansion of the anaerobic infection.[3] The neurotoxin tetanospasmin (TeNT) is a 150-kD polypeptide that is immediately cleaved by tissue proteases into active heavy and light chains connected by a single disulfide bond. It diffuses from the site of production into the vascular system and is distributed hematogenously to somatic neuromuscular junctions and autonomic ganglia, where it binds to nerve terminals. Once bound, the toxin is internalized and transported retrograde in axons of both somatic and autonomic motor neurons at 75-250 mm/day.[15] After 1 to 14 days the toxin enters the CNS, reaches the neuronal cell body, traverses the synaptic cleft, and binds irreversibly to presynaptic inhibitory interneurons. Intact toxin is internalized, and then light chain is released into the cytosol, where it acts to inhibit membrane fusion and recycling, events crucial in the release of the inhibitory neurotransmitters glycine and γ-aminobutyric acid (GABA).[14] The resulting disinhibition of motor neurons is the proximate cause of muscle rigidity and spasms.[3]

Preganglionic autonomic motor neurons in the lateral column of the gray matter and parasympathetic centers in the brainstem are affected by a similar mechanism but with delayed kinetics compared with somatic motor neurons.[16] Both a basal increase in sympathetic activity and episodes of intense hyperactivity ("autonomic storms") occur, involving α-adrenergic and β-adrenergic receptors. During autonomic storms there is up to a 10-fold increase in the concentration of circulating epinephrine. The resulting sympathetic overactivity causes hemodynamic instability and is an important cause of death in ventilated human tetanus patients.[17] Its significance in large animal patients is unclear.

VetBooks.ir

Neuronal binding of toxin is thought to be irreversible.[18] Recovery requires sprouting and growth of new nerve terminals, a process that is completed in weeks to months.

Diagnosis Routine blood work is unhelpful, and abnormalities found are nonspecific. Gram stain of wound exudates reveal the characteristic drumstick-shaped gram-positive bacilli in about 30% of human tetanus patients,[19] but Gram stain and culture are seldom attempted in large animals with tetanus. With the development of a real-time PCR assay for the TeNT gene,[20] timely confirmation of *C. tetani* wound infection is now theoretically possible and may have application to veterinary cases.

Necropsy findings of animals with tetanus are nonspecific with secondary signs of musculoskeletal trauma and pulmonary congestion, atelectasis, and edema most common.[9,10] The diagnosis can theoretically be confirmed by detection of TeNT antigen in spinal cord ventral or intermediate horn cells by immunohistochemical staining with antibody directed against tetanus toxin.[21]

Clinical Signs Signs occur 1 to 60 days after wound inoculation by *C. tetani* spores with most animals affected between 7 and 21 days.[9,10] The incubation period varies depending on the size of the wound, redox potential of the contaminated tissue, number of spores inoculated, and host's antitoxin titer. Probably because cranial somatic nerves are shorter then nerves to the limbs, the first signs of tetanus are associated with rigidity of muscles around the head and neck. These signs are commonly missed in livestock that are not closely watched but are usually recognized in horses. Increased tonus of the masticatory muscles (trismus), rigidity of facial expression (risus sardonicus), and neck stiffness are typical early signs.[9,22] Prolapse of the membrana nictitans begins during this phase and may be a prominent sign in the horse but is inconsistent in cattle and usually not seen in sheep.[12] The head and neck are held in an extended position, and the face has a fixed anxious expression. The ears and commissures of the lips are retracted caudally, and the upper eyelids are elevated. Often the mouth is clamped shut and the jaws cannot be pried apart manually (lockjaw). Hyperthermia (usually <102.5° F) occurs in some animals during the early stages, and rectal temperature may rise further after tetanic convulsions.

In mildly affected animals, signs may be restricted to the head and neck; however, in most cases, generalized spasticity is evident within the first 2 days. The limbs, back, and neck are held in a characteristic rigid extended posture that resembles the legs of a sawhorse (i.e., "sawhorse" stance).[9] The tail is elevated from the ischiorectal fossa (i.e., "pump handle"). Affected animals display a stiff, toe-scuffing gait and an extended head posture. Gas bloat usually begins during the first 24 hours in ruminants and camelids, and colic is occasionally an early sign in horses.

In all cases of generalized tetanus, tonic muscle spasms develop shortly after the onset of rigidity. These can be initiated by external tactile, visual, emotional, or auditory stimuli or by voluntary movements such as posturing to acquire food or water, urinate, or defecate. The limbs and head are resistant to passive flexion and dramatic responses to even minor stimuli manifest as hyperresponsiveness or hyperesthesia. When the face is touched, there is reflex retraction of the eye and prolapse of the nictitans.[12] This is inconsistent in cattle and sheep. Attempts to chew or suckle set off rounds of masseter contractions that are easily visible under the skin. Unmasticated feed is lodged in the cheeks or between the teeth. Even if ingesta can be moved to the pharynx, reflex pharyngeal and laryngeal spasms result in nasal regurgitation, drooling of saliva, and stridor. Aspiration pneumonia may develop as a result of impaired swallowing.

Disturbances of autonomic function have not been well documented in large animals but are presumed to occur after the development of muscle spasms, as is the case in humans with tetanus.[17] There may be increased or dramatically fluctuant heart rate and blood pressure with profuse sweating in horses.[9,11] It is not clear whether these signs represent TeNT-induced sympathetic overactivity or are physiologic responses to the pain of and anxiety caused by muscle rigidity and spasms. Signs of sympathetic overactivity are usually overlooked until after muscle spasms have been controlled. It is reported in humans that hypersalivation, increased respiratory secretion, and late-onset hypotension occur because of parasympathetic overactivity.[23]

Severely affected animals are at high risk of falling to the ground, especially during spasms. Once recumbent they lie in lateral recumbency with the head and legs in full extension and the ears held almost parallel to the back. Frothy saliva accumulates at the commissures of the lips because the animals are unable to swallow. Spontaneous deaths are usually due to respiratory failure because of laryngeal spasm and asphyxia; contractions of the chest wall, diaphragm, and abdomen; accumulation of excessive respiratory secretions; and aspiration pneumonia. Autonomic overactivity may cause fatal cardiac dysrhythmia or heart failure and death secondary to hypertension. Ventrolateral strabismus and dilated, fixed pupils may occur in advanced tetanus of cattle. Animals often die during a tetanic convulsion.

Treatment The general principles that guide tetanus treatment of large animals are as follows: provide muscle relaxation, ensure good footing, eliminate the infection, neutralize the unbound toxin, maintain hydration and nutritional status, and establish active antitoxic immunity.[24]

PROVIDE MUSCLE RELAXATION. All possible external stimuli including light and noise should be minimized. Packing the ears with cotton to minimize auditory stimulation can also help reduce muscle spasms. Sedatives and muscle relaxers are used for control of muscle spasms and rigidity.[25] The cornerstone of this approach is the combination of a phenothiazine-based ataractic sedative such as acepromazine with a GABAergic agent such as pentobarbital or diazepam.[18] An IV catheter should be placed to minimize treatment-associated stimulation. In mild to moderately affected animals, acepromazine (or chlorpromazine) produces obvious muscle relaxation within minutes of treatment that lasts for hours. Acepromazine additionally has α-adrenergic antagonist and anticholinergic actions that may help suppress autonomic overactivity.[26] Pentobarbital sodium provides additional muscle relaxation in cattle but in horses must be titrated carefully in order to avoid recumbency.[9,27] Phenobarbital, at a dose of 10 mg/kg IV and then by NG tube q8h, provided effective muscle relaxation for a neonatal foal with tetanus that had not to that point been controlled by high and frequent doses of diazepam.[28] Large doses of diazepam or midazolam by repeated injection or constant rate infusion (CRI) are effective for control of muscle rigidity, but these drugs are expensive and impractical in many settings. The direct muscle relaxant dantrolene is used in horses for prevention of myopathy and might have application to the treatment of tetanus. This drug has been used successfully in human tetanus.[29] Methocarbamol, glycerol guaiacolate, mephenesin, and d-tubocurarine have all been used for muscle relaxation in horses with tetanus but have not found wide application.

Magnesium infusion has multiple potentially useful actions against spasms and autonomic dysfunction and is inexpensive. It blocks neuromuscular transmission, interferes with catecholamine release from nerves and the adrenal medulla, reduces receptor responsiveness to released catecholamines, antagonizes the actions of calcium, and is an anticonvulsant and vasodilator.[30,31] Magnesium has been shown to reduce the requirements for other drugs used to control muscle spasms and cardiovascular instability in human tetanus patients.[30] Interestingly, electromyographic studies show that magnesium tends to spare the respiratory muscles, which is a marked advantage. Effective serum/plasma Mg concentrations are 5 to 10 mg/dL. An electrocardiogram should be monitored continuously and infusion discontinued if the width of the QRS complex increases by more than 25%.

ENSURE GOOD FOOTING. The affected animal should be moved carefully to a large well-bedded stall. Feed and water should be hung

VetBooks.ir

so that the animal does not need to lower its head. Horses and, theoretically, cattle, in danger of falling may be maintained in a body sling, tackle and girdle, stocks, or walking frame. Appropriate caution must be exercised to ensure that such procedures do not cause the patient to become frantic.

ELIMINATE THE INFECTION. Because *C. tetani* grows in nonvascularized sites, the infection is best eliminated by surgical débridement of the affected area. If a recent wound or other infection can be identified, it must be opened, cleaned, débrided, and flushed. Penicillin (22,000 IU/kg as procaine penicillin G IM bid) traditionally has been given to kill remaining *C. tetani* organisms and remains the drug of choice for food animals; however, there is a theoretical concern that penicillin has anti-GABA and proconvulsant activities.[32] Metronidazole is now the preferred antimicrobial[26] and has outperformed penicillin in two clinical trials of human patients. It can be given at 20 to 30 mg/kg PO every 12 hours (q12h) for 3 to 5 days. If the horse's condition precludes oral medication, give 40 to 60 mg/kg per rectum, or 10 to 20 mg/kg IV q6-8h (neonates).

NEUTRALIZE THE UNBOUND TOXIN. Tetanus antitoxin (TAT) can be infiltrated into the tissues around the lesion, although this procedure is not recommended in protocols for treatment of human tetanus.[3] Despite the lack of evidence for efficacy of large TAT doses, it is prudent to ensure neutralization of any residual unbound toxin by administration of at least 20 IU/kg IV, IM, or SC, repeated daily for up to 5 days. The results of intrathecal therapy as reported in small case series in horses have been inconclusive.[9,10,33] Although the data for human studies prior to 1991 were not supportive, meta-analysis of 12 more recent studies of both neonatal and adult cases detected a statistical survival advantage for intrathecal versus intramuscular TAT.[34] A suggested protocol is 400 to 1000 IU/kg by slow installation via the lumbosacral space including frequent cycles of aspiration of CSF into the loaded installation syringe in order to dilute the biologic before delivery. Alternatively, TAT can be infused into the AO cistern, but this route requires general anesthesia. Because of severe reactions to intrathecal equine serum in ruminants, intrathecal administration of equine-origin tetanus antitoxin is contraindicated.[24] Administration of TAT has been associated with acute hepatic necrosis in horses.[35,36] The first clinical sign of this potentially fatal adverse reaction may appear 4 to 10 weeks after administration of TAT and has been reported in horses that received TAT for treatment of clinical tetanus (see Acute Hepatitis in Horses, Chapter 33).

MAINTAIN HYDRATION AND NUTRITIONAL STATUS. The patient's hydration and food intake should be monitored daily. Food should be placed off the ground in an elevated feed bunk or hay net to allow easier access. Intravenous fluids should be administered as needed to correct dehydration and electrolyte abnormalities. Alimentation via a nasogastric tube may be attempted in horses with tetanus, but because of adverse reactions, supplementation via an indwelling esophagotomy tube or IV may be necessary. A 5- to 10-cm-diameter rumenostomy should be created in cattle with anything more than mild tetanus.[37] This has the dual advantage of relieving bloat and providing a portal for water and feed (usually alfalfa pellets).

ESTABLISH ACTIVE ANTI-TOXIC IMMUNITY. Clinical tetanus does not elicit a protective immune response. Affected animals should begin a primary toxoid series (see Prevention later).

Prognosis

The fatality rate for adult dairy cattle is up to 50% and, for horses, was 75% and 68% in the most recent North American and European series, respectively.[9,10,24] Outbreaks of tetanus associated with contaminated procedure wounds in small ruminants usually have high mortality rates (>80%). Most animals that die are recumbent by 24 to 48 hours after admission. In survivors, there is usually stabilization of signs by 2 to 7 days, with gradual recovery over the next several weeks. However, one horse reportedly remained stiff at 6 months but was normal at 9 months after onset of signs.

On the basis of various prognostic scoring systems used for human tetanus[26] and the few small large animal series published, negative prognostic indicators are incubation period less than 7 days, period of onset (time from first sign to first spasm) less than 2 days, umbilical or uterine entry site, no vaccination within the previous year, and presence of comorbid disease. Severe signs at presentation, recumbency, or initial rapid progression of clinical signs are all predictive of poor outcome.

Prevention

Because cattle are more resistant to tetanus than horses and small ruminants, they are not routinely immunized against the disease unless outbreaks have occurred previously.[24] Nonvaccinated adult horses should be given an initial two-dose series of tetanus toxoid administered 3 to 6 weeks apart. Protective responses are usually attained within 2 weeks after the second dose. Current recommendations are to give booster doses annually thereafter or additionally at the time of injury or surgical procedure.[38] Broodmares should be revaccinated 4 to 6 weeks before foaling to provide for colostral transfer of immunity to their foals. Passively transferred antibody suppresses the IgG response of foals to toxoid vaccination at 3 months but not 6 months of age.[39] Therefore it is recommended that foals from vaccinated mares be given a three-dose initial series beginning at 4 to 6 months of age, with a second dose 4 to 6 weeks later and the third dose at 11 to 12 months. Foals from nonvaccinated mares are vaccinated three times at 4-week intervals beginning at 1 to 4 months of age. Pregnant ewes and does should be boostered with *C. perfringens* types C and D/tetanus toxoid trivalent vaccine approximately 4 weeks before parturition to cover lambs and kids during the early high-risk period around common husbandry procedures.[40] Young replacement animals can be given a primary series of inoculations at 1 and 2 months of age and annual boosters thereafter.

Tetanus antitoxin is produced by hyperimmunization of donor horses with tetanus toxoid. Administration of one vial of antitoxin (1500 IU) to a nonvaccinated horse provides immediate protection that lasts for 2 to 3 weeks. Antitoxin is indicated in foals from nonvaccinated mares and in any wounded horse that has not been vaccinated within the previous year. In these cases, antitoxin and toxoid should be administered concurrently, with separate syringes at separate sites. Because the use of antitoxin is associated with hepatic necrosis (serum hepatitis) in a small number of horses, antitoxin should not be given in horses that are adequately covered by toxoid vaccination.

Spinal Abscesses

Lisle W. George

Definition and Etiology

Most abscesses of the spinal cord originate from a preexisting vertebral body osteomyelitis. The bone is usually infected hematogenously. Extension of bacteria from the lungs, heart, or a septic injection site is common. Neonates frequently develop vertebral abscesses secondary to septicemia.[1,2] Bone lesions may develop from sequestra broken from fractured vertebrae. Epizootics of spinal abscesses can result from injection of contaminated vaccines or mineral supplements near the spinal column. Similarly, spinal abscesses may be seen along with other diseases in groups of animals that are immunocompromised.[3] Infectious agents isolated from spinal abscesses of ruminants include *Corynebacterium pseudotuberculosis, Arcanobacterium pyogenes, Mannheimia haemolytica, Staphylococcus aureus,* and *Fusobacterium necrophorum.*[1,4-6] Agents typically found in vertebral infections of foals include β-hemolytic streptococci, *Salmonella* spp., *Actinobacillus equuli, Escherichia coli, Rhodococcus equi,* and *Klebsiella pneumoniae.*[6-10] In rare cases, septic arthritis of the atlantooccipital joint may result from extension of a mycotic guttural pouch lesion.[11,12]

If the infectious agent remains localized in the vertebral body, the patient usually shows signs consistent with a transverse myelopathy. If the infection erodes through the dura mater, the animal develops signs of septic meningitis. If the bone infection is extensive, the

VetBooks.ir

vertebrae may fracture suddenly, resulting in signs characteristic of spinal trauma.

Clinical Signs The neurologic deficits of animals with vertebral body abscesses without pachymeningitis are similar to those described previously for spinal fractures.[5] Animals with mildly compressive cervical abscesses show a characteristic "weather-vane" attitude, appear stiff, and are reluctant to eat food from the ground.[5,7,8] Ruminants with this lesion hold the neck in extension and attempt to prehend the food from the ground by using their tongue.[5] Additional signs of spinal abscess include heat, pain, swelling, or crepitus over the affected areas and associated signs of bacteremia. Abscesses in the thoracolumbar spine cause hindlimb weakness and ataxia of variable severity, from mild gait abnormalities to complete recumbency. Stud males may be unable to breed because of weakness and pain.[13] Differential diagnoses include trauma, aberrant parasite migration, tumor and pathologic fractures, hemorrhage into or around the spinal cord (e.g., postanesthetic myelopathy), myopathies, caprine arthritis-encephalitis, and fibrocartilaginous embolism.[14] Spinal abscesses can be mistaken for other painful conditions such as orthopedic disorders or traumatic reticuloperitonitis.[15]

Clinical Pathology and Radiographic Findings Radiographs are the best method for obtaining a definitive diagnosis of spinal abscess. A random pattern of lucency and increased bone density characteristic of osteomyelitis is seen in the affected vertebrae, with or without adjacent soft tissue mass lesions indicative of abscess formation.[16] Diskospondylitis usually results in detectable osteolysis in the intervertebral joints.[7] Nuclear scintigraphy can be used when the bone lesions are not well defined in plain film radiography.[17] In addition, myelography can be used to detect the specific site of the spinal cord compression.

A CBC may indicate the presence of a chronic inflammatory focus. Specific changes in the CBC include hyperfibrinogenemia, neutrophilia, monocytosis, nonresponsive anemia, and left shift. The plasma globulin levels are often increased in adults but may be increased or decreased in neonates, depending on the adequacy of colostral immunoglobulin transfer.

The changes in the CSF depend on the location of the abscess in the nervous system tissue and the meninges. In most cases the abscess does not infiltrate through the meninges, and the CSF is normal or shows xanthochromia and mild increases in the protein concentration (60 to 120 mg/dL), with mild to no increase in nucleated cell count.[18] The CSF of animals with pachymeningitis contains high numbers of WBCs (>100 neutrophils/μL) and a greatly increased protein concentration (>200 mg/dL). The CSF may clot after collection because of high concentrations of fibrinogen. Bacteria may be observed in a Gram-stained smear of CSF sediment. Spinal abscesses have been associated with *Brucella abortus* and *Mycobacterium bovis* in horses, so affected horses should be tested for exposure to these organisms.[19,20]

Pathophysiology Hematogenously derived abscesses arise because of embolization of septic thrombi into the metaphyseal arteries. These vessels have a sluggish blood flow because they become tortuous as they approach the physis. The metaphyseal vessels communicate with the ventral vertebral plexus, which in turn drains into the post cava, portal vein, and pulmonary veins. The ventral vertebral plexus does not have valves; blood flow reverses with an increase in abdominal or pleural pressure. Regurgitated blood from infected sites in the body cavities may shower the vertebrae and spinal cord with bacteria.[4,17]

Necropsy Findings The most common sites of involvement are the costovertebral and intervertebral articulations and the vertebral body epiphyses.[21] Lumbar vertebrae are frequently involved. The bone is uneven, deformed, and softened. The abscessed area is interspersed with calcified trabeculae and pockets of necrotic debris. Sequestration of necrotic bone may be seen in some cases. The meninges may be adherent to the abscessed site, and occasionally a fistulous tract may be seen from the center of the abscess pocket to the subarachnoid space. In other cases the abscess is compartmentalized away from the CSF, but the proliferating bone impinges on the spinal cord.

Treatment and Prevention If spinal abscessation is recognized early, prolonged antimicrobial therapy is generally effective. Selection of the appropriate antimicrobial agents should be based on the results of cultures from the patient's blood, urine, feces, and CSF. When bacteriologic culturing is inconclusive, a broad-spectrum antimicrobial should be chosen. Phenylbutazone, flunixin meglumine, or aspirin may be administered for pain relief. Immobilization of the head and neck in a fiberglass cast extending from the thorax to the nose may provide support to smaller patients with a cervical abscess. Surgical drainage of the abscess and curettage of the necrotic bone may be feasible in animals with sufficient economic value to justify the procedure.[10,22] Surgical intervention in adult cattle and horses is usually difficult because of the size of the epaxial musculature and inaccessibility of the spine in large animals.

Triaryl Phosphate Poisoning (Chronic Organophosphate Poisoning; Dying-Back Axonopathy)

Ingestion of lubricants containing triaryl phosphates causes a neurologic disturbance of livestock characterized by a delayed neuropathy resulting in incoordination and paralysis. Common sources of the triaryl phosphate esters include motor lubricants, hydraulic oils, industrial solvents, plasticizers, and automotive brake fluid. Chronic organophosphate poisoning also occurs in some families of sheep after treatment with organophosphorous anthelmintics.[1]

Triaryl phosphates have few effects on the glial cells,[2] but they have profound neurotoxicity for the longest axons.[3] These fibers degenerate first at the distal, nonterminal areas. The degenerative lesions then spread proximally from the terminal nerve rootlets into the spinal cord until the cell body dies (dying-back axonopathy). Dosages of triaryl phosphate ranging from 5 to 10 g/kg cause paralysis by 19 to 36 days after exposure.[4]

Clinical Signs The onset of slowly progressive neurologic signs occurs about 10 days to a few months after exposure.[5-7] The clinical signs of chronic organophosphate intoxication are rough hair coat, bloat, dyspnea, muscular weakness, and incoordination of the rear legs. The animals may slip on their hindlimbs and assume a dog-sitting posture. The limbs are circumducted and lack normal conscious proprioceptive responses. Affected animals become recumbent. When they attempt to rise, they do so incompletely and fall. Muscular tone and flexor reflexes may be normal, or flaccid paralysis may be evident.[6] The tail, bladder, and rectum are often paralyzed, and affected animals show signs of incontinence, constipation, and perineal scalding. Slight ventrolateral strabismus has been described, and some animals have been reported to become mute.[7,8] Most animals retain a normal appetite and sensorium during the development of the paralysis. Electromyographic changes in experimentally poisoned animals include increased insertional activity, positive sharp waves, and fibrillation potentials in the muscles of the hindlimb, consistent with denervation of affected muscles.[9] Organophosphate-induced neuropathy has also been reported in horses, where the most striking clinical sign was bilateral laryngeal paralysis.[10,11] Degeneration similar to that caused by delayed organophosphate toxicity in other species was most severe in the recurrent laryngeal nerves, but milder changes were present in other peripheral nerves.

Pathology Laboratory confirmation of the condition is usually based on histopathologic detection of a dying-back axonopathy. Clinical pathologic parameters are usually normal. The RBC

VetBooks.ir

cholinesterase is low or undetectable at clinical onset but may return to normal concentrations by the time the animals display profound paralysis. The specific concentration of cholinesterase depends largely on the type of organophosphate and the patient's genetic ability to metabolize the toxic compounds. Whole-blood cholinesterase concentrations in haloxon-treated esterase A–deficient animals remain significantly lower than in controls for at least 27 days after administration of 375 mg. In comparison, the enzyme concentrations in the plasma of normal sheep do not decrease after drug treatment.[12] Cholinesterase levels in exposed animals are not predictive of the later onset of delayed neurotoxicity.[7]

Macroscopic lesions are not usually seen. Microscopic lesions are found exclusively in the central nervous system, and their severity appears to be dose dependent. The lesions begin distally and progress retrograde along the long, unsynapsed proprioceptive and motor tracts. The dorsospinal, cerebellar, gracile, and cuneate tracts are most susceptible to the effects of the toxins.[9] Specific lesions include demyelination, internodal axonal swelling, and Wallerian degeneration. There is also a vacuolation of the large neurons of the ventral motor nucleus of the spinal cord. The mechanism of neurotoxicity is unknown, but alteration of a cell membrane protein found in neurons and some other cells has been implicated.[12-14] This protein has been designated a "neuropathy target esterase" and is thought to be "aged" by phosphorylation induced by the toxicosis.

Newer compounds in the triaryl phosphate group are less capable of causing delayed neurotoxicity, which offers some hope that the incidence of this type of toxicity may decline in the future.[14] Delayed organophosphate toxicity is not treatable and is irreversible.

Motor Unit and Cauda Equina Diseases

Botulism

Robert J. MacKay

Botulism is a highly fatal disease characterized by muscle flaccidity and progressive generalized paralysis. Death results from euthanasia or respiratory failure. Clinical signs are caused by the potent botulinum neurotoxin (BoNT), an exotoxin produced by the anaerobic, spore-forming, gram-positive bacterium *Clostridium botulinum*. Eight distinct antigenic types have been identified: A to G, with C1 and C2 subgroups.[1,2] All but C2 are BoNT toxinotypes. Two other clostridial species, *C. barati* and *C. butyricum,* also produce BoNT. Mosaic recombinant toxins, with either type C or type D light chains, designated BoNT/CD and BoNT/DC, have increasingly been identified in outbreaks of bovine botulism in Asia and Europe and likely are the dominant toxinotypes of animal botulism in Europe.[3,4] *C. botulinum* spores are ubiquitous in the soil and marine sediments of most regions of the world. In general, soil-origin botulism in large domestic animals in the United States is caused by BoNT/A and BoNT/B (and occasionally BoNT/C), whereas botulism caused by contamination of feed by animal carcasses is BoNT/C and BoNT/D. Botulism caused by *C. botulinum* type B is endemic among horses in Kentucky and in the mid-Atlantic states and accounts for most cases in the United States.[5] Almost all type A equine cases and outbreaks in the United States have occurred in western states, with Oregon and Idaho overrepresented.[6] Type C cases occur sporadically throughout the country, and type D botulism has rarely been reported in horses.[5] BoNT is acquired either by ingestion of preformed toxin (forage poisoning), germination of ingested spores in the GI tract (toxicoinfectious botulism), or contamination of wounds with spores and subsequent vegetative growth and toxin production (wound botulism).[6] Forage poisoning is the most common route of infection, although shaker foal syndrome, a form of toxicoinfectious botulism caused by *C. botulinum* type B, is endemic in the United States.[5]

Horses are much more susceptible to the effects of botulinum toxin than are cattle.[5] In fact, horses and humans are among the most sensitive mammals.[1] Botulism in horses typically affects one or a few members of a group. By contrast, the disease in cattle is usually in the form of outbreaks.[5] Increasingly, these outbreaks in cattle have been associated with ingestion of poultry litter.[7-10]

Pathogenesis The seven authentic BoNTs, BoNT mosaic toxins, and tetanus neurotoxin (TeNT) are closely related 150-kDa proteins that differ in receptor and substrate specificities.[1] Unlike TeNT, which is released alone, BoNTs are associated with a variable number of accessory proteins. It is believed that these proteins stabilize BoNTs during transit of the stomach and then may facilitate transport across intestinal epithelial cells. BoNTs are distributed hematogenously to bind to presynaptic cholinergic nerve terminals, most importantly at the somatic neuromuscular end plate. Tissue proteases activate the toxin by cleavage into light and heavy chains connected by a disulfide bridge. After receptor-mediated internalization of BoNT in endosomes, the light chain, which is a zinc endopeptidase, is released into the cytosol, where it inactivates the SNARE complex and thereby prevents docking and fusion of synaptic vesicles.[1] Vesicles containing acetylcholine are thus prevented from undergoing exocytosis and release of neurotransmitter at the neuromuscular junction. Flaccid paralysis of striated muscle is the main clinical result; however, there is also paralysis of smooth muscle and failure of parasympathetic effector functions. Once toxin is bound at the motor end plate, recovery is only possible by the sprouting of new axons and formation of new motor end plates, a process that requires weeks to complete.

Soil contamination of forage (including pasture) is the usual cause of botulism affecting one to several animals in the United States. In endemic areas of the United States this is almost always caused by BoNT/B; cases associated with type BoNT/A are also reported.[5,6] In small outbreaks or individual cases involving types C and D (or mosaic toxins), it is often not clear whether the source is carrion or soil contamination. Birds may play a role in carrying spores from a carcass to feeding areas.[5,11-13] Large outbreaks of food-borne botulism are of two types: germination of *C. botulinum* spores and bacterial growth in spoiled or moldy forage and point contamination of feed (forage or concentrate) by animal carcasses. Spoiled forage can be in the form of hay (especially large bales) or chaff or even grass clippings stored improperly or left out to rot, but usually it involves some type of improperly fermented forage.[5,14-16] Conditions of high pH, low oxygen, and high water content favor spore germination and toxin production.[17] Traditionally, small-grain silage (i.e., rye, wheat, oats, and barley) has been a common source of botulism for cattle,[18] but corn silage has also been implicated in several outbreaks.[13] The use of plastic film or bags to envelop (or encircle in the case of round bales) partially dried cut forage has become a popular way to produce and preserve silage and haylage for both cattle and horses. Unfortunately, plastic-wrapped forage has been the source of numerous outbreaks of botulism in both species.[5,18-20] These outbreaks have usually involved *C. botulinum* types B or A. In many cases, the plastic on the offending bale is found to be torn.[5] Accidental incorporation of an animal corpse into feed can have devastating consequences. For example, a single cat carcass that contaminated feed caused the deaths of 420 cattle.[5,21] Carcass-origin botulism is usually BoNT/C, BoNT/D, or, perhaps more often, either of the mosaic variants BoNT/DC or BoNT/CD.[14,22] Rodents can be caught in a grain auger and contaminate cereal grain or killed by hay mowers and incorporated into the center of bales. Poultry litter has become by far the most important source of carrion-based botulism. Processed broiler litter is widely used as a cheap source of nonprotein nitrogen in feed for beef cattle and as a fertilizer for pastures and hayfields. Accidental incorporation of chicken or rodent carcasses into these litter products has resulted in botulism outbreaks all over the world affecting up to 5500 steers in a single outbreak.[7-9,23,24] For this reason, feeding of poultry litter to cattle is now banned in Australia and guidelines are provided for resting of pasture after litter fertilization. Even free-ranging poultry were suspected as a source of botulism in outbreaks in dairy herds in the Netherlands.[25] Type D botulism in cattle has

VetBooks.ir

been associated with osteophagia (chewing on bones of decaying carcasses) by cattle deficient in phosphorus.[17]

C. botulinum can colonize the GI tract of normal infants or adult humans whose intestinal microflora has been disrupted by intercurrent disease or antimicrobial treatment. Shaker foal syndrome, an endemic form of toxicoinfectious botulism caused by *C. botulinum* type B, is of this type.[26] The peak age of occurrence of shaker foal syndrome is 4 weeks, with 70% of cases occurring between 2 and 6 weeks of age.[5] The juvenile equine GI tract, possibly influenced by putative risk factors such as a high milk intake, gastric ulceration, and heightened stress, is relatively hospitable to colonization and toxin production by the organism.[27,28] Toxin is detectable in the feces of approximately 30% of shaker foals, but only in the acute clinical phase of the condition.[5] Normal intestinal flora of mature horses presumably are inhibitory to colonization by *C. botulinum*.

Diagnosis Routine bloodwork is unhelpful, and abnormalities found are nonspecific.

Demonstration of botulinum toxin or spores is required for diagnosis. The level of diagnostic support ranges from definitive to presumptive for detection of the following: (1) botulinum toxin in serum, GI contents, or wounds; (2) antibodies against botulinum toxin in the serum of convalescent animals; or (3) *C. botulinum* spores in the GI contents or suspect feed materials. Toxin is detected by the sensitive mouse lethality bioassay and typed by mouse protection experiments. With mosaic toxins, mice may be protected by both type C and type D antisera, likely explaining why many outbreaks are recorded as involving both toxinotypes.[29] Detection of toxin in serum is only possible in animals with peracute onset and rapidly progressive clinical signs and is more likely in cattle than horses.[17] Spores are detected by inoculation of mice with culture filtrate after incubation of samples anaerobically for several days in enrichment media.[6] ELISA and real-time PCR tests have been used on enriched samples to detect and distinguish botulinum toxins or toxin genes, respectively.[3,30,31] Spores are found in the feces of approximately 34% of adult horses and 70% of foals affected with endemic type B botulism but are rarely detected in samples from normal foals or adult horses.[5] The presence of toxin antibodies in survivors has been used diagnostically in outbreaks of type C and D botulism in cattle in Australia[32] but lacked sensitivity when used in similar outbreaks in England and Wales.[33]

Needle electromyography and decremental responses to repetitive nerve stimulation can be used to support the diagnosis.[34,35] Typically, no obvious gross or histologic lesions are associated with botulism in most species.

Clinical Signs The severity and rate of progression of clinical signs are dose dependent. Horses given low (e.g., 10^3 mouse lethal dose units) or very high (e.g., 10^8 units) doses of BoNT display the extremes of the clinical spectrum of botulism.[36] The low dose may only cause dysphagia with some progression over 5 to 7 days, then recovery with minimal treatment. By contrast, the high dose causes recumbency within 8 to 12 hours and death within 48 hours of the first detectable signs. After high experimental doses, signs may begin as soon as 12 hours after toxin challenge, whereas cases may continue to develop for up to 14 days after removal of the suspect feed source when low amounts of toxin have been ingested.

Signs of dysphagia, lethargy, and generalized muscle weakness are the first indications of most naturally occurring cases. In horses, an early sign that can be exploited diagnostically is slow, clumsy prehension and swallowing of concentrates. Normally, bright horses require less than 2 minutes to eat 250 mL of sweet feed from a shallow pan; horses with botulism might take at least twice as long. Efforts to swallow are made with the head extended and seem exaggerated and prolonged; mixtures of food and saliva are retained in the cheeks, between the teeth, or drop out of the mouth. There are often thin trails of green-stained saliva from each nostril. Endoscopic examination of the nasopharynx usually reveals persistent displacement of the soft palate and aspiration of feed into the trachea. With progression, water runs freely from the nostrils during attempts to drink. Drooling of saliva in cattle is continuous, although the volume is usually not great, perhaps because of inhibition of saliva production by BoNT. In foals, dysphagia is evident during attempts to suckle as spillage of milk from the mouth and regurgitation through the external nares. Some horses present with colic, and most have reduced auscultable borborygmi. Affected cows have decreased strength and frequency of rumen contractions and firm feces.

Although animals showing the first signs of botulism may appear obtunded, it is facial muscle weakness and lack of facial expression that creates this impression. Even mildly affected animals tend to lie down more frequently than usual. With stimulation, such an animal may stand and initially walk quite normally before moving in a progressively more stilted and hypometric manner. When the patient is made to stand in one place, tremors may be apparent in the triceps muscles. As the disease progresses, tremoring spreads to other antigravity muscles and increases in intensity until the animal collapses into recumbency. Prominent, generalized tremors of this type in foals in the United States with endemic toxicoinfectious botulism gave rise to the descriptive name "shaker foal syndrome."

Tongue weakness is an important and consistent early clinical sign and, at least for type B botulism, a reliable indicator of impending limb weakness in at-risk cattle and horses. Tongue tone is assessed for this purpose as the ability of the animal to withdraw its tongue back into the oral cavity after the tip has been pulled out several inches through the interdental space. Another sign of myasthenia around the head is jaw "looseness," evaluated in cattle as lack of resistance to forced lateral movements of the lower jaw. Mydriasis and sluggish pupillary light reflexes are variable early signs; the prominence and persistence of these signs likely corresponds well with the dose and type of botulinum toxin ingested.

Between episodes of recumbency, moderately affected animals walk with a slow, shuffling, toe-scuffing gait and the head is held progressively lower.[22] Recumbent animals mount increasingly more ineffectual attempts to stand and often adopt unusual positions while recumbent; severely affected cattle often lie in sternal recumbency with both pelvic limbs extended caudally. Other animals lie in lateral recumbency with intermittent weak voluntary limb movements. Heart and respiratory rates rise during these struggles and, in some cases, respiratory efforts may seem labored, with a prolonged expiratory lift. Animals often die within 3 days of becoming recumbent. In survivors that remain standing, signs of limb weakness, dysphagia, and slow pupillary light reflexes completely reverse over several days to several weeks. Most persistently recumbent horses die, but in those that live and in the larger proportion of cattle that survive after becoming recumbent, efforts to stand typically resume after 1 to 4 weeks. Once such animals have successfully regained their feet, they remain standing for increasingly longer periods until recovery is complete weeks to months later. Generalized but reversible muscle atrophy may be evident in long-standing cases.

Differential diagnoses for horses include any disease associated with muscular weakness and dysphagia including infectious encephalomyelitis (equine protozoal myeloencephalitis; eastern, western, and Venezuelan equine encephalomyelitis; equine herpesvirus myeloencephalopathy; West Nile); generalized myopathy (nutritional, seasonal pasture, polysaccharide storage myopathy); equine motor neuron disease (EMND); grass sickness; hyperkalemic periodic paralysis; and heavy metal toxicity. Diagnostic ruleouts for cattle include hypocalcemia, hypokalemia, sulfur toxicity, listeriosis, epidural lymphosarcoma, and organophosphate toxicity.

Treatment Treatment involves nursing care and the use of specific anti-BoNT. Early treatment with specific antitoxin is a critical determinant of survival in horses. Eighty-nine of ninety-one untreated horses of various ages died with presumptive type B botulism,[36] whereas 27 out of 28 foals[26] and more than 70% of adults[36] survived when treated early with antitoxin. The trivalent antitoxin commercially available in the United States (*Clostridium botulinum* A, B, C TRIVALENT Antitoxin, Lake Immunogenetics, Ontario,

VetBooks.ir

N.Y.) covers cases typically seen in this country. Only one dose of antitoxin is necessary because the half-life of botulinum antitoxin (equine origin) is about 12 days in normal horses.[5] Unfortunately, antitoxin has minimal efficacy if used after the onset of recumbency in adult horses. The dose of antitoxin is 200 mL (≈20,000 IU) for a foal and 500 mL (≈50,000 IU) for an adult horse.[36] Clinical signs may progress for 12 to 24 hours after antitoxin administration. Horses with mild, slowly progressive disease may survive without antitoxin, as long as they are confined to stalls to restrict activity as much as possible.

Recumbent animals need to be kept on deep clean bedding and, if in lateral recumbency, need to be rolled to the opposite side several times daily. Bony prominences need to be padded with pillows or circular inflatable tubes in an effort to prevent decubital ulcers. Standing horses with prominent neck weakness may suffer life-threatening edema of the head and upper respiratory tract as a result of persistently hanging their heads near to the ground. This was noted to be a feature of the presentation during an outbreak of type C botulism in horses.[22] These horses need to have their heads supported above the level of the heart for several hours daily to allow mobilization of tissue fluid. Adults that are dysphagic can be fed and watered via an indwelling stomach tube. Thoroughly soaked and suspended complete pelleted feed (e.g., Equine Senior, Purina Mills, St. Louis, Mo.) can be fed indefinitely by this route. It is important to establish the patient's tolerance for bolus feedings and adjust volume and frequency of feedings accordingly. A reasonable starting point is 50% maintenance caloric requirement in 50 mL/kg water divided over 4 to 6 feedings. Caloric intake is progressively increased, and feeding frequency decreased as the animal's GI motility permits. Foals are initially fed at least 100 mL/kg of milk daily via this route, in 6 to 12 feedings, increasing to 200 mL/kg if tolerated. All recumbent animals must be in sternal position during feeding and remain sternal for at least 30 minutes after feeding. Patients without auscultable or other evidence of GI motility may be hydrated intravenously and may also be given intravenous parenteral nutrition. Recumbent adults that are being fed by nasogastric tube are at increased risk for large intestinal impactions and should be given 1 to 2 L mineral oil daily with feedings (or equivalent twice weekly) in an effort to lubricate digesta. Recumbent male horses including foals are prone to retention of urine and bladder distention and must be catheterized with meticulously clean technique at least twice daily to prevent pressure necrosis and failure of the bladder wall. Animals that are able to support their own weight when assisted to a standing position should be lifted several times daily by an abdominal sling and allowed to stand with sling support for brief periods (or simply helped to their feet in the case of small ruminants). Flotation tanks may be used intermittently for this purpose in recovering cattle, especially those that are limited by recumbency-associated peripheral neuropathies.

A minimal database of laboratory monitoring in recumbent horses with botulism should include daily hematocrit and total solids for hydration status, twice-weekly urine dipstick and specific gravity measurements to detect urinary tract infections and monitor hydration, and twice-weekly chemistry panels to assess organ function and electrolyte homeostasis. Total CO_2 values should be accorded particular attention. Values below 18 mEq/L indicate metabolic acidosis, whereas values above 35 mEq/L indicate significant metabolic alkalosis. The latter finding suggests compensation for chronic respiratory acidosis caused by respiratory paralysis or aspiration pneumonia and may prompt management changes such as improved sternal body position, frequent monitoring of respiratory function via arterial blood gas testing, or even initiation of mechanical ventilation. Foals with PaO_2 persistently below 65 mm Hg should be given humidified oxygen by nasal insufflation; those with $PaCO_2$ persistently above 60 mm Hg need to be mechanically ventilated. Of thirty foals with type B toxicoinfectious botulism admitted to a referral hospital and given antitoxin, 16 required nasal insufflation with oxygen and 8 of these foals also required mechanical ventilation.[26,37]

Antibiotics are generally used only to treat known infections (e.g., aspiration pneumonia or cystitis) or to prevent or treat bacterial sepsis in heavily instrumented foals. In cases in which wound botulism is suspected, the responsible wound must be opened, drained, cleaned, and débrided, following the same approach as is used for wounds associated with tetanus. Antibiotics such as metronidazole and penicillin G that are clostridiocidal are generally not recommended for treatment of wound or infant botulism in humans, out of concern that lysed organisms will release another pulse of BoNT into the circulation.[38] Presumably, pretreatment of large animal patients with antitoxin would remove this theoretical risk. Aminoglycosides should also be avoided if possible because they may potentiate the action of BoNT and were a significant risk factor for a subsequent requirement for ventilation in cases of infant botulism.[38] Because gastric ulcers were an important feature of the original postmortem descriptions of shaker foals,[27,28] such foals are usually on a regimen of acid suppression (e.g., omeprazole, 4 mg/kg PO once daily) and sucralfate (40 mg/kg PO every 6 hours), although the importance of this approach is unknown.

The rate of recovery from botulism depends on the toxin type and dose, the species and body weight of the patient, and the dose and timing of antitoxin. Dysphagic horses that are able to stand and are given antitoxin will gradually regain the ability to swallow over 1 to 14 days, with most cases resolving within 7 days.[5,36] Mydriasis usually resolves within several days, but the pupillary light reflexes may remain sluggish for weeks. Return to full limb strength often takes more than 1 month.[5,36] Few adult horses that become persistently recumbent recover unless they are provided meticulous nursing care, and most such horses should be euthanized. Decubital ulcers and secondary respiratory problems are the major complications. Recumbent foals that were treated with antitoxin and intensive care at a referral hospital were able to stand in an average of 7 days if they did not need ventilation and 10 days if they did.[26,37]

Prevention

BoNT/B toxoid (BotVax B, Neogen Corporation, Lexington, Ky.) is a safe and highly effective vaccine. The primary series is three inoculations, each 4 weeks apart, and then annual revaccination of broodmares 4 to 6 weeks before foaling to provide passive immunity to their foals. Although multivalent and BoNT/C toxoid vaccines for horses and cattle are available in many parts of the world, no vaccine of this type is licensed for horses in the United States.

Equine Motor Neuron Disease

Robert J. MacKay

Equine motor neuron disease is an acquired neurodegenerative disorder of the ventral horns of the gray matter of the spinal cord and selected brainstem nuclei.

History and Epidemiology

Equine motor neuron disease (EMND) was first reported in 1990 in 11 horses from 4 northeastern states.[1] Hundreds more cases occurred in the northeast section of the United States over the subsequent 20 years with many fewer cases scattered elsewhere across the country.[2,3] Additional solitary cases or outbreaks of EMND were reported in Great Britain, Canada, Ireland, Switzerland, Belgium, Japan, Brazil, and the Netherlands.[2-5] Annual incidence of EMND cases in the United States peaked in about 1997 and has now declined to low levels with less than one new admission annually to Cornell University College of Veterinary Medicine's Equine Animal Hospital.[6]

The disease usually occurs sporadically, with only one case on a given premise at any time; however, one or more additional cases have occurred on the same premise within 2 years of the original diagnosis.[2] An unusual cluster of more than 80 cases was seen among horses in a city police cavalry in Brazil during the 1990s.[2] The age range of reported cases is 2 to 27 years[3,7] with a mean of 9 years and estimated maximal risk at 16 years of age.[8,9]

In the United States, Quarter Horse breed and age,[8] duration of residence, lack of recent rabies vaccination, exercising in a dirt

VetBooks.ir

paddock, a history of cribbing or coprophagia, use of pelleted feed (alone or with sweet feed), and frequent supplementation with vitamin/mineral supplements lacking vitamin E/selenium were significant nutritional risk factors in multivariate logistic regression models.[9] Most important, after controlling for other significant risk factors, a strong negative association was demonstrated between vitamin E concentration and EMND risk.[10] Interestingly, 13/32 cases in Europe had part- or full-time exposure to pasture, yet all had low plasma vitamin E, suggesting that bioavailability of ingested vitamin E was low in these horses.[7] A horse in Finland developed EMND despite supplementation with 300 mg α-tocopherol daily for the previous 10 years.[11] In that case, daily supplementation with excessive amounts of iron was suggested as a possible cause. In the United States, horses with EMND that had normal access to pasture had enteric or hepatic disease, presumably resulting in malabsorption of vitamin E.[3,12]

Cause and Pathogenesis

EMND is a spontaneous, progressive, sporadic, even solitary, condition that closely resembles progressive spinal muscular atrophy, a variant of amyotrophic lateral sclerosis (ALS; Lou Gehrig disease) of humans.[8] Although sporadic ALS is likely multifactorial, it is widely believed that oxidative stress is involved in the final common pathways of neuronal injury. Evidence of systemic oxidant stress in horses with EMND includes the dominant involvement of oxidatively active type 1 myofibers in atrophied skeletal muscles and the abundant deposits of ceroid lipofuscin found in the retinal pigmented epithelium and in the endothelium of spinal cord capillaries.[3,13] Such deposits are thought to be the end products of peroxidation of membrane polyunsaturated fatty acids.[14]

In addition to the epidemiologic evidence for an association between hypovitaminosis E and EMND, the disease has been reproduced experimentally by prolonged feeding of vitamin E–deficient diets. After 21 to 28 months on a diet deficient in vitamin E but high in the pro-oxidant transition elements Fe and Cu, 4 of 8 horses developed clinical signs of EMND that were confirmed histologically.[15] In a separate experiment, 4 of 10 horses on the vitamin E–deficient diet but with normal Fe and Cu developed clinical signs of EMND after 18 to 37 months, and the remaining horses had histologic confirmation of the disease via peripheral nerve biopsy and/or necropsy.[16] Taken together, the results of these experiments and epidemiologic studies confirm that a diet low in vitamin E is a strong risk factor for EMND. Left unresolved is whether or not vitamin E intake is the *only* responsible nutritional or management factor influencing the development of EMND in these experimental horses and in other affected horses around the world.

Clinical Signs

The clinical signs of EMND reflect denervation of skeletal muscles. Signs of muscle weakness and atrophy dominate the clinical presentation.[2-4,12,15] Weakness may occur acutely in horses with (common) or without (uncommon) noticeable muscle wasting. In four horses that developed EMND when fed a vitamin E–deficient diet, there was mean weight loss of 92 kg at the time signs of limb weakness occurred.[2] In rare cases, the atrophy may advance insidiously without sudden weakness. Typically, there is acute onset of trembling in antigravity muscles and generalized sweating. Episodes of recumbency are frequent. When standing in one place, horses with EMND adopt a characteristic "horse-on-a-ball" stance with the limbs gathered close together under the body (Fig. 35-18).[17] Affected horses lack the strength necessary to engage the stay apparatus of the limbs when standing still; thus they constantly shift weight between limbs and have great difficulty standing in a confined area such as stocks. Acutely affected horses are more comfortable walking than standing, although even brief walking exercise may cause signs of distress such as sweating, tachypnea, and nasal flaring. Typically, at the walk, protraction phases appear somewhat short and hypometric. Horses with EMND do not have signs of ataxia such as interference between limbs or circumduction of the pelvic limbs.

In most horses with EMND, the head is carried below the shoulders, usually reflecting obvious wasting of the neck muscles.[2] The tail head is elevated in many cases because of atrophy and contracture of the dorsal coccygeal muscles.[2] If not present at presentation, widespread muscle atrophy develops quickly (days to weeks) and is most obvious in the quadriceps, triceps, and gluteal areas.

FIG. 35-18 Equine motor neuron disease in a 13-year-old Quarter Horse mare showing characteristic stance in which feet are placed close together under the body in a "horse on a ball" stance. Also note the generalized muscle atrophy, extended tail, and flared nostrils (indicative of severe exercise intolerance).

Despite the frequent occurrence of pathologic changes in the motor nuclei of cranial nerves V and XII, noticeable atrophy of the masseters or tongue has not been reported. The only clinical signs possibly ascribable to cranial nerve involvement are weak palpebral tone, dilated pupils, and sluggish pupillary light reflexes reported in a horse examined in the United Kingdom.[18]

In some 40% of cases, fundoscopic examination reveals a horizontal band of pigment above the optic disc at the tapetal-nontapetal junction.[2,14] The pigment may be brown-black to yellow-brown and has a reticulated or mosaic appearance. Surprisingly, problems with vision have not been reported even in EMND horses with severe pigment retinopathy.[14]

Laboratory Findings

Typical cases have below-range plasma/serum vitamin E concentration. However, as a stand-alone test, vitamin E is quite nonspecific[17]: Normal pasturemates of experimentally induced[15] or naturally occurring[12] EMND horses often also have low vitamin E. In healthy pasture-fed horses, vitamin E concentrations are variable during the day and often drop transiently below the normal range.[19] For this reason, it is recommended that plasma (or serum) from serial blood collections throughout the day be combined for the purpose of vitamin E assay.[19]

Mild to moderate increases in plasma or serum creatine kinase (CK) and aspartate transaminase (AST) activity are found during the initial rapid progression of clinical signs, but muscle enzyme activities may be normal in chronic stable cases.

Changes in cytology of cerebrospinal fluid are not seen in EMND; however, there may be increased total protein concentration and CK activity.[3,15] IgG index is high in many cases, suggesting the presence of intrathecally produced IgG.

Ancillary Tests

NEEDLE ELECTROMYOGRAPHY. Needle electromyography (EMG) can be performed in the standing or recumbent, anesthetized horse. Horses with EMND often have abnormal EMG findings including prolonged insertional activity and pathologic spontaneous activity such as fibrillation potentials and trains of positive sharp waves.[17] Signs of denervation are found in facial muscles, as well as appendicular and epaxial muscles.[3] Standing EMG is preferred in order to avoid anesthesia in weak compromised animals; however, interpretation of these studies is difficult because of movement

VetBooks.ir

artifacts associated with reluctance of affected horses to stand in one place. The use of sedation and caudal epidural anesthesia (lidocaine, 0.2 mg/kg) was reported to facilitate the procedure in a horse with EMND.[18] Techniques for quantitative analysis of motor action potentials have been published, and results are abnormal in horses with EMND.[20,21] Regardless of the EMG technique used, abnormal results are nonspecific as to cause, suggesting only denervation or myopathy.[17]

GLUCOSE ABSORPTION/METABOLISM. Oral glucose tolerance tests in horses with EMND were abnormal in approximately 50% of reported cases, whereas results of oral xylose absorption tests were normal or slightly low.[2,12,21] It appears that increased glucose metabolism, possibly associated with increased glucose sensitivity, rather than reduced intestinal absorption, is the cause of abnormal oral glucose tolerance in horses with EMND. Euglycemic clamp results from one horse showed a 5.4-fold increase in insulin sensitivity compared with control horses.[22]

NERVE BIOPSY. Biopsy of the ventral branch of the spinal accessory nerve allows reliable antemortem diagnosis of EMND, at least in subacute and chronic cases.[3,23] A 5-cm section of the nerve is excised as it courses over and into the medial belly of the sternocephalicus muscle. The procedure can be performed either in the standing or recumbent, anesthetized patient and does not induce visible muscle atrophy at the surgical site. A positive histologic result is evidence of mild to severe Wallerian degeneration of axons and Schwann cell proliferation. Chronic cases are marked by loss of myelinated fibers, presence of compact Büngner's bands, and increased endoneurial collagen. Positive predictive value of nerve histology for EMND was 77.4%, and negative predictive value was 90%.[23] False-negative results appeared to be most likely in acute cases (<2 weeks). Nerve biopsy has largely been supplanted as an initial test by evaluation of sacrocaudalis dorsalis muscle biopsies (see next section).

MUSCLE BIOPSY. The initial invasive procedure of choice is biopsy of the sacrocaudalis dorsalis tailhead muscle.[3,24] This muscle is rich in type I myofibers, a fiber type that is highly sensitive to the effects of denervation. The muscle sample is obtained under local anesthesia, placed on a tongue depressor, and sent chilled or in 10% formalin for histologic examination. There is neurogenic atrophy characterized by variable numbers of angular atrophied fibers. Atrophied muscle fibers are of both types, but type I fibers predominate. The use of muscle biopsy has high sensitivity for EMND (>90%) but relatively low specificity.[3] In chronic EMND cases, histology of nerve biopsy may have higher sensitivity for diagnosis than muscle histology.[3]

Diagnosis

Antemortem diagnosis of EMND is not usually difficult. It is based on typical clinical signs, age of 2 years or older, and diet low in green forage and high in carbohydrates. Needle EMG findings of denervation, especially in the deep limb muscles, are difficult technically because of movement artifact in weak horses but are supportive of the diagnosis as are mild to moderate increases in plasma CK and AST activity and low plasma vitamin E concentration. Finally, evidence of denervation in muscle or nerve biopsies in the context of the preceding clinical and laboratory findings is tantamount to a definitive diagnosis of EMND. Occasionally, in cases of insidiously progressive EMND, especially in nonendemic areas, diagnosis is only made postmortem.

Necropsy Findings

Although there is obvious weight loss in horses with EMND, fat deposits noted postmortem are usually within normal limits.[1,4,24] In acute cases, there is widespread degeneration and loss of somatic motor neurons in the ventral horns of the spinal cord accompanied by degenerative axonal changes in the ventral roots and peripheral nerves. All brainstem cranial nerve somatic motor nuclei, except those of cranial nerves III, IV, and VI, are variably involved. Most affected neurons are swollen, markedly chromatolytic, and diffusely argyrophilic while severely affected neurons are shrunken or vacuolated. In chronic burnout cases, there are glial scars consisting of astrocytes and lipofuscin-laden microglia. Additional deposits of ceroid lipofuscin are found in the retinal epithelium and occasionally in the liver and intestine. Relatively minor neurodegenerative changes may be found in dorsal root ganglia. By contrast with grass sickness, there are minimal or no lesions in the autonomic nervous system. In skeletal muscles, there is angular atrophy of all myofiber types with some selectivity for type I fibers. Atrophied fibers are intermingled among normal fibers and fascicles. Involvement of the deeper muscles of the limbs may be grossly evident as pale discoloration.

Treatment

The only treatment recommended for horses with EMND is vitamin E. This can be supplied in good-quality grass and alfalfa hay or by vitamin E supplementation (at least 10 IU/kg). Natural vitamin E (RRR-α-tocopherol) has higher bioavailability and potency than synthetic vitamin E (all-rac-α-tocopherol acetate or dl-α-tocopherol). Although vitamin E treatment appears logical, there has been no clinical trial that has evaluated the efficacy of treatment.

The frequent clinical observation that many EMND horses have increased appetite may be explained by an estimate that daily caloric requirement of horses could be doubled.[17] Thus as part of the convalescent program of surviving horses, high quantity and quality of pasture, hay, and concentrate is recommended.

Clinical Course

Within 6 weeks after onset of signs, approximately 40% of horses progressively deteriorate and are euthanized while a similar number undergo marked improvement in clinical signs (usually following relocation to another premise and /or administration of antioxidants).[2] These "recovered" horses look normal but may recrudesce under the pressure of intensive training or competition.[1] In the remaining 20%, the disease appears to "burn out" and such horses survive with permanent and obvious muscle wasting and emaciation.

Acquired Equine Polyneuropathy (Scandinavian Knuckling Syndrome)

Robert J. MacKay

A disease characterized by bilateral knuckling of pelvic limbs has been observed in Sweden, Norway, and Finland and is sometimes referred to as *Scandinavian knuckling syndrome*.[1,2] Polyneuropathy with inflammatory demyelination and Schwann cell inclusions has been reported in affected horses.[2] The cause of the disease is unknown, although an ingested neurotoxin is considered most likely. Clinical signs appear mainly in late winter to spring, and almost all affected horses have been fed wrapped forage (haylage/silage). Affected horses in Sweden and Norway have clustered within farms and all cases on a particular farm occurred within 100 days of the index case on that farm.[1] As of 2012, no outbreak had occurred in Sweden since 2009, whereas several outbreaks every year have occurred in Norway. The clinical signs are bilateral pelvic limb weakness, with hyperflexion and collapse of the limb and knuckling, such that the dorsum of the hoof contacts the ground. Surprisingly, there is no or only slight atrophy of digital extensor muscles. Mild and inconsistent thoracic limb weakness has been described in a few cases. Apparently there is no cutaneous sensory or proprioceptive component to the disease, and cranial nerve abnormalities are not found. Approximately one third of affected horses become recumbent and do not recover. Survivors in a recent case series fully recovered in a median 7 months, and all horses recovered within 19 months.[1] Acquired equine polyneuropathy was less prevalent in horses older than 12 years, and young horses had a higher chance of survival than older horses. An apparently similar syndrome, termed *idiopathic peripheral*

VetBooks.ir

polyneuropathy, has been reported in horses in Japan.[3] Affected horses are severely affected in all limbs.

Polyneuritis Equi (Neuritis of Cauda Equina)

Robert J. MacKay • Mary O. Smith

Definition and Etiology Polyneuritis equi (PNE) is a progressive granulomatous polyradiculoneuritis involving the cauda equina and, less commonly, cranial nerves and other spinal nerves.[1-4] The disease usually occurs in adult horses,[2] although it has been described in a yearling filly.[5] No breed or gender predilection has been noted.[6]

The cause of PNE is unknown. The lesions are characterized by heavy infiltrations of cytotoxic T cells and macrophages with lesser populations of helper T cells, B cells, and plasma cells.[1,7] This pathology is similar to experimental allergic neuritis of rats, coonhound paralysis of dogs, and Guillain-Barré syndrome in humans, all of which are suspected of having an autoimmune basis.[1,8] Other proposed etiologies include a hypersensitivity reaction after systemic infection, aberrant migration of helminth larvae, and association with equine herpesvirus type 1, equine viral arteritis, or adenovirus infections.[5,6,9,10] However, conclusive evidence for any of these theories is lacking.

Clinical Signs The clinical signs of PNE reflect destruction of somatic and autonomic lower motor neurons and sensory neurons at the level of the nerve roots and dorsal root ganglia. Vague signs of dysuria and tail rubbing may precede the neurologic syndrome.[1] The onset of acute signs is marked by cutaneous and muscular hyperesthesia around the hindquarters, focused on the tailhead. Rubbing and chewing of this area is characteristic. Over days to weeks, there is progressive desensitization of previously hyperesthetic areas until the skin over the caudal rump, tail, perineum, and caudal thighs becomes anesthetic. At least initially, there may be a zone of residual hypersensitivity around the margins of the desensitized skin. There is progressive paresis of the tail, bladder, rectum, anal sphincter, and penis with neurogenic atrophy of the muscles of the tail. Fecal retention and overflow urinary incontinence reflect paralysis of rectal and detrusor muscles, respectively. Urine dribbling causes scalding and staining of the perineum (in mares) and hindlimbs. In males the penis may remain dropped out of the sheath, although penile and preputial sensation is preserved. Impotence resulting from incomplete erection and inability to achieve intromission was the presenting complaint in one stallion with PNE.[11] In some cases, involvement of the lumbosacral nerve roots causes variable weakness and ataxia of the pelvic limbs and atrophy of muscles of the rump or legs. Any spinal nerve root may be affected symmetrically or asymmetrically, so discrete areas of muscle atrophy, cutaneous desensitization, and sweating are possible anywhere along the spine. Weakness and ataxia have been observed in all four limbs of a few horses.[12-14]

Cranial nerves can be involved. The signs depend on the individual nerves affected and the severity of the disease. The nerves most often affected are the motor division of the trigeminal (atrophy of chewing muscles), the facial (facial paralysis), and the vestibular (head tilt and ataxia), although signs due to involvement of cranial nerves XII (tongue weakness and atrophy), III (reduced pupillary light reflex), IX, and X (dysphagia) have also been reported.[9,12-14] Signs of cranial nerve involvement are usually asymmetric.

Any disorder that affects the cauda equina may cause similar signs. These include instabilities of the caudal spine caused by luxations or fractures, EHM, sorghum-sudan intoxication, rabies and other infectious diseases that involve the cauda equina or sacrocaudal spinal cord segments, and some primary diseases of the lower urinary tract.

Diagnosis CSF may have a moderate mononuclear pleocytosis with lesser numbers of nondegenerate neutrophils and high protein concentration. Electromyographic abnormalities occur in PNE as a result of denervation of affected muscles. Horses with PNE have high circulating antibodies to P2 myelin basic protein, but this test is not available commercially and is reported to be nonspecific.[15,16] The diagnosis was supported in one case by the finding of an intense mononuclear neuritis in a biopsy from the sacrocaudalis dorsalis muscle.[1] Thickened sacral nerves were also imaged by transrectal ultrasonography in this horse.

Necropsy Findings The cauda equina is thickened, discolored, and covered with edematous tissue and fibrous material. There may be adhesions of the nerve roots or the spinal cord to the meninges and the periosteum of the vertebral canal. Subdural or epidural petechiation and hemorrhage are sometimes seen.

At the microscopic level the major finding is granulomatous inflammation of the extradural and intradural parts of the nerve roots. The nerve sheaths are thickened and infiltrated to varying degrees by lymphocytes, plasma cells, lymphoblasts, macrophages, giant cells, eosinophils, and, in rare cases, neutrophils. Nerves are obliterated by intraneural inflammation, necrosis, and endoneurial thickening. Axonal degeneration and demyelination are present in surviving nerves. Nerve bundles are separated by large amounts of fibrous tissue. There is minimal to moderate evidence of nerve regeneration.

Treatment and Prognosis Treatment with corticosteroids at antiinflammatory doses early in the course of the disease may be palliative but is not curative. Immunosuppressive gold salts and cytotoxic drugs such as azathioprine have been used for the treatment of PNE, but the efficacy of such approaches has not been reported. General supportive care should be given including fluid therapy when necessary, and the rectum and bladder must be emptied manually and by catheter, respectively. With careful management, affected horses can be kept alive for months but the prognosis for extended life is still regarded as hopeless with the usual cause of death being euthanasia for humane reasons.

Sorghum Toxicity

Robert J. MacKay • Mary O. Smith

Definition and Etiology A syndrome of ataxia and cystitis in horses, cattle, and sheep has been linked to the consumption of annual grasses of the genus *Sorghum*.[1-4] Incriminated species have included *Sorghum bicolor* (sorghum), *Sorghum sudanense* (sudangrass), sorghum-sudan hybrids, and *Sorghum halepense* (Johnson grass, oxgrass). The causative toxin is not known, although there is evidence supporting a role for chronic cyanide toxicity.[5] This disease does not appear to be linked to the breed, gender, or age of an animal.[3]

Clinical Signs The first sign observed is usually ataxia of the pelvic limbs, followed by urinary incontinence. Affected animals have a swaying pelvic limb gait and a tendency to knuckle in the fetlocks. Occasionally, affected horses may walk with a hopping gait, in which both pelvic limbs are lifted off the ground simultaneously. Signs in horses tend to worsen on backing, and animals may fall or even become recumbent.[3] During an outbreak of the disease in cattle, 3 of 54 affected cows became recumbent and 2 died.[6] The perineal muscles are relaxed, and urine dribbles from a flaccid, distended bladder.[4,6] In mares the vulva opens and closes repeatedly; in stallions and geldings the penis is relaxed and protrudes from the prepuce.[7] There may be paresis of the tail in affected horses and cattle. Loss of skin sensation over the hindquarters has been described in a cow, suggesting involvement of both sensory and motor nervous pathways.[6] Headshaking, ataxia, weakness, recumbency, opisthotonos, and death have been reported in sheep, and mortality can approach 50%.[8]

Cystitis in affected animals may be severe and occurs secondary to urine retention. Dribbling of urine onto the skin of the perineum

VetBooks.ir

and pelvic limbs results in scalding of the skin and dermatitis. Pyelonephritis is a common sequela to chronic cystitis and may be fatal.[2,3] Sometimes the clinical signs may be chronic; in one outbreak, horses had been showing signs for as long as 3 years.[3]

Abortion in mares, arthrogryposis as a congenital deformity of foals and lambs, and neurologic abnormalities in newborn lambs have also been linked to the feeding of *Sorghum* plants.[3,8]

Clinical Pathology Diagnosis of sorghum toxicity is made by the presence of typical clinical signs in association with a history of feeding *Sorghum* plants. No specific diagnostic test is available. Cystitis and pyelonephritis are identified by typical findings on routine urinalysis, serum biochemistry, and urine culture.

Pathophysiology The precise nature of the toxic substance in *Sorghum* plants that causes this syndrome is unknown. Most *Sorghum* spp. are cyanogenic plants that contain the cyanogenic glycoside surrina, which, when hydrolyzed, releases hydrocyanic acid at potentially toxic concentrations.[1] Acute, sometime fatal, cyanide toxicosis has been described in cattle that ingest large amounts of rapidly growing sorghum.[9,10] Chronic exposure to cyanide has been suggested as the cause of the neuropathologic changes found in animals with ataxia-cystitis syndrome.[3] Experimental long-term dosing of potassium cyanide to goats caused histologic changes in the CNS that were comparable with those seen in the natural disease.[5] It has also been suggested that the toxic principle in *Sorghum* plants may be a lathyrogen-like substance.[2]

Epidemiology The cyanide content of *Sorghum* plants is increased by rain after drought and higher in new shoots and wet plants.[1] In one survey of the disease in horses, most cases occurred during the wet season and involved young, growing plants.[3] The period of grazing before the onset of signs ranges from 1 week to many months.[3,6]

Necropsy Findings Wallerian degeneration, swelling of axons and myelin sheaths, and demyelination in a small number of nerve fibers throughout the length of the spinal cord and in the cerebellum, cerebellar peduncles, and pons have all been described, together with the presence of phagocytic gitter cells. In lambs grazing sorghum, there were also lesions in the ventral horn gray matter of the spinal cord.[3,6,8] These changes are not associated with specific tracts. Ultrastructural studies of brains and spinal cords of affected sheep have revealed that the axonal swelling (spheroids) are composed of aggregates of neurofilaments, mitochondria, vesicular bodies, and dense bodies, enclosed within a thin myelin sheath.[8]

Treatment and Prognosis Withdrawal of *Sorghum* plants from the diet of affected animals results in a gradual improvement in the clinical signs over weeks to months, although recovery may not be complete.[6,8] Death is a potential outcome, however, and mortality can be high in some cases.[8] There is no specific treatment for affected animals. Supportive therapy includes antibiotics for treatment of bacterial urinary tract infections.

Control Avoidance of feeding *Sorghum* plants as a predominant part of the diet or the sole diet is the only method of control. This plant has considerable feed value and should not present a major hazard when used as part of a diversified feeding regimen.

Stringhalt

Robert J. MacKay

Stringhalt is a condition of horses characterized by sudden exaggerated flexion of one or both pelvic limbs during the swing phase of locomotion. Two distinct syndromes are recognized: *classical stringhalt,* a persistent condition of individual horses involving only one limb, and bilateral or Australian stringhalt, which involves both pelvic limbs and occurs in outbreaks in horses at pasture. Both forms occur worldwide, but *bilateral stringhalt* is most common in Australasia, South America, and the western United States.[1-5]

FIG. 35-19 Bilateral hyperflexion of the pelvic limbs in a horse with pasture-associated (Australian) stringhalt.

Clinical Signs The defining clinical sign of stringhalt is abrupt hyperflexion of the hock and stifle during attempted movement. In classical stringhalt only one limb is affected; by contrast, Australian stringhalt is almost always bilateral, although signs may be asymmetric (Fig. 35-19). Stringhalt is most evident during backing, sharp turning, when going down a slope, after a sudden stop, and during the transition from standing still to walking forward.[2,6] Signs may be exacerbated by excitement, cold weather, or hard exercise.[2,7] The clinical presentation of stringhalt varies greatly, even among horses with bilateral stringhalt grazing the same pasture. In mild cases flexion is only slightly exaggerated and pelvic limb action may be completely normal at gaits above the walk. Such horses are able to perform without impairment. At the other end of the spectrum, the upper joints of the limb flex so violently that the dorsum of the fetlock slaps against the horse's abdomen with each stride.[6] When the condition is bilateral, the result is a bouncing bunny-hopping gait in which "progression can only be accomplished with a series of bounds and plunges extremely painful to witness."[4,8] In the most severe cases, movement is impossible. An atypical bilateral stringhalt syndrome is described wherein the forelimbs are also involved and there are signs of generalized weakness.[1,2,4,9,10] Nine of seventy horses with stringhalt studied in France had signs of obtundation or increased aggressiveness.[11] A variable proportion of horses with bilateral stringhalt have abnormal laryngeal movement, stridor, or abnormal vocalization.[4,5,11,12] Onset of stringhalt is usually sudden. Signs may fluctuate but tend to worsen over several weeks in horses with bilateral stringhalt, before plateauing, often for several months, then beginning to improve.[2] Within 2 weeks after onset of severe bilateral stringhalt, atrophy of the muscles of the gaskin and, less obviously, the thigh and other parts of the body, becomes apparent.[2,13] Horses with severe or atypical bilateral stringhalt may develop profound generalized neurogenic muscle atrophy that results in marked weight loss despite normal appetite and food consumption.[10]

Clinical Pathology No abnormal clinical pathologic findings are associated with stringhalt. Electromyography of affected muscles reveals increased insertion activity and abnormal spontaneous activity such as fibrillation potentials and positive sharp waves consistent with denervation.[2,12] Nerve conduction velocity is slowed in the peroneal nerves of affected limbs, indicating demyelination, and improves as animals recover clinically.[2]

Pathophysiology The cause of classical stringhalt is unknown. Foot conditions and articular lesions of the hock or stifle are possible

VetBooks.ir

risk factors.[4,6,14] Trauma to the proximal dorsal metatarsus, particularly over the digital extensor tendons, often precedes classical stringhalt and likely is an important factor in the development of this form of stringhalt.[2,4] Months may elapse between injury and the onset of stringhalt.[15]

Since 1884,[8] most reports of bilateral stringhalt have implicated the common pasture weed *Hypochaeris radicata* (also known as flatweed, castear, cat's ear, or false dandelion).[†] Most outbreaks occur in late summer or autumn among horses grazing drought-damaged pastures heavily infested with *H. radicata*. Cases often occur following weeks to months of grazing on suspect pastures.[8,11] Interestingly, some affected horses are thought to have developed a taste for flatweed, to the exclusion of other forage.[11] Several outbreaks have been associated with "true" dandelion *(Taraxacum officinale),* and one has been associated with mallow *(Marva parviflora).*[1,4,16] Attack rates during bilateral stringhalt outbreaks are usually less than 50% but vary widely.[2,7,11] Some attempts at producing bilateral stringhalt by feeding cut *H. radicata* to horses have been unsuccessful; however, recently, stringhalt was induced in a 6-month-old colt fed a daily average amount of nearly 10 kg *H. radicata* harvested from a pasture where the disease had occurred.[3]

Bilateral stringhalt is a distal neuropathy primarily affecting large myelinated axons of the peripheral nervous system.[13,17] The longest nerves in the body—namely, the recurrent laryngeal nerves and the peroneal and tibial branches of the sciatic nerve—appear to be most severely affected. This also explains why tall horses are more prone to the condition than young horses, ponies, or small native Chilean breeds.[16] Shetland ponies have been affected, however.[7] The lesions of bilateral stringhalt are consistent with ingestion of a neurotoxin produced by either pasture weeds such as *H. radicata* or, less likely, by associated fungi.

It is likely that bilateral stringhalt and some cases of classical stringhalt result from interference with myotatic reflexes.[15] The immediate cause of pelvic limb hyperflexion in bilateral stringhalt is presumably progressive degeneration of large myelinated axons in tibial and peroneal nerve branches including α motor neurons to skeletal muscle, 1A and 1B sensory neurons from muscle spindles and Golgi tendon organs, and γ-efferents to muscle spindles. Classical stringhalt may be the final common sign for a variety of insults: besides interference with limb reflexes, mechanical effects of adhesions involving the muscles and tendons of the digital extensors of the pelvic limb may be important, as well as painful conditions of the hock or distal limb.

Pathology In long-standing cases of bilateral stringhalt there is variable, often severe, atrophy of the muscles of the pelvic limbs, especially distally, and atrophy of the muscles of the larynx supplied by the recurrent laryngeal nerves.[1,10,17] In peripheral nerves there are decreased numbers of myelinated fibers, perineural fibrosis, and accumulation of myelin debris. Evidence of nerve regeneration including regenerating nerve clusters, onion bulbs, and Schwann cell proliferation is usually found. Recurrent laryngeal nerves, branches of the sciatic nerves, and variably other nerves are affected with a proximal to distal gradient of severity.

Treatment Care should be taken to identify sources of pain (e.g., arthritis, hoof abscess, recent hoof trimming) that might account for stringhalt-like signs. Signs of stringhalt were blocked in one horse by intraarticular anesthesia of the distal tarsal joints; use of intraarticular corticosteroids permanently resolved the problem.

Several skeletal muscle relaxants have been investigated in horses with bilateral stringhalt. Phenytoin, an inhibitor of voltage-gated sodium channels, gives partial to complete remission of signs in horses given 10 to 15 mg/kg PO, once or twice daily.[2,10,12] Mephenesin, which acts in the spinal cord to specifically inhibit polysynaptic reflexes, suppressed signs in a horse with chronic bilateral stringhalt[6] but was ineffective in an outbreak of bilateral stringhalt.[1] Baclofen, an analogue of the inhibitory neurotransmitter GABA, had no effect in a horse with severe stringhalt.[7,12] Taurine (10 mg PO q24h) may help behavioral abnormalities.[11]

Although the results of the procedure are unpredictable, surgical removal of the distal muscle belly and tendon of insertion of the lateral digital extensor effects a clinical cure in a proportion of horses with either classical stringhalt or bilateral stringhalt.[3,4] Of four horses with classical stringhalt treated with lateral digital extensor myotenectomy, two resolved and the other two improved partially. The surgery was precluded in two other horses because of adhesions involving the tendon.[15] Responses to a survey of veterinarians in Australia indicated that more than 50% of over 100 lateral digital extensor surgeries had been successful in eliminating signs of stringhalt.[2] Even more impressively, 11 of 13 horses with bilateral stringhalt were normal within 12 days of surgery.[5] The surgery can be performed standing or in lateral or dorsal recumbency. An initial skin incision is made over the lateral digital extensor tendon immediately proximal to its junction with the long digital extensor, and the tendon is isolated and exposed. A second incision is made over the muscle belly proximal to the hock, and the muscle belly is dissected free of overlying fascia. The tendon is severed through the distal incision and then the tendon is pulled through its sheath into the proximal incision by exerting traction on the muscle. The muscle belly is then incised 2 cm proximal to the musculotendinous junction. A modification of the technique, which may improve success rate, removes 7 to 10 cm of muscle. After the fascial and skin layers have been closed, a bandage is applied over the surgical site and maintained, with box stall rest, for 2 to 3 weeks.

Prognosis There is almost no information on outcomes for horses with classical stringhalt; however, it is commonly supposed that most cases persist, although they may improve with time. Of one series of four cases that developed after proximal dorsal metatarsal trauma, one recovered, two improved, and one was unchanged for at least 6 months after onset of signs.[15] Many cases of bilateral stringhalt recover normal gait and muscle mass if removed from toxic pasture. In a series of 70 cases followed over several years in France, 36 recovered in an average of 8 months, with 6 deaths, and 14 still had stringhalt signs at least 2 years after onset.[11] The few reported deaths are in horses that are either unable to stand or unable to move to sources of water and feed and are euthanized for humane reasons. Recovery times of 3 days to 3 years have been recorded, with most horses taking 6 to 12 months.[2,6] It is unclear to what extent athletic performance returns after clinical recovery from severe bilateral stringhalt. There is evidence that laryngeal dysfunction may persist beyond the time of recovery from gait abnormalities.

Tick Paralysis

Robert J. MacKay

Definition and Etiology An ascending lower motor neuron paralysis has been described in foals, a Miniature Horse adult, sheep, calves, and pigs in Australia, associated with feeding by ticks of the genus *Ixodes,* especially *Ixodes holocyclus.*[1-6] In the United States a similar disease occurs in dogs, humans, cattle, New World camelids, and wild animal species as a result of infestation with several *Dermacentor* spp.[7,8] A similar problem occurs in small ruminants in Africa, where *Ixodes rubicundus* and *Rhipicephalus evertsi* are the tick species implicated.[9-11]

Clinical Signs Progressive generalized flaccid paresis develops over one to several days, terminating in recumbency. Death from respiratory paralysis may occur in as little as 24 hours in severe cases.[6] Animals may be found recumbent or may be paraparetic and ataxic in the early stages of disease. When signs are mild to moderate, differential diagnoses include a variety of neurologic and nonneurologic diseases such as botulism, rabies, colic, uterine torsion, trauma,

[†]References 1, 3, 4, 7, 10, 11, 14.

VetBooks.ir

myelopathies, myopathies, and metabolic disorders. Of these, only botulism progresses to the profound muscular flaccidity seen in tick paralysis. Reflex withdrawal from a noxious stimulus and the blink reflex are both reduced to absent, although sensory function appears normal.

Tick paralysis may be fatal when caused by *I. holocyclus* even when ticks have been removed. By contrast, paralysis caused by *Dermacentor* spp. is usually reversible if the ticks are removed before the animal is moribund.

Diagnosis Diagnosis is made on the basis of the clinical signs and finding ticks on the affected animal. There are no pathognomonic findings in affected animals except for the presence of ticks on the patient. Electromyography in tick paralysis in dogs in North America reveals minimal spontaneous activity and lack of evoked compound muscle action potentials in response to motor nerve stimulation.[12] Findings in large animals can be expected to be similar. Cerebrospinal fluid is normal in tick paralysis, helping to differentiate it from some, but not all, myelopathies.

Pathophysiology The cause of tick paralysis is believed to be a neurotoxin in the saliva of female ticks that is inoculated into the host when the tick feeds. Nymphs and larvae in large numbers may also cause the disease. In the case of *I. holocyclus* the toxin has been named *holocyclotoxin.*[13] The toxin(s) elaborated by *Dermacentor* spp. has (have) been less well characterized. The toxin acts by inhibiting release of acetylcholine from nerve terminals at the neuromuscular junction.

Epidemiology The disease occurs worldwide, associated with different tick species in different areas. In North America the region from the Pacific coastal range to the Continental Divide provides especially favorable conditions for the proliferation of *Dermacentor andersoni.*[8] Tick paralysis in the United States and Canada occurs mainly in the Pacific Northwest and the Rocky Mountains, although the geographic range of the responsible tick species is much larger. The disease tends to be seasonal in North America, with most cases occurring in the spring, when ticks are most active. Smaller animals such as sheep and New World camelids are more often affected than cattle, probably because they receive a larger dose of the tick neurotoxin relative to their body size.[14] Tick factors probably influence disease severity, and genetic variation within *I. holocyclus* may play a role in toxin potency.[15] A short-lived immunity has been demonstrated in dogs exposed to ticks. Tick paralysis is most common in the early part of the season and in younger animals, suggesting that a similar phenomenon may occur in other species.[14]

Necropsy Findings There is no pathognomonic finding at necropsy, although the presence of ticks should increase suspicion of this disease. Death usually results from respiratory paralysis.

Treatment and Prognosis Treatment is symptomatic after removal of the tick(s), which is essential. Lack of improvement suggests that ticks remain on the animal, except in cases of *I. holocyclus* infestation, where signs persist and may worsen for 1 to 2 days after removal of all ticks. Spraying or dipping affected animals facilitates tick removal. In small animals, shaving the hair coat may be necessary to ensure detection and removal of all ticks. Areas such as the axillae and groin, in particular, provide good sites of attachment for ticks. The prognosis is good in the case of *Dermacentor*-induced paralysis when tick removal and supportive care are instituted before animals are moribund. Fatalities occur in cases of *Ixodes*-induced paralysis despite removal of ticks. Cooling of the patient has been suggested in treatment of *I. holocyclus* toxicity, but this practice is controversial and a better approach may be to avoid warming the patient excessively.

Administration of hyperimmune serum has been shown to be beneficial in the treatment and prevention of this disease in dogs and in one llama.[16] Adverse reactions such as anaphylaxis, bradycardia, and hypotension occur in a small number of dogs and cats treated with hyperimmune serum, but these can be avoided by premedication of atropine.[17] No report of such treatment in other species was found.

Control Environmental control to reduce tick populations and routine use of acaricides may decrease the incidence of tick paralysis.

Equine Grass Sickness

Robert J. MacKay

Grass sickness is a debilitating, often fatal, dysautonomia of equids associated with full-time access to pasture.[1] Because lesions are also found in somatic lower motor neurons, it has been suggested that it is more accurate to describe grass sickness as a polyneuropathy rather than a dysautonomia. A comparable fatal polyneuropathy has also long been recognized in the Patagonia region of South America, where it is known as "mal seco."[2] Equine grass sickness (EGS) is endemic in Scotland, England, and Wales and has also been reported from Western Europe, Cyprus, the Falkland islands, and Colombia with isolated cases in Australia, Ethiopia, and the United States.[1,3-5]

Epidemiologic studies conducted since the early 1970s have identified high horse density, full-time grazing, a recent change in pasture or premises, previous occurrence of the disease on the premises, lack of hay in the diet, pasture disturbance, mechanical removal of horse manure from pastures, sandy or loamy soils, recent deworming with ivermectin, and good bodily condition as risk factors.[1,6-13] Cases occur throughout the year with peak numbers in the spring and a smaller peak in the autumn. The risk of disease was highest in horses aged 2 to 7 years (peak 5 to 6 years), although cases have been reported in horses from 2 months to 27 years of age. Horses of all breeds, ponies, donkeys, Przewalski's horses, and zebras are all affected. Males and females are equally represented in recent surveillance data. Protective factors included contact with previous cases, daily feeding of hay or haylage, chalky soil, manual removal of feces from pastures, pasture grass mowing, and co-grazing with ruminants.

Cause and Pathogenesis Theories as to the cause of EGS have included mineral or vitamin deficiencies or exposure to toxic plants, secondary metabolites and trace minerals in pasture grass, insects, mycotoxins, viruses, or bacterial toxins.[14,15] Although the clinical syndrome of EGS has not been reproduced experimentally, the characteristic neuropathology has been induced by administration of serum from acute cases into the peritoneal cavity or parotid salivary gland.[16,17] The activity was found in a greater than 30-kD fraction of serum but was not further characterized.

Since the 1990s, a hypothesis has been developed that EGS is a toxicoinfectious form of botulism involving a type C strain commonly carried by birds.[18] Strong support for this hypothesis has been (1) the demonstrated association between EGS and the presence in ileal contents of *Clostridium botulinum* type C and type C1 neurotoxin (BoNT/C)[18]; (2) the observation that horses with EGS have significantly lower serum antibodies to *C. botulinum* and BoNT/C than do pasturemate controls[19,20]; and (3) presence of rising titers of specific IgG antitoxin in chronic EGS cases. *C. botulinum* type C is unique among clostridial organisms in that its major toxin, BoNT/C, possesses potent and nonspecific neurotoxicity in vitro, probably via action on cellular syntaxin.[18] It has been hypothesized that toxin production and absorption occur in the ileum due to overgrowth from normal intestinal flora and/or to spore germination in association with *nutritional or environmental triggers* involving factors such as changes in feed, pasture, and weather conditions and parasite status.[1,3] An EGS pilot study involving use of a *C. botulinum* type C vaccine in 100 horses is under way, and its results will be used to design a larger trial of approximately 1000 horses, beginning in 2013.

VetBooks.ir

Clinical Signs The major clinical signs of grass sickness reflect dysfunction of the autonomic nervous system, particularly of the gastrointestinal tract.[1,21] There is dysphagia, gastric and small intestinal dilation, nasogastric reflux, colonic impaction, and colic. Clinical presentations are classified as acute (course of <48 hours), subacute (2 to 7 days) and chronic (>7 days).[22] Since 2000, 66% of reported cases have been acute or subacute, with 34% classified as chronic.[1] Acutely affected horses may be found dead or in abdominal crisis with signs of colic, tachycardia, generalized sweating, nasogastric reflux including spontaneous nasal regurgitation of stomach contents, absence of intestinal borborygmi, and abdominal distention. Rectal palpation and transabdominal ultrasonography reveal distended loops of small intestine and gas-filled large bowel. Affected horses are unable to swallow food or water, and thick ropy saliva may drool from the mouth. Fine muscle fasciculations similar to those seen with equine motor neuron disease may affect the triceps and quadriceps. Horses with subacute EGS survive long enough to develop colonic impactions and secondary large intestinal tympany. Chronic EGS may develop insidiously, and only a minority of these cases show mild, intermittent colic. There is patchy sweating and/or piloerection on the neck, flanks, and behind the shoulders. Typically, the appetite is reduced and there are varying degrees of difficulty in chewing and swallowing; however, salivation, accumulation of fluid in the stomach, and impaction are not usual features. There is often bilateral ptosis with ventral deviation of the eyelashes secondary to loss of sympathetic eyelid tone. Because of suppression of normal nasal secretions there is a characteristic dry crusty nasal exudate (rhinitis sicca). Fecal production is reduced, and feces are unusually firm and small. There is rapid and severe weight loss.

Acute and subacute cases are invariably fatal. Death occurs from gastric rupture, circulatory compromise, cardiopulmonary failure, or, most commonly, euthanasia. Before the 1980s, it was thought that chronic EGS was usually fatal or associated with hopeless emaciation. EGS is unlikely to recur in recovered horses.[12]

Diagnosis Definitive diagnosis requires histopathologic examination of autonomic neurons for chromatolytic changes.[1] Antemortem, the sample of choice is an ileal biopsy, which is typically obtained during exploratory celiotomy of horses presenting with signs of colic. Nasal and rectal biopsies have been investigated for diagnostic accuracy but are currently regarded as unreliable for diagnosis in the live horse.

There is no confirmatory blood test for EGS. Nonspecific abnormalities are consistent with severe dehydration, hypovolemia, stress, loss of GI secretions, and anorexia.[23] Peritoneal fluid protein concentration may be high, although nucleated and red cell counts are usually normal. Serum concentrations of numerous acute phase proteins including α2 macroglobulin, serum amyloid A, ceruloplasmin, haptoglobin, and orosomucoid are high, but such changes are not specific to EGS.[24]

In EGS cases with ptosis, topical application of 0.5 mL 0.5% phenylephrine eyedrops results in normalization of the eyelash angle within 30 minutes and is supportive of the diagnosis.[25]

Treatment and Prevention All cases of acute and subacute EGS are considered incurable and therefore require euthanasia on humane grounds as soon as possible after diagnosis. Treatment of selected chronic cases involves excellent nursing care and provision of palatable, easily swallowed food and high energy concentrates. Clinical recovery occurs in about 70% of preselected treated cases.[1]

Current efforts at prevention involve minimization of known risk factors and introduction of suspected protective practices. Thus in endemic areas, horseowners are advised to avoid exposure to pastures where previous cases have occurred, minimize disturbance of pasture or soil, prevent overgrazing of pasture, and avoid the "overuse" of ivermectin dewormers. On the other hand, owners are encouraged to co-graze horses with ruminants, mow pastures regularly, remove feces by hand, and supplement pasture feeding with hay or haylage. These practices are particularly important during seasonal and climatic risk periods, as well as for young horses in good bodily condition, especially those recently imported.

Necropsy Findings Gross necropsy findings in horses with EGS include esophageal ulceration, fluid distention of the stomach and small intestines, impaction of the large colon and/or cecum, and the presence of inspissated mucus within the small colon and rectum. Subacute and chronic cases do not have gastric and small intestinal distention but do have variable degrees of large intestinal impaction and often rhinitis sicca.[21] Histologic lesions of neuronal degeneration are most evident in the autonomic ganglia, gut wall nerve plexuses, brain, and spinal cord.[22,26] There is chromatolysis, nuclear eccentricity, nuclear degenerative changes, cell death and neuronophagia, cytoplasmic vacuolation, and spheroid formation.

Peripheral Nerve Disorders

Robert J. MacKay • Lisle W. George

Most peripheral nerve disorders of large animals are traumatically induced, but injections, abscesses, tumors, and parasitic invasion of the nerves may occur in rare cases. Damage to nerves fall into two major functional categories.[1] Type 1 injury refers to loss of function without loss of axonal continuity. Type 2 injury represents damage to axonal structures such that Wallerian degeneration of the axon ensues distal to the site of injury; the proximal axonal segment and the cell body remain intact. Retrograde degeneration of the proximal nerve occurs if connectivity is not reestablished.

Type 1 or *neurapractic* lesions are characterized by a failure of conduction of the action potential across the injured axonal segment. The pathologic basis for these reversible injuries could be nerve compression, damage to the myelin sheath, or alteration of the functions of the axonal cell membrane or its channel proteins. Type 2 injuries are characterized by axonal interruption, or *axonotmesis*. If there is also disruption of components of the connective tissue sheath and axon, the process is termed *neurotmesis*. Immediately after axonotmetic injury, the distal axonal segment is competent to conduct action potentials; however, within 3 to 8 days after injury, the distal segment degenerates and no longer responds to electrical stimulation. In this way, *neurapractic* (type 1) and axonotmetic (type 2) injuries of greater than 8 days' duration can be theoretically distinguished. After axonotmesis of motor nerves, muscle reinnervation occurs by two separate mechanisms: collateral sprouting and axonal regrowth. If there is incomplete loss of axons to a muscle, surviving motor axons generate sprouts from their nerve terminals, which can establish competent junctions with adjacent denervated muscle units. Reinnervation of muscle units by this process occurs within days to weeks. However, if the motor axons to a muscle are severed, reinnervation occurs by growth of collateral sprouts from the proximal stump. Axonal sprouts grow at a rate of 1 mm per day (≈1 inch per month). Because of progressive fibrous replacement of denervated muscle and retrograde degeneration of the proximal parts of affected motor neurons, it has been suggested that reinnervation may not be possible if more than 12 months have elapsed since the original injury. However, reinnervation surgery has been successful when performed on human patients 20 years or more after denervation.[2]

Large-diameter myelinated fibers are most sensitive to compression forces. The largest axons (sensory axons) including afferent fibers conveying touch-pressure, vibration, and proprioception are usually damaged first (resulting in ataxia or inappropriate limb placement); second, the large myelinated motor axons are compromised; third, the smaller axons are affected, which carry cutaneous and deep mechanoreceptor sensory information; last to be lost are the smallest-diameter fibers transmitting pain sensation.

The following section discusses the peripheral nerves most often damaged in large animals.

VetBooks.ir

FIG. 35-20 Sweeney (neurogenic atrophy) of the left supraspinatus and infraspinatus muscles in a Quarter Horse gelding. The lesion was caused by trauma related to running into a fencepost 2 months previously.

Suprascapular Nerve

Mechanical damage to the suprascapular nerve results in paralysis of the infraspinatus and supraspinatus muscles.[3] Such injuries occur most commonly when the animal collides at speed with gateposts, trees, or other objects.[4] Acute injury or local anesthesia of the suprascapular nerve is characterized by outward bowing and/or "popping" of the scapulohumeral joint as weight is placed on the limb. Neurogenic atrophy develops after 2 to 4 weeks, and the scapular spine becomes prominent (Fig. 35-20). The common name for this condition is "sweeney."

Brachial Plexus

Damage to the brachial plexus may result in any combination of dysfunction of the radial, pectoral, axillary, musculocutaneous, median, and ulnar nerves, although radial nerve signs usually dominate.[5,6]

Lesions of the brachial plexus are caused by trauma to the shoulder with or without scapular or rib fracture, deep penetrating axillary wounds, neoplasia or bacterial cellulitis, or forced extraction of a fetus to relieve a dystocia.[7] Because of their tendency to move at high speeds, horses are most susceptible to brachial plexus injuries. The condition may occur in small ruminants after automobile accidents, carnivore attacks, or blows from larger animals.

Avulsion of the brachial plexus results in complete flaccidity, lack of reflexes, and desensitization of the affected thoracic limb. Disruption of the origins of the cervical sympathetic trunk in the caudal aspect of the plexus results in ipsilateral Horner syndrome. With lesser injuries there may be abduction of the elbow (pectoral nerve), dropped shoulder (subscapular), hyperextension of the elbow (musculocutaneous), or signs of radial paralysis (next section).[8]

Radial Nerve

The radial nerve provides motor input to a flexor of the shoulder and extensors of the elbow, carpal, and digital joints. The nerve courses over the lateral aspect of the elbow joint and is vulnerable to traumatic insult at that point. Radial nerve paralysis arises from injury to the T1 nerve root or nerve from vertebral or rib fracture, as part of a brachial plexus injury, as a result of humeral fracture, from direct trauma to the nerve over the elbow, as part of an ischemic myoneuropathy during prolonged anesthesia, or during restraint in lateral recumbency with inadequate padding of the forelimb.[7,9-11]

With radial paralysis, the limb position varies, depending on the location of the lesion in the radial nerve. Lesions at or near the elbow joint are characterized by dropped elbow, inability to protract the limb, scuffing of the toe, and flexion of all distal limb joints (Fig. 35-21). The foot is knuckled over at rest, and the animal is unable to bear weight on the leg. Lesions distal to the elbow cause knuckling of the carpus, fetlock, and pastern joints, but the animal can support weight on the affected limb if the metacarpus and distal limb are held in extension. The triceps reflex is depressed to absent. After weeks of radial denervation, there is atrophy of the extensor muscles of the thoracic limb. Detectable sensory deficits resulting from radial nerve paralysis tend to be vague and probably vary from patient to patient.

FIG. 35-21 High radial nerve paralysis in a horse showing knuckling of the carpus and digit and dropped elbow.

Kangaroo Gait in Sheep

A locomotor disorder predominantly involving the thoracic limbs of lactating ewes has been reported in New Zealand, Australia, Scotland, and northern England.[12,13] There is knuckling and paresis of the thoracic limbs suggestive of radial paresis and a high-stepping forelimb gait. In advanced cases the pelvic limbs are also involved. Limited necropsy data suggest both CNS and peripheral nerve involvement.[14,15] Affected ewes are usually of large breeds and nursing twins. Most recover after weaning their lambs. Affected sheep are usually grazing mixed forage, often with some concentrate supplementation. A clinically identical condition has been reported in Israel and in Australia among sheep grazing the legume fenugreek.[16] A causative toxin or nutritional deficiency is suspected for both kangaroo gait and fenugreek staggers, but no toxin has yet been identified.

Femoral Nerve

The femoral nerve is distributed to the quadriceps femoris muscles and the skin of the rear limb over the medial thigh. Traumatic overextension of the hip and stifle joint from a fall or other injury or forced posterior delivery of a fetus can damage the femoral nerve(s).[17] The nerve courses too deeply to be directly affected by an external blow to the pelvic limb; however, it can be damaged by ilial, femoral, or vertebral fractures. Ischemic injury caused by prolonged stretch or increased tissue pressure during anesthesia in dorsal recumbency may cause bilateral femoral neurapraxia.[18] A similar presentation, presumably caused by compression of lumbar spinal branches by the foal in the birth canal, is seen in mares after severe prolonged dystocia.

VetBooks.ir

The clinical signs of femoral nerve paralysis are related to an inability to extend and fix the stifle.[3] The reciprocal apparatus is unable to fix the stifle and hock, resulting in collapse of the limb during weight bearing and constant flexion of all distal digital joints. The hoof usually remains flat on the ground. Chronic femoral denervation causes atrophy of the quadriceps femoris muscles. The patellar reflex is absent or depressed, and the patella is often displaced laterally. There is hypoesthesia to anesthesia of the medial part of the rear limb extending from the proximal thigh to the medial malleolus of the tibia.

Sciatic Nerve

The sciatic nerve is the largest nerve in the body and innervates the extensor muscles of the hip, flexor muscles of the stifle, and most of the muscles of the distal limb. Sciatic nerve paralysis occurs most often in postpartum cows after forced fetal extraction.[19] Injury to the sixth lumbar nerve proximal to the lumbosacral plexus is the usual cause of so-called calving or obturator paralysis syndrome. Injection of irritating drugs into the space between the greater trochanter and the ischial tuberosity may cause a sciatic neuritis.[20] This occurs most frequently in young animals but can occur rarely in adult cattle and small ruminants. Other causes of sciatic nerve damage are pelvic fractures, sacroiliac or coxofemoral dislocations, tumors, or abscesses located along the course of the nerve. Sciatic neuropathy is a rare complication of sacroiliac joint injections in horses.

The sciatic nerve innervates most of the musculature of the rear limb, so the motor deficits associated with denervation are profound. At rest the limb hangs behind the animal. The stifle is dropped and extended, and the hoof rests on its dorsum (Fig. 35-22). If the limb is positioned properly, the animal usually can bear some weight because of the normal function of the quadriceps muscles and the action of the reciprocal apparatus. Chronic sciatic denervation results in neurogenic atrophy of the caudal thigh muscles and all of the muscles distal to the stifle.

The sciatic nerve divides into the tibial and the peroneal nerves in the distal limb. Therefore except for the medial part of the thigh and gaskin, there is hypoesthesia and anesthesia of the entire limb distal to the stifle.

FIG. 35-22 Characteristic posture of a foal with partial sciatic nerve paralysis. The condition pictured here was induced during correction of a severe dystocia. Not the flexion of the hocks, fetlocks, and stifle. The signs were the result of an intramuscular injection in the gluteal area.

Peroneal Nerve

The peroneal branch of the sciatic nerve is distributed to the flexor muscles of the hock joint and the extensor muscles of the digit. The nerve becomes superficial and is exposed to damage as it crosses over the lateral condyle of the fibula immediately distal to the stifle. Peroneal paralysis of this type is seen in all species of large animals and is common in postpartum dairy cattle that have been recumbent as a result of hypocalcemia or other causes and in horses because of postanesthetic ischemic myoneuropathy. There is hyperextension of the hock joint and flexion of the fetlock and pastern, and the dorsum of the hoof usually rests on the ground[3,21,22] (Fig. 35-23). Affected animals can bear weight when the limb is manually placed in the proper position. There is desensitization of the skin over the craniolateral aspect of the limb extending from the stifle to the hoof.

Tibial Nerve

The tibial nerve supplies the extensor muscles of the hock joint (i.e., the gastrocnemius) and the digital flexors. Tibial paralysis is most often observed in periparturient cattle or neonates that have been given an injection of an irritant drug in the caudal leg at the level of the stifle. Tibial paralysis is also seen in sheep and goats and is a common sequela to dog-bite injuries. The resting limb is held more flexed than is normal, and, although the foot contacts the ground in normal position, the metacarpophalangeal (MCP) joint often partially collapses into a flexed position (i.e., "knuckles"). The limb moves in stringhalt-like fashion, with exaggerated flexion of the tarsus and stifle during protraction, followed by sudden extension to the weight-bearing phase of the stride. At rest the pelvis is asymmetric, with the affected side held lower than normal.[3] Chronic loss of tibial nerve function results in atrophy of the gastrocnemius and digital flexor muscles. There is anesthesia of the skin of the caudomedial aspect of the leg.

Obturator Nerve

The obturator nerve supplies the adductor muscles of the pelvic limb. The nerve is well protected in the horse and small ruminants, so injury is rare in these species. By contrast, because the cow has a relatively shallow acetabulum and poorly developed round ligament, the obturator nerve and the lumbar branches that supply it are vulnerable to injury during forced extraction of a calf to relieve a dystocia. Reports of obturator nerve paralysis of cattle accompanied by

FIG. 35-23 Calf with peroneal nerve paralysis. Note the flexed fetlock and digit and the hyperextended carpus. This condition was caused by injection of antibiotics into the peroneal nerve on the caudolateral aspect of the leg.

VetBooks.ir

FIG. 35-24 Cow with obturator nerve paralysis caused by relief of a difficult dystocia. Note the basewide stance, yet the apparent ease with which the cow is able to stand on the deep bedding. Note also that rope hobbles are being applied to prevent further abduction and trauma.

knuckling and inability to support weight on the rear limbs probably represent a combination of sciatic and obturator nerve dysfunction. Coxofemoral dislocation is a common complication of obturator paralysis in cattle housed in stalls with slippery flooring.

Obturator nerve paralysis is most common in cattle and is almost exclusively a result of dystocia. The nerve injury is located in the pelvis at the level of the obturator foramen. Of all dystocias in dairy cattle, 9.2% result in paraplegia.[23] The obturator nerve innervates the adductor, pectineus, and gracilis muscles. Only minimal effects are seen if the cow is placed on a surface that has good traction. Clinical signs of an obturator nerve injury include a hopping pelvic limb gait when the animal attempts to run and severe pelvic limb abduction or splay-leggedness when the animal stands on a slippery surface (Fig. 35-24). In severe cases the cow may be sternally recumbent with the pelvic limbs extending laterally to each side. Experimental studies have indicated that the so-called calving paralysis syndrome is actually a result of a combination of injuries to the obturator nerve and to the sixth lumbar spinal nerve (L6), a major contributor to the sciatic and obturator nerves. Experimental sectioning of the obturator nerve alone does not produce paralysis, provided the animal has secure footing.[3,19,24] Obturator nerve paralysis does not result in a cutaneous sensory deficit.

Compression damage to one or more peripheral nerves during parturition or milk fever is a frequent factor in the so-called downer cow syndrome (see later discussion). The incidence of the condition ranges from 4% to 28% of all cases of milk fever and, before the advent of flotation tanks for treatment, was associated with a mortality rate of 20% to 67%.[25,26]

Peripheral Facial Nerve Paralysis

Facial paralysis is common in horses but uncommon in other large animals. Depending on the site of damage, some or all of the facial muscles can be affected. Complete unilateral facial paralysis in horses is evident as deviation of the nose toward the normal side, reduced flaring of the ipsilateral nostril during inspiration, and ipsilateral drooping of the lip, eyelid, and ear. Reflexes involving cranial nerve VII, such as the lip, eyelid, menace and ear reflexes, are reduced or absent. Inability to close the eyelid causes exposure keratitis, which may be particularly severe when there is damage to the secretomotor fibers of the facial nerve at or proximal to the geniculate ganglion (keratitis sicca). The tongue protrudes out of the paralyzed side of the mouth, often erroneously suggesting a problem with lingual function. Because of paralysis of the buccinator cheek muscle, boluses of feed accumulate between the cheek and teeth from where they may be dropped from the mouth. With chronic facial denervation in horses neurogenic atrophy of the parotidoauricularis muscle becomes apparent as a groove behind the vertical ramus of the mandible. In cattle, because of the rigid structure of the planum nasale, muzzle deviation is not seen. In small ruminants, subtle muzzle deviation can usually be appreciated.

Injury to the facial nerve proximal to the vertical ramus of the mandible causes full facial paresis. Proximal facial nerve trauma in horses is usually caused by fractures of the vertical ramus of the mandible, stylohyoid bone, or petrous temporal bone (after a blow to the head or as a complication of temporohyoid osteoarthropathy). Damage within the facial canal is often associated with concurrent signs of vestibular nerve damage such as head tilt, nystagmus, and circling. Tear production may also be reduced or absent. Hemorrhage into the middle/inner ear, otitis media/internal guttural pouch mycosis, and parotid lymph node abscessation each can involve the adjacent facial nerve, causing ipsilateral facial paralysis. Distal facial nerve damage is usually due to direct injury from a blow or lateral recumbency or strangulation by a tight-fitting halter. The nerve or its branches are often damaged as they cross the mandible and/or zygomatic arch. Facial paresis following recumbency during general anesthesia is common and usually involves only the nose and/or lips. Similar conditions occur in goats and are caused by excessive pull on neck chains while the animal is being led onto the milk stand or tied with the neck chain. In cattle, facial nerve paresis is usually the result of space-occupying masses at the caudal aspect of the mandibular ramus.

Most animals with facial nerve paralysis caused by trauma have neurapractic (type 1) nerve injury and recover within 2 weeks; those with type 2 (axonotmetic) injuries regrow axons from the site of injury at the rate of about 1 inch per month, so several months may be required for full resolution. Occasionally the paralysis is permanent. In chronic cases, food should be removed from the cheek pouches twice daily and the tongue and fauces should be routinely examined for ulcers. If present, oral ulcers should be treated by flushing the mouth.

Treatment

The objectives of medical treatment of peripheral nerve injury are (1) reduction of swelling and inflammation at the site of injury, (2) support and stabilization of the denervated area, and (3) maintenance of the general health of the animal.

In the case of lacerating trauma, the general principles of wound management apply. The wound should be cleaned, irrigated, débrided, and dressed and ventral drainage established. If severed nerve ends are visible, they can be tagged for later identification and surgical repair. Medical therapy for inflammation and swelling should be initiated, especially if there is obvious tissue swelling. This may include any combination of a cyclooxygenase inhibitor (e.g., flunixin meglumine, 1.1 mg/kg IV, IM, or PO once or twice daily); dimethyl sulfoxide (DMSO; 1 g/kg as a 10% solution IV or by nasogastric tube once or twice daily); and a glucocorticoid (e.g., dexamethasone, 0.05 mg/kg IV or IM once daily). An additional antiinflammatory effect can be provided by cold water hydrotherapy or local application of skin-permeant drugs such as DMSO or diclofenac. In the presence of an open wound or other risk for bacterial infection, broad-spectrum antimicrobial therapy should be initiated. This can be directed by culture results, if available. Fractured or dislocated bones that have the potential to further injure nerves must be reduced and stabilized. Stall rest is helpful to prevent further injury. In the case of paralyzed limbs, a protective wrap may be necessary to prevent damage caused by dragging or improperly placing the limb. A support wrap, splint, or light cast should be maintained on a leg

VetBooks.ir

affected with radial paralysis so as to prevent limb contracture. A heavy support wrap, possibly with additional fetlock support, should also be placed on the opposite limb to protect against breakdown caused by prolonged increased weight bearing. If the horse has difficulty alternating between recumbency and standing, it should be supported as needed in an abdominal sling (horses and small ruminants) or flotation tank (cattle) until it is able to rise unassisted. Because of the buoyancy provided by water, affected animals (usually horses) may be able to exercise affected limbs in swimming pools. Skin over bony prominences should be padded to prevent decubital injury; such injuries must be treated aggressively if they occur.

If possible, passive range-of-motion exercises should be performed on paralyzed limbs in an attempt to preserve joint flexibility and prevent contracture. Faradic or galvanic electrical muscle stimulation, acupuncture, and hyperbaric oxygen therapy are other procedures advocated for treatment of peripheral nerve injury. Calcium gluconate can be given empirically to down cows (500 mL SC daily), as may potassium chloride (100 g in 20 L of water given daily by stomach tube). Abduction of the rear limbs may be prevented in cattle by application of a hobble around the metatarsus. The distance between the legs should be approximately 35.6 to 50.8 cm (14 to 20 inches) when the legs are tied together and held abducted. It is important to apply the hobbles with a nontightening bowline knot to prevent strangulation of the foot.

Surgical procedures for repair of peripheral nerves are beyond the scope of this text but are described elsewhere. External neurolysis refers to the dissection of the nerve from a bed of scar tissue.[1] This is indicated if there is obvious compression from fibrous tissue, and it is performed routinely in horses with suprascapular neuropathy.

Down Cows (Alert Downers)

John A. Angelos • Bradford P. Smith

Down cows, downer cows, or downers are cattle that are recumbent and cannot stand; those that can maintain sternal recumbency while continuing to eat and drink are classified as "alert downers." Common underlying causes of recumbency in cattle include severe mastitis, metritis, musculoskeletal disease (primary musculoskeletal injuries including fractures and torn muscles/tendons), neuropathies secondary to pelvic trauma (calving paralysis), spinal cord compression (e.g., secondary to lymphosarcoma), and metabolic disease (hypocalcemia, hypokalemia, hypophosphatemia, hypomagnesemia).[1] Following the initial episode of recumbency, secondary muscle and nerve injury caused by extended periods of recumbency on a firm surface may further exacerbate the recumbency. Heavy cattle down on concrete are particularly susceptible to pressure ischemia of the muscles and nerves and to muscle and ligament tearing secondarily to repeated struggling and slipping. The severity of pressure damage depends on the nature of the surface on which the animal is recumbent and the duration of compression.

Identifying underlying causes for recumbency in downer cattle represents a diagnostic challenge for the practitioner. Assessing prognosis and determining reversibility of the underlying condition are necessary for practitioners to assist producers in making treatment decisions, as well as to conform to laws and abide by ethical norms surrounding humane handling of down animals. In short, dragging of down livestock is considered inhumane, and down livestock that are in distress or that do not respond to treatment should be humanely euthanized.

Pathogenesis and Laboratory Findings Laboratory testing for metabolic causes of recumbency would be ideal in all circumstances, but this is often not feasible or possible. As such, many downer cattle are treated empirically for suspected metabolic abnormalities and response to treatment aids in establishing the diagnosis. Periparturient downer cows should be treated for hypocalcemia with one or more doses of calcium. Animals that become more alert but that are not standing after one or two doses of calcium are classified as alert downer cows. It is reported that 3.8% to 28.2% of all milk fever cases become alert downers,[2-5] with a mortality rate of 20% to 67%.[3-7] The incidence of downers (24 hours or longer) was 21.4 cases per 1000 cow-years in Minnesota dairy herds, with a 33% recovery rate.[7] Fifty-eight percent of downers occurred within a day of calving, and 97% occurred within the first 100 days after calving.[7] Because the pressure damage done to muscles and nerves is aggravated by recumbency, it is desirable to have the animal on soft bedding (e.g., sand, grass) and to have the animal stand as soon as possible. Eight of 16 normal cows anesthetized for 6 to 12 hours in sternal recumbency with the right hindlimb under the body were unable to stand on recovery and became alert downers.[8] Those that could stand exhibited swelling and stiffness and peroneal nerve deficits and paresis in the right hindlimb.[8] These signs are typically seen in cows that have been recumbent for several hours on a hard surface. As pressure applied to a nerve increases, nerve conduction is impaired and eventually lost.[9]

Serum CK values in experimental downer cows increased, starting at 12 hours and continuing up for the first 48 hours, and then decreased, even though the cow remained down.[8] The CK values at 12 and 24 hours did not differ statistically for the cows that could rise after anesthesia and the downers. After 48 hours and 96 hours, the downers had higher mean CK values than the ambulatory group, but there was a great range in values.[8] The clinical difference between cows that recovered and those that remained downers was attributed to damage to the sciatic nerve or its branches, particularly the peroneal nerve.[8] Peroneal nerve damage results in knuckling over at the fetlock. In another study of downers, AST levels were greatly elevated on days 4 to 7, even after CK levels fell.[10]

Serum levels of creatine phosphokinase, AST, and lactate dehydrogenase have been examined to determine whether these indices of muscle damage can predict recovery of recumbent dairy cattle. Of the three enzymes, AST has been shown to be most useful in predicting nonrecovery. Dairy cattle with an AST level greater than 171 IU/L are 80% more likely not to recover than a dairy cow with an AST level less than 171 IU/L.[11]

Treatment Devices that aid and promote standing traditionally include hip lifters (hip clamp), slings, and inflatable bags. Although these devices help less severely affected animals to stand temporarily, they do not allow the animal to stand comfortably for hours and may even cause further trauma in animals that struggle. For these reasons, the use of water flotation has been explored as a tool in the management of downer cows. Rasmussen[12] first reported on the use of a warm-water flotation system in Denmark in 1982. Commercial flotation systems practical for cows (Aqua Cow Rise System, St. Johnsbury, Vt.; www.downcow.com) are marketed in the United States.

For flotation therapy to allow the best chances for recovery, the animal should first be examined to determine that it is a good candidate for flotation, by ruling out fractures, severe spinal cord compression, and severe systemic illness. Identifying and correcting electrolyte disturbances (e.g., hypocalcemia, hypophosphatemia, hypomagnesemia, hypokalemia) are required for successful application of flotation therapy. Once metabolic or systemic illnesses have been addressed and the cow is considered strong enough to stand once supported by water, the cow is placed in the flotation tank as follows: (1) the water tank is positioned near the down cow; (2) the wheels and tongue are detached, and both ends of the tank are removed; (3) a mat is pulled from the tub to a position beside the cow, and the down cow is rolled or slid onto the mat; (4) the mat is winched or otherwise pulled into the tub, and the ends of the tub are put in place; they seal with rubber gaskets and large turnbuckles; and (5) the cow's head is held up a few inches by a rope halter, and a hose is inserted into the tub, which is filled with water as quickly as possible; the water temperature should be 37.7° C to 38.7° C (100° F to 102° F). Cows in lateral recumbency on the mat become sternal when 12 to 24 inches of water fills the tub and usually attempt to stand beginning when the tub is one-half to two-thirds full. If no hot water

VetBooks.ir

is available near the cow, or if the tub is not next to dirt or grass suitable for the cow to exit on, the wheels can be put back on and the cow easily trailered to a better location. In addition, it is helpful to have an assistant support the tail or have a means to pull the tail once the cow attempts to rise. This helps the cow maintain a sternal position during early efforts at struggling before the cow is actually standing. Before flotation of lactating cattle at the University of California, Davis, cows are milked and teat ends sealed with a rubber teat sealant; this is removed once the cow is removed from the tank before milking. The sealant is reapplied after milking in preparation for the next flotation.

Once the cow is standing in warm water, it is possible to determine which limb or limbs are paretic or painful by observing which limbs the cow is using to support weight. Most cows calm down and relax in a standing position within 5 minutes. Most will eat hay, and even first calf heifers that have not been handled much seem to be remarkably calmed by the warm water. Unlike horses, cattle do not panic or attempt to jump out. The cow can be left in the water for 12 to 24 hours. If the water temperature drops below 35° C (95° F), some water should be released from the discharge valve and replaced with hot water; this is especially recommended in cold weather. When the decision is made to remove the cow from the tub, the water is drained, and the end of the tub facing the dirt, sand, or grass is opened. The cow is encouraged to exit *slowly* into a pen with good footing. Some cows fall as the water is let out, and others collapse once they try to walk. By observing how a cow is ambulating on exit, it is possible to determine whether hobbles should be placed onto the cow before the next flotation. If cows are considered at risk for splaying out while exiting the tank, it is recommended to apply hobbles before placing the cow in the tank.

Careful observation as the cow moves can be helpful in trying to locate anatomic or functional problems. The animal that collapses can be pulled out on the mat and left on suitable bedding, dirt, sand, or grass until refloated after a period of rest. Advanced planning on location is important for successful use of flotation therapy. Cows that can walk out into a pen may or may not be able to stand by the next day and may need to be refloated. Cows may need to be floated for up to 10 consecutive days before they can arise by themselves. If cases are carefully selected to rule out fractures, severe traumatic stifle injuries, septic arthritis, and spinal cord compression, a recuperative success rate of 46% to 90% can be expected.[12,13]

Flotation is most effective if applied early, before a downer cow develops serious myopathy and neuropathy. Studies have shown that water flotation is practical and effective, even when cattle have been down for 24 hours or longer.[1] The sooner a postparturient alert downer cow can be floated after onset of recumbency, the shorter the time to stand. In one study of postparturient alert downer cattle treated with flotation therapy, the mean time to stand was shorter for cattle floated within 1 day of going down (mean, 2.8 days to stand) than for cattle floated after being down for 2 or more days (mean, 5.3 days to stand).[13]

Mammary Gland Health

PAMELA L. RUEGG and RONALD J. ERSKINE, *Consulting Editors*
DAWN E. MORIN

Specialized mammary glands to feed progeny are a defining characteristic of mammals, but the milk of several breeds of cattle, goats, and sheep has such excellent nutritional qualities, dairy herds are bred to produce milk for human consumption. Mammary gland diseases in these animals thus have important repercussions not only for the animals' health but also for human well-being.

Mammary Gland Health of Dairy Cattle

The global dairy industry has changed dramatically in the past quarter century. Volatile milk prices, increasing herd size, reliance on hired labor, more complex feeding and housing systems, and increased pressure for environmental stewardship have fostered greater diversity among dairy enterprises. Bovine mastitis is the most common and economically important disease of dairy herds in developed countries[1-3] and hinders realization of optimum farm productivity, milk quality, and supply of dairy foods. Mastitis remains the most common cause of antimicrobial drug therapy for cows on U.S. dairy farms.[4] An important and often unrecognized obstacle to implementation of mastitis control practices is the behavior and attitude of farmers and employees.[5] Veterinarians can play a critical role in controlling this disease as part of a quality milk team that targets drug use, environment, milking practices, and the epidemiology of mastitis within each dairy herd. Successful implementation of quality milk programs within dairy herds will increase productivity for dairy producers, supply milk processors with superior raw milk, offer consumers better-quality dairy foods, improve cow health and well-being, establish the dairy industry as advocates for antimicrobial stewardship, and promote a global sustainable market for U.S. dairy products.

Economic Impact of Dairy Cattle Mastitis

Decreased milk production in affected mammary glands is the primary economic loss associated with mastitis. Inflammation causes pathologic changes in milk-secreting epithelial cells that results in decreased functional capacity. Depending on the type of pathogen, losses may continue into subsequent lactations. Most infections result in local inflammation, or relatively mild clinical cases.[6,7] However, chronic infections can lead to agalactia in the affected quarter, or in the case of severe clinical cases, profound systemic involvement that occasionally results in death.

Somatic cells in milk are indicators of leukocytosis and primarily due to infection of the mammary gland. Bulk tank somatic cell counts (BTSCCs) strongly correlate with the proportion of infected cows within a dairy herd[8] and are an indication of milk quality. Substantial economic loss may be incurred when regulatory or processor limits for BTSCCs are exceeded. Many milk processors routinely monitor BTSCCs, and dairy producers may be paid considerable monetary premiums for low BTSCCs or be penalized for high BTSCCs. Premium and penalty programs vary widely by location, but in some cases, penalty payments or unearned premiums account for the greatest loss associated with subclinical mastitis.[9]

Milk from cows with subclinical mastitis is not usually withheld from the bulk tank and may result in increased BTSCC and reduction in milk quality. Proteolytic and other changes in milk due to subclinical mastitis adversely affect organoleptic qualities and shelf life of milk and milk products. BTSCCs greater than 100,000 cells/mL are associated with decreased productivity per cow, shorter shelf life of fluid milk, and reduced yield of products like cheese.[1,10,11] Individual cow milk yield is estimated to decrease 0.5 to 0.6 kg/day for each twofold increase in SCC over 50,000 cells/mL.[12,13] However, the magnitude of the milk decrease relative to SCC increase has been reported to be higher in later lactation and older cows.[13] Thus, a cow with subclinical mastitis and a SCC of 800,000 cells/mL is potentially losing 2 to 2.5 kg of milk each day relative to having a SCC of 50,000 cell/mL.

High-BTSCC milk also has a greater risk of condemnation because of violative antimicrobial residues.[14-16] In a retrospective study, the rate of antibiotic residue violations increased as herd SCC increased, and the relative risk of antibiotic residue violations (compared to herds with SCC < 250,000 cells/mL) was 2.4, 2.8, and 7.1 times greater for herds with SCCs of over 400,000, over 550,000, and over 700,000 cells/mL, respectively.[14]

Cows with chronically increased SCC caused by intramammary infections (IMIs) are often culled prematurely as a consequence of decreased milk production. The cost of premature culling depends on the perceived value of the cow, market prices for culled cows and replacement heifers, and the potential value of the replacement heifer.[9] Cows with average SCCs above 700,000/mL were twice as likely to be culled than cows with SCCs under 250,000/mL, especially in herds with low BTSCCs.[17] Cows that are not culled may be segregated or require use of milking procedures that increase labor costs. For example, cows with chronic IMI caused by *Staphylococcus aureus* or *Mycoplasma* may have to be housed separately and milked last.

The incidence of clinical mastitis averages between 15% and 25% of lactations, although some herds may have rates greater than 45%.[18-20] Estimates of lost milk production from a case of clinical mastitis over an entire lactation range from 110 to 552 kg, depending on the parity and stage of lactation when the case occurred.[21] Further losses from clinical mastitis can result from subsequent repeated episodes during the same or later lactations. In a study of seven New York dairies, milk losses in the first 50 days following onset of clinical mastitis were 304, 128, and 92 kg for cases caused by gram-negative, gram-positive, and other pathogens, respectively.[22] Clinical mastitis also results in additional economic losses beyond milk production. In a 1700-cow dairy, cows with clinical mastitis lost 341 kg of saleable milk, compared to projected yield, during the first 60 days after case onset.[23] Nearly 75% of the milk loss was discarded because of treatment, with the remainder accounted for by lost production. Cows in their second or later lactation or more than 150 days in milk incurred greater losses, although the type of causative pathogen was not

VetBooks.ir

associated with differences in losses.[23] The average total costs per case (in U.S. dollars) of gram-positive, gram-negative, and other pathogens were estimated to be $133, $211, and $95, respectively.[24] Premature culling resulting from unresolved clinical mastitis cases or subsequent suboptimal milk yield of the affected cow may increase these costs to as much as $600 per case.[25]

The occurrence of both subclinical and clinical mastitis has been associated with reduced reproductive performance. In a preliminary field study, cows were almost two times more likely to have altered interestrus intervals following an episode of clinical coliform mastitis compared to herdmates without clinical mastitis.[26] Conception rates for cows with clinical mastitis between 3 weeks before and 5 weeks after insemination have been reported to be lower compared to cows without clinical mastitis.[27,28] Clinical mastitis due to gram-negative bacteria has a more detrimental effect on the probability of conception than clinical mastitis caused by gram-positive bacteria or other organisms.[28] Additionally, the days to first service, services per conception, and the days to conception were all increased in cows with clinical mastitis as compared to non-mastitic cows.[29] Cows with a case of clinical mastitis in the first 45 days of gestation are nearly three times more likely to abort within the next 90 days than non-mastitis cows.[30] Cows with increased SCC (>150,000 cells/mL) also have decreased conception rates compared to cows with lower SCC, and as the SCC increases the odds of pregnancy decreases.[31,32] Inflammatory mediators released in response to IMI likely play a role in oocyte and embryonic degradation.[33,34] For example, lipopolysaccharide endotoxin in cattle induces a prolonged release of inflammatory mediators including $PGF_{2\alpha}$, leading to uterine smooth muscle contraction and luteolysis, a gradual decline in plasma progesterone, and thus abortion, especially in the first trimester of pregnancy.[33]

The total cost of mastitis is impossible to quantify accurately, varies over time, and is herd dependent. Nationally, the cost of mastitis has been estimated at $200/cow/yr, or $1.5 to $2 billion.[9,35] Costs associated with implementation of mastitis control programs can be substantial. In one survey the cost of mastitis prevention accounted for 50% of the cost for preventing all diseases.[36] Return on investment in mastitis control is more important than the absolute cost and ranged from −$20 to $275/cow/year in a review of 9 studies.[37] However, this return depends on the prevalence and type of mastitis in the herd, existing control measures, and producer compliance.[38] Although the costs incurred by producers to control mastitis are significant, the benefits of reducing mastitis include improved cow health and productivity, a superior raw milk supply for processors, better quality and safer dairy foods for consumers, and a more sustainable global market for dairy products.

Anatomic Structures of the Bovine Mammary Gland

Cattle have a single udder composed of four independent mammary glands that are referred to as *quarters*. Suspensory ligaments attach the udder to the pelvic bone and abdominal muscles of the ventral body wall. The four quarters are independent and have no direct connections among them.[39] Each mammary gland consists of a teat with a single opening, small cisterns (also called *sinuses*) in the teat and base of the gland, a system of ducts, and secretory tissue. The secretory tissue is organized into lobes composed of lobules containing hundreds of microscopic alveoli lined by mammary epithelial cells that synthesize and secrete milk.[40] Nutrients required for milk synthesis are delivered to each mammary gland by the circulatory system and transported into epithelial cells or directly into the alveolar lumen. Milk components (e.g., casein, lactose, fat) are synthesized within epithelial cells and secreted into the alveolar lumen, where they combine with other constituents to form milk. Production of milk is continuous, and during the interval between milkings, about 20% of the milk accumulates in the larger spaces of the udder like the teat cistern, gland cistern, and large ducts *(cisternal fraction)*. However, about 80% of the milk remains fixed by capillary forces within the alveoli *(alveolar fraction),* and removal of this fraction is dependent upon achieving successful milk ejection *(milk letdown).*[41]

Milk letdown occurs in response to tactile stimulation of teats, which triggers a neurohormonal reflex, causing the pituitary gland to release *oxytocin* into the bloodstream.[41] Milk is ejected from the alveoli into the cisterns when the surrounding myoepithelial cells contract after binding oxytocin. Milk flows through the teat orifice after resistance of the teat canal (also called the *streak canal*) is overcome owing to pressure of milk in the teat, suckling by offspring, or through the process of milking. Activation of the sympathetic nervous system during periods of stress or excitement can inhibit oxytocin release from the pituitary gland or oxytocin binding to myoepithelial cells, thus preventing milk ejection.[42]

The teat canal and surrounding musculoelastic tissue provide the primary physical barrier to microbial invasion and also prevent milk leakage between milkings.[43,44] The teat canal is a narrow, longitudinally folded cylinder lined with stratified squamous epithelium. The tortuous shape of the canal provides physical protection against infection, as does protein-rich *keratin,* which is continually produced by the epithelial cells and lines the canal. Lack of keratin in the teat canal greatly increases the risk of IMI, because keratin physically plugs the teat canal, traps invading microbes, and contains bactericidal fatty acids and proteins.[45-47] Hyperkeratosis of the teat end, trauma-associated abrasion of the teat orifice, or teat damage from ineffective pulsation, excessive milking vacuum, or poorly fitting teat cup liners can also increase the risk of IMI.[48-50]

Because of the importance of the teat in mammary gland defense, dairy producers should routinely monitor teat condition and use a combination of genetic selection and management practices to promote teat health and sound conformation of the udder. However, it must be emphasized that cows that are housed on wet or soiled bedding or have udders and teats exposed to excessive water during milking preparation are at high risk for IMI, despite good teat end health.[51-53] Additionally, lack of aseptic preparation of teat ends before cannula insertion or use of multiple-dose drug preparations that are not intended for intramammary infusion can result in outbreaks of infection caused by opportunistic pathogens.[54]

Immunologic Response to Intramammary Infection

Preventing exposure to pathogens is the foundation of controlling infectious disease, including mastitis. When exposure to pathogens is sufficient to traverse the teat canal and multiply in milk, the ensuing host immune system response initiates inflammation of the mammary gland, which is recognized as subclinical or clinical mastitis. If the innate and acquired immune systems effectively eliminate the invading microbes, the mastitis will be mild and transient. However, when defense mechanisms are compromised (e.g., during the periparturient period or following transportation and comingling of new animals in the herd) or when the pathogen expresses virulence factors that resist phagocytosis or intracellular destruction, severe or chronic mastitis may develop. The intensity of the inflammatory response determines whether mastitis is subclinical or clinical.

With *subclinical mastitis,* the inflammatory process does not result in visible abnormalities in the milk, mammary gland, or cow, although leukocytosis and other soluble changes in milk occur. With *clinical mastitis,* milk from the affected quarter is visibly abnormal, the gland may undergo marked inflammation, and the cow may exhibit signs of systemic illness. Although mastitis can result from trauma, the vast majority of mastitis is caused by IMI via the teat canal. As stated earlier, limiting exposure to pathogens at the teat end remains the primary means to prevent infection, but mastitis will occur even in well-managed herds.

MAMMARY INFLAMMATION. If invading pathogens overcome the teat canal barrier and gain entry into the gland, a series of innate host defenses help limit bacterial growth. Since bovine mastitis is essentially a disease of bacterial (and occasionally mycotic or algal) pathogens, the primary effectors of mammary immunity are polymorphonuclear neutrophils. However, as in other tissues, these

VetBooks.ir

phagocytes rely on a complex system of soluble and cellular mediators that recognize pathogen presence and subsequently recruit and activate phagocytes to eliminate the microbes. This system is called the *innate immune system*. Soluble factors include complement, lactoferrin, and acute-phase proteins (e.g., mannose-binding lectin, C-reactive protein). Lactoferrin is an iron-binding glycoprotein produced by mammary epithelial cells and found in neutrophil granules.[55] By sequestering iron, lactoferrin prevents multiplication of iron-dependent microorganisms like coliform bacteria.[56] Mannose-binding lectin and C-reactive protein will bind to molecules specific to pathogen cell walls and help activate the complement cascade.[57] Innate host defenses differentiate host tissue from pathogens by recognizing molecules that are universal to many microbes but not present on the body's own cells.[58] These pathogen-associated molecular patterns (PAMPs) are recognized and selectively bound by serum proteins and receptors in host cells called *pathogen recognition receptors* (PRRs).[58]

Toll-like receptors (TLRs) are an important class of PRRs that reside both on cell surfaces and within host cells. These receptors invoke gene expression and release of inflammatory cytokines (e.g., interleukins [ILs], tumor necrosis factor [TNF]-α) from the host cells and act as the critical link between recognition of foreign agents and initiation of the host response.[58,59] Examples of specific pathogen targets bound by TLRs include peptidoglycan and lipoteichoic acid of gram-positive bacteria (TLR-2), gram-negative lipopolysaccharide (LPS [TLR-4]), bacterial flagellin (TLR-5), and bacterial DNA as CpG oligonucleotides (TLR-9).[60] Much of the local inflammation and systemic signs (when they occur) associated with mastitis are due to this response. Numerous cell types, including epithelial and endothelial cells, macrophages, and other phagocytic cells, possess TLRs that can contribute to an inflammatory response.[61] The inflammatory response is further modulated by activation of eicosanoid (arachidonic acid) metabolites such as prostaglandins and leukotrienes, as well as endocrine and adipose mediators.[62]

Milk from healthy mammary glands contains a low concentration of cells, the majority of which are macrophages. However, when microbial ligands (molecules) are detected by TLRs on macrophages and epithelial cells, these cells release proinflammatory cytokines like IL-1, IL-6, and TNF-α.[58] These mediators cause vasodilation and expression of adhesion molecules on endothelial cells, which in turn triggers an influx of neutrophils.[60,63] Circulating blood neutrophils must adhere to the vascular endothelium before migrating into the milk. Vascular neutrophils loosely bind and roll along the endothelium, using a surface adhesion molecule (CD62L or L-selectin).[64] L-selectin is highly expressed on the surface of normal circulating neutrophils, whereas similar molecules, E-selectin (CD62E) and P-selectin (CD62P), are expressed on vascular endothelial cells at the site of inflammation.[64,65] Neutrophil CD62L is responsible for making initial contact between fast-flowing blood neutrophils and the vascular wall, which rapidly slows neutrophil movement in small postcapillary vessels, whereas endothelial CD62E and CD62P direct slow-moving neutrophils to the specific site of inflammation. Additional proinflammatory mediators like IL-8, leukotriene B-4, and complement component 5a serve as neutrophil chemotactic agents and promote expression of surface receptors on endothelial cells.[64] This in turn causes neutrophils to express the β_2-integrin adhesion complex CD11b/CD18. The CD11b/CD18 complex firmly anchors neutrophils to vascular and intercellular adhesion molecules.[64,66,67] Once bound, neutrophils migrate between the endothelial and mammary epithelial cells into the milk *(diapedesis),* traveling along a chemotactic gradient to the site of infection.[64] During infection, neutrophils often exceed concentrations of 1 million cells/mL. Both the speed of recruitment and extent of neutrophil influx into milk influence microbial clearance and are critical determinants of infection outcome.[60,68-70]

During migration and under the influence of proinflammatory cytokines (e.g., TNF-α and interferon [IFN]-γ), neutrophils are further activated to become focused killer cells.[64] In this way, the leukocytes arrive at the infection site ready to recognize, phagocytose, and kill infecting pathogens. Phagocytosis is accomplished through a variety of specialized receptors on the surface of neutrophils, which are generally upregulated in response to the proinflammatory signals received during diapedesis and chemotaxis. Expression of CD14 receptors enables neutrophils to bind bacterial lipopolysaccharide (LPS) in the presence of LPS-binding protein (LBP); this binding facilitates nonopsonic phagocytosis of gram-negative bacteria.[71] At the same time, soluble CD14 is shed into the milk, where it neutralizes free LPS and binds to epithelial cells, enhancing chemoattractant release.[70] The most important neutrophil receptor for opsonic phagocytosis is the Fc receptor, which binds the Fc region of immunoglobulins (Ig), particularly IgG2 and IgM, enabling the phagocytosis of antibody-coated pathogens.[72,73] Complement component 3b is also opsonic for bovine neutrophils.[66]

Receptor binding stimulates the neutrophil to extend pseudopods and engulf the adhered pathogen into a phagosome. The phagosome fuses with cytoplasmic secretory granules to form an intracellular vesicle (phagolysosome), where degranulation and microbial killing take place. Neutrophil granules contain cationic peptides called *defensins* that have broad-spectrum antibacterial and antifungal activities.[55,60] These proteins, along with lactoferrin and hydrolytic enzymes, contribute to O_2-independent killing of engulfed pathogens.

To effectively respond to pathogen invasion, the lactating mammary gland of ruminants must overcome numerous deficits. The number of somatic cells in milk, which in lactating dairy cattle are primarily leukocytes, is typically less than 100,000 cells/mL in uninfected glands—about 100-fold lower than in blood. Concentrations of factors like lactoferrin and complement are also lower in milk relative to plasma.[74] The ability of circulating macrophages in milk to reenter tissue for antigen presentation remains speculative, but compared to blood, macrophages and neutrophils in milk have decreased phagocytic ability.[75,76] Neutrophils engulf fat globules and casein, which reduces subsequent pseudopod formation as well as intracellular killing capacity.[70] Host-adapted pathogens (e.g., *S. aureus*) often have numerous virulence factors to help evade recognition and phagocytosis, which further compromises the ability of host defenses to eliminate the infection.

Specific Immune Responses. If a pathogen survives innate host defenses, the specific (also called *acquired*) immune system is triggered. This branch of the immune system recognizes specific antigens of pathogens, and if repeated exposure occurs, an immunologic "memory" initiates a faster and more intense response with longer duration. As with neutrophils, mammary macrophages ingest and kill microorganisms.[77] Macrophages appear to be particularly important in chronic IMI and during involution (dry-off) of the mammary gland. In addition to initiation of inflammation and pathogen killing, macrophages and dendritic cells play a key role in processing and presenting antigen to T lymphocytes. Antigen presentation is critical to activating T cells ($CD4^+$), thus enabling cytokine secretion, activation of B lymphocytes, and cytotoxic ($CD8^+$), suppressor, and memory functions.[78] To date, the role of the $CD4^+$ (helper), $CD8^+$ (cytotoxic and suppressor), and CD17 (phagocyte agonist) subsets in bovine mammary immunity are best understood.[79,80] B-lymphocytes are also critical for antigen processing and serve as precursors to immunoglobulin-producing plasma cells.

Concentrations of immunoglobulin are low in normal milk but rise in response to IMI. This increase is partly a result of local Ig production but is mostly due to increased permeability of vascular endothelial cells and mammary epithelial cell tight junctions, which allows an influx of plasma Ig (and other plasma proteins) into milk. Influx of opsonizing Ig (IgM and IgG2) enables efficient phagocytosis of microorganisms by neutrophils.[72,73,81] Nonopsonizing Ig (IgG1 and IgA in cattle) has other beneficial functions like neutralization of bacterial toxins, agglutination of bacteria, and prevention of bacterial adherence to epithelial cells. Immunoglobulins in milk also mediate antibody-dependent cell-mediated cytotoxicity by leukocytes.[78,82]

VetBooks.ir

DEFENSE MECHANISMS IN THE PERIPARTURIENT PERIOD. Mammary gland defense mechanisms are greatly reduced in the periparturient period, increasing the animal's vulnerability to IMI. Indeed, both the incidence and severity of mastitis are greater in the periparturient period than during other periods of lactation.[64,83-85] Phagocyte diapedesis and killing and lymphocyte mitogenic responses are markedly decreased during the periparturient period.[79,82,86-88] Cows infected with *S. aureus* have a subpopulation of $CD8^+$ lymphocytes within the mammary gland that suppress proliferation of $CD4^+$ lymphocytes, and this class of $CD8^+$ cells is preferentially trafficked into the gland during the postpartum period.[80]

The immunosuppression accompanying parturition is partly caused by increased circulating cortisol concentration, which impairs neutrophil margination and recruitment.[64] Neutrophils of periparturient cows also undergo apoptosis more rapidly than neutrophils of cows in later lactation, and early onset of apoptosis reduces phagocytic and intracellular killing activity.[70] Low circulating concentrations of insulin-like growth factor (IGF)-1 in periparturient cows may reduce neutrophil viability and impair cytokine secretion.[85]

Nutrition of cows during the transition period can also play a critical role in mammary immunity. Recently a critical link between negative energy balance and immune function in dairy cattle has been elucidated. Nonesterified fatty acids (NEFAs) are released from adipose tissue in response to negative energy balances that are typical for cows in the transition period from late gestation through peak milk production. Particularly before calving, cows with excessive negative energy balances and high serum NEFAs are more at risk for culling and diseases during early lactation.[89,90] Additionally, elevated serum NEFAs lead to undesirable expression of proinflammatory mediators, adhesion molecules, and reactive oxygen species.[91] The altered plasma fatty acid profile in cattle during periods of negative energy balance also changes the phospholipid content in membranes of endothelial and mononuclear cells.[92] Fatty acids from membrane phospholipids are the precursors for numerous arachidonic acid metabolites, the control of which is critical for the magnitude of inflammatory responses.

Antioxidant supplementation has also been shown to play an important role in mammary immune function. Vitamin E, selenoenzymes, and zinc-dependent superoxide dismutase protect cells and membranes from oxidative damage that could result from expression of reactive oxygen species during phagocyte killing.[93] Compared to selenium-supplemented cows, cows that were selenium deficient showed reduced neutrophil phagocytosis and killing.[94] Selenium deficiency also resulted in more severe outcomes in cows with coliform mastitis.[95] In one herd, vitamin E supplementation above National Research Council (NRC) guidelines (4000 IU/day) to dry cows in the last 14 days before calving was reported to decrease clinical mastitis in the first 7 days of lactation.[96] However, in a larger field study in five herds, feeding dry cows 3000 IU/day of vitamin E (which exceeds NRC recommendations) was found to increase both subclinical and clinical mastitis in the first 3 months after lactation.[97] In this field study, antioxidant status in cows fed high levels of vitamin E varied, which may reflect the dependency of plasma α-tocopherol concentrations on lipid mobilization, which itself varies with individual cow energy balance.[98] Although antioxidant supplementation is critical for mammary health, there is no compelling evidence to feed selenium, vitamin E, or any other nutrient of this type above NRC guidelines.

Diagnosis and Detection of Mastitis

Definitions Technically, *mastitis* can be defined as any inflammation of the mammary gland (including inflammation caused by injury), but almost all mastitis occurring in dairy cows is caused by pathogenic organisms that are mostly of bacterial origin but can also include yeasts, fungi, and algae.[6] Like infections occurring in other tissues, mastitis begins with invasion of a pathogen, followed by a brief latent period, and then progression to either subclinical or clinical states or resolution of the infection as a result of the cow's immune response.[99] Detection of mastitis is almost never based on identifying the precise moment of infection but rather on observing the resulting inflammation. Recognition of mastitis is dependent on pathogen and cow characteristics that govern the magnitude of the immune response and the intensity and accuracy of the detection methods used on the farm.

Subclinical mastitis is characterized by inflammation of the udder that is usually detected by enumeration of inflammatory cells in the milk. By definition, milk obtained from mammary gland quarters of cows experiencing subclinical mastitis appears normal but contains an abnormal number of somatic cells with or without the detectable presence of mastitis-causing bacteria.[100] In most instances, detection of subclinical mastitis is based on evaluation of the SCC in an appropriate milk sample. The SCC can be measured using milk collected from individual quarters or composite milk samples that are a mixture of milk from all functional glands of an individual cow. Composite milk samples are routinely used in Dairy Herd Improvement Association (DHIA) programs for monitoring SCCs of individual cows. When composite SCC values are used, some subclinical infections will not be detected because the SCC of the composite milk will be reduced by dilution with milk from healthy quarters that contain few somatic cells.[101] When cows are not routinely tested for individual SCC, veterinarians cannot determine important epidemiologic characteristics of subclinical infections (e.g., prevalence, incidence) necessary for implementing mastitis control programs.

The distribution of cell types found in bovine milk varies depending on infection status and milk fraction.[102] The SCC of healthy quarters is quite low and usually remains well below 100,000 cells/mL.[103] However, based on detection of IMI (microbiologically positive milk samples), a threshold of less than 200,000 cells/mL is usually considered the optimal value to define a mammary quarter as healthy.[100,104-106] Selecting the appropriate threshold for defining subclinical mastitis depends the goal of the control program. Lower thresholds will identify more animals with subclinical infections (increased sensitivity and fewer false negatives), whereas higher thresholds (increased specificity) will result in fewer false positives.[106] Regardless of the threshold selected, reviewing the history of SCC values for a cow is much more informative than observing a single monthly value.

A SCC above 200,000 cells/mL in milk does not mean bacteria will be recovered from milk samples obtained from the affected gland. The immune response reflected by the influx of leukocytes can be quite effective at reducing the number of bacterial colonies in milk, and about 10% to 25% of quarters that are above a threshold of 200,000 cells/mL will be apparently bacteriologically negative.[100,104-107] When historically important contagious pathogens (e.g., *Streptococcus agalactiae* and *S. aureus*) have been controlled, the rate of apparent "false negatives" (inability to recover bacteria from quarters that exceed the SCC threshold) is often even greater. These culture-negative samples do not always indicate that the quarter is cured, but merely that the immune response has reduced the number of bacteria to below normal laboratory detection limits. It is useful to educate clients that about 30% to 50% of milk samples collected from mammary glands with high SCCs will be culture negative, so sufficient samples should be collected to ensure meaningful diagnostic test results.

The duration of the subclinical phase of IMIs will vary depending on etiology. In most herds, a greater proportion of subclinical mastitis is caused by gram-positive than by gram-negative pathogens (Table 36-1). Usually, gram-negative opportunistic pathogens like *Escherichia coli* have a shorter subclinical phase than gram-positive pathogens like *S. aureus* or most IMIs caused by *Streptococcus* spp.[108,109] In general, some 25% to 35% of cows experiencing chronic subclinical mastitis caused by gram-positive pathogens may eventually exhibit clinical symptoms.[110] For opportunistic environmental pathogens, the likelihood of a clinical episode occurring in a cow with subclinical IMI varies among pathogens. For example, about

*Results of selected studies that describe the distribution of bacteria recovered from milk obtained from cows with clinical and subclinical mastitis in modern dairy herds located in developed countries.

†Results characterized as contaminated and mixed infections were excluded.

‡NR indicates that the study did not report that outcome.

§Contaminated cases are included.

50% of IMIs caused by streptococci progress to clinical signs, but over 80% of coliform infections will exhibit clinical signs.[108]

It is important to diagnose the prevalence and incidence of subclinical infections within a dairy herd. Cows with subclinical mastitis infections are known to produce considerably less milk and maintain a reservoir of infection that can result in increased exposure to potential pathogens of otherwise healthy cows.[111] Subclinical infections that persist for long durations are especially costly. For example, cows that maintain subclinical mastitis across the dry period (SCC > 200,000 cells/mL at the last test of the completed lactation and first test of the subsequent lactation) have been shown to produce 9.1 kg (20 lb) less milk at their first DHIA test day.[106]

In diagnostic laboratories, SCCs of milk can be determined using methods like direct microscopic observation or, more commonly, electronic counting of dyed cells in either fresh, preserved, or frozen milk.[112,113] About half of U.S. dairy farms subscribe to monthly DHIA testing and have access to SCC values determined using composite milk samples collected from individual cows.[114] SCC values are not usually normally distributed, and many DHIA centers report the SCC using a linear score transformation that is calculated using a simple formula ($LS = \log_2 [SCC/100] + 3$). This transformation results in a normal distribution of the values and a linear association of the transformed data with estimates of losses in milk yield that are caused by subclinical infections.[115] Review of monthly summarized SCC values at the herd level is a critical component of udder health programs and should be part of routine veterinary activities on dairy farms.

Laboratory-based methods for identification of subclinical mastitis are considered to be accurate, but because they are removed from the farm, they are sometimes criticized as too slow for making cow-side decisions. To overcome this hurdle, a number of indirect measures of SCC have been developed. The California Mastitis Test (CMT) is an example of an indirect test that has been used for more than 50 years to help guide mastitis control programs.[116] The CMT was developed to test milk from individual quarters but has also been used on composite milk samples and bulk milk samples.[116] The CMT reagent is a mixture of a detergent plus bromcresol purple (used as an indicator of pH). The degree of reaction between the detergent and the DNA of cell nuclei is a measure of the number of somatic cells in milk. The CMT test is generally read using a five-point scale that begins with "negative" (SCC range of 0 to 200,000 cells/mL) and "trace" scores (SCC range of 150,000 to 500,000 cells/mL) and ends with a maximum score of 3 (SCC > 5,000,000 cells/mL). The CMT was developed during an era when many cows had very high SCCs as a result of chronic subclinical infections caused by *S. agalactiae* and *S. aureus*. Adoption of standardized best management practices has decreased the prevalence of these pathogens,[117] and SCC values of cows infected with other pathogens are typically much less. Although the CMT continues to have considerable utility, it is important to note that even "trace" scores indicate the presence of subclinical mastitis, and the test may be difficult to read when used on milk obtained from cows in the first few days of lactation.[118,119]

In addition to increased SCC, a number of changes in milk composition are due to the immune response to infection. Compositional changes include reduced casein, lactose, and α-lactalbumin concentrations; an influx of sodium, chloride, and plasma proteins; increased proteolytic and lipolytic activity; an increase in lactoferrin concentration and enzyme activities; and a rise in pH.[120] Many of these changes can be used as indicators of subclinical mastitis. Among the more common milk tests are those that detect albumin, sodium, chloride, lactose, or adenosine triphosphate (ATP) concentration; *N*-acetyl-β-D-glucosaminidase (NAGase) activity; antitrypsin activity; or pH. Plasma tests detect α-lactalbumin, casein, or lactose concentration.[120,121-125] Milk concentrations of the acute-phase proteins amyloid A and haptoglobin are also used to distinguish healthy quarters from those with subclinical mastitis.[121,125] With increases in diagnostic technology and increased emphasis on production of high-quality milk, considerable research has been focused on producing tools for continuous in-line monitoring of milk quality. The increased use of automatic milking systems (robotic milking) has led to the search for automated methods that can consistently and accurately detect abnormal milk.[126] Current testing technology generally gives accurate results, but the ultimate value of the test depends on the value of the management decision that is based on the test result; veterinary practitioners should continuously review how such tests can be best used on dairy farms.

Clinical mastitis is usually defined as the production of abnormal milk with or without secondary symptoms. Detection of clinical mastitis is based on observation of foremilk prior to attaching the milking unit, but the working definition of clinical mastitis varies greatly among farm personnel. Many farms do not routinely remove or observe foremilk of all cows, so detection of clinical mastitis is limited to cases with more severe signs.[114,127] To better understand the incidence of mastitis, veterinarians should ask milking technicians to describe their individualized definition of clinical mastitis symptoms. Clinical signs of mastitis result from inflammation and may include abnormal appearance of milk (presence of clots or serum); swelling, redness, or edema of one or more quarters; or severe systemic signs

VetBooks.ir

such as anorexia, fever, or agalactia. Compared to subclinical mastitis, a much greater proportion of clinical cases are caused by gram-negative pathogens (see Table 36-1). Like other bacterial diseases, many cases of mastitis occur as a syndrome, with the infected quarters alternating between a clinical state and a subclinical state.[108] The disappearance of clinical signs simply indicates that inflammation has decreased and does not always coincide with bacteriologic cure.[128] The ability to achieve a bacteriologic cure depends on the etiology, case severity, variation in immune response among cows, efficacy of the treatment protocol, and promptness of initiating treatment.[129]

Recording the standardized severity scores can help veterinarians to better define the pattern of clinical mastitis on individual farms.[128,130-132] One severity scoring system uses a three-point scale that combines the appearance of milk with the progression to additional clinical signs. A score of 1 (mild mastitis) = abnormal milk only; 2 (moderate mastitis) = abnormal milk and abnormal udder; 3 (severe) = systemic symptoms.[128] This system is practical, simply recorded, and can be an important way to assess detection intensity. In most herds, the distribution of clinical mastitis by severity is approximately 40% to 50% mild cases, 40% to 50% moderate cases, and 5% to 15% severe cases.[7,128,130,132,133] Veterinarians are rarely asked to treat mild and moderate cases of clinical mastitis and therefore may not understand the true incidence of clinical mastitis on many dairy farms.[134] Veterinarians need to promote the use of clinical mastitis records that allow them to monitor the occurrence of mild and moderate cases and also the ability to evaluate outcomes of mastitis treatments.

Identification of Etiologic Agents

Treatment and prevention of mastitis is based on understanding the etiology of mastitis. As dairy farms increase in size, an increasingly diverse group of pathogens have been associated with the occurrence of mastitis.[7,134-136] Clinical signs may be suggestive of some pathogens, but it is impossible to diagnose the etiology based on the appearance of the milk, gland, or animal.[137,138,139] Some practitioners erroneously believe they can recognize coliform infections based on severity of the symptoms, but researchers have consistently shown that the majority of clinical cases caused by coliform bacteria present with only mild or moderate symptoms,[7,131,133] and misdiagnosis of coliform infections is common.[139] Submission of an aseptically obtained milk sample to a laboratory qualified to perform appropriate microbiological or molecular testing is necessary to determine etiology.

MILK SAMPLES COLLECTED FROM INDIVIDUAL ANIMALS. Milk samples may be individually collected from affected quarters (quarter milk samples) or combined from all four glands into a single vial (composite milk samples). Quarter milk samples collected from affected glands are more sensitive than composite samples in detecting bacteria from subclinical infections, but the sensitivity of composite samples increases with the number of infected glands per cow.[140,141] Sampling the cow on more than one occasion also increases the likelihood of detecting glands that are intermittently shedding some pathogens.[142] The concentration of bacteria per milliliter of milk varies among pathogens. Some pathogens (e.g., *S. agalactiae* and most other *Streptococcus* spp.) consistently shed large numbers of bacteria in milk. For these pathogens, composite milk samples may be acceptable because concentrations of bacteria will more consistently exceed the microbiological detection limit.[143] For other pathogens (e.g., *S. aureus* and *Mycoplasma* spp.) composite samples will often result in apparently culture-negative samples, because these pathogens are often shed in fewer numbers, and dilution with milk from healthy quarters will result in samples that contain less than the limit of detection in most laboratories (100 colony-forming units [CFU]/mL of milk).[144]

Composite milk samples are often used in an attempt to reduce the cost of routine screening of high-risk animals for the presence of existing subclinical infections with potentially contagious mastitis pathogens. Pooling 5 to 10 aseptically collected milk samples is another strategy used in some herds to further reduce costs. When either of these strategies is used, it is important to recognize that the potential for false-negative outcomes is increased. The sensitivity of composite milk samples for detection of *S. aureus* and *Streptococcus dysgalactiae* was estimated to be about 73% to 77%, in contrast to about 60% to 62% for *Streptococcus uberis* and coagulase-negative staphylococci (CoNS).[145] In all instances, sensitivities increase as the number of infected mammary gland quarters increases.[145] When using pooled or composite samples, veterinarians should routinely review cow histories to identify cows with increased SCCs that are typical of cows with subclinical infections.

Mastitis is usually caused by a single type of bacteria, and the National Mastitis Council (NMC) has developed standards that specify that recovery of more than two types of bacteria from an aseptically collected milk sample is indicative of contamination.[6] Before collection of milk samples, technicians should be trained in aseptic collection techniques. To maximize the possibility of recovering bacteria from the sample, milk should be collected after the teats have been prepared for milking (application of pre-milking disinfectant and drying) but before the units are attached.[146] Sampling before milking is usually easier because cows are generally more likely to stand still and there is less pressure from farm workers to release the cows. Before obtaining the sample, the udders should be clean, and dry-wiping the udder with a paper or cloth towel is often helpful in reducing the possibility of contamination. Milk should be collected in sterile vials by technicians who are wearing disposable nitrile or latex gloves and using a standardized process. After thoroughly drying the teat using a cloth or paper towel, the teat end should be vigorously scrubbed using 70% ethyl or isopropyl alcohol. If composite samples are collected, a separate alcohol swab must be used for each teat. Sanitation is not complete until the surface of the swab remains clean after it is used.

The cap should be removed from the sample vial without touching the inside, and it should be held so that the inner surface faces down. Milk from the teat to be sampled can be directed at an angle into the sampling vial. A sample size of 3 to 5 mL is usually adequate. The cap should be immediately replaced after the sample is obtained. When sampling multiple teats, the far teats should be scrubbed before the near teats, and the near teats sampled first to avoid contamination by the sampler's arm or hand. Samples must be immediately cooled, refrigerated at 4° C, held on ice, or frozen until cultured. Failure to use aseptic technique or mishandling after collection can produce erroneous results. If samples are to be submitted to a diagnostic laboratory, they should be submitted within 24 hours of collection. If samples cannot be processed within 24 hours, they should be frozen until transported to the lab. Freezing for periods of less than 2 weeks has minimal effects on recovery of most mastitis-causing bacteria but can reduce recovery of *Mycoplasma* spp.[147]

When proper sampling and laboratory techniques are used, recovery of bacteria from milk samples is highly specific for mastitis. However, microbiological examination of milk obtained from glands affected with clinical or subclinical mastitis is not very sensitive.[148] Failure to recover bacteria from a milk sample obtained from a gland with a high SCC does not usually mean that bacteria are not the causative agent for mastitis. When a single milk sample is obtained from dairy cattle exhibiting clinical or subclinical mastitis, approximately 35% to 50% of milk samples will be culture negative (see Table 36-1).[7,117,149] Repeated sampling of affected quarters can increase the probability of reaching a diagnosis.[142,144]

Laboratory Methods. Standardized laboratory methods for identifying mastitis pathogens have been well defined by the NMC.[6] In general, technicians inoculate media that contain nutrients required for bacterial growth, and the inoculated media are placed in an incubator that contains the appropriate atmosphere and temperature to encourage growth of the target organisms. After 24 to 48 hours, the plates are examined for growth, and the bacteria are identified using a variety of specific test methods that depend on observable bacterial characteristics. In most mastitis laboratories, 10 to 100 µL of each milk sample are inoculated onto a portion of a blood agar plate (5%). The inoculum volume determines the lower limit of

VetBooks.ir

detection. For example, one colony observed on a plate inoculated with 0.01 mL (10 µL) is equivalent to roughly 100 CFU/mL of milk, whereas one colony observed using a 0.1-mL (100-µL) inoculum is equivalent to about 10 CFU/mL. The use of larger (0.05- or 0.10-mL) volumes of inocula increases recovery rates for pathogens shed in low concentrations *(E. coli, S. aureus)*.[151] Other ways to increase recovery are preculture centrifugation,[150] incubation,[141,152,153] or freezing[152] of the milk, or a combination of these methods. The optimal method is pathogen dependent. Augmented methods are most useful for detecting subclinical *S. aureus* infections and reducing false-negative results for clinical mastitis samples.

After inoculation, agar plates are incubated at 37° C (98.6° F) and observed for growth at 24 and 48 hours. There is no absolute definition of IMI, but the presence of at least 100 to 300 CFU/mL is usually required to define an infection. Bacterial identification is based on phenotypic characteristics of the colonies and the result of additional laboratory tests. *S. aureus* is usually differentiated from other staphylococci based on a positive coagulase reaction and other typical phenotypic characteristics (e.g., hemolysis).[6] *Streptococci* are usually identified using the Christie-Atkins-Munch-Petersen (CAMP) test and esculin reactions. When milk samples originate from cases of clinical mastitis, MacConkey agar is usually also inoculated to facilitate rapid identification of gram-negative, lactose-fermenting organisms (coliforms). Additional biochemical tests are required for final identification at the species level. Identification of *Mycoplasma* spp. requires use of media containing specific nutrients not found in general media and incubation in a CO_2-enhanced environment.

On-Farm Culturing. As farms have increased in size, on-farm culture (OFC) programs have been developed.[153] Methods used for OFC are not usually the same as those used in professional diagnostic laboratories, and are often performed by farm personnel who may have some technical expertise but lack formal training in microbiological methods. On most farms, OFC methods are based on using laboratory shortcuts and have a goal of rapidly reaching a presumed diagnosis to guide treatment. The most basic OFC method uses biplates, triplates, or quadplates that contain selective media.[154] Growth on a selective medium is used to differentiate cases caused by gram-positive or gram-negative bacteria, culture-negative cases, or in some instances specific pathogens. After 24 hours of incubation, culture plates are observed, and the treatment protocol is specified based on the culture outcome.[153,155,156] Typically used agars include MacConkey agar (selective for growth of gram-negative bacteria), TKT agar (selective for growth of streptococci) and Factor, Baird-Parker, or KLMB media (selective for growth and differentiation of some staphylococci). Studies show that using selective media in OFC systems is about 80% accurate in differentiating gram-positive and gram-negative pathogens when compared to diagnostic laboratories.[157-160] Using OFC to make more specific pathogen diagnoses is not as accurate and requires additional training of farm personnel.

Most smaller herds do not have sufficient cases of mastitis to develop the expertise needed for OFC, so one alternative is to offer in-veterinary clinic culturing (IVCC). In these instances, farmers usually collect a milk sample and immediately initiate treatment, but they may stop or modify treatment duration or the drug after receiving a preliminary microbiological diagnosis from their veterinarian within 24 hours. Development and oversight of a culture program (either OFC or IVCC) is an ideal way for veterinarians to increase involvement in mastitis control programs. The use of veterinary technicians to supervise these programs may also increase veterinary involvement and oversight of mastitis treatments. When OFC is used, veterinary technicians can visit farms to restock supplies, train farm personnel, and provide oversight and quality control.

MICROBIOLOGICAL ANALYSIS OF BULK TANK MILK. Depending on the objective of the testing, microbiological examination of bulk tank milk samples is performed using a variety of laboratory techniques.[101] Enumeration of the total number of aerobic bacteria in bulk milk is routinely performed by milk processors as part of the regulatory requirements for milk production. Standardized methods for counting bacteria may be based on culture or performed using automated counting of stained bacterial cells.[113] Processors also commonly perform additional laboratory tests to assess hygienic conditions of milk harvest and storage and may use results of these tests to determine premium payments.[161] Comparison of the number of psychotropic, thermoduric, or coliform bacteria from various milk samples can be used to identify problems with dirty udders, poor premilking preparation, cleanliness of milking equipment, or problems with cooling stored milk.[162] Methods that count bacteria are simply quantitative and do not identify specific microorganisms.

Qualitative bulk tank cultures (BTCs) are usually performed with the objective of identifying specific pathogens shed by cows being milked while affected with subclinical mastitis.[101,163] Methods of sampling, types of laboratory techniques, and the reporting format have not been standardized, making it difficult to compare BTC results among laboratories. Because of the variation in laboratory methods, it is best to submit bulk tank milk samples to a specialized laboratory that tests several dilutions using selective media for isolating and counting colonies.[6] The laboratory should be informed if identification of *Mycoplasma* spp. is of interest so that proper media and incubator conditions are used.

Interpretation of BTC results can be confusing because bacteria can originate from teat skin, subclinical mastitis infections, failure of milking technicians to exclude milk from cows that have clinical mastitis, poor hygienic conditions, failure to adequately cool milk, and the use of inadequately cleaned milking equipment. Interpretation of BTC is based on knowledge of the expected reservoirs of the organisms found in the milk.[163,164] A few organisms *(S. agalactiae, S. aureus, Mycoplasma bovis)* are known to originate primarily from infected cows, but many organisms have multiple potential sources. Pathogens such as CoNS originate from infected udders, poorly disinfected teat skin, and udders that have been contaminated by bedding sources. Non-*agalactiae* streptococci are commonly found in the dairy farm environment and are associated with dirty udders, but these organisms can also cause subclinical mastitis. The natural duration of subclinical IMI caused by *E. coli* is short, and there are multiple environmental sources of this organism.[108] Thus, when many *E. coli* are found in bulk milk, the most likely source is contamination during the milking process. When organisms that have environmental niches are found in bulk tank milk, sources other than IMI should first be investigated before assuming infected cows are the cause of the increased count.

The sensitivity of a single BTC for detecting herds with infected cows is generally considered fairly low, so results should not be used to estimate the prevalence of infected cows.[163-166] However, the positive predictive values of BTC (detection of at least one positive cow when the organism was found in BTC) are estimated to be better than 97% for *S. agalactiae* and *S. aureus* and better than 80% for *Mycoplasma* spp.[166] Because of this low sensitivity, inability to isolate contagious pathogens from bulk milk does not necessarily mean infected cows are not present; negative bulk tank cultures routinely occur in herds with some infected cows. The relatively low sensitivity of a single bulk tank culture for screening herds for contagious pathogens can be improved by using enhanced laboratory techniques or by increasing the frequency of sampling. The use of commingled samples that have been independently collected for 3 to 5 consecutive days is recommended to reduce false-negative results that are due to variations in bacterial shedding.[163]

MOLECULAR TESTING. The continued development of molecular techniques has the potential to improve diagnosis of mastitis, but a full review of these technologies is beyond the scope of this chapter. A variety of molecular methods have been used to diagnose mastitis pathogens, identify potential zoonotic agents in milk, and investigate mastitis outbreaks and milk quality problems.[167-169] Some molecular methods are used to identify specific strains of bacteria to determine the likely source of transmission of mastitis pathogens.[170] Other methods are used to improve diagnosis of pathogens for which biochemical methods for identification of species are known to be

VetBooks.ir

inaccurate[171,172] or to more rapidly arrive at a diagnosis.[173] In general, genotypic methods of identifying bacteria are based on identifying unique sections of DNA that are compared to characteristics of known library strains. Several polymerase chain reaction (PCR)-based methods of identifying bacteria have been developed,[173-175] and at least one real-time (rt)PCR method for diagnosis of bovine mastitis pathogens is widely commercially available (PathoProof [Thermo Fisher Scientific]). PathoProof can accurately detect the presence of bacterial DNA of at least 11 mastitis pathogens but requires aseptically collected milk samples to limit the number of false-positive results.[176,177] In one study, this test resulted in identification of bacterial DNA of potential mastitis pathogens in 43% of culture-negative milk samples.[178] However, 31% of the culture-negative milk samples contained DNA from two or more types of organisms, and major mastitis pathogens were grown from a few of the PCR-negative samples.[176] Thus, the use of molecular testing for making individual cow decisions is not yet well defined.

Use of the PathoProof test to evaluate milk quality of bulk tank milk has also been investigated.[179] As expected, rtPCR testing is useful to detect the presence of obligate udder pathogens (e.g., *S. agalactiae*) in bulk milk, especially when there is a low prevalence of infected cows within the herd.[179] However, interpretation of rtPCR test results for other bacteria found in bulk milk is difficult. PCR test results are interpreted relative to the cycling threshold (Ct) values, which indicate the number of PCR cycles required to reach a signaling threshold. In general, the lower the Ct value, the greater the amount of the specified DNA in the sample. When using PCR on bulk milk samples, there is limited understanding of how to interpret Ct values for bacteria that can originate from either the environment or from IMI, and validated guidelines for interpretation at the herd level are unavailable.

Decision making for management of milk quality based on PCR results is complicated because DNA from both live and dead bacteria is detected. Just as the occurrence of a few colonies of environmental pathogens on a blood agar plate would not be sufficient evidence to initiate treatment,[6] identification of bacterial DNA from milk is not always sufficient evidence on which to base a treatment protocol. To improve the utility of diagnostic methods based on DNA, aseptic samples should be collected,[177] and the medical history and SCC of the cow should be reviewed before making treatment or culling decisions. For some pathogens (e.g., *Mycoplasma* spp., *S. agalactiae, S. aureus*) the cow's history will generally support the presumed diagnosis; for other pathogens the relationship may be less apparent. The cost of using molecular methods will likely decrease and their use likely increase, but continued research is warranted to help define practical ways of best using these methodologies.

Epidemiology of Mastitis Pathogens

TRANSMISSION AND RESERVOIRS. Mastitis is an infectious disease that occurs when udders become infected with pathogens, most of which are bacteria. With the exception of infections caused by a few unique microorganisms (e.g., *Mycoplasma* spp.), exposure of the teat sphincter to bacteria is the primary route of almost all mammary gland infections. Microorganisms that can potentially cause mastitis are typically categorized as either environmental or contagious based on the likely reservoir on the farm and the most probable source of the initial exposure.

Opportunistic organisms found in the cow's surroundings are generally considered to be primarily environmental pathogens. Transmission occurs when teats are exposed to bacteria found in environmental sources like fecal material, bedding, soil, and contaminated water.[53] Contamination of teat skin with environmental pathogens increases the probability of IMI, especially when defense mechanisms (e.g., teat sphincter patency) are compromised. IMI with environmental pathogens can also occur when teat ends are insufficiently disinfected before infusing antibiotics, or when a contaminated infusion preparation or cannula is used.[53,180,181] Gram-negative bacteria (e.g., *E. coli* and *Klebsiella* spp.) are the most commonly isolated environmental pathogens,[7] but many gram-positive organisms (e.g., *S. uberis, S. dysgalactiae*) can be found in the cow's surroundings, and initial infection with these pathogens is often from an environmental source. Although coliforms and streptococci are commonly isolated, many other organisms are found in the environment of cows and capable of causing mastitis. The diversity of environmental mastitis pathogens is increasing as management of dairy farms intensifies and a variety of bedding sources are used.[53,133,135] Reducing exposure to environmental pathogens is based on improving hygiene of cows, housing areas, and the milking process.

Mammary glands with chronic subclinical infections are the predominant reservoirs of contagious mastitis pathogens. Transmission occurs when teats are exposed to bacteria present in milk that came from an infected gland. In many instances, exposure to infected milk occurs during the milking process. Infected milk droplets can be found in teat cup liners, hands of milking technicians, towels used to wash or dry teats, or in milk droplets that leak onto bedding surfaces. The presence of these organisms on teat skin increases the probability of infection. In some cases, abrupt vacuum fluctuations within the milking cluster (reverse-pressure gradients) can propel contagious pathogens from the milk of an infected gland into the teat canal of a healthy gland.[183] The most common contagious mastitis pathogens are host-adapted bacteria that cause long-term subclinical infections. Historically, *S. agalactiae* was considered one of the most important causes of contagious mastitis,[6] but this obligate udder pathogen is controlled in most developed dairy regions, and it is not commonly isolated from bulk milk of U.S. dairy herds.[117,184,185] In recent years, *S. aureus* and *M. bovis* have been the most prevalent contagious mastitis pathogens found in U.S. dairy herds.[184] Most organisms that cause chronic subclinical mastitis are introduced by contagious transmission, so successful control programs for pathogens must reduce the prevalence of subclinically infected cows to reduce the probability that healthy cows are exposed to milk that originated from infected udders.

Classifying organisms as contagious or environmental is a broad characterization of the most common sources of initial exposure to pathogens and does not preclude other potential routes of transmission.[133] Such classifications were developed prior to the development of molecular tools that allow differentiation among bacterial strains of the same genus and species.[167,191] Historically, contagious pathogens were considered to be caused by highly contagious identical clones that were transmitted only among cows, whereas environmental bacteria were often considered to consist of diverse strains found only in the environment. However, DNA fingerprinting has demonstrated that several different strains of contagious organisms like *S. aureus* can be present in cows on a single farm.[192] Similarly, a single dominant strain of *Klebsiella* spp. isolated from multiple cases of mastitis has been reported as evidence of contagious transmission of a supposedly environmental pathogen.[170] Molecular methods have demonstrated that microbes are continually evolving in response to control measures and changes in farm management. Although the traditional categories still provide a reasonable basis for initiating control programs, veterinarians should be aware of the possibilities of additional routes of transmission and the necessity for comprehensive control programs that may exceed typical recommendations.

PREVALENCE OF MASTITIS PATHOGENS. More than 130 organisms, including bacteria, algae, yeasts, and fungi, have been documented to cause mastitis.[193] Some regional differences in prevalence have been demonstrated, but the distribution of pathogens that cause clinical and subclinical mastitis on modern dairy farms is remarkably consistent (see Table 36-1). In recent years, widespread adoption of standardized mastitis control procedures in developed dairy regions has resulted in decreased prevalence of mastitis caused by contagious pathogens such as *S. aureus* and *S. agalactiae* (see Table 36-1).[117,135,194] Failure to control these herd pathogens is typically a consequence of failure to effectively implement well-known mastitis control procedures like postmilking teat dipping and comprehensive use of antimicrobial dry-cow therapy.[185,186] On most dairy farms, about 25% to 30% of milk samples obtained from cows secreting

VetBooks.ir

abnormal milk result in no significant growth of bacteria (see Table 36-1), usually because of an effective immune response to infection by opportunistic environmental pathogens. Coliform bacteria and environmental streptococci are the most common pathogens identified from milk samples collected from cases of clinical mastitis (see Table 36-1). In contrast, when milk samples are collected from cows with subclinical infections, few coliform bacteria are identified, indicating the short duration and clinical nature of most of these infections.[108,187-190] In regions that have controlled *S. aureus* and *S. agalactiae,* CoNS are the most prevalent pathogen group associated with subclinical infections (see Table 36-1). Although epidemiologic studies of mastitis pathogens within regions have resulted in consistent recovery of typical groups of pathogens, pathogen distribution often varies among farms, based on individual risk factors. Implementing effective control programs and correct treatments must be based on understanding the etiology of mastitis, and sufficient diagnostic testing should routinely be used by veterinary practitioners who are working to control mastitis.

CHARACTERISTICS OF PATHOGENS. The pathogenesis, virulence, and prognosis of IMI is influenced by important characteristics that vary among pathogens. General characteristics of the most common mastitis pathogens are described in Table 36-2. Depending on specific virulence factors, organisms infect different locations in the mammary gland, have differing abilities to cause systemic symptoms, vary in the expected duration of subclinical phases of infection, and differ in the expected rate of spontaneous bacteriologic cure (see Table 36-2). Understanding these differences is fundamental to developing effective control programs.

MASTITIS CAUSED BY STAPHYLOCOCCAL SPECIES

Staphylococcus aureus. The genus *Staphylococcus* contains at least 47 species and 24 subspecies (available at http://www.bacterio.cict.fr/s/staphylococcus.html), and the initial differentiation of this genus is based on its ability to coagulate plasma.[6] Of staphylococci associated with bovine mastitis, *S. aureus* and *Staphylococcus hyicus* are coagulase positive, but *S. hyicus* is considered a minor mastitis pathogen and is usually grouped with CoNS. *S. aureus* is considered a major mastitis pathogen because of its impact on SCC and widespread prevalence. *S. aureus* has been isolated from bulk tank milk of about 40% of U.S. dairy herds,[184] but the prevalence and economic impact vary tremendously among herds. Most IMIs caused by *S. aureus* are chronic and subclinical, with periodic bouts of mild clinical mastitis. However, clinical mastitis caused by *S. aureus* can result in systemic signs, or the affected mammary gland can become gangrenous. Herds with a large proportion of cows with *S. aureus* mastitis tend to have higher BTSCCs and many cows with chronically increased SCCs (see Table 36-2).

IMI caused by *S. aureus* is diagnosed by isolating coagulase-positive staphylococci from milk samples of cows. When grown on appropriate media, colonies usually demonstrate hemolysis and other typical phenotypic characteristics.[6] Some *S. aureus* strains are coagulase negative,[195] and other *Staphylococcus* spp. (e.g., *S. hyicus*) can be catalase positive,[196] so definitive identification requires additional diagnostic testing. There are many different strains of *S. aureus*. When DNA fingerprinting is used, some herds may have a predominant strain while other herds may exhibit diverse strains.[192,197] Strains of *S. aureus* differ in contagious transmission, virulence, and antibiotic susceptibility, leading to variable responses to treatment and control measures among herds and among cows.[198-200] In some cases, multiple strains of *S. aureus* co-inhabit a gland or cow.[201] Resolution of infection with one strain can be followed by infection with another strain.[202]

S. aureus adheres to and invades mammary epithelial cells and interstitial tissue.[203-205] The organism also resists phagocytosis by neutrophils. Antiphagocytic mechanisms include a capsule that inhibits opsonization and a surface protein (protein A) that binds the Fc portion of host Ig. Leukotoxin production enables some *S. aureus* strains to kill phagocytes.[206] Other mechanisms allow *S. aureus* to survive within leukocytes and epithelial cells and induce apoptosis.[205,207,208] *S. aureus* strains produce a variety of enzymes and exotoxins that damage mammary cells and result in fibrosis and abscess formation.[209] Some strains produce β-lactamase, conveying resistance to antibiotics such as penicillin and amoxicillin. Others convert to L-form or small-colony variants that can persist with antibiotic therapy.[210-212] Certain *S. aureus* strains form adherent colonies surrounded by a biofilm, making them inaccessible to phagocytes and antibiotics[213,214]; biofilm-associated proteins are associated with persistent *S. aureus* mastitis.[213] For these reasons, *S. aureus* IMIs seldom resolve spontaneously and are difficult to treat with antibiotics.

Herds where replacement heifers or lactating cows are purchased without screening the animals or source herds often have a greater prevalence of *S. aureus* mastitis and more *S. aureus* strains than closed herds, illustrating the importance of biosecurity in mastitis control.[197] The prevalence of infected cows within a herd is an important risk factor for new infections. Cows with chronic *S. aureus* infections or characteristics that predict a low likelihood of cure should either be culled as soon as economically feasible or segregated and milked last.[185,215] Alternatives are simply to stop milking the infected gland or induce cessation of lactation in an individual gland.

Coagulase-Negative Staphylococci. In most studies, CoNS are the most prevalent bacteria isolated from milk samples obtained from cows with subclinical infections and from mammary secretions of dry cows and prepartum heifers (see Table 36-1).[216] Based on use of traditional microbiological methods of identification, at least 10 species of CoNS have been isolated from IMIs of dairy cows.[135,216-218] Epidemiologic differences among various infective species have not been well defined, and control programs are not currently based on differentiation among species.[219] Thorough understanding of epidemiologic characteristics and differences in pathogenesis among species of CoNS has been limited by the relatively poor discriminatory ability of diagnostic tests that are based on phenotypic or biochemical features.[171] Accurate identification of CoNS associated with bovine mastitis is greater for genotypic methods, and use of these methods in research will likely result in better understanding of potential differences among CoNS species.[171,220]

Staphylococcus chromogenes, S. hyicus, and *Staphylococcus simulans* are the most common species associated with bovine mastitis.[154,217] Staphylococci are the most common organisms recovered from mastitis in heifers, and a variety of CoNS species have been recovered from teat skin, the streak canal, and precalving udder secretion obtained from heifers.[216,221-223]

Because IMIs due to CoNS typically cause subclinical infection associated with only modest increases in SCC,[217] they are often referred to as "minor" mastitis pathogens despite their widespread prevalence.[220] Most infections caused by CoNS remain subclinical with SCCs less than 500,000 cells/mL.[105] However, when CoNS infections persist, they may be characterized by greater increases in SCC.[224] Some researchers have suggested that CoNS infection protects the mammary gland against infection with major pathogens[225,226] or shortens the duration of infection with other pathogens.[227] However, other researchers have demonstrated either no protective effect or that IMI caused by CoNS increased the risk of infection with other pathogens.[228,229] Current research is not definitive, but current information suggests that IMIs caused by CoNS are not protective against other infections and should not be considered as a management strategy that will result in reduced mastitis or improvements in milk quality.

Although CoNS account for about 15% to 20% of subclinical IMIs, they are recovered from a relatively small proportion of cases of clinical mastitis, and clinical signs are usually mild (see Table 36-1).[7,133] The rate of spontaneous cure is often high,[230] but intramammary treatment used for cases of clinical mastitis caused by CoNS usually results in bacteriologic cure rates that exceed 80%.[217,220] Use of β-lactam intramammary antibiotics at dry-off is often successful in treating subclinical IMI caused by CoNS. Treatment of subclinical IMI caused by CoNS during lactation is unlikely to be profitable because a potential increase in milk yield after treatment has not been

VetBooks.ir

TABLE 36-2

Summary of Characteristics of Common Mastitis Pathogens

Pathogen	Most Common Point of Infection in Mammary Gland	Duration of Subclinical Phase	Clinical Cases That Develop Systemic Signs (%)	Typical SCC Response (Cells/mL)	Common Source of Infection	Risk of Cow-to-Cow Transmission	Expected Rate of Spontaneous Bacteriologic Cure	Key Preventive Strategies
Gram-Positive Organisms								
Staphylococcus aureus	Adheres to and invades mammary parenchyma	Long	10%-20%	Variable, ranging from 250,000 to >1,000,000	Exposure to milk from infected cows	Moderate to high	Very low	Cull or segregate infected cows, five-point plan, good biosecurity
Coagulase-negative staphylococci (CoNS)	Usually mucosal surfaces	Short to moderate	2%-10%	<500,000	Teat skin	Low to moderate	Moderate to high	Teat dipping and hygiene
Streptococcus agalactiae	Mucosal surfaces of ducts and cistern	Long	<1%	>800,000	Obligate udder pathogen	High	Negligible	Identify and treat infected cows, dry-cow therapy, five-point plan, good biosecurity
Other *Streptococcus* spp. (*S. uberis, S. dysgalactiae,* others)	Variable depending on species	Moderate to long	10%-20%	>500,000; varies by spp.	Environment and milk from infected cows	Varies by spp.	Low to moderate	Improve environmental hygiene
Corynebacterium bovis	Teat canal		<1%	<200,000	Exposure to milk from infected cows	Moderate	Moderate to high	Teat dipping
Gram-Negative Organisms								
Escherichia coli	Mucosal surfaces	Short	25%-30%	>1,000,000	Environment	Low	Usually high	Improve hygiene; vaccination
Klebsiella spp.	Variable by strain	Moderate to long	25%-30%	>500,000	Environment and milk from infected cows	Varies by strain	Low to moderate	Improve hygiene; vaccination
Serratia spp. (*S. marcescens, S. liquefaciens,* others)	Can invade mammary parenchyma	Moderate to long	<15%	>500,000	Environment, chlorhexidine teat dips	Moderate	Moderate	Change to iodine dip, cull or segregate infected cows
Other Commonly Isolated Organisms								
Mycoplasma bovis and other spp. (*M. californicum, M. bovigenitalium,* others)	Distributes throughout udder and other organs	Long; often multiple glands affected	Variable depending on herd	>500,000	Infected cows; aerosol transmission among cows infected with respiratory disease is common	High	Low	Cull or segregate infected cows, five-point plan, good biosecurity, control respiratory disease
Prototheca spp. (*P. zopfii, P. blaschakeae, P. wicherhamii,* others)	Epithelial layer of mammary alveoli	Often long	Few	>500,000	Environment and milk from infected cows; poor hygiene during IMM treatments	Moderate	Low to moderate	Cull or segregate infected cows, five-point plan, reduce exposure to water, improve hygiene for IMM infusions

IMM, Intramammary.

VetBooks.ir

documented. There are no specific control measures for CoNS mastitis. Effective pre- and postmilking teat dipping, use of comprehensive antibiotic treatment of cows at dry-off, and attention to udder and milking hygiene are recommended.

MASTITIS CAUSED BY STREPTOCOCCAL SPECIES

Streptococcus agalactiae. *S. agalactiae* is considered an obligate udder pathogen, and control measures focused on reducing the prevalence of infected cows are highly effective.[5,231] This organism is rarely isolated from individual cow milk samples (see Table 36-1) or bulk tank milk obtained from U.S. dairy farms.[184] However, without proper attention to biosecurity and milking procedures, *S. agalactiae* can be introduced and spread rapidly throughout a herd, resulting in substantial economic loss. Mastitis caused by *S. agalactiae* is usually subclinical and if not treated can persist for months or years (see Table 36-2). Subclinical infection may be interspersed with bouts of mild clinical mastitis, but only rarely will cows exhibit systemic signs.

S. agalactiae adheres to epithelial cells in the mammary gland and localizes primarily in the ducts. Milk production declines when ducts become blocked with cells and debris and the associated alveoli involute. Early treatment can result in increased milk production because the superficial nature of the infection results in minimal damage to the milk secretory cells.[231] However, tissue damage, fibrosis, and a permanent decrease in milk production can occur if infection becomes chronic. *S. agalactiae*–infected glands tend to shed high concentrations of bacteria and SCCs in milk, and this organism should be suspected when BTSCC exceeds regulatory limits.[18]

S. agalactiae is easily isolated from milk samples and is diagnosed when esculin-negative, CAMP-positive streptococci are identified in milk samples obtained from bulk tanks or individual cows. Because *S. agalactiae* is an obligate udder pathogen, rt-PCR is a useful diagnostic tool for rapid diagnosis of infected cows.[173,232-235] When the organism is found in bulk milk or milk samples of affected cows, a sampling plan should be developed to screen the herd to identify and treat all infected cows. Control programs for *S. agalactiae* are based on eradication through identification, treatment, culling, and biosecurity.[185,231]

Environmental Streptococcal Species. A number of streptococci and closely related organisms are frequently isolated from milk samples collected from cows with clinical and subclinical mastitis (see Table 36-1). *S. uberis* and *S. dysgalactiae* are the most common streptococcal species recovered from IMI, but other species such as *Streptococcus parauberis, Streptococcus equinus, Streptococcus saccharolyticus, Streptococcus salivarius,* and *Streptococcus canis* have also been associated with mastitis.[236] A number of gram-positive, catalase-negative cocci such as *Enterococcus faecalis, E. faecium, Aerococcus viridans,* and several species of *Lactococcus* have similar reservoirs and are often grouped with streptococci.[172] Because the primary reservoir of these opportunistic pathogens is bedding materials in cow housing areas, they are collectively referred to as *environmental streptococci.* Many IMIs caused by environmental streptococci result in subclinical infections, and strains that become chronic may be contagiously transmissible among cows.[237-239]

Environmental streptococci are shed in cattle feces and are often ubiquitous in the dairy farm environment.[240] Infected dogs and cats can carry *S. canis* in their respiratory and urogenital tracts and serve as potential sources of infection for cows.[237,239] *S. uberis* is found in the vagina of cows,[240] but genital tract secretions probably play little role in transmission of infection. Teats are often exposed to environmental streptococci that are present in bedding contaminated with feces and urine[241]; straw is well known to support growth of *S. uberis.* *S. uberis* also affects cows in pastures and is the most frequent cause of mastitis in New Zealand dairy herds.[149,194] High-traffic cow lanes and areas of pastures or lots where cows congregate and defecate harbor *S. uberis* and serve as reservoirs.[240]

Roughly 50% of environmental streptococcal infections are initiated during the dry period.[242] The mammary gland is highly susceptible to environmental streptococcal infection during the early and late stages of the dry period, when mammary secretions accumulate and host defense mechanisms are compromised.[243-246] However, infection may develop at any stage of lactation. Infection is accompanied by a rapid influx of neutrophils into the mammary gland and a resultant increase in SCC. Based on experimental inoculation studies with *S. uberis,* the recruited neutrophils are unable to fully prevent bacterial multiplication.[210,241] Ineffective host response probably explains the prolonged infections and persistently high SCCs seen in some cases.

Environmental streptococcal infections often remain subclinical and induce large increases in SCC.[105] A high prevalence of IMI caused by environmental streptococci may result in increased BTSCCs and loss of quality premium payments. In rare instances, the number of environmental streptococci in bulk tank milk may result in bacterial counts that exceed the regulatory limit of 100,000 CFU/mL.[248]

Although many IMIs caused by environmental streptococci spontaneously cure within 30 days, about one third of infections persist for long periods, sometimes more than a lactation. Up to 50% of IMIs caused by environmental streptococci may result in clinical signs,[242] but only about 10% to 20% of those cases will become systemically ill.[7,130,133] Control of IMI caused by environmental streptococci is based on reducing exposure in housing areas and ensuring that cows remain healthy, clean, and dry.

MASTITIS CAUSED BY COLIFORMS

Characteristics Shared Among Coliform Bacteria. *Coliform bacteria* are defined as gram-negative rod-shaped organisms that can ferment lactose.[6] These organisms are fairly easy to identify because growth on MacConkey agar results in a characteristic pink colony. *E. coli* and several other genera, such as *Klebsiella, Enterobacter,* and *Serratia* (some are non–lactose fermenting), are commonly associated with bovine mastitis (see Table 36-1), while other coliforms such as *Citrobacter* spp. only rarely cause mastitis. Coliform organisms include both pathogenic and non-pathogenic strains that are ubiquitous in the dairy farm environment and are frequently shed in feces. Within individual bacterial species, a wide variety of strains are capable of causing mastitis.[249] Teats are initially exposed to these organisms in housing or pasture areas, so coliforms are considered primary environmental pathogens. Organic bedding materials like straw, wood chips, sawdust, recycled manure or solids from methane digesters, pelleted corncobs, and newspaper support the growth of coliform bacteria, particularly under warm, wet conditions.[250] Environmental conditions like increased ambient temperatures and increased rainfall influence the growth of bacteria and thus the extent of teat end exposure and risk of IMI. Likewise, management decisions such as increased housing density, poor stall design, failure to use sufficient bedding materials, or poor pasture management can increase the probability that teats will be exposed to coliform bacteria in manure.

In early lactation, clinical mastitis caused by coliforms may be the result of IMI acquired during the dry period.[246,251] However, coliform infections can be acquired at any time during lactation, particularly if the exposure is great and primary defense mechanisms (e.g., teat sphincter patency) are compromised.

After coliform bacteria infect the mammary gland, they multiply rapidly, but most do not adhere to or invade the epithelial cells.[252] If the cow's immune response is rapid and efficient, infection will be quickly eliminated and there will be little long-term impact on cow health or productivity. Although the majority of clinical cases of mastitis caused by coliform bacteria are mild, up to 30% of cases may result in systemic signs like anorexia, fever, or a marked drop in milk production.[7,120,130,131,133] On most farms, IMI caused by coliform mastitis accounts for the majority of mastitis cases accompanied by systemic signs.[247,248] Development of systemic signs and severe disease is primarily associated with characteristics of the cow that influence her ability to respond to the infection.[252] When influx of neutrophils is delayed or phagocytosis or intracellular killing mechanisms of neutrophils impaired, bacterial multiplication continues, resulting in greater concentrations of inflammatory mediators and more severe

VetBooks.ir

clinical disease.[253] Severe cases occur most frequently in the periparturient period and early lactation.[69,254,255]

The outcome of clinical mastitis caused by coliform bacteria depends on the severity of the case, which is usually dependent on the balance between the dose (relative degree of exposure) and the ability of the cow to respond immunologically. Increased or subnormal rectal temperature, reduced rumen contraction rate and amplitude, marked dehydration, and marked depression are associated with increased risk of death, culling, or poor return to milk production.[131,256] Severe neutropenia[131] and high bacterial concentration in the milk[131,257] are also indicative of a poor prognosis. Cows in early lactation do not develop neutropenia to the extent observed in later lactation, so the leukogram is not a good indicator of mastitis severity in early lactation.[258,259]

In contrast to environmental streptococcal mastitis, intramammary antibiotic treatment at dry-off is considered less effective in preventing coliform infections during the dry period.[260,261] The spectrum of activity of many antibiotics (β-lactams and macrolides) used for dry cows in the United States is primarily directed toward gram-positive pathogens. Infusion of internal teat sealant at dry-off reduced the incidence of new *E. coli* infections compared with infusion of antibiotics (cephalonium) in one study.[262] However, the risks of new gram-negative IMIs during the dry period and clinical mastitis during early lactation were similar when quarters were treated with teat sealant plus antibiotics (cloxacillin) or antibiotics alone.[263] The use of internal teat sealant combined with appropriate intramammary antibiotics has been shown to result in reduced frequency of new IMI caused by coliform bacteria.[264]

Control of mastitis caused by coliform bacteria is based on reducing teat end exposure to these organisms. This is especially true for periparturient cows that may have compromised immune responses. Improving hygienic conditions of the cows' surroundings and during the milking routine, reducing cow density, and ensuring that cows have access to an adequate diet are fundamental steps used for reducing the incidence of coliform infections. Although coliforms are often referred to as a group, there are some important differences in pathogenicity and expected outcomes of IMI among the coliform genera.

***Escherichia coli*.** Most IMIs caused by *E. coli* are of short duration, and these organisms are rarely isolated from cases of subclinical mastitis.[265] Although many producers may believe *E. coli* typically causes severe mastitis, research demonstrates that about one third of cases of clinical mastitis will present with mild symptoms (only abnormal milk), one third will present with moderate symptoms (abnormal milk accompanied by local signs in the udder), and one third will present with systemic signs.[7,133] Most cases of clinical mastitis caused by *E. coli* are preceded by low SCC values, and the transient nature of most *E. coli* infections is evidenced by the rapid return of SCC to relatively normal levels within weeks of occurrence of a clinical case.[109] As expected for opportunistic pathogens, a large number of *E. coli* strains have been demonstrated to cause bovine mastitis, and most of these strains lack known virulence markers.[266] However, about 10% of *E. coli* cases can result in persistent infections that may result in recurrent clinical mastitis in the same or another quarters.[267,268] Persistent strains have been shown to be able to invade and replicate within mammary epithelial cells, and the ability to survive in an intracellular reservoir is likely a survival mechanism of some *E. coli* strains.

***Klebsiella* Species.** *Klebsiella oxytoca* and *Klebsiella pneumoniae* are the two most common species associated with bovine mastitis. Recent molecular studies have shown that some organisms previously identified as *Klebsiella* spp. are actually *Raoutella* spp.[170,269] The clinical presentation and management of mastitis caused by *Raoutella* spp. are identical to recommendations for control of mastitis caused by *Klebsiella* spp.[269] The distribution of symptom severity is similar for clinical mastitis caused by *Klebsiella* and *E. coli,*[7] but the impact of *Klebsiella* spp. mastitis on milk yield is significant and long lasting.[128,263] In contrast to *E. coli,* IMIs caused by *Klebsiella* spp. are often of much longer duration[259] and are often accompanied by longer-lasting increases in SCC. Initial IMI may be environmental, but between-cow transmission can occur during periods of subclinical infection. Sawdust bedding has been implicated in outbreaks of *Klebsiella* mastitis,[270] but *Klebsiella* spp. can proliferate rapidly in other bedding materials, and fecal shedding from healthy dairy cows has been documented.[271]

***Serratia* Species.** *Serratia marcescens* and *Serratia liquefaciens* are the species most commonly associated with bovine mastitis. Many *Serratia* spp. produce bright red colonies on blood agar, but they are easily outcompeted by other pathogens, and prevalence may be underestimated unless special media and cultural conditions (e.g., incubation at 20° C) are used.[272,273]

In contrast to mastitis caused by other coliforms, IMI caused by *Serratia* spp. often persists in a subclinical form for many months. Field observations and experimental infections have demonstrated that *Serratia* spp. are less pathogenic than most other coliform infections, probably because they stimulate a less profound immune response.[274] In contrast to other coliform bacteria, few cases of mastitis caused by *Serratia* result in severe clinical signs.[275,276] However, *Serratia* infection persists longer than *E. coli.* A mean duration of 55 days has been reported,[275] but many infections persist for 6 to 10 months.[272,276] Substantial SCC increases in cows and bulk milk are often associated with herd outbreaks of mastitis caused by *Serratia* spp.[272,273]

Serratia IMI can originate during lactation or the dry period. In one longitudinal study, 48% of *Serratia* infections were acquired during the first half of the dry period and 31% during the second half, with only 21% initiated during lactation.[275] IMI caused by *Serratia* can originate from environmental reservoirs like organic bedding material,[272,273] but *Serratia* mastitis is frequently associated with contaminated chlorhexidine teat dips or teat dip cups.[269,277-279] In one outbreak that used molecular analysis to identify a source, the diversity of *Serratia* strains identified indicated that chlorhexidine teat dips became contaminated with unique strains at each farm.[270] Antibiotic therapy is usually ineffective,[275,276] but up to 50% of infected quarters may eventually self-cure.[269,275] Segregation of chronically infected cows may help contain an outbreak.[272] Culling is recommended for cows with recurrent cases of clinical mastitis or persistently high SCCs.

MASTITIS CAUSED BY OTHER ORGANISMS

***Mycoplasma* Species.** *Mycoplasma* spp. are well-known dairy cow pathogens that infect a number of organs and cause a variety of cattle diseases.[280] *Mycoplasma* spp. are associated with otitis media in calves, infections of the urogenital tract, arthritis in calves and cows, pneumonia, and mastitis. Infections caused by *Mycoplasma* spp. can be recognized in disease outbreaks that present with a variety of symptoms and result in significant economic losses for dairy farms. *Mycoplasma* has been isolated from bulk tank milk of less than 4% of U.S. dairy herds,[184] but the prevalence is strongly associated with herd size and region. In 2007, *Mycoplasma* was isolated from some 14% of bulk tank milk samples obtained from herds that contained over 500 cows.[184] Risk factors for mycoplasmal mastitis include co-mingling of cattle from multiple herds, off-site rearing of calves, and stressors like overcrowding, unhygienic milking practices, and insufficient biosecurity programs.

A number of *Mycoplasma* spp. are considered pathogenic for cattle, but the most common species associated with mastitis include *M. bovis, Mycoplasma californicum,* and *Mycoplasma bovigenitalium.*[281] *M. bovis* is the most common species associated with bovine mastitis. *Mycoplasma* spp. can be isolated from a variety of mucosal surfaces of both normal and ill cattle, but increasing evidence suggests that *M. bovis* is an important cause of chronic nonresponsive pneumonia in cattle.[282] Although *Mycoplasma* spp. can be isolated from the nares of clinically normal cattle, several researchers have noted that the prevalence of nasal shedding is greater in herds that have problems with mycoplasmal mastitis than in herds that have not identified a mycoplasmal mastitis problem.[281] Colonized cattle may remain asymptomatic or may develop bronchopneumonia, otitis, polyarthritis, or mastitis. Because of the unique nature of

VetBooks.ir

carriage and transmission of this organism, veterinarians should review detection, diagnosis, and treatment of bovine respiratory disease as part of an investigation into mastitis outbreaks associated with *Mycoplasma* spp. In dairy herds with mycoplasmal mastitis, otitis media-interna, respiratory disease, or swollen joints may be seen in calves, especially if unpasteurized milk is ingested.[182,280,283]

Transmission of *Mycoplasma* spp. is unique in that multiple routes of infection of the mammary gland are possible. Asymptomatic carrier animals may infect herdmates by shedding the organisms in nasal or vaginal secretions, feces, or milk. Infection can occur at milking time when teats are exposed to fomites infected with *Mycoplasma* organisms that originated from the udder of another cow. However, IMIs can also occur when *Mycoplasma* spp. are spread from other infected body sites like the respiratory tract.[281] In one study, intramammary inoculation of *Mycoplasma* spp. into a single mammary gland was followed by detection of phenotypically identical *Mycoplasma* spp. in extramammary body sites, blood, and noninoculated mammary glands.[284,285] Biddle and associates[286] found that isolates of *Mycoplasma* species from the milk, mammary gland parenchyma, and supramammary lymph nodes of infected cows all had the same pulse-field gel electrophoresis pattern, and that all cows had at least one extramammary isolate with the same pattern. These findings suggest that cows with mycoplasmal mastitis frequently have disseminated infections, and that internal transmission may occur.

The presentation of mastitis outbreaks caused by *Mycoplasma* spp. is extremely variable among farms.[281] On many farms, most IMIs caused by *Mycoplasma* result in persistent subclinical infections. However, clinical mastitis often affects multiple glands (as a result of internal transmission of infection) and will not respond to antibiotic therapy. Many outbreaks of disease caused by *Mycoplasma* are not recognized because diagnosis is dependent on the use of appropriate laboratory methods. *Mycoplasma* spp. have unique growth requirements and must be cultured using appropriate media and incubation under specific conditions such as 10% CO_2. Prolonged freezing of milk samples reduces the concentration of viable organisms and may result in false-negative diagnoses, but broth enrichment before culturing can enhance detection of *Mycoplasma*.[147] When culture is used for diagnosis, the plates must be allowed to incubate for up to 7 to 10 days, because some colonies grow very slowly. Identification of *Mycoplasma* DNA in milk is indicative of an IMI, so diagnosis using PCR is useful because a diagnosis can be achieved more rapidly. PCR-based diagnostic methods have acceptable limits of detection (<100 CFU/mL) and use primers that differentiate among several *Mycoplasma* spp.[168] Although PCR-based methods will be increasingly used, it is important to review the health and SCC history of PCR-positive cows to ensure that identification based on DNA is indicative of active infection.

The recovery of *Mycoplasma* spp. from bulk tank milk is strongly suggestive of the occurrence of at least one infected animal in the milking herd,[144] but failure to find *Mycoplasma* does not necessarily mean the herd is free of infection. Infected cows may not be contributing to the bulk tank, they may be culled, or they may be not be shedding sufficient numbers of bacteria to be detected using typical culture methods. After identification of an infected herd, the next step is to identify the infected animals by obtaining milk samples from high-risk cows. It is possible to collect samples of milk from each string during milking to narrow sampling of individual cows to groups that test positive. Individual milk samples can then be collected and pooled to identify individuals for further testing. Cows with clinical mastitis and those with high SCC are good candidates for testing, but some infected animals may not exhibit clinical mastitis and may maintain relatively low SCC values, so diagnostic testing should continue until the bulk tank tests negative and symptoms of an outbreak subside.

Mycoplasma organisms lack a cell wall, so most antibiotics approved for use in dairy cattle are not effective. Antibiotic treatment during lactation or at dry-off is not useful for control of mycoplasmal mastitis. Although some IMIs may resolve spontaneously, infected cows should be considered permanently infected. Even if repeated culturing of milk from an individual quarter yields negative results, infection might persist in an extramammary site and spread to the mammary gland later. For this reason, the most commonly and least risky control strategy is based on an aggressive test and culling program for all cows diagnosed with mycoplasmal mastitis.[287] However, even aggressive diagnosis and culling programs may not prevent periodic mycoplasmal mastitis incidents if infections persist asymptomatically in extramammary sites. Controlling mycoplasmal mastitis in a herd is possible without aggressive culling if within-herd segregation, effective biosecurity, and excellent milking techniques are implemented.[281] This strategy is risky, however, because even with these practices, airborne transmission among cows may still occur. Vaccination against *M. bovis* is possible because bacterins are available, but their efficacy for control of mastitis has not been demonstrated. Vaccination against *M. bovis* is hindered because of variable expression of a diverse and ever-changing set of genes encoding variable surface lipoproteins (Vsps).[288]

Overall, control of *M. bovis* is based on identifying infected cows, preventing transmission through excellent biosecurity, and implementing milking and management programs that prevent new infections.[281] As with other pathogens that can be transmitted in a contagious manner, effective postmilking teat dipping is required. *Mycoplasma* spp. are susceptible to most germicides found in teat dips.[289] Effective premilking and postmilking teat dipping and other measures used to prevent the spread of contagious pathogens in the milking parlor help limit mycoplasmal mastitis transmission. Care must be taken to ensure that hospital pens do not become a source of transmission either through direct contact with infected cows or through fomites or airborne transmission.[290] Control of respiratory disease and provision of housing with excellent ventilation are also necessary. Pasteurization of waste milk reduces the risk of *Mycoplasma* transmission to milk-fed calves.[283]

Pasteurella multocida. *Pasteurella multocida* is found in the upper respiratory tract of cattle and can be considered both normal flora and a contributor to bovine respiratory disease complex. This organism is occasionally associated with bovine mastitis. Most episodes are sporadic, but herd outbreaks can occur.[291,292] Mastitis caused by *P. multocida* can be recognized by increased incidence of clinical mastitis and BTSCC increases indicative of cows with subclinical infections.[291] Hematogenous or lymphatic spread of *P. multocida* from the respiratory tract to the mammary gland has been proposed, and *P. multocida* has been isolated from the blood of cows with severe coliform mastitis.[293] However, it is unlikely that hematogenous or lymphatic spread is responsible for herd outbreaks. Contamination of teats by nasal secretions (e.g., from nursing calves or intersucking cows), cow-to-cow spread at milking time, or inappropriate infusion practices may contribute to outbreaks.[291] Antibiotic treatment has historically been unrewarding, and infected cows are often culled. However, spontaneous resolution appears to occur in some cases.[291] Control of herd outbreaks associated with *P. multocida* should be directed at reducing the possibility of cow-to-cow transmission at milking time and improving ventilation of cow housing areas.

***Prototheca* Species.** *Prototheca* species are unicellular algae that are widespread in nature and occur throughout the world in habitats that contain moisture and organic matter.[52] *Prototheca* have been frequently isolated from feces of cows and other warm-blooded animals such as pigs and rodents.[294,295] On dairy farms, several different *Prototheca* spp. have been found in moist areas like soil, mud, vegetation, and water.[294] *Prototheca blaschkeae* and *Prototheca zopfii* genotypes 1 and 2 have all been associated with bovine mastitis,[296] but *P. zopfii* genotype 2 is the main species associated with herd outbreaks of *Prototheca*-related mastitis.[297,298] Initial IMI is likely due to environmental reservoirs, but several risk factors for *Prototheca* mastitis have been identified.[54] Important risk factors include the use of intramammary infusions of unapproved products and use of internal teat sealants at dry-off. On many farms, *Prototheca* is ubiquitous in the environment, and these risk factors illustrate the importance

VetBooks.ir

of hygienic technique when performing intramammary infusions. When *Prototheca* is identified as a cause of mastitis, veterinarians should investigate treatment practices and ensure that teats are thoroughly cleaned before infusion and that intramammary products are not warmed by being placed in potentially contaminated farm water before infusion into the udder.

P. zopfii will grow on blood agar and can be detected on microscopic examination of colonies stained with Gram stain, but the colonies are easily overgrown and may be underdiagnosed. Diagnosis can be improved by culturing milk on selective media. *Prototheca* Isolation Medium (PIM) contains inhibitory substances that facilitate identification of the organism and is often used in mastitis laboratories. Identification of specific genotypes is not routinely performed but can be done for research or epidemiologic purposes using several molecular techniques.[299,300]

IMI with pathogenic *Prototheca* can result in both subclinical and clinical symptoms, and infections can occur sporadically, endemically, or acutely.[52] Most clinical cases are of mild or moderate severity. Infected cows may become chronically infected and experience persistently increased SCC.[301] Shedding of *P. zopfii* in milk can be persistent or intermittent.[302] Most *Prototheca* IMIs are probably acquired from the environment, but the possibility of contagious transmission among cows should be recognized and prevented as part of a control program.

Treatment of mastitis caused by *Prototheca* is not recommended.[52] *P. zopfii* is resistant to antimicrobial therapy, and infection can persist through the dry period.[302] Therefore, identification, segregation, and progressive culling of infected animals are required to control *Prototheca* mastitis. On most farms, searching for point sources of environmental contamination will not be useful, but hygienic conditions of the environment should be improved. Culling of infected cows should be coupled with identifying and avoiding contaminated environmental sites, enhanced cleaning of feed bunks and watering devices, and use of milking procedures that ensure clean teats and minimize contagious spread of infection.

Corynebacterium bovis. *Corynebacterium bovis* is commonly found in the streak canal and can cause occasional IMIs that result in mild increases in SCC and very little impact on milk yield.[6] It is rarely a cause of clinical mastitis. *C. bovis* can be cultured on routine media like blood agar, but colonies may not be apparent until after 48 hours of incubation. *C. bovis* can be a frequent contaminant in milk samples, and DNA from this organism is frequently identified in association with other bacteria when PCR testing is used on milk samples.[176] This organism can be transmitted from cow to cow at milking time, but effective use of pre- and postmilking teat germicides is effective in controlling transmission.

Trueperella pyogenes. *Trueperella pyogenes* is the current name assigned to an organism that was formerly known as *Arcanobacterium pyogenes;* in the past, this organism was identified as *Actinomyces pyogenes* or *Corynebacterium pyogenes*. IMI with this organism usually results in acute purulent symptoms of clinical mastitis. In most instances, treatments are ineffective, and mastitis caused by this organism has a poor prognosis.[6] Few cases remain subclinical; identification of this organism in bulk tank milk is usually a result of failure to detect and divert milk from cows with clinical symptoms. The outcomes of most cases occurring in lactating cows is loss of the quarter or culling of the cow.[303] Transmission among cows can occur by flies or through environmental exposure of teat skin, especially if teat ends are damaged.[6]

Historically, this organism was considered one of the etiologic agents of "summer mastitis," a condition of prepartum heifers and nonlactating cows that has been recognized mainly in Europe and Japan during summer months.[304] In most cases, anaerobic bacteria (e.g., *Peptococcus indolicus, Bacteroides* spp., *Fusobacterium necrophorum*) and facultative anaerobes (e.g., *S. dysgalactiae*) are also involved.[304,305] Summer mastitis is characterized by a swollen, hard, painful mammary gland containing purulent, foul-smelling secretion. Acutely affected animals typically demonstrate systemic signs ranging from lethargy and reduced feed intake to high fever, severe depression, abortion, and death. Systemic administration of procaine penicillin G often resolves systemic illness, but neither systemic nor intramammary antibiotics are effective at eliminating IMI.[305] The outcome of most episodes of summer mastitis is chronic clinical mastitis or a nonfunctional quarter. Horn flies are believed to be responsible for transmitting summer mastitis. Because *T. pyogenes* is often found in the environment on farms and on body sites of cattle, teat skin contamination may predispose to infection, as occurs with coliform or environmental streptococcal mastitis, particularly if teat defenses are compromised.

Control of summer mastitis is accomplished by fly control, infusion of mammary glands with antibiotics at dry-off, appropriate environmental hygiene practices and stocking density, prevention and treatment of teat lesions, and prompt recognition and segregation of infected cows. Amputation of the teat, which facilitates drainage of secretions, increases environmental contamination and should not be done unless the cow can be segregated.

Yeast Mastitis. Yeasts are microorganisms that are ubiquitous in the environment of dairy farms, and they can cause opportunistic IMIs. Sources of exposure of teats include contact with soil, plants, and water and feedstuffs such as total mixed rations (TMR).[306] *Candida* spp., *Trichosporon beigelii,* and other yeast organisms can cause clinical mastitis in individual cows or herds.[6] Yeast infection usually follows intramammary antibiotic treatment or teat skin injury. Outbreaks often occur when homemade infusion products or associated equipment (e.g., needles, syringes, bottles, cannulas) are contaminated or when the teat is not adequately disinfected before infusion.[180,307] In one study, six cows treated with a homemade intramammary antibiotic solution contaminated with *T. beigelii* all developed fever, hypogalactia, and swollen mammary glands within 2 weeks, and two of the six died. When the producer continued to use homemade solutions, an additional 23 cows (over half the herd) became infected, and the herd was dispersed.[307] Yeast can be cultured from towels or teat cup liners used on infected cows, suggesting that contagious transmission may occur.[307,308]

On blood agar, yeast colonies appear similar to CoNS colonies, so it is important to examine the colonies microscopically. Sabouraud dextrose agar with antibiotics is a common alternative medium that selects for yeasts. Yeast infections are not susceptible to antibiotic treatment, and infusion of antibiotics may potentiate infection. Use of antifungal agents is prohibited in the United States, but experimental use has not been demonstrated to be effective. Infection (especially with *Candida* spp.) often resolves spontaneously within 2 to 4 weeks,[306,308] but cows with severe or recurrent clinical mastitis, reduced milk production, or persistently high SCC should be culled.[307] Control of yeast mastitis includes aseptic intramammary infusion procedures, use of single-dose commercially prepared antibiotic infusion products, segregation of infected cows at milking time, and use of individual rather than shared towels. Feeding contaminated silage or TMR can promote fecal excretion of yeast and has been blamed for outbreaks of yeast mastitis in some instances.[306,308]

***Pseudomonas* Species.** *Pseudomonas* is considered an environmental pathogen and is commonly isolated from water sources on dairy farms.[6] *Pseudomonas* spp. typically appear on blood agar as white or gray hemolytic colonies and may produce a grapelike odor. *Pseudomonas aeruginosa* is the most common spp. isolated from milk of mastitic cows. IMI with *Pseudomonas* spp. can result in severe clinical mastitis that may develop into gangrene.[309] However, chronic subclinical mastitis with periodic bouts of mild clinical mastitis is the more common presentation.

After IMI with *Pseudomonas* spp. is established, it usually persists, and antibiotic therapy is unsuccessful. This is due in part to production of factors (e.g., biofilm) that inhibit host defenses and reduce antibiotic efficacy.[71] Cows with persistently high SCC or repeated bouts of clinical mastitis should be culled, or individual glands may be dried off.[310]

IMI of cows usually occurs when teats come in contact with contaminated water, and the use of water to wash teats before milking has frequently been implicated in outbreaks of *Pseudomonas*

VetBooks.ir

mastitis.[311] Water sources should always be investigated when *Pseudomonas* spp. are responsible for mastitis outbreaks on dairy farms. The use of predipping for teat disinfection rather than washing with water reduces the risk of infections caused by contaminated water sources. Similar to IMI caused by *Prototheca,* mastitis caused by *Pseudomonas* has also been attributed to use of contaminated intramammary infusion products[312] or teat cannulas, inadequate teat end sanitation before drug infusion, contaminated teat wipes,[313] and exposure of cows to stagnant water. Investigation of a herd problem should focus on hygienic practices for intramammary infusion practices and reduction of exposure to water in the environmental and milking process.

***Nocardia* and *Mycobacterium* Species.** *Nocardia* spp. and mastitis-causing *Mycobacterium* spp. are saprophytes and therefore may cause IMI when teats are exposed to unhygienic environmental conditions. However, both *Nocardia* and *Mycobacterium* spp. are uncommon causes of mastitis that have typically been associated with unhygienic use of intramammary infusions or with use of contaminated intramammary products.[6,314] Both of these organisms have been associated with sporadic cases or herd outbreaks of mastitis. Symptoms are variable and can range from greatly increased SCC[315] to death. A tentative diagnosis can be made by observing acid-fast rods or gram-positive rods with branching filaments in a milk smear, but culture of aseptically obtained milk samples is required to diagnose and differentiate *Nocardia* and *Mycobacterium* spp. Prolonged freezing can reduce recovery of *Nocardia* from milk samples.[6] Antibiotic therapy is futile. *Nocardia* is a potentially zoonotic pathogen, and affected animals should be segregated and culled. Control of mastitis caused by these organisms involves proper intramammary infusion practices and general environmental hygiene.

Prevention and Control of Mastitis

Prevention of Intramammary Infection

At the herd level, the prevalence of mastitis is a function of the incidence and duration of IMI. Control programs are directed toward implementing management programs that can influence either duration of IMI or development of new infections. After an infection is acquired, duration of IMI is influenced by the inherent characteristics of the pathogens involved (see Table 36-2), treatment efficacy, and culling decisions. Management practices that focus on limiting IMI duration typically occur after infection-related financial losses have already been incurred. In contrast, control programs that focus on preventing development of new infections are profitable because they reduce mastitis-related losses. Thus, the emphasis on controlling mastitis should be directed toward implementation of management practices that prevent new infections.

Prevention is based on knowledge of where the exposure to pathogens is occurring. In general, contagious transmission occurs when teats of healthy cows are exposed to bacteria that originated from subclinically infected udders of other cows. The primary principle of reducing exposure to pathogens that can be transmitted in a contagious manner is to reduce the possibility of contact with milk that came from subclinically infected cows. Successful implementation of the five-point plan is the basis for control of pathogens that can be transmitted contagiously.[316] The components of the five-point plan are discussed throughout this chapter and include:

1. Postmilking teat dipping
2. Comprehensive use of intramammary antimicrobial therapy at the end of every lactation
3. Appropriate therapy of clinical cases
4. Proper maintenance and functioning of milking equipment
5. Appropriate culling of chronically infected cows

The components of the five-point plan are now widely viewed as standard management procedures and are highly adopted in many developed dairy regions.[127,186] As a result, many regions have dramatically reduced the prevalence of IMI caused by organisms that are primarily transmitted in a contagious manner.

To address the increased incidence of mastitis caused by environmental pathogens, the NMC has added five additional components focused on implementation of a comprehensive mastitis control program (available at www.nmconline.org/docs/NMCchecklistna.pdf). The 10-point mastitis control program incorporates all the components of the five-point plan and is organized in the following checklist:

Point 1: Establishing goals for udder health. As with management of reproduction, nutrition, and production, it is difficult to improve udder health without having clear goals. Although establishing goals seems intuitive, few farmers set aside sufficient time to develop an udder health plan that includes herd-specific goals. Surveys of veterinarians and other professionals who work with dairy producers suggest that barriers to improvement in milk quality are often related to motivation and implementation rather than lack of technical knowledge or skills.[127,317-319] Several studies have shown that many dairy veterinarians are only marginally involved in mastitis control programs. Upon beginning a team-based milk quality improvement program, only 24% of dairy farmers ($n = 180$) indicated that they used their herd veterinarian to plan milk quality programs.[127] In a companion survey, most dairy veterinarians ($n = 42$) interested in participating in a mastitis control program reported that they spent less than 10% of their professional time actively working to improve milk quality.[317] Increased involvement in the development of annual udder health plans is an area of opportunity for dairy veterinarians, and the initial step can be to begin a discussion of herd-specific goals.

Point 2: Maintaining a clean, dry, comfortable environment. Exposure to pathogens that have environmental reservoirs is strongly associated with facility and animal hygiene. Numerous hygienic practices on dairy farms have been associated with the incidence of clinical mastitis.[320-322] The rate of clinical mastitis occurring in dairy cows has been shown to be strongly associated with the cleanliness of animal housing and bedding sources.[320] The number of bacteria on teat skin is associated with bacterial count in bedding,[323] and a linear relationship between the rate of clinical mastitis and the number of gram-negative bacteria in bedding has been demonstrated.[182] Nutritional management can have an indirect influence on hygiene. High-concentrate diets have been associated with looser feces and reduced facility cleanliness.[324] Cow cleanliness can be evaluated using several scoring systems.[322,325] A four-point udder hygiene scoring (UHS) system for assessing udder hygiene has been described by Schreiner and Ruegg.[322] Cows that are scored as having dirty udders were at increased risk of IMI and increased SCC.[322] Similarly, Reneau's group used hygiene scores to evaluate five body areas on dairy cows.[325] The udder and hindlimb scores were significantly associated with SCC.[325] Research has demonstrated that neither UHS nor the rate of new IMI is improved by the use of tail docking, and this practice should not be encouraged.[326,327]

Mastitis control programs should be focused on reducing bacterial exposures by improving facility hygiene. In many herds, clean or recycled sand will be the recommended bedding material because it does not support as much growth of coliform bacteria as organic bedding materials.[182,328,329] In some herds, bacterial counts can be reduced by adding lime and other bedding conditioners, or using other methods to reduce bacterial counts, but the effect is generally short lived.[330,331] Use of dried manure solids as bedding is a risky strategy because these substances are ideal to support growth of bacteria found in the intestinal tract of dairy cows.

Point 3: Proper milking techniques. Milking hygiene and the risk of new IMI can be improved by ensuring that milking technicians wear disposable nitrile or latex gloves.[127,332-334] Essential aspects of an effective premilking routine include effective teat disinfection, examination of foremilk, sufficient stimulation to allow for effective milk letdown, complete drying of the teats, and timely attachment of the milking unit. Research has definitively established that the gold standard for premilking teat disinfection is applying an effective disinfectant for a sufficient contact time, then drying the teat using a single cloth or paper towel for each cow.[335-337] To ensure that clinical mastitis

VetBooks.ir

is detected and abnormal milk does not reach the human food chain, two or three streams of foremilk should be removed and examined before attaching milking units. Teat drying has been demonstrated to reduce bacterial counts of teat ends,[335] reduce the number of colonies of spore-forming bacteria in bulk milk,[338] and effectively reduce the risk of contaminating milk with iodine residues from predips.[339] Separate drying cloths or paper towels should be used for each cow. Using towels to dry teats on multiple herdmates has been associated with a greater monthly rate of clinical mastitis than using a single towel per cow.[127]

Modern dairy cows in high-producing herds have been selected to milk rapidly, and removal of foremilk is often sufficient stimulation to achieve milk letdown. The period of time between stimulation and attachment of the milking unit should be about 60 to 90 seconds, but disturbances in milk flow and yield have not been reported until lag times have exceeded 3 minutes.[340,341] To prevent bimodal milk flows, premature attachment of the milking unit should be avoided.[340] To minimize stress on teat ends, milking units should be removed when milk flow rates drop to a level that indicates most milk has been harvested. In most high-producing herds, milking units are removed when milk flow rates fall below 0.5 to 1 L/min. Automatic take-off units are encouraged because they increase consistency of milking and allow milking technicians to focus more on premilking preparation.

The purpose of postmilking teat disinfection is to reduce contagious transmission of pathogens.[185,342,343] The principle is to kill pathogens deposited on teat skin during the milking process before they colonize the teat orifice and invade the gland. Effective application of postmilking teat dips can result in over 50% reduction in new IMI.[343] Postmilking teat dipping is a highly adopted practice,[127,186,344] but it is not always properly implemented. Milking technicians should be trained to use an application method (e.g., use of a dip cup) that ensures that at least 75% of the teat skin is covered with an approved, commercially formulated teat disinfectant. Efficacy of the postmilking teat dip should have been demonstrated through properly performed scientific trials. The NMC maintains a list of peer-reviewed publications about efficacy trials of teat dips (available at www.nmconline.org/docs/Teatbibl.pdf).

Point 4: Proper maintenance and use of milking equipment. The impact of machine milking on development of new IMI is well known, and veterinarians should be aware of how to evaluate key indicators of milking equipment function. Improper functioning of milking machines can result in reduced resistance of the teat canal to IMI; vacuum fluctuations and liner slips may provide forces that overcome the resistance of the teat canal to bacterial invasion or dispersion of bacteria within the udder; and milking equipment parts can serve as fomites to transfer bacteria among cows.[345] Provision of stable teat end vacuum is a central objective of a properly functioning milking system.[346] A high rate of liner slips has been demonstrated to be associated with increased rates of clinical mastitis and increased risk of IMI.[183] Improperly functioning machines may cause congestion in the teat wall, which can result in slower closure of the teat canal and development of IMI.[345]

Point 5: Good record keeping. Measuring outcomes is an integral part of effective management.[347] Mastitis is a bacterial disease that occurs in individual animals, but mastitis control programs must be implemented at the herd level. Successful mastitis control is dependent on effective detection, accurate diagnosis, evaluation of appropriate treatment options, and implementation of preventive practices that address herd-specific risk factors associated with exposure to mastitis pathogens. Veterinarians who wish to reduce mastitis should regularly review herd records for SCC and clinical mastitis and evaluate key performance indicators relative to herd goals.[347] The program should be structured to allow for the evaluation of cow factors, environmental factors, and milking machine factors that can contribute to exposure to mastitis pathogens. An effective surveillance system for mastitis includes clear case definitions and effective mechanisms to detect both clinical and subclinical mastitis, use of recording systems that allow for timely evaluation of risk factors, and feedback mechanisms that allow management personnel and veterinarians to develop goals and evaluate actions.

Points 6 and 7: Appropriate management of clinical mastitis during lactation and effective dry cow management. These topics are discussed later in this chapter.

Point 8: Maintaining biosecurity of contagious pathogens and marketing of chronically infected cows. Biosecurity programs are designed to reduce the risk that healthy cows will be exposed to bacteria originating from other animals. The goal of mastitis biosecurity programs is to reduce the probability that teats of healthy cows will be exposed to infected milk and to enable the cow to have an effective immunologic response if exposure occurs (see section on immunization later in this chapter). Many farmers arrange the milking order so that lower-risk animals (first-lactation cows or cows with lower SCCs) are milked first to reduce the risk of transmission of mastitis pathogens during the milking process. Physical segregation of chronically infected cows has been shown to be an effective method of reducing the new-infection rate[348,349] but depends on diagnostic methods that can accurately detect infected cows. Use of automated disinfectants to backflush teat cups between cows has been demonstrated to reduce the risk of developing new IMI caused by *S. aureus*,[350] but the cost-effectiveness of these systems depends on the prevalence of infection within the herd.[108] Use of an automated teat dipping and backflush system was shown to result in reduced bulk tank SCC, fewer cows with elevated SCC, and fewer cows with newly increased SCC, but the effect became more significant after 6 to 18 months of use.[351]

The prevalence of chronically infected cows is a strong predictor of risk of new infection with pathogens that can be transmitted in a contagious manner. One study demonstrated that the odds of a cow becoming infected with *S. aureus* doubled with each 5% increase in the herd prevalence of existing infection.[332] Chronically infected cows must be identified through routine testing of individual cows' SCCs, and microbiological analysis should be performed to identify the causative pathogens. Cows that develop chronic infections with pathogens that are refractory to treatment should be culled to reduce the risk of transmission to healthy animals.

When animals from outside sources are purchased, they should be bought from recognized individual herds (rather than sale barns), and historical information such as bulk tank culture results and individual cow SCC histories should be reviewed. Animals should be screened for *Mycoplasma* spp.; a history of recent respiratory disease should be viewed as an important risk factor for this infection.

Point 9: Regular monitoring of udder health status. Udder health recording systems must include monitoring programs that allow assessment of both clinical and subclinical disease. Animal health recording systems for mastitis should consist of both temporary cow-side records that are used for day-to-day decision making and permanent records (e.g., cow cards, computerized records) that are used to summarize trends over time.[352,353] The recording system should be accessible and allow the veterinarian to determine important risk factors and epidemiologic trends.[353] The first step in monitoring subclinical mastitis is to ensure that SCC values are routinely obtained from all cows on a regular basis. Generally, all cows with SCC values above 200,000 cells/mL (linear somatic cell score ≈ 4.0) are considered to have subclinical mastitis. SCCs should be reviewed monthly at both the herd level and the cow level. At herd level, evaluation of monthly SCC patterns can be highly diagnostic for troubleshooting subclinical mastitis problems. Several recommendations for key performance indicators for monitoring udder health are available.[347,353]

Point 10: Periodic review of mastitis control programs. Dairy farming is a complex process that involves interactions among animals, nature, and people. Like other research-based businesses, the growth in knowledge about dairy management practices is extraordinary. Dairy farmers acquire information about animal health from a variety of sources, including veterinarians, nutritionists, other producers, dairy magazines, and consultants. Veterinarians visit multiple farms, see results from a wide variety of management decisions, and bring an outside perspective to farm decisions.

On-farm management teams can be formed to troubleshoot specific farm issues or to meet periodically and review farm performance. A properly formed management team can aid the farmer by bringing together advisors with a range of experiences. Management teams also allow for dialogue between consultants (e.g., veterinarians and dairy plant personnel) that have shared interest in specific outcomes. The management team format is extremely successful in problem-solving mastitis problems. Farms that participated in a team-based milk quality program in Wisconsin increased adoption of best management practices and improved mastitis control.[354]

Prevention through Immunization

The 10-point mastitis control plan includes an emphasis on biosecurity and immunization as aspects of ensuring effective control of mastitis. Understanding the principles of the immunologic response is necessary to successfully implement an effective vaccination program.

Lymphocytes will respond to a specific microbial antigen only if the antigen (protein) is combined with a major histocompatibility complex (MHC) molecule on the surface of host cells, a process referred to as *antigen presentation*.[61] Cells like macrophages and dendritic cells are particularly efficient in antigen processing by phagocytizing, digesting, and presenting antigens on their membrane surface in conjunction with an MHC molecule. In response to antigen presentation, naïve lymphocytes then undergo clonal expansion and differentiation. A specific antigen can only be presented to a lymphocyte that solely recognizes that antigen.[58] Thus, successful immunization against a pathogen must link the invasion of the pathogen with recruitment of innate phagocytic cells that recognize and digest the microbe and subsequently present one of potentially hundreds of different protein antigens from the pathogen on the cell surface to attract and activate a matching lymphocyte that specifically recognizes the antigen. T helper cells play a central role by (1) enhancing B-lymphocyte clonal expansion and differentiation to antibody-producing plasma cells, and (2) completing the inflammatory response loop by releasing cytokines like IL-17 and IFN-γ that stimulate phagocytes to more efficiently phagocytize and kill ingested microbes. Antigen-specific antibodies that arise from the acquired immune response also enhance phagocyte function by opsonizing microbes, thus assisting in target recognition and ingestion.

The decision to employ a vaccine as part of a mastitis control program should be founded on the practitioner's ability to access peer-reviewed studies and compare incidence and severity of natural infections between vaccinated animals and unvaccinated controls. Studies should encompass a diversity of herd management practices and geographic regions. Unfortunately, such trials require a large number of animals and long duration. Alternatively, challenge-exposure trials are often performed to assess vaccine efficacy. This type of trial requires fewer animals and less time, and many variables (e.g., different strains of bacteria, challenge dose, physiologic and lactation status of the animal) can be uniformly standardized. More comprehensive outcomes (e.g., bacterial shedding in milk, physical examination of the cow, changes in biochemical parameters of serum and milk) can also be reliably measured. Unfortunately, these studies may have limited application to the diversity of dairy farm management and environment, as well as among pathogens.

As with therapeutics, appraisal of vaccine efficacy should *not* be made on testimonials, especially herd-level impressions of "before-and-after" responses. Assertions are often made on perceptions that initiating a vaccine program decreased the incidence and severity of mastitis cases, lowered SCC, increased milk production, and so forth, without employing a concurrent non-vaccinated control group for comparison. This is a frequent flaw in the evaluation of autogenous bacterins, in addition to a lack of quality control standards that are rigorously followed in commercial production. Mastitis incidence and SCCs within a herd can rise and fall from many factors, including weather, changes in proportion of younger to older animals in the herd, history of herd additions, correction of milking techniques or deficiencies in equipment, and culling decisions.

IMMUNIZATION AGAINST SPECIFIC MASTITIS PATHOGENS

Gram-Negative Core Antigen (J5 *Escherichia coli*) Bacterins. Gram-negative core antigen bacterins are used on many dairy herds. The most extensively studied variants are formulated with a mutant strain of *E. coli* O111:B4 (Rc mutant, commonly termed *J5*) lacking the "O" antigen capsule of the cell wall but with the core lipopolysaccharide, membrane proteins, and lipid A antigens intact. These core antigens are highly conserved among gram-negative bacteria[355-357] and elicit cross-reactive anti–gram-negative antibodies in J5-vaccinated cows.[357-359] Dairy cattle immunized with these bacterins develop immune resistance against a wide variety of gram-negative bacteria, including mastitis-causing coliforms.

Initial studies in California determined that higher serum anti-J5 *E. coli* IgG correlated with a lower incidence of clinical coliform mastitis.[360] A subsequent field trial demonstrated that compared to unvaccinated cows, animals administered three immunizations (at drying off, 30 days after drying off, and in the postpartum period) had a fivefold decrease in the rate of clinical coliform mastitis in the first 100 days of lactation.[361] A field trial in Ohio using a similar dose regimen reported that J5 immunization did not reduce the prevalence of gram-negative IMIs at calving, but 67% of the infections present at calving in unvaccinated cows developed clinical mastitis, compared to only 20% of the J5-vaccinated cows.[362] In a comparison with unvaccinated controls, cows vaccinated with J5 bacterin demonstrated increased anti-J5 *E. coli* IgG in serum and milk,[362-364] although anti-J5 *E. coli* antibody titers in milk are orders of magnitude lower than in serum. Following intramammary challenge of *E. coli,* J5 immunization reduced the severity of infection but did not prevent infections.[362]

The pathogenesis of severe coliform mastitis is dependent upon LPS-induced immune mediator responses, and a high proportion of severe coliform mastitis cases become bacteremic.[293] J5 bacterins may likely have a greater impact on the systemic effects of coliform mastitis than on local mammary inflammation. This concept is supported by a field trial from New York that determined two doses of J5 bacterin decreased the proportion of clinical mastitis cases that resulted in culling or death by threefold, but did not reduce the overall incidence of clinical mastitis cases.[365] However, coliform mastitis cases contracted during the first 50 days of lactation resulted in less milk production loss among J5-vaccinated cattle.[366]

Gram-negative bacterins are regarded as weakly immunogenic in dairy cattle because they elicit poor amnestic IgG1 and IgG2 responses.[76] An Ontario study found that a substantial population of cows given two J5 bacterin doses during the dry period had poor antibody responses and a higher incidence of mastitis in the subsequent lactation.[367] This relatively short duration of immune protection is supported by several trials.[368-370] A New York study determined that compared to unvaccinated cows, cows vaccinated with two doses of J5 bacterin lost less milk production following clinical mastitis and survived longer. However, this protection, as well as anti-J5 antibody titers, declined as lactation (and time since vaccination) progressed and did not exist by 75 days in milk.[368] In a Michigan study, hyperimmunization of cows with six doses of J5 bacterin resulted in a threefold decrease in severe clinical coliform mastitis from 42 to 126 days in milk, compared to cows that received three doses. This suggested that supplemental immunizations extended protection beyond that offered by traditional vaccination regimens.[369] A subsequent Michigan study determined that cows immunized with five doses of J5 bacterin had elevated anti-J5 *E. coli* antibody IgG1 and IgG2 titers, relative to unvaccinated cows, for up to 60 to 90 days longer than cows administered three doses of J5 bacterin only.[370] The best response to immunization in terms of intensity and duration of antibody response was gained when multiple immunizations were given as a series in different anatomic locations on the cow.[370]

Use of J5-type bacterins relies on five principles:

1. Diagnose if coliform organisms cause a substantial portion of clinical mastitis within a herd.
2. Determine the severity and incidence of clinical coliform mastitis cases.

VetBooks.ir

TABLE 36-3

Guidelines for Core Antigen Gram-Negative Bacterin Use in Dairy Herds

1. Diagnose the cause of clinical mastitis.	Does bacteriology of clinical mastitis cases frequently yield coliforms (gram-negative)?	Bacterin ineffective for gram-positive pathogens.
2. Determine the incidence of severe mastitis caused by coliforms.	Are >1% clinical mastitis cases?	Bacterin reduces severity, not incidence of infection.
3. Describe affected animals.	What are the risk factors associated with animals with severe coliform mastitis in the herd?	Determine whether stage of lactation, age, or season are associated with the problem.
4. Decrease risk factors of exposure.	Are there other critical risk factors for coliform mastitis prevention that should be addressed?	Bacterin effects are diminished in herds with poor sanitation, cow comfort, intramammary infusion techniques, teat end health, or milking preparation.
5. Develop a protocol that best fits the herd.	Will the compliance of the protocol likely be followed? Is it likely to offer the best return on investment?	Immunization programs should be designed to reduce unnecessary doses and target affected animals.

3. Describe the epidemiology of the problem in the herd.
4. Decrease other herd risk factors that may contribute to clinical coliform mastitis.
5. Develop a vaccination protocol that best integrates immunology with herd needs and practical limitations (Table 36-3).

Veterinarians should review these steps when developing a protocol for dairy herds and periodically review progress and changes in the herd that may lead to a reevaluation of the immunization protocol.

Use of *Staphylococcus aureus* Bacterins. Considerable effort that encompasses numerous antigens, virulence factors, and bacterial strains has been made to develop an efficacious and practical *S. aureus* vaccine; interest has focused on vaccination of primiparous heifers. A bacterin containing a lysed culture of polyvalent phage types, including a variety of capsular serotypes, is commercially available in many regions (Lysigin). This product originated from work in Louisiana that determined two initial doses 2 weeks apart, followed by doses at 6-month intervals, reduced IMI at calving caused by both CoNS and *S. aureus*.[371] However, a subsequent challenge-infection study determined that this bacterin did not prevent IMI, accentuate clearance of IMI, or affect SCC or milk yield post challenge.[372] Lysigin-vaccinated heifers did have improved clinical scores and shorter duration of clinical mastitis.[372] Although immunization with Lysigin increased serum anti–*S. aureus* IgG1 in heifers, milk concentrations of IgG1, IgG2, or IgM were not affected.[373] In a subsequent report in lactating cows, representing multiple parities, two doses of Lysigin administered 14 days apart did not reduce the number of mammary quarters that developed new *S. aureus* or CoNS IMI, the time after vaccination to develop new IMI, SCC, or milk antibody isotype sample-to-positive (S:P) ratio.[374] The authors speculated that the bacterin may have induced insufficient opsonizing antibodies in milk to promote phagocytosis.

S. aureus vaccines would likely have limited use in many dairies, especially in herds with a low prevalence of IMI, as is typical for herds with SCCs below 200,000 cells/mL. In herds where contagious mastitis is successfully controlled by practicing excellent milking techniques and maintaining milking equipment, *S. aureus* bacterins are unlikely to have a significant impact. Conversely, immunization in lieu of good management practices is likely to produce disappointing results. Investigators have administered *S. aureus* bacterins in an attempt to augment antimicrobial therapy, with conflicting results.[375,376]

Mastitis Therapy Using Antimicrobial Drugs

General Concepts

Mastitis remains the most common cause of antimicrobial drug therapy for cows on U.S. dairy farms. In 2007, 16.4% of cows were treated for this disease.[114] If this use represents the majority of all U.S. dairy herds—with approximately 9 million dairy cows—nearly 1.5 million mastitis cases are treated annually. Surveys from Wisconsin and Canada estimated that between 2 and 4 doses of intramammary infusions are used per cow per year, or for a 1000-cow dairy, an average of 5 to 10 doses of intramammary antimicrobials would be administered daily.[190,377] Antimicrobial therapy benefits animal health and well-being, but economic losses associated with antimicrobial therapy of mastitis include drug and veterinary expenses, extended labor, and most importantly, discarded milk.[2,378] Unwarranted antimicrobial use in dairy cattle can result in residue violations in milk and meat, eroding consumer confidence in food safety. Culled dairy cows account for 65% of residue violations among all marketed animals in the United States, and 80% of the residues in these animals arise from antimicrobial use.[379]

To date, the risk of emerging antimicrobial resistance among bovine mastitis pathogens has been low, particularly for drugs with high therapeutic value in human medicine.[380-382] Nonetheless, prudent administration of antimicrobials is necessary on dairy farms, similar to stewardship of antimicrobial resources as advocated in human medicine.[383] Responsible antimicrobial stewardship minimizes the emergence and dissemination of antimicrobial resistance among pathogens and preserves the therapeutic integrity of the drugs.

In human medicine, physician behavior when administering antimicrobial therapy is altered by cultural and economic factors that include lack of information, desire to satisfy patient demand, and pressure from managed care organizations to speed throughput.[384] These same behavioral pressures are germane to veterinarians who design therapeutic regimens for dairy farms, although farm personnel, not managed care organizations, drive the desire for economic and labor efficiency. Mastitis therapy is often initiated empirically without consideration of case risk factors for efficacy and as a substitute for an integrated mastitis control program.[385] Standardizing mastitis therapeutic protocols should diminish spontaneous cow-side biases and establish uniformity for therapeutic regimens. However, farmers' therapeutic decisions often differ from veterinary recommendations.[386] Risk factors that decrease therapeutic efficacy include increasing age of the cow, preexisting SCC before treatment, duration of infection, number of quarters infected, and *S. aureus* infections.[128,215,387] In particular, chronic infections have poor therapeutic outcomes and may require extended duration of antimicrobial therapy.[378-389] To reduce antimicrobial use associated with mastitis, we need to change behaviors and attitudes of farm personnel to (1) utilize bacteriology to the best of herd labor abilities, (2) determine the history of the cow, and identify cow-level risk factors that may impact the efficacy of therapy, and (3) apply standardized therapy protocols that are based on sound pharmacology.

A small proportion of cows can be responsible for a large proportion of clinical mastitis episodes in a herd; antimicrobial therapy is unlikely to cure infections in glands with repeated bouts of clinical mastitis episodes. As mentioned previously,[128,215,387] chronic

VetBooks.ir

non-responsive IMIs are poor choices for therapy. Unnecessary losses of time and money are incurred by treating "repeat offender" clinical mastitis cases. When coupled with the lack of bacteriologic culture, thus opening the door for treatment of unresponsive pathogens, a majority of clinical mastitis may be treated unnecessarily on many dairy farms. Veterinarians should direct not only drug selection and protocols for mastitis therapy on dairy farms, but more importantly establish selection criteria for cows to be either included or excluded for treatment.

Alternatives to antibiotic treatment include euthanizing or culling the cow, drying off the cow or gland, administering supportive treatment alone, or doing nothing. The cow's welfare (i.e., minimizing pain and suffering) must be considered when choosing among these options. If supportive treatment or no treatment is chosen, the cow should be milked after healthy cows and the milk withheld from sale as long as it is visibly abnormal. If a single gland is dried off, antibiotics should not be infused; this may result in antibiotic residues in milk from the other glands.

LIMITATIONS OF ANTIMICROBIAL SUSCEPTIBILITY TESTING. Antimicrobial susceptibility test results should not be used as the primary basis for antibiotic selection. In most cases, susceptibility cut-points for zone diameters (for the disk diffusion test) or minimum inhibitory concentration (MIC) values are based on antibiotic concentrations in human serum or interstitial fluid after oral (PO) or intravenous (IV) dosing; these are not equivalent to concentrations achieved in milk or mammary tissue after intramammary or systemic dosing.[390] The absolute MIC value is more useful than a dichotomous result (susceptible or resistant) based on an irrelevant cut-point. However, the reported MIC value may not reflect the MIC in milk because MICs in milk are often higher than in blood, especially for non–β-lactam drugs.[391] The newest intramammary antibiotics have MIC or disk diffusion cut-points that are relevant to treatment of mastitis, but the cut-points have to be validated in vivo. Recent studies have determined that susceptibility test results (susceptible vs. resistant) had no impact on the outcome (clinical cure, bacteriologic cure) of clinical mastitis episodes.[230,392-394] Interestingly, *S. aureus* isolates that are penicillinase-producing strains are less responsive to treatment even if penicillinase-resistant antibiotics are used.[200]

Treatment of Mild and Moderate Cases of Clinical Mastitis

TREATMENT OF CLINICAL MASTITIS CAUSED BY STREPTOCOCCI AND STAPHYLOCOCCI. The effectiveness and selection of antibiotic therapy depend on the pathogen causing clinical mastitis. Cows with cases of mild (severity score 1) or moderate (severity score 2) clinical mastitis and no bacterial growth in the milk are unlikely to benefit from antibiotic therapy, as are cows with a low concentration of *E. coli* in the milk. Cows with mycoplasmal mastitis or mastitis caused by opportunistic pathogens like *P. aeruginosa, S. marcesens, P. zopfii,* or *Candida* spp. are unlikely to respond to antibiotic therapy.[52,281,311,378] Antimicrobial therapy for mastitis cases caused by these pathogens should be avoided and may lead to unnecessary risks for drug residues.

On the other hand, antimicrobial drugs can enhance resolution of many cases of streptococcal or staphylococcal mastitis episodes. The prototype for therapeutic success is treatment of IMI caused by *S. agalactiae*. This organism tends to be highly susceptible to intramammary therapy with β-lactam drugs, with cures of 85% to 90% often reported.[185,231,395] This organism is essentially an obligate udder pathogen in dairy cattle, remains superficial in mammary tissue, and has a high level of susceptibility to therapy. Thus, *S. agalactiae* can essentially be eradicated from a herd by simultaneously treating all infected cows, including subclinical infections.[231,395,396] This can be economical for a dairy, but only if proper prevention programs (e.g., postmilking teat dipping, dry cow treatment) are in place to prevent new infections after herd treatment.[185,231] For this and other gram-positive pathogens, systemic administration of antimicrobial drugs is not likely to attain any better cure rates than intramammary infusions. In one study, cure rates for *S. agalactiae* following intramammary infusion was 91% of treated cows, as opposed to only 9% for cows administered intramuscular (IM) ceftiofur.[395] This outcome also reflects the relatively poor distribution of most drugs used in dairy cattle into the mammary gland, particularly β-lactams, sulfonamides, and aminoglycosides.[385]

Therapeutic efficacy of other gram-positive cocci, with the exception of *S. aureus,* can also be efficacious in many cases. About 10% to 20% of clinical mastitis caused by environmental streptococci are severe.[397] Similarly, the vast majority of clinical mastitis caused by CoNS is mild to moderate. Intramammary infusion of commercial products is the treatment of choice, although some strains of streptococci have been reported to be resistant to cloxacillin and pirlimycin.[200,398,399] Treatment of experimental infections with intramammary therapy attained 90% bacterial cures, compared to no cures in untreated controls.[400] Likewise, studies of naturally occurring clinical streptococcal mastitis determined that intramammary pirlimycin or amoxicillin therapy attained bacterial cures of 70% to 75% of infected quarters, compared to 29% to 39% in untreated quarters.[398,401] However, results can vary depending on the herd, and as mentioned earlier, the duration of infection at the time of treatment has a significant impact on outcome. Cures following pirlimycin therapy for CoNS did not differ from untreated controls in one study (≈45% for both groups).[398] Similarly, about 66% of subclinical quarters infected with streptococci or staphylococci cured whether treated with two doses of intramammary pirlimycin or not treated.[392]

Several studies have described the potential benefits of extended intramammary therapy (beyond the traditional two doses) for the treatment of mastitis caused by streptococci and *S. aureus*.[402-404] This may be appropriate from a pharmacodynamic standpoint because all antimicrobial drugs that are labeled for intramammary use in dairy cattle (U.S.) rely on time-dependent inhibition of bacterial growth. Inhibitory action of the drug is more likely to be efficacious if the concentration of the drug is maintained above the MIC for extended periods of time at the site of infection, as opposed to peak concentrations. Experimental *S. uberis* infections treated for 2, 5, or 8 days (q24h) with intramammary ceftiofur attained bacterial cures in 43%, 88%, and 100% of the infections, respectively.[389] Similar results were obtained for chronic streptococcal and *S. aureus* infections treated with intramammary pirlimycin.[402] In naturally occurring subclinical mastitis, two doses of intramammary ceftiofur cured 39% of infections (including all gram-positive cocci), as opposed to 66% cured in quarters treated with eight doses; however, the sample was insufficient to determine pathogen-specific effects.[404]

The decision to use extended therapy as part of a herd mastitis therapy protocol should be made carefully and when possible should be based on microbiological diagnosis (see earlier section about OFC). The success of therapy with conventional dosing should first be considered. If deemed unsatisfactory, extended therapy may be a viable choice. To date, the benefits of extended therapy have best been determined for infections caused by streptococci and *S. aureus*. One study has determined that extended treatment of mild cases of clinical mastitis caused by a variety of coliform bacteria increased bacteriologic cures and reduced culling but did not influence posttreatment milk yield or SCC, although the outcomes were highly herd dependent.[405] The ability of herd personnel to perform aseptic infusions into the teat canal is critical. Extended therapy is associated with an increased risk of infection from opportunistic pathogens, and herds with poor infusion techniques are not good candidates for multiple doses of intramammary tubes.

S. aureus IMIs often result in deep-seated abscesses. Therapy is difficult because resistance to antibacterials (particularly β-lactams) is more common than with streptococci, and *S. aureus* may survive intracellularly following phagocytosis, where antibacterial concentrations are reduced.[378] Additionally, *S. aureus* has numerous extracellular substances that impart an ability to survive in the presence of a hostile host immune system. Consequently, elimination of IMIs caused by this pathogen is often not as successful as with other gram-positive pathogens.

VetBooks.ir

Cure rates of 25% to 55% of infected quarters have been reported in experimentally induced *S. aureus* IMIs when evaluated for 21 to 60 days after infection.[406] However, the pretreatment duration of natural infections is usually longer before detection and subsequent therapy and thus more refractive to therapy. The importance of duration of infection was evident in a study that determined that intramammary penicillin-novobiocin cured 70% in quarters that had been infected for 14 days or less, compared to only 35% in chronically infected quarters.[388] Similarly, Barkema and colleagues[215] reported a wide variation in the success of therapy: near 60% for younger, newly infected animals but less than 5% in older animals with chronic infections. Even modest results of efficacy reported in the literature may be optimistic, since relapses occurring more than 30 days after treatment are common.[210,404,406] This not only reaffirmed the difficulty in attaining successful therapy but also suggests a poor correlation between in vitro culture and susceptibility and therapeutic outcome in chronic IMI caused by this organism.[407]

Consequently, combinations of parenteral and intramammary treatment regimens may be helpful to eliminate a higher proportion of *S. aureus* infections. In experimental infections in lactating cows, the combined use of IM procaine penicillin G and intramammary amoxicillin achieved a better cure rate (18/35 infected quarters) than intramammary amoxicillin did alone (10/40 infected quarters).[408] Dry cows with *S. aureus* IMI had improved cure rates when administered 11 mg/kg of oxytetracycline IM in addition to intramammary antibacterials as compared to cows administered intramammary infusions only.[409] Other studies have not found any benefit from systemic antimicrobial use to eliminate chronic infections caused by *S. aureus*.[410,411] Additionally, systemic therapy for mastitis is an off-label drug use, and milk and meat withholding periods must be determined judiciously. Therapy should be administered for periods long enough (7 to 10 days) to allow effective elimination of the pathogen and would be more economical and less likely to result in residues in milk if this therapy were administered to dry cows. Depending on susceptibility testing, lipophilic antibacterial drugs that distribute well into mammary tissue (e.g., oxytetracycline) are the best candidates for systemic administration. Cure rates may not be much better than those attained from spontaneous cure, especially in chronic IMI, and efficacy must be defined critically. Affected quarters should be monitored by culture or SCC for at least 60 days to encompass the refractory period when bacteria may not be isolated.

USING BACTERIOLOGY AS A CRITERION FOR THERAPY. Microbial culture of milk is a practical tool to identify causative agents and the foundation to better target therapeutic regimens for mastitis. In a large Michigan dairy, cows with mild to moderate clinical mastitis were sampled for on-farm bacteriologic culture of milk samples. Cows that were infected with gram-positive cocci were included, but cows with no organism isolated or gram-negative organisms were excluded from therapy. This reduced the number of treated cows by 80%.[153] A recent multistate study further demonstrated that culture-based therapy of gram-positive and mixed isolates only, compared to empirical therapy of all mild mastitis cases, reduced antimicrobial use by 50%.[155] No differences were found between mastitis cases assigned to the empirical therapy or culture-based treatment program in recurrence of clinical mastitis (35% vs. 43%), linear somatic cell count (4.2 vs. 4.4), daily milk production (30.0 kg vs. 30.7 kg), and culling or death (28% vs. 32%) for the rest of the lactation after the clinical mastitis case.[156]

Thus, selective treatment of mild clinical mastitis based on culture results does not affect long-term outcomes but does decrease antibiotic use. If farms do not routinely culture milk from cows with clinical mastitis, it is still important to determine the most frequent clinical mastitis pathogens in the herd to make appropriate treatment and prevention recommendations. It is particularly important to determine whether *Mycoplasma* spp. or opportunistic pathogens that are unresponsive to antibiotic therapy are contributing to clinical mastitis.

TREATMENT OF SEVERE CLINICAL MASTITIS. Clinical mastitis cases that include systemic involvement are termed *severe* (severity score 3).[128] Coliform organisms are the most common cause of severe mastitis in most dairy herds and are the common cause of cases that result in loss of a cow from death or agalactia (see Tables 36-1 and 36-2).[412,413] Thus, primary therapy for severe clinical mastitis should be directed against coliform organisms, although secondary consideration must be given for other pathogens. From a cow-side appraisal, treatment of severe clinical mastitis is a forced decision (i.e., empirical treatment is indicated). Although the basis for antimicrobial therapy is knowledge of the causative pathogen, this is not attainable for some hours after initial case recognition, so the practical problem is to design a therapeutic regimen on clinical impression. In addition, systemic antimicrobial therapeutic regimens currently are not labeled by the U.S. Food and Drug Administration (FDA). As a result, veterinarians often formulate therapeutic management of severe mastitis with off-label drug use.

Experimental challenge models have clarified much of the pathophysiology of mastitis resulting from infection with gram-negative organisms.[95,363,414] Following infection, bacterial numbers in milk rapidly increase, and depending on the size of the challenge, peak bacterial concentrations in milk often occur within a few hours. Typically, a subsequent rapid decline in bacterial concentration follows neutrophil migration into the gland. Though often severe, experimental IMIs caused by *E. coli* usually clear spontaneously and rarely last more than 10 days. The resulting inflammation and leukocytosis in the affected quarter may persist for several weeks, or the quarter may become agalactic, despite the inability to isolate bacteria on culture. Although useful for determining the pathogenesis of coliform IMI, experimental challenge models should not be universally applied for therapeutic decisions. Most challenge infections do not include recently calved cows, use strains of bacteria that may not be as virulent as some of the wild types of pathogens, and are generally not administered if other possible immune stressors (metabolic or heat) are present. All these variables could reduce the severity of clinical outcome for experimental (compared to natural) infections. Herd factors like nutrition and housing can also affect the outcome of naturally occurring infections, and host-adapted strains that may persist in affected cows have been identified.[269]

Many of the inflammatory and systemic changes that occur during severe coliform mastitis result from the release of lipopolysaccharide (LPS) endotoxin from the bacteria, which is released from the bacterial cell wall following phagocytosis and killing by neutrophils. As previously mentioned in the discussion of host defenses, LPS is a potent stimulator of the inflammatory cytokine response through the action of TLRs.[415-418] This results in subsequent activation of the cyclooxygenase (COX) and lipoxygenase pathways, releasing prostaglandins, leukotrienes, and thromboxanes, compounds that are potent mediators of local inflammatory and systemic circulatory events.[91] Also, endotoxin-induced cytokines initiate a wide range of systemic responses, including fever, leukocytosis, protein synthesis and release by hepatocytes, and serum iron sequestration, collectively termed the *acute-phase response*.[417,419,420] Although LPS concentration in milk may be high, LPS is usually undetectable or in low concentration in plasma.[421] This suggests that the fever, tachycardia, reduced rumen motility, and signs of shock that accompany severe coliform mastitis are not a consequence of endotoxemia, but production and absorption of inflammatory mediators like TNF-α. The concentration of TNF-α in milk is positively correlated with coliform mastitis severity, and a high concentration of TNF-α in blood is seen only in severe responders.[69,421-423] Hematologic and plasma biochemical changes that often accompany clinical coliform mastitis include leukopenia (neutropenia, lymphopenia, monocytopenia), hypocalcemia, and reductions in plasma concentrations of zinc, copper, and iron.[258,424]

To reduce the severity of acute coliform mastitis, either bacterial growth must be inhibited to reduce exposure of the quarter and the cow to LPS, or the effects of LPS release must be neutralized. From a practical standpoint, therapy of severe coliform infections cannot

VetBooks.ir

begin until clinical signs appear. Clinical recognition of coliform mastitis usually occurs after peak bacterial numbers have been attained, so by the time therapy is initiated, maximal release of LPS has likely occurred. This raises concerns regarding the advantages of antibacterial therapy in alleviating the effects of acute coliform mastitis. The primary therapeutic concern should be treating endotoxin-induced shock with fluids and other supportive care.

Antibacterial therapy may be of secondary importance relative to immediate supportive treatment of endotoxic shock, but it remains an integral part of a therapeutic regimen for severe mastitis. Because of low MICs for gram-negative rods relative to other antimicrobials, aminoglycosides were considered for many years to be a drug of choice for coliform mastitis. However, cows experimentally challenged with *E. coli* and dosed with 500 mg of intramammary gentamicin q12h did not have lower peak bacterial concentrations in milk, shorter duration of infection, lower convalescent SCC or serum albumin concentrations in milk, or decreased rectal temperatures compared to untreated challenged cows.[425] Additionally, gentamicin readily diffused through the milk-blood barrier, evidenced by detectable concentrations in serum throughout the treatment period and the first 12 hours after the last dose. Consequently, urine gentamicin concentrations were detectable 14 days after the last infusion, and concentrations of 1 µg of gentamicin/g in renal tissue were detected in cows 6 months after the trial.[425] IM gentamicin was not more efficacious in preventing agalactia or death resulting from severe coliform mastitis, or in improving other clinical outcomes, than IM erythromycin or no systemic antimicrobial therapy.[426]

Considering the lack of efficacy in controlled studies, increased sophistication of drug residue testing among regulatory agencies, zero tolerance for residues in renal tissue of culled cows, the 30- to 45-day half-life for clearance in the bovine kidney, and extended milk withdrawal periods following use of aminoglycosides, use of this class of drugs in adult dairy cattle has little merit.

Seminal research from Colorado found that bacteremia occurs in nearly half of severe coliform cases and increases with the severity of clinical signs.[293,427] Numerous pathogens, in addition to mammary-derived coliforms, that are likely opportunistic invaders from the respiratory and gastrointestinal tract, were also isolated from blood.[293] This is likely a consequence of the profound neutropenia that occurs in many severe coliform cases.[258] Cows that remain neutropenic for 4 or more days or have high metamyelocyte and myelocyte concentrations in their blood are more likely to be bacteremic than cows with a normalizing leukon.[427] Bacteremia is a very poor prognostic indicator, and these cows are at greater risk of death or culling.[293] Thus, a primary target of antimicrobial therapy for severe coliform mastitis should be highly perfused tissue and selecting drugs that remain in the plasma compartment and have low MICs for gram-negative rods.

Three doses of parenteral sulfadiazine-trimethoprim failed to achieve clinical improvement in experimental *E. coli* infections.[428] In another study that compared cloxacillin or ampicillin use to three IM doses of cefquinome, a fourth-generation cephalosporin that has better distribution into mammary tissue than sulfonamides, cefquinome improved clinical outcomes of experimentally infected cows.[429] Further research confirmed the possible benefits of systemic antimicrobial administration; IV oxytetracycline improved clinical outcomes of cows with coliform mastitis (not necessarily severe), compared to cows that did not receive systemic antibacterials.[430] Ceftiofur sodium, a third-generation cephalosporin, has been reported to have excellent activity against gram-negative pathogens, with a suggested MIC for *E. coli* of 0.25 to 1.0 µg/mL. Mammary tissue and milk concentrations of ceftiofur following systemic treatment remain below these concentrations.[431,432] This is probably due to low bioavailability as a result of a high degree of protein binding. However, in a study of naturally occurring cases in Michigan, cows with severe coliform mastitis that were administered IM ceftiofur at a dose of 2.2 mg/kg once daily for 5 days were three times less likely to be lost from the herd and had significantly higher marketed milk than cows not receiving systemic antimicrobial therapy.[413] This strongly emphasizes the inclusion of possible bacteremia in therapeutic considerations for severe coliform mastitis.

Intramammary antimicrobial therapy should be administered for most severe mastitis cases, at least until bacterial culture results are determined. Numerous severe mastitis cases are caused by gram-positive cocci and can be difficult to distinguish from cases caused by coliforms at initial presentation. Chronic IMI caused by pathogens such as *S. aureus* can become acutely gangrenous at times of neutropenic dysfunction (e.g., parturition).[433] Bacterial culture of cases can also help identify other causative agents unlikely to respond to antimicrobial therapy, including *M. bovis,* mycotic organisms, and *Prototheca* spp. Severe overwhelming IMIs that lead to bacteremia can occur from *S. marcesens, P. aeruginosa,* and *Bacillus cereus*.

Therapeutic regimens for severe clinical mastitis should (1) administer supportive care, especially for those cows displaying shock, (2) target antibacterial therapy to maintain effective concentrations in plasma with a drug that has a broad-spectrum of activity, and (3) administer intramammary antibacterial drugs to reduce the effects of a gram-positive IMI, unless bacteriology results suggest otherwise.

Summary of Antimicrobial Therapy

Judicious antibiotic use is necessary for successful mastitis treatment programs. Case selection is critically important to avoid unnecessary antibiotic use, which is costly to the producer and of concern to the public. When producers are unwilling or unable to use culture results as the basis for treatment determination, a decision may be necessary to avoid treatment completely, or alternatively, treat all cows empirically. In some herds, complete avoidance of antibiotics resulted in increased streptococcal mastitis prevalence and reduced milk quality,[434] but this will vary depending on the herd. Antibiotic selection and the timing, dose, frequency, and duration of treatment impact the outcome. Therefore, antibiotic treatment protocols should be designed with veterinary input and monitored for efficacy. Monitoring requires that farm personnel record the incidence, severity, and duration of clinical mastitis, as well as the treatments administered. The occurrence of relapses, SCC, and targeted milk bacteriology also facilitate assessment of treatment efficacy.

SUPPORTIVE MASTITIS THERAPY. A variety of supportive measures are used in cows with severe clinical mastitis, often in conjunction with antibiotic therapy. Fluids and electrolytes are administered to correct circulatory and electrolyte disturbances. Steroidal and nonsteroidal antiinflammatory agents are used to reduce pain, inflammation, and fever. Dairy producers and veterinarians use many other systemic and local treatments, most of which have not been scientifically evaluated or shown to be effective. This section discusses the most frequently used supportive treatments.

FLUID AND ELECTROLYTE THERAPY. Cows with severe clinical mastitis can develop fluid and electrolyte disturbances as a result of decreased feed and water intake, rumen stasis, ileus, and diarrhea. Severely affected cows, particularly those with coliform mastitis, may develop septic or endotoxic shock; death or organ damage can result from decreased effective circulating volume.

The hydration status of an adult cow is assessed subjectively by observing skin tent duration on the neck or eyelid and position of the globe in the orbit. Unfortunately, findings can be influenced by the body condition of the cow. Objective criteria for estimating the extent of dehydration have been reported for dairy calves but have not been established for adult cows.[435] Extrapolating from calves, a healthy cow should have cervical skin tenting of 2 seconds or less and no recession of the eyeball. Skin tent durations of 4, 6, or 8 seconds and eyeball recession of 2, 4, or 7 mm would correlate with 4%, 8%, and 12% dehydration, respectively. Indicators of reduced peripheral perfusion are cold extremities (ears, tail, fetlocks (only reliable at moderate ambient temperatures) and a dry muzzle or mouth.[436] Hematocrit and plasma protein concentration are not reliable indicators of hydration status in an individual cow because of the wide

VetBooks.ir

range of normal values and the effects of inflammation and stage of lactation on total protein concentration.

Most cows with clinical mastitis, even severe mastitis, have normal acid-base balance or metabolic alkalosis; metabolic acidosis is uncommon and associated with a poor prognosis.[427,437] Therefore, there is no need for routine IV administration of alkalizing agents like bicarbonate or lactate. Oral products containing magnesium hydroxide or sodium bicarbonate likewise should not be administered.

Fluids can be administered by the oral (intraruminal) or IV route. The oral route is least expensive and is often adequate for cows with mild to moderate dehydration. Oral fluids should be hypotonic or isotonic and should contain sodium to create an osmotic gradient between rumen fluid and blood, and enable sustained absorption of fluid and electrolytes; hypertonic oral fluids should be avoided.[438] A 600-kg cow that is 6% dehydrated needs to absorb 36 L of fluid to replace her deficit. This volume can be safely administered orally, but administration of larger volumes of hypotonic fluid might lead to intravascular hemolysis.[439] Oral fluids are not sufficient for cows with severe dehydration, because they do not cause rapid resuscitation.

Ringer's solution, which is an isotonic (isosmotic), mildly acidifying solution that contains physiologic concentrations of sodium, chloride, potassium, and calcium, is the fluid of choice for rapid IV resuscitation of adult ruminants.[438] Isosmotic (0.9%) sodium chloride is an alternative that can easily be constituted using table salt and distilled water in a sterile carboy. However, administration of isosmotic crystalloid solutions is impractical in many situations because of the large volume of fluid required and the need for IV catheterization. A 600-kg cow that is 10% dehydrated requires 60 L of fluid to replace her deficit.

A more practical (although inferior) alternative to isosmotic IV fluid therapy for on-farm treatment is IV administration of hypertonic (7.2%, 2460 mOsm/L) saline. Hypertonic saline is administered through a large-bore needle at 4 to 5 mL/kg body weight over 4 to 5 minutes, in conjunction with oral administration of water (5 gal). Rapid administration of hypertonic saline is required to effectively create an osmotic gradient that draws fluid from the intercellular spaces and gastrointestinal tract (mainly rumen) into the vasculature. Although hypertonic saline does not have a sustained effect and will not completely correct a large fluid deficit, it rapidly increases plasma volume and improves cardiac output and tissue perfusion. Hypertonic saline has been shown to be safe in cows with endotoxic mastitis.[440,441]

Mild to moderate hypocalcemia often accompanies clinical mastitis, with the odds of hypocalcemia increasing with the severity of mastitis,[131] although other serum electrolytes are variable. Affected cows may show muscle tremors or weakness but are seldom recumbent. Calcium supplementation can be by the PO, subcutaneous (SC), or slow IV route, depending on the severity of clinical signs and product used. Anorexic cows often become hypokalemic, especially if anorexia persists for several days. Hypertonic saline administration also causes a transient reduction in serum potassium concentration. Potassium chloride can be supplemented orally at a rate of up to 240 g divided two to three times daily, with lesser amounts (30 to 120 g) satisfactory for mild to moderate hypokalemia.[442] Sodium and chloride derangements are usually mild and can be addressed by administering balanced PO or IV fluids or hypertonic saline. Blood glucose concentration is usually normal or high in cows with clinical mastitis, so dextrose should not be administered routinely. However, IV dextrose treatment may be warranted in cows with concurrent ketosis.

ANTIINFLAMMATORY DRUGS. Most of the physiologic and pathologic changes associated with clinical mastitis are a result of the inflammatory response to infection, so it is logical to administer antiinflammatory agents. Also, antiinflammatory agents can reduce the pain associated with clinical mastitis.[443] However, the inflammatory response is necessary for resolving IMI, and antiinflammatory agents can produce detrimental side effects. Many of the agents used in other countries are not labeled for use in lactating dairy cows in the United States. The choice of antiinflammatory agents in the United States is limited to three approved drugs: dexamethasone, isoflupredone acetate, and flunixin meglumine.

Dexamethasone and isoflupredone acetate are inexpensive steroidal antiinflammatory agents that have no milk-withholding requirement. Glucocorticoid drugs inhibit the production of inflammatory molecules and the adhesion molecules that facilitate transport of inflammatory cells from the bloodstream to the site of inflammation.[444] Glucocorticoids also help maintain microcirculation and cell membrane integrity, interfere with dissolution and disruption of connective tissue, decrease formation of histamine by injured cells, and antagonize toxins and kinins.[444] These actions of glucocorticoid drugs could be expected to benefit mastitic cows, particularly those with mastitis caused by endotoxin-producing coliform bacteria. Glucocorticoids prevent arachidonic acid release by stabilizing cell membranes and inducing lipocortin production. Lipocortin prevents phospholipase A_2 from contacting cell membrane–associated arachidonic acid and effectively limits the precursor needed for eicosanoid production.[445] Endogenous cortisol release has also been identified as playing an important role in down-regulating neutrophil trafficking into the site of infection and production of inflammatory cytokines.[64,446]

Data on the efficacy of steroidal antiinflammatory agents for treatment of clinical mastitis are limited to experimental mastitis trials. A single 30-mg IM dose of dexamethasone given at the time of *E. coli* inoculation reduced local signs of inflammation, tachycardia, rumen motility impairment, and 14-day milk production loss, compared with untreated controls.[447,448] A large IV dose of dexamethasone (0.44 mg/kg) given to goats 12 hours after *E. coli* infusion reduced fever and appetite suppression but had no effect on heart rate, rumen contractions, serum biochemical parameters, SCC, milk yield, or histopathologic changes.[449] Isoflupredone acetate (20 mg IV) administered to endotoxin-challenged cows after the onset of clinical mastitis had no beneficial effect on systemic parameters, mammary gland swelling, or milk production, compared with untreated controls.[450] However, each of these agents has potential adverse effects. Dexamethasone can cause abortion in pregnant cows, especially after 5 months of gestation, although this would be less of a concern for cows in early lactation. Repeated dosing (0.04 to 0.08 mg/kg IM for 3 days) of cows with subclinical IMIs resulted in increased bacterial shedding and development of clinical mastitis.[451] Perhaps more problematic is the use of isoflupredone acetate, because this drug reduces plasma potassium concentration, and repeated doses can lead to severe hypokalemia and recumbency.[452-454]

The above studies suggest that the most likely benefit of corticosteroid treatment would be for severe coliform mastitis, and delays in therapy relative to the onset of infection may hamper efficacy. Nonetheless, dexamethasone is a potent antiinflammatory agent, and it is difficult to extrapolate the benefit for cattle in terms of improved attitude and shock mitigation from experimental mastitis trials to naturally occurring clinical mastitis. Because of mineralocorticoid effects on serum potassium, dexamethasone may be preferred over isoflupredone. Additionally, corticosteroid use in chronic IMI is contraindicated.

A variety of nonsteroidal antiinflammatory drugs (NSAIDs) are used to treat clinical mastitis worldwide,[443] but only flunixin meglumine is approved for use in lactating dairy cows in the United States. Dipyrone and phenylbutazone are banned, and other NSAIDs can be used off-label only if appropriately justified. NSAIDs are not immunosuppressive but carry a risk of abomasal ulceration and renal damage. These complications are not well documented in cattle and presumably are minimized if treatment is of short duration, hydration is maintained, and appetite is restored. The primary mode of action of NSAIDs is to inhibit synthesis of prostaglandins and thromboxanes through COX inhibition. NSAIDs also inhibit formation of prostaglandin (PG)E_2 in the brain, which effectively reduces fever.[455]

Treatment of cows with flunixin meglumine at 0 and 3 to 5 hours after *E. coli* inoculation abolished fever and improved rumen motility

VetBooks.ir

compared with untreated controls, but it had no effect on gland or milk appearance, heart rate, or respiratory rate.[456] Similarly, administration of flunixin meglumine every 8 hours beginning 2 hours after endotoxin infusion reduced fever and improved gland appearance and attitude compared with untreated controls, but it had no effect on milk appearance, heart rate, rumen motility, SCC, or milk production.[457] When administered after the onset of fever and gland swelling, flunixin meglumine (2.2 mg/kg IV) reduced heart rate and rectal temperature and increased rumen motility in cows with endotoxic mastitis but had no effect on milk production or mammary gland inflammation.[458] As with the steroids, the relevance of these trial results to cows with naturally occurring clinical mastitis is uncertain. Meloxicam, although not available for use in U.S. cattle, was shown to reduce pain associated with clinical mastitis.[459]

Other studies found that increased survival and improved milk production did not occur following treatment of clinical cases of acute mastitis with flunixin meglumine.[460,461] Additionally, withdrawal times are significantly increased for milk and meat if this drug is administered IM rather than IV. In summary, it appears that NSAIDs can improve well-being and outcome in cows with clinical mastitis, but specific criteria for instituting NSAID therapy, timing of therapy relative to infection onset, and optimal duration of treatment remain to be determined.

OXYTOCIN AND FREQUENT MILKING. Oxytocin is administered to stimulate milk ejection and facilitate removal of secretions from mastitic mammary glands. Frequent milk-out (stripping) reputedly augments the removal of pathogens, toxins, and inflammatory mediators from the mammary gland. Although seemingly logical practices, no solid evidence exists to support their routine use, and some data suggest they can be detrimental. Oxytocin (20 IU IM twice daily for 3 days) at milking time prevented development of clinical mastitis in only two of eight cows experimentally inoculated with *S. uberis;* once clinical mastitis developed, oxytocin was ineffective at resolving the *S. uberis* infections.[462] When initiated at the onset of clinical *S. uberis* mastitis, oxytocin (80 IU IM, followed by 20 IU IM twice daily) resulted in no clinical or bacteriologic cures by 3 or 6 days.[463] In contrast, clinical and bacteriologic cure rates of 91% and 64%, respectively, were achieved by intramammary antibiotic administration by 3 and 6 days. When oxytocin was used in conjunction with intramammary antibiotics, clinical and bacteriologic cure rates at 6 days dropped to 10%, implying a significant adverse effect of oxytocin and stripping. Frequent milk-out (every 4 to 6 hours) in conjunction with oxytocin administration did not shorten the time to clinical or bacteriologic cure or resolution of systemic illness in cows with experimentally induced coliform mastitis, compared with no treatment.[464] When oxytocin administration (100 IU IM twice daily for 1 week) was compared with no treatment (udder massage only) in cows experimentally inoculated with *S. aureus,* oxytocin administration reduced bacterial concentrations in the milk but did not improve the bacteriologic cure rate or reduce SCC.[465] Oxytocin administration increases the permeability of mammary epithelial cell tight junctions in a dose-dependent manner, which can alter milk composition in non-mastitic glands, particularly if high doses (100 IU) are administered repeatedly.[466]

Oxytocin and frequent milk-out have not been evaluated extensively in the field. In a California study, oxytocin (100 IU IM twice daily for three treatments) at milking time resulted in clinical and bacteriologic cure rates similar to intramammary antibiotics, although an untreated control group was not evaluated.[467] However, no overall benefit resulted, because the oxytocin-treated cows had a higher recurrence rate of clinical mastitis, particularly environmental streptococcal mastitis.[468] In a Virginia study, frequent milk-out (six times daily) in conjunction with oxytocin administration (20 IU) did not improve clinical or bacteriologic cure rates, time to cure, or return to milk production compared with no treatment.[469] In an Illinois herd, cows treated with supportive therapy alone (oxytocin administration [all cases], frequent milk-out [moderate and severe cases], antiinflammatory therapy [severe cases], and fluid therapy [severe cases]) had lower clinical and bacteriologic cure rates and a higher recurrence rate than cows given antibiotics in addition to the same supportive therapy.[470] Furthermore, two studies showed that 50 IU of oxytocin q12h for 19 or 22 days increased residual (non-harvested) milk by 15% each milking.[471,472] From their study, Bruckmaier and colleagues[471] noted, "Cows increasingly refused to enter the milking parlor voluntarily and had to be fetched by the milker, and cow entry into the parlor remained disturbed for up to one week after the end of injections."

In summary, oxytocin administration and frequent milk-out are unlikely to be effective stand-alone treatments for clinical mastitis, particularly mastitis caused by streptococci, and may even be detrimental. In certain circumstances, when a cow clearly will not eject milk or when garget in the milk prevents effective milk removal, these practices might be of some benefit. Otherwise, unnecessary administration of oxytocin injections and frequent milking of painful teats should be avoided for welfare reasons. Sustained use of this drug as a routine therapy is a poor substitute for good milking preparation and will likely incite cows to be reluctant to enter the milking parlor and milk out effectively, which is the opposite of therapeutic intentions with this drug.

Prevention and Treatment of Mastitis during the Dry Period

The dry (nonlactating) period of the lactation cycle is a critical time for udder health in dairy animals. The major proportion of calf growth occurs during this time, and metabolically this is the most critical time for the cow to prepare for the next lactation. Prevention of new infections during the dry period hinges on prevention of teat end exposure to environmental pathogens. Rates of new IMI of coliforms are thought to be greater in dry periods than during lactation.[53] Thus the same management practices that prevent infections from these organisms in lactating cows apply to dry cows (i.e., maintaining cows in clean, dry, comfortable housing).[53] The importance of dry cow management is apparent from studies that found that (1) nearly two thirds of clinical coliform mastitis cases in the first 2 months of lactation were newly acquired infections during the dry period,[108] and (2) the rate of environmental streptococcal IMI was 5.5-fold greater during the dry period than during lactation.[246]

During involution, the mammary gland undergoes marked biochemical, cellular, and immunologic changes. Involution of the mammary parenchyma begins 1 to 2 days after the end of lactation and continues for 10 to 14 days. During this time, the gland is particularly vulnerable to new IMI and, in conjunction with the periparturient period, constitutes the times of greatest risk for new IMI in the lactation cycle of the cow.[473] The most important defense, as with lactating cows, remains the teat canal. When a cow is dried off at the end of lactation, the teat canal does not fully fill with keratin for days to months. This contributes to the risk of infection during mammary involution, and cows that have higher milk production at dry-off are more at risk to have teats remain open throughout the dry period.[243,474] Leukocytes increase to millions per milliliter as involution progresses and then decrease prepartum. Macrophages are predominant in lacteal secretions, followed by lymphocytes and neutrophils.[473] Lactoferrin is also associated with resistance to infection during the nonlactating period.[74,473] Lacteal immunoglobulins increase throughout involution and function by opsonizing bacteria, neutralizing toxins, and preventing bacterial adherence.[473] Consequently, the dry period is an ideal time to attain synergy between antibacterial therapy and immune function to eliminate pathogens from the gland, and not incur the extensive costs of milk withholding typical of lactating cow therapy.

Intramammary administration of antibacterials at the end of lactation (dry-cow therapy) has been a standard of dairy mastitis management for 40 years, particularly as a tool to help reduce the prevalence of contagious mastitis.[18,260] Cure rates for IMI caused by all gram-positive cocci (those IMIs that existed prior to the dry period but were not detected following calving), as with lactational therapy, vary from farm to farm and are pathogen dependent. A New

VetBooks.ir

Zealand study determined that dry-cow therapy eliminated 85%, 90%, and 90% of IMI caused by *S. aureus, S. uberis,* and *S. agalactiae,* respectively, as opposed to spontaneous cures of 31%, 50%, and 29% in untreated controls.[475,476] Cures for chronic *S. aureus* IMI or gram-negative organisms may be considerably less.[410] However, a ceftiofur dry-cow therapy is now labeled for use in North America. A previous dry-cow therapy study that compared cows treated with cloxacillin to cows treated with a product with significant activity against gram-negative bacteria (100 mg framycetin, 100 mg penethamates, and 300 mg procaine penicillin) showed decreased clinical coliform mastitis in the framycetin-penethamate-penicillin–treated cows during the dry period and early lactation.[261]

Because of concern regarding overuse of antibacterial drugs and potential effects on antimicrobial resistance of bacteria, selective dry-cow therapy (treatment of infected cows only) versus total or blanket dry-cow therapy (treatment of all cows) is debated. Decisions should be made on an individual herd basis, and results monitored to determine the success of a dry-cow mastitis program based on numbers of new IMIs during the dry period, cures of existing infections, and impact on the rate of clinical mastitis, particularly in early lactation.

In addition to the role dry-cow therapy plays in eliminating existing IMI, one dry-cow therapy is also thought to prevent new IMI. Early studies suggested that dry-cow therapy reduced new IMI during the dry period by 50%.[476] Overall rates from multi-institution studies reported new IMI rates during the dry period as 11% to 25% of quarters in herds that practiced blanket dry-cow therapy.[263,477] Intramammary infusion of tilmicosin reduced new infection rates by more than 33% in a Canadian study.[477] Selective dry-cow therapy can also result in more clinical mastitis in the dry period, more new IMI during the dry period, and subsequently more clinical mastitis in early lactation than blanket dry-cow therapy.[478] A technology consisting of a bismuth subnitrate paste in a paraffin base is being applied in many dairies, with the intent to create a barrier in the teat canal during the dry period. This is an inert product with no activity or food residue risks. When infused into the teat following intramammary cloxacillin at dry-off, investigators determined that the combined use of the teat sealant and antimicrobial infusions resulted in 30% fewer new IMIs during the dry period and 33% fewer clinical mastitis cases from drying off until 60 days in milk, compared to quarters that were infused with cloxacillin only.[263]

As with lactational therapy, systemic administration as an adjunct to intramammary administration has stimulated interest in potential alternative therapeutic regimens. Subcutaneous norfloxacin nicotinate administered at the start of the dry period achieved a better cure rate and lower new infection rate over the dry period for *S. aureus* infections, as compared to untreated cows and cows administered intramammary cephapirin benzathine preparations.[479] However, in a Michigan study, cows administered IM oxytetracycline and intramammary cephapirin did not have better cure rates for quarters infected with *S. aureus* than cows treated with cephapirin only, although this study was performed in a herd where 50% of cows were infected with *S. aureus* with a history of long duration of infection.[410] Systemic therapy should be reserved for use in dry cows for animals of exceptional value and for infections deemed to be difficult to attain cures (i.e., chronic). However, success rates are likely to be low and in most cases will not be worth the injection and withholding time risks, especially with off-label drug use.

Epidemiology and Management of Mastitis in Heifers

Mastitis in heifers is rarely apparent prior to calving, but few farms actively look for mastitis before parturition. Many farms raise healthy dairy heifers, but in some studies, bacteria have been isolated from more than 50% of quarters of prepartum heifers.[480-482] Reviews of heifer mastitis studies indicate that the prevalence of mastitis pathogens recovered from mammary secretions obtained before the first parturition ranged from 29% to 74%, while the prevalence of infection at first calving ranged from 12% to 57%.[483] Recovery of *Mycoplasma* organisms from milk samples was not included in these studies.

Staphylococci (primarily CoNS but also *S. aureus*) are the most frequent isolates recovered from heifers, but environmental pathogens like streptococci are also frequently recovered.[484] CoNS are the most common pathogens recovered from heifers, and a variety of CoNS species have been recovered from teat skin, the streak canal, and precalving udder secretion obtained from heifers.[221,222] CoNS are the most common group of bacteria recovered from postpartum heifers, but many apparent IMIs spontaneously disappear within the first week after calving. One study reported that 41% of mammary quarters had CoNS infections between days 1 and 4 post calving, but 46% of those infections had spontaneously disappeared by days 5 to 8 post calving.[485] However, some herds may experience persistent infections with CoNS in heifers, resulting in increased SCC values and potentially decreased milk production. These herds require interventions to limit long-term effects on milk quality and production.

Detection of *S. aureus* in dairy heifers usually indicates that a significant number of lactating cows are infected. Although *S. aureus* has been controlled in many herds, regional differences in the prevalence of infected dairy heifers have been reported.[483] The exact mechanism of how nonlactating heifers develop *S. aureus* infections is unknown, but studies have demonstrated that teat canals of heifer calves can become colonized at very young ages.[486] *S. aureus* can spread to heifers when they are fed unpasteurized milk or colostrum or when calves come in contact with objects contaminated with infected milk.[487] Ingested milk is not transmitted directly from the digestive tract to the mammary gland, but it is possible calves may lick their udder or legs and colonize the teat skin, eventually leading to increased risk of infection. *S. aureus* can also be transmitted to heifers during the immediate pre- or postpartum period. Comingling ill animals with periparturient heifers may result in exposure to infected secretions (milk, blood, feces, etc.) from sick animals. These secretions may remain infectious for variable periods of time (depending upon the characteristics of the organism, type of bedding, and environmental conditions) and serve as a point of exposure. Milking heifers using equipment that has been previously used on infected cows is also a common route of exposure. Several studies have demonstrated that biting flies can play a role in the transmission of *S. aureus* between infected and healthy heifers.[222] It is thought that flies congregating on teat ends of infected cows can become contaminated with bacteria present in milk droplets and mechanically transfer the bacteria when they land on the teats of uninfected animals.

M. bovis is an important pathogen that often affects heifers. This organism is associated with respiratory disease, ear infections, joint infections, mastitis, and other diseases of dairy calves and cows.[488] *M. bovis* dwells primarily in the respiratory tract of cattle, often without causing apparent clinical disease in the host.[280] This organism is unique in that respiratory infections can spread through the lymphatic and bloodstreams to infect other mucosal tissue such as the udder. Animals colonized with *M. bovis* can develop long-term infections and infect other animals. *M. bovis* is usually introduced into herds by clinically healthy cattle that are carriers of the organism.[488] *M. bovis* has been demonstrated to colonize developing udders of prepubertal heifers and eventually cause mastitis.[489] The feeding of waste milk from infected cows has long been considered a primary route of infection with *M. bovis.* One study demonstrated that 100% of 50 calves fed milk experimentally contaminated with *M. bovis* became colonized in their respiratory tract.[490] Comingling of calves from different sources has consistently been identified as a risk factor for infection with this organism. Control of *M. bovis* in heifers is based on reducing the potential for contact with potentially infected shedders of the organism and ensuring calves never receive unpasteurized milk. The organism's ability to colonize the respiratory tract of cattle also requires strict attention to limiting the potential for airborne transmission, so adequate ventilation, isolation of calves from older animals or ill calves, and reduced stocking densities are commonsense precautions.

VetBooks.ir

RISK FACTORS FOR MASTITIS IN HEIFERS. Most risk factors that contribute to the development of mastitis in heifers are related to exposure of heifers to mastitis-causing organisms. The exception is the occurrence of udder edema. Calves that are group housed have the opportunity for cross-suckling, resulting in increased risk for transmission of contagious pathogens.[491] Several studies have shown that contact of heifers with older cows before calving (even housing in the same barn) increases the risk of clinical mastitis after calving, and separation of heifers from older cows is generally recommended.[492] The hygiene of the environment is also an important determinant of the risk of developing mastitis in heifers, and this is true for heifers raised on pasture as well as heifers raised in confinement.[228]

PREVENTION OF MASTITIS IN HEIFERS. Prevention of mastitis in heifers is based upon reducing exposure to mastitis pathogens and enhancing the ability of the heifer's immune system to respond to exposure. Strategies for preventing mastitis in heifers include:

1. Controlling the prevalence of mastitis in the existing adult herd. Exposure to contagious mastitis is more likely in herds where many animals are infected than in herds with few animals infected.
2. Use individual stalls for preweaned calves.
3. Cull calves that persist in suckling other calves.
4. Feed milk replacer or pasteurized milk from healthy uninfected cows rather than waste milk.
5. Control flies—especially important in the control of *S. aureus*.
6. Milk fresh heifers first, using clean milking equipment.
7. Calve heifers in clean pens that have not been used to house sick cows.
8. House growing and prepartum heifers in an adequately bedded area that is clean and dry and provides sufficient space for all animals.
9. Feed a well-balanced diet that enhances heifers' immune systems. Recommended values include 1000 IU/day vitamin E during the prefresh period and adequate selenium.
10. Boost the immunity of heifers by using gram-negative J5 vaccines. These vaccines work to reduce the severity of infections caused by gram-negative bacteria like *E. coli*.
11. In problem herds, prepartum teat dipping several times a week[493] or use of internal teat sealants administered about 1 month precalving can be considered.[494]

PREPARTUM TREATMENT OF HEIFERS. Intramammary therapy with antibiotics is one of the tools used to control mastitis in heifers.[486] Intramammary treatment of prepartum heifers is generally considered efficacious in reducing the prevalence of infection, can result in a reduction of SCCs, and in some cases has been shown to increase milk production in the subsequent lactation.[495-499] However, research shows that the production response is highly variable among herds, and this strategy should only be routinely recommended for herds that have demonstrated problems with heifer mastitis.[221] Oliver and associates[500] reported cure rates of 84% and 97%, respectively, for heifers infected with CoNS that received intramammary treatment using 200 mg of either sodium cloxacillin or cephapirin sodium; the spontaneous cure rate was 27% for heifers in an untreated control group. Research has shown that administration of intramammary antimicrobial treatments during late gestation is generally highly effective, and cure rates for staphylococcal infections frequently exceed 90%.[498] Intramammary products designed for both lactating and nonlactating cows (dry-cow products) have been evaluated for use in precalving heifers.[486] In virtually all instances, high rates of bacteriologic cure have been reported. No significant difference in treatment efficacy was found based on treatments given during the first, second, or third trimester of pregnancy, but fewer new *S. aureus* infections were reported for animals treated in the third trimester.[497-501] To minimize the potential for residues after calving, treatments should be administered at least 60 days before the expected due date, and milk should be checked for residues after calving. Unlike intramammary treatments, systemic antibiotics administered to heifers have not been shown to be effective in reducing the prevalence of mastitis.[502] The effect of precalving treatment on production of heifers appears to be variable among herds[481] and is not performed without introducing the risk of infections caused by improper administration of the intramammary tubes. Internal teat sealants or intramammary antibiotics should only be given under hygienic conditions and following effective sanitation of teat ends. This practice is generally only recommended for herds that have demonstrated problems with mastitis in heifers.

Other Conditions of the Mammary Gland

UDDER EDEMA. Dairy cattle frequently develop physiologic edema of the udder during the periparturient period, and heifers have increased incidence of this disorder. Physiologic udder edema must be differentiated from pathologic edema, which can accompany mastitis and diseases of other body systems. Physiologic udder edema is symmetric, cool to the touch, and pits on palpation. It can be limited to the udder or extend cranially along the ventrum or into the perineal region. In contrast, the edema that accompanies mastitis is more focal, asymmetric, and accompanied by abnormal milk and an inflamed mammary gland. Intermandibular and brisket edema, which are often observed in cows with congestive heart failure or severe hypoproteinemia, do not occur in cows with physiologic udder edema.

In most cases, physiologic edema is of little consequence and resolves spontaneously after parturition. However, treatment is recommended if the udder becomes excessively large and heavy, because this threatens the integrity of the udder suspensory apparatus and predisposes to teat injury and mastitis. Severe edema also can hinder ambulation or impair milking or nursing of the teats. If the edematous udder impinges on the skin of the thigh, moist dermatitis and secondary infection may develop and the skin may slough; this condition is referred to as *udder scald*.

The mechanism(s) of physiologic udder edema is uncertain. Supplementing the ration of prepartum dairy cows with high concentrations of sodium or potassium salts significantly increases the incidence and severity of edema.[503] However, serum biochemical values and fractional clearance of electrolytes are similar in affected and unaffected cows.[504] Increased capillary hydrostatic pressure (resulting from changes in mammary blood flow and intramammary pressure that occur around parturition) might be involved, as might incompetent valves in the cranial superficial epigastric veins draining the udder. Cows with udder edema have higher blood pressure in the cranial superficial epigastric veins than unaffected cows, and blood pressure is inversely related to mammary blood flow.[505] Poor udder suspension can also predispose to physiologic udder edema.

First-calf heifers and high-producing cows are at greatest risk of developing udder edema. Other risk factors are not well documented. In a case-control study of heifers in Florida, the risk of udder edema increased as height of the heifer increased, was higher if calving occurred in winter than in summer, and was higher if the fetus was male rather than female.[506] Heifers with udder edema in the first lactation were more likely than unaffected heifers to develop edema in subsequent lactations.[506]

Treatment of udder edema includes preventing excessive salt intake and administering a diuretic. In the United States, furosemide is labeled for use in dairy cows, has 48-hour milk-withholding and slaughter-withholding times, and is the diuretic of choice for treating udder edema. In one study, high cranial superficial epigastric venous pressure in cows with udder edema was reduced by IV administration of furosemide (500 mg) but not hydrochlorothiazide (250 mg) or acetazolamide (500 mg).[501,505] Repeated administration of furosemide for several days should be avoided, but if repeated dosing is necessary, cows should be monitored for signs of electrolyte imbalance. Although corticosteroids have been recommended for treatment of udder edema, their efficacy is questionable. Prepartum milking reduces the severity of edema[507] but also decreases colostral immunoglobulin concentration at calving, so an alternative source of colostrum is needed. Prepartum milking of affected heifers has also

VetBooks.ir

been shown to reduce the risk of developing mastitis, but care should be taken to manage energy balance to prevent development of ketosis.[491] Increased milking frequency has not been demonstrated to reduce udder edema. Milking first-lactation animals four times daily neither reduced nor increased udder edema scores.[508] Udder massage, exercise, and hydrotherapy are empirically justified treatments for udder edema. Udder supports are available for cows with excessively pendulous or heavy udders.

BLOODY MILK. It is not uncommon to observe blood in postpartum mammary secretions. Small vessels may rupture as a result of trauma or in conjunction with udder edema. The milk is usually light pink to red or brown and may contain small blood clots. Antibiotic treatment is not indicated. Bloody milk can also accompany severe clinical mastitis or gangrenous mastitis, both of which have a poor prognosis, but physical examination of the animal will identify these conditions.

Bloody milk should be withheld from sale for human consumption. The milk usually returns to normal appearance within 1 week. However, because blood contains natural antimicrobial inhibitors, bloody milk may cause false-positive antibiotic residue test results. The IgG1 concentration of bloody colostrum is similar to that of normal-appearing colostrum, meaning it is unnecessary to discard colostrum simply because it contains blood.[509]

TEAT AND SKIN CONDITIONS. Several noninfectious diseases of teats are recognized to occur.[510] The color and condition of teats can be influenced by milking equipment, overmilking, use of caustic chemicals, or environmental conditions. The development of hyperkeratosis of the teat ends is not uncommon and occurs more commonly during winter months. *Hyperkeratosis* is a thickening of the skin that lines the teat canal and is the result of a localized hyperplasia of the stratum corneum.[511,512] Mild hyperkeratosis is a normal physiologic response to forces applied to the teat during milking and does not increase the risk of IMI. However, moderate and severe hyperkeratosis can become a problem. Various scoring systems have been developed to assess teat end health. In general, teats are scored on a 1 (N = no ring) to 4 (VR = very rough ring) scale based on the teat end callosity observed. It is recommended that herds should have less than 20% of scores of 3 (R = rough ring) and 4 and less than 10% of scores of 4.[512] Rough teat ends are not only difficult to clean but also provide a surface for pathogenic bacteria to harbor.[511] Hyperkeratosis is a multifactorial problem, and risk factors must be determined and addressed for individual farms. Areas to investigate that may resolve a problem with hyperkeratosis include liner compression, excessive teat end vacuum or overmilking, environmental conditions, and use of teat dips that do not provide sufficient skin conditioning.

Infectious lesions of teats have been associated with several viruses.[511,513] Pseudocowpox is caused by a paravaccinia virus that can cause acute infection in cattle. This disease results in lesions that include center vesicles that ulcerate to form scabs. As the lesions heal, they result in a characteristic ring or horseshoe-shaped scab. This virus can also affect the hands of milking technicians. Diagnosis is based on observation of lesions on hands of milking technicians and animals' teats. The condition is generally self-limiting within 3 to 5 weeks.

Bovine herpes mammillitis has been associated with both herpesvirus type II and herpesvirus type IV.[511,513] The resulting lesions appear similar and can occur either sporadically or in an outbreak. These viruses can present with a wide range of symptoms ranging from mild edema to development of vesicles that result in severe ulceration and formation of painful scabs. This condition appears to be more common during winter months. Diagnosis is based on observation of clinical signs and can be confirmed by histopathology. There is no effective therapy, but teat dipping using an effective germicide is recommended. This virus can spread among animals, so affected animals should be segregated and milked with separate milking equipment.

Teat warts are not uncommon and can be caused by several different papillomaviruses. The appearance of the warts is variable, ranging from small, smooth lesions to large frondlike protuberances.[511,513] Younger animals are often more susceptible and will develop immunity. Warts are generally self-limiting and will resolve within several months. No therapy is recommended.

Mastitis in Beef Cows

Several surveys have demonstrated that about 15% to 40% of beef cows have IMI in at least one mammary gland.[514-516] Similar to heifers and small ruminants, CoNS are the predominant bacteria that are generally isolated, but *S. aureus* has been recovered from 7% to 10% of milk samples. Milk from infected glands has significantly higher SCC than milk collected from healthy glands.[514,515,517,518] Clinical mastitis occurs rarely and is diagnosed and treated when economically feasible, but most mild cases of clinical mastitis likely go undetected.

Several modes of transmission of mastitis pathogens have been proposed for beef cattle. Flies are believed to serve as vectors for staphylococci, and fly-induced teat scabs of beef heifers have been shown to harbor staphylococci.[519] Calves may also serve as vectors by transmitting oropharyngeal organisms to the teats or carrying bacteria-laden milk from teat to teat. Unsanitary housing conditions probably increase the risk of infection with environmental pathogens.[515,519] As with dairy cows, poor udder conformation and teat injuries may predispose to mastitis.

Several studies have demonstrated numeric or significant decreases (up to 40 kg) in weaning weights of calves from beef cows with subclinical mastitis,[514-516,518] probably as a result of reduced milk production.[517] The adverse effect on weaning weight appears to increase with the number of infected glands.[515] Use of dry-cow antimicrobial therapy has been associated with decreased IMI in the subsequent calving and increased body weight gain of calves.[518] However, the economic justification for routine use of antibiotic treatment at dry-off is lacking. Selective intramammary antibiotic treatment at weaning based on CMT reaction has been suggested, but CMT score is unlikely to be an accurate predictor of infection. Sanitary housing conditions, appropriate stocking density, and good fly control should help minimize mastitis risk in beef cattle.

Mastitis in Small Ruminants

General Concepts

The udders of sheep and goats differ from cows in that they have only two mammary glands, which are logically referred to as *halves*. With the exception of the relative proportion of the cisternal cavities, anatomic structures, milk secretion, and milk letdown of small ruminants are similar to cattle. Both goats and sheep have much larger cisterns than dairy cows, and the cisternal fraction of milk may approach 50% to 75% for these species.[520]

Just as in dairy cows, mastitis of small ruminants is a bacterial disease that occurs in either a subclinical or clinical state. Subclinical mastitis is an important and underrecognized disease in small ruminants. In two separate studies, an Israeli research group compared milk production and composition of healthy and CoNS-infected half-udders in ewes.[521,522] These studies demonstrated large increases in SCC and 30% to 50% reductions in milk yield of infected half-udders. Subclinical mastitis is generally defined by the migration of neutrophils into the mammary gland in response to bacterial infection. This response occurs in all dairy species, but the magnitude of the response and distribution of cell types in the healthy mammary gland differ considerably among species.[523-525] In both sheep and cows, a significant increase in somatic cells occurs almost exclusively in response to bacterial infection of the mammary gland. The SCC response in dairy goats is not as specific to infection, so different interpretation criteria are necessary. The proportion of neutrophils (PMNs) and the number of cytoplasmic particles present in milk are

VetBooks.ir

very different in milk produced by goats, compared to milk produced by ewes or cows. Part of this difference is generally attributed to different milk secretion mechanisms. Both goats and sheep are thought to produce milk using a largely apocrine process, where the apical portion of the secretory cell is excreted into the milk. Despite similar secretory processes, the number of cytoplasmic particles found in milk obtained from both healthy and infected glands is approximately 10- to 20-fold greater for goats (≈70,000 to 300,000 cells/mL) than for sheep (≈15,000 cells/mL).[523] The large number of cytoplasmic particles necessitates use of DNA-specific counting mechanisms to accurately enumerate somatic cells in goat milk.[523] Similar to dairy cows, microbiological analysis of milk samples obtained from affected glands is the only way to determine the etiology of mastitis.

As noted, enumeration of SCC of goat milk must be performed using DNA-specific methods.[523] The CMT test is based on reaction of the detergent with DNA in cells and is also considered accurate. When enumeration of SCC in goat milk is properly performed, IMI is a well-known cause of increased SCC, but the threshold used to determine infection must be determined relative to stage of lactation.[526] Milk samples obtained from infected udder-halves of goats generally exhibit SCC values over 500,000 cells/mL (first 90 DIM) and over 1,000,000 cells/mL (later stages of lactation). Important factors that must be considered when evaluating SCC of goats include parity, stage of lactation, breed, and estrus.[523,526,527] In does, the ability of estrus to stimulate increased SCC in the absence of IMI has been demonstrated in a controlled study using induced estrus.[517] In one part of the trial, the day after inducing estrus, SCC values were 1,778,000 cells/mL for does in estrus versus 363,000 cells/mL for does in the control group; both values have been converted from the reported log values. These physiologic increases were not associated with IMI or decreased milk production, but the mechanism behind the increase was not elucidated. Overall, while several noninfectious causes for increased SCC are observed in goats, IMI remains an important cause of increased SCC. Although it is more complex to use SCC values to investigate mastitis problems in goats, the large variation observed among herds indicates that control of mastitis can result in lower bulk-tank SCC, and veterinarians should work with producers to understand the factors that influence SCC in their herd.

The types and proportions of cells present in sheep milk are more similar to dairy cows than goats, and standard methods used to count somatic cells in cows' milk are considered accurate for counting somatic cells in ewes' milk. Evaluation of SCC data is considered an effective tool for diagnosing IMIs in dairy sheep.[528,529] In an uninfected half-udder, the SCC count is generally lower than 200,000 to 400,000 cells/mL.[526,529] Higher counts are almost always associated with bacterial infections and indicate the presence of subclinical mastitis. Individual gland SCC values increase in response to IMI in ewes, so bulk-tank SCC values are an indication of milk quality and increase when the prevalence of subclinical mastitis increases. Dairy sheep producers should monitor bulk-tank SCC and manage the flock to maintain SCC less than 300,000 cells/mL.

Mastitis in Dairy Sheep

In North America, most sheep are kept for production of meat, and most research literature discusses symptoms of mastitis occurring in ewes that are nursing lambs. In this population, only severe clinical mastitis is likely to be diagnosed. This lack of emphasis on milking ewes has led to an overemphasis on the occurrence of clinical mastitis and a lack of appreciation for subclinical mastitis. There are no national studies assessing the incidence of clinical mastitis in dairy ewes milked in the United States, but based on research in other regions, clinical mastitis is thought to occur in less than 5% of ewes per year.[526] Limited U.S. data are available to define the prevalence of subclinical mastitis, but researchers believe that up to 30% of ewes in some flocks may be affected.

In almost all instances, mastitis is caused by a bacterial infection. Although most bacteria can cause both clinical and subclinical mastitis, *S. aureus, Pasteurella hemolytica,* and various yeasts and molds are organisms frequently reported to be recovered from milk samples of ewes affected with clinical signs. Bluebag (clinical mastitis with a hard, cold, swollen udder) is typically caused by either *Pasteurella hemolytica* or *S. aureus*. CoNS are considered to be minor pathogens in dairy cows but behave as major pathogens in dairy sheep and have been frequently reported to be the most commonly isolated pathogens recovered from cases of subclinical mastitis of dairy ewes.[530-532] Subclinical infection caused by CoNS and other mammary pathogens has been associated with increased SCC.[529,530] Other pathogens typically recovered from subclinical mastitis infections in ewes include *Corynebacterium* spp., yeast, *Streptococcus* spp., Enterobacteriaceae, and *S. aureus*. Yeast and mold infections in ewes are often associated with unhygienic administration of intramammary treatments, and great care must be taken when these treatments are used.[533]

In rare instances, the lentivirus that causes ovine progressive pneumonia (OPP) has been associated with mastitis in sheep,[534] but there is no evidence this virus has influence on SCC of sheep milk.[526] Mammary gland symptoms are associated with lesions in secretory tissue. Although it is known that this virus has an affinity for mammary glands, the disease is slowly progressive and results in weight loss, greatly reduced milk production, and other clinical signs that make it unlikely to become widespread in flocks used for dairy production.

Risk factors for subclinical mastitis are not well defined for intensively managed milking sheep in North America. European research in Mediterranean countries has indicated that most of the variation in mastitis is associated with differences in herd management.[535] In the same study, higher-producing breeds were at greater risk of mastitis, and the use of dry-off treatment resulted in less mastitis.[536] Practices that improve udder hygiene and reduce teat exposure to bacteria are likely to result in less mastitis.

Ewes that develop clinical mastitis are often seriously ill and should be treated immediately according to protocols that have been developed in consultation with the flock veterinarian. Most treatments for severe clinical mastitis are administered systemically, and the ewe may require supportive therapy. No antibiotic compounds are FDA-approved for treatment or prevention of mastitis in milking sheep, and off-label use of drugs for these purposes must be prescribed and supervised by a licensed veterinarian. Administration of a drug approved for treatment of another sheep disease (e.g., ceftiofur for treatment of pneumonia) to treat mastitis is also considered off-label use. It is important to recognize that systemic administration of ceftiofur will not achieve effective inhibitory levels in the mammary glands of cows, sheep, or goats.

Intramammary dry-off therapy has been shown to positively influence milk yield and SCC in the subsequent lactation, and is recommended.[533,536] However, administration of intramammary treatments does increase the risk of mastitis caused by yeast, and selective dry-off treatment can be recommended in flocks that have a relatively low prevalence of subclinically affected ewes. Milk samples obtained from ewes with three or more monthly SCCs of 400,000 or more cells/mL in the previous lactation were six to eight times more likely to be positive for mastitis pathogens in the next lactation than milk from ewes with SCCs below that threshold. That threshold may be appropriate to identify ewes that should receive dry-off treatment.[537]

Mastitis in Dairy Goats

Similar to ewes, the incidence of clinical mastitis is generally reported to be less than 5% of lactating does per year.[526] A recent study that surveyed about 90% of all goat dairy farms in Holland (≈300 farms) reported the incidence of clinical mastitis was 2% per year, and about two thirds of the farms culled the majority of affected does rather than treat them.[538] One interesting study conducted in Spain linked the incidence of clinical mastitis to selenium deficiency.[539] Spanish researchers reported that for does consuming a selenium-deficient diet, the incidence of clinical mastitis was 3.8% and 15.4%, respectively, for does that had been treated with slow-release barium selenite or were enrolled in a nonsupplemented control group.[539]

VetBooks.ir

There are neither national surveys nor comprehensive reviews that describe the prevalence of subclinical mastitis in dairy goats in the United States or Canada. Review of existing data about the prevalence of subclinical infection is further complicated by the lack of a uniform SCC threshold and the influence of intervening factors (e.g., estrus) on SCC. When recovery of bacteria from milk samples is used as the gold standard to identify subclinical mastitis, several studies have indicated that half-udder prevalence of subclinical mastitis varies between about 15% and 40%.[540] When using the SCC threshold of 500,000 cells/mL as a threshold for defining subclinical mastitis, researchers have estimated sensitivity (probability of recovery of pathogen when the SCC is > threshold) as ranging from 0.69 to 0.90, and specificity (probability of not recovering pathogen when the SCC is < threshold) of about 0.35 to 0.77.[540] Although some high SCC values are likely associated with physiologic changes, some reflect IMI, and it is likely that the prevalence of subclinical mastitis in many goat herds is greater than commonly recognized.

Similar to dairy sheep, researchers have consistently reported that CoNS are responsible for the greatest proportion of subclinical mastitis infections occurring in this species.[526,527,541] Infections with CoNS are especially prevalent in goats at parturition, with recovery of CoNS from up to 17% of goats reported.[527] Similar to ewes, the early lactation spontaneous cure rate is only about 50% for IMI caused by CoNS, and up to 25% of does may remain infected 6 weeks after parturition.[527] SCC values of infected half-udders of does are always significantly greater than SCC values of healthy half-udders.[527] Other pathogens frequently recovered from goats with subclinical mastitis include *Corynebacterium* spp., *Streptococcus* spp., and *S. aureus*. The relationship between lentiviral infections (caprine arthritis-encephalitis virus [CAEV]) and SCC has been reviewed,[526] and herds with greater prevalence of seropositive does have been shown to have greater SCC values. However, this relationship is considered weak and may have been a result of immunosuppression caused by CAEV infection.

Clinical mastitis in goats is often associated with infection by *S. aureus, Streptococcus* spp., *Pseudomonas,*[542] or miscellaneous pathogens like yeast. In many regions of the world, IMIs are associated with infection by a variety of *Mycoplasma* spp., and milk samples obtained from goats with chronically increased SCC should be submitted for *Mycoplasma* culture. When clinical mastitis cannot be explained by bacterial or fungal infection, *Mycoplasma* infection should be suspected. A variety of *Mycoplasma* spp. can cause clinical mastitis outbreaks in small ruminants. *Mycoplasma mycoides* subspecies *mycoides,* large-colony type, is an important mastitis pathogen in goats in the United States, especially in California.[543,544] *Mycoplasma putrifaciens* is involved in some outbreaks,[458] and *Mycoplasma agalactiae* is isolated on rare occasions.[545] Does with mycoplasmal mastitis often exhibit severe clinical illness and reduced milk yield, in addition to an inflamed udder and visibly abnormal milk, but subclinical IMIs can occur. Adult goats and kids in herds with mycoplasmal mastitis may experience polyarthritis and pneumonia, and pregnant does may abort. Morbidity and mortality can be very high, with more than 90% of goats dying or euthanized in some herds.[545]

Because all mastitis treatments involve off-label drug usage, treatment of clinical mastitis should be performed using protocols developed by the veterinary practitioner who has a valid veterinary-client-patient relationship. Treatment of systemically ill animals should be focused on supportive care and appropriate antimicrobial therapy. Treatment of animals with local signs of clinical mastitis generally involves administration of commercial intramammary products, and should be accompanied by microbiological assessments of at least some cases. Treatment of subclinical mastitis is unlikely to be pursued by most farms, and aggressive culling of affected animals has been shown to be associated with herds that have lower bulk-tank SCCs.[538] At least one study has demonstrated that treatment of subclinical mastitis in early lactation based on CMT resulted in increased bacteriologic cure but was not economically beneficial.[538] Thus, treatment of subclinical infections during lactation is not currently recommended. However, the use of dry-off therapy has been shown to effectively cure CoNS infections and result in lower SCC in early lactation.[546] As with sheep, producers should be taught to use extreme care when disinfecting teat ends to prevent the iatrogenic development of IMI caused by yeast.

Mastitis is an important disease of small ruminants used in dairy production, and its prevalence varies with management. Most mastitis occurs in a subclinical form, and producers who do not routinely measure individual animal SCCs will be unable to determine the impact of subclinical mastitis on production and milk quality. Most subclinical mastitis in small ruminants is caused by CoNS, which should be considered major mastitis pathogens in these species. Prevention of infection is the key to mastitis control, and good hygienic housing and milking practices are a necessity to minimize the impact of this disease. As in all dairy species, exposure of the teat end to bacteria is the mechanism for development of mastitis, and control programs are based on principles that improve hygiene and reduce exposure to potential pathogens. The prevalence of subclinical mastitis has been shown to be decreased in goat herds that practice good teat dipping and premilking teat sanitation.[547]

Mastitis in Horses

Mares have a uniquely different anatomic structure of the udder. Similar to cows, the equine udder is composed of four independent glands, but the pairs of glands on either side of the midline share a single teat and are referred to as *halves.*[548] Mastitis occurs uncommonly in horses, in part because of the relatively small size and inguinal location of the udder, which minimizes exposure to potential pathogens. Little research has been done on the prevalence of subclinical mastitis in horses, but it is not recognized to be a serious problem. In one study, no pathogens were grown from the milk of 11 mares sampled repeatedly during the first 2 months of lactation, and average SCC was less than 50,000/mL at most sampling times.[549]

Clinical mastitis occurs sporadically in lactating and nonlactating mares; signs range from mild to severe. The most common clinical mastitis pathogen is *Streptococcus zooepidemicus,* but a variety of aerobic bacteria have been isolated from the milk of affected mares.[550,551] In a retrospective study of 28 cases, gram-negative bacteria (coliform bacteria, *Pseudomonas, Actinobacillus, Pasteurella*) were isolated from 42% of milk samples.[550] Streptococci and staphylococci constituted most of the gram-positive isolates. Rarely, mastitis is caused by nonbacterial pathogens. For example, one mare developed unilateral mastitis as a component of disseminated coccidioidomycosis.[552] Verminous mastitis has even been reported.[553]

Clinical signs of mastitis in horses include an enlarged, firm, warm, painful mammary gland and edema of the udder and surrounding tissues. The mare resists milking, and secretions are abnormal in appearance (color, viscosity, consistency). About half of all mares with clinical mastitis are systemically ill, with signs such as fever, tachycardia, tachypnea, anorexia, depression, or agalactia. The mare may be reluctant to move or may adopt an abnormal gait to minimize contact between the hindlimb and the painful gland. Sedation or anesthesia is necessary to achieve a thorough examination of the udder and collection of milk in some horses.[551]

Culturing of the milk is required to definitively identify the causative pathogen of equine mastitis and confirm that antibiotic selection is appropriate. However, bacteria can often be observed on cytologic examination of the milk.[550,554] A differential diagnosis for a firm, enlarged, painful mammary gland is adenocarcinoma, particularly if the udder skin is ulcerated and the secretion is serosanguineous.[555] With adenocarcinoma, neoplastic cells may be seen during cytologic examination of the secretion, or a mammary biopsy may be required. Because bacterial mastitis and adenocarcinoma can occur simultaneously, it is important to reevaluate mares that do not respond as expected to antibiotic treatment. Fescue toxicosis should be included in the differential diagnosis for agalactia. With fescue toxicosis, the udder is not inflamed, and mares may sweat profusely, have prolonged gestation, or give birth to weak or dysmature foals.[556]

VetBooks.ir

Treatment of bacterial mastitis in horses consists of intramammary and systemic antibiotics to combat infection; NSAIDs to reduce pain, inflammation, and fever; and fluids to correct dehydration. Hot packing, hydrotherapy, and frequent stripping of the affected gland are empirically justified supportive measures but may be difficult to accomplish. Furosemide can be administered if edema is substantial.

Broad-spectrum antibiotics should be given until results of cytologic examination or culture of the milk are available. Potentiated sulfonamides, or a combination of penicillin and an aminoglycoside, are reasonable systemic antibiotic choices. Because no antibiotics are labeled for intramammary administration in horses in the United States, intramammary infusion products for cattle are used. Infusion products containing ceftiofur, cephapirin, amoxicillin, or hetacillin are appropriate until the cause of the mastitis is determined. A commercial intramammary infusion product is preferable to a homemade solution, because the latter carries a greater risk of unintentional contamination. Intramammary infusion of antibiotics can be difficult to accomplish in horses because of the small size of the teat orifice and the presence of two distinct lobes within each udder half. One or both lobes can be infected, so antibiotics must be directed appropriately. Antibiotic treatment should be continued for at least 5 days to avoid relapse.

The prognosis for survival of horses with bacterial mastitis is good, but milk production may be transiently or permanently reduced. Fortunately, mastitis is usually unilateral, and recurrence is rare.[550] Most mares respond rapidly to antibiotic treatment. Although spontaneous recovery is possible, it is unethical to withhold treatment from a mare that is ill or in discomfort. The prognosis for mammary adenocarcinoma is poor, even with surgical removal of the affected mammary gland(s) and local lymph nodes, because of the high rate of metastasis.[555]

• CHAPTER 37

Diseases of the Hematopoietic and Hemolymphatic Systems

JOHANNA L. WATSON, *Consulting Editor*

Diseases Associated with Blood Loss or Hemostatic Dysfunction

Johanna L. Watson • Debra Deem Morris

Blood loss may be acute or chronic, and the clinical and laboratory manifestations are widely different because physiologic adaptation occurs in the chronic state.

Acute Blood Loss

Common causes for acute blood loss include trauma (e.g., severe lacerations), surgical procedures (e.g., dehorning, castration), and erosion of the carotid artery by guttural pouch mycosis in horses. External hemorrhage is immediately obvious, but hemorrhage into a major body cavity may be occult (e.g., spontaneous rupture of the middle uterine artery, splenic rupture resulting from trauma or erosion of a major vessel by abscess, aneurysm, or neoplasia). Hemoperitoneum may induce signs of colic, and hemothorax is generally attended by dyspnea. Acute massive blood loss induces hypovolemic shock characterized by tachycardia, tachypnea, cold extremities, pale mucous membranes, muscle weakness, and eventual death resulting from cardiovascular collapse.

Acute blood loss does not initially cause a change in the packed cell volume (PCV) or total plasma protein, although rapid mobilization of extracellular fluid to maintain circulating blood volume causes PCV and total plasma protein to decline within 12 to 24 hours. The severity of blood loss may be partially masked by splenic contraction, because shock causes activation of the sympathetic nervous system. Icterus is absent, and bone marrow erythroid hyperplasia is delayed by 3 to 4 days. Peripheral signs of erythroid regeneration in horses are limited to mild anisocytosis with a variable increase in mean corpuscular volume. Ruminants show erythrocyte polychromasia, basophilic stippling, Howell-Jolly bodies, and occasionally nucleated erythrocytes within 4 days of hemorrhage onset.

Diagnosis Diagnosis of acute blood loss is based on clinical signs, evidence of recent hemorrhage, and anemia accompanied by hypoproteinemia. Hemoperitoneum and hemothorax may be suggested by ultrasound and abdominocentesis and thoracocentesis, respectively.

Treatment Treatment of acute blood loss should initially be aimed at stopping the hemorrhage. External hemorrhage may be managed by pressure wraps or appropriately placed ligatures, but attempting to control internal hemorrhage when the patient is a poor risk for general anesthesia may be inadvisable, and the source of hemorrhage may not be found. Hypovolemic shock should be treated by prompt intravenous (IV) administration of 40 to 80 mL/kg of sodium-containing crystalloid solutions. Studies indicate that a small volume of hypertonic saline (2 to 4 mL/kg 7.2% sodium chloride) may temporarily reverse the pathophysiologic sequelae of severe hemorrhagic shock.[1,2] The total volume of crystalloid solution required is usually much greater than the volume of blood lost, because crystalloid solutions distribute throughout the extracellular space. The clinical response to fluid administration should be evaluated in light of ongoing losses to determine the necessary replacement volume.

If anemia becomes life threatening, whole blood transfusion must be considered. A PCV less than 20% in an animal with acute blood loss suggests depletion of erythrocyte reserves, and persistent reduction of the PCV over a period of 24 to 48 hours to 12% or less indicates the need for blood transfusion. A low but stable PCV (12% to 20%) does not necessitate transfusion, because transfusion should be reserved for instances in which oxygen delivery to the tissues is inadequate to support life. Blood transfusion can only be viewed as a temporary therapeutic procedure because even crossmatch-compatible allogeneic erythrocytes are removed from the circulation by the mononuclear phagocyte system (MPS) within 2 to 4 days of transfusion.[3] Horses and cattle display a high degree of blood type polymorphism, and minor antigenic incompatibilities are only delineated by blood typing.[4] Serum antibodies against nonhost erythrocyte antigens (erythrocyte alloantibodies) probably mediate the short lifespan of transfused erythrocytes. Compatibility testing is used to avert life-threatening antigen-antibody reactions caused by major blood group mismatching.

The routine crossmatch involves incubating washed erythrocytes from donor (major) and recipient (minor) with serum from the other. Gross and microscopic examination for clumping demonstrates serum agglutinins in horses. Sensitized cattle erythrocytes do not become clumped in saline solution but do lyse in the presence of rabbit complement, so only a hemolytic crossmatch can be performed in this species. Not all equine erythrocyte alloantibodies act as agglutinins, and hemolysins must be detected by adding complement to the reaction mixture. Pooled rabbit serum must first be absorbed with equine erythrocytes to remove naturally occurring antibodies. The necessity for special handling and storage of rabbit serum makes hemolytic crossmatch procedures impractical for most veterinarians. These tests are best performed by veterinary

VetBooks.ir

hematology laboratories (e.g., Veterinary Genetics Laboratory, School of Veterinary Medicine, University of California, Davis), which usually require serum and whole blood in sodium citrate or acid-citrate-dextrose (ACD) to crossmatch.

The first transfusion of whole blood to a horse or ruminant not previously transfused or sensitized by immunization or pregnancy is usually well tolerated because natural alloantibodies are of low concentration and weak activity. After incompatible transfusions, alloantibodies develop rapidly, making subsequent transfusions more hazardous.

Blood for transfusion should be collected aseptically into sterile containers containing sodium citrate (2.5% to 4%) or ACD solution and used immediately. The necessary dosage can only be estimated, but in most instances replacing 20% to 40% of the calculated blood loss is sufficient to maintain life until the bone marrow can respond. A drop in PCV from 36% to 12% in a 500-kg animal (8% body weight blood) represents a loss of 27 L of blood. In this case, 6 to 8 L of whole blood would be therapeutic and easily donated by another 500-kg individual. Blood warmed to 37° C (98.6° F) should be administered through an in-line filter to remove clots. After pretransfusion vital parameters have been recorded, 0.1 mL of blood/kg body weight is given over 5 to 10 minutes and the evaluation is repeated. If parameters and attitude are unchanged, the transfusion can be continued at a rate not to exceed 20 mL/kg/h. The recipient should be continuously monitored so the transfusion can be stopped if adverse reactions like tachypnea, dyspnea, restlessness, defecation, tachycardia, piloerection, muscle fasciculations, or sudden collapse occur. Although these signs may not indicate anaphylaxis, severe reactions should be treated with epinephrine (0.01 to 0.02 mL/kg, 1:1000). Mild signs may respond to a slowed transfusion rate or administration of corticosteroids or flunixin meglumine. Because it is often impossible to delineate the cause of transfusion reactions, the safest approach is to discontinue the blood and administer isotonic crystalloid solutions.

The prognosis is good for most cases of acute blood loss if hypovolemic shock is quickly treated and bleeding stops. Normal bone marrow begins to replace lost cells within 5 days. Sequential PCV analysis will be necessary to determine whether blood loss is controlled. Examples of specific disorders follow.

Guttural Pouch Mycosis

See Chapter 31 for an in-depth discussion of this and other respiratory diseases.

Hemoperitoneum in Horses

Monica Aleman • Johanna L. Watson

Hemoperitoneum is accumulation of blood in the abdominal cavity and can be a life-threatening problem. In the horse, associated causes are trauma, postoperative abdominal hemorrhage, neoplasia, complications from pregnancy and foaling (utero-ovarian, middle uterine, and external iliac artery rupture), organ rupture, mesenteric injury, coagulopathies, ovarian hematoma, systemic amyloidosis, and idiopathic hemoperitoneum.[5-11] The underlying cause is identified in the majority of cases (78%).[11] Trauma (spleen and in mares, reproductive tract with associated vessels) and neoplasia are the most common causes of hemoperitoneum.[7,11]

A recent retrospective study of 67 horses with hemoperitoneum revealed that Thoroughbreds and Arabians were overrepresented breeds.[11] Middle-aged and older horses (>13 years of age) and females may be overrepresented.[10,11] The most common clinical signs include abdominal discomfort, lethargy, hypovolemic shock, pale mucous membranes, prolonged capillary refill time, tachycardia, and tachypnea.[10,11] Other clinical signs are anorexia, reluctance to move, weakness, trembling, cool extremities, and abdominal distention.[10]

Clinicopathologic abnormalities include anemia, neutrophilia, lymphopenia, thrombocytopenia, hypoproteinemia, hypocalcemia, and azotemia.[10] Abnormalities in clotting parameters may be observed, depending on the cause. Hemorrhagic abdominal effusion is characterized by high red blood cell (RBC) count (>2,400,000 RBC/μL), PCV (≥18%), and total protein (≥3.2 g/dL), with a normal to high leukocyte count.[10] Central venous pressure and blood lactate concentration appear to be early indicators of hypovolemia due to acute blood loss.[12] Fluid swirling and site of hemorrhage may be evident on abdominal ultrasound.

Primary goals of therapy are treating hypovolemic shock, restoring perfusion and oxygen delivery to tissues, correcting fluid deficits, stopping further blood loss, and preventing complications. Blood transfusion should be considered if anemia becomes life threatening. The use of antifibrinolytic and procoagulant agents have been reported in the literature, but controlled studies on efficacy and safety in the horse with acute blood loss are lacking. Physical activity must be restricted in affected patients.

The short-term outcome is strongly associated with the underlying cause.[11] Horses with neoplasia, uterine artery rupture, mesenteric injury, or disseminated intravascular coagulation (DIC) have a greater risk of not surviving. The survival rate has been reported to range from 51% to 74%.[10,11] Poor short-term outcome was significantly associated with high respiratory rate in one study.[11] Prepartum hemorrhage appears to be associated with a poorer prognosis than postpartum hemorrhage (100% vs. 20% mortality, respectively).[11]

Hemothorax

Hemothorax may occur secondary to trauma (including lung biopsy), neoplasia, and strenuous exercise (see Chapter 31).[13] Hemothorax in neonatal foals may be the result of lacerated lungs and vessels from fractured ribs (see Chapter 20).[14]

Exercise-Induced Pulmonary Hemorrhage

Exercise-induced pulmonary hemorrhage (EIPH) has not been identified as a major cause of blood loss. EIPH is associated with high-intensity exercise in horses. An estimated 14% to 75% of racehorses examined by endoscopy have EIPH.[15] Based on bronchoalveolar lavage analysis, a study suggested that 100% of horses performing strenuous exercise have EIPH.[16] EIPH has been reported in various breeds. A recent study reported that the frequency of EIPH is associated with race type, distance, gender, and age. In one study, epistaxis was more common in females, older horses (vs. <2 years of age), following steeplechase races (vs. flat races), and at shorter distances (≤1600 m long).[17] Recurrence rate in that study was reported to be 4.64%. The pathophysiology of EIPH is not completely known. For a complete description of this disorder, see Chapter 31.

Chronic Blood Loss

Johanna L. Watson • Debra Deem Morris

A number of diseases can result in chronic loss of blood that is insidious until clinical signs of anemia develop. Physiologic adaptation to gradually developing tissue hypoxia generally masks signs of anemia until the PCV is less than 15%. Causes for chronic blood loss include bleeding gastrointestinal (GI) lesions, certain renal diseases, hemostatic dysfunction, bloodsucking external parasites, and haemonchosis (especially in goats and sheep).

GI hemorrhage is usually caused by neoplasia (especially gastric squamous cell carcinoma in horses and abomasal lymphoma in cattle), parasitism, or mucosal ulceration (e.g., abomasal ulcers in cattle and nonsteroidal antiinflammatory drug [NSAID] toxicity in horses). Significant hemorrhage may occur in ruminants heavily infested with *Haemonchus contortus* shortly after they are treated with an anthelmintic. Generally, GI hemorrhage is best detected by chemical determination of fecal occult blood, because melena rarely occurs in horses, and bleeding abomasal ulcers cannot be excluded in cattle when melena is absent. Because of the low specificity of tests for fecal occult blood, the diagnosis of chronic GI blood loss is usually supported by strong clinical suspicion and ruling out other sources of hemorrhage.

VetBooks.ir

Although both renal calculi and renal papillary necrosis due to NSAID therapy cause hematuria, anemia rarely results. Renal neoplasia and congenital renal vascular anomalies are rare causes of chronic blood loss anemia. Other causes of blood loss include idiopathic hematuria and idiopathic recurrent hematuria of Arabian horses.

Disorders of hemostasis can cause internal or external hemorrhage that leads to anemia if enough blood is lost. Qualitative or quantitative abnormalities of blood vessels, platelets, or coagulation factors result in hemostatic dysfunction (see next section). Loss of erythrocyte iron secondary to chronic severe blood loss may result in iron deficiency anemia. Hypoferremia or reduced serum ferritin develops with increased total iron-binding capacity and reduction in marrow iron.

The key to managing chronic blood loss is determining the primary cause; treatment of the anemia per se is rarely indicated. Iron deficiency may be alleviated by oral (PO) supplementation with ferrous sulfate, although good-quality forages contain more than adequate amounts of iron. Parenteral iron supplementation as iron dextran should be avoided because it has been associated with anaphylactoid reactions in large animals. Examples of specific disorders follow.

Gastric Ulceration

Monica Aleman • Johanna L. Watson

Gastric ulceration is also known as *equine gastric ulceration syndrome* (EGUS). Although EGUS is not an important cause of blood loss, it has a high prevalence among adult horses. Thoroughbred racehorses have the greatest prevalence (range, 82% to 93%), followed by endurance horses (67%), show horses (58%), hospitalized horses (49%), and geriatric patients with abdominal pain (18%).[18-22] Gastric ulcers were found in 66.6% of pregnant and 75.9% of nonpregnant mares on a Thoroughbred breeding farm.[23] Clinical signs may include poor hair coat, decreased appetite, poor performance, nervous disposition, abdominal pain, teeth grinding, and salivation among others. Proposed causes of gastric ulceration include exercise, transportation, grazing deprivation, alternating periods of feeding and fasting, diets with high-concentrate content, and confinement. For a complete description of gastric ulceration see Chapter 32.

Right Dorsal Colitis

Right dorsal colitis (RDC) is an enteropathy associated with NSAID administration, most commonly phenylbutazone.[24,25] Other factors that may predispose to RDC are infection, immune-mediated response, genetics, and stress; pathogenesis is unknown. NSAIDs act by inhibiting cyclooxygenase (more inhibition of constitutively expressed COX-1 than inducible COX-2 expression during states of inflammation), which will cause inhibition of prostaglandin E production, resulting in hypoxic or ischemic GI mucosal damage and delayed mucosal healing.[25]

Ponies and young performance horses appear to be predisposed. Clinical signs include inappetence, lethargy, intermittent or episodic colic, diarrhea, and weight loss. Clinicopathologic abnormalities may include mild anemia, moderate to severe hypoproteinemia with hypoalbuminemia, hypocalcemia, and in some cases azotemia. Although mild anemia is seen in most cases, horses occasionally present with severe anemia and hematochezia. RDC often develops over a period of days or a few weeks. The complete discussion of diagnosis and treatment is included in Chapter 32.

Hemostatic Dysfunction

Johanna L. Watson • Debra Deem Morris

Basic Physiology of Normal Hemostasis

The basis for understanding the pathogenesis and manifestations of hemostatic disorders is a thorough understanding of the normal physiologic mechanism of hemostasis. Hemostasis can be viewed as two interrelated components—coagulation and fibrinolysis (both with their respective inhibitors)—which function to arrest bleeding from a damaged blood vessel and maintain nutrient blood flow.

Coagulation is mediated by blood vessels, platelets, and blood procoagulant proteins. When a blood vessel is damaged, vasoconstriction occurs, followed by rapid adherence of platelets to subendothelial collagen. Platelet adhesion causes membrane conformational changes that trigger aggregation, contraction, and granule secretion (the basic platelet reaction). Platelet phospholipoprotein (platelet factor 3) provides the necessary surface to catalyze interactions among the activated coagulation proteins that result in thrombin formation. Coagulant proteins are localized to this hemostatic plug because the platelet surface protects them from plasma anticoagulants. Through an incompletely understood mechanism, platelets also prevent spontaneous hemorrhage into the skin and mucous membranes by maintaining vascular integrity.

Procoagulant proteins circulate in the blood as precursor forms (zymogens) that must be altered during coagulation to become active. Numerous communications exist between the traditional extrinsic and intrinsic pathways, although initiating mechanisms remain distinct.[26] The extrinsic system is initiated when lipoprotein tissue factor (TF) gains access to the bloodstream. TF is widely distributed in most tissues, including endothelial cells and monocytes, and it may be increased or secreted in response to numerous pathologic stimuli like bacterial endotoxin. Intrinsic coagulation is initiated when blood is exposed to a negatively charged surface (e.g., activated platelets). Because of reciprocal activation between factor XII and prekallikrein, the intrinsic coagulation pathway stimulates formation of numerous inflammatory mediators such as kinins and complement. Both coagulation pathways culminate in the formation of activated factor X (Xa) by which thrombin is generated. In addition to catalyzing the conversion of fibrinogen to fibrin, thrombin promotes platelet aggregation, enhances cofactor activities of factors V and VIII, and activates factor XIII and protein C.[27] Mechanisms to localize coagulation to the site of vascular injury are critical to protect against generalized thrombosis.[28] Plasma anticoagulant proteins include the serpins, which inhibit activated coagulation factors, and the protein C system, which is directed against cofactors V and VIII.[29] Antithrombin III (AT III), the main physiologic inhibitor of thrombin and Xa, normally provides 70% of the anticoagulant activity of plasma. Although not absolutely necessary, heparin accelerates AT III action by 2000-fold.[30] Activated protein C destroys factors V and VIII, ultimately limiting its own activation, which depends on thrombin and endothelial cofactor, thrombomodulin. Protein S enhances the anticoagulant ability of protein C.

The fibrinolytic system is activated at the same time as coagulation and functions to prevent tissue ischemia by limiting the extent of fibrin clot formation. Plasmin, primarily responsible for degradation of fibrin, exists in the plasma as the zymogen plasminogen. Plasminogen has a high affinity for fibrin, as does tissue plasminogen activator (tPA); because clots contain the necessary components to allow lysis from within, systemic plasmin formation is avoided. α_2-Antiplasmin (α_2-AP), the main physiologic inhibitor of plasmin, competes with the binding of plasminogen to fibrin, and the clot contains equal amounts of both glycoproteins. Because of this molar balance between α_2-AP and plasminogen, a normal blood clot does not lyse spontaneously, despite fixation of tPA. Physiologic plasminogen activator inhibitors (PAIs) are found in plasma, platelets, and endothelial cells; platelet-derived PAI protects a blood clot against premature lysis. Clot lysis is initiated if additional tPA is taken up from the surrounding tissues, and stasis upstream from the occluded vessel is a potent stimulus for release of endothelial tPA. Conversion of plasminogen to plasmin allows partial digestion of fibrin and exposure of additional plasminogen binding sites. When this additional plasminogen is converted to plasmin, the inhibitory effect of α_2-AP is overcome, and clot lysis is accelerated. Plasmin hydrolyzes fibrinogen and fibrin with equal affinity, as well as numerous other procoagulants, and it can activate complement and kininogen. The

VetBooks.ir

physiologic actions of plasmin are limited to the fibrin clot by the affinity between the latter and plasminogen and the presence of α_2-AP in blood. Because of multiple interactions between the coagulation and fibrinolytic systems, the most important factor that determines the rate of fibrinolysis is the rate of fibrin formation.[31]

Inherited Coagulation Disorders

Jeffrey W. Norris

The presentation of patients with reductions in protein levels or activity associated with the traditional coagulation pathways may range from asymptomatic to severe prolongation of bleeding subsequent to trauma, including that associated with diagnostic procedures, surgery, and parturition. Other signs of pathologic hemorrhage associated with coagulation factor deficiency include subcutaneous hematomas, hemarthroses, epistaxis, melena, or hematuria. Several coagulation factor deficiencies have been described in domestic herd animals.

Prekallikrein, or Fletcher factor, deficiency has been described in both Miniature[1] and Belgian horses.[2] Conversion of prekallikrein to kallikrein is traditionally thought of as initiating the intrinsic pathway of coagulation through activation of factor XII. Recent studies have demonstrated that prekallikrein and factor XII are critical factors in thrombosis but not hemostasis.[3,4] This subtle role of prekallikrein in the coagulation system is consistent with observations that many patients with prekallikrein deficiency are asymptomatic, but bleeding in response to trauma (e.g., surgery) is possible.[2] The inheritance pattern of this deficiency and the causal mutation have not been determined.

The second step of the intrinsic pathway of coagulation is activation of factor XI by activated factor XII. Factor XI deficiencies have been reported in Holstein,[5] Holstein-Friesian,[6] and Japanese Black cattle.[7] The deficiency has been reported in Canada,[5] Britain,[6] the United States,[8] Poland,[9] Turkey,[10] and Japan.[7] Factor XI deficiency in cattle is transmitted as an autosomal recessive trait.[11] Most cases result from a 76–base pair (bp) insertional mutation in exon 12 of the F11 gene,[8] but a 15-bp insertional mutation in exon 9 of the F11 gene has also been identified in a group of Japanese Black cattle.[7] Estimates of the prevalence of the former mutant gene allele are approximately 1.2%,[8,12] but the latter mutant allele may have a prevalence as high as 23.1% in Japanese Black cattle.[13] Cattle with factor XI deficiency may be asymptomatic or present with a range of signs that includes prolonged bleeding, reduced resistance to infection (particularly mastitis, metritis, and pneumonia),[11,14] and an increased prevalence of repeat breeding, possibly due to a slower estrus cycle.[15] Distribution of this deficiency within a family group is best determined by genetic analysis because there is poor segregation in factor XI plasma levels between normal and heterozygous cattle.[16]

Factor VIII deficiency, or hemophilia A, has been reported in a range of breeds, including Quarter Horses,[17] Japanese Brown cattle,[18] and Hereford cattle.[19] Congenital factor VIII deficiency is X-linked and recessive, with clinical disease occurring predominantly in males, although homozygous females or heterozygous females with X inactivation may also be affected. A leucine-to-histidine mutation leading to the deficiency was recently found in the F8 gene of Japanese Brown cattle.[20] Factor VIII levels of 5% or less are considered to be moderate to severe hemophilia and may predispose patients to spontaneous hemorrhage; a less severe deficiency may lead to excessive hemorrhage only after trauma.

Factor VIII is stabilized in circulation via non-covalent association with von Willebrand factor, which also promotes platelet-endothelial adhesion at sites of vascular injury. Deficiency of von Willebrand factor has been reported in a Quarter Horse filly that had hemorrhage from mucosal surfaces following trauma.[21]

A combined deficiency of the vitamin K–dependent coagulation factors (factors II, VII, IX, and X) was reported in a family of Rambouillet sheep.[22] Signs included excessive subcutaneous bleeding and bleeding from the umbilicus in newborn lambs following parturition. Evidence that (1) affected lambs were consistently produced by a single sire in the flock and (2) failure to identify a known vitamin K antagonist in affected lambs was consistent with an inherited disorder. Breeding data from the study supported an autosomal recessive mode of transmission. The molecular defect underlying this coagulopathy is unknown, but mutations leading to altered vitamin K metabolism or γ-glutamyl carboxylase function are possible.

A second combined deficiency with moderate decreases of factors VIII, IX, and XI was reported in an Arabian colt.[23] Factors VII and prothrombin were also moderately reduced in this colt, but no abnormalities were apparent in plasma from the sire, mare, or other half-siblings, raising the possibility of an acquired coagulopathy. Additional differential diagnoses for coagulation factor deficiencies include DIC, warfarin toxicosis (horses), moldy sweet clover toxicosis, and acute hepatic disease.

The heritable clotting factor deficiencies involve proteins in the intrinsic pathway, and prolonged activated partial thromboplastin time (APTT) is the primary hemostatic abnormality. However, multifactor defects in the vitamin K–dependent coagulation factors (e.g., that described in Rambouillet sheep[22]) and acquired coagulation factor deficiencies also involve proteins in the extrinsic or common pathways of coagulation, which will cause a trend toward prolongation of both the prothrombin time (PT) and APTT. Except as noted for factor XI deficiency in cattle, the definitive diagnosis of heritable clotting factor deficiencies is based on specific quantitative assays of those factors.

Heritable clotting factor deficiency is treated by replacing the factors through the administration of fresh plasma. Specific clotting factor concentrates are not commercially available for large animals, and development of such products is unlikely because of the rarity of these disorders. The expense of therapy and potential for complications makes the long-term prognosis poor for horses with hemophilia A or animals with multiple congenital coagulation factor defects. Cattle with factor XI deficiency apparently have a normal lifespan but may require treatment for secondary diseases like infection, owing to their increased susceptibility.

Thrombasthenia in Horses

Jeffrey W. Norris • Monica Aleman

GLANZMANN THROMBASTHENIA. Glanzmann thrombasthenia is a rare, inherited platelet defect caused by either a quantitative or qualitative change in the platelet glycoprotein complex IIb-IIIa (integrin $\alpha_{IIb}\beta_3$). This complex is made from two subunits encoded by separate genes that must both be expressed to form stable, functional heterodimers on the platelet surface. This complex is the receptor that binds fibrinogen and mediates platelet aggregation. Glanzmann thrombasthenia has been documented in humans and dogs.[1,2] Of the six reports of thrombasthenia in the horse,[3-7] four have been confirmed to be Glanzmann thrombasthenia by genetic analysis.

Interestingly, mutations associated with Glanzmann thrombasthenia in horses have only been found in the α_{IIb} subunit. An 18-month-old Oldenburg filly was shown to be homozygous for a G-to-C mutation of codon 72 in exon 2 that causes an arginine-to-proline substitution.[8] A similar G-to-C mutation, also causing an arginine-to-proline substitution, was identified at codon 41 in exon 2 of both a 7-year-old Thoroughbred cross gelding that was homozygous for the mutation, and a 4-year-old Quarter Horse mare that was heterozygous.[9] Both arginine-to-proline mutations occur in a single highly conserved portion of the α_{IIb} gene and are expected to destabilize the protein structure, leading to an absence of the complex on platelet surfaces.[9] Further analysis of the Quarter Horse mare revealed a 10-bp deletion in the second α_{IIb} allele that spanned the distal (5′) exon 11 splice site and likely led to decay of the mRNA transcribed from the allele.[10] This deletion was also identified in a 17-year-old Peruvian Paso that was homozygous for the mutation.[7]

VetBooks.ir

The prominent clinical sign of Glannzman thrombasthenia in the horse is chronic intermittent epistaxis unrelated to exercise. Other signs include petechial and ecchymotic hemorrhages in the nasopharynx.

Conclusive diagnosis usually requires nonstandard testing procedures. Clinical biochemistry may indicate mild anemia in the face of normal platelet count, activated coagulation time, partial thromboplastin time (PTT), PT, thrombin time, fibrin degradation products, and plasma concentration of von Willebrand factor. However, gingival bleeding time is prolonged (>60 minutes, control horses <2 minutes), clot retraction is markedly reduced, and platelet aggregation in response to various agonists as measured by aggregometry is markedly impaired. Closure time measured using a PFA-100 analyzer with collagen/ADP cartridges is markedly prolonged.[6] Also, the amplitude of thromboelastograph (TEG) tracings may be reduced, consistent with weakened tensile strength of kaolin- or tissue factor–induced clots.[6] Flow cytometric studies using CD41/CD61 monoclonal antibodies have revealed a reduction in $\alpha_{IIb}\beta_3$ integrin on platelet surfaces.[5]

Currently, no treatment is available. Superficial cauterization of bleeding sites in nasal mucosa using silver nitrate swabs and a CO_2 laser has been attempted but provided only temporary hemostasis.[7] Clients have been advised to be observant for signs of bleeding requiring supportive care; regular monitoring for anemia is recommended.[7]

HERITABLE BLEEDING DIATHESIS (OTHER THAN GLANZMANN THROMBASTHENIA). Severe intermittent bleeding was reported in a 2-year-old Thoroughbred filly subsequent to minor insults.[11] Platelet concentration, PT, PTT, antithrombin III, and the coagulation factors (von Willebrand, VIII, IX, XI, and XII) were unremarkable. Several integral platelet membrane glycoproteins involved in aggregation and clotting, including GPIb, GPVI, and $\alpha_{IIb}\beta_3$, were present on platelets from this filly. The filly's template bleeding time was over 120 minutes, compared to 5.5 minutes in control horses. Platelet-rich plasma aggregated normally in response to a range of agonists (ADP, thromboxane A_2) but was prolonged in response to thrombin and collagen.[12]

Consistent with the reduced aggregation in response to thrombin, fibrinogen binding to platelets from the filly was markedly decreased in comparison to control platelets.[12] Platelets from this filly also had reduced prothrombinase activity, which reflects decreased thrombin activation and catalysis of fibrinogen polymerization. Reduced fibrinogen binding and prolongation of the template bleeding time was also observed in one of two offspring from the affected mare. In a screen of 444 randomly selected horses from a single breeding facility, a normal distribution of fibrinogen binding was established for equine platelets, and 0.7% of the population was found to have reduced levels of fibrinogen binding (67.6% to 83.4% reduction) that were comparable to the affected mare and offspring.[13]

Unlike Glanzmann thrombasthenia, in which platelets lack the ability to bind fibrinogen entirely, the $\alpha_{IIb}\beta_3$ integrin on platelets from horses with this bleeding diathesis functions normally. Therefore, acute bleeding in established cases has been managed by stabilization of clotting through inhibition of fibrinolysis using ε-aminocaproic acid.

Acquired Hemostatic Disorders

Monica Aleman • Johanna L. Watson

Acquired defects of hemostasis may be divided into those involving blood vessels, platelets, and coagulation factors, although some diseases affect more than one component.

VASCULITIS. Vasculitis is a clinicopathologic process that involves inflammation and necrosis of blood vessel walls, regardless of size, location, or cause.[1] Vasculitis in large animals is generally a secondary manifestation of a primary infectious, toxic, or neoplastic disorder and has characteristics of hypersensitivity vasculitis in humans. The predominant involvement of small vessels in the skin (e.g., venules, arterioles) is the hallmark of hypersensitivity vasculitis.

Clinical manifestations of vasculitis include demarcated areas of dermal or subcutaneous edema that may progress to skin infarction, necrosis, and exudation.[2] Hyperemia, petechial and ecchymotic hemorrhages, and ulceration of mucous membranes are common. Although the skin and mucous membranes are predominantly involved, hemorrhage and necrosis may occur in any organ system, resulting in conditions like lameness, colic, dyspnea, and ataxia. Subclinical renal disease is not uncommon. Vasculitis is often attended by a number of adverse sequelae such as cellulitis, thrombophlebitis, laminitis, and pneumonia. Characterized vasculitis syndromes with predominant cutaneous involvement include equine purpura hemorrhagica (EPH), equine viral arteritis (EVA), equine infectious anemia (EIA), and equine granulocytic ehrlichiosis (EGE). There are also a number of vasculitis syndromes in horses for which cause, pathogenesis, and clinical course are poorly defined.[3,4] Vasculitis is apparently uncommon in ruminants but may accompany certain septicemic diseases (e.g., malignant catarrhal fever of cattle, bluetongue of sheep).[5] Hematologic and serum biochemical findings in vasculitis are determined by the underlying disease, length of illness, organ involvement, and secondary complications. Chronic inflammation may be attended by neutrophilia, mild anemia, hyperglobulinemia, and hyperfibrinogenemia. Some horses with EPH develop a moderate anemia (PCV 20% to 25%) that is thought to be caused by increased erythrocyte destruction.[6] The platelet count is generally normal. Muscle damage may be reflected by increased serum concentrations of creatine phosphokinase (CPK) and aspartate aminotransferase (AST). The creatinine may be elevated, and urinalysis may rarely show trace hematuria or proteinuria if there is glomerulonephritis.

Definitive diagnosis of vasculitis is made by demonstration of the characteristic histopathology of involved vessels. Full-thickness punch biopsies (at least 6 mm in diameter) of skin in an affected area should be obtained and preserved in 10% formalin and Michel's transport medium. Multiple biopsies from different sites may be necessary to reach the diagnosis. The most common inflammatory pattern is neutrophilic infiltration of venules in the dermis and subcutaneous tissue, with nuclear debris in and around involved vessels (leukocytoclasis) and fibrinoid necrosis. Immunofluorescence on biopsies preserved in Michel's medium may reveal immune complexes. Considerable evidence suggests that most vasculitis syndromes are mediated by immunologic mechanisms—that is, a hypersensitivity reaction to a microbe, drug, toxin, or protein.[1] In some instances an exogenous stimulus cannot be identified, and an autoimmune pathogenesis is suspected. Immune complex deposition in vessel walls, with subsequent complement activation and chemoattractant production, seems to be the major pathogenic mechanism. Infiltrating neutrophils and macrophages release proteolytic enzymes that cause vessel wall necrosis with subsequent edema, hemorrhage, and infarction of supplied tissues. Size and physiochemical properties of immune complexes, blood flow turbulence in sites of vessel bifurcation, and hydrostatic forces in dependent areas account for preferential formation of lesions in certain disease states and anatomic locations. Horses and cattle with idiopathic vasculitis may have incomplete response to therapy with an unpredictable poor prognosis.[5,6]

Equine Purpura Hemorrhagica. Purpura hemorrhagica (PH) is a noncontagious disease of horses characterized by vasculitis leading to extensive edema and hemorrhage of the mucosa and subcutaneous tissue. The disease has been recognized as a sequela to infection with or exposure to *Streptococcus equi, Streptococcus zooepidemicus, Rhodococcus equi, Corynebacterium pseudotuberculosis*, and others, and vaccination against *S. equi*.[2,7]

Young to middle-aged horses are commonly affected (mean, 8.4 years of age; range, 6 months to 19 years).[7] Clinical signs usually develop acutely within 2 to 4 weeks of a respiratory infection.[8]

VetBooks.ir

Predominant signs are well-demarcated subcutaneous edema of all four limbs, lethargy, anorexia, hemorrhages on mucous membranes, fever, and tachycardia. Other signs are tachypnea, reluctance to move, serum exudation from the skin, colic, and epistaxis.

The predominant laboratory abnormalities include anemia, neutrophilia, hyperproteinemia, hyperfibrinogenemia, hyperglobulinemia, and elevated muscle enzymes. Thrombocytopenia is rarely detected in horses with PH.

Skin biopsy shows evidence of acute leukocytoclastic or nonleukocytoclastic vasculitis with necrosis of blood vessels. The lesions are marked dermal and subcutaneous hemorrhage, protein-rich edema, and multifocal areas of dermal infarction. Small arteries and capillaries are swollen and infiltrated by degenerate or nondegenerate neutrophils. Hyaline thrombi may be observed.[7] Immune complexes have been demonstrated to be primarily composed of immunoglobulin (Ig)M or IgA and streptococcal M protein and may be present in capillaries and small blood vessels of horses with PH, leading to a type III hypersensitivity reaction.[9] Deposition of immune complexes in vessel walls and subsequent complement activation may result in cell death. Extensive hemorrhages in the dermis, subcutis, skeletal muscles, lungs, kidneys, spleen, intestinal walls, and blood vessels have been observed in postmortem examination.

Horses with infarctive PH can present with colic, lameness, muscle swelling, and stiffness.[10] Extensive GI infarction results in severe colic signs. Significant findings in these horses include leukocytoclastic vasculitis and necrosis of various tissues, neutrophilia with a left shift, hypoalbuminemia, and high serum creatine kinase.[10]

Treatment should aim to address the primary cause if identified, reduce the immune and inflammatory response, initiate antimicrobial therapy in cases of active infection or prevent infection if indicated, provide supportive care, and prevent complications. Horses with known streptococcal infection should receive penicillin (22,000 IU/kg of intramuscular [IM] procaine penicillin G twice daily, or IV potassium penicillin G q6h) or other antibiotic with excellent efficacy against streptococcal organisms for at least 2 weeks. Hydrotherapy, limb bandages, and light exercise (hand walk) have been helpful in reducing limb edema. Fluids administered IV or via nasogastric tube may be necessary for animals that become severely lethargic and fail to drink or those that develop dysphagia from laryngeal edema. Stridor and dyspnea may indicate the need for tracheostomy. Prolonged treatment with corticosteroids (2 to 4 weeks) has resulted in favorable outcome and low relapse rate. However, some horses may require a longer course of therapy than 4 weeks. Depending on severity of clinical signs, proposed dosages are 0.04 to 0.2 mg/kg of dexamethasone (IV, IM, or PO) once (morning) or twice a day, or 0.5 to 1 mg/kg of prednisolone PO once (morning) or twice a day (0.05 to 1 mg/kg), with gradual reduction of the dosage.[7] It has been suggested that antimicrobials be used throughout the course of corticosteroid therapy to reduce the occurrence of secondary sepsis.[2]

Outcomes will depend on early detection, early aggressive treatment, and extent of organ involvement. Skin sloughing, laminitis, cellulitis, pneumonia, and diarrhea are common and may significantly prolong convalescence. The prognosis is fair with early aggressive therapy and supportive care; a recent retrospective study of 53 horses with purpura hemorrhagica reported a mortality rate of 7.5%.[7]

Equine Viral Arteritis. Equine viral arteritis (EVA) is an infectious disease characterized by panvasculitis, edema, hemorrhage, and abortion in pregnant mares. EVA is caused by an enveloped, spherical, positive-stranded RNA virus with a diameter of 50 to 70 nm. Equine arteritis virus (EAV) is a nonarthropod-borne virus classified as a member of the new order Nidovirales within the family Arteriviridae.[11] EAV was first isolated from fetal lung collected during an epizootic of abortion in Bucyrus, Ohio.[12] Clinical signs may be absent or may develop 1 to 10 days after infection and include pyrexia, lethargy, anorexia, limb edema, stiffness, rhinorrhea, epiphora, conjunctivitis, rhinitis, and abortion. Edema of several regions can be observed, including periorbital, supraorbital, ventrum, mammary gland, scrotum, and limbs.[13] Other signs include urticarial rash, abortion, respiratory signs, ataxia, mucosal eruptions, submaxillary lymphadenopathy, and intermandibular and shoulder edema. EAV can present as epidemic abortion, with occasional fatalities in foals and adults. With natural exposure, abortion rate varies widely (<10% to >60%) and can occur from 3 to 10 months of gestation.[14] Infected mares do not become EAV carriers or chronic shedders and do not appear to have fertility problems.

Laboratory abnormalities are variable and not diagnostic for EVA. Experimentally infected mature horses had a consistent leukopenia due to neutropenia and lymphopenia.[15] After infection, EAV can be localized in macrophages and lymph nodes within 24 and 48 hours, respectively. Various tissues are affected, but blood vessels are the principal target of EAV. Within vessels, EAV localizes in endothelium, medial myocytes, and pericytes. The virus causes vasculitis with fibrinoid necrosis of the tunica media, abundant vascular and perivascular lymphocytic and lesser granulocytic infiltration with karyorrhexis, loss of endothelium, and formation of large fibrinocellular stratified thrombi.[13] Body cavity effusion is common.

The virus is mainly transmitted through aerosols from respiratory, urinary, or reproductive tract secretions of acutely infected animals. The other route of transmission is via semen from shedding stallions; the virus remains viable in fresh, chilled, and frozen semen.[14] Horizontal transmission via fomites is possible.[16] Natural EAV exposure results in long-term immunity to the disease. Mares and geldings eliminate virus within 60 days, but 30% to 60% of acutely infected stallions will become persistently infected, temporarily or permanently shedding virus in semen.[13] The virus is maintained in the accessory organs of the male reproductive tract (ampullae, vasa deferentia).[14] Seroprevalence for EAV is very common in the Standardbred and warmblood breeds and, more recently, EAV infection has been established within some Quarter Horse populations.[17]

Laboratory diagnosis of EVA can be based on virus isolation, viral nucleic acid detection (polymerase chain reaction [PCR] assay), or serology. In the case of serology, a fourfold or more increase in serum neutralizing antibodies between acute and convalescent samples (3 weeks apart) is required for diagnosis. Stallions with positive titers of 1 : 4 should be tested for persistent infection by virus isolation from sperm-rich ejaculate.[14] Viral isolation and PCR can be attempted from respiratory secretions or fetal and placental tissues. Semen can be tested for viral shedding by culture, isolation, or PCR. Identification of carrier stallions is crucial in preventing dissemination of EAV. A modified live vaccine is commercially available (Arvac [Fort Dodge Animal Health, Livestock Division, Overland Park, Kan.]). Vaccination will result in development of a serum titer that will be detected on EVA testing and cannot be distinguished from active infection. Horses vaccinated for the first time should have serum submitted to a U.S. Department of Agriculture (USDA)-approved laboratory to confirm seronegative status. After vaccination, these animals should be isolated because they may temporarily shed the modified virus.

Equine Infectious Anemia. See section on hemolytic anemia.

ANAPLASMA PHAGOCYTOPHILA INFECTION IN HORSES

John E. Madigan • Johanna L. Watson

Definition and Etiology Equine granulocytic ehrlichiosis (EGE) was first reported in the late 1960s in the foothills of Northern California.[1] The disease is caused by *Anaplasma phagocytophila*. This organism was formerly known as *Ehrlichia equi,* but it was reclassified in the *Anaplasma* genus based on genetic analysis.[2] Recently, the agents of human granulocytic ehrlichiosis (HGE), *Ehrlichia phagocytophila* and *E. equi,* were grouped into a single species and named *A. phagocytophila*.[2] These organisms are identical based on 16S rRNA gene sequences, and they have similar morphology, host cell tropism, and indirect fluorescent antibody (IFA) response.[3]

The organism is found within vacuoles (1.5 to 5 μm in diameter) in the cytoplasm of infected granulocytes, primarily neutrophils and eosinophils. These vacuoles or inclusion bodies are pleomorphic and

VetBooks.ir

contain one or more coccobacillus or large granular aggregates called *morulae*. The organisms are visible under light microscopy as deep blue to pale blue gray with Giemsa or Wright-Leishman stains.

Epidemiology Since the disease was first reported in California,[4] cases have been diagnosed in Colorado, Connecticut,[5] Florida, Illinois, Minnesota, New Jersey, New York, Oregon, Washington, Wisconsin, Canada, Brazil, northern Europe, and Israel. Equine cases occur during late fall, winter, and spring. There is no apparent gender or age predilection, but the disease appears to be less severe in younger horses. Persistent, chronic, or latent infections or carrier status have not been demonstrated and are unlikely to occur, since the presence of *A. phagocytophila* is limited to the acute phase. Therefore, it is also unlikely that infected horses could serve as reservoirs. The disease is not contagious but could be readily transmitted through the administration of infected blood. The vectors of granulocytic ehrlichiosis are *Ixodes pacificus* in California, *Ixodes scapularis* in the eastern and midwestern United States, and *Ixodes ricinus* in Europe.[6-9] Potential or proposed reservoirs are white-footed mice, chipmunks, white-tailed deer, dusky-footed wood rats, cervids, lizards, and birds.[9]

Pathogenesis The pathogenesis of the disease is unknown. Entry of the organism occurs after inoculation from a biting tick and is presumed to be spread via blood and/or lymph. The organism has cell tropism toward neutrophils and eosinophils, where it replicates within vacuoles, forming characteristic morulae. Presumed cytolysis, induction of inflammation, cell sequestration, consumption, or destruction result in the observed clinical signs and pancytopenia.[10] Cell- and humoral-mediated immune responses develop in affected animals. Antibody titers peak at 19 to 81 days after the onset of clinical signs, and immunity likely persists for a long period of time (>2 years).[11]

Clinical Signs Clinical signs include reluctance to move, fever ranging from 39.4° to 41.3°C (102.9° to 106.3°F), mild to moderate tachycardia (50 to 60 beats/min [bpm]), lethargy, decreased appetite, limb edema, petechiation, icterus, weakness, ataxia, and recumbency (reported in one case). Secondary trauma may result from falling in severely ataxic horses. These clinical signs appear to be less profound in younger horses. The incubation period after natural infection is believed to be less than 14 days. The prepatent period after experimental exposure to infected ticks or inoculation with infected blood is 8 to 12 days and 3 to 10 days, respectively. The disease is self-limiting and nonfatal provided no complications develop. However, affected horses may be predisposed to secondary bacterial, fungal, and viral infections.[1] Abortions and laminitis have not been reported in affected horses.

Clinical Pathology Laboratory alterations include anemia, leukopenia characterized by granulocytopenia and lymphopenia, and thrombocytopenia. Morulae may be observed within the cytoplasm of neutrophils and eosinophils during the acute phase of the infection.

Diagnosis Definitive diagnosis is based on the presence of characteristic morulae (minimum of 3) within the cytoplasm of neutrophils and eosinophils, or positive PCR assay for *A. phagocytophila* in peripheral blood (buffy coat).[12] Morulae may be observed in less than 1% of cells in the initial stages of the infection, rising to 20% to 50% of cells a few days later. A fourfold or greater increase in IFA titer of paired samples confirms recent exposure.[13]

Pathologic Findings Petechiae and ecchymosis of subcutaneous tissues, and edema of the ventral abdomen, limbs, and prepuce are characteristic in infected animals. Proliferative and necrotizing vasculitis, thromboses, and perivascular cuffing in subcutaneous tissue, fascia, kidneys, heart, brain, lungs, ovaries, and testes have been reported.[1,10]

Treatment, Prognosis, and Prevention The treatment of choice is IV administration of oxytetracycline at 7 mg/kg, or oral administration of doxycycline at 20 mg/kg of body weight once a day for 5 to 7 days. Prompt response to treatment is seen within the first 24 hours. Supportive therapy may be necessary in some cases. The disease can be self-limiting in 2 to 3 weeks if untreated. Prognosis is excellent provided no secondary complications develop. At present, prevention is limited to tick control.

THROMBOCYTOPENIA

Johanna L. Watson • Debra Deem Morris

Thrombocytopenia (platelet count < 100,000/μL) can result from one or more of three basic mechanisms: (1) decreased or ineffective platelet production; (2) abnormal sequestration (usually in the spleen); or (3) shortened platelet survival (consumption or destruction). Thrombocytopenia causes a hemorrhagic diathesis characterized by multiple sites of small vessel bleeding. Petechial hemorrhages with or without ecchymotic hemorrhages are generally found on the oral, nasal, or vaginal mucous membranes, as well as on the nictitans and sclera. Epistaxis, melena, hyphema, or microscopic hematuria may occur, but spontaneous hemorrhage is unusual unless the platelet count is less than 10,000/μL. Prolonged bleeding from wounds, injections, or surgical procedures and the propensity to form hematomas after minor trauma are quite common when the platelet count drops below 40,000/μL. The platelet count below which bleeding occurs varies among individuals and seems to be determined by concurrent diseases.

The interaction of blood platelets with a discontinuous vascular surface constitutes the basis for primary hemostasis. In addition, platelets provide the phospholipoprotein surface necessary to catalyze interactions among the activated coagulation proteins that culminate in fibrin formation. The platelet surface also protects activated clotting factors from destruction by plasma anticoagulants, thereby localizing coagulation to the hemostatic plug. Platelets maintain vascular integrity through mechanisms involving immunoreceptor tyrosine activating motif (ITAM) signaling and prevent spontaneous hemorrhage into the skin and mucous membranes. Severe thrombocytopenia produces prolonged bleeding time and abnormal clot retraction without affecting clotting times or plasma fibrinogen.

Persistent life-threatening hemorrhage caused by thrombocytopenia may be treated with a transfusion of compatible fresh whole blood or, preferably, platelet-rich plasma. The latter may be produced by centrifugation thrombocytopheresis[1] or by centrifugation of freshly collected blood, 3 to 5 minutes at 250 *g*.[2] Blood or plasma must be used immediately, and contact with glass must be prevented to avoid platelet adhesion and activation. Platelet transfusion is a very transient life-saving measure, and the ultimate prognosis for thrombocytopenia depends on the cause.

Decreased production of platelets may occur secondary to replacement of the normal marrow architecture by neoplastic or inflammatory tissue (myelophthisic disease) or bone marrow aplasia. Both conditions are characterized by peripheral pancytopenia of variable severity and are extremely unusual in large animals. Myelophthisic disease with thrombocytopenia has been described in horses with various forms of myelogenous neoplasia[3-5] and eosinophilic myeloproliferative disorder.[6]

Hypoplastic anemia with leukopenia and thrombocytopenia has been reported in horses and cattle and is discussed later in the chapter in the section on aplastic anemia. Shortened platelet lifespan is by far the most common cause of thrombocytopenia in large animals. Increased platelet consumption accompanies DIC (discussed in the next section) and rare cases of vasculitis. Immune-mediated mechanisms result in platelet destruction.

Immune-mediated thrombocytopenia (IMTP) may be primary (idiopathic) or secondary to drug administration, infections, neoplasia, or other immunologic disorders.[2] This disease is most common in horses and has been reported secondary to EIA,[7] lymphoma,[8] and autoimmune hemolytic anemia.[9] The clinical signs of IMTP include

VetBooks.ir

mucosal hemorrhages and the propensity to bleed from small blood vessels. Horses with idiopathic IMTP are usually bright, afebrile, and without overt hemorrhage despite severely reduced platelet numbers. Thrombocytopenia in a horse with obvious primary disease should prompt a thorough hemostatic workup to rule out DIC.

Alloimmune thrombocytopenia of neonates has been recognized as a spontaneous disease of human infants, piglets, foals, and possibly mule foals.[10] Clinical signs include depression, loss of suckle, a bleeding tendency, blood loss, and rapidly developing anemia due to a profound thrombocytopenia. The condition occurs in multiparous dams, and immunoglobulins from the mare, found in her plasma, serum, and milk, bind to the foal's platelets. Alloimmune thrombocytopenia should be considered in neonates with severe thrombocytopenia when other causes can be excluded, and platelet antibody assays should be used to support this diagnosis. Differential considerations include neonatal sepsis, neonatal maladjustment syndrome, and neonatal isoerythrolysis. Laboratory findings of IMTP include severe thrombocytopenia (<40,000/μL), prolonged bleeding time, and abnormal clot retraction with normal thrombin time (TT), PT, APTT, and plasma fibrinogen. Fibrin(ogen) degradation products (FDPs) may be mildly increased, and anemia accompanied by hypoproteinemia develops if there is ongoing blood loss. In most cases of IMTP and other causes for shortened platelet lifespan, megakaryocytic hyperplasia is evident on examination of bone marrow aspirates or biopsies. Megakaryocytic destruction by the immunologic process could induce megakaryocytic hypoplasia, although this is apparently rare in horses. The definitive diagnosis of IMTP requires demonstration of increased quantities of platelet-associated IgG or C3 or antiplatelet activity in the serum. Flow cytometric methods to detect platelet surface–associated IgG (PSAIgG) have been adapted for horses.[11] Without PSAIgG testing, the diagnosis of IMTP must be based on small-vessel hemorrhagic diathesis and severe thrombocytopenia in a horse with normal coagulation times and no other evidence of DIC. Response to therapy (see next section) supports the diagnosis. A tentative diagnosis of IMTP in the horse should prompt a thorough search for an underlying disorder, especially lymphoma.

Platelet destruction in IMTP is apparently mediated by antibodies coating the platelet surface that cause premature platelet removal from circulation by the mononuclear phagocyte system (MPS).[12] In primary IMTP the platelet-associated Ig is directed against a membrane antigen, is usually of the IgG class, is produced in the spleen, fixes complement, and can be absorbed from serum by platelets from a normal individual of the same species. Autoantibodies may attach to megakaryocytes, but the latter are not necessarily destroyed because they do not circulate through the spleen or liver. In secondary IMTP the Ig bound to the platelet surface is part of an immune complex composed of antibody directed against a drug, microbe, or neoplastic antigen that is nonspecifically attached to the platelet Fc receptor. For secondary IMTP to be perpetuated, the foreign antigen must be constantly replenished or difficult to excrete. Drug-induced IMTP generally subsides within a few days of drug discontinuation, although thrombocytopenia secondary to chrysotherapy (gold therapy) may persist for weeks to years. Because gold is occasionally used to treat pemphigus foliaceus in horses, thrombocytopenia should be considered as a potential side effect. The spleen is the major site of platelet phagocytosis because (1) much antiplatelet antibody is secreted locally, (2) more than 30% of circulating platelets are normally stored there, and (3) the stagnant splenic blood flow allows sensitized platelets to pass slowly through a dense network of phagocytic cells. The mean cell life of circulating platelets and the platelet count are inversely proportional to the quantity of platelet-associated IgG.

When any unexplained case of thrombocytopenia is treated, all current medication should be stopped. If a drug is absolutely necessary, it must be replaced by the chemically most dissimilar substitute. Drug-induced IMTP usually responds within 14 days of drug withdrawal. Most animals with suspected IMTP improve when treated with corticosteroids. Although their precise mechanisms of action are speculative, corticosteroids improve capillary integrity, impair clearance by the MPS, decrease the number and avidity of macrophage Fc receptors, impair antiplatelet antibody production, impede platelet-antibody interactions, and increase thrombocytopoiesis.

Dexamethasone (0.04 to 0.2 mg/kg IV or IM) given once daily generally results in an elevation in the platelet count within 4 to 7 days. Once the platelet count is greater than 100,000/μL, the dose of dexamethasone can be reduced by 10% to 20% daily while the platelet count is monitored for a relapse. Occasionally, animals with IMTP are refractory to dexamethasone, in which case prednisolone (0.5-1 mg/kg IM twice daily) may be tried. Treatment with corticosteroids can usually be discontinued after a period of 10 to 21 days, provided the platelet count has been normal for at least 5 days. Most horses with IMTP have a favorable prognosis, and the disease resolves within 14 to 21 days. This suggests that many cases may be secondary, yet the initiating cause is rarely found. Chronic or recurrent IMTP requiring prolonged corticosteroid therapy has been reported.[13] Alternative treatment modalities for IMTP are largely unproven in horses, because most cases are responsive to corticosteroids.[14-16]

DISORDERS OF COAGULATION FACTORS

Johanna L. Watson • Debra Deem Morris

Normal blood coagulation proceeds in an integrated sequence that can be simplistically viewed as three key reactions: formation of activated factor X, formation of thrombin, and formation of fibrin. Other protein interactions serve to accelerate or inhibit the reaction rates of coagulation factors. Excessive use or inhibition of these proteins produces a relative deficiency that causes hemorrhagic diathesis. Alterations in the coagulation cascade, including thrombocytopenia and procoagulant and anticoagulant effects, can be observed with snakebite (e.g., rattlesnake) envenomation (see Chapter 54).

Disseminated Intravascular Coagulation. The most common form of hemostatic dysfunction in large animals is a syndrome known variously as *DIC, consumption coagulopathy, defibrination syndrome,* or *intravascular coagulation fibrinolysis.*[1,2] The pathologic process is characterized by widespread fibrin deposition in the microcirculation (with subsequent ischemic damage) and development of a hemorrhagic diathesis caused by the consumption of procoagulants and hyperactivity of fibrinolysis. Never a primary disease entity, DIC represents an intermediary mechanism of underlying disease. In large animals, DIC has been described in association with forms of localized or systemic septic processes,[2-5] neoplasia,[2] GI disorders,[6] renal disease,[6] and hemolytic anemia.[5,7] Diffuse activation of the hemostatic system is particularly prevalent in horses with acute GI disorders that cause colic[5,6] and is a likely initiating factor for laminitis.[8,9] Because of the dynamic nature of DIC, clinical manifestations may fall anywhere on the spectrum from diffuse thrombosis leading to ischemic organ failure to severe hemorrhagic diathesis. The most important determinants are the rate of thrombin generation (which depends on the triggering disease), the adequacy of fibrinolysis, and the functional state of the MPS, which is largely determined by peripheral circulation. Coagulopathy usually occurs in a compensated form in horses and cattle and is rarely attended by overt hemorrhage; however, microvascular thrombosis and subsequent ischemia to vital tissues leads to organ malfunction (e.g., renal failure), which contributes to the morbidity and mortality of the primary disease process.

Renal involvement is common in DIC, which produces ischemic cortical necrosis followed by acute tubular necrosis. Renal disease may be manifested by oliguria, depression, and ileus caused by azotemia and electrolyte imbalances. GI microthrombosis may induce colic as a result of submucosal necrosis and superficial ulceration. Spontaneous GI hemorrhage caused by DIC may cause melena in ruminants and occult fecal blood loss in horses. Pulmonary function may rarely be compromised by microvascular thrombosis in DIC, causing tachypnea and variable hypoxemia. Altered consciousness, delirium, convulsions, or coma may follow cerebral microvascular thrombosis, although these signs are not common in DIC in large animals. Although reported in both horses[10] and cattle,[7]

VetBooks.ir

microangiopathic hemolysis is rare in large animals with DIC because of their small erythrocyte size.

Digital ischemia frequently accompanies DIC in horses and may play a role in the development of acute laminitis. Laboratory evidence of DIC has been documented during the developmental phase of equine laminitis,[9] and digital microvascular thrombosis occurs in horses that develop laminitis with colic or septic conditions.[8] The tendency for thrombosis of major peripheral veins is another prominent manifestation of coagulopathy in horses. Venous thrombosis occurs in horses and is associated with needle- or catheter-induced intimal trauma, nonsterility during catheterization, blood sampling or treatment procedures, and thrombogenic catheter materials. However, the strong clinical impression remains that severely ill horses with diseases known to induce coagulopathy have a greater tendency toward venous thrombosis. Spontaneous thrombosis of smaller cutaneous vessels also occurs.

As the thrombotic stimulus continues or intensifies, the tendency for hemorrhage develops because of clotting factors and platelet depletion or generation of excessive fibrinolytic by-products (FDPs). Petechial or ecchymotic hemorrhages on mucosae and sclerae and a tendency to bleed from venipuncture or after minor trauma are the principal signs. Spontaneous life-threatening hemorrhage is very rare, but trauma or surgery may induce uncontrollable hemorrhage. Once signs of blood incoagulability develop, the prognosis is poor.

Horses may develop a chronic compensated form of DIC that is attended by few or no clinical signs. This entity develops in patients with illnesses that produce a low-grade or intermittent procoagulant stimulus that allows used coagulant proteins and platelets to be partially or totally replenished, and activated clotting factors and FDPs to be cleared by the MPS. Localized sepsis (e.g., pleuritis), neoplasia, protein-losing enteropathy, and immune-mediated disorders (vasculitis, anemia) are common initiating diseases. This compensated state may become imbalanced by stress, concurrent diseases, or worsening of the primary process, resulting in clinically obvious DIC. Diseases that must be differentiated from DIC include IMTP, warfarin toxicosis (horses), moldy sweet clover toxicosis, and inherited coagulation abnormalities.

Numerous laboratory tests of hemostasis may be abnormal during DIC, but no one test consistently or specifically provides a definitive diagnosis. Lack of test sensitivity results from the dynamic nature of DIC, the laboratory reflection of which is determined by the balance between coagulation and fibrinolytic forces, as well as MPS integrity at the time of blood sampling.

The most widely used hemostatic function tests in large animals include platelet count, plasma fibrinogen, PT, APTT, and serum FDPs. Because clinical manifestations of DIC vary widely, clarification of the most frequent laboratory abnormalities in large animals with DIC is hindered by lack of a definitive diagnosis in most instances. A disseminated coagulopathy is characterized by multiple hemostatic abnormalities, and serial analyses should reveal reduced platelet numbers and a trend toward prolongation of PT, APTT, and TT. Repeated hemostatic testing is advised when there is strong suspicion for DIC. Serum FDPs are most often elevated by DIC, but they are usually normal in the early or compensated form of the disease. Hypofibrinogenemia is an uncommon manifestation of DIC in large animals and, when present, should strongly suggest concomitant liver dysfunction. Hemostatic function tests are totally unreliable unless blood samples are collected and handled properly.

Criteria used for diagnosis of DIC are extremely arbitrary, and laboratory results must be interpreted in light of the patient's underlying disease. The combination of thrombocytopenia with mild to moderate PT or APTT prolongation strongly suggests DIC. The clinician should seek laboratory assistance when considering the diagnosis of DIC, but appreciate that the findings are often not helpful. Clinical signs and specific situations suggest the possibility of DIC, and laboratory tests are only used to provide support.

Diseases initiate DIC by two major mechanisms: (1) generation of excessive procoagulant activity within the blood or (2) contact of blood with abnormal surfaces. Many diseases act by more than one mechanism to induce the overwhelming stimulus needed to trigger DIC. The nature and intensity of the procoagulant force (which determines the rate of thrombin formation), the concentration of natural coagulation inhibitors, and the functional capacity of the MPS determine whether an individual with a given disease process develops DIC, as well as the clinical manifestations. Many diseases that produce DIC have the propensity to cause endotoxemia. The intestinal tract in large animals normally contains large quantities of endotoxins, only a small part of which is absorbed through the portal vein and removed by the liver. Conditions that cause intestinal mucosal edema or disruption allow endotoxins to gain access to the peripheral circulation and initiate many morbid sequelae, one of which is DIC. Intestinal strangulating obstruction, thromboembolic infarction, and severe colitis induce mucosal abnormalities, allowing endotoxemia to occur. The proliferation of gram-negative bacteria within tissues and the blood is also accompanied by endotoxemia.

Gram-negative endotoxins are capable of direct factor XII activation. However, most studies indicate that the procoagulant effects of endotoxin are primarily mediated by cytokine production by mononuclear phagocytes.[11] After endotoxin stimulation, phagocytes produce a platelet-activating factor (PAF), tissue factor, prostaglandins, interleukins (ILs), tumor necrosis factor (TNF), and other mediators with procoagulant activity.[12]

The net result of any triggering mechanism for DIC is exaggerated generation of systemic thrombin, which causes widespread microcirculatory thrombosis. In addition to the cleavage of fibrinogen to produce fibrin monomers, thrombin activates factor XIII to render fibrin more resistant to fibrinolysis, enhances the cofactor activity of factors V and VIII, and induces platelet aggregation and exposure of platelet phospholipid. Circulatory obstruction produces organ hypoperfusion, leading to ischemic necrosis.

The counterbalance fibrinolytic system is also activated by DIC, and plasmin contributes to factor consumption by destroying factors V, VIII, XIIa, IX, and XI, in addition to fibrin and fibrinogen. FDPs contribute greatly to the hemorrhagic manifestations of DIC because they have antithrombin activity, interfere with fibrin monomer polymerization, and cause platelet dysfunction. Paradoxically the combination of consumption and anticoagulation predisposes to hemorrhage at the same time disseminated thromboses occur.

The MPS plays a vital role in the pathogenesis of DIC. The tissue-fixed macrophages of the spleen and liver normally remove FDPs and activated clotting factors from the peripheral circulation, and FDPs only increase when their rate of formation exceeds the ability of the MPS to clear them. Shock and hypoperfusion of the liver and spleen or diseases associated with excessive tissue debris that must be removed by the MPS (e.g., sepsis, metastatic neoplasia) reduce its ability to function effectively and predispose to or perpetuate DIC.

Therapy for DIC is highly controversial, and the only noncontended modalities are those directed toward identification and treatment of the primary disorder, along with general supportive measures to combat shock and maintain tissue perfusion.[13,14] IV fluid administration helps prevent organ dysfunction after microvascular thrombosis and can correct existing acid-base or electrolyte imbalances. Septic conditions should be treated with appropriate antimicrobial agents, and necrotic tissue or purulent exudate removed whenever possible (e.g., immediate surgical intervention to resect nonviable bowel). Flunixin meglumine mitigates the deleterious effects of endotoxin caused by eicosanoids and is used in horses at a dosage of 0.25 mg/kg IV q8h). Corticosteroids may worsen DIC because they reduce the phagocytic action of the MPS and potentiate the vasoconstrictor effects of catecholamines.

Significant life-threatening hemorrhage is rare in large animals with DIC, but if it occurs, fresh plasma should be administered (15 to 30 mL/kg) to replace used coagulant and anticoagulant proteins. The use of heparin in DIC has been recommended in various regimens to stall the disseminated microvascular thrombosis that precipitates organ failure; there is still controversy regarding its efficacy.[14] In dogs, minidose heparin therapy (50 to 75 units/kg subcutaneously [SC] three times daily, or 5 to 10 units/kg/h) is commonly used with

VetBooks.ir

blood products to treat DIC.[13] Efficacy of heparin for DIC in horses is unproven. Heparin in all species can predispose to hemorrhage, thrombosis, and thrombocytopenia[15] and causes anemia and erythrocyte agglutination in horses.[16] If heparin therapy is considered, one must ensure there is adequate plasma AT III, which is necessary for heparin action. Because AT III is often depleted by DIC, plasma may be necessary. Clinical trials in humans have not shown therapeutic benefit of anticoagulants in chronic DIC.

The prognosis for DIC in large animals depends largely on the nature and severity of the underlying disease and how effectively the latter is treated. Once DIC has progressed to the stage where signs of blood incoagulability predominate, the prognosis is generally very poor.

Warfarin Toxicosis. Horses may develop a hemorrhagic diathesis due to warfarin toxicosis.[17] This coumarin-derivative anticoagulant is used by some to treat horses with navicular disease.[18] Rarely, horses and other animals may be exposed to coumarins used as rodenticides in grains or other feedstuffs. Therapeutic concentrations of warfarin can have a cumulative toxic effect if the diet is altered to contain less vitamin K or if there is concurrent protein-bound drug therapy. The clinical signs of warfarin toxicosis include hematomas, ecchymoses of mucous membranes, epistaxis, and hematuria. The earliest laboratory indication of warfarin toxicosis is prolongation of the PT, because the plasma half-life of factor VII is shorter than the other clotting factors.[19] As the disease progresses, the APTT becomes prolonged, and the animal may develop blood-loss anemia and hypoproteinemia. The diagnosis of warfarin toxicosis is based on a history of exposure, clinical signs of large-vessel hemorrhagic diathesis, and prolonged PT with or without APTT and with no other abnormalities of the clotting profile.

Warfarin acts through competitive inhibition of vitamin K, which is necessary for liver production of clotting factors II, VII, IX, and X.[18] Factor activity is reduced in the blood at a rate dependent on its individual half-life. In most species, factors VII, IX, X, and XI have increasingly greater half-lives, accounting for the greater sensitivity of PT for the early diagnosis of warfarin toxicosis. After GI absorption, warfarin is highly bound to plasma proteins. Drugs that are normally protein bound (e.g., phenylbutazone, chloral hydrate) can enhance warfarin's toxicity by allowing a greater proportion of the administered drug to be unbound and active.[20] In the same manner, hypoalbuminemia may increase the likelihood of warfarin toxicosis. Corticosteroids and thyroxin can lower the necessary therapeutic dose of warfarin by increasing both receptor affinity and clotting factor catabolism. Drugs that induce hepatic microsomal enzyme activity (e.g., barbiturates, rifampin, chloramphenicol) can accelerate warfarin metabolism and reduce therapeutic response to a given dose. Any reduction in hepatic function or content of vitamin K in the diet can also precipitate warfarin toxicosis.

Treatment of warfarin toxicosis depends on clinical signs. Warfarin therapy should be stopped if the PT exceeds twice the pretherapeutic value. Vitamin K_1 (0.5 to 1 mg/kg SC) must be given every 6 hours until the PT is again normal and stable. Significant hemorrhage can be controlled by giving fresh plasma to provide necessary clotting factors. If the anemia is life threatening, whole blood transfusion should be considered. Although warfarin is eliminated rapidly, some potentiated coumarins have a prolonged half-life, requiring a longer course of vitamin K therapy. With early diagnosis and prompt vitamin K treatment, the prognosis for warfarin toxicosis is good. However, it is imperative that vitamin K_3 *not* be used because it has poor therapeutic action and is highly nephrotoxic for horses.[21]

Prevention of warfarin toxicosis is based on limiting access of livestock to rodenticides and carefully monitoring the therapeutic use of warfarin in horses. Warfarin's benefits for horses are highly controversial, and many question whether its advantages outweigh the risks.

Sweet Clover Toxicosis. Sweet clover (*Melilotus* spp.) toxicosis is caused by ingestion of moldy sweet clover hay or silage containing dicoumarol. Natural coumarins in sweet clover can be converted to dicoumarol when hay or silage is improperly cured and mold forms. The toxin persists in moldy hay or silage and is palatable. This disease can occur in all species but is most commonly seen in cattle fed sweet clover hay in the northern plains states. Early signs include epistaxis and melena, with the development of subcutaneous hematomas and periarticular swellings as the disease progresses. Visible swellings occur at points of trauma such as the brisket, tuber coxae, or carpi and are not hot or painful, although they may cause stiffness and disinclination to move. Accidental and surgical wounds cause severe hemorrhage and may precipitate fatal blood-loss anemia.

Clinical pathology is similar to that described for warfarin toxicosis, with prolonged PT being the earliest abnormality (detected before clinical evidence of hemorrhage). The platelet count remains normal, which differentiates this syndrome from DIC and bracken fern toxicosis. Other diagnostic ruleouts include mycotoxicosis and toxicosis from trichloroethylene-extracted soybean meal. In the absence of fever and anorexia, coagulopathy should make moldy sweet clover toxicosis a strong tentative diagnosis in animals with a history of access. Chemical analysis for dicoumarol in suspected feed or in the blood and liver of affected animals aids in the diagnosis,[22] but the disease cannot be excluded if dicoumarol is not detected.

The pathogenesis of moldy sweet clover toxicosis is identical to that of warfarin toxicosis. Dicoumarol interferes with hepatic synthesis of clotting factors II, VII, IX, and X by inhibiting vitamin K. Usually the syndrome appears in cattle 2 to 7 days after they ingest the moldy hay. Lower levels of dicoumarol (<70 mg/kg) in feed may prolong the onset of signs for up to 3 months.

The succulent nature of sweet clover creates a high incidence of molding in hay. Grazing the crop is not dangerous. Because of its high forage yield, sweet clover is usually harvested as silage, which should carry less danger of molding when properly cured. The toxic level of dicoumarol in sweet clover feed samples is 10 mg/kg of feed.[22]

Treatment of sweet clover toxicosis involves discontinuing the use of contaminated feed and administering vitamin K_1.[20] Dosages between 0.5 and 1 mg/kg of body weight should be administered IM every 6 hours; response occurs within 24 hours. Animals with severe blood-loss anemia or ongoing hemorrhage should be treated with plasma or whole fresh blood. Sweet clover toxicosis can be prevented by careful forage preparation, followed by the inspection of hay and silage before feeding. When the disease is suspected, questionable feed should be removed from the diet.

Diseases Associated with Increased Erythrocyte Destruction (Hemolytic Anemia)

Gary P. Carlson

Hemolytic disorders are characterized by an increased rate of red cell destruction. Anemia results when the rate of red cell destruction exceeds the bone marrow capacity for increased proliferative response. Although intravascular hemolysis occurs in some circumstances, these anemias are primarily due to an increased rate of extravascular erythrocyte destruction and shortened intravascular lifespan.

Hemolytic anemias are associated with a wide range of systemic disease processes. The mechanisms responsible for the enhanced red cell destruction also vary markedly. A list of differential considerations for possible causal factors of hemolytic anemia in large animals is presented in Box 37-1. Clinical manifestations of hemolytic anemia vary with the degree of anemia, rate of red cell destruction, and primary or underlying disease process. However, several common clinical signs are seen in animals with severe hemolytic anemia, regardless of the cause: mucous membrane pallor, fatigue, depression, and anorexia. Clinical icterus can be quite variable depending on the rate of red cell destruction and the liver's ability to excrete bilirubin. Icterus is a characteristic feature in hemolytic anemia, but intense icterus is noted only after massive red cell destruction and is often

transient. With continued low-level hemolytic processes, the liver may be able to excrete bilirubin at a rate sufficient to avoid clinical icterus. Hemolytic icterus must be differentiated from other potential causes like liver disease or anorexia in horses. If icterus is caused by hemolytic processes, clear clinical and hematologic evidence of anemia should exist. Massive intravascular hemolysis may result in an orange to reddish discoloration of the mucous membranes. Modest to marked and often variable febrile responses are frequently encountered in hemolytic anemias caused by infectious agents and during periods of active erythrocyte destruction. With advanced anemia the pulse and respiratory rates are elevated at rest. Death losses may occur, and neurologic abnormalities ranging from bizarre behavior to mania, collapse, and death may be associated with handling animals with a severe anemia.

The hematologic manifestations of hemolytic anemia also vary with the rate of red cell destruction, time course of the anemia, and primary or underlying disease process. Anemia may be modest to severe, and after the first few days in all species except the horse, there is usually hematologic evidence of enhanced erythropoietic response seen as increased anisocytosis, polychromasia, reticulocytosis, and the presence of nucleated red blood cells in the circulation. Morphologic abnormalities of diagnostic significance (e.g., intracellular or epicellular parasites, granulocytic inclusion bodies, Heinz bodies, spherocytes, schistocytes, or poikilocytes) may be noted on examination of stained blood smears. Responsive anemias often are accompanied by neutrophilia and a regenerative left shift. Bone marrow usually shows an active erythropoietic response with a decreased myeloid/erythroid (M:E) ratio. The serum concentration of haptoglobin is decreased, and serum lactate dehydrogenase enzyme activity may be elevated during acute hemolytic episodes. An increase in serum bilirubin concentration caused primarily by an increase in indirect reacting bilirubin is a reflection of active red cell destruction. Specific serologic diagnostic procedures are available for many of the infectious causes of hemolytic anemia. Immunohematologic procedures like the direct and indirect Coombs test provide an indication that immune-mediated processes contribute to enhanced erythrocyte destruction. It should be noted that the principal mechanisms responsible for the increased rate of red cell destruction associated with many infectious causes of hemolytic anemia (parasitic, bacterial, viral) are immunologically mediated, and affected animals may be transiently Coombs positive.

Infectious Causes of Hemolytic Anemia

Bovine Anaplasmosis

Guy H. Palmer • Kristin A. Clothier

Definition and Etiology In livestock medicine, *anaplasmosis* traditionally refers to disease characterized by progressive anemia caused by intraerythrocytic infection with *Anaplasma marginale* in cattle and *Anaplasma ovis* in sheep and goats. In addition, a subspecies of *A. marginale, A. marginale* subsp. *centrale* (also referred to as *A. centrale*) causes mild disease in cattle and has been used as a live vaccine to induce partial protection against *A. marginale*.[1,2]

Molecular characterization and genetic analysis of *Anaplasma* and *Ehrlichia* have resulted in identification of six species in the *Anaplasma* genus: *Anaplasma phagocytophilum* (formerly called both *Ehrlichia equi* and *Anaplasma equi*), which infects granulocytes in a wide range of mammalian species including dogs, horses, and humans; *A. marginale, A. ovis,* and *A. centrale,* which infect erythrocytes of wild and domestic ruminants; *Anaplasma bovis,* which infects monocytes of cattle and related species; and *Anaplasma platys,* which primarily affects platelets in small animal species.[2,3,4] Although many species become infected and demonstrate symptoms of disease due to *A. phagocytophilum* infection, there is no evidence *A. marginale* or *A. ovis* are capable of infecting humans or any non-ruminant mammalian species. This discussion primarily addresses bovine and, to a lesser degree, ovine and caprine anaplasmosis.

Clinical Signs and Differential Diagnosis Clinical signs are highly variable, from acute severe disease to subclinical infection, and reflect variation in virulence among pathogen strains, breed resistance, and age-related host susceptibility.[1,6] The typical incubation period ranges from 15 to 30 days. Primary exposure in calfhood often produces asymptomatic or mild clinical disease resulting in slight lethargy and anorexia for 24 to 48 hours. In contrast, acute anaplasmosis in adult cattle is typified by fever with rectal temperatures ranging from 39.5° to 41°C (103° to 106°F). Within 12 to 24 hours the fever subsides, and the temperature may become subnormal before the animal dies. Anorexia, lethargy, and in dairy cows, a dramatic decrease in milk production are often observed. Concurrently there is suppression of rumination, dryness of the muzzle, and lethargy. Cattle may stagger or become aggressive as a result of cerebral hypoxia associated with anemia. Care must be taken not to stress severely anemic cattle, since this may result in collapse and death. Mucous membranes are pallid, or icteric if an animal has survived for 2 to 3 days past the acute crisis. Additional clinical signs include constipation characterized by dark brown feces covered with mucus, pollakiuria with dark yellow urine, and abortion in late-gestation animals. Hemoglobinuria does not occur. If an animal survives the acute crisis, the convalescent period is protracted (3 to 4 weeks) depending on the severity of the anemia, and icterus and weight loss are common. Recovered animals remain infected for life and serve as a reservoir for ongoing transmission. Persistent infection is not associated with any disease or decrease in production status, so there is no basis for the diagnosis of "chronic anaplasmosis." Although *A. ovis* infection in sheep and goats is often asymptomatic, anemia occasionally becomes severe enough to produce signs similar to those seen during *A. marginale* infection of cattle.

VetBooks.ir

Definitive diagnosis of acute anaplasmosis requires identification of *A. marginale*– or *A. ovis*–infected erythrocytes by microscopic examination of blood smears, concomitant with a significant decrease in hematocrit (see Clinical Pathology and Serology). Differential diagnoses include diseases that can produce anemia and/or icterus (babesiosis, bacillary hemoglobinuria, leptospirosis); hepatotoxic plant poisonings *(Senecio),* chemicals, and other causes of liver disease; and copper poisoning in sheep.

Clinical Pathology and Serology Because acute bovine anaplasmosis is characterized by anemia, a falling hematocrit provides an estimate of the severity of infection. PCV may drop precipitously within 24 to 48 hours. Death can occur during this period despite a PCV above 20%. In other cases, the PCV may decrease below 10% before death. During this acute phase, *A. marginale* can be detected within the erythrocytes by microscopic examination of blood smears stained with Wright's, new methylene blue, or Giemsa stain. The inclusion is composed of a small morula of 2 to 8 individual organisms, and over 5% (as many as 20% to 70%) of erythrocytes may be infected. After several days of anemia the percentage of infected erythrocytes decreases dramatically, and evidence of erythrocyte regeneration can be detected. Blood smears demonstrate anisocytosis, basophilic stippling, poikilocytosis, polychromatophilia, and reticulocytosis.

Following recovery from acute disease, cattle and sheep remain persistently infected with 0.000001% to 0.1% of erythrocytes affected. Detection of organisms in erythrocytes at this stage is unreliable; persistently infected animals that serve as reservoirs for transmission have to be detected serologically. Serologic diagnosis is most commonly by competitive enzyme-linked immunosorbent assay (cELISA [VMRD Inc., Pullman, Wash.]), which provides both high specificity and, unlike the complement fixation (CF) test, high sensitivity in detecting persistently infected carrier cattle.[1,5] The cELISA test, approved as an official test by the USDA and the Office of International Epizootics (OIE), is conducted by most if not all state diagnostic laboratories. Currently, negative status with the cELISA is required for importation of live cattle into Canada. Although cattle will seroconvert by cELISA during acute infection, organism-based assays, including PCR, are more reliable for diagnosing acute anaplasmosis.[1]

Pathophysiology *Anaplasma* spp. are naturally transmitted by ixodid species ticks, most commonly *Dermacentor* in the U.S. mainland and *Rhipicephalus* spp. (including tick species previously classified in the genus *Boophilus*) in tropical and subtropical regions worldwide. Organisms can be transmitted transstadially (from larvae to nymphs and nymphs to adults), indicating that ticks can become infective and transfer *Anaplasma* spp. to a new host after only a single molt.[2] Direct mechanical transfer of infected erythrocytes by biting flies, as well as iatrogenic spread through management practices (contaminated needles, dehorning, castrating, hormone implanting, and ear tagging instruments), can result in transmission.[1,2] Bacteria replicate within parasitophorous vesicles in the red blood cells; similar invasion mechanisms are used within tick cells to propagate infection.[6] Sequential rounds of bacterial invasion of mature erythrocytes, replication, and egress result in a progressively increasing cell-associated bacteremia, with a doubling time of roughly 24 hours. Depending on the strain of *Anaplasma* and host susceptibility, 10% to 90% of erythrocytes may become infected; clinical signs appear when over 15% of erythrocytes are infected.[1,6] Anemia is due to splenic and hepatic macrophage-mediated phagocytosis of both infected and uninfected erythrocytes, reflecting induction of autoantibodies against the erythrocyte surface, as well as activation of acute-phase reactants, including complement activation, during high-level rickettsemia. The regenerative response to anemia can be vigorous and does not appear to be suppressed by the infection.

Protective immunity appears to require induction of both antibody against the outer membrane proteins and macrophage activation for enhanced phagocytosis and bacterial killing.[7,8] Although the immune response controls the acute phase of infection, organisms are not completely cleared from the blood, owing to emergence of antigenic variants.[8] These variants are responsible for persistent infection, characterized by recurring waves of bacteremia that reflect sequential emergence and then immune control of antigenically variant organisms.

Epidemiology *A. marginale* is the most prevalent of the tick-borne diseases of cattle worldwide and remains as a serious constraint to livestock production in tropical, subtropical, and even temperate regions. In the United States, infection is endemic in much of the West and occurs episodically in at least 40 states, but Canada is considered to be free of widespread anaplasmosis. Endemic regions are maintained by the prevalence of both competent arthropod vectors and persistently infected carrier cattle. These carrier cattle, which are typically asymptomatic, are efficient reservoirs for tick-borne transmission.[1,2,8] Vector activity varies by region, but outbreaks of anaplasmosis occur most frequently in the late spring and summer when arthropod activity is highest. In contrast, iatrogenic transmission can occur anytime and can be controlled by avoiding blood contamination during veterinary medical procedures. Although wild ruminants (deer, elk, bison) rarely have clinical disease and are generally asymptomatic persistently infected carriers, their overall importance in the epidemiology of infection is unclear. Currently, wild ruminants are thought to play at most only a minor role in natural transmission.

Pathology At necropsy, there are no pathognomonic lesions for the diagnosis of disease. In acute anaplasmosis the blood is thin, watery, and fails to clot readily. Mucous membranes, subcutaneous tissues, and skeletal musculature are pale; in later stages of acute disease, the same tissues may be icteric. Splenomegaly is a consistent finding; hepatomegaly and gallbladder distention are commonly but less frequently observed. Urine is deep yellow, but neither hemoglobinuria nor hematuria occurs, which helps differentiate anaplasmosis from other hemolytic diseases (babesiosis, bacillary hemoglobinuria, leptospirosis, onion toxicity, copper poisoning in sheep). Occasionally petechiae may be found in the subepicardium, subendocardium, and other serous membranes. Detection of *A. marginale*–infected erythrocytes within capillaries of Giemsa-stained histologic sections can be used to confirm a diagnosis of anaplasmosis.

Treatment Tetracyclines are the antibiotic of choice for treating acute disease, and therapy is aimed at minimizing or preventing the effects of *A. marginale* infection; however, treatment does not eliminate persistent infection.[1,9] In acute anaplasmosis, oxytetracycline 11 mg/kg IV q24h for 3 to 5 days may be effective. One to two administrations of long-acting oxytetracycline at 20 mg/kg IM at 72-hour intervals is an alternative treatment regimen. In addition to antibiotic therapy, supportive therapy is important to maximize the chance of survival. If the PCV is 12% or below, whole blood transfusion (4 to 8 L) may be indicated to prevent death and shorten the convalescence period. A PCV of 8% or below indicates an unfavorable prognosis, and death often occurs despite appropriate antibiotic and supportive therapy. Evaluations of a variety of chemical compounds and treatment regimens have determined that chemosterilization for *A. marginale* infection is rarely successful.[1,10] If required for exportation, clearance should be confirmed by conversion to seronegative status.

Prevention and Control The control measures used vary depending on the geographic region and type of livestock production system. In endemic regions with high transmission rates, beef cattle are often allowed to become naturally infected at a young age and remain asymptomatic carriers with minimal risk of later acute disease. In regions with lower transmission rates, live blood-based vaccines may be used to ensure infection of cattle at a young age. This is exemplified by the use of trivalent *(A. marginale, Babesia bovis, Babesia bigemina)* live vaccine in Australia. Similarly, live vaccines

based on *A. centrale* or weakly virulent strains of *A. marginale* are commonly used in Africa, Asia, and Central and South America. However, these are not licensed for use in the United States, largely because of the risk of transmitting known or newly emergent pathogens contaminating the blood-based vaccine. The exception to this is the licensing of a live vaccine for use in California (AnaVac [PHL Associates, Davis, Calif.]). Importantly, these live vaccines should only be used in young animals and are contraindicated for pregnant and older animals. Killed vaccines are less efficacious and require multiple immunizations but can induce at least partial protection against severe morbidity and mortality. Unfortunately, none of the federally licensed killed vaccines previously marketed in the United States is currently available. However, an experimental killed vaccine (Experimental Anaplasmosis Vaccine [University Products LLC, Baton Rouge, La.) has been licensed for use in 14 states and Puerto Rico. In the absence of immunoprophylaxis, anaplasmosis is usually controlled by preventing transmission. While it is difficult to absolutely prevent the contact of ticks and biting flies with cattle grazing on open ranges or farm pastures, strategic use of acaricides and insecticides can reduce transmission during periods of high vector activity. Periodic spraying for tick control and the use of insecticide-impregnated ear tags or insecticide dust bags for biting fly control are cost-effective for controlling both anaplasmosis and pinkeye and directly reduce irritation and increase weight gain. Appropriate sanitary measures to prevent mechanical transmission should be implemented when injections or surgical procedures are performed.

Maintenance of an *A. marginale*–free herd in nonendemic areas can be accomplished by quarantine and serologic screening of all additions using the USDA-approved cELISA. Control within endemic regions requires extreme vigilance in screening and prevention of both direct contact and sharing pasture with other domestic and wild ruminants that may result in vector-borne transmission. The risk of maintaining a fully susceptible herd within an endemic region should not be taken lightly.

Babesiosis

Jerry L. Zaugg

Babesiosis is a tick-borne intraerythrocytic disease of domestic and wild mammals and humans caused by protozoan parasites of the genera *Babesia* and *Theileria*. The acute disease is characterized by fever, hemolytic anemia, icterus, hemoglobinuria, and death. Although both morphologic and serologic differentiation is required for specific identification of the various disease-producing species, all can be categorized as being either "large" or "small" in size. A list of the commonly encountered *Babesia* spp., *Theileria equi,* their usual biological vectors, and livestock hosts is presented in Table 37-1. Babesiosis has a wide geographic distribution, particularly in the tropics and subtropics, largely related to the distribution of vector ticks. Of the different diseases, the economically most important infections of livestock are those of cattle and horses.

BABESIOSIS IN THE BOVINE

Etiology Known variously by such names as *bovine babesiosis, piroplasmosis, Texas fever, redwater, tick fever,* and *tristeza,* the disease may be caused by at least six *Babesia* spp. (see Table 37-1). Some animals other than cattle known to be susceptible to agents of bovine babesiosis include white-tailed deer, American bison, water buffalo, reindeer, and the African buffalo. Infections in these species are nominal, and except under unusual conditions, such hosts are probably not significant reservoirs.

Of greatest concern in the western hemisphere are *Babesia bigemina* and *Babesia bovis. B. bigemina* is a large *Babesia* characteristically appearing within mature erythrocytes as nonpigmented, paired, pear-shaped bodies joined at an acute angle. Irregularly shaped, round, or amoeboid forms are also seen. *B. bovis* is a small, pleomorphic *Babesia* often identified as a single round body or as paired pear-shaped bodies joined at an obtuse angle within mature erythrocytes. Of the two species, *B. bovis* is usually considered the most virulent.

VetBooks.ir

Natural transmission of both species occurs primarily by the feeding of various stages of the one-host ticks of the genus *Boophilus*. Ticks are most commonly infected transovarially (vertically). The female tick becomes infected by the ingestion of parasites during engorgement. After it drops off the host, the babesial organisms reproduce within the tick's tissues. Some of the reproducing organisms are incorporated within developing tick embryos, and the disease agents are transmitted to new vertebrate hosts by the feeding of ensuing tick larvae, nymphs, or adults. Larval ticks may transmit *B. bovis,* but *B. bigemina* is not transmitted until the larvae have molted into the nymphal or adult stages. Both *Babesia* spp. may also be transmitted iatrogenically through blood-contaminated fomites as described under anaplasmosis.

Clinical Signs Clinical signs manifest 2 to 3 weeks after tick infestation. The incubation period following blood inoculation may be less than 5 days to more than 3 weeks, depending on the volume of inoculum. Clinical signs of fever (40° to 42°C [104° to 107.6°F]), depression, icterus, anorexia, tachycardia, tachypnea, anemia, hemoglobinemia, hemoglobinuria, abortion, and death are seen. Anemia is caused by intravascular destruction of erythrocytes by escaping merozoites following intraerythrocytic reproduction of the babesias by binary fission. In addition, the osmotic fragility of the whole erythrocyte population increases terminally, such that massive lysis occurs even though the parasitemia may be less than 1%.[1] Additionally, as also seen with anaplasmosis, an autoimmune condition may result in which the spleen removes damaged and apparently healthy erythrocytes from circulation. Thus the degree of anemia may exceed that expected with a low parasitemia. Anemia may occur very rapidly, with 75% or more of erythrocytes destroyed in just a few days. The exit of *B. bigemina* and *B. bovis* parasites from infected erythrocytes releases two or more parasite-associated proteolytic enzymes into the plasma. These enzymes and other parasite metabolic products are believed to interact with blood components and are responsible for such clinical signs as metabolic acidosis and anoxia. Tachycardia may be dramatic and heart sounds pronounced.

Cerebral babesiosis, characterized by hyperexcitability, convulsions, opisthotonos, coma, and death, may be observed in cattle infected with either *B. bigemina* or *B. bovis,* but especially with the latter. Central nervous system (CNS) signs are due to brain anoxia resulting from severe anemia and/or erythrocyte blockage of cerebral capillaries.

Death is caused by a shock-like syndrome associated with the accumulation of toxins, release of vasoactive substances, and anemic anoxia. Most cases with cerebral involvement are fatal, but mortality is extremely variable and depends on the *Babesia* strain, host susceptibility, and management and environmental stress factors. Many cattle that survive the acute phase recover but become chronic carriers. Other survivors often experience episodes of recrudescence, eventually succumbing to the disease, or they may die from secondary infections contracted during their debilitated state.

Cattle of all breeds are susceptible to babesiosis, but *Bos indicus* breeds exhibit a definite degree of resistance to both *B. bigemina* and *B. bovis* and the tick vectors.[2] Calves possess a natural immunity to babesiosis. Such immunity was believed to be reinforced by colostral antibodies for calves born to previously infected dams.[3] However, erythrocytes of young bovines may contain factor(s) independent of antibody that provide an innate resistance to severe babesiosis.[4] Thus calves infected up to the age of 9 months experience a minimum reaction to the disease, becoming asymptomatic carriers. Carriers remain resistant to clinical disease for at least 4 years.[5] The carrier state can be overcome, however, by such stresses as calving, malnutrition, or concurrent disease.[6]

Clinical Pathology Clinical signs observed in cattle located in enzootic areas where *Boophilus* ticks occur may provide sufficient data for a presumptive diagnosis. Other conditions that may exhibit some of the same signs as babesiosis are anaplasmosis, trypanosomiasis, theileriosis, leptospirosis, chronic copper toxicity, and bacillary hemoglobinuria. The cerebral signs may be confused with rabies and other encephalitides. A positive diagnosis requires identification of *Babesia* on Giemsa-stained thin blood smears, positive serologic tests, or inoculation of splenectomized calves with infective blood. In acute infection, *Babesia* spp. can usually be detected in smears made from peripheral blood. In chronic cases the numbers of parasitized erythrocytes diminish, becoming so sparse as to make detection difficult. This is especially true with *B. bovis,* which shows a marked tendency to accumulate in capillaries, particularly those of the brain. *B. bovis* may favor capillaries in the brain and kidney because the major energy-producing pathway of *Babesia* appears to be anaerobic glycolysis. The blockage of cerebral and renal capillaries by parasitized erythrocytes results in an anaerobic condition that enables the parasites to absorb preformed substrates by pinocytosis and diffusion through their surface membranes. PCV values drop rapidly from a normal of 35% to below 10% in less than a week after the onset of clinical signs.[7] Serum potassium levels decrease in some infected animals, whereas urine potassium levels increase in nearly all cases.[8]

Specific anti-*Babesia* antibodies are detectable in cattle sera in fewer than 7 days following infection.[9] Such antibodies also exist for at least 252 days after the disappearance of detectable parasites.[10] The CF and IFA tests are the most widely used.[9,11] The CF test follows the same basic procedure used in anaplasmosis CF testing,[11] but with a *Babesia* antigen.[12] The test is effective, but about 100 days after infection, CF antibodies drop below a reliable diagnostic level.[9] The IFA test uses the whole intraerythrocytic parasite as antigen rather than an extract, and commercially prepared rabbit antibovine γ-globulin conjugated to fluorescein.[9] Other serologic tests include gel precipitation,[13] latex particle agglutination,[14] rapid card agglutination,[15] and enzyme-labeling immunoassay (EIA).[16] It should be noted that the immunologic assays are indirect methods and do not detect the causal organisms in samples obtained from a suspected infected animal. Recombinant DNA techniques using selected clones containing inserts of *Babesia* genomic DNA sequences are now available to be utilized as specific, highly sensitive DNA or RNA probes to detect the presence of the hemoparasite DNA in an infected animal or tick vector.[17]

Necropsy Findings Postmortem findings in cattle that die peracutely are characteristic of an acute hemolytic crisis. Such findings include a generalized pallor or icterus throughout the carcass; an enlarged icteric liver; gallbladder distended with thick, dark green bile; and a markedly enlarged dark, soft spleen. Hydropericardium and subepicardial/subendocardial petechiation may be seen. The blood is thin and watery. The urinary bladder is frequently distended with dark red urine. There may be subserosal ecchymotic hemorrhages in abomasal and intestinal mucosa, and the lymph nodes are edematous. The carcass of an animal that dies after a prolonged illness is generally emaciated and icteric. The blood is thin and watery, and the intermuscular fascia is edematous. The kidneys are pale and edematous, and the bladder may contain pink-tinged or normal urine. The liver is enlarged and jaundiced, and the bile may contain flakes of semisolid material.

Treatment and Prognosis After the onset of hemoglobinuria or cerebral signs, the prognosis is poor. Acute cases with PCV values above 12% usually respond well to treatment. The prognosis decreases for cases with PCV values below 10%. Successful treatment depends on early diagnosis and prompt therapy. In addition to specific treatment, supportive therapy such as blood transfusions (4 L of whole blood per 250 kg of body weight), fluids, hematinics, and prophylactic antibiotics are important. However, wild excitable cattle may best be left alone. With severe hemolytic anemias, any exertion associated with restraint and treatment may precipitate an anoxic crisis.

The small *Babesia* spp. are more resistant to chemotherapy and may require increased dosages or additional treatments. The

VetBooks.ir

most commonly used, effective, and relatively less toxic specific babesiacides are diminazene diacturate (Berenil [Intervet Inc., St. Millsboro, Del.] or Ganeseg [Squibb & Sons de Mexico, Mexico City]) at 3 to 5 mg/kg; phenamidine diisethionate (Lomidine [May and Baker Ltd., Dagenham, England]) at 8 to 13 mg/kg; imidocarb dipropionate (Imizol [Pittman-Moore, Middlesex, England]) at 1 to 3 mg/kg; and amicarbalide diisethionate (Diampron [May and Baker Ltd., Dagenham, England]) at 5 to 10 mg/kg.[18] Generally, treated cattle become chronic carriers and are resistant to further clinical episodes of the disease. However, treatment of *B. bigemina* may be so effective that sterilization occurs, eventually leaving the animal susceptible to reinfection. Imidocarb has both therapeutic and prophylactic activities. In enzootic areas its use prevents clinical infection for as long as 2 months, but at the same time allows mild subclinical infections to occur, resulting in premunition immunity.[19,20]

Prevention and Control Eradication of *Boophilus* tick vectors has provided effective control in the United States. Other such projects attempted elsewhere have not been successful owing to such diverse reasons as tick resistance to acaricides, ability of some ticks to infest alternate non-bovine hosts, failure to obtain 100% cooperation of cattle producers, and lack of financial resources to sustain a prolonged program.

Most procedures aimed at reducing tick infestations (i.e., acaricide applications [on host or over environment], controlled range burning, cultivation, prolonged pasture rest, and use of repellents) are beneficial. Care should be taken to prevent accidental transfer of blood from one animal to another in routine surgery (e.g., dehorning, castration, ear marking, hormone implanting) and vaccination procedures.

The most common form of immunization consists of inoculating live organisms (virulent or attenuated) into susceptible calves to induce a state of premunition. Inoculation of older animals is followed by nonsterilizing chemotherapy as needed to modify clinical effects.[21] Although a premunition approach is useful in endemic areas, it is less desirable in areas with low infection rates, because the premunized carriers provide a large reservoir of infection. In vitro cell cultivation techniques have yielded highly immunogenic soluble antigens of *B. bovis*. Subunit vaccines were proven effective in protecting against severe clinical disease.[22,23] Subunit vaccines may not prevent disease, but they may moderate the effects of infection and do not directly produce carriers.

BABESIOSIS IN THE HORSE

Etiology Babesiosis/theileriosis of the horse (piroplasmosis) is a febrile tick-borne disease of equids caused by *Babesia caballi* and *Theileria equi*. Until recently *T. equi* was known as *Babesia equi,* but because the organism more closely resembles members of the genus *Theileria,* with its exoerythrocytic (lymphocytic) stages within the vertebrate host and development of microschizonts and macroschizonts, it is now classified as *T. equi*[24] (see Table 37-1). *B. caballi* is a large *Babesia* resembling *B. bigemina,* which affects cattle. Although *T. equi* is not a member of the genus *Babesia,* for practical purposes it is still considered a "small" parasite somewhat like *B. bovis* in stained thin blood smears. However, a unique characteristic of *T. equi* is that the intraerythrocytic parasites divide into four cells to form a Maltese cross.[25]

Equine piroplasmosis is widely distributed throughout the tropics and subtropics and to a lesser extent in temperate regions. The distribution roughly corresponds to those of the tick vectors. Both species are naturally transmitted by ticks of the genera *Dermacentor, Hyalomma,* and *Rhipicephalus. B. caballi* is passed transovarially (vertically) from one tick generation to the next. Transmission of *T. equi* apparently only occurs transstadially (horizontally); that is, one tick stage (larvae or nymphs) becomes infected, and the disease agent is passed to the next vertebrate host in the next tick stage (nymph or adult). Because of the widespread prevalence of potential tick vectors in the United States *(Dermacentor albipictus, Dermacentor ieus, Dermacentor variablis),* equine piroplasmosis could become a problem in the United States at any time.

Clinical Signs Apparently, all equids are susceptible to both parasite species. The zebra in Africa is naturally infected with *T. equi* but not with *B. caballi*. Once infected, survivors remain chronic carriers. At least *T. equi* can be transmitted transplacentally. Clinical features following an incubation period of 5 to 28 days are fever (39° to 42° C [102° to 107.6° F]), hemolytic anemia, jaundice, hemoglobinuria, and death. Generalized signs of depression, anorexia, incoordination, lacrimation, mucous nasal discharge, swelling of the eyelids, and frequent lying down are seen. *T. equi* is considered the most pathogenic of the two species and is responsible for a greater incidence of hemoglobinuria and death. *B. caballi* causes a more persistent fever and anemia. Differential diagnoses include equine monocytic ehrlichiosis, EIA, liver failure with hemolytic anemia, and other hemolytic anemias of the horse.

Clinical Pathology A fever associated with anemia, jaundice, and hemoglobinuria, with the detection of parasite-infected erythrocytes in Geimsa-stained blood smears, is diagnostic. A significant increase in relative and absolute numbers of monocytes and absence of eosinophils may be observed in horses infected with *T. equi*. Hemoglobinuria is rare in animals infected with *B. caballi,* but urine is often dark yellow in color. The official testing method is the cELISA test. There is also a PCR test for both equine diseases. As with the bovine infections, both *B. caballi* and *T. equi* infections can be specifically detected with nucleic acid probes.[17]

Necropsy Postmortem features are similar to those seen in bovine babesiosis, but jaundice is even more prominent throughout the carcass. There is excessive fluid in the body cavities, especially the pericardial sac. Pulmonary edema is evident. The liver is swollen, and hepatic vessels contain large yellowish clots. The spleen in enlarged, with rounded edges.

Treatment and Prognosis Generally both *B. caballi* and *T. equi* respond to the same babesiacidal drugs used to treat bovine babesiosis, but *T. equi* is more refractory to treatment than *B. caballi*. If diagnosed early and treated promptly, recovery is the rule. The drug of choice for eliminating the carrier state of infected animals is imidocarb. Imidocarb at the level of 2.2 mg/kg given two times in 24 hours is effective against *B. caballi*. A 4-mg/kg dose given four times over 72 hours is effective against *T. equi* of eastern hemisphere origin.[26] However, donkeys receiving similar treatment died from drug toxicosis.[26] The higher doses of imidocarb often produce transient colic in horses. To date, attempts to consistently eliminate the carrier state of *T. equi* of Eastern European origin have been unsuccessful.[27] However, an earlier proposal[28] suggested that irregular chemical sterilization success could be obtained with concurrent IV administration of buparvaquone (Butalex [Coopers Animal Health Ltd., Hertfordshire, U.K.]) at 4 mg/kg and IM imidocarb at 4 mg/kg.

Prevention and Control Control of tick infestations does much to reduce disease incidence, as does care to prevent blood transfer during such routine surgical procedures as castration. No vaccines effectively prevent equine babesiosis. Although premunition as used in bovine babesiosis is of limited value in some enzootic areas, it is not widely practiced. This is because early treatment without sterilization is effective, and the resulting chronic carriers resist further disease challenge.

Haemobartonellosis (Eperythrozoonosis)

Gary P. Carlson

Haemobartonella bovis is an epicellular organism closely associated with the surface of erythrocytes. It may appear as a rod shape, an ovoid, or in chains with conventional stains. Haemobartonellosis is

VetBooks.ir

primarily of academic interest in North America; it is rarely a cause of anemia. The organism has been found in association with other rickettsial diseases and has been experimentally transmitted in splenectomized calves. The agent may be visualized as delicate ovoid, rod, or dumbbell forms arranged in chains or tight groups or randomly distributed epicellularly throughout appropriately stained blood smears.

EPERYTHROZOONOSIS IN CATTLE. The causal agent is *Eperythrozoon wenyonii (Mycoplasma wenyonii).* Infection is usually latent, producing no clinical signs in normal cattle, but it may become apparent in animals that have been severely stressed by some other systemic disease. The disease can be produced experimentally if infected blood is administered to splenectomized calves. Even under experimental circumstances, clinical signs consist of mild depression, fever, and modest anemia. The disease in cattle is of little clinical consequence except for the potential for confusion should the organism be seen on stained blood films. Occasionally cattle may have swollen and tender teats and legs.[1]

EPERYTHROZOONOSIS IN SHEEP AND GOATS. The causal organism in sheep and goats is *Mycoplasma ovis (Eperythrozoon ovis),* which appears to be very similar morphologically and serologically to that found in cattle. The disease can produce more prominent clinical signs in sheep, with profound depression, anemia, and significant death losses in young lambs.[2] Red cell destruction is thought to be caused by intravascular hemolysis and erythrophagocytosis.

Theileriasis

Gary P. Carlson

Theileriasis is caused by a small hemoparasite of the genus *Theileria* that infects lymphocytes and erythrocytes of ruminants and is most common in tropical and subtropical climates. The organism is spread by bloodsucking arthropods, particularly ticks of the Ixodidae family. *Theileria parva* is the cause of East Coast Fever, a highly fatal disease of cattle in Africa. Other members of the genus *Theileria* (spp. *annulata, mutans, hirci,* and *ovis*) tend to be less pathogenic and produce diseases with a wider geographic distribution.[2] *Theileria cervi* has been seen in North American deer. *Theileria mutans* has been seen in erythrocytes of both cattle and deer in North America. Theileriosis due to an agent indistinguishable from *Theileria buffeli* has been described in cattle from Texas and North Carolina with parasitemia, but clinical signs were not reported.[3] Recently *T. buffeli* was reported as the cause of hemolytic anemia in a 6-month-old Simmental calf.[4] There was serologic evidence of a high herd prevalence of *Theileria* infection, and the agent was transmitted to splemectomized calves that developed mild anemia. The organism produces a brief illness characterized by mild fever, anorexia, and modest anemia, followed by rapid recovery.

Trypanosomiasis

Gary P. Carlson

Trypanosomes are flagellated protozoal organisms that can produce a variety of serious diseases of humans and animals, although many are nonpathogenic. Nagana, a disease of cattle in Africa, is caused by *Trypanosoma congolensi. Trypanosoma evansi* is the cause of Surra, a disease of cattle in India, and *Trypanosoma equiperdium* produces Dourine in horses. In North America, *Trypanosoma theileri (Trypanosoma americanum)* is the only agent reported and is principally of academic interest, since it is relatively nonpathogenic. On stained blood films from cattle, small numbers of the organism can occasionally be seen free in plasma, appearing as large flagellated protozoa with undulating membranes.[30] *Trypanosoma* is best visualized in buffy coat smears, which tend to concentrate it. *T. theileri* rarely produces clinical signs, but occasionally a fulminating parasitemia may develop, resulting in fever, depression, and decreased milk production.

Leptospirosis

Gary P. Carlson

Leptospira infections produce disease in several species including cattle, sheep, swine, horses, dogs, and humans, but the acute hemolytic syndrome associated with these infections is seen most commonly in calves and lambs. *Leptospira interrogans* serovars *pomona* and *icterohaemorrhagiae* are the serotypes usually involved in the hemolytic syndrome. Clinical signs of the hemolytic syndrome vary but generally include fever, lethargy, icterus, anemia, and petechial hemorrhages. The anemia is brought about at least in part by immune-mediated mechanisms. Cold-reacting IgM antibodies have been implicated in the hemolytic anemia seen in lambs. The degree of anemia is variable but can be severe, with evidence of erythropoietic response apparent in the peripheral blood within 4 to 7 days. A moderate leukocytosis and elevation in plasma fibrinogen are often associated with the hemolytic anemia. The diagnosis is generally made on the basis of demonstration of the organism in the urine, PCR, and an increase in serum antibody titer. Discussion of leptospirosis as a reproductive, renal, and ocular problem can be found in other chapters.

Equine Leptospirosis

Monica Aleman

Leptospirosis is a bacterial zoonotic disease that is prevalent worldwide.[1] The organism can be readily transmitted between mammalian species (cattle, pigs, horses, dogs, and humans) through infected urine, body fluids, and contaminated soil or water.[2] In horses from North America, infections are primarily caused by *Leptospira pomona kennewicki*.[3] There are various maintenance hosts for this serovar, with the skunk being the most common host. *Leptospira bratislava* has been considered to be the host-adapted serovar of the horse, but this has been controversial. Some researchers believe this serovar is also pathogenic to the horse, and when infected, the organism can be shed indefinitely in urine and possibly the reproductive tract.[3]

L. pomona can cause uveitis, placentitis, abortion, stillbirth, renal disease, and hemolysis. Clinical signs include fever, jaundice, anorexia, and lethargy. Leptospirosis is a sporadic cause of abortions; in endemic areas it may account for 13% of bacterial abortions.[4] In general, abortions occur during late-term gestation. The organism can be found in the placenta, umbilical cord, kidney, and liver of the aborted fetus. *L. pomona* can be shed in urine for up to 14 weeks post infection. *Leptospira grippotyphosa* and *Leptospira hardjo* are also known to cause equine abortions.[3]

Renal disease, tubulointerstitial nephritis, pyuria, and rarely acute renal failure have been reported in horses with leptospirosis. More commonly, two ocular disorders appear to be associated with *L. pomona* in horses: equine recurrent uveitis (ERU) and immune-mediated keratitis. It has been postulated that the immune-mediated response results from the cross-reaction between leptospiral antigens and uveal tissue, cornea, lens, vitreous body, and retina.[5] Recent reports have confirmed the presence of live *Leptospira* in the uveal tissue of horses with uveitis through isolation of the organism, positive PCR, or high antibody titer in the aqueous humor.[5]

Diagnosis Variable serologic results make a diagnosis of leptospirosis challenging. Microscopic agglutination titer (MAT) in serum and/or fluorescent antibody titer (FAT) in infected tissues have been routinely used. Sensitivity and specificity of FAT in tissues of aborted fetuses is nearly 100%.[4] In cases of uveitis, high antibody titers in aqueous humor may be found despite variable serum titers,

VetBooks.ir

suggesting local antigenic stimulation.[5] Serum titers of 1:6400 are considered significant and consistent with infection.[6] Serum titers of 1:3200 that are stable for a period of 2 to 3 weeks are not considered significant. Rising titers after a 2- to 3-week period are considered significant, and the patient should be isolated and treated. Other diagnostic modalities are PCR, histology, and bacterial isolation. Recently, genes of two surface proteins of *L. pomona* (Ig-like protein A and B) that are only expressed during active infection were isolated by Divers and collaborators.[4] These proteins may improve diagnostic testing and potentially lead to future development of a protective vaccine for leptospirosis.

Treatment Treatments advocated for leptospirosis include ampicillin, amoxicillin, procaine penicillin (22,000 IU/kg IM q12h), oxytetracycline (5 to 10 mg/kg IV q24h, slowly administered in fluids not containing calcium) or doxycycline (10 mg/kg PO q12h) for 7 days. The inflammatory response in horses with ERU and immune-mediated keratitis has been managed with corticosteroids and cyclosporine, but this may provide only temporary relief. Affected horses tend to develop ocular complications like cataracts, glaucoma, blindness, and intractable pain that may result in the need to consider enucleation. The inability to cure many cases of ERU may be due to lack of treatment of the potential active infection; treatment should be directed toward controlling the ocular inflammatory response and ongoing infection if indicated. An intact blood-ocular barrier may render systemic antimicrobial therapy unsuccessful despite the local inflammation.[4]

Prevention Prevention must be aimed at controlling exposure to shedding hosts, infected animals, and contaminated fomites. Thorough cleaning and disinfection of contaminated areas and proper disposal of infected material are essential measures to minimize exposure. Pregnant mares should be isolated from other animals because bacterial shedding may last several weeks. If abortions occur in endemic areas, testing horses for leptospiral antibodies and isolating those with a serum titer of 1:6400 or higher is recommended.[6] Horses with a negative or low titer should be retested in 2 to 3 weeks. Horses with rising titers should be isolated. Attempts to decrease shedding with oxytetracycline, penicillin G, and streptomycin in horses has not been effective.[4] Vaccination is sometimes performed on farms with endemic abortions or a high rate of uveitis.[4]

Bacillary Hemoglobinuria (Red Water)

Gary P. Carlson

Bacillary hemoglobinuria is an acute hemolytic disorder caused by *Clostridium haemolyticum* (*Clostridium novyi* type D). Also known as "Nevada red water," it has been reported as a naturally occurring disease in cattle and experimentally produced in sheep. Clinical signs develop rapidly, and death losses are often seen. Affected animals may manifest severe depression, anorexia, fever, hemoglobinemia, and hemoglobinuria. The disease is endemic in certain poorly drained areas of the western United States and is caused by ingestion of infectious spores. The organism finds a favorable environment for development in areas of preexisting liver damage that most often have been produced by migrating liver flukes. The hemolytic syndrome is produced by toxins elaborated by the organism, which also produce a characteristic focal liver lesion. The anemia produced may be marked, and both icterus and evidence of erythropoietic response may be seen in animals that survive for more than a few days. For a complete description of the disease, see Chapter 33.

Equine Infectious Anemia

Brett A. Sponseller

Equine infectious anemia virus (EIAV) is an RNA virus, a member of the Retroviridae family, belonging to the lentivirus genus. It has a structure and genome organization similar to other animal and human lentiviruses and uses virally encoded *reverse transcriptase* to convert the RNA genome to a DNA intermediate that is integrated into the host's genome by another virally encoded enzyme, *integrase*. The integrated DNA intermediate, or provirus, usurps the host cell to replicate its genome, manufacture viral proteins, and assemble the virally encoded proteins into virions that subsequently bud from the cell. Thus, infection by a lentivirus results in lifelong persistent infection. EIAV causes equine infectious anemia, first described in 1843 by Lignée.[1] In 1904, Vallée and Carré determined that EIA was associated with a filterable agent, making it the first animal disease determined to be caused by a virus.[2]

IDENTIFICATION OF EQUIDS SEROPOSITIVE FOR EIAV. EIA is a USDA-regulated disease. In 2003, the USDA estimated that serosurveillance of nearly 2 million samples cost U.S. horse owners in excess of $48 million. USDA-accredited laboratories use a testing scheme that detects the presence of serum antibody to the virus. The Coggins test, developed by Dr. Leroy Coggins in 1970, provided the first efficient serologic test for detection of EIAV-infected animals and remains a USDA-accepted test.[3,4] There are also four licensed ELISAs, one of which is a cELISA. These ELISAs detect antibody directed at the transmembrane glycoprotein (gp45) and/or the p26 antigen.[5] All U.S. states, Canada, and Mexico accept either the Coggins test or one of the licensed ELISAs when EIA testing is required for entry. Equids that cross state lines or attend many equestrian events (e.g., shows, races, etc.) have to be seronegative for EIA. The required period of seronegativity between tests varies state by state, however. No tests based on detection of viral nucleic acid are currently USDA approved for EIA diagnosis.

Serosurveillance can lead to detection of horses infected with EIAV that otherwise appear healthy. Indeed, most horses infected with the virus are inapparent carriers. However, blood transferred from an inapparent carrier to another horse, either through instruments (needles, nasogastric tubes, dental equipment, etc.), blood products, or by insect vectors (primarily tabanids) can lead to infection and a fatal outcome.

EQUINE INFECTIOUS ANEMIA. The clinical form of the disease is characterized by three defined temporal stages: acute, chronic, and inapparent. The acute stage occurs with the initial burst of viremia and is characterized by high fever, thrombocytopenia, and nonspecific signs of malaise, including lethargy and inappetence. In experimentally infected horses, thrombocytopenia inversely correlates with virus load and occurs slightly in advance of onset of fever. Ecchymoses and petechiae may also be detected on mucous membranes. During the chronic stage, similar clinical features occur during recurrent episodes of viremia, which are interspersed with periods of clinical quiescence and low viremia. Throughout the chronic stage, clinical episodes tend to gradually diminish in severity and duration. The inapparent stage occurs once levels of viremia are immunologically contained and no clinical signs are detected. Horses experiencing clinical disease at any point may develop DIC and die. In addition, episodes of stress (e.g., transportation, racing, extreme temperatures, etc.) may precipitate clinical disease. Corticosteroids have been experimentally used to induce recrudescence of clinical disease.[6] Other chronic manifestations of EIA include development of dependent edema, weight loss, anemia, and other signs of ill thrift. Rare manifestations that may develop include leukoencephalitis and enterocolitis.[7] Expression of clinical disease, particularly during acute infection, likely involves multiple factors, including inoculating dose, virulence factors of the inoculating viral strain, immune status, and immunogenetics of the host, age, stress, and so forth. Indeed, clinical disease occurs concomitantly with high-titered viremia. Horses with high-titered viremia pose the biggest risk of transmission to uninfected horses.

Lentiviruses have a DNA-dependent RNA polymerase (reverse transcriptase) that misincorporates nucleotides, resulting in changes in the viral genome.[8] This mechanism allows for generation of viral

VetBooks.ir

variants that differ genetically from preexisting ones. As a result, genetic and antigenic variation of epitopes for neutralizing antibody and cytotoxic T lymphocytes allows viral escape from adaptive immune responses.[9,10] Antigenic variation plays a central role in clinical disease recurrence throughout the chronic stage of infection and thwarts attempts to develop an effective vaccine.[8]

EIAV can replicate effectively in monocytes, dendritic cells, and tissue macrophages[11-13] and has been shown to replicate in endothelial cells. EIAV replication in endothelial cells may play a role in the development of DIC by viral damage to endothelial cells, with subsequent exposure of subendothelium.[14] This in turn could lead to platelet aggregation and formation of thrombi.[15] In addition, damaged endothelium may lead to development of dependent tissue edema by transudation of fluid through compromised small vessels.[14]

Pathology and Clinical Pathology Necropsy examination of horses that die of EIA may demonstrate splenomegaly, lymphadenopathy, hepatomegaly, pronounced hepatic lobular architecture, ecchymoses of the mucosa and viscera, dependent subcutaneous edema, and thrombotic disease of small vessels. Histologic findings may include a mononuclear cell infiltrate of periportal regions of the liver, adrenals, spleen, lymph nodes, meninges, and lungs. Hemosiderophages are frequently detected in the spleen, lymph nodes, liver, and bone marrow. Glomerulonephritis due to immune complex deposition is commonly observed.

Clinicopathologic abnormalities will vary depending on the stage and severity of infection. During clinical disease, a frequently profound thrombocytopenia develops concurrently with each successive episode of fever. Platelet function of EIAV-infected horses has been demonstrated to be hypofunctional, possibly exacerbating bleeding tendencies and the progression to DIC in clinically affected equids.[16] Anemia due to intravascular hemolysis, extravascular hemolysis, and depression of bone marrow erythropoiesis may progressively develop during the chronic stage of infection.[17] During the inapparent stage of infection, horses typically have increased plasma total solids and globulin concentrations, mild anemia, and decreased albumin concentration.[18] Polyclonal B-cell activation is also evident, suggesting chronic antigenic stimulation despite clinical quiescence.[18] Concomitant fever and thrombocytopenia should prompt immediate consideration of EIA. A history of recurring fever is also suggestive of EIA, particularly when other causes of fever have been ruled out.

Prevention, Control, and Regulatory Considerations It is well recognized that seroprevalence varies with the region of the United States.[17] States considered at a high risk include Texas, Oklahoma, Louisiana, and Arkansas, whereas the mid-Atlantic area, New England, Alaska, and Hawaii are considered low-risk regions. The remaining states are classified as being at intermediate risk. Despite regional differences in risk to noninfected horses, sporadic outbreaks do occur. Veterinarians should encourage all horse owners to annually test for EIAV, test new arrivals, and maintain good fly control, and the veterinary community should encourage organizers of equestrian events to require proof of seronegativity of attending horses.

Once a seroreactor is identified, all contact horses are quarantined and undergo testing until two negative test results at 30- to 60-day intervals are obtained for all individuals in the quarantined herd.[15] The required interval is based on the need to allow recently infected horses to seroconvert. Seroreactors may be either quarantined or euthanized, depending on state regulations. Quarantined horses must be at least 200 yards from seronegative animals, the distance shown to be sufficient to obviate viral spread by insect vectors. In addition, seroreactors remaining in permanent quarantine must be permanently identified. A USDA code number followed by the letter *A* is assigned to the quarantined horse and permanently applied to the horse in the form of a brand or lip tattoo.

Because an EIA eradication program has never been implemented in the United States, persistence EIAV-infected horses can be expected. The vast majority of horses in the United States are not tested annually, so to encourage horse owners to voluntarily maintain vigorous surveillance testing, the veterinary community must educate them about the consequences of EIAV infection. Horse owners are often unprepared to deal with the financial and emotional losses associated with detection of a horse seropositive for EIAV.

Immune-Mediated Hemolytic Anemia

Autoimmune Hemolytic Anemia

Gary P. Carlson

Definition and Etiology Autoimmune hemolytic anemia is associated with production of autologous antibodies directed against the patient's own red cells. These antibodies combine with complement and antigens on the red cell membrane, leading to rapid removal of affected red cells from the circulation and their accelerated destruction. Autoimmune hemolytic anemia occurs rarely as a primary idiopathic disorder[1,2] but more commonly is found secondarily associated with some other primary disease process.[1] An idiopathic immune-mediated hemolytic anemia (IMHA) was recently reported in a calf[2] and pony.[3]

Clinical Signs and Differential Diagnosis The presenting clinical signs of autoimmune hemolytic anemia are quite variable depending on the degree of anemia and the animal's primary disease. Marked anemia (PCV < 15%) manifests signs typical of those seen in any animal with a severe hemolytic anemia (i.e., depression, pale mucous membranes, variable icterus, elevated heart and respiratory rate, and variable to intermittent fever). Secondary autoimmune hemolytic anemia in horses has been associated most often with some other primary problem like purpura hemorrhagica, lymphoma, other neoplasms, protein-losing enteropathy, or chronic bacterial infections.[4,5] Clinical features are typical of the primary problem, with additional findings of a hemolytic anemia. In humans, exposure to a wide variety of drugs has been causally associated with development of autoimmune hemolytic anemia. There are a number of reports of an association between procaine penicillin and autoimmune hemolytic anemia in horses.[6-10] Autoimmune hemolytic anemia was recently reported in a 10-year-old horse that was treated with trimethoprim-sulfamethoxazole.[11] This apparently occurs rarely, perhaps only in specific individuals, but drug history should be ascertained in all animals with an otherwise unexplained hemolytic anemia.

It should be noted that the anemia in cattle with anaplasmosis and babesiosis or that in horses with equine infectious anemia, piroplasmosis, or ehrlichiosis is largely the result of an immune-mediated hemolytic process. These diseases are discussed fully elsewhere in this book.

Clinical Pathology The hemolytic process is often rapid and persistent, leading to a pronounced anemia. Hematologic features are those typically expected for a responsive hemolytic anemia. The anemia is often progressive and may become severe, even life threatening (i.e., PCV < 10%). Erythrophagocytosis and autoagglutination may be noted on blood smears. Spherocytosis may be difficult to recognize in large animals, owing to the relatively small erythrocyte cell size and lack of a clear area or central pallor. If the process has gone on for 4 days or more, hematologic evidence of active erythropoietic response may be seen in the peripheral blood of all species except the horse. This evidence of bone marrow response is a favorable prognostic indicator, even when anemia is quite advanced. A moderate neutrophilic leukocytosis is a common feature, and thrombocytopenia may be noted in some individuals if the autoimmune process is directed at platelets and megakaryocytes in addition to erythrocytes.

Diagnosis The direct Coombs test can detect the presence of antierythrocyte antibodies and/or complement on the red cell

VetBooks.ir

membrane, whereas the indirect Coombs test detects antierythrocyte antibody in the serum. It is important to remember that the Coombs test is based on species-specific reagents. These reagents are commercially available in the United States for small animals and horses, but not all diagnostic laboratories will have suitable Coombs reagents for other species. Special procedures may be necessary to adsorb these reagents to avoid nonspecific reactions. Multivalent Coombs reagent directed against IgG, IgM, and complement is most commonly used. The Coombs test is usually conducted at body temperature and also in the cold. A positive reaction at body temperature indicates that the antibodies are primarily IgG. These warm antibodies are associated more commonly with anemia, generally produce a more severe anemia, and tend to be more responsive to corticosteroids than cold-reacting antibodies. Cold-reacting antibodies detected with the saline agglutination test (run at 25° and 4°C [39° and 77° F]) are primarily of the IgM class. Exposure to a cold environment may be necessary to produce clinical signs associated with cold agglutinin disease. Both warm- and cold-reacting antibodies are capable of fixing complement. Unfortunately the Coombs test is not always positive in affected animals. In humans and the dog, approximately one third of patients with autoimmune hemolytic anemia have a negative direct Coombs test, possibly because of low concentrations of antibody or low binding to the red cell membrane. The diagnosis in these cases is contingent on ruling out other causes of a responsive hemolytic anemia and on the response to corticosteroid therapy. Recently, direct immunofluorescence flow cytometry was used to determine the classes of antibody bound to erythrocytes in three horses and 12 dogs with IMHA. The three horses had surface-bound IgG, including a horse with suspected penicillin-induced IMHA, a foal with neonatal isoerythrolysis, and a foal with clostridial septicemia.[12]

A substantial proportion of otherwise normal horses have small amounts of cold-reacting Coombs antibodies, and spontaneous agglutination may be noted in blood sample tubes exposed to the cold. In most instances these cold agglutinins appear to occur naturally, and in low levels are of little clinical significance. Prior treatment with corticosteroids may inhibit antibody production and could lead to a false-negative Coombs test.

Pathophysiology Autoimmune hemolytic anemia has rarely been reported as a primary or idiopathic process in large animals, but immune-mediated anemia occurs more commonly as a secondary problem (1) in association with certain types of neoplasia; (2) with a variety of viral, bacterial, rickettsial, and protozoal infections; (3) following exposure to certain drugs; or (4) in association with other immune-mediated disorders like systemic lupus erythematosus.[13] The initiating factors for this autoimmune disorder are not completely understood but may be related to alterations in the red cell membrane through direct or indirect injury, which elicits an abnormal response by the immune system. The red blood cell membrane is no longer recognized as self but is treated as a foreign antigen. Alternately, alterations in the immune system or stimulation by some other antigenic source may result in production of antibodies with a misdirected cross-reactivity with the patient's own normal red cells. Structural and functional changes in the red cell membrane are induced by the antigen-antibody reaction and complement fixation. The complement-fixing IgG or IgM antigen-antibody reaction may produce sufficient erythrocyte damage to result in intravascular lysis of erythrocytes, but more commonly, affected cells are removed from the circulation at a rapid rate by the reticuloendothelial system of the liver and spleen. Partial phagocytosis of affected cells may result in spherocyte formation. Although the presence of spherocytes on blood smears is a characteristic diagnostic feature in human and canine patients with autoimmune hemolytic anemia, the relatively small size of red cells of most large domestic animals may make it difficult to recognize spherocytes.

Treatment and Prognosis The approach to treating autoimmune hemolytic anemia depends on causal factors. If the animal has a history of drug therapy, it is advisable to discontinue medication or change to another class of drug. Patients with primary or idiopathic autoimmune hemolytic anemia may be the best candidates for treatment. IMHAs that are secondary to other diseases can only be managed if the primary problem is amenable to treatment. Thus treatment of an IMHA in a patient with extensive lymphoreticular neoplasia is likely to be unrewarding, and thorough diagnostic efforts should precede case selection for treatment. Although immune-mediated processes are responsible for hemolytic anemia in a number of infectious diseases, therapy must be directed at the primary agent, and corticosteroids are contraindicated in these diseases. Corticosteroids can cause recrudescence of viremia in horses with EIA, and a negative Coggins test should be a prerequisite to treating horses with an autoimmune hemolytic anemia of undetermined cause.

Treatment of autoimmune hemolytic anemia is directed at providing supportive care and interrupting the immune response responsible for antibody production. This is usually accomplished with systemic glucocorticoids. For a 450-kg horse, parenteral dexamethasone is recommended at an initial dosage of 30 to 40 mg/day This dosage is continued for 3 to 5 days and then decreased gradually over a period of 7 to 14 days, depending on response to therapy. The hematologic response to therapy should be closely monitored. If there has been no response in 5 to 7 days, the diagnosis of autoimmune hemolytic anemia should be reviewed, and potential causes of bone marrow suppression should be evaluated. Once the hemolytic process is well under control, treatment can be switched to oral prednisolone, 0.8 to 1 mg/kg daily. Human patients and small animals with IMHA that is unresponsive to corticosteroids are often treated with cyclophosphamide. One case of successful management of a horse with cyclophosphamide and azathioprine when anemia failed to respond to corticosteroids has been reported.[14] Supportive care consists of providing a quiet, restful environment and good nutrition, including vitamin supplementation. Iron- and copper-containing hematinics are generally of little benefit; neither of these elements is lost with hemolytic anemia. Blood transfusion is also of little benefit, since it is often impossible to find a compatible donor, and transfused cells are rapidly removed from the circulation. Blood transfusion should not be administered unless anemia is life threatening and the immune response can be controlled with corticosteroids.

Neonatal Isoerythrolysis in Horse and Mule Foals

Monica Aleman

Neonatal isoerythrolysis (NI) is the most common alloimmune disease in neonatal foals 7.5 hours to 12 days old (median age, 2.5 days).[15] NI is characterized by hemolytic anemia, icterus, and hemoglobinuria. Clinicopathologic abnormalities include anemia, high serum indirect and direct bilirubin concentrations, and sorbitol dehydrogenase activity. NI is caused by a blood group incompatibility between the foal and dam. The foal inherits from the sire and expresses an erythrocyte antigen (alloantigen) that is not present in the mare. The hemolytic syndrome is mediated by maternal antibodies against foal erythrocytes (alloantibodies) absorbed from colostrum. Blood factors associated with NI in horse foals are Qa, Qb, Qc, Aa, Pa, and Dg, and donkey factor in mule foals.[15] The most common antigens are Qa and Aa. Foals with NI may also present with alloimmune thrombocytopenia. For a complete description of NI, see Chapter 53.

Heinz Body Hemolytic Anemia

Gary P. Carlson • Monica Aleman

Definition and Etiology An acute hemolytic anemia can develop following exposure to a variety of oxidizing agents. These include chemicals such as phenothiazine, methylene blue, acetylphenylhydrazine, or plants like wild or domestic onions, members of the *Brassica* family (rape or kale), and wilted or dried leaves of the

VetBooks.ir

red maple *(Acer rubrum)*.[1-7] Red maple toxicosis (RMT) has been reported in horses, zebras, and alpacas.[5,8-10] Heinz body hemolytic anemia also occurs in sheep on specially formulated diets that are low in molybdenum, which results in chronic copper toxicity; as herd problems in cattle grazing rye grass *(Secale cereale)*[11] or selenium-deficient pastures in Florida[12]; and in association with selenium deficiency as a contributing factor in postparturient hemoglobinuria in cattle in New Zealand.[13] These agents produce or allow oxidative denaturation of hemoglobin and resultant aggregation of the protein globin, which appears as Heinz body inclusions within the red blood cells. Heinz body anemia has been seen in association with lymphoma in a horse and was possibly due to failure of the reticuloendothelial system to remove Heinz bodies, as has been reported in horses with EIA.[14]

Clinical Signs and Differential Diagnosis Clinical signs vary with the species involved, specific toxin or toxic metabolites, amount of toxin ingested, time course of the disease process, and occurrence of complicating secondary factors like hemoglobin nephrosis and acute renal failure. Weakness, lethargy, anorexia, and exercise intolerance are the usual presenting complaints, and death losses can occur. Mucous membranes are generally pale with variable to marked icterus. Heart and respiratory rates are generally elevated, but rectal temperature is usually within normal limits. Horses with RMT may be subclinical or may present with lethargy, muddy or cyanotic mucous membranes, tachycardia, inappetence, weakness, colic, icterus, brown discoloration of the blood, and pigmenturia. Rarely, sudden death occurs.[10] Most horses develop clinical RMT during summer and fall, and the high mortality rate may relate to the combination of a rapidly progressive hemolytic anemia and the formation of methemoglobin. Urine output may be reduced, and the presence of hemoglobin, methemoglobin, or bilirubin may make urine appear dark.

It is not possible to differentiate Heinz body hemolytic anemia from other potential causes of hemolytic anemia without laboratory evaluation. The absence of fever may help differentiate these anemias from infectious causes of hemolytic anemia. History of exposure to potential oxidizing agents and the fact that these toxic plants may produce death losses or clinical signs in multiple animals at the same time should help differentiate these cases from autoimmune hemolytic anemia.

Clinical Pathology Poisoning or intoxication resulting in Heinz body formation usually causes acute and profound anemia. In the early stages a very high percentage of erythrocytes may have Heinz body inclusions. Later, as these cells are removed from the circulation and replaced by young cells from the bone marrow, the relative number of affected cells may decrease markedly. Heinz bodies are round, oval to serrated, refractile granules usually located near the cell margin or protruding from the cell. They are best visualized with vital stains like crystal violet or new methylene blue applied to unfixed blood smears. Heinz bodies appear as bluish-green inclusions with new methylene blue stain. Fixing blood smears with methanol in preparation for staining with the classic Wright stain interferes with stain uptake, and Heinz bodies appear as a pale area within or projecting from the cell margin and can easily be missed. After the first 3 or 4 days the anemia is usually associated with hematologic evidence of an active erythrogenic response in all species except the horse. Total plasma protein usually remains within normal limits, and the Coombs test is negative. Red maple poisoning also results in depletion of red cell mass, reduced glutathione, methemoglobinemia, increased osmotic fragility, and modest elevations of liver-derived serum enzyme activities.

Rapid and profound erythrocyte destruction may lead to hemoglobinemia and hemoglobinuria. Development of renal failure secondary to hemoglobin nephrosis is a definite risk in these animals and is reflected by modest to marked increases in the BUN and creatinine, as well as changes in the urinalysis.[6,7] These parameters should be monitored in severely affected animals. As with other causes of hemolytic anemia, serum bilirubin, particularly indirect-reacting bilirubin, is elevated.

The clinicopathologic abnormalities of horses with RMT include anemia (PCV as low as 7.5%), eccentrocytes, Heinz bodies, and elevated plasma methemoglobin concentration.[10] Other significant findings are an inflammatory leukogram and renal insufficiency (75% and 40% of cases, respectively).[10] Mild serum total bilirubin elevation is observed in most cases, and hemoglobinuria is seen in all affected patients.

Pathophysiology Heinz bodies are formed by precipitation of oxidatively denatured hemoglobin. The hemoglobin contained within the red blood cell is constantly undergoing mild oxidative stress associated with oxygen transport, as well as generation of superoxide radicals and hydrogen peroxide within the cell. There are a number of reducing mechanisms within the red cell to counteract these oxidative processes through production of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and reduced glutathione. The occurrence of Heinz body hemolytic anemia could be viewed as a consequence of exposure to oxidative stresses that simply overwhelmed the cells' reductive capacity. Selenium deficiency results in a decrease in glutathione peroxidase, a selenium-containing enzyme, and selenium deficiency may in special circumstances contribute to Heinz body formation by impeding the ability of the cells to respond to oxidative stress. There are substantial species variations in the rate of Heinz body formation that relate to the chemical structure of hemoglobin and the efficacy of erythrocyte-reducing mechanisms in the face of oxidative stress.[1] Red cells with Heinz bodies are less deformable than normal cells and are rapidly removed from the circulation by the reticuloendothelial system in the spleen, where they are phagocytized and broken down. Splenectomy or corticosteroid therapy may alter Heinz body clearance mechanisms, allowing significant numbers of affected red cells to remain in the circulation of otherwise normal animals.

Gallic acid is a strong oxidant present in red maple leaves. Gallic acid has been implicated in the oxidation of hemoglobin, methemoglobin formation, and Heinz body anemia.[5,6,15] Methemoglobin results from the oxidative change of hemoglobin iron to the nonfunctional ferric state (see discussion of nitrate poisoning in Chapter 54). This is normally prevented by glutathione reductase, ascorbic acid, and reduced glutathione. Methemoglobin cannot load or transport oxygen and, when present in sufficient quantities, results in a brown color of peripheral blood and mucous membranes. An estimation of methemoglobin concentration in a blood sample can be made by comparing the hemoglobin concentration measured by the cyanmethemoglobin method, which measures all forms of hemoglobin, and the oxyhemoglobin method, which only measures oxyhemoglobin but not other forms (e.g., methemoglobin). Methemoglobinemia and hemolytic anemia have been reported in a mare and her dam in association with decreased levels of red cell glutathione and glutathione reductase, presumably as a result of an inherited enzymatic defect.[16]

Treatment Treatment is largely a matter of removal from the source of toxicity and provision of supportive care. Blood transfusion can be very beneficial in severely anemic patients, particularly when there is insufficient evidence of active erythropoietic response. Iron-containing hematinics are of little benefit. IV fluid therapy is indicated in animals with hemoglobinuria or azotemia to reduce the potential for further renal damage. High doses of vitamin C (ascorbic acid, 50 to 100 g IV daily), together with fluids and transfusion, were thought to aid recovery in two horses with red maple poisoning.[17] A recent report suggests that vitamin C therapy may have little impact on survival of affected horses, and when methylene blue was used to treat the associated methemoglobinemia in two horses, both died.[18] Therapeutic goals should be to improve tissue oxygenation and perfusion and control inflammation and pain (e.g., with NSAIDs). Horses treated with corticosteroids have an increased likelihood of death.[10]

VetBooks.ir

Prognosis Prognosis in animals with modest anemia and evidence of response is good if the inciting factor can be controlled or eliminated. The mortality rate of experimental and naturally occurring cases of RMT in horses is said to be 60% to 65%.[18] In animals with rapidly progressive and profound anemia, prognosis is poor unless blood transfusion is undertaken. Complications are associated with hypoxia, hypoperfusion, and inflammation. Horses may develop acute renal failure, colic, pyrexia, and laminitis. A retrospective study of 32 horses reported a fatality rate of 59% but failed to show an association between mortality and severity of anemia.[10]

Other Causes of Hemolytic Anemia

Intravascular Hemolysis Following Cutaneous Burns

Monica Aleman

Intravascular hemolysis has been reported in horses following severe cutaneous burns affecting more than 25% of their body surface. Plasma on admission showed hemolysis along with abnormal RBC morphology, increased osmotic fragility, hemoglobinuria, azotemia, and hemoglobin pigment nephropathy.[1] The pathophysiology of hemolysis is unclear but suspected to be associated with the production of hydroxyl radicals by complement-activated neutrophils. Abnormal findings reported in humans include intravascular hemolysis, increased RBC osmotic fragility, decreased membrane deformability, RBC crenation, eccentrocytosis, spherocytosis, bud formation, fragmentation, and vesiculation.[2] These abnormalities are dependent on severity of burn trauma.[2] Pseudothrombocytosis has been reported and is presumably due to the incorrect recognition by automatic counters of red cell microvesicles as platelets.[2] Early fluid therapy and free radical scavengers have been beneficial for burn treatment in humans, along with supportive and wound care, control of pain and inflammation, and sepsis prophylaxis. A recent study in mice suggested that the level of plasma free hemoglobin is related to the size and depth of burn injury, which may be difficult to determine in some cases.[3]

L-Tryptophan-Indol Intoxication

Gary P. Carlson

Experimental studies in ponies have demonstrated an acute hemolytic process associated with orally administered L-tryptophan, which is converted to indol in the GI tract.[4] Intoxication was associated with an acute onset of restlessness, tachypnea, intravascular hemolysis, and hemoglobinuria. At necropsy there was evidence of hemoglobinuric nephrosis and bronchiolar degeneration in some ponies. Similar clinical signs were noted following oral administration of tryptophan at 0.35 to 0.60 g/kg, and indol at 0.1 to 0.2 g/kg.[4,5] Intravascular hemolysis was associated with increased osmotic fragility and with Heinz body formation in a few of the experimental ponies.

Water Intoxication

Gary P. Carlson

Massive water intake may produce marked hypotonicity of body fluids, with subsequent intravascular hemolysis of erythrocytes.[6] This problem has been described as a naturally occurring entity in milk-reared calves when they are first given access to unlimited quantities of water.[7,8] Severe neurologic signs may be seen (e.g., depression, convulsions, coma). Respiratory distress, hemoglobinuria, and death losses occur in some cases. Clinicopathologic features include hemolytic anemia, hypoproteinemia, hyponatremia, hypochloremia, hyposmolality, hemoglobinuria, and hyposthenuria. A sudden decrease in serum osmolality is believed to result in osmotic lysis of erythrocytes.[9] Erythrocytes are most susceptible to osmotic shock when calves are between 4 and 5 months of age. Treatment is primarily a matter of temporarily restricting water and providing supportive care. Calves with marked hyponatremia (sodium of 110 mmol/L) that are manifesting neurologic signs may benefit from hypertonic saline, mannitol, and corticosteroids. The goal of treatment is restoring serum sodium to 120 to 125 mmol/L without overcorrection. Death losses can occur in as little as 2 hours, but most calves recover without long-term adverse effects.

Postparturient Hemoglobinuria

Gary P. Carlson

A syndrome of intravascular hemolysis, hemoglobinuria, and anemia has been recognized in postparturient dairy cattle around the world.[10] The disease occurs sporadically, and the incidence is relatively low. Affected animals are most often high-producing multiparous cows that develop clinical signs during the first month after calving.[11] Depression, decreased feed consumption, and decreased milk production are associated with hemoglobinuria, anemia, and icterus. The anemia is often marked and after 4 or 5 days is associated with evidence of a marked erythropoietic response. The precise mechanism by which the intravascular hemolysis occurs has not been fully elucidated. The condition has been related to the marked hypophosphatemia commonly found in affected cows and moderately low phosphate levels in unaffected herdmates. Hypophosphatemia is brought about by inadequate dietary phosphorus intake in animals grazing phosphorus-deficient soils or fed fodder grown on such soils. Low intracellular phosphate concentration may interfere with energy metabolism, thus affecting cell viability and the ability of the red cells to deal with potential hemolysins (e.g., saponins from sugar beets or alfalfa). A postparturient hemolytic problem associated with copper deficiency and Heinz body formation has been described as a herd problem in New Zealand (see previous section).

Blood transfusion and supportive IV fluids are indicated in valuable cows with severe life-threatening anemia. Correcting hypophosphatemia consists of providing phosphate, initially as sodium acid phosphate ($NaH_2PO_4H_2O$), 60 g/300 mL of water IV, followed by oral phosphorus supplementation. Correction of dietary imbalances is indicated.

Copper Toxicosis

Lisle W. George

Copper is an essential nutrient for domestic animals, but excessive supplementation can result in toxicity. Copper poisoning is a common intoxication in ruminants. Reviews of the toxicodynamics and clinical syndromes have been published.[1-3] Lambs are most susceptible to the toxic effects of copper, but poisonings have occurred in adult sheep, goats, and cattle; Merino sheep are more resistant than British breeds.[4] Cattle have been poisoned by ingesting diets containing 37 mg of copper/kg of feed for 2 years.[5] Cattle fed 12 mg or more of copper/kg of body weight have been reported to develop subclinical hepatic disease.[6]

Elemental copper is an essential trace mineral with a narrow therapeutic window. Dietary requirements for growing sheep range between 4 and 6 parts per million (ppm), yet toxicity can occur whenever sheep are exposed to diets containing as little as 10 to 20 ppm.[7-9] Phytogenous copper poisoning results from concomitant ingestion of copper at 20 ppm of food, molybdenum, and sulfate. Ingested salts of copper are absorbed through enterocytes by carrier proteins and transported to blood in loose complexes with albumin and amino acids.[10] Roughly 20% of total plasma copper is ionized copper. Between 70% and 90% of this ionic copper is internalized by hepatocytes, where it is redistributed to bile, packaged in lysosomes in protein complexes, or used for the formation of ceruloplasmin.[10] Accumulation of copper occurs because daily hepatic biliary copper

VetBooks.ir

excretion amounts to less than 1% of ingested copper in ruminants.[11] Hepatic storage can buffer high levels of copper intake until the sites become saturated. At that time, hepatocytes die spontaneously or in response to environmental stress or dietary changes. Hepatocyte death causes the release of large amounts of cuprous copper into the blood. Animals that have preexisting hepatitis from pyrrolizidine alkaloids store less copper and are more susceptible to the hemolytic crisis.[4,12]

Free inorganic copper is an oxidant and can participate in the Fenton reaction. Cellular damage is related to production of oxidative hydroxides and peroxides, not to copper oxidation. These reactive intermediates are thought to initiate lipid peroxidation and oxidative denaturation of proteins within erythrocytes. Oxidation of heme protein produces Heinz bodies, and oxidation of hemin produces methemoglobinemia. Oxidized erythrocytes either lyse spontaneously intravascularly or are sequestered in the spleen and degraded to constituent amino acids. Vitamin E is also denatured. This latter reaction removes a potent antioxidative protective factor and enhances cellular susceptibility to additional oxidants. Differences in genetic susceptibility to copper poisoning are unknown.

The hemolytic phase of copper poisoning is often initiated by noxious stimuli that could include shipping, hierarchal change, administration of oxidative drugs, starvation, or change of housing.[13] High-protein diets have increased resistance to the hemolytic crisis in sheep, but the role of extra molybdenum intake in these supplemented animals was unclear.[9,14] The mechanistic relationship between stressful events and hepatocyte release of copper is unknown.

Sources of copper that have been responsible for copper accumulation in animals include trace mineralized salt, inappropriately formulated cereal grain mixtures, forages from pastures that have been fertilized by swine or chicken manure,[15] orchard pastures that have been contaminated by copper-containing fungicides, rations containing more than 20% chicken litter, or diets that contain high concentrations of palm kernel oil. Other potential sources of copper include fencing and copper piping and overdoses of parenterally administered copper salts. In one recent case at our institution (University of California, Davis), dairy goats were poisoned by supplementation of trace minerals that were formulated for dairy cattle.

The toxic dose of copper for each species is variable and depends on duration of exposure, the animal's genetics, and the amount of molybdenum being fed. Diets with copper/molybdenum ratios over 6:1 are more likely to result in copper poisoning than diets with lower ratios. The interaction between the two minerals may occur in the solid phase of rumen ingesta, where insoluble and nonabsorbable complexes between copper, sulfur, molybdenum, and large-molecular-mass protein complexes are formed. The highly complexed copper is unabsorbed and hence not toxic. High dietary intake of zinc and iron also inhibit absorption of copper, and although the precise mechanism of antagonism is unknown, the elements share a competitive affinity for metallothionein.[16-18] Competition for this protein could alter the storage capacity for copper. Soil sulfates reduce molybdenum absorption by plants, increasing the potential for pathologic accumulation of copper in herbivores.

The respective single toxic doses of copper for sheep and cattle range between 20 and 110 mg/kg and 220 to 880 mg/kg of body weight. Most poisonings occur after long-term, low-dose ingestion of the element. Copper poisoning can occur in sheep after 2 months of daily dosing of 3.5 mg/kg of copper, feeding a ration that contains 20 ppm of copper for several months, or after a single SC injection of copper EDTA salt at a dose of 2 mg/kg.[19] Sheep have been poisoned by subcutaneous injection of 3 to 4 mg/kg of copper-calcium EDTA but remained normal after 6 mg/kg of copper methionate.[20] Sheep have died after single injections of 2 mg/kg of diethylamine copper oxyquinoline sulfonate.[20] One study that fed 3.7 mg/kg of copper daily for 84 days reported peak hepatic copper levels that ranged between 258 and 375 mg/kg wet weight by 26 days after the final copper feed.[21] A single dose of 50 mg of copper caused acute hemolytic crisis in sheep when treated during mid-pregnancy. The largest incidence of hemolytic anemia occurred in Welsh sheep, and the lower cumulative incidence in Cheviot sheep.[22] Single doses of copper calcium ETDA at 25 mg/animal has killed lambs.[23] Cumulative doses of copper ranging between 12.8 and 22 g have produced hemolytic anemia in Suffolk lambs by 42 days.

Goats may show signs of copper poisoning by 144 days after daily feeding of a ration that contains 80 mg copper/kg. Placental transfer of copper occurs, but concentrations in the tissues of lambs are not toxic even during the hemolytic phase in the dam.

Adult cattle may be poisoned by feeding 5 g of copper sulfate daily for as long as 4 months. Calves may be poisoned after 6 to 8 weeks of feeding milk replacer containing 115 ppm of copper.[10,24] Horses are resistant to high dietary concentrations of copper and may remain clinically normal after prolonged feeding of diets containing levels as high as 791 ppm. In those horses, hepatic concentrations of copper at the end of the feeding period reached 4000 ppm. Adult ponies that were treated once with an oral dosage of copper of 40 mg/kg did not develop hemolytic anemia.

Clinical Signs

Animals exposed to high levels of copper are asymptomatic for weeks until the onset of hepatic necrosis.[25,26] Signs develop rapidly thereafter and are reflective of coexisting anemia, myopathy, and neurologic, renal, and hepatic disease. Clinical signs include inappetence, lethargy, weakness, recumbency, cool extremities, pallor, and greyish discoloration of the mucous membranes. Affected animals have a markedly increased pulse rate, tachypnea, hypotension, and hypothermia. The pulse amplitude of the linguofacial artery is decreased. Urine is dark red from the presence of free hemoglobin products. Feces are dark or have yellowish discoloration but are normally formed and do not contain hemoglobin unless secondary abomasal ulceration has occurred. Animals may have marked petechiation of the conjunctival mucosa. Pregnant animals often abort secondary to hypoxemia. Recumbent patients usually expire without struggling. Exposed ewes that survive copper poisoning tend to have dystocia and dilation failure in subsequent lambing periods.

Pathology

The tissues of hemolyzing animals are pale and icteric, and serous surfaces are covered by petechial and ecchymotic hemorrhages. The liver is often pale and yellow, and the lungs are firm. Kidneys turn black and have a metallic sheen due to entrapped hemoglobin. The urinary bladder of copper-poisoned animals is filled with serosanguineous urine. Microscopic changes include hemoglobinuric and tubular nephrosis, and necrosis of the splenic follicles and hepatocytes. There is also biliary ductular proliferation and pericholangitis.[21,27] Hepatic necrosis may be detectable by microscopic examination for as long as 412 days post poisoning. Microscopic brain changes in poisoned animals include spongy degeneration of the pons and brainstem.

Diagnosis

Normal hepatic concentrations in sheep have been reported as 173 ± 130 (mean ± SD) and 129 ± 59 ppm (wet matter) for adults and lambs, respectively.[28] Wet matter hepatic concentrations of copper in poisoned animals were 429 ± 249 (mean ± SD) ppm. Dry weight concentrations may be greater than 3000 ppm. Hepatic concentrations are usually high prior to and after the hemolytic episode, but normal hepatic copper concentrations in hemolyzing animals have been reported.[19] The correlation between plasma and hepatic copper concentrations in prehemolytic animals is poor.[29-30] Copper poisoning in animals with normal plasma concentrations and near-toxic liver levels have been reported.[31] Normal plasma copper concentrations range from 13 to 20 µmol/L (0.8 to 1.2 µg/mL).[21] Serum copper concentrations range between 0.60 and 1.50 µg/mL (0.6 to 1.5 ppm). Plasma copper concentrations that range between 2.4 and 20.0 µg/mL (2.4 to 20 ppm) are diagnostic for acute toxicosis.

Clinical Pathology

There are no consistent hematologic changes until 24 hours prior to the hemolytic crisis, when sudden

VetBooks.ir

concentrations of cytosolic hepatic enzymes rise coincidentally with a sharp rise in plasma copper concentration. Plasma copper concentrations fall rapidly following the hemolytic crisis and are often near normal by 4 days after hemolysis.[25] Copper concentrations within erythrocytes remain high.

Hepatic concentrations of 16 mmol copper/kg of dry matter are the threshold for development of hemolytic anemia. The half-life of copper in the liver of untreated poisoned sheep has been estimated to be 175 ± 91 days,[21] and high copper concentrations in hepatic tissues can be found for as long as 100 days after initiation of the hemolytic episode.[29]

Kidney concentrations of copper in animals with hemolytic crisis are 15 and 50 ppm for dry and wet weight volumes, respectively. Sheep may have increased plasma concentrations of γ-glutamyltransferase (GGT) and AST for 3 days prior to the onset of hemolysis, and glutamate dehydrogenase may be increased for as long as 700 days after cessation of copper ingestion.[21,32] Fecal copper concentrations may exceed 10,000 ppm during the hemolytic episode.

Clinicopathologic changes that occur during the acute hemolytic crisis include Heinz body formation, intravascular hemolysis, methemoglobinemia (as much as 5%), decreased PCV, and increased concentrations of plasma bilirubin, AST, GGT, alkaline phosphatase, total bilirubin, creatine kinase, creatinine, plasma urea nitrogen, and plasma ceruloplasmin. Urine is dark brown to black and contains high concentrations of protein, blood, and hemoglobin casts. Microscopic examination of urine may detect erythrocytic casts and inflammatory cells.[33] Sheep that survive the hemolytic episode develop reticulocytosis by 4 days after the onset of clinical signs.[34]

Treatment Animals with acute hemolytic syndrome should be insufflated with oxygen and treated with vitamin E (3 to 5 daily doses consisting of 3000 IU/dose). If PCV is below 8%, animals should be given packed washed homologous erythrocytes. Additional therapy should include D-penicillamine (Cuprimine [Merck Sharp & Dohme, Rahway, N.J.] at 52 mg/kg of body weight daily for 6 days), anhydrous sodium sulfate (1 g/sheep daily for 6 days) and ammonium molybdate (100 mg/sheep daily for 6 days). Treatment with D-penicillamine increases urinary copper excretion by 10- to 20-fold.[35] Single-dose therapy with D-penicillamine (28 mg/kg body weight) increases copper excretion, but the effect is transient and insignificant for reducing the total hepatic copper load.[36]

Dietary supplementation with 7.7 ppm ammonium molybdate also results in hepatic copper concentrations that are 40% lower than in unsupplemented controls. Addition of 7 or 15 mg molybdenum for 80 days to experimentally poisoned sheep has reduced hepatic copper concentration in sheep by 34% and 46%, respectively.[37] Copper-poisoned cattle have been successfully treated with oral sodium molybdate (3 g daily) and sodium thiosulfate (5 g daily). When introduced into the sulfur-rich rumen contents, molybdenum salts complex with high-molecular-weight proteins in the solid phase of the digesta.[38] The protein-bound thiomolybdate aggregates strongly chelate copper in insoluble and indigestible complexes. Molybdenum salts also enhance biliary copper excretion and selectively remove copper from hepatic metallothionein.[16,39,40] For poisoned cattle, top dressing food with 500 to 1000 mg ammonium molybdate daily for 18 days markedly reduced the amount of hepatic copper.[41]

Parenterally administered ammonium tetrathiomolybdate has been recommended for treatment of acute hemolytic crises due to copper poisoning. IV administration of ammonium tetrathiomolybdate reduces both lysosomal and cytosolic copper in hepatocytes. The drug has been given as a 5% solution in sterile saline with an IV dosing schedule of either 50 to 100 mg twice weekly for up to 11 weeks, or as 3 doses consisting of 3.4 mg/kg of body weight on alternate days and beginning at the onset of hemolytic crisis.[42-46] Concomitant administration of 36 mg of xylazine IV increased copper excretion in bile by as much as 2.25-fold over controls that were treated with thiomolybdate only.[47] Parenteral administration of thiomolybdate results in transient increases of copper concentrations in blood for as long as 24 hours. Because copper is acid insoluble, the effect is to protect copper-exposed animals from hemolytic crises and reduce tissue damage during a hemolytic event.[48,49] Biweekly injection of 100 mg molybdenum as tetrathiomolybdate increased daily hepatic biliary copper excretion by a factor that ranges between 150% and 300%.[50]

Prevention Owing to the sporadic nature of copper poisoning and lack of signs during the accumulative phase, it can be difficult to prevent. Clients should be counseled to purchase concentrates with label claims for the species being supplemented. Copper-supplemented salts should be restricted, especially in sheep. Pastures heavily contaminated by copper can be top dressed with molybdenum phosphate (113 g molybdenum/acre). Fencing and plumbing that contain copper sulfate or metallic copper should be removed from the environment. One study in sheep receiving 36 mg copper/kg daily for 18 months controlled the hemolytic crisis and associated mortality due to copper poisoning by SC injection of sterile ammonium tetrathiomolybdate (containing 3 to 4 mg molybdenum) on alternate days for three injections.[45] The sheep in this study were given either IV or SC molybdenum at dosages that amounted to 1.7 and 3.4 mg/kg of ammonium tetrathiomolybdate. Addition of ammonium molybdate at 7.7 ppm and sodium sulfate at 4200 ppm reduced liver copper and decreased plasma ceruloplasmin in experimentally exposed lambs.[30]

Feeding experimentally poisoned lambs sodium molybdate and sodium sulfate at respective daily dosages of 20 mg and 6 grams reduced hepatic copper content after 90 days.[51] Molybdenum and sulfur protect sheep by converting ingested copper to nonabsorbable thiomolybdate complexes in the rumen. The antagonistic effects are most marked at times of rapid hepatic accumulation of copper. Addition of 3 mg/kg of food (dry matter) molybdenum in the form of tetrathiomolybdate reduced hepatic copper accumulation by as much as 33-fold.[44] Lambs fed diets containing 7.7 ppm of ammonium molybdate after weaning until 14 weeks of age had reduced hepatic copper and decreased ceruloplasmin concentrations.[30] Cattle can tolerate indefinite periods of ingesting copper at dosages of less than 0.6 mg/kg daily.[31] Addition of 220 to 420 ppm of zinc may be protective against copper poisoning in sheep, but this is not put into practice in clinical situations.[38]

Hemolytic Syndrome in Horses with Liver Failure

Gary P. Carlson

A fulminant intravascular hemolytic syndrome has been reported as a near-terminal event in horses with either acute or chronic liver failure.[1] Marked hemoglobinemia and hemoglobinuria are associated with intense icterus, and the sclera and conjunctiva often take on a distinctive deep reddish-orange color. The onset of intravascular hemolysis is sudden and rapidly progressive. The prognosis is highly unfavorable; nearly all horses that develop this syndrome die or must be euthanatized because of clinical deterioration.[2] IV fluids, corticosteroids, and supportive care do not appear to alter the clinical course or unfavorable outcome.

The cause of this syndrome is unknown, but release of hepatic copper stores does not appear to be a factor. The hemolysis seems to be associated with increased erythrocyte osmotic fragility. Human patients with liver cirrhosis develop a hemolytic syndrome associated with alterations in the exchangeable lipoproteins of the red cell membrane. A similar mechanism has not been shown in horses, but morphologic alterations in these horses' red cells resemble the burr cells described in human patients.[3] Bile acids and their salts are markedly increased in liver failure and could play a contributing role in the hemolytic process. At necropsy, widespread hemorrhagic lesions that resemble those described for DIC are often present.[3] It may be that DIC and activation of various mediators may play a role in the terminal stages of this almost invariably fatal process.

Congenital Erythropoietic Porphyria

Gary P. Carlson

A rare congenital disorder of hemoglobin production that is inherited as an autosomal recessive has been recognized primarily in Holstein cattle, but has also been reported in Shorthorns and Jamaican cattle.[4-6] Commonly called "pink tooth," the disorder is characterized by slow growth rates in calves, photosensitization and exfoliation of nonpigmented skin when exposed to sunlight, reddish-brown teeth, and modest anemia. The teeth and bones exhibit a pink fluorescence under ultraviolet light, and the presence of uroporphyrin turns urine a brownish-red color. The condition is present at birth, and the metabolic defect is a hereditary deficiency of the enzyme uroporphyrinogen III synthase (UROS), which catalyzes an essential step in the synthesis of the porphyrin structure of hemoglobin. This leads to accumulation of uroporphyrin and coproporphyrin, which deposit in the teeth where they are concentrated in the dentin, bones, and other tissues. The anemia seen in these cattle is variable among individuals, and several factors contribute to it. Reduced intravascular red cell lifespan is related to the high concentration of uroporphyrin and coproporphyrin within the cells. Porphyrins may induce hemolysis and delay red cell series maturation in the bone marrow, although there is often evidence of active erythropoietic response in peripheral blood.[5]

There is no treatment for this inherited disorder, but genetic counseling is advisable. Substantial efforts have been made to reduce the incidence of this disease in the Holstein breed. It may be possible to detect carrier animals. Affected cattle have much lower levels of UROS than normal cattle, and carrier animals have intermediate levels of this enzyme. Despite their rather serious problems, these cattle do reasonably well if housed indoors out of direct sunlight. The principal differential consideration is chronic fluorosis, which also produces brown discoloration of the teeth, but they do not fluoresce under ultraviolet light.

Another form of altered porphyrin metabolism, erythropoietic porphyria, has been described in humans and cattle.[5] In humans the mode of inheritance is autosomal dominant, whereas in cattle the disorder appears to have a recessive pattern of inheritance and may be sex linked, since it is only seen in females. The disease does not produce anemia, porphyrinuria, or teeth discoloration, but ferrochelatase (heme synthase) deficiency leads to high concentrations of erythrocyte and fecal protoporphyrins.

Porphyria has also been reported in swine, where it exhibits a dominant pattern of inheritance.[5] Health effects are minimal and there is no photosensitivity, but the pigs' teeth have reddish-brown discoloration. There are similarities with bovine congenital erythropoietic porphyria, but the precise defect in pigs has not been found.

Finally, animals may develop acquired toxic porphyrias. This can occur with heavy metal poisonings, principally lead, but has also been produced experimentally with hexachlorobenzene and other chemicals. Lead inhibits several key enzymes of heme synthesis. Inhibition of aminolevulinate dehydrase leads to accumulation of aminolevulinic acid, and decreased aminolevulinate dehydrase activity is a sensitive indicator of lead poisoning. Lead also inhibits ferrochelatase and leads to marked elevation of erythrocyte zinc protoporphyrin IX, making measurement of zinc protoporphyn IX levels a means of monitoring lead exposure.[5]

Depression Anemia

Gary P. Carlson

The most common form of anemia in domestic animals is associated with inadequate erythropoiesis or bone marrow depression. Depression anemia can be caused by (1) deficiencies of vitamins or minerals essential for erythrocyte production, (2) systemic disease processes that interfere with normal erythropoiesis, or (3) processes that damage or displace normal bone marrow elements. Common causes of depression anemia are listed in Box 37-2. Depression anemia is often mild to moderate in severity and generally is only slowly progressive. Depressed erythropoiesis is occasionally associated with processes that also result in blood loss and/or an increased rate of erythrocyte destruction. When this occurs, a profound rapidly progressive and potentially life-threatening anemia can develop. With the possible exception of chronic iron or copper deficiency, depression anemia tends to be normocytic and normochromic. Bone marrow evaluation is an extremely useful diagnostic tool in animals with nutritional deficiencies or when bone marrow damage or dyscrasia is suspected. A thorough clinical evaluation and vigorous application of appropriate diagnostic procedures are necessary to establish a diagnosis of depression anemia and determine the factors responsible.

BOX 37-2

Causes of Depression Anemia

Nutritional Deficiency

Iron deficiency
Copper deficiency
Cobalt deficiency
Vitamin B_{12} deficiency
Folic acid deficiency

Anemia of Inflammatory Disease

Chronic infection
Chronic inflammation
Fractures and severe trauma
Neoplasia

Anemia Secondary to Organ Dysfunction

Chronic liver disease
Chronic renal disease
Chronic gastrointestinal disease
Parasitism (trichostrongylosis)

Bone Marrow Damage/Dysplasia

Myeloid and megakaryocytic bone marrow hypoplasia in Standardbred horses
Bracken fern poisoning
Congenital dyserythropoiesis and keratosis in polled Hereford calves
Trichloroethylene-extracted soybean meal toxicity
Myelophthisic disorders (myeloproliferative disease, lymphoma)
Aplastic anemia

Iron Deficiency Anemia

Gary P. Carlson • Monica Aleman

Iron is present in most forages and grains. In neonates, the major source of iron is colostrum (≈0.79 mg/L in mare's milk).[1] Soil, dam's feces, and milk are other important sources of iron.[1] Iron deficiency is most commonly associated with chronic blood loss due to internal or external parasitism, bleeding GI lesions, or hemostatic defects. Dietary iron deficiency is seldom the sole cause of anemia, even in neonates on an all-milk diet, unless they are raised on cement or in barns or hutches with no access to the soil. A modest anemia is anticipated in veal calves. The anemia seen in some young calves during the first few days to weeks of life is apparently the result of congenital iron deficiency,[2] but the causal factors have not been determined. Altered immune functions, high incidences of infection, and reduced growth performance are reported in veal calves on low-iron diets.[3] Alterations in GI pH may alter absorption of iron by the small intestine. States of inflammation and infection cause iron sequestration, not deficiency, by the reticuloendothelial system and lactoferrin. Iron deficiency has been well documented in calves and

VetBooks.ir

piglets housed exclusively indoors or in hatches with no access to soil.[4] Absolute iron deficiency anemia is not commonly reported in horses.[5-8]

Circulating erythrocytes account for about two thirds of the total iron reserves found in the body. The remaining iron stores are distributed in the liver, spleen, and bone marrow. With chronic blood loss anemia, iron depletion is first indicated by decreased marrow iron, which can be appreciated with special staining of the bone marrow with Prussian blue stain for iron. As blood loss continues and iron deficiency progresses, serum iron is decreased, whereas iron-binding capacity may actually increase. Late in this process, iron-deficient erythropoiesis results in the typical microcytic, hypochromic erythrocytes generally thought to be characteristic of iron deficiency anemia (decreased PCV, hemoglobin concentration, mean corpuscular volume, and mean corpuscular hemoglobin concentration). Other laboratory findings include echinocytosis, keratocytosis, schistocytosis, acanthocytosis, ovalocytosis, hypoferritinemia, and hypoferremia.[5-8] The observed RBC morphologic abnormalities are thought to be due to oxidative damage. Normal serum iron and iron-binding capacity for most domestic animals is 100 and 300 µg/dL, respectively. There is one report of a neonatal foal with iron deficiency with refractory anemia and severe abnormal RBC morphology but no microcytosis and hypochromasia.[8]

Treatment Treatment of iron deficiency anemia is contingent on evaluation of the cause and correction or resolution of the process responsible for chronic blood loss. Iron is usually supplied as an oral supplement or feed additive, and many commercial preparations are available. Injectable iron dextran intended for use in baby pigs should be avoided in horses and cattle, because it can induce anaphylaxis, especially if administered repeatedly.[9] Iron cacodylate was a safe parenteral iron preparation for use in horses but is no longer readily available. An injectable iron preparation intended for use in horses was reported to result in acute iron overload, massive hepatic necrosis, and severe death losses in a group of young cattle.[10] Iron overload has resulted in acute death losses in neonatal foals fed an iron-containing microbial supplement. Iron accumulation resulting in hemochromatosis and extensive liver damage has also been reported in adult horses, although the mechanism responsible for the iron accumulation has not been explained.[11]

Copper Deficiency

Gary P. Carlson

Copper deficiency can occur as a primary problem in milk-fed animals or in pastured animals in copper-deficient areas. More commonly, copper deficiency occurs secondarily in association with other trace mineral imbalances such as dietary molybdenum excess and is influenced by the sulfur and zinc content of the diet. Copper is an essential cofactor for a wide variety of enzymatic reactions, and copper deficiency produces a constellation of clinical signs related to impairment of these reactions.[12] Clinical signs of copper deficiency are most prominent in young, growing animals and may include reduced growth rate, rough and depigmented hair, diarrhea, osteoporosis with spontaneous fractures, and anemia. In lambs, copper deficiency can produce a demyelinating syndrome known as *swayback* or *enzootic ataxia*. Copper deficiency has also been associated with hemolytic anemia in postparturient dairy cattle in New Zealand.[10] Copper plays an important role in iron transport from the gut to the marrow, and in the incorporation of iron into the heme moiety. The anemia produced by copper deficiency is generally moderate, slowly progressive, and closely resembles iron deficiency in that it is usually a microcytic, hypochromic anemia. Bone marrow evaluation often reveals intracellular accumulations of iron known as *sideroblasts*. This finding indicates that the principal problem is a function of altered incorporation of iron into the erythrocyte hemoglobin rather than an actual deficiency of iron. Copper deficiency can be documented by measuring serum copper as ceruloplasmin, erythrocyte superoxide dismutase, or the copper content of hair, liver, or kidney. Serum iron tends to be low in animals with copper deficiency. Copper can be supplied as a dietary supplement or as an injectable copper glycinate preparation.

Vitamin B_{12} and Folic Acid Deficiency

Gary P. Carlson

Nearly all of the vitamins are necessary for normal erythropoiesis, but in ruminants and horses only deficiencies of vitamin B_{12} and folate have been associated with development of anemia. These two vitamins play essential roles in DNA synthesis. When deficiency of both vitamins coexists, as has been experimentally produced in pigs, a marked macrocytic anemia with hypersegmented circulating neutrophils and giant metamyelocytes and neutrophils in the bone marrow may be found. In ruminants, vitamin B_{12} deficiency has been associated with grazing cobalt-deficient pastures. A macrocytic to normocytic anemia may be noted in these animals. Folate deficiency has been reported as a cause of a mild seasonal decline in erythrocyte parameters in horses.

Anemia of Inflammatory Disease

Gary P. Carlson

A depression anemia associated with characteristic disturbances of iron metabolism is often found in animals with conditions that result in a chronic inflammatory response.[13,14] These conditions include chronic internal or cutaneous infections, infectious diseases, or immune-mediated processes that result in chronic inflammation, severe traumatic injury or fractures, and active malignant neoplasia. The anemia tends to be mild, slowly progressive, and of little clinical consequence. Clinical signs relate to the primary disease process, and hematologic features are those of a mild, unresponsive anemia, often with indications of a chronic inflammatory response (neutrophilic leukocytosis and monocytosis with elevated fibrinogen, total protein, and globulin). Serum iron and iron-binding capacity are decreased, but marrow iron reserves and serum ferritin are increased.[14] Anemia in these animals is partially due to a modest decrease in circulating red cell lifespan, but it is primarily caused by major alterations in iron metabolism and depressed bone marrow response to the anemia. These alterations represent part of the body's response to inflammation, which includes release of interleukin and other mediators and production and release of a variety of acute-phase proteins from the liver. The body tends to sequester iron from the circulation into storage forms, primarily in the liver and bone marrow, where it is retained and relatively unavailable for erythropoiesis. This general reaction may play a protective role by denying readily available iron to potential bacterial pathogens that require iron for rapid growth and multiplication. Iron supplementation is not indicated to treat the anemia of chronic inflammation; therapeutic effort should be directed at resolving the primary disease process.

Anemia Secondary to Organ Dysfunction

Gary P. Carlson

A mild to moderate unresponsive anemia can develop in patients with chronic endocrine, hepatic, renal, or GI diseases. These disorders can produce bone marrow depression by reducing production or absorption processing and distribution of elements essential for erythropoiesis, by allowing elaboration or accumulation of toxic compounds, or by interfering with the production or action of erythropoietin.[15,16] These effects can occur independently of the alterations in iron metabolism that characterize the anemia of inflammatory disease.[14] However, should inflammatory processes be responsible for the specific organ damage or dysfunction, the same pattern of anemia

VetBooks.ir

as described in the previous section would apply. Specific therapy for anemia in these patients is not indicated, and resolution of the anemia depends on successful management of the primary disease process.

Internal parasitism, particularly that associated with *Trichostrongylus* spp. in ruminants, can result in a marked anemia that is primarily the result of bone marrow depression in which failure to absorb iron, copper, and essential amino acids plays a major role.

Myeloid and Megakaryocytic Bone Marrow Hypoplasia

Gary P. Carlson

Myeloid and megakaryocytic bone marrow hypoplasia has been reported in eight young Standardbred horses sired by the same stallion.[17] Clinical signs were variable and in some individual horses included nonhealing wounds, unresponsive fevers, pleuritis, pneumonia, ataxia, hemoperitoneum, and bleeding into the bowel. Seven of eight horses died or were euthanized. The principal laboratory findings were a variable red cell count from normal to modest to marked anemia, moderate to profound neutropenia, and intermittent thrombocytopenia in most of the horses. There appeared to be a cyclic variation in neutrophil and platelet counts. A bone marrow microenvironment or growth factor defect are suspected causes of this problem; myeloid progenitor cells were present, and cells were able to respond to exogenous growth factors. A familial basis for the disease is suspected.[17]

Aplastic Anemia

Debra Deem Morris

Aplastic anemia is a stem cell disorder characterized by reduced marrow production of all blood components in the absence of a primary disease process infiltrating the bone marrow or suppressing hematopoiesis.[18,19] Peripheral pancytopenia secondary to marrow aplasia is apparently very uncommon in horses, although idiopathic hypoplastic anemia has been reported,[20-22] as well as rare cases associated with phenylbutazone use.[15-23] Hemorrhagic diathesis caused by thrombocytopenia is often the first indication of disease, manifested by epistaxis, mucosal petechiae, or prolonged hemorrhage after trauma or injections. Pallor may be present, with other signs of anemia (e.g., reduced exercise tolerance) depending on the severity and rapidity of aplasia progression. Neutropenia causes increased susceptibility to infections, which may result in intermittent fever or weight loss. Lymphocyte production is reportedly not impaired, but absolute lymphopenia is common in aplastic anemia. Circulating lymphocytes are often highly reactive, producing the suspicion of neoplasia or a preleukemic syndrome.[15]

Marrow aplasia in humans is generally termed *idiopathic,* although some cases are associated with exposure to a drug, chemical, ionizing radiation, or presence of another disease.[19] Marrow failure results from damage to the hematopoietic stem cell compartment. This may be in the form of DNA damage to stem cells or depletion of later progenitor cells by a cycle-active agent. Some cases of marrow aplasia appear to be immune mediated, either genetically determined or incited by a particular viral infection or drug exposure.

The diagnosis of aplastic anemia is based on the combination of peripheral pancytopenia and bone marrow hypoplasia with fatty replacement. Because the normal erythrocyte lifespan in horses is roughly 140 days and in cattle exceeds 160 days,[24] neutropenia with no left shift and thrombocytopenia are earlier hematologic manifestations.

The major aims in treatment of aplastic anemia are to remove the animal from suspected causative agents and provide supportive care, in the hope spontaneous remission will occur. Broad-spectrum antimicrobials are necessary to control infections. Blood transfusions are rarely indicated, and platelet transfusion should be reserved for severe bleeding episodes, which rarely occur. Bone marrow transplantation is used with some success in humans, although graft-versus-host disease poses significant risk. The latter would presumably limit this therapy in horses; too few horses with aplastic anemia have been studied to give a clear indication of prognosis.

Bracken fern toxicosis in ruminants causes bone marrow depression and subsequent pancytopenia.[24] Most field outbreaks of the disease occur in cattle. The toxic effects of the plant are cumulative, and clinical signs occur suddenly 2 to 8 weeks after cattle gain access to the plant. Clinical signs include fever, melena, epistaxis, hematuria, mucosal petechiae, hyphema, and bleeding from the eyes and vagina. Hematology reveals a platelet count less than 40,000/μL and profound leukopenia with essentially no neutrophils present. Death may follow in 1 to 3 days as a result of the combined effects of multiple internal hemorrhages and bacteremia. The aplastic anemia factor in bracken fern has not been identified, although ptaquiloside has been suggested.[24] Necropsy of cattle with bracken fern toxicosis reveals multiple hemorrhages throughout most tissues, necrotic GI tract ulcers, and pale bone marrow. Antibiotics and blood and platelet transfusions may be appropriate, but cattle with advanced bracken fern toxicosis (platelet count < 50,000/μL, leukocyte count < 2000/μL) usually die.

Paradoxical Erythroid Hypoplasia

Monica Aleman

Recombinant human erythropoietin (rhEPO) has been used in racehorses to enhance their athletic activity by stimulating erythrocyte production in the bone marrow. Mild to moderate anemia and paradoxical erythroid hypoplasia based on bone marrow cytology were reported in two Standardbred racehorses following rhEPO administration.[25] Serum from these horses inhibited the rhEPO-induced activity of mouse bone marrow in vitro. The degree of inhibition was inversely proportional to the amount of exogenous rhEPO added to the serum, suggesting the presence of anti-rhEPO antibodies. Anti-rhEPO antibodies to exogenous rhEPO likely cross-reacted with the horses' endogenous rhEPO. These horses were treated with dexamethasone and returned to their usual athletic activity.

Erythrocytosis (Polycythemia)

Debra Deem Morris

Absolute erythrocytosis is caused by increased erythropoiesis that creates a circulating erythrocyte mass above normal for the species. Relative erythrocytosis caused by hemoconcentration, endotoxemia, and splenic contraction (horses) must be ruled out because these conditions are much more common in large animals than absolute erythrocytosis. Diagnosis of absolute erythrocytosis is based on persistently elevated PCV, hemoglobin, and erythrocyte count without clinical evidence of shock or dehydration and without response to IV fluid therapy. Primary erythrocytosis is associated with normal arterial oxygen tension and reduced plasma erythropoietin, whereas secondary erythrocytosis is due to increased production of erythropoietin.

All disorders characterized by an absolute erythrocytosis share clinical manifestations caused by expanded blood volume and increased blood viscosity. Generalized vascular expansion and venous engorgement cause the characteristic "muddy" hyperemia of mucous membranes. A marked decrease in cardiac output accompanies blood hyperviscosity and ultimately impairs tissue oxygenation, producing the vague signs of lethargy and weight loss. There may be an increase in thrombotic complications like laminitis and renal failure.

VetBooks.ir

Congenital Erythrocytosis

Familial erythrocytosis, described in cattle[1] and humans,[2] is due to autonomous erythropoietin production without a demonstrable lesion. Congenital erythrocytosis is thus a form of inappropriate secondary erythrocytosis. Chronic hypoxia should be ruled out by measuring arterial oxygen concentration. The only way to definitively differentiate secondary erythrocytosis from primary erythrocytosis is by determination of serum erythropoietin.

Acquired Erythrocytosis

Primary Erythrocytosis

Polycythemia vera, an idiopathic myeloproliferative disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic elements, has not been reported in large animals.

Secondary Erythrocytosis

PHYSIOLOGICALLY APPROPRIATE ERYTHROCYTOSIS. In domestic animals, absolute erythrocytosis is usually secondary to chronic diseases that produce tissue hypoxia. Chronic tissue hypoxia that attends residence at high altitude, congenital heart defects that produce right-to-left shunting, and some forms of chronic pulmonary disease induce a compensatory increase in plasma erythropoietin that results in absolute secondary erythrocytosis.[3]

The partial pressure of oxygen (P_{O_2}) in capillaries must be maintained close to 40 mm Hg to ensure adequate off-loading of oxygen to tissues. At elevated altitudes, diminished atmospheric oxygen tension produces a much smaller alveolar capillary P_{O_2} gradient and an inadequate driving force for tissue oxygenation. Erythropoietin production in response to hypoxia causes erythrocytosis to increase the oxygen-carrying capacity of circulating blood. Cattle are most susceptible to the effects of high altitude, and some develop polycythemia at 1800 m above sea level. Horses develop an increased erythrocyte mass above 2200 m, especially when in training. Sheep are similar to cattle, but goats are apparently least susceptible to elevation hypoxia.

Congenital cardiac disorders that produce right-to-left shunts are a common cause for absolute erythrocytosis in large animals. Tetralogy of Fallot is the most common defect to cause shunting of unoxygenated blood into the peripheral circulation, although a number of other defects (ventricular septal defect [VSD] being the most common) may eventually result in right-to-left shunting and secondary erythrocytosis.[4]

Chronic impairment of alveolar ventilation may eventually cause erythrocytosis, although most chronic pulmonic diseases in large animals are not associated with significant hypoxemia. Chronic obstructive pulmonary disease in horses may produce enough ventilation/perfusion mismatching to reduce the pressure of arterial oxygen below normal, but the resultant hypoxemia is insufficient to induce erythrocytosis.

PHYSIOLOGICALLY INAPPROPRIATE ERYTHROCYTOSIS. Inappropriate elaboration of erythropoietin (i.e., normal P_{O_2} and secondary erythrocytosis) may rarely accompany renal, hepatic, or endocrine disorders, especially those caused by neoplasia. Secondary erythrocytosis may accompany nonmalignant renal disorders, in which local intrarenal ischemia is believed to mediate increased erythropoietin production. Paraneoplastic erythrocytosis with normal serum erythropoietin is due to tumor production of androgenic steroids or a protein with erythropoietin-like action.[5] Increased plasma erythropoietin and secondary erythrocytosis has been identified in horses with hepatocellular carcinoma.[3,6] Erythrocytosis was described in a horse with hepatoblastoma[7,8] and in another with lymphoma,[9] but serum erythropoietin levels as measured by a human assay were normal in both instances. In the horse with lymphoma, erythropoietin gene expression was identified in the lymphoma tissue. Typically, the diagnosis of inappropriate secondary erythrocytosis is based on elevated serum erythropoietin in the absence of hypoxemia. Elevated serum erythropoietin may not be demonstrated because of the nature of the assay or other compounds causing erythrocytosis.

Treatment of Erythrocytosis

When erythrocytosis is not in response to an appropriate physiologic stimulus (e.g., primary erythrocytosis and inappropriate secondary erythrocytosis), phlebotomy to keep PCV below 50% is the mainstay of treatment to control hypervolemia and blood hyperviscosity. Initially 2 to 4 L of blood may have to be removed every 2 to 3 days, but as iron deficiency supervenes, the frequency of phlebotomy may be reduced. The myelosuppressive drug hydroxyurea, used in humans and dogs with *polycythemia vera,*[2,10] has not been tried in large animals.

Appropriate management of secondary erythrocytosis is more complex because there is a need for increased oxygen-carrying capacity of the blood. The beneficial effect of expanded red cell mass is ultimately offset by the detrimental effect of increased blood viscosity on oxygen delivery. Oxygen delivery is impaired when PCV exceeds 60%, although continued erythropoietin output may result in overcompensation. Phlebotomy is indicated when PCV is over 60%, but the optimum PCV for patients residing at high altitudes or those with right-to-left cardiac shunts must be determined by trial and error.

The long-term prognosis for patients with erythrocytosis is determined by the severity and cause of the disorder. Congenital cardiac defects, neoplastic diseases, and chronic organ insufficiency carry a guarded to poor prognosis. Familial or primary erythrocytosis may be managed by phlebotomy, although there are no long-term follow-ups for large animals with these disorders.

Proliferative Disorders of Lymphoid and Myeloid Systems

The lymphoproliferative disorders reported in large animals are lymphoma, lymphocytic leukemia, and plasma cell myeloma. The myeloproliferative disorders are myeloid leukemias and malignant histiocytosis.[1] The following sections will describe lymphoma, leukemia, and myeloma.

Bovine Lymphoma

John A. Angelos • Mark C. Thurmond

Bovine lymphoma (lymphosarcoma) is characterized in terms of the frequency of occurrence (sporadic or endemic/enzootic), age at onset, organ involvement, and associated etiologic agent. Sporadic bovine lymphoma occurs as generalized lymphadenopathy in calves (calf or juvenile form), as thymic involvement in cattle between 6 months and 2 years of age (thymic or adolescent form), and as a cutaneous form in cattle between 1 and 3 years of age. Lymphoid tumors of cattle with sporadic bovine lymphoma are of the B- or T-cell lineage.[1] The most common form of lymphoma appears endemically in adult cattle (>2 years of age) and is associated with *bovine leukemia virus* (BLV) infection and typically involves multiple organ systems; BLV-associated lymphomas of adult cattle are of the B-cell lineage.[2] BLV is classified in the genus *Deltaretrovirus,* subfamily Orthoretrovirinae, and family Retroviridae.

Sporadic Lymphoma

CALF OR JUVENILE FORM. The prevalence and cause of juvenile lymphoma are unknown, but this form of lymphoma is rare and does not appear to be associated with BLV infection. Age at onset ranges from 3 to 6 months, but juvenile lymphoma can be seen in calves as young as 1 month or in cattle as old as 3 years. There have been reports of fetal involvement with the calf form.[3] Calves generally

VetBooks.ir

present with a history of slight to moderate depression, weight loss, weakness (mainly in older calves and despite good appetite), or lymphadenopathy (mainly in younger calves). The onset of signs can be sudden (within a week).

Physical examination may reveal generalized bilateral enlargement of lymph nodes, particularly the deep cervical and parotid nodes and occasionally the popliteal and hemal lymph nodes. Moderate to marked enlargement may be noted for the iliac and mandibular nodes. Rarely, node enlargement is not generalized but restricted to a regional anatomic site. Enlarged nodes tend to be smooth and firm but are not hot or painful. Mucous membranes are usually pale as a result of anemia. Tachycardia, tachypnea, hyperpnea, cough, and harsh respiratory sounds may be evident on auscultation. Less frequently reported signs include fever, ruminal tympany, enlarged liver, ataxia, and diarrhea.

Hematologic features include a microcytic, hypochromic anemia, low hemoglobin (<7 g/100 mL), low PCV (typically mid-20s), and leukocytosis primarily caused by lymphocytosis. Bone marrow examinations may reveal an elevated myeloid/erythroid ratio with massive neoplastic infiltration in some calves. Affected calves also tend to have low serum globulin and elevated AST. Neoplastic involvement of a variety of organs—spleen, heart, kidney, liver, pancreas, uterus, and thymus—may occur. Less thymic involvement occurs than with the thymic form of lymphoma; neoplastic tissue is found only as small, microscopic nodules. Subperiosteal neoplastic infiltration may produce spinal cord compression and result in paresis. The disease is rapidly progressive and usually fatal within 2 to 8 weeks of onset.

THYMIC OR ADOLESCENT FORM. The thymic form of lymphoma is very rare. The disease is usually seen in cattle 6 to 24 months of age but may occur in newborn calves and cattle up to 4 years of age. Clinical signs are produced by space-occupying lesions in the neck or thorax. Metastatic mammary lymphoma along with thymic lymphoma was reported in a 3-year-old beef heifer.[4] Cattle with thymic lymphoma typically present with brisket enlargement or firm swelling in the presternal area of the brisket, associated with pitting edema.[5] Loss in body condition, rumen tympany, and dysphagia are common. A space-occupying lesion around the esophagus can cause bloat secondary to the animal's inability to eructate rumenal gas. Although generalized lymphadenopathy is uncommon, enlarged superficial cervical and prescapular nodes are usually observed. Jugular veins are distended and nonpulsating; there may be muffled heart sounds and diminished resonance on thoracic percussion. Tachycardia, dyspnea, coughing, or respiratory distress may be present. Hematologic features are generally unremarkable. Anemia is not a consistent feature, and lymphocytosis is only seen occasionally. The course of the disease from the time of recognition is generally from 2 to 9 weeks, but poor condition may have been present for several months before presentation. The disease is fatal, often as a consequence of bloat.

Although thymic lymphoma is not associated with BLV infection, there has been one report of a BLV-positive 18-month-old heifer with thymic lymphoma. In situ PCR was used to detect the presence of BLV proviral DNA in lymphocytes of the thymus and in liver and kidney epithelium.[6]

ATYPICAL FORMS. A 7-month-old Holstein heifer with diffuse swelling over the left thigh, difficult ambulation, and peroneal and tibial nerve deficit had an infiltrative B-cell lymphoma involving the semitendinosus, semimembranosus, and gluteal muscles.[7] This heifer was serologically positive for BLV antibody, but the possibility of maternally derived antibody could not be ruled out. In another case report, the external and internal surfaces of the trachea of an 18-month-old Friesian heifer with cutaneous lymphoid tumors also had extensive lymphoid nodules covering the external and luminal surfaces of the trachea.[8] An 8- to 9-year-old beef cow with weight loss was reported with pleural and pericardial invasion with a lymphoid tumor of T-cell lineage; the animal tested negative for BLV by PCR.[9] Four of 10 cattle 3 years of age or less diagnosed with sporadic lymphoma had BLV provirus in tumor DNA as detected by PCR, and a possible role for BLV in some cases of sporadic lymphoma of cattle has been suggested.[10]

CUTANEOUS FORM. Cutaneous lymphoma is not as age specific as the other forms of sporadic lymphoma and may affect cattle between 1 and 3 years of age. The history may reveal an initial period of 1 to 3 months, during which cutaneous swellings are observed around the anus, vulva, escutcheon, shoulders, or flank. These signs may regress and subsequently recur. Lesions tend to be raised and can be ulcerated. They are generally about 2 to 3 cm in diameter with necrotic centers and may be painful on palpation. Other clinical signs depend on additional organ system involvement of the tumor and may include cardiac insufficiency, with brisket edema extending along the ventral abdomen and jugular pulsation. Pulse and respiration may be elevated as a result of anemia. Hematologic features include anemia and presence of atypical lymphocytes. The mandibular, prescapular, prefemoral, and supramammary lymph nodes are usually enlarged.

At necropsy, a variety of organs may be involved, including heart, brain, skin, spinal cord, liver, lung, kidney, and abomasum. The massive lymphoid infiltration of the skin resembles the clinical manifestations of mycosis fungoides of humans. In a report of a 12-month-old red Holstein heifer with cutaneous T-cell lymphoma, serum activity of lactate dehydrogenase (LDH) was moderately increased despite normal to minimally increased activities of liver- and muscle-specific enzymes.[11]

HEMONODE ENLARGEMENT (HEMAL LYMPH NODE). A lymphoproliferative condition associated with hemonode enlargement and some generalized lymphadenopathy has been described for cattle infected with a lentivirus[12] that is now called *bovine immunodeficiency virus* (BIV). BIV belongs in the genus *Lentivirus,* subfamily Orthoretrovirinae, and family Retroviridae. BIV has molecular similarity to human immunodeficiency virus and is associated with persistent lymphocytosis, lymphadenopathy, CNS lesions, progressive weakness, and emaciation. Infected calves may develop enlarged superficial nodes (hemonodes), mainly in the cervical region anterior and dorsal to the prescapular lymph node, over the spine of the scapula, in the paralumbar fossa, and dorsal to the prefemoral lymph node. Lymphocytosis is possibly related to an increase in B lymphocytes. In utero transmission of BIV has also been documented.[13]

Adult Lymphoma (Bovine Leukemia Virus)

The adult, or enzootic, form of lymphoma is the most common neoplastic disease of cattle and is associated with BLV infection. Rates of lymphoma in cattle vary considerably, probably reflecting variation in BLV infection rates. In 1978 the U.S. condemnation of carcasses because of lymphoma was reported to be 170 per 100,000 head slaughtered.[14] A high condemnation rate, sometimes exceeding 1%, was reported for slaughtered California dairy cows,[15] and about 1.73% of BLV-infected cattle had lymphoma.[16] The rate of lymphoma-associated cattle condemnations appears to have increased over time.[15]

Epidemiology The epidemiology of adult lymphoma is not completely understood. Herd size might be positively correlated with a high rate of lymphoma, which may reflect higher rates of BLV infection in large herds or a preponderance of susceptible pedigrees in some of the herds studied.[16,17] Susceptibility to BLV infection is associated with BoLA type,[18,19] which may explain why higher rates of lymphoma are found in certain families of cattle. The progression of disease to lymphocytosis in some BLV-infected cows may also be influenced by BoLA type, suggesting a genetic predisposition to development of lymphoma through the antigens of the major histocompatibility complex (MHC) encoded at closely linked loci. Polymorphisms at the MHC class II BoLA-DRB3.2 gene have been

VetBooks.ir

associated with differing circulating proviral loads in blood of Argentinian Holstein cattle and can be used to define BLV-resistant versus susceptible genotypes in these cattle.[20] Other potential contributing factors (e.g., nutrition, concurrent infections, environmental/meteorologic stressors) have not been explored sufficiently. There is no evidence for a seasonally associated pattern to appearance of clinical lymphoma.[15] Antigenic and molecular evidence for the presence of BLV in mammary glandular epithelium has been demonstrated.[21] The effect of BLV persistent mammary infection on the mammary gland is not completely understood. Although one study identified increased average milk production in BLV-infected versus uninfected cattle,[22] others report negative associations between milk production and BLV status.[23,24]

Economics The economic importance of adult lymphoma varies according to production type.[24,25] Producers incur losses from lymphoma associated with death of cattle (particularly genetically valuable livestock), loss of milk production, costs of treatment and diagnosis, and premature replacement costs for cattle dying or culled as a result of lymphoma. The latter may explain, in part, an observed increased rate of culling found for BLV-infected dairy cattle.[22,26] Besides premature culling and replacement costs, losses due to failure to retain salvage value of cows condemned for lymphoma at slaughter are also incurred.[15] A hidden cost may also be in the perpetuation of BLV-infected cattle via in utero infection of calves born to cows with lymphoma.[27,28] Although economic losses are associated with morbidity and mortality of cattle that develop lymphoma, estimates of production losses associated with BLV infection are variable. BLV positivity, as determined by serum BLV ELISA or milk ELISA, has not been associated with production losses in dairy cattle in Canada or Turkey.[29-31] In Michigan dairy herds, an increased prevalence of BLV was associated with decreased herd milk production and decreased cow longevity.[32]

Diagnosis Cattle presented with the adult or enzootic form of lymphoma usually are older than 4 years of age but may be as young as 2 years. Cattle are often presented with a history of loss in condition, an abrupt drop in milk production (over a period of a few days), enlarged peripheral nodes, exophthalmos, or partial to complete anorexia, particularly with regard to grain or concentrates. Because dry cows are not observed as closely as lactating cows and are not monitored for milk yield, lymphoma is less likely to be recognized until they freshen. Subclinical lymphoma may be diagnosed in cows submitted for routine reproduction examinations; other signs may include diarrhea, ataxia, paresis, ketosis, and infertility.

Physical examination often reveals an organ system failure resulting from tumor involvement. Thoracic auscultation may reveal cardiac dysrhythmia, tachycardia, tachypnea, and hyperpnea. Common sites of lymphoid tumor predilection in adult lymphoma include heart (usually right atrium), abomasum, uterus, kidney, and spinal cord (epidural space); other common sites include the retrobulbar space and rumen/reticulum.[33] Epicardial lymphosarcoma has been described in three dairy cows 3 to 19 months after diagnosis and treatment for idiopathic hemorrhagic pericardial effusion; at the time of initial presentation with pericardial effusion, none of the three had cytologic evidence of neoplasia in pericardial fluid.[34] Dependent pitting edema is common when cervical or supramammary lymph nodes are involved. Involvement of intestinal lymphatics is often associated with generalized dependent edema anterior to the udder. Peripheral lymph nodes typically found to be enlarged are the prescapular, femoral, and supramammary nodes. Feces may be scant, pasty, or watery, probably reflecting the presence of lesions within the GI tract. Melena may be present in animals with ulceration of the abomasum and lymphoid cell infiltration in the abomasal wall. The main ultrasound finding in a case of abomasal lymphosarcoma was enlargement of lymph nodes caudal to the reticulum, as well as severe enlargement of the abomasum with thickening of the abomasal wall.[35] Rectal palpation can be useful in cases lacking peripheral node enlargement or exophthalmos. Tumor masses palpated in the abdomen typically are multiple and range in size from only slightly enlarged lymph nodes to massive lesions half a meter in diameter. The internal iliac nodes are involved in most cattle with abdominal tumors.

Tumors tend to be firm but not hard and may feel slightly lobulated. Differentiation by palpation of lymphoma tumors from other masses is highly subjective. Carcinomas tend to be of similar consistency but are seldom larger than 15 cm in diameter and are usually associated with intestinal tissue. Lymph nodes of cows with carcinoma are not usually enlarged unless a secondary infection is present. Melanomas are generally less than 15 cm in diameter and hard, sometimes with protrusions 1 to 2 cm high along the surface, and not usually found associated with lymph nodes. Masses of fat necrosis tend to be firm and are usually associated with omental tissue. Internal abscesses are often single and associated with the uterus, as a consequence of uterine tear and infection during parturition, or with gluteal muscles of the pelvic ceiling, as a consequence of injection-related infections. Exploratory laparotomy may be indicated as an additional diagnostic tool in difficult cases, particularly in valuable cattle.

The hemogram of cattle with lymphoma is often unremarkable. A microcytic, hypochromic anemia may be present in cattle with GI hemorrhage. Because fibrinogen levels have been inconsistent in lymphoma, measurement may be helpful only in differentiating an abscess. Some 30% of cattle with BLV infection develop persistent lifelong lymphocytosis, composed mostly of B cells.[36,37] Lymphocytotic cattle have higher BLV proviral loads in peripheral blood lymphocytes than nonlymphocytotic cattle, but some nonlymphocytotic cattle may have high BLV proviral loads and could represent obstacles to successful eradication efforts.[38] Low antibody response to the BLVp24 antigen was observed in cattle with low BLV proviral loads.[38] In a majority of calves that were experimentally infected with BLV, calves became PCR positive sooner than they seroconverted (as determined by a commercial BLV antibody test).[39]

Cytologic analysis of aspirates of tumors or tumorous nodes may not always be a reliable diagnostic tool, although it can be helpful. Discrimination cannot be made between a normal node responding to an infectious agent and a node involved with neoplastic lymphocytes; in both situations, cells resembling young, poorly differentiated lymphocytes may be present. Examination of nontumorous active lymph nodes may reveal an elevated proportion of large, young lymphocytes that could resemble those of lymphoma. In a retrospective study, the sensitivity of antemortem diagnostic testing found peripheral lymph node biopsy to be 100% sensitive while fine-needle aspirate was only 41% sensitive.[33] When compared to core needle biopsy of peripheral lymph nodes, fine-needle aspiration is more specific and more predictive for a positive test.[40] Cytology and culture of aspirates can be helpful in differentiating a tumor from an abscess. Failed attempts at collection of cerebrospinal (lumbosacral) fluid in cattle with recumbency or rear limb weakness may be associated with the presence of lymphoid tumors in the vertebral canal; cytologic examination of cells from the collection needle in such cases may reveal abnormal lymphoid cells.

Standard serologic testing for BLV involves identification of antibody against the 51-kD envelope glycoprotein (gp51). BLV diagnosis historically involved use of the agar-gel-immunodiffusion (AGID) test, but that method has been shown to be less sensitive than ELISA.[41] Commercially available ELISA test kits (e.g., HerdChek Bovine Leukemia Virus Antibody Test Kits [IDEXX Laboratories Inc., Westbrook, Me.], Bovine Leukemia Virus Antibody Test Kit, ELISA [VMRD Inc., Pullman, Wash.], SVANOVIR BLV gp51-Ab ELISA [Svanova Biotech AB, Uppsala, Sweden]) can detect antibodies to gp51 in serum and/or milk. A recombinant p24 antigen ELISA has been developed.[42] Diagnosis is also possible with PCR to detect BLV nucleic acid,[43-45] as well as by a combined PCR-ELISA that is more sensitive than staining of PCR amplicons with ethidium bromide.[46] ELISA-positive cattle that were not detected by PCR testing have been reported; this is most likely related to a low number of infected circulating lymphocytes at the time of sample collection.[47] PCR by

VetBooks.ir

itself is considered unreliable for routine detection of BLV in herds with a high prevalence of disease.[48] The ability of PCR to detect a BLV-infected animal is improved by means of a nested PCR, which was reported to be effective in diagnosing infection when seroconversion had not yet occurred.[49] A loop-mediated isothermal amplification (LAMP) assay has been developed to diagnose BLV infection in cattle; this test has sensitivity at least as good as the conventional single PCR and has the advantage of not requiring specialized thermal cycling equipment.[50]

The presence of antibodies to gp51 is generally considered to be a prerequisite to a diagnosis of lymphoma, except for cows during the periparturient period, when circulating antibodies may fall below the level detectable by a serologic test.[51] The mere presence of BLV antibodies does not necessarily mean an animal has lymphoma, which is found in only about 1.7% of BLV-infected cattle.[52] However, serology can be helpful in predicting the chance of lymphoma in cattle seropositive to the gp51 antigen. Sera from cattle with lymphoma generally have high titers to the gp51 antigen (a score of 3 or 4 on AGID) compared with those of infected cattle without lymphoma (score of 1 or 2 on AGID). Cattle that do not have lymphoma tend not to have antibodies to the p24 antigen of BLV, as detected by AGID. The percentage of cattle with histologically confirmed lymphoma but in which lymphoma was not diagnosed by a gp51-positive and p24-negative test result (false-negative rate of the diagnostic test) has been found to be only 0.21% using the AGID test.[16] Unfortunately, most diagnostic laboratories do not have the capability to perform the test using the p24 antigen.

At necropsy, tumors are found enclosed in a capsular-like tissue that, when sectioned with a knife, results in an eversion of tumor stroma. Cut tumor tissue is cream colored and friable, with little binding structure. Centers of tumors may appear necrotic and mushy, whereas peripheral regions are firmer and pink to white. Histopathologic analysis provides the only definitive diagnosis. Tissue should be biopsied by surgical removal of as much of the node (or mass) as possible.

Control No curative treatment for lymphoma exists. Supportive therapy may be indicated to reduce discomfort and prolong life long enough to remove valuable ova/embryos or calves or to harvest semen.

Until more information is available on the epidemiology of lymphoma, control and eradication hinge on success of efforts to eradicate BLV from a herd. No vaccines presently offer effective protection from BLV infection.[53-56] Control and eradication of BLV require reduction of blood transmission through iatrogenic means and through physical contact among cattle.[57] Transmission associated with physical contact between infected and susceptible cattle can be reduced by segregating infected and uninfected cattle.[58,59] Separation of cattle by 10 feet is preferred, but a single fence may sufficiently reduce the degree of contact necessary for transmission. Transmission after physical contact may be via inhalation of BLV shed in nasal secretions.[60-63] Experimental studies have found that under extreme conditions of blood contamination and mucosal irritation, BLV can be transmitted rectally.[64-68] Under conditions typical of routine palpation during pregnancy examination, however, BLV does not necessarily appear to be transmitted to any measurable degree.[66,68] If potential for rectal transmission is a concern, palpation sleeves may be rinsed or replaced between cows. Although insect transmission of BLV is theoretically possible[69] and has been demonstrated experimentally by interrupted feeding of tabanids from cattle with persistent lymphocytosis to uninfected cattle,[70] studies of natural infection have not linked flies to new natural infections.[71,72] Several studies have failed to demonstrate transmission after use of a common needle.[73-75] However, infection after use of a tuberculin needle dipped in blood of a BLV-infected animal could be prevented by wiping the needle with cotton before injection.[76] Although data have not shown the use of common needles to be an important means of BLV transmission, it would be prudent to use individual sterile needles for treatment, testing, or vaccination.

Transmission of BLV has not been shown in cows inseminated artificially using commercially prepared frozen semen.[77-81] However, infection by an infected bull during natural breeding may be possible.[82,83] Semen of 27 bulls that were BLV PCR positive in peripheral blood had no evidence of BLV by PCR.[84] Embryo transfer recipients should be tested for BLV before transfer.[85] Embryo transfer using uninfected recipients offers a means of producing phenotypically preferred cattle from BLV-infected cows and controlling in utero infection,[71,77,86,87] because at harvesting, embryos are not infected.[79] Through a washing procedure, it is possible to produce transferable in vitro–fertilized embryos that are free of BLV provirus from oocytes that are exposed to BLV during maturation, fertilization, or after fertilization.[88]

For most herds, control and eradication of the infection would require modification of facilities, alteration of management practices, and serologic surveillance at least annually. Planning a control program should include a cost/benefit analysis to evaluate potential return on the investment. Financial benefit of a BLV control program has been documented in herds where prevalence of BLV infection is 12.5% or higher.[89] Selective culling of BLV-infected cattle based on positive lymphocyte BLV antigen expression in vitro was reported to be effective in preventing transmission of BLV infection.[90]

Feeding colostrum from BLV-positive cows to calves known to be BLV negative at birth was shown to decrease the risk of BLV exposure that presumably occurred during calving.[91] In Japan, feeding colostrum from the dam was also found to be protective against within-farm BLV transmission.[92]

Lymphoma in Horses

Monica Aleman • Johanna L. Watson

Lymphoma and *lymphosarcoma* are terms that have been used interchangeably to describe a group of neoplasias originating from the lymphoid system, such as nodal (lymph nodes) or extranodal lymphoma (thymus, spleen, mucosal-, conjunctival-, or skin-associated lymphoid tissue). The mucosal-associated lymphoid tissue includes mucous membranes lining the digestive, respiratory, and urogenital systems. Metastasis can occur to other organs, including primary lymphoid tissues like bone marrow. Based on its embryologic origin, lymphoma is classified as a mesenchymal neoplasm. Although the suffix *-oma* indicates a benign neoplasm, whereas *-sarcoma* indicates a malignant mesenchymal neoplasm, the Leukemia and Lymphoma Society determined that *lymphoma* is the appropriate term because all neoplasms of the lymphatic system in humans are malignant. In veterinary medicine, lymphomas are also malignant, so the term *lymphoma* has been adopted. It is important to emphasize that *lymphoid hyperplasia* is not synonymous with lymphoma.

Lymphoma is one of the most common malignant neoplasias in the horse; in postmortem studies, its prevalence is estimated to be 2% to 5%.[1,2] In contrast to other species, there is no proven viral etiology for development of lymphoma in the horse. Virus-like particles in lymph nodes of neonatal foals with lymphoma have been described, but no causal relationship has been proven.[3,4] Lymphomas can occur at any age, with reports as early as in an aborted equine fetus to horses older than 30 years,[4-6] but the average age of onset of all forms of lymphoma has been reported to be between 5 and 10 years of age. Studies of intestinal lymphoma report the mean age of onset to be 16 years.[6,7] There is no apparent breed or sex predilection. Clinical signs vary depending on tumor location, but the most common include lymphadenopathy, lethargy, weight loss, edema, and pyrexia. Affected lymph nodes tend to be firm, cool, and nonpainful. In one retrospective study of 79 horses with lymphoma, 21 cases had ocular involvement.[8] Paraneoplastic pruritus and alopecia were described in a horse with diffuse lymphoma.[9] Neurologic alterations, lameness, osteolysis, and pathologic fractures have been described as the result of lymphoma.[10-15]

Although the hematologic features of lymphoma vary, anemia is a relatively common finding and is thought to be due to suppression

VetBooks.ir

of erythropoiesis, bone marrow infiltration, blood loss, or IMHA. Frank leukemia is rare, but when present, neoplastic cells are generally found in the bone marrow.[16] More often the lymphocyte count is within reference range or low. Atypical lymphocytes may be noted in the blood smears of 20% to 50% of affected horses, especially late in the disease course.[17-20] A modest neutrophilic leukocytosis with an elevated fibrinogen is often seen. This inflammatory response can be confounding when attempting to differentiate neoplasia from internal abscessation.[21] Serum biochemistry profiles may provide indication of internal organ involvement. Serum protein alterations are frequently observed and include hypoalbuminemia, hyperglobulinemia with polyclonal gammopathy (most cases), and decreased albumin/globulin ratio. However, deficiencies in IgG and IgA concentrations were reported in a horse.[22] Neoplastic lymphocytes may arise from reactive B-cell clones producing antibodies responsible for gammopathies and immune-mediated processes (hemolytic anemia, neutropenia, lymphopenia, thrombocytopenia). Although low serum IgM concentrations and hypercalcemia have been reported in few cases, these are not consistent features of lymphoma in the horse.[20,22-24]

Lymphomas in horses have been classified based on anatomic distribution, morphology, and cell lineage.[24-27] Based on anatomic distribution, lymphoma classification in the horse is as follows: multicentric, generalized, alimentary or intestinal, splenic, mediastinal, thymic, and cutaneous.

Morphologically, lymphocytes are classified as small-cell type if their nuclear diameters are 1.5 times the diameter of erythrocytes or less; cells are classified as large if their nuclei average 2 times or more the diameter of erythrocytes.[26] Small-cell–type lymphoma consists of 60% or more of small cells. Large-cell lymphoma consists of 60% or more of large cells. A lymphoma designated as "mixed" is a tumor that contains both small and large neoplastic cells of the same immunophenotype.[26]

Immunohistochemical classification of lymphomas can be determined using monoclonal antibodies such as CD79a (mb-1) and B29 for B-cell lymphomas and CD3 and CD5 for T-cell lymphomas. All three—B-, T-, and mixed B- and T-cell lymphomas—have been reported in the horse.[26,27] The monoclonal antibody proliferating cell nuclear antigen (PCNA) has been used to determine the proliferative status of the cells.[26] Frequently, lymphomas are described as T-cell–rich B-cell lymphoma or vice versa. T-cell–rich, large B-cell lymphoma is a neoplastic proliferation of large B cells associated with a prominent component of non-neoplastic reactive T lymphocytes that constitute a significant percentage of the cellular population.[26] The presence of large numbers of non-neoplastic T cells within a B-cell lymphoma could result in erroneous diagnosis of a T-cell tumor. Neoplastic cells are characterized by large cell size, large vesicular and irregularly shaped nuclei with coarse chromatin, atypical mitotic figures, and positive immunostaining to PCNA markers. Non-neoplastic cells are identified by their normal morphology and lack of immunoreactivity to proliferation markers. However, discriminating between neoplasia and chronic inflammation with reactive lymphocytes can be difficult. Molecular clonality assays can be used to make this determination. Clonality assay results indicating a polyclonal population of lymphocytes support a classification of inflammation, whereas results indicating a monoclonal population support a diagnosis of neoplasia. Accurate lymphoma characterization and staging in humans has been critical to establishing effective therapeutic management plans and accurate prognoses.

Multicentric Lymphoma

Multicentric lymphoma involves lymph nodes (veterinary oncology terminology: nodal = lymph node; multiple lymph nodes = multinodal = multicentric), regardless of location. Extranodal lymphoid tissue (lymphoid tissue other than lymph nodes) is not involved, but multicentric lymphoma may metastasize to extranodal areas, in which case it will be classified as generalized (diffuse) lymphoma. In veterinary medicine, the terms *multicentric* and *generalized* have been used interchangeably.

Generalized Lymphoma

Generalized lymphoma is considered an end-stage disease characterized by involvement of both nodal and extranodal lymphoid tissue. This form is more common than the intestinal (extranodal) and mediastinal (nodal) forms alone. Horses often present with severe lethargy, emaciation, anorexia, generalized lymphadenopathy, and edema due to impaired lymphatic drainage.[6,29] Anemia is common, and hypoproteinemia due to hypoalbuminemia may be found. Although leukemia is rare, it is generally associated with this form of lymphoma.[16] In addition to lymphoid tissue involvement, infiltration of neoplastic lymphocytes has been reported in the spleen, liver, bladder, kidney, lung, heart, nasopharynx, eye, ovary, uterus, brain, and spinal cord.[4,16,22] Multifocal eosinophilic granulomas have been identified in neoplastic lymph nodes and are hypothesized to be a response to paraneoplastic production of IL-5 and granulocyte-monocyte colony-stimulating factor (GM-CSF).[15]

Alimentary or Intestinal Lymphoma

Alimentary tract lymphoma involves the GI tract, more frequently the small intestine.[27,30] Lymphoma is the most common neoplasia of the intestinal tract in horses.[6] The mean age of onset of intestinal lymphoma is 16 years (range, 2 to 30 years). Arabian horses are the most common breed affected.[6] Lymphoma arises from the lymphocytes of the lamina propria (extranodal lymphoid tissue) of the intestinal tract, resulting in diffuse or segmental thickening, focal masses, or scattered crater-like ulcers with raised margins on the intestinal wall.[27,28,30] Lymphadenopathy is generally not present. Metastases to mesenteric lymph nodes, liver, and spleen have been reported.[28] Transabdominal ultrasound may be very useful for detecting intestinal thickening and cecal lymphadenopathy. Clonality analysis of tissues from affected horses reveals that T-cell lymphomas are more common than B-cell lymphomas in the intestinal tract.[6] This neoplasia is usually associated with malabsorption, protein-losing enteropathy (hypoalbuminemia), weight loss, edema, abdominal effusion, mild recurrent colic, and diarrhea.[30-33] Affected horses frequently have abnormal glucose or xylose absorption tests, indicating small intestinal malabsorption. In one study, cytologic analysis of abdominal fluid provided support for the diagnosis of intestinal neoplasia of any kind in 38% of the cases examined.[6]

Thoracic Lymphoma: Mediastinal/Thymic

Lymphoma is the most common thoracic neoplasia in horses, and it may involve mediastinal lymph nodes and the thymus and/or lungs.[34,35] Exclusive involvement of mediastinal lymph nodes is called *mediastinal lymphoma,* whereas exclusive involvement of the thymus is called *thymic lymphoma.* Its prevalence varies from 18% to 29% of all forms of lymphoma.[32,36] Primary and secondary (metastatic) mediastinal lymphomas have been reported, with metastatic being more common.[34] Primary mediastinal lymphoma is usually seen in adult horses (mean age, 10 years; range, 2 to 30 years); however, the disease has been reported in a 1-month-old foal with a 1-week history of respiratory distress.[5] Metastasis from primary mediastinal lymphoma often occurs. In the early stages of the disease, minimal clinical signs may be observed. Common clinical signs include nasal discharge, adventitious lung sounds, pleural effusion, thoracic ventral and limb edema, and regional lymphadenopathy at the thoracic inlet.[32,34] Other signs may include cough, pyrexia, pleurodynia, and in some cases respiratory distress.[34,37] Temperature, pulse, and respiratory rate are often elevated. Dysphagia may be observed in cases with retropharyngeal lymphadenopathy.[38] An elevated nucleated cell count of several thousands per µL, with a large percentage of abnormal lymphocytes, may be evident in pleural fluid cytologic analysis. However, collection of multiple pleural fluid samples may be necessary to establish a definitive diagnosis.[37] Cytologic abnormalities include the presence of prolymphocytes, lymphoblasts, nuclear blebbing, indented and cleaved nuclei, amorphous nuclei, altered nuclei/cytoplasm ratio, and mitotic figures.[37] Thoracic lymphomas may

VetBooks.ir

be of B-, T-, or mixed-cell origin, but T-cell lymphomas are most common.[26,37]

Cutaneous Lymphoma

Cutaneous lymphomas are confined to the skin-associated lymphoid tissue. Single or multiple subcutaneous firm, nonpainful nodules ranging from less than 1 cm to greater than 20 cm in diameter can develop rapidly or slowly, regionally or over most of the body surface.[39,40] The nodules are usually covered with hair. In some cases, the lesions tend to wax and wane spontaneously, or in association with sex hormone levels, seasonality, or steroid therapy. There is one report of complete regression of cutaneous lymphoma following surgical removal of an ovarian tumor.[41] Depending on the anatomic location, cutaneous lymphomas may cause mechanical lameness and limb edema secondary to vascular and lymphatic obstruction. In most cases, there are no associated hematologic abnormalities, and generalized lymphadenopathy and internal organ involvement is rare. Cutaneous lymphomas are usually of B-cell origin. A far less common form of cutaneous lymphoma, mycosis fungoides, is characterized by diffuse infiltration of neoplastic T lymphocytes in the epidermis, dermis, and subdermis. Mycosis fungoides has been reported in a mare with a vulvar mass that infiltrated the skin of the perineum and ventral abdomen.[42] This type of lymphoma may involve mucocutaneous junctions and carries a poor prognosis if deeper tissues are involved.[42]

Angiotrophic Lymphoma

This neoplasia, also known as *endotheliotropic lymphoma* or *intravascular lymphangiomatosis,* has been described in humans, dogs, and cats.[43-45] There is a single report in a 12-year-old pregnant Thoroughbred mare with anorexia, tachycardia, and mild fever.[46] The significant laboratory abnormalities were profound anemia (PCV 12%), decreased RBC count, marked anisocytosis, mild lymphopenia, low IgM, and marked erythroid hyperplasia and erythrophagocytosis on bone marrow biopsy. Triglycerides, cholesterol, and total bilirubin were elevated on serum biochemistry. Coombs and Coggins tests were negative. Postmortem examination revealed generalized icterus and moderately enlarged mediastinal and mesenteric lymph nodes. Histologic examination revealed thickened pulmonary alveolar septae and vessels crowded with atypical lymphoid cells with scattered mitoses. Similar atypical cells were evident within renal vessels. The neoplastic cells were determined to be of T-cell origin based on immunohistochemical staining. Angiotrophic lymphoma may represent an antemortem diagnostic challenge owing to the lack of circulating neoplastic lymphocytes and identifiable masses.

Chemotherapy for the Treatment of Lymphoma

There is limited information about chemotherapy for lymphoma in horses. One protocol used in two pregnant mares with lymphoproliferative disease consisted of a combination of cytarabine (200-300 mg/m^2 SC or IM q7-14d), chlorambucil (20 mg/m^2 PO q14d) or cyclophosphamide (200 mg/m^2 IV q14-21d), and prednisolone (1.1 to 2.2 mg/kg PO q48h).[47] Vincristine (0.5 mg/m^2 IV q7d) can be added if no clinical improvement is noticed in the first month of therapy. This protocol was continued for 2 to 3 months, then followed by a maintenance protocol consisting of gradual decreases of prednisolone and extending by 1 week the administration of other chemotherapeutic agents for the next 2 to 3 months. This was followed by extending the administration interval by another week for 2 to 3 months for a total of 6 to 9 months.[47] Other protocols include drugs used alone or combined such as L-asparaginase (10,000-40,000 U/m^2, IM q14-21d), doxorubicin (50 mg/m^2 IV), vincristine (1.4 mg/m^2 IV), and rituximab (375 mg/m^2 IV). A horse with thoracic lymphoma was treated with cytarabine (170 mg/m^2 IM) 2 weeks apart, alternating with cyclophosphamide (142 mg/m^2 IV) 7 days after each dosage of cytarabine.[37] In addition, the horse received prednisolone (86 mg/m^2 PO q48h) and was discharged 1 month after the initiation of chemotherapy with instructions to continue prednisolone at the previous dosage every 48 hours for the remainder of its life. Eight months after discharge, the horse was in good health and resumed light exercise. Therapy may be attempted with dexamethasone (0.2 mg/kg IV or PO q24h for 5 days) followed by prednisolone (1 to 2 mg/kg PO q24h).

Complications associated with chemotherapeutic agents in horses may include anorexia, lethargy, thrombosis, arrhythmias, laminitis, bone marrow damage, GI and genitourinary toxicoses, urticaria, and immunosuppression. Anemia, thrombocytopenia, leukopenia, and secondary infections may occur.[48] Successful management of cutaneous lymphomas has been achieved with glucocorticoids like dexamethasone, prednisolone, and betamethasone. Controversy exists regarding the nature of cutaneous nodules (i.e., possible lymphoid hyperplasia, not true lymphomas). Other treatment modalities that have been tried include autologous tumor vaccines and radiation therapy.[49-51] Although periods of remission have been reported with chemotherapy,[37,47] the long-term prognosis has been poor for the majority of horses.

Leukemia in the Horse

Monica Aleman

Leukemia is a rare neoplasia of the hematopoietic system that originates from the bone marrow (primary leukemia). A leukemic phase (secondary leukemia) has rarely been reported in horses.[16,18,19] Based on the cell of origin, the major forms of leukemia include myeloid and lymphoid leukemias, which can have an acute or chronic clinical course. According to the Leukemia and Lymphoma Society, *acute leukemias* are rapidly progressing disorders that affect mostly primitive or immature cells that lack normal function, whereas *chronic leukemias* progress slowly, allowing some growth and cell maturation that may preserve limited normal function. Reported leukemias in the horse include myelomonocytic, monocytic, granulocytic, eosinophilic, and lymphocytic forms.[16,18,51-66] Based on the presence and numbers of cells in blood, other terms used are *leukemic, subleukemic,* and *aleukemic leukemia.* Leukemic leukemia is characterized by an increase in cell numbers in peripheral blood; subleukemic leukemia is defined by an increase in abnormal blast cells in blood, with a total white cell count within the reference range or low; and aleukemic leukemia is characterized by the presence of abnormal cells in the bone marrow but not in peripheral blood.

There is no apparent breed or gender predisposition, based on the few reported cases.[16,18,52-66] The age at onset of clinical signs ranges from 2 to 25 years. The most common clinical signs are weight loss, lethargy, anorexia, pyrexia, and lymphadenopathy if associated with lymphoma. Other signs are weakness, ventral edema, exercise intolerance, colic, and recurrent or concurrent infections.

At the initial stages of disease, laboratory features may show mild hematologic abnormalities and include one or more of the following: anemia, neutropenia, lymphopenia, thrombocytopenia, hyperproteinemia, and hyperfibrinogemia. As the disease progresses (days to months), marked leukocytosis (counts may be >200,000 WBC/μL) and hyperproteinemia will be observed in leukemic leukemias.[16] Thrombocytopenia is a common hematologic feature.[16,62,63,66] Pancytopenia and high blast cell counts (up to 1.6×10^9 cell/μL) were reported in a lactating mare with myeloblastic leukemia.[66] Pancytopenia due to severe infiltration of leukemic cells in the bone marrow, ineffective hematopoiesis, and myelofibrosis has been reported.[62] Horses with multicentric lymphoma, pancytopenia, severe leukocytosis (more than expected for severe inflammation), or presence of atypical or blast cells in peripheral blood should prompt the collection of a bone marrow aspirate or biopsy. Bone marrow aspirates may have normal to altered myeloid/erythroid ratio (reference range, 0.5 to 3.76) with a disproportion of atypical or poorly differentiated blast or mature cells of certain lineage. Decreased or absent megakaryocytes is a common observation.

Hyperproteinemia due to hyperglobulinemia is a consistent finding. Serum electrophoresis typically shows a polyclonal increase of β_2- and γ-globulin fractions, and in some cases α-globulin fraction.

TABLE 37-2

Monoclonal Antibodies for Specific Equine Leukocyte Antigens (ELAs)

ELA Marker	Specificity
EqCD2	T cells
EqCD3	T cells
EqCD4	Helper T cells (T_H cells)
EqCD5	T cells
EqCD8	Cytotoxic T cells (T_C cells)
EqCD11a/18	Panleukocyte
EqCD13	Myeloid cells
CD21	Most B cells
CD79a	B cells
EqWC1	Large T-cell and neutrophil subsets
EqWC2	T cells and neutrophils
EqWC4	Minor T-cell subset
MHCI	Nucleated cells
MHCII	B cells, macrophages, dendritic cells, and a large T-cell subset
IgM	B cells

CD, Cluster of differentiation; *Eq,* equine; *IgM,* immunoglobulin M; *MHC,* major histocompatibility complex; *WC,* white cell.

Marked increases in serum IgG and IgA concentrations have been detected in horses with lymphocytic leukemias.[16] Deficiencies in IgA and IgM have been reported in a single horse with chronic lymphocytic leukemia.[59]

Necropsy findings may include mucosal ulceration, edema, thrombosis, and hemorrhages of various organs due to intravascular leukostasis (aggregates of leukemic cells in blood vessels), disseminated intravascular coagulopathy, and thrombocytopenia secondary to decreased production of megakaryocytes. Leukemic-induced cell lysis may occur as the result of mediators released by neoplastic cells. Peripheral and internal lymphadenopathy may also be observed.

The diagnosis is based on results of a complete blood cell count (CBC) and chemistry panel, with cytologic and histopathologic evaluation of bone marrow, immunocytochemical analysis, flow cytometry, and immunophenotyping. Previously, leukemic cells in peripheral blood and bone marrow were described based on their morphology. However, this may result in leukemia misclassification, especially in acute leukemias where mononuclear blast cells comprise the leukemic clone, which may lack specific morphologic identifying features. Numerous cytologic and cytochemical stains (e.g., Wright, Giemsa, Sudan black B, peroxidase, periodic acid-Schiff, alkaline phosphatase, acid phosphatase, various esterases, and surface glycoproteins) have been used to determine leukemia type. Leukemic cells may lack specific cytochemical properties, however. Currently, the various types of leukemias are identified by specific cellular antigens, using a panel of monoclonal antibodies and flow cytometry to analyze peripheral blood and/or bone marrow. Examples are B-cell/IgM-positive, B-cell/IgM-negative, CD3/CD4/CD5-positive T-cell, CD3-negative/CD4-positive T-cell, and CD13-positive/myeloid leukemias.[16,59,63] The various monoclonal antibodies for specific equine leukocyte antigens are shown in Table 37-2.

The prognosis is grave, resulting in death within days to a few months after its diagnosis. Treatment of leukemia in horses has been attempted with cytosine arabinoside, cytarabine, and prednisolone, but without much success.[55,59,65]

Myeloma in the Horse

Monica Aleman

Myeloma is a neoplastic proliferation of plasma cells that primarily originates in the bone marrow but may have an extramedullary source.[67] Both forms have been reported in the horse.[68-70] Accumulations of neoplastic plasma cells outside the marrow is called *extramedullary plasmacytoma.*[67] Plasmacytomas can form in several organs and tissues, including the skin. The most common extraosseous sites in horses are lymph nodes, kidneys, spleen, and liver.[68,70,71] Multiple myeloma involves bone marrow at multiple locations and other tissues, and it is the most common form of myeloma in humans.[72] In human medicine, causes of myeloma include chromosomal translocation, irradiation, and chronic antigenic stimulation.[67]

Myeloma is a rare neoplasia of the horse (only 16 cases reported in the literature), with a median age of 14 years and a range of 3 months to 25 years of age.[68-71,73-83] Almost half of the horses were Quarter Horses, but various breeds including draft horses and ponies were represented. There is no apparent gender predilection. Clinical signs vary with the degree of plasma cell infiltration, extent, and location. The most common clinical signs are weight loss, anorexia, fever, pale mucous membranes, lethargy, limb edema, and recurrent infections.[68-71,82,83] Bone pain due to osteolytic disease is the most common early sign of myeloma in humans.[72] Four horses from the literature were reported to have osteolysis. The clinical signs in these horses included paresis, cervical pain, and lameness.[71,74,76,79]

Laboratory features are anemia, hyperproteinemia due to hyperglobulinemia, hypoalbuminemia, and proteinuria. Anemia results from reduced erythropoiesis secondary to myelophthisis, blood loss, and as a result of the osmotic effect of paraproteins. Pancytopenia is observed if myelophthisis develops. Hypercalcemia has been reported in a few cases.[68,70,71] Significantly different features have been reported (hypoproteinemia, hypoglobulinemia, hypoalbuminemia, hypocalcemia) in a gelding with systemic amyloidosis and multiple myeloma, thought to be the result of severe protein-losing enteropathy.[83] Concurrent systemic amyloidosis and multiple myeloma is common in humans but extremely rare in domestic animals, with only one cat and one horse reported in the literature.[83,84] Serum parathyroid hormone–related protein concentration was mildly elevated in one horse with multiple myeloma.[71]

In secretory myelomas, neoplastic plasma cells are responsible for overproduction of a monoclonal Ig called *M protein* or *paraprotein.* M protein may be fragments (mainly light chains also called *Bence Jones protein*) or a complete Ig. Subclasses of IgG are the predominant paraprotein associated with myeloma in horses,[68,82] but there are three reported cases with IgA paraprotein.[70,71]

Plasma cells are relatively sparse in normal bone marrow. Involvement of marrow is usually focal rather than diffuse, requiring multiple marrow aspirates in some cases to confirm plasmacytosis. The diagnosis of multiple myeloma in humans is based on the presence of at least 10% of plasma cells in the affected tissue, monoclonal protein in serum or urine, and evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia, or bone lesions). Renal insufficiency has not been reported in horses with myeloma.[68,70] Bleeding and blood hyperviscosity syndrome are common complications of multiple myeloma in humans.[72] These complications have been reported in four horses.[68,77]

The median length of survival after diagnosis in humans is approximately 3 years.[72] Owing to poor prognosis or deterioration of condition, most reported horses were euthanized within a few days to months of diagnosis. However, two horses survived for 1 and 2 years, respectively.[78,81] One horse was euthanized 3.5 years after the diagnosis for deteriorating condition.[70]

Lymphangioma in the Horse

Monica Aleman

Lymphangioma is a rare tumor in horses that originates from lymphatic vessels. Morphologically, lymphangiomas are classified into three types: simplex or capillary, cavernous, and cystic.[85] This tumor may involve cutaneous tissues of the mammary gland, thigh and inguinal regions, pleural cavity, and intestines and has only been observed in young horses.[86-88] Clinical signs vary depending on tumor location. At diagnosis, these tumors were extensive; surgical

VetBooks.ir

removal was not attempted, and all horses were reportedly euthanized.

Other Diseases of the Hemolymphatic System

Anthrax

Kristin A. Clothier*

Anthrax is a soil-borne bacterial disease primarily affecting herbivores and most often presenting as acute septicemia with high mortality. Other animal species, including humans, can be infected. Anthrax occurs worldwide and is noteworthy both because of its impact on agriculture and its potential to cause zoonotic infections. *Bacillus anthracis,* the etiologic agent of anthrax, has been classified by the Centers for Disease Control and Prevention (CDC) and the USDA as a "select agent" because it is one of the microbes most likely to be used as a bioterrorism agent. Dissemination of genetically modified *B. anthracis* spores through the U.S. Postal Service (USPS) in 2001 demonstrated its usefulness in this capacity.[1] Possession of this organism is under federal jurisdiction and is highly regulated.

Etiology

In the vegetative form, *B. anthracis* is a large, rectangular-shaped, gram-positive rod. Vegetative cells are predominantly found in tissues of infected animals, but *B. anthracis* exchanges genetic information with other *Bacillus* spp. in the environment, indicating vegetative cells can exist outside animal hosts.[2] Under nutritionally limiting conditions, vegetative cells are induced to form spores. Sporulation is an oxygen-dependent process and does not occur under anaerobic conditions. The spore form of *B. anthracis* is highly stable and resists many chemical and heat treatments, as well as adverse environmental conditions.[3] Spores can survive and remain infectious in the environment for decades.

Pathogenesis

Exposure of animals occurs primarily from grazing contaminated pastures and ingestion of spores.[4] Forage grown on anthrax-positive premises and animal by-products containing spores are other sources for infection. In swine, consumption of contaminated animal by-products in feed is the usual source of infection.

Ingested anthrax spores cross mucosal barriers, are phagocytosed by macrophages, and traffic to regional lymph nodes. As spores convert to their vegetative phase, they are able to avoid the antimicrobial action of the phagocyte, kill the host cell, and escape into the extracellular environment. Plasmid-encoded virulence factors, particularly a poly-D-glutamic acid capsule and a three-component toxin, are keys to survival in the host.[4] Production of the capsule by vegetative cells enables the bacterium to resist phagocytosis and mask surface antigens, resulting in evasion of the host's phagocytic defenses.[5] The three components of the toxin are protective antigen (PA), lethal factor (LF), and edema factor (EF). Protective antigen attaches to host cells through surface receptors, polymerizes to form a prepore, and binds one or both of the other two toxin components, LF and EF. This entire complex enters the cell by endocytosis. In the endosome, the polymerized prepore becomes a functional pore and allows LF and EF to enter the host cytoplasm.[6] The enzymatic effects of EF and LF disrupt host cell functions including innate and adaptive immune responses.[7] EF increases cyclic adenosine monophosphate (cAMP) production, leading to tissue edema and suppression of phagocytic capability. LF causes cell death by interrupting signal transduction pathways and inducing expression of numerous proinflammatory cytokines. The result is rapid proliferation of *B. anthracis* in the host and an overwhelming septicemia. Death is due to toxic shock with hypotension and multiorgan failure.

*Previous contributions by Richard L. Walker (deceased) are acknowledged.

Epidemiology

Anthrax occurs worldwide. Frequency of outbreaks depends on geographic location. Some parts of the world (sub-Saharan Africa, central and south Asia) with high concentrations of spores in the soil are referred to as "anthrax zones." In the United States, anthrax occurs more frequently in certain states or geographic regions (e.g., Texas and the plains regions). Some areas with greater incidence of disease follow old cattle trails, which may have been the primary source for contaminating those environments.[8,9]

Environments favorable for anthrax spores include soils with elevated pH and concentrations of selected cations (Ca^{++}, Mn^{++}) and soils rich in organic material.[4] Droughts followed by heavy rainfall or flooding often precede outbreaks, as do earth-disturbing activities like excavations. Topography that favors collection of runoff and establishment of temporary water storage areas (seasonal ponds) may promote the concentration of spores.[8,9] Outbreaks usually occur during warmer months of the year.

Bites from bloodsucking insects can spread anthrax organisms from infected septicemic animals through mechanical transmission.[10] Scavenging animals can also disseminate organisms.[9] Carcasses of affected wildlife are an additional source for contaminating environments, because they are unlikely to be disposed of properly.

Clinical Presentation

Susceptibility to infection depends on the individual animal species and the route of infection (respiratory, GI, cutaneous).[11] Ruminants (cattle, sheep, and goats) are most susceptible to peracute infections, and clinical signs prior to death may not be observed. If present, nonspecific clinical signs include fever, depression, respiratory distress, congestion of mucous membranes, and convulsions.[12] In more protracted cases, bloody diarrhea, hematuria, and localized tissue swelling may be observed.

Horses develop an acute intestinal form. Associated clinical signs include colic, diarrhea, fever, and depression followed by a fatal septicemia. A more localized form, possibly initiated by insect transmission, typically involves massive edema in the neck region. A dependent edema may result, involving the thorax, abdomen, prepuce, or mammary gland.

Swine are less susceptible to infection. Oropharyngeal involvement with swelling of the head and neck is the most common presentation; edematous tissue may obstruct breathing and swallowing.[4] Cervical lymph nodes are prominently involved. An intestinal form may present as dysentery. Pregnant animals may abort.

Pathology

Animals that die of anthrax sometimes produce bloody exudates from body orifices and show incomplete rigor mortis. Blood often will not clot. Carcasses undergo rapid decomposition. If a carcass is opened, the spleen is frequently enlarged and has a "blackberry jam" consistency. Lymph nodes and internal organs may be edematous and hemorrhagic. Localized exposure may result in enteritis, regional lymph node involvement, or peripheral tissue edema.[12] Histologically, large numbers of bacilli are observed in affected tissues. Spleen and lymph node architectures are obscured by massive hemorrhages.

Diagnosis

Initially, anthrax may be confused with clostridial infections, lightning strikes, plant poisoning (e.g., oleander), other intoxications, or mineral deficiencies. To prevent sporulation of vegetative cells and further contamination of the environment, carcasses of animals suspected to have died of anthrax should not be opened. Definitive diagnosis is based on microscopic exam of blood or tissue smears and bacteriologic cultures performed in the laboratory, particularly for index cases. Samples that minimize potential for environmental contamination and maximize diagnostic accuracy include unclotted blood collected from superficial veins or ocular fluid collected in a sterile syringe using a large-gauge needle. An intact eye can also be removed and submitted to the laboratory for diagnostic evaluation. In the more localized form of anthrax, samples from regional lymph nodes may be required. Tissue samples containing normal bacterial flora (e.g., ear, skin, intestinal content) are not

VetBooks.ir

recommended for testing, because recovery of normal flora may obscure the presence of *B. anthracis* in culture. Anthrax carcasses undergo rapid putrefaction, and vegetative *B. anthracis* cells are destroyed during decomposition, so the time between death and sample collection can substantially affect the recovery rate of *B. anthracis*. To ensure specialized diagnostic and safety procedures are followed, always notify laboratory personnel whenever a case of anthrax is suspected. Gram stain of direct smears demonstrates typical large, gram-positive, squared-ended rods found singly or in chains of two to four cells. A polychrome methylene blue (M'Faydean) stain confirms the presence of the *B. anthracis* capsule surrounding organisms. Anthrax bacilli must be distinguished from postmortem invading clostridial species, which have more rounded ends and are acapsular when examined with M'Faydean stain. *B. anthracis* also stains well with other common laboratory stains, including Wright and Giemsa.

Isolation of *B. anthracis* is readily made on standard sheep blood agar. Many organisms grow on this media, so cultures of samples from sterile sites are more likely to identify *B. anthracis* if it is present. With a doubling time of 30 to 60 minutes, colonies are apparent after as little as 6 hours of incubation.[11] Typical *B. anthracis* colonies after 24 hours incubation are large, gray-white in color, have a rough, dry texture, and are usually nonhemolytic. Gram stains of young colonies show very long chains (10 or more cells) of large, square-ended, gram-positive rods often described as having the appearance of a row of "railway boxcars."

Verification of isolates as *B. anthracis* is based on lack of motility, lysis by a specific bacteriophage (gammaphage), protoplast formation in the presence of penicillin (string of pearls test), and confirmatory PCR.[13] Capsules are induced in culture by growing isolates on bicarbonate agar under an increased CO_2 atmosphere. Spores that are centrally located and do not cause the cells to bulge develop in cultures after approximately 48 hours of incubation. Care should be taken to prevent exposure to air and inadvertent spore dissemination from culture plates. Other available molecular- and antigen-based rapid screening tests are primarily used by first responders in potential bioterrorist events and to discriminate between vaccine and wild-type strains. Definitive diagnosis of a *B. anthracis* isolate must be made at a CDC Laboratory Response Network (LRN) confirmatory lab. All positive samples must be destroyed within 7 days of diagnosis.[14]

Treatment, Control, and Prevention Any suspected anthrax case should be reported to appropriate local or state veterinary regulatory officials as soon as possible. The peracute nature of many anthrax infections can make early intervention impossible and treatment unrewarding. Penicillin and tetracycline remain the drugs of choice for treating animals. Treatment should be continued for a minimum of 5 days. Rare *B. anthracis* strains resistant to these antibiotics have been reported.

Carcass management is critical in controlling anthrax outbreaks. Carcasses should not be opened or moved from the area where they are discovered and should be destroyed either by burning or deep burial. Burning carcasses is preferred to burial, because it is more effective at destroying spores, but may not be permitted in certain areas. Any contaminated bedding or soil should be handled similarly.

In the face of an outbreak, regulatory officials will likely quarantine affected premises. All potentially exposed animals should be closely observed for clinical signs of infection. Clinically normal animals should be vaccinated using a commercially available live acapsular vaccine (Sterne) strain (Anthrax Spore Vaccine [Colorado Serum Co., Denver, Colo.]). Prophylactic antibiotic treatment of unaffected herdmates is sometimes practiced, but concurrent use of the live, attenuated product with antibiotics may lessen effectiveness of the vaccine and should be undertaken only after consultation with local veterinary public health or regulatory officials. Vaccination of neighboring herds should be initiated to prevent new infections due to either exposure to similar predisposing environmental conditions or through spread from initial outbreak sources. Controlling insects and both avian and mammalian scavengers will aid in preventing dissemination to neighboring premises.[9]

Prophylactic vaccination of animals in endemic areas should be performed annually 4 weeks prior to turning animals onto pastures where outbreaks have occurred. A single dose of vaccine is given subcutaneously in the neck. In heavily contaminated areas, a second dose may be given 2 to 3 weeks later to enhance protection. Follow vaccine manufacturer's recommendations or local regulatory officials' instructions regarding postvaccination market withholding time for meat and discard time for milk. Localized swelling may occur at the site of vaccination. Goats and llamas may exhibit serious adverse reactions to the vaccine.

Insuring that pastures are of good quality so that grazing close to the soil is avoided will minimize exposure to spores. Avoiding rough feed that might traumatize mucosal surfaces will also decrease incidence rates. If possible, avoid grazing animals on highly contaminated pastures altogether and encourage alternate uses for the land.

Public Health Anthrax is a zoonotic disease. Humans develop three forms of anthrax: cutaneous, inhalational, and gastrointestinal.[4] Occurrence of the different forms depends on the route of exposure. Naturally acquired anthrax cases in humans in the United States are rare. When they occur, the cutaneous form is most common. Veterinarians are included among at-risk individuals because of the potential for contact with organisms while handling infected carcasses. If anthrax is suspected, proper personal protective equipment, including physical barriers (e.g., gloves) and respiratory protection, should be used when collecting diagnostic samples and during carcass disposal. Naturally acquired inhalational anthrax in humans is rare because of the relatively high LD_{50} (8000 to 10,000 spores) required for infection and because spores carry static charges. These charges result in spores binding to larger particles, making aerosolization of spores more difficult.[8] Contact with *B. anthracis* should always be taken seriously, and owners of affected animals should be advised to consult with their physician for advice on medical care.

Lyme Disease

Monica Aleman • John E. Madigan

Lyme disease, also known as *borreliosis,* is one of the most important arthropod-borne bacterial infections in the United States. It is caused by the spirochete *Borrelia burgdorferi* and affects humans, horses, dogs, and cats.[1-4] Because Lyme borreliosis was first identified as the causative agent of an epidemic of juvenile inflammatory arthritis in children and adults in Old Lyme, Lyme, and East Haddam, Connecticut,[5,6] medical references commonly cite "Lyme disease" when referring to *B. burgdorferi* infection.

Epizootiology *B. burgdorferi* is widely distributed in the northern hemisphere all over the world. Prevalence of infection or exposure in horses has been reported to be high in the northeastern United States (50%), Midwest, Texas, and California.[7] Lyme borreliosis has been extensively reported in Europe, England, the Soviet Union, China, Japan, Southeast Asia, and South Africa.[8] *B. burgdorferi* is transmitted from ticks to humans and animals by ticks belonging to the *Ixodes ricinus* complex.[9] These ticks each feed three times during the larval, nymphal, and adult stages.[5] The larvae and nymphs feed on wild animals, and adults are found most commonly on deer.[9] On the east coast, *Ixodes scapularis* ticks are the principle vector, whereas on the west coast *Ixodes pacificus,* the western black-legged tick, is the main vector identified.[10] *I. scapularis* is seen from the Atlantic coast to Oklahoma and Texas.[11] A much higher percentage of *I. scapularis* ticks (12% to 99%) will carry the spirochete compared with *I. pacificus,* in which the maximum number of infected ticks is 4% to 5%.[10,11] *I. scapularis* larval ticks principally acquire the

VetBooks.ir

spirochete from *Peromycus leucopus,* the white-footed mouse, and the nymphal stages are the major transmitters of disease to animals and humans.[12] With *I. pacificus,* the California kangaroo rat, *Dipodomys californicus,* and the dusky-footed wood rat, *Neotoma fusicipes,* are the likely enzootic reservoirs of *B. burgdorferi.*[13]

B. burgdorferi is found in many arthropods, but the major route of transmission to animals and humans is believed to be limited to *Ixodes* spp. ticks. Experimental studies have demonstrated that ticks may harbor and transmit several pathogens, the human granulocytic ehrlicheal agent, and *B. burgdorferi* at the same time.[14] Exposure to ticks infected with *B. burgdorferi* produced seroconversion without detectable histopathologic changes except for skin lesions in experimental horses.[15] *B. burgdorferi* is maintained in a 2-year enzootic cycle that involves *Ixodes* spp. ticks and mammals. Ticks are usually attached for at least 24 hours for *B. burgdorferi* transmission.[15] Birds are frequently infected with *B. burgdorferi* and may be responsible for disease spread to new areas.[9]

Public Health Considerations

The CDC initiated surveillance for Lyme disease in 1982, and in January 1991 it became nationally reportable. Cases have been reported from 46 states, and the annual number of Lyme disease cases has increased 18-fold, from 497 to 8803. It is now the most common tick-transmitted disease in the United States.

B. burgdorferi organisms have been recovered from the urine of feral white-footed mice *(P. leucopus).*[16] Contact transmission has been reported between white-footed mice,[16] further complicating the understanding of transmission. Lacking any proof to the contrary, it is generally believed that any potential increased risk to humans from infected animals is due to animals bringing ticks into areas of human habitation, rather than any animal transmission.[17]

Molecular Biology

Immunochemical analysis of North American strains of *B. burgdorferi* reveal two abundant surface proteins termed *outer surface protein A* (OspA, 30 to 32 kD) and *outer surface protein B* (OspB, 34 to 36 kD).[18] The 41-kD antigen is located on the flagellum and is similar to the flagellar antigens of other spirochetes.[19] All isolates to date have four to nine pieces of extrachromosomal plasmid DNA. Plasmid may code for proteins that are important in pathogenicity, because the loss of infectivity of isolates that have been heavily passaged in the laboratory correlates with the loss of particular plasmids in culture.[20] Recent work suggests that *B. burgdorferi,* like the relapsing fever–causing *Borrelia* (e.g., *Borrelia hermsii*), can vary its antigenicity, although by a different mechanism and using subtle alterations in the genome.[21]

Clinical Signs

EQUIDS. Clinical signs are nonspecific but may include low-grade fever, stiffness, lameness in more than one limb, muscle tenderness, hyperesthesia, swollen joints, and behavioral changes.[22,23] The most common signs are lameness and hyperesthesia. These signs have been more commonly reported in performance horses. *Borrelia* may be found concurrently with *A. phagocytophilum* in *Ixodes* ticks, resulting in dual infection in the horse.[14]

Horses from endemic areas have serologic evidence of exposure.[24-27] Attempts have been made to correlate individual cases of arthritis, uveitis, or brain infection with this organism.[26,28,29] Experimental infection has produced seroconversion and shedding of the organism in the urine and seroconversion in contact controls.[30] In the United Kingdom, most seropositive horses do not show clinical signs of disease.[31]

RUMINANTS. Although there are some reports in the literature of seropositive animals with arthritis, the evaluation performed on these patients makes it difficult to determine whether *B. burgdorferi* was the cause of the signs.[32] It appears many ruminants are seropositive to *B. burgdorferi* but do not have clinical signs. Whether these tests lack specificity in the ruminant or represent a host-adapted strain of the *Borrelia* organism is unknown.[33] A recent report correlates exposure of *I. scapularis* ticks in dairy cattle with titers to *B. burgdorferi.*[34] An attempt to develop a more specific test in cattle using the 41-kD flagellin antigen has been reported.[35]

Diagnosis

A number of diagnostic methods are available, including IFA, ELISA, indirect complement fixation, and Western blot.[29,32] Culture of the organism requires special media (BSK) and is difficult but may be possible from blood, urine, or cerebrospinal fluid. Diagnosis of recent or active *Borrelia* infection has been based on high ELISA titers (>300 kinetic ELISA [KELA] units), positive Western blot, or PCR.[36] In an experimental infection study, *I. scapularis* ticks infected with *B. burgdorferi* were placed in healthy ponies for 7 days. These ponies developed detectable antibody at 5 to 6 weeks.[36] KELA units were elevated at 3 to 4 months post exposure and remained elevated for several months until euthanasia. Western blot became positive at 10 to 12 weeks post exposure.[36] Throughout the duration of the study, the organism was isolated from the skin where infected ticks were attached. Histopathologic examination revealed lymphohistiocytic nodules in the dermis, lymph node enlargement, and perivascular and perineural lymphocytic infiltrates in the skin, fascia, and perisynovial membranes. PCR was useful for detecting organisms in the skin, lymph nodes, skeletal muscle, fascia, and synovial membranes. Less commonly, organisms were detected in the heart, pericardium, kidney, bladder, and meninges.[36] More recently, detection of serum antibodies to *B. burgdorferi* in horses was improved (84% detection) by using an ELISA based on whole-cell and recombinant antigens.[37]

Treatment

Antibiotic susceptibility of *B. burgdorferi* has been reported but may lack appropriate standardization.[38] *B. burgdorferi* is sensitive to tetracycline and moderately sensitive to penicillin. Amoxicillin, ceftriaxone, and imipenem are highly active against *B. burgdorferi.* Aminoglycosides, ciprofloxacin, and rifampin lack activity.[39] Doxycycline twice daily in humans has been frequently used. Probenecid and ampicillin or amoxicillin also have been used.[38] When CNS involvement is present, ceftriaxone or IV penicillin G has been used. The appropriate duration of therapy is unknown but is related to the stage of infection.

Three different antimicrobials that included ceftiofur sodium (2.2 mg/kg/day IM), doxycycline (10 mg/kg/day PO), and tetracycline (5 mg/kg/day IV) were used for a 28-day period in experimentally infected ponies.[40] High KELA titers and *B. burgdorferi* isolation from skin biopsies confirmed infection. Antimicrobial therapy was initiated 3 months post exposure. Tetracycline was the most effective antimicrobial; it decreased KELA antibody titers (<110 units) during and months after treatment, and bacterial isolation became negative in tissues. However, tissues were still positive for the spirochete on PCR.[40] The efficacy on decreasing titers of tetracycline in the clinical setting has not been highly successful.[41] Proposed treatment for *Borrelia* infection includes tetracycline (6.6 mg/kg IV q12h), doxycycline (10 mg/kg PO q12h), or ceftiofur (2.2 mg/kg IM q12h) for 3 to 4 weeks.[36]

A recombinant outer surface protein A (rOspA) subunit vaccine was shown to be effective in preventing infection in challenged horses with infected ticks.[14,42] Specific recommendations for its use in the clinical setting are lacking.

Tularemia

Bradford P. Smith

Tularemia, an infectious disease of humans, wild animals, livestock, and pets throughout the northern hemisphere, is caused by *Francisella (Pasteurella) tularensis.* There are four major subspecies: *tularensis, holarctica, mediaasiatica*, and *novicida*, with *tularensis* being the most virulent.[1] The organism is a facultative, intracellular, non–spore-forming, gram-negative coccobacillus that survives frozen or in mud and water for a period longer than 1 year,[2] but it only survives for hours in carcasses. The natural hosts are rabbits and rodents, and

VetBooks.ir

transmission to livestock occurs chiefly through ticks, fleas, deerflies, and other insects.[3] Sheep are the most frequently affected livestock species, along with dogs, cats, and humans. Massive epidemics with high mortality in range sheep have been reported.[3] One paper describes three late-term abortion outbreaks, with one also including sick/dead ewes, between 1997 and 2007 in Wyoming and South Dakota.[4]

Humans are stricken with a plague-like illness when bitten by infected ticks, fleas, or insects and from handling infected rabbits or other infected animal carcasses.[5] The disease has also been called *rabbit fever, deer fly fever,* and *meat cutter's disease.*[6] Sheep shearers may become infected by bites of parasites from the sheep. Disease in horses has also been documented.[7] Oral infection from contaminated water occurs, so fresh water should be provided.[3]

The disease causes an acute septicemia, with localization and granulomatous lesions in the organs (particularly the liver and spleen). Signs are very nonspecific, as expected with bacteremia, and include fever, anorexia, lethargy, and in some cases cough, rapid respiration, or diarrhea. Stiffness and edema of the limbs may be seen. The course of disease is usually 2 to 14 days.

Agglutination titers in recovered affected sheep range from 40 to 5000. Agglutination titers persist for very short periods (21 days) in horses,[3] probably because they measure mainly IgM. Diagnosis is based on culture of the organism from blood or organs. Samples must be specially handled and tests done in BSL-3 laboratories.[6] Diagnosis can also be made by IFA testing or PCR[8] or ELISA.[6]

Necropsy usually reveals ticks on the carcass. Often, reddened or necrotic areas appear in and under the skin at the site of infected bites. Regional lymph nodes may be swollen and congested. Congestion and edema of the lungs are common. Fetal lesions from abortions have multifocal pinpoint necrosis of the liver, spleen, and lung.[4] Differentials include other bacteremias such as *Mannheimia (Pasteurella) haemolytica* in sheep, *Histophilus somni* (formerly *Haemophilus somnus*) in cattle, *Mycoplasma mycoides* subsp. *mycoides* in goats, and anthrax in all livestock. Treatment early in the course of infection is effective. Aminoglycosides, tetracyclines, cephalosporins, chloramphenicol, or quinolones all are probably beneficial initially until results of antimicrobial susceptibility testing are available. Insecticide removal of ticks from affected animals and herdmates is important. No vaccine is currently available, so insect and tick control in endemic areas remains the major prevention. Because oral infection from contaminated water has also been documented, fresh water should be provided.

Corynebacterium pseudotuberculosis Infection

Monica Aleman • Sharon Jane Spier

Definition

Corynebacterium pseudotuberculosis infections occur worldwide and cause external and internal caseous lymphadenitis in sheep and goats; cutaneous excoriated granulomas and mastitic, visceral, or mixed infection in cattle; and ulcerative lymphangitis and external and internal abscesses in horses.[1-4] Subacute to chronic lymphadenitis and pneumonia have been reported in humans handling infected sheep.[5,6] Several zebras in the United States developed severe or multiple internal abscesses and died weeks after being exposed to horses in California.[7] There have been reports of the disease in camels, alpacas, and buffalo.[8,9]

Microbiology

C. pseudotuberculosis infection is caused by a 2-µm gram-positive, intracellular, nonmotile, pleomorphic, rod-shaped facultative anaerobe.[10] *C. pseudotuberculosis* grows well at 37°C on blood agar in 24 to 48 hours, and it forms small, pinpoint in diameter, whitish, opaque colonies that are surrounded by a weak zone of hemolysis. Because of the high lipid content in the bacterial cell wall, particularly corynomycolic acid, the colonies spatter in a flame pushed across the agar surface.[11] High lipid content may facilitate survival of the organism in macrophages.[12] Two species-specific biotypes of *C. pseudotuberculosis* have been identified based on differences in nitrate reduction[5] and DNA fingerprinting techniques.[11,13,14] Strains isolated from small ruminants are nitrate negative, strains from horses are nitrate positive (except for two horses that were nitrate negative), and both strains have been isolated from cattle.[1,5,13,15] From the results of DNA studies, the terms *biovar equi* for nitrate-positive and *biovar ovis* for nitrate-negative strains were proposed.[11] Recent studies revealed that there is more heterogeneity of the isolates of *C. pseudotuberculosis* from small ruminants and from horses[13,14,16] and concluded that nitrate reduction may not absolutely distinguish between the isolates, as does ribotyping.[13] On the basis of ribotyping, sheep and goats have specific isolates throughout the world, and horses and cattle have two distinct groups of isolates depending on geographic location, one from the United States and the other from South Africa and Kenya.[13] Natural cross-species transmission does not seem to occur.

C. pseudotuberculosis produces various exotoxins: phospholipase D (PLD), sphingomyelinase, inhibitory factor of staphylococcal β-hemolysin, hemolysis factor, dermanecrotoxins, and mouse lethality toxins.[17] Phospholipase D and sphingomyelinase are important in the pathogenesis of the disease, because they hydrolyze lysophosphatidylcholine and sphingomyelin, respectively, enabling degradation of the endothelial cell wall and increasing vascular permeability.[18] The synergistic activity of sphingomyelinase with the exotoxin of *Rhodococcus equi* in lysing red blood cells in agar forms the basis for the synergistic hemolysis inhibition (SHI) test.[19]

Molecular characterization of *C. pseudotuberculosis* isolates from four different states (California, Colorado, Kentucky, and Utah) was determined by random amplified polymorphic DNA (RAPD) PCR.[20] The identity of *C. pseudotuberculosis* in these isolates was confirmed by the presence of the gene encoding the PLD toxin by PCR. Ten distinct genotypes (I to X) were identified. Types IV to VIII and X were isolated only from horses, whereas types III and IX were isolated from horses and cattle. This study also found differences in genotypes among states as follows: California (III, IV, V, VI, IX, X), Colorado (III, VI, VII, IX, X), Kentucky (III, IV, V, VI, VIII), and Utah (III). In horses, types III, VI, and X were isolated from internal abscesses from California and Kentucky; types III to VI and VIII to X were isolated from external abscesses from one or more states.[20] More recently, the complete genome of *C. pseudotuberculosis* causing an abscess in a horse was reported.[21]

Clinical Signs and Differential Diagnosis

SHEEP AND GOATS. *C. pseudotuberculosis* causes caseous lymphadenitis (CLA) in sheep and goats worldwide. Caseous lymphadenitis is a major cause of poor production, premature culling, and mortality. There are two forms of CLA: external and internal abscesses.[22] The infection in small ruminants is primarily characterized by suppuration and necrosis of the large superficial lymph nodes. External abscesses are found more commonly involving the mandibular, parotid, prefemoral, or prescapular lymph nodes. The exudate present in those abscesses is thick or inspissated and may appear white in sheep and greenish in goats.[4] A breed association with the type of CLA cutaneous lesion was observed in an outbreak in a commercial ram stud in Scotland.[23] The disease is commonly known as "cheesy gland" in Australia. Differential diagnosis should include abscesses caused by other organisms, trauma, seroma, hematoma, foreign body, injection reaction, and less commonly, tumors. *C. pseudotuberculosis* infection represents a major herd health problem, so abscess culture to determine the precise causative agent is important. Mastitis occasionally develops.[2]

Internal abscesses can be found in the lungs, kidneys, and mediastinal, bronchial, mesenteric, and lumbar lymph nodes.[22] Chronic weight loss is the most common presenting complaint. Other clinical signs are related to the organ or tissues affected. Other diagnostic procedures may be necessary for the differentiation of internal abscesses as the cause of weight loss. Signs of spinal cord compression by vertebral abscesses have been seen in lambs born in unsanitary

VetBooks.ir

conditions.[4] Knowledge of the local prevalence can aid diagnosis of the infection when uncommon anatomic locations are affected. The prevalence in large breeding operations in endemic areas is estimated to be between 5% and 10%.

CATTLE. *C. pseudotuberculosis* infection in cattle occurs as a herd problem with sporadic incidence. The most common clinical form affecting cattle is cutaneous excoriated granulomas; other forms are mastitis, visceral, and mixed infections.[2] In the most common form, the lesions do not occur as abscesses but as ulcerative, exuding granulomatous lesions as large as 20 cm in diameter, with necrotic areas that are easily surgically removed, leaving granulation tissue underneath.[3,4] Lesions are usually located in the lateral exposed areas of the body: face, neck, thorax, and flanks. The exudate varies from bloody to thick greenish in color. Lesions heal spontaneously in 2 to 4 weeks and do not appear to cause significant illness or decrease milk production in cattle in California.[4] However, monthly milk production was decreased by 6% in Israeli cattle.[3] The prevalence of the infection has been reported to be up to 10% in California dairies.[4] Morbidity was reported to be up to 35% in Israeli herds.[3] Management problems like broken posts or exposed wires traumatize the skin of cattle, allowing penetration of the organism. Young cattle appeared to be less susceptible to the disease than older cattle in Israel.[3] Differential diagnoses include trauma, foreign body, and other masses like tumors. Cutaneous lesions and mastitis were seen in 6%, and cutaneous lesions with concurrent visceral involvement in 1.6% of the Israeli cases.[3] The rest of the cows (92%) only had the cutaneous form.[3] The most affected organ in the visceral form was the lung.[3] The infection has been reported in bison from Egypt, resulting in severe emaciation and edema in the ventral areas and flanks.[24]

CAMELS AND CAMELIDS. Caseous lymphadenitis has been reported in alpacas in South America.[25] A recent study documented five young alpacas (aged 22 days to 14 months old) in North America with caseous lymphadenitis or subcutaneous abscesses that developed during late summer and early fall.[9] The alpacas did not appear clinically ill but developed swellings that progressed to abscesses. The abscesses (1 to 3 per alpaca) were located in the submandibular and cervical areas, and in one case adjacent to the eye. Abscess excision appeared to be the most effective treatment in those cases. Differential diagnoses include abscesses caused by *Streptococcus* spp., *Corynebacterium* spp., and *A. pyogenes*.[26] Severe lymphadenitis was reported in camels in Asia.[8] A study of experimental infection of adult alpacas resulted in abscesses at the inoculation site and renal lymph nodes.[27]

HORSES. Three forms have been described in horses: ulcerative lymphangitis and external and internal abscesses. In a previous study of *C. pseudotuberculosis* infection in horses from California, ulcerative lymphangitis was diagnosed in 1%, external abscesses in 91%, and internal abscesses in 8% of the cases.[28] There appears to be no breed or sex predilection for development of infection. Ulcerative lymphangitis appears as a severe cellulitis, where the lymphatics are affected in one or more limbs, with multiple draining ulcerative lesions. Horses often develop a non–weight bearing lameness, fever, lethargy, and anorexia. This form of the disease occurs worldwide and often becomes chronic, resulting in limb edema, lameness, weakness, and weight loss.[4] The differential diagnosis should include blunt trauma, fracture, foreign body, puncture wounds, nonseptic cellulitis, staphylococcal cellulitis, and other septic cellulitis. Musculoskeletal infection can result in marked lameness (grade 4 to 5 out of 5) and most commonly involves the axillary and triceps areas, followed by the stifle area.[29] Besides diffuse lymphangitis of the limbs, it can also cause osteomyelitis and septic arthritis.[28,29]

The median age for horses with external abscesses is 5 years (range, 3 months to 28 years).[28] Young horses appear to be predisposed to infection; 52% of the cases in a large retrospective study were 5 years old or younger.[28] Few cases involved foals younger than 6 months of age, suggesting that foals born to mares in endemic areas may be protected for several months by colostral antibodies.[28] External abscesses located primarily in the pectoral and ventral abdominal regions are common in geographically restricted areas of the western United States (Texas, New Mexico, Nevada, California) and Brazil.[1,4,28,30] However, the infection has been diagnosed in other states, such as Arizona, Colorado, Kentucky, Utah, and Wyoming.[20,31] This form of infection is commonly known as "pigeon fever" because of the large size of pectoral abscesses, giving the appearance of a pigeon's breast. "Dryland distemper" is another name that reflects its geographical distribution primarily in arid areas. Other common anatomic locations are the prepuce, mammary gland, axilla, inguinal region, limbs, and head.[28] Abscesses involving the head include the ears, eyelids, forehead, maxillary, and mandibular regions.[28] Severe facial suppurative cellulitis and panniculitis with skin sloughing have also been reported.[32] Other less common areas are the thorax, neck, parotid gland, guttural pouches, larynx, flanks, umbilicus, tail, and rectum.[28] CNS infection has also been reported.[28,33] A large area of edema develops in the area of abscess formation. While the abscess matures, the area becomes hard and painful, and some get very large, particularly in the pectoral area. These abscesses typically have a thick capsule measuring up to 10 cm, and can cause severe lameness if located in the axillary or inguinal region.[1,28] Maturation can be slow and drainage difficult to establish if the abscess lies deep to muscle. Once drainage is established by spontaneous rupture or lancing, the majority of cases resolve within 10 to 14 days without complications. Abscesses may contain from 5 to 400 mL of thick, tan, purulent exudate.[1] The majority of affected horses present with a single abscess rather than multiple abscesses.[28] Fever up to 40° C develops in about 25% of cases. Other signs are nonhealing wounds, lameness, ventral dermatitis, and (less commonly) depression, anorexia, mastitis, and other problems, depending on abscess location.[28] In the majority of horses (91.4%), complete recovery occurred, with no recurrence of infection in subsequent years, implying a long-lasting immunity. However, 8.6% of the horses' infections persisted for longer than 1 year or recurred as external or internal abscesses.[28] In sheep and goats, humoral and cellular immune responses develop following infection, and macrophages acquire the ability to kill the organism.[6] The case fatality for horses with external abscesses is very low (0.8%).[28] The differential diagnosis for external abscess, particularly pectoral, should include trauma, seroma, hematoma, foreign body, or abscess due to a different organism.

In a large retrospective study of *C. pseudotuberculosis* infection in the horse, 8% of 538 horses developed internal abscesses.[28] In two different studies, almost half to 63% of horses that had internal abscesses also had concurrent (or a history of) external abscesses.[28,34] In a study of 30 horses with internal abscesses, a female predilection (70%) was apparent.[34] Mean age is 8 years, with a range of 10 months to 23 years.[28,34] The most common clinical signs are anorexia, lethargy, fever (up to 41.1° C), tachycardia, and weight loss. Other signs are colic, pale mucous membranes, ventral and/or limb edema, ventral dermatitis, ataxia, hematuria, nasal discharge, and abortion.[28] The most commonly affected anatomic location is the liver, followed by mesentery, mediastinum, lungs, kidneys, diaphragm, spleen, pericardium, blood, and uterus.[1,28,34] A postmortem examination was performed on an aborted fetus from a mare with pneumonia and revealed *C. pseudotuberculosis* abscesses in the liver, lungs, spleen, diaphragm, kidney, and bladder.[34] Bacteremia may also occur. Both single and multiple organ involvement have been documented.[34] The case fatality for horses with internal abscesses ranges from 30% to 40%.[28,34] The differential diagnosis should include other types of abscesses, such as *Streptococcus, Actinomyces, Staphylococcus, R. equi* in foals, *Coccidioides immitis,* anaerobes, neoplasia, and other causes of weight loss. The clinical signs and differential diagnosis will depend on the location of the abscess.

HUMANS. Human infection may result from consumption of unpasteurized infected milk or milk products, continued close contact with infected animals, handling contaminated equipment,

VetBooks.ir

and exposure to wounds with exudates.[6,35] Human infection has been reported from strains of small ruminants.[6] Transmission from horses to humans has not been reported, but precautions should be taken when handling infected horses. Infection in humans occurs as a subacute to chronic lymphadenitis and pneumonia.[6]

Clinical Pathology and Laboratory Diagnosis Common findings include anemia of chronic disease.[28,29,34] Leukocytosis with neutrophilia and elevated fibrinogen are common features of developing bacterial infections, particularly in the case of internal abscesses.[28,29,34] Leukocytosis with neutrophilia was seen in 36% and 76% of horses with external and internal abscesses, respectively.[28] Hyperproteinemia due to increased globulins was observed in 38% and 59% of horses with external and internal abscesses, respectively.[28] Similarly, infected cattle and small ruminants had increases in white cell counts.[2,3]

Peritoneal fluid from 93% of horses with abdominal abscesses was abnormal.[28] The remaining horses with abdominal abscesses and normal peritoneal fluid had abscesses located retroperitoneally in the kidneys, without involvement of other abdominal structures. *C. pseudotuberculosis* was isolated in 32% of the samples of peritoneal fluid.[28] Failure to isolate the organism from peritoneal fluid does not rule out the disease. The organisms could be located retroperitoneally, sequestered within a thick capsule, or suppressed by local factors or nucleated cells.[36]

The ELISA test for detection of cell wall antigens is somewhat inaccurate in horses.[4,17] It appears to be more useful for detecting infection in sheep.[37-40] The synergistic hemolysis inhibition (SHI) test measures IgG response to exotoxin in the patient's serum by detecting the highest dilution that will prevent hemolysis of *R. equi* exotoxin–sensitized bovine red cells when mixed with *C. pseudotuberculosis* exotoxin of a known concentration.[19,41] The IgG response to the exotoxin depends on the chronicity and severity of the infection and antibody availability.[4] It has been reported that a serum antibody titer of 1:128 indicates exposure, while 1:512 or higher indicates the presence of infection.[4] Studies in goats have demonstrated that most animals have serum antibody titers that correlate with bacterial culture results.[42] The SHI test can be used in sheep and goats to monitor prevalence and exposure of incoming animals and to detect subclinical infections.[4,41] Only 40% of horses with external abscesses (infection confirmed by culture) had serum antibody titers over 256. However, a low SHI titer does not rule out the disease. Possible reasons for lack of titers include acute onset of infection and rapid maturation of the abscess prior to developing an Ig response, presence of a thick capsule isolating the organisms and preventing a serologic response, consumption of antibody during active infection, or horses with compromised immune systems.[4,28] Many horses that are seronegative at the time an external abscess is drained seroconvert later. In contrast, almost all horses with confirmed *C. pseudotuberculosis* internal abscesses have SHI titers of 512 and higher.[28,34] The high titers in horses with internal abscesses probably reflect the chronicity of the disease and the resulting prolonged immune stimulation. However, high titers can be seen with both internal and external abscesses.[28,34,43] Further, in the presence of external abscesses, an SHI titer higher than 512 may not necessarily indicate internal infection.[43] Exposed herdmates can also have SHI titers in the absence of clinical infection. Prolonged seropositivity has been observed in horses and goats.[28,41,44] Other serodiagnostic tests used in sheep and goats are tube agglutination, complement fixation, and gel immunodiffusion.[17,45]

A presumptive diagnosis can be made based on history, local prevalence, time of year, clinical signs, and exudate characteristics.[4] For the diagnosis of internal abscesses, the previous features must be considered as well as the presence of an inflammatory leukogram with elevated fibrinogen, serum chemistry abnormalities, abnormal peritoneal fluid or transtracheal wash, positive blood culture, SHI titer of 512 or higher, and ultrasonographic and/or radiographic evidence of masses.[28,34] A definitive diagnosis is established by isolating the organism from abscesses or draining wounds. The organism is readily isolated and grows well in blood agar in 24 to 48 hours, even when contaminant bacteria are present.[28]

Pathophysiology and Epidemiology *C. pseudotuberculosis* is a soil-borne organism that survives for long periods of time, months to years, even in direct sunlight at environmental temperatures.[6,46,47] The incidence of infection in horses varies considerably from year to year. External and internal abscesses in horses can present at any time of the year, but are more commonly observed during the fall and early winter months, with the highest incidence in September, October, and November.[28] However, internal infections are more frequently seen in November through January, 1 to 2 months following the peak number of cases with external abscesses.[34] The largest numbers of equine cases have been observed during the dry months of the year, following heavy rainfall, which may result in optimal breeding conditions for insects.[1,28,30] The seasonal incidence in horses has been associated with the presence of biting insects like *Haematobia irritans* (horn fly); this insect's feeding pattern causes ventral midline dermatitis. Insect vectors involved in transmission of disease in horses (e.g., *H. irritans, Stomoxys calcitrans, Musca domestica*) were identified by detecting the PLD exotoxin gene of *C. pseudotuberculosis* in an endemic area.[48] Results of a recent study suggest the disease could be transmitted by horse-to-horse contact, vectors, or contaminated soil.[49] Temporal and spatial analysis indicated an incubation period of 3 to 4 weeks in horses.[50] There is no breed or sex predilection.[28] However, a retrospective study indicated a predilection for internal abscesses in females.[34] A case-control study in an endemic area revealed young adult horses (<5 years of age) had increased risk of infection.[49] Horses housed outside or with access to an outside paddock or in contact with other horses on pasture appeared to be at higher risk than stabled horses.[49]

The disease in cattle from Israel occurred during the spring and summer dry season (March to October) when the housefly population is high.[3] *C. pseudotuberculosis* was isolated from houseflies collected over an Israeli cow lesion.[51] The infection in cattle may spread by direct contact or indirectly by houseflies or fomites.[3] The disease in sheep and goats is not seasonal, and transmission is through contact of exudate from a draining abscess from animal to animal or via contaminated equipment.[1] Lambs born in contaminated surroundings can be infected through the umbilicus, mouth, or inhalation.[4] Sheep that acquire the organism orally or from shearing wounds tend to have parotid, submandibular, prefemoral, or thoracic abscesses.[4] Goats can be infected when wounds are exposed to contaminated milking equipment. The incubation period is long and variable. In experimental infections in small ruminants, the incubation period was from 2 weeks to several months.

The pathogenesis of the disease in horses is unclear, but it has been speculated that the organism enters the equine host through skin or mucous membrane abrasions or wounds, as has been confirmed in sheep.[52,53] Experimentally induced infections in small ruminants revealed that once *C. pseudotuberculosis* gains access via wounds or abrasions, the organisms spread to subcutaneous or submucosal lymphatics, where they are phagocytosed by macrophages that migrate to the invasion site to engulf them.[54] The organism survives intracellularly because of its high lipid content (corynomycolic acid), resisting the action of lysosomal enzymes.[10,54] *C. pseudotuberculosis* replicates in the phagolysosome; if large numbers of organisms are engulfed, phagocytic cells die. Experimental inoculation of the organism in sheep revealed a massive infiltration with polymorphonuclear leukocytes,[55] which are believed to carry the bacteria to regional lymph nodes.[4] A PLD toxin of approximately 31.5 kD, produced by all *C. pseudotuberculosis* isolates, increases vascular permeability, causing spread of the organism regionally and systemically.[6,42,56] Development of abscesses at secondary locations in horses can occur in up to 25% of cases.[28] PLD toxin can cause lymphatic necrosis and thrombosis and may enhance survival and multiplication of the organism via complement depletion and inhibitory effects on phagocytic cells.[6] Corynomycolic acid and PLD toxin contribute to inflammation, edema, and pain during abscess development.[57] The profound

VetBooks.ir

reaction of these compounds is probably responsible for the formation a thick abscess capsule that develops as phagocytes accumulate in the abscess core. The abscess eventually matures and drains, but if removal of infected material is incomplete, recurrence may be expected, particularly in small ruminants.[4] The development of internal abscesses in horses is unclear but has been postulated to result from hematogenous or lymphatic spread of bacteria from more superficial sites.[4,28,34]

Treatment and Prognosis Important features to consider when treating external abscesses are to (1) allow the abscess to mature, (2) establish drainage, (3) collect and properly dispose of the infective exudate, and (4) lavage the wound with an antiseptic solution. In a retrospective study in horses, the majority of external abscesses were incised to establish drainage, then some received antimicrobials after drainage in an effort to decrease cellulitis.[28] Many horses received no treatment; abscesses broke and drained without clinical intervention.[28] Other horses were only treated with antimicrobials.[28] Outcomes were successful for 99% of horses with external abscesses.[28] Horses with abscesses in the axillary region or deep within muscles have considerable pain, necessitating incision and drainage. Ultrasound is useful for localization of deep abscesses.[34]

In one report, median resolution time for horses with external abscesses that did not receive antimicrobial therapy before abscess drainage was 18 days, versus 30 days for horses that received antimicrobials.[28] These data suggest that systemic antimicrobial therapy before abscess drainage in horses with external abscesses may prolong the disease course.[28] However, when abscesses recur, drainage and concurrent antimicrobials may improve the chance of resolution. Conversely, long-term (minimum 4 to 6 weeks) antimicrobial therapy is necessary for the treatment of internal abscesses and ulcerative lymphangitis. Median resolution time for horses with internal abscesses treated with antimicrobials was 36 to 42 days, with a maximum duration of 97 days.[28,34] The case fatality for horses with internal abscesses treated with antimicrobials was 30% to 40%, but 100% if not treated.[28,34] A study describing 35 horses with musculoskeletal infection reported surgical drainage in 60%, antiinflammatories in 97%, and antimicrobials in 86%.[29] In vitro, *C. pseudotuberculosis* is susceptible to nearly all commonly used antimicrobials, including penicillin, trimethoprim-sulfonamide, tetracyclines, cephalosporins, chloramphenicol, doxycycline, erythromycin, and rifampin.[58,59] Most isolates are resistant to nitrofurans, cycloheximide, and nalidixic acid.[59] Bacitracin has marked activity against the bacterium.[60] In selecting an antimicrobial, the following features must be considered: the intracellular location of the organism, presence of a thick abscess capsule and purulent exudate, the lengthy course of treatment that may be required (e.g., internal abscesses, persistent or recurrent external abscesses), risk of complications (e.g., diarrhea), and cost. Antimicrobial-associated diarrhea was seen in 6% of horses receiving antimicrobials for *C. pseudotuberculosis* infection in a retrospective study.[28] The antimicrobials associated with diarrhea included rifampin, trimethoprim-sulfas, and penicillin.[28] Additional therapies include marsupialization of internal abscesses if location allows. NSAIDs like phenylbutazone or flunixin meglumine may be used to control the pain and/or fever while waiting for external abscesses maturation.

The prognosis for external abscesses is good. Most resolve in 3 weeks from the day of drainage.[4] The prognosis for horses with internal abscesses and ulcerative lymphangitis is guarded but improves if infection is detected early and appropriate long-term therapy is administered. Horses with musculoskeletal infection tend to have a favorable prognosis, but osteomyelitis and septic arthritis can complicate recovery.[29]

In a study in cattle, skin lesions on individual cows healed (on average) in 23 days after local or parenteral treatment; 17% of severely affected cattle were culled.[3] Simple drainage in small ruminants does not usually result in resolution of the disease and can become a potential source of infection. Dilute iodine solutions can be used for abscess lavage. Complete excision of the abscess under general anesthesia may be necessary to keep the abscess from draining and prevent spread of the infection to other animals.[4] The treatment of choice in small ruminants is complete surgical removal of affected lymph nodes.

Prevention and Control Even though *C. pseudotuberculosis* infection is one of the most commonly diagnosed infectious diseases in California, little is known about its prevention and control. General recommendations to prevent its spread are isolation of infected animals, fly control, good sanitation, careful shearing practices, disinfection of contaminated fomites, and careful disposal of bedding. On small-ruminant farms, morbidity can reach 100%, with depopulation being the most economic option. Because *C. pseudotuberculosis* can survive in soil and fomites, the potential for environmental contamination is very high.[46,49]

Immunization trials utilizing whole cells, cell wall toxoids, and bacterin-toxoid combinations have been used to prevent CLA in small ruminants.[61-65] These vaccines have been shown to provide a high degree of protection, decreasing the number of infected sheep and the number of abscesses per sheep.[61-65] *C. pseudotuberculosis* toxoids are commercially available for sheep and goats (e.g., Caseous D-T [Colorado Serum Co., Denver, Colo.], Glanvac [Australia]). The use of autogenous bacterin-toxoid in horses resulted in fewer abscesses and less postchallenge pain in experimentally inoculated horses but did not reduce the incidence of infection on one farm, owing to the low prevalence of disease.[66] Use of an experimental bacterin-toxoid demonstrated increased SHI titers following two injections; however, the protection remains to be established.[67]

Diseases of the Bones, Joints, and Connective Tissues

ROBIN M. DABAREINER, *Consulting Editor*

Physitis (Epiphysitis)

A. Berkley Chesen

Definition and Etiology *Physitis* is a term used to describe a developmental orthopedic condition where there is a disturbance in endochondral ossification at the physis, or growth plate. Of the developmental orthopedic diseases (osteochondrosis, physitis, subchondral bone cysts, flexural limb deformities, cuboidal bone malformation, acquired angular limb deformities, and juvenile arthritis), physitis is the most common.[1,2] In one study of 1711 Irish Thoroughbred foals, 67% had signs of developmental orthopedic disease.[2] The term *physitis* may better be defined as physeal dysplasia, since there is typically no evidence of an inflammatory process.[3] Physitis due to copper deficiency and interactions with molybdenum, zinc, and sulfates, as well as in calves raised on slatted floors, has been seen in growing cattle.[4] Two common antagonists of copper include zinc, which when prevalent at high levels prevents absorption of copper by the body, and molybdenum, which is found in alfalfa.[5] Other animals in which physitis has been reported include show rams being heavily fed and sheep and goats with pregnancy-associated ephiphysitis.[4] Physitis typically affects the given physis during its active growth phases. Many factors have been implicated as causes of physitis in horses, including[4]:

1. A genetic component for faster-growing horses and for specific conformation (e.g., an upright pigeon-toed appearance)
2. Overweight foals
3. Growth spurts in foals
4. Intake of high levels of carbohydrates, causing hormonal changes affecting the physis
5. Improper mineral balance (e.g., copper or zinc deficiencies)
6. Excessive or deficient calcium intake
7. Excessive exercise, especially on hard ground, may cause strain on maturing cartilage

More recently, physitis has been implicated as a complication after treatment with a transphyseal screw for angular limb deformities in the distal radius. It was shown that the single transphyseal screw had a significantly higher complication rate of physitis when compared to the technique using screws and wires.[6]

Clinical Signs Physitis in horses is seen mainly in three specific locations at certain ages. Foals ranging in age from 3 to 6 months most commonly have signs of physitis at the distal metacarpal/metatarsal growth plate (with or without involvement of the proximal physis of the first phalanx).[7] Older foals (8 to 24 months) may have signs of physitis at the physis of the distal radius.[7] Less frequently, the distal physis of the tibia may be involved. Physitis is characterized by firm swellings that may be warm and painful upon palpation. Typically the swellings are medial and due to increased weight bearing on this portion of the limb.[7] Foals may or may not be lame. Radiographic changes include a sclerotic, roughened physis with an irregular metaphyseal shape.[2] If physitis continues, the growth plate may close prematurely, leading to an irreversible angular limb deformity (usually a varus deformity due to decreased growth on the medial physis).[2]

Diagnosis A diagnosis of physitis is usually made by appreciation of the clinical signs, including warm, sometimes painful, firm swellings in the locations mentioned. Physitis at the fetlock may appear to have an hourglass appearance if the proximal physis of the first phalanx is affected.[7] A convex appearance just proximal to the distal tibial and radial physis may be seen early in the disease process.[7] Recently a quantitative method for detecting physitis was investigated in Thoroughbred foals.[2] This method was based on the observation that when the physis is enlarged, both the metaphysis and ephiphysis are more concave.[8] Results of this study showed that epiphyseal concavity may indicate the degree of physeal swelling by using the maximum second-derivative value of that contour.[2] Radiographically, physitis is characterized by a growth plate that is irregularly thickened with sclerotic adjacent bone.[2]

Treatment and Prognosis Treatment of physitis should begin with management changes. Special attention should be given to the nutrition of these foals and weanlings. Ensuring a proper balance of minerals, especially calcium, phosphorus, and adequate amounts of trace minerals like copper and zinc, is necessary. Copper is required for successful cross-linking of collagen. When a copper deficiency exists, the cartilage matrix weakens and microfractures occur.[5] Because mare's milk is very low in copper, foals rely on hepatic stores gained during the last trimester of gestation.[5] One study showed that supplementation of mares with copper during gestation significantly reduced radiographic signs of physitis in their foals at 150 days of age.[9] Supplementation of foals did not affect the incidence of physitis in the same study. The results of this study strongly suggested that on farms with a high incidence of physitis, copper supplementation of mares during the second half of gestation may be beneficial in preventing physitis in their foals.[9] A general reduction in energy is necessary to slow growth rates and, when necessary,

VetBooks.ir

decrease body weight. Total concentrate for nursing foals should be 0.5 to 0.75 kg/100 kg body weight, 1 to 1.5 kg/100 kg for weanlings, and 0.5 to 1 kg/100 kg for yearlings.[9] Physitis involves varying degrees of discomfort. For horses with very painful, warm physes, judicious use of nonsteroidal antiinflammatory drugs (NSAIDS) is indicated. Exercise restriction—specifically stall rest—is indicated in affected horses. Without exercise restriction, these horses continue to load the physes, which may lead to permanent conformational changes like angular limb deformities. With early detection and treatment, the athletic prognosis for physitis is good.

Osteochondrosis

Jason C. Mez

Definition and Etiology Osteochondrosis is a developmental orthopedic disease characterized by failure of, or a defect in, endochondral ossification; it can lead to cartilage flaps, osteochondral fragments, or subchondral bone cysts. It is classified as a developmental orthopedic disease (DOD) along with physitis, angular limb deformities, subchondral bone cysts, flexural deformities, incomplete ossification of the cuboidal bones, and juvenile arthritis.[1] *Chondrodysplasia* and *dyschondroplasia* are more descriptive terms because they imply a primary defect in cartilage maturation, but their use is generally reserved for abnormalities of limb and vertebral development. The terms *osteochondrosis, osteochondritis,* and *osteochondritis dissecans* have all been used synonymously in discussing the condition. To maintain consistency and avoid confusion, the following designations are used here: *osteochondrosis* refers to the disease, *osteochondritis* refers to the synovial inflammatory response caused by the disease, and *osteochondritis dissecans* refers to the condition when a cartilaginous flap is identified.[2]

Osteochondrosis has been recognized in most domestic species, including horses, swine, and less often in cattle, sheep, and goats. The main focus has been in horses, owing to the economic impact and performance-limiting characteristics of the disease, and in swine, owing to effects on production traits[3] and development of comparative models for study of the disease.[4]

Clinical Signs and Differential Diagnosis Osteochondrosis can present with a variety of clinical signs that are frequently recognized in juvenile animals. Effusion of the affected joint with or without accompanying lameness is common. The tarsocrural and femoropatellar joints are most often affected, but the condition can be seen in any joint. In young animals, physitis (i.e., inflammation at the physeal plate) can have a similar appearance, with generalized enlargements adjacent to synovial structures. Osteomyelitis can cause a periosteal reaction that, if located in the area of a joint, can have a similar appearance. Septic arthritis can closely mimic the signs of osteochondrosis, but the associated lameness is often much more severe. Physitis, osteomyelitis, synovitis, and septic arthritis should all be considered in the differential diagnosis of osteochondrosis in juvenile animals. In older animals the clinician should consider synovitis, osteoarthritis, and trauma in the differential diagnosis.

Osteochondrosis is generally diagnosed in horses when they are started into training programs or begin athletic activity. They often present with a complaint of joint effusion that can be acute or insidious. Lameness is usually nonapparent to mild, except in cases with large osteochondral fragments or subchondral bone cysts. Severe cases seem to be more common in the stifle, and associated clinical signs may be present in foals as young as 6 months. Warmblood horses generally present later, at 3 to 4 years of age, because it is common practice to delay training until this stage.

Reports in cattle indicate that young, intact male, purebred animals are most often affected. The typical clinical signs are lameness with associated joint effusion. Osteochondrosis in swine has been associated with a syndrome known as "leg weakness." Affected animals can show a range of signs from mild lameness to inability to rise and inability or refusal to mount.[5] Evaluation of performance data from swine herds can be a useful indicator of osteochondrosis, because it has been shown to have a significant effect on production traits.[3,6] Being that production animals are usually slaughtered prior to 2 years of age, recognizable clinical signs of the disease in cattle and swine may only be apparent in breeding animals.

Sites of Predilection Osteochondrosis can be found in any diarthrodial joint, but sites of predilection exist in all species affected. In horses the stifle and hock are most frequently affected. In the stifle, in order of frequency, the lateral trochlear ridge of the femur, medial trochlear ridge of the femur, trochlear groove, and distal end of the patella are affected.[7] The medial femoral condyle is the site of predilection for subchondral cystic lesions. In the hock, in order of frequency, the distal intermediate ridge of the tibia, lateral trochlear ridge of the talus, and the medial malleolus are affected.[7] Predilection sites in cattle are similar to those in horses, with the hock and stifle most often affected and similar distribution in the joints.[8] Swine show a slightly different pattern, with the medial condyle of the humerus and femur most frequently affected.[6]

Diagnostic Tests Animals presenting with signs of joint effusion and lameness should undergo a thorough physical examination. A compete blood cell count (CBC) indicating a septic process, along with radiography, help differentiate osteomyelitis, septic physitis, or septic arthritis from osteochondrosis. In cases with any indication of a septic process, appropriate cultures should be taken. Horses should be observed in motion and given flexion tests, using local and intraarticular anesthesia to localize the site of lameness. Swine and cattle can be observed in their normal surroundings for signs of lameness. Once localized, the affected joint should be radiographed, as should the corresponding joint on the contralateral limb in the tarsocrural and femoropatellar joints, because lesions are often bilateral (Fig. 38-1). If lesions are detected in the metacarpophalangeal or metatarsophalangeal joint, the remaining three limbs should be radiographed because these can occur quadrilaterally.[9]

Lameness and effusion are more reliably seen in cases of osteochondritis dissecans and subchondral bone cysts than in osteochondrosis. Intraarticular anesthesia of the affected joint will alleviate the lameness, localizing the source. After the lameness has been localized, appropriate radiographs of both the affected area and the contralateral or quadrilateral limbs should be obtained (Fig. 38-2), as described previously.

Swine and cattle will often present with signs of lameness and mild joint effusion. Careful physical examination of the restrained animal should allow the affected area to be localized and appropriate radiographs to be obtained. As with equine patients, the lesions are rarely unilateral, and corresponding limbs should be radiographed. Reviewing production records of finishing or breeding swine herds may also be of diagnostic value, because osteochondrosis has been shown to cause significant reductions in performance and production traits.[3]

The manifestation of osteochondrosis may not be adequately represented by clinical signs and radiographs. Clinical signs of lameness and joint effusion have been shown to precede changes within the joint, and serial radiographs may be needed to diagnose the condition.[10] Radiographic abnormalities consistent with osteochondrosis of the distal intermediate ridge of the tibia and lateral trochlear ridge of the femur can return to a normal appearance by 5 and 8 months, respectively, in warmblood foals.[11] Radiographs often underrepresent the severity or size of the lesion seen at surgery.

Pathophysiology Endochondral ossification is the process of bone formation that begins with a cartilage scaffold arranged in zones that are gradually replaced by bone. It occurs at the articular/epiphyseal and metaphyseal growth plates and secondary centers of ossification, such as the carpal and tarsal bones. Directly beneath the articular cartilage is a zone of resting chondrocytes that divide to form the next zone, the proliferating chondrocytes. These

VetBooks.ir

FIG. 38-1 Osteochondrosis in the tarsocrural joint of a horse. Note the characteristic osteochondral fragments located at the distal intermediate ridge of the tibia.

FIG. 38-2 Osteochondrosis in the femorotibial joint of a horse. Note the large subchondral cystic lesion in the medial distal femoral condyle, a typical location for a bone cyst in the stifle.

proliferative cells divide rapidly, organizing into columns perpendicular to the long axis of growth. The cells progress to the hypertrophic zone, where they swell and become vacuolated, and the columns become more organized. The chondrocytes in this zone also become surrounded by increasing amounts of extracellular matrix, which becomes mineralized in the zone of calcification. These columns of chondrocytes are invaded by metaphyseal blood vessels supplying nutrients from below, and bone forms on these calcified cartilage columns, creating the primary spongiosa, which is subsequently remodeled into mature bone.

The exact pathogenesis of osteochondrosis is still undefined. The traditional theory is that the process of endochondral ossification is disrupted, resulting in areas of thickened cartilage. The deeper layers of these retained cartilage plugs do not receive adequate nutrients, and necrosis of the cells develops along with failure of proper ossification. These retained cartilage plugs have less structural integrity than normal cartilage and are prone to damage. Shear forces acting on the abnormal cartilage can lead to fissure formation. These fissures can then form dissecting cartilage flaps, free flaps, or fragments of cartilage and subchondral bone. When compressive forces predominate on an area of thickened cartilage, it can cause infolding of the cartilage plug. Normal endochondral ossification proceeds around the infolded plug, forming a subchondral bone cyst.

This traditional theory of defective endochondral ossification is still well accepted, but recent literature suggests this may be a simplistic view of a multifactorial condition. Limited reparative responses of bone and cartilage make it difficult to determine whether the origin of a lesion is developmental or traumatic. A recent report failed to distinguish articular cartilage differences in naturally occurring osteochondrosis versus healing osteochondral fragments.[12] Arthroscopic observations of normal-thickness cartilage defects and normal subchondral bone, as well as lesions occurring preferentially at single sites at the limits of articulation, suggest causative factors other than defective endochondral ossification.[9] The development and spontaneous regression of osteochondrosis lesions suggest that the condition is a dynamic process that can be affected by numerous intrinsic and extrinsic factors, and a "window of susceptibility" may exist whereby lesions are repaired and normal articular development proceeds.[13] These findings and observations suggest that multiple pathologic pathways exist and that a single etiologic explanation of osteochondrosis is unlikely.

Etiology

As with its pathophysiology, the exact etiology of osteochondrosis is unclear and likely multifactorial in origin. Several factors, including biomechanical forces, failure of vascularization, nutrition, growth rate, genetics, and hormones, have been implicated and are likely interrelated in the etiopathogenesis of the disease.

The consistent distribution of lesions at specific anatomic sites within the joint implicates trauma as a causative factor. The bilateral or quadrilateral nature of the disease would indicate that trauma or biomechanical stress is a necessary factor rather than direct cause. It has been established in pigs that microtrauma or disruption of the metaphyseal blood vessels supplying the developing cartilage canals causes ischemic necrosis, failure of mineralization, and a retained cartilage plug.[14] The same vascular pattern has been shown to be present in young foals, with the arterial supply crossing the ossification front from metaphyseal blood vessels to nourish the developing cartilage canals.[15-17] There is little doubt that failure of vascularization, resulting in ischemic necrosis of the cartilage canal and retention of a cartilage plug, plays a role in the development of osteochondrosis in both swine and horses.[18] To date, these mechanisms have not been studied in cattle.

VetBooks.ir

Nutritional influences have been extensively studied in relationship to osteochondrosis. Studies have focused mainly on dietary energy levels and mineral composition (copper and zinc). The growth rate of the animal is directly affected by energy intake as well as the genetic predisposition of the animal for growth and size. Animals fed high-energy levels for accelerated growth rates have a much higher incidence of osteochondrosis than those fed for lower rates of growth.[4,19,20] When looking at growth characteristics in pigs, it was shown that for every 100-g increase in average daily gain during the weaning and finishing period, a 20% increase in cartilage lesions or osteochondrosis in the humeral condyle occurred.[21] This is important when considering ration planning and growth rates of replacement animals, where longevity is a greater concern than in the production animal.

Low copper levels and increased zinc concentrations have both been implicated in the etiology of the disease. Low copper is thought to exert its effect through lysyl oxidase, a copper-dependent enzyme essential in the cross-linking of collagen molecules. Increased levels of zinc antagonize copper and could work indirectly through a similar mechanism. There is conflicting evidence on the causative nature of low copper levels, and lesions seen in copper-deficient animals do not always mimic those of naturally occurring osteochondrosis. More recently, evidence suggests that neonatal copper levels exert a positive effect on the resolution of osteochondrosis lesions but are not directly involved in the pathogenesis of the disease.[22]

Genetics have been shown to be at least partially responsible in the etiopathogenesis of osteochondrosis in different species. Landrace and Yorkshire breeds of swine show a high frequency of osteochondrosis, whereas domestic pigs crossed with wild hogs do not develop the disease.[4] Heritability has also been demonstrated in Standardbred trotters in the tibiotarsal and metacarpal/metatarsal phalangeal joints.[23,24] A genetic component is also likely interrelated with nutrition levels because an animal must have the genetic capacity for increased growth rate and size while on high planes of nutrition.

Alterations in hormone concentrations have been implicated in the etiology of osteochondrosis, but the mechanisms remain in question. Numerous hormones (e.g., insulin, somatotropin, thyroxine) are involved in the process of endochondral ossification. Physiologic or iatrogenic alterations of these hormones or their derivatives could theoretically lead to the development of osteochondrosis. The contribution of these factors to the etiology of osteochondrosis will likely not be elucidated until the molecular mechanisms of endochondral ossification are better understood.

The current focus of research has been on the molecular mechanisms involved in the development of the disease. Much has been published in this area, but no definitive conclusions have yet been reached. The exact molecular mechanisms of normal endochondral ossification are not yet fully understood, making comparison to a normal process difficult to impossible. Also, the reparative process in lesions begins almost immediately, and it was shown that there is no difference between tissue types in healing, naturally occurring osteochondrosis lesions compared to surgically created fragments.[12]

Treatment and Prognosis Treatment of osteochondrosis should take several factors into account: clinical signs; lesion severity; species, age, intended use, and relative value of the animal; and owner expectations. Treatment options include both nonsurgical and surgical management.

Nonsurgical management should consist of rest, controlled exercise, and dietary evaluation. Dietary mineral and carbohydrate levels should be evaluated carefully and any deficiency or excess corrected. Systemic NSAIDs and intraarticular medications like corticosteroids, hyaluronic acid, and polysulfated glycosaminoglycans (GAGs) can all be administered, but minimal clinical evidence exists to support their use. In food-producing animals the clinician must take into consideration that these are not approved treatments and that withdrawal times may not be established. Given the nature of the disease, nonsurgical management may provide a favorable outcome only in very young animals with regenerative capacity or in those with very mild lesions and minimal to no clinical signs.

Animals with osteochondritis dissecans are best treated with arthroscopic surgery. Cases with no radiographic evidence of degenerative joint disease (DJD) before surgery and minimal articular damage at arthroscopy carry a favorable prognosis. Animals that show radiographic evidence of DJD before surgery or considerable damage to the articular surfaces at arthroscopy carry a guarded prognosis. Arthroscopic approaches to the joints of cattle have been described, but the procedure is more difficult than in the horse.[8] In selected cases, reattachment of large cartilage flaps with absorbable poly-*p*-dioxanone pins may be warranted.[25] Dietary evaluation of surgical patients should be included and appropriate adjustments made.

Treatment of subchondral cystic lesions is still controversial, and many options are available. Nonsurgical management can be attempted and should consist of rest, controlled exercise, and intraarticular injection of corticosteroids along with hyaluronic acid or polysulfated GAGs. The prognosis is guarded except in cases with very narrow openings into the synovial cavity, and alternate treatments should be considered in refractory cases. Cysts can be treated with ultrasonographically or arthroscopically guided intralesional deposition of corticosteroids.

Arthroscopic guided injections into the fibrous lining of the cyst carries a 67% success rate in horses without preexisting secondary radiographic changes.[26] Arthroscopic débridement and curettage of the cystic lesion is another option with similar success rates, and horses younger than 3 years of age carry a better prognosis. Recent investigations show promise for arthroscopic débridement and curettage of lesions followed by packing the remaining defect with either a cancellous bone graft covered by a chondrocytic growth factor or with various bone substitutes, even in older horses and those with preexisting osteoarthritis.[25,27] Cysts located in the proximal interphalangeal joint (PIP) are generally unresponsive to conventional treatment, and arthrodesis of the joint offers the best prognosis.

Treatment of osteochondrosis in food animals is generally limited by the economic value of the animal. Show animals or valuable breeding animals may be treated by any of the methods described, and the surgical options will offer a better prognosis than nonsurgical treatment. In production herds, ration evaluation and genetic predisposition may be the only variables that can be addressed. Because production animals are slaughtered at an early age, treatment is generally unnecessary. A review of production records and estimates of monetary loss will indicate whether intervention is necessary in herd situations.

Angular Limb Deformities

Jeffrey P. Watkins

Definition, Etiology, and Clinical Signs Angular limb deformities are deviations in the axis of the forelimbs or hindlimbs in the frontal plane. *Valgus deformity* denotes a lateral deviation of the limb distal to the origin of the deformity; *varus deformity* denotes a medial deviation. The deformity is further described by naming the joint adjacent to the origin of the deformity; for example, *carpus valgus* describes an angular deformity arising in the carpal region, with lateral deviation of the metacarpus (knock-kneed conformation) (Fig. 38-3).

Angular limb deformities may be either congenital or acquired. In general, they are due to laxity of periarticular supporting structures, incomplete ossification, or asynchronous growth rate. Although the underlying cause of these abnormalities remains undefined, potential causes include intrauterine malpositioning, relative immaturity, hereditary predisposition, rapid growth, dietary imbalances, osteochondrosis, and trauma.[1-3]

Congenital angular deformities are frequently attributed to intrauterine malpositioning and laxity of periarticular supporting

VetBooks.ir

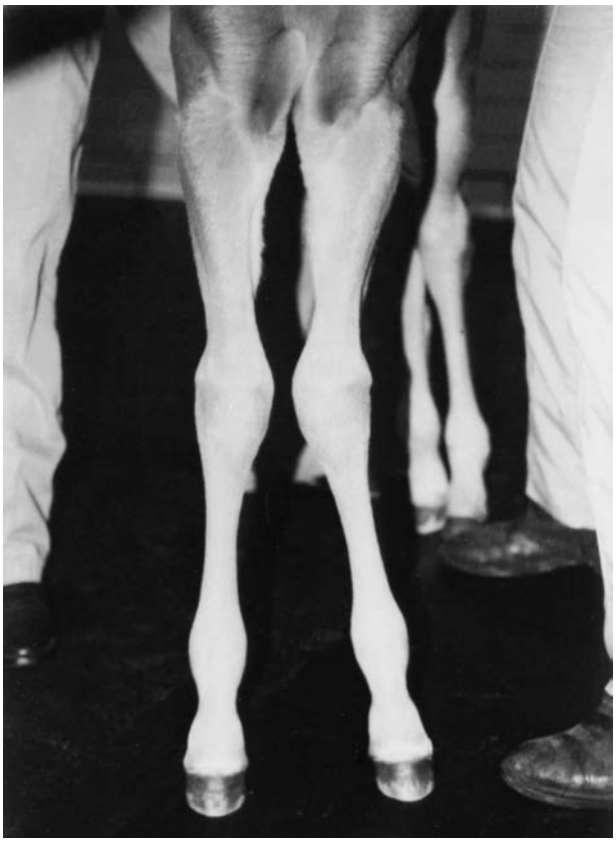

FIG. 38-3 Carpus valgus deviation.

structures. They typically originate in the region of the carpus and tarsus, resulting in bilateral valgus deformity. It is also common to identify a "windswept" foaling in which valgus deformity of one limb is accompanied by varus deformity of the contralateral limb. Acquired angular deformities usually occur secondary to asynchronous growth. A foal born with incomplete ossification may acquire an angular deformity secondary to crushing of the cartilaginous precursors of the cuboidal bones. A hereditary angular limb deformity of Suffolk, Suffolk crossbred, and Hampshire sheep is known as *spider lamb syndrome* (see later discussion).

Pathophysiology Incomplete ossification is an important cause of angular deformities originating at the carpus and tarsus. The epiphyses and cuboidal bones of the carpus (ulnar, third, and fourth carpal bones) and tarsus (central and third tarsal bones) are primarily affected.[1] Ossification of the cartilaginous precursors of these bones occurs in late gestation; prematurity or relative immaturity results in the birth of a foal before these precursors are completely ossified (Figs. 38-4 and 38-5). If laxity of the periarticular supporting structures accompanies incomplete ossification, the deformity is congenital and may progressively worsen with weight bearing. If laxity is not present, the foal may be born with straight legs and later acquire an angular deformity after deformation of the precursors of the cuboidal bones during weight-bearing activity.

Foals can acquire an angular limb deformity as a result of asynchronous growth at the metaphyseal and epiphyseal growth cartilages.[2,3] An important cause of asynchronous growth is trauma to a portion of the growth cartilage of the physis.[4] In many foals this trauma is in the form of nonphysiologic compression of the growth cartilage. Excessive exercise in foals with mild angulation and normal activity in foals with moderate to severe preexisting angular deformity may cause sufficient trauma to the growth cartilage to cause progressive deformity.

Asymmetric loading also occurs when severe lameness is present. With the change from a rectangular stance with four weight-bearing limbs to a triangular stance with three weight-bearing limbs, asymmetric, nonphysiologic loading of the weight-bearing limb occurs, which predisposes it to developing an angular deformity. Because compressive forces are concentrated along the medial aspect of the growth cartilages, a varus deformity usually develops in the overloaded limb. Abnormalities of the growth cartilage that affect ossification (e.g., osteochondrosis) may also be responsible for angular deformities caused by asynchronous growth. Foals with a predisposition for rapid growth or those exposed to nutritional imbalances appear to be at greatest risk for developing the disease. Rapid growth may also result in a foal with a large body size disproportionate to its skeletal structures. This condition may cause increased compressive forces, nonphysiologic loading of the growth cartilages, and angular deformity.[4]

FIG. 38-4 Premature foal with incomplete ossification of the cuboidal carpal bones, showing marked bilateral carpal valgus.

Ruminants raised in confinement may experience endochondral dysplasia and angular limb deformities if dietary iron is high or dietary vitamin D is low[5] (rickets). Elevated dietary iron results in elevations in serum phosphorus, which may in turn inhibit 1,25-dihydroxycholecalciferol synthesis by the kidney, resulting in rickets.[5] Pregnancy-associated epiphysitis in primiparous dairy goats[6] can also result in angular limb deformities.

Evaluation and Radiographic Findings When evaluating a foal with an angular deformity, important historical information includes age, onset and progression of the deformity, and intended use of the foal. The foal should be observed carefully while standing and walking to characterize the degree of deformity and

VetBooks.ir

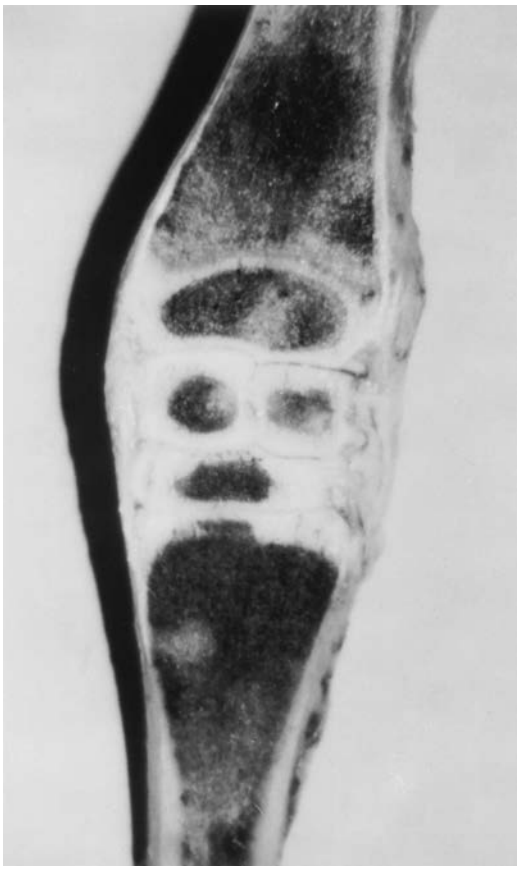

FIG. 38-5 Specimen from a foreleg of the premature foal in Fig. 38-4, cut in the frontal plane. Note the thick cartilage surrounding the centers of ossification of the cuboidal bones of the carpus.

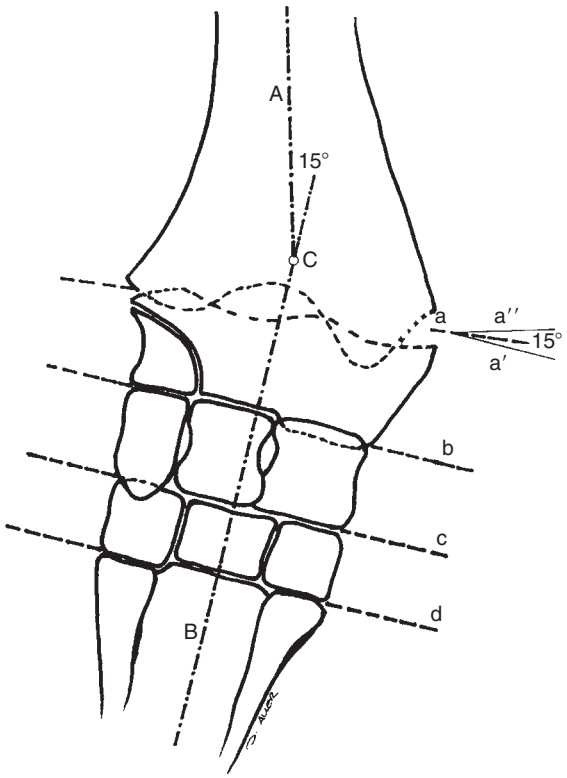

FIG. 38-6 Two methods for geometric evaluation of an angular deformity at the carpus. Lines A and B are drawn through the long axis of the radius and metacarpus, respectively. The angle of incidence is 15 degrees. Lines a, b, c, and d are drawn through the distal radius physis, antebrachiocarpal (radiocarpal), middle, and carpometacarpal joints, respectively. Line a′ is drawn parallel to line b, and line a″ is perpendicular to A. Their angle of incidence is 15 degrees. *(Reprinted with permission from Compend Contin Educ Pract Vet 4:S330, 1982.)*

determine the presence of compensatory problems or lameness. Physical examination includes careful palpation of the affected limb and a determination of whether the deformity can be corrected by manual manipulation of the limb. If the foal is examined before ossification has progressed, deformities resulting from laxity of periarticular supporting structures and incomplete ossification can be corrected manually. On the other hand, if deformities in foals born with incomplete ossification are left untreated and the cuboidal bones are in a collapsed configuration, or if deformities are the result of asynchronous growth, they cannot be corrected manually.

An arthropathy should be suspected if lameness is present. Collapse of incompletely ossified cuboidal bones may result in deformation of articular surfaces and subsequent DJD. When this occurs in the carpus, the prognosis for athletic performance is guarded to poor. If the cuboidal bones of the tarsus are affected, mild collapse may not adversely affect performance, but with significant collapse, degenerative change is likely. A less common cause of lameness in foals with angular limb deformity is osteochondrosis. The prognosis for athletic performance in foals with osteochondrosis-associated angular limb deformities is guarded, depending on the severity of the cartilage lesions.

The importance of early radiographic evaluation of foals with angular deformity cannot be overemphasized. If a diagnosis of incomplete ossification is delayed, irreparable damage may occur. In fact, a strong argument can be made for radiographic evaluation of all foals shortly after birth before uncontrolled exercise is allowed. Radiographic evaluation is mandatory to determine the degree of ossification in premature foals, twins, foals that appear to be relatively immature at birth, and foals born with angular deformities.

Radiographic evaluation allows the examiner to identify the origin of the deformity and determine its severity. Dorsopalmar views for the carpus and fetlock using 7 × 17-inch film cassettes and a lateromedial view of the tarsus are recommended. In the carpus and fetlock the origin of the deformity may be subjectively determined by two geometric methods (Fig. 38-6). One is to draw longitudinal lines bisecting the long bones above and below the joint. Where these lines intersect is the *pivot point,* which is considered the origin of the deformity; the angle of incidence of these lines is an estimation of the degree of deformity. Another method, which we prefer for the carpus and fetlock, is to draw lines through the joints and adjacent physes. These lines should be parallel to each other and perpendicular to the long axis of the long bones proximal and distal to the affected joint. The origin and degree of deformity are estimated by determining where and by what degree these lines deviate from normal. Both asynchronous growth and incomplete ossification can occur concurrently, which is most easily determined with the latter method of geometric evaluation[1] (Fig. 38-7). Geometric examination to determine the degree of deformity in the tarsus is less reliable because the tibia and third metatarsus are not in the same frontal plane. The severity of the angular deformity in this location is best determined by a careful visual assessment.

Radiographic examination of foals with incomplete ossification reveals a rounded contour to the affected bones instead of their normal angular appearance. The width of the radiolucent cartilage is increased, appearing radiographically as an increase in the width of the joint space (Fig. 38-8). As ossification progresses, the bones may appear wedge shaped or crushed because of deformation of the cartilage during weight bearing. This phenomenon often is noted in the ulnar, fourth, and lateral aspect of the third carpal bones in the forelimb and the central and third tarsal bones in the hindlimb. In severe cases the affected bones may be grossly deformed and appear to be partially extruded from the joint (Fig. 38-9). In the tarsus, lateromedial radiographs are used to determine whether ossification is complete (Fig. 38-10).

VetBooks.ir

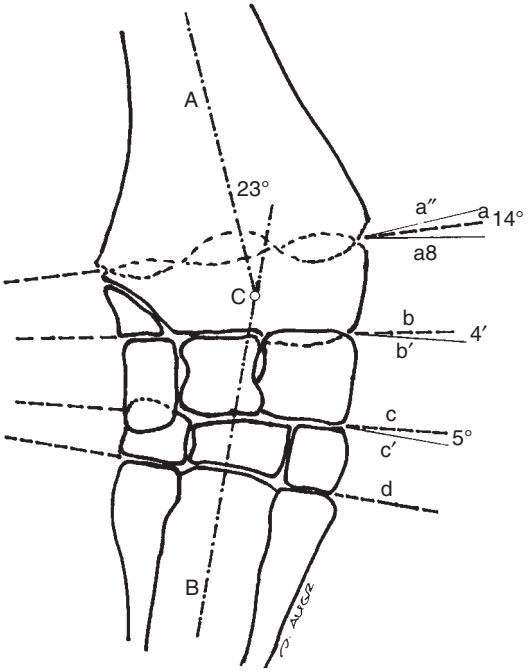

FIG. 38-7 Geometric evaluation of an angular deformity at the carpus caused by a combination of asynchronous growth and incomplete ossification. The pivot point, C, identified by lines A and B, indicates that the origin of the deformity is in the distal radial physis. However, lines a, b, c, and d are not parallel to each other, and lines a, b, and c are not perpendicular to the long axis of the metacarpus and radius. Their orientation indicates that the deformity is in the distal radial physis and the cuboidal bones as well. Note that the sum of angles a-a′, b-b′, and c-c′ equals the angle of incidence of lines A and B. *(Reprinted with permission from Compend Contin Educ Pract Vet 4:S330, 1982.)*

Radiographic evaluation of foals with angular deformity caused by asynchronous growth may show wedging of the epiphysis (Fig. 38-11), widening of the physis, and sclerosis adjacent to the physis. Geometric evaluation places the deviation in the metaphysis or the epiphysis of the long bone proximal to the affected joint. The joints are parallel to each other and perpendicular to the longitudinal axis of the adjacent long bones.

■ ***Treatment and Prognosis*** Neonatal foals with an angular deformity should be confined to a stall until clinical and radiographic examinations are completed. If the deformity is 10 degrees or less and radiographs reveal normal ossification, stall confinement with periods of controlled exercise is recommended. This regimen promotes continued development of the supporting structures while minimizing trauma to growth cartilages that could result if the foal were allowed uncontrolled exercise.

Foals with a congenital angular deformity of more than 10 degrees accompanied by incomplete ossification or ligamentous laxity failing to improve with controlled exercise should be externally supported. If incomplete ossification is present and the limb is not supported in axial alignment, continued weight bearing can cause deformation of the cartilaginous structures. Subsequent ossification results in permanent deformity of the affected bones (see Fig. 38-9).

Methods of externally supporting the carpus and tarsus vary from tube casts or rigid splints to custom-made orthotic devices. Tube casts have been recommended and used successfully for several years,[1-3] but although they provide the rigid external support required to maintain axial alignment while ossification progresses, several potential complications are associated with their use. The most serious is the potential for coxofemoral luxation when tube casts are used on the hindlimbs. In addition, foal skin is easily traumatized by a poorly fitting cast, and deep ulcerations may occur. Other considerations include the cost of materials and necessity for constant monitoring to detect signs of a poorly fitting cast. Monitoring the status of a cast requires daily evaluation by a trained individual, and owners are seldom capable or willing to take on this responsibility; hospitalization is recommended. Rigid splints are an alternative method of support. The leg is protected with a padded support bandage, and the splint is applied with nonelastic tape while the limb is held in alignment by an assistant. These splint bandages are changed every third or fourth day. Pressure sores beneath the splint bandage are a concern and must be prevented. A splint for the tarsus may be fashioned from synthetic casting material molded lengthwise over the cranial aspect of a padded bandage centered at the joint. Once the material has dried, the splint is taped to the dorsal surface of the bandage.

FIG. 38-8 Dorsopalmar radiograph of a foal with mild incomplete ossification of the cuboidal carpal bones. Note the difference in width of the medial aspect *(a)* and the lateral aspect *(b)* of the third carpal bone. Normally, width a should be approximately three-fourths the width of b. Also note the appearance of an increase in the width of the joint space *(c)* as a result of incompletely ossified joint cartilage.

Regardless of the means of external support used for the carpus or tarsus, it should not extend beyond the distal metacarpus or metatarsus. Continued weight bearing by the suspensory apparatus of the fetlock helps prevent development of fetlock hyperextension after removal of the external support. A degree of carpal hyperextension is usually present immediately after removal of external support from the forelimb, and exercise should be controlled until the tendons and periarticular supporting structures regain their normal tone.

Foals with an angular deformity resulting from asynchronous growth should also be confined to a stall and allowed only controlled

VetBooks.ir

FIG. 38-9 Dorsopalmar radiograph of a foal with incomplete ossification that was not externally supported. Severe deformation and collapse of the fourth and third carpal and proximal fourth metacarpal bones have occurred.

exercise to minimize the magnitude of asymmetric loading at the growth cartilages and encourage spontaneous correction. In these cases, reducing the magnitude of the forces acting asymmetrically at the growth cartilage should encourage compensatory growth to occur and correct the deformity. Additional therapy consists of corrective hoof trimming. Because foals with valgus deformity typically have a toe-out conformation, emphasis in the past has been to lower the lateral hoof wall of the affected limb. If this mode of therapy is vigorously pursued, compensatory varus deformity may develop in the fetlock region. This form of corrective trimming concentrates forces asymmetrically on the medial aspect of the distal metacarpal and proximal phalangeal growth cartilages. Currently, trimming the hoof level and squaring the toe to promote breakover at the toe are recommended. If the lateral hoof wall is to be lowered, only a few millimeters should be removed each week.

Foals with angular limb deformities that fail to respond to stall confinement are candidates for surgical therapy. Animals with angular deformities arising distal to the physis were not considered candidates for surgical therapy in the past, but it has been shown that they can respond favorably to surgery.[7,8]

The decision for surgery should take into account the amount of correction required (degree of deformity) and the age of the foal. The more severe the deformity, the earlier the surgical intervention should be. Timing of surgery should consider the periods of rapid and predictable growth at the physis. The most rapid and predictable rate of growth occurs from birth to 10 weeks of age.[9] In the distal radius, continuous but declining growth occurs until 60 weeks of age. In the distal third metacarpal and metatarsal bones, growth rate slows dramatically by 10 weeks of age and stops shortly thereafter.

Surgical manipulation of physeal growth is intended to asymmetrically alter the elongation occurring at the physis, thereby realigning the axis of the limb. Growth at the physis can be altered surgically in one of two ways: retardation or acceleration. Growth retardation is accomplished by bridging the physis with metallic implants. When applied to the convex side of the affected physis, growth is disallowed on the long side of the bone while continued growth on the opposite of the bone brings the limb into alignment. As long as the implants are in place, the effect continues and is limited only by the amount of growth remaining at the physis. If the physis is still active once the limb is aligned, it is extremely important that the implants be removed, or overcorrection will occur. Techniques of transphyseal bridging include stapling, screw and wire implants, use of a small bone plate, and more recently, a single transphyseal screw. Indications for transphyseal bridging include deformities that present after the period of rapid and reliable physeal growth, severe angulations, and based on the author's experience, deformities of the carpus and tarsus resulting from cuboidal bone malformations.

In the second surgical approach to altering physeal growth, periosteal transection and elevation (stripping) is aimed at promoting growth acceleration on the concave side of the bone.[10] Reported advantages include rapid correction without the potential for overcorrection.[7,10] Because periosteal transection does not require implants, the likelihood of infection and excessive fibrosis are reduced. Implant failure is not a consideration, and a second surgery for implant removal is unnecessary. The procedure does not require specialized equipment and is technically easy to perform. In one series of foals, correction of the deformity occurred in 22 of 25 limbs treated with periosteal transection.[10] In a second series of 23 foals,

VetBooks.ir

FIG. 38-11 Dorsopalmar radiograph of a foal with angular deformity caused by wedging in the distal radial epiphysis, the result of asynchronous growth of the epiphysis growth cartilage.

83% had straight limbs and were sound for their intended use at long-term follow-up.[7] The success rate was not affected by the origin of the deformity, degree of deviation, or presence of mild to moderate morphologic changes in the involved bones.[10] Indications include mild to moderate deformities present during the rapid, reliable growth at the involved physis. The periosteum will reestablish itself, so the surgical effect is short-lived, and if correction is not adequate within 4 to 6 weeks, additional therapy is indicated.

Ovine Hereditary Chondrodysplasia (Spider Lamb Syndrome)

Juan E. Romano, Sr.

Ovine hereditary chondrodysplasia, also known as *spider lamb syndrome* (SLS), is an inherited semilethal musculoskeletal disease primarily affecting lambs of Suffolk or Hampshire breeding. The clinical signs are characterized by deformities affecting the appendicular and axial bones, with elongated extremities, scoliosis, abnormal ribs, and sternum concavities.[1] Other signs include extreme height, fineness of bones, Roman nose with facial deformities, lack of body fat, and scarcity of muscling. At present, it is the most common skeletal inheritable disorder in sheep.[2] Males and females are affected equally[3] and called *spider lambs, spiders, monkey lambs,* and *crooked-legged* or *corkscrew lambs*.[4] This disease was first described in 1980 in the United States in the Suffolk breed[5,6] and then in the Hampshire breed. The disorder was also reported in Shropshire, Texel, Southdown, and Oxford breeds.[7] It has now been disseminated into several sheep breeds that used Suffolk for breeding purposes and has been

FIG. 38-12 Twin Suffolk lambs (12 weeks old), with normal lamb (78 lbs) at left and spider syndrome lamb (37 lbs) at right. Note extreme height, narrow chest, scoliosis, kyphosis, and facial deformity of the affected lamb.

propagated worldwide in the United States and Canada,[7] Australia,[8] New Zealand,[9] Brazil,[10] and Germany.[11] The frequency of this disorder was reported to be 4% in Germany by detecting the mutation using blood samples.[11]

Transmission Pedigree analyses and breeding studies have established that the gene responsible for this disease has a simple autosomal recessive mode of inheritance.[12-15] The breeding of carrier animals will produce 25% of offspring with the genetic disorder.[14,15] The breeding of a spider ram in a population of carrier females produces 50% of offspring with spider lamb syndrome.[6,13] The breeding of a carrier ram with his daughters also produced offspring with this disorder. The transfer embryos produced between a spider ram and spider donor females to normal recipients' ewes resulted in all the offspring having spider syndrome.[16]

Etiology Genetic linkage between SLS and several microsatellite makers was detected. Mapping the SLS locus was suggested to be the telomeric end of ovine chromosome 6.[7] The causative mutation was identified after positional cloning of the ovine fibroblast growth factor receptor 3 (FGFR3).[7,17] A transversion at nucleotide position 69 of ovine FGFR3 exon 17 causes a non-conservative amino substitution of nonpolar valine (V) to charge glutamate (E) at residue 700 in the second tyrosine kinase domain of the receptor. The mutation leads to loss of receptor function in homozygotes. FGFR3 acts as a negative bone growth regulator by restricting chondrocyte proliferation and endochondral bone elongation.[17,18] Heterozygous (Ss) animals are phenotypically indistinguishable from unaffected normal (SS) animals. The genotypes of presumed heterozygous carriers of SLS are detectable only after test-mating of suspect animals to proven heterozygous carriers, with subsequent evaluation of all resulting progeny or by using blood or hair follicles to detect the mutation in the FGFR3.

Clinical Signs Clinical presentation of the syndrome is also highly variable, with some lambs severely affected at birth and others developing the condition in the first 6 weeks after lambing.[1] External symptoms characteristic of the disease included extreme height, fineness of bones, and lack of muscling and angular deformities of the limbs (Fig. 38-12) along with kyphoscoliosis. Affected lambs tend to be thin and arthritic, with poor muscling and insufficient weight gain. The affected individuals rarely survive and are an economic liability in market lamb production.

The order of frequency of the abnormalities was in the forelimb (81% to 87%), hindlimb (63% to 69%), spine (52% to 62%), and skull (19% to 35%).[19] No differences between Suffolk and Hampshire

VetBooks.ir

FIG. 38-13 Rotation and deviation of front legs (carpal valgus) characteristic of spider lamb syndrome in a 16-week-old Suffolk lamb.

FIG. 38-14 Lateral radiograph of front leg of a lamb with spider syndrome. Note thick growth plates and multiple ossification centers near the olecranon and distal humerus.

lambs were detected in the type, extent, or incidence of lesions.[19] The forelimbs and hindlimbs were characterized by mild to severe carpus (Fig. 38-13) and tarsus valgus, respectively. The most common spine abnormality was kyphoscoliosis. SLS was observed in aborted fetuses, stillborn viable neonates, and lambs younger than 6 weeks of age.[19]

Detection of this abnormality during pregnancy, either by radiography or transabdominal ultrasonography, even at the second or third tiers was not possible.[16] Diagnosis was possible only by direct examination of the fetus.[16]

Laboratory Analyses No differences in hematologic and biochemical analyses between chondrodysplastic lambs and normal flock mates were detected. Serum levels of vitamin A and E and liver levels for selenium and vitamin E were within normal parameters.[4] Serum trace element levels for iron, magnesium, zinc, and copper were no different than in normal lambs.[4] Serum alkaline phosphatase activity has been reported either high or low in affected lambs compared with healthy lambs.[1] The only difference was a trend in a high level of skeletal muscle enzymes in serum.[4]

Some data suggest that the regulation of insulin-like growth factor (IGF)-1 and IGF-binding proteins may be involved in this disorder. SLS lambs between 50 and 80 days of age showed a significant decrease in serum IGF-1 levels and an increase of IGF-binding proteins compared with a control group of lambs of the same age.[20]

No differences in the number of morphologic features of the chromosome were detected, and there was no evidence of deletions, duplications, translocations, or inversions observed when lymphocytes from clinically normal lambs and lambs affected with ovine hereditary chondrodysplasia were cultured, G-banded, and karyotyped.[21]

Necropsy The primary lesions affect the musculoskeletal system. The gross lesions observed were similar to the changes noted radiographically. Lesions were observed in the skull, sternebrae, atlas, elbows, other vertebrae, and physes of the long bones, as well as other areas. The lesion noted in all locations was an excess of cartilage.[4] Marked muscle atrophy was also present. The principal lesions in bones are an increase in the width of the zone of proliferation and hypertrophy and an unevenness of the growth cartilage. A cartilage column disorder, with failure to form or maintain orderly columns of chondrocytes, is characteristic.[1] The chondrocytes and cartilage matrix appear histochemically normal and have proper ultrastructure.[22]

Radiography Chondrodysplastic lambs have characteristic radiographic patterns in the elbow, sternum, shoulder, and spine, with multiple irregular islands of ossification.[1] Radiography may be the technique of choice for identifying affected lambs prior to detecting clinical signs or when in doubt.[23] A flexed lateral radiograph of the elbow of a suspect lamb appears to be diagnostically reliable when there is suspicion of the syndrome (Fig. 38-14).[1]

Control The mode of inheritance for SLS is autosomal recessive, making identification and culling of carrier (heterozygous) animals difficult owing to their normal phenotype. Eliminating these heterozygous animals from an affected sheep flock is possible by identifying individuals that are carriers of the mutation. This can be done by collecting peripheral blood or hair follicles and performing polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) analysis. The best approach is performing this test in males, but depending on the objectives of the program, the test can also be run in females. Genetic testing by using blood and then PCR-RFLP permits a quick and accurate detection of heterozygotes. The presence of a lamb spider is an indication that both parents are heterozygous for the disorder, so no test is required. Since the introduction of this test in the year 2000, a significant reduction in the incidence of heterozygous animals in New Zealand and the United States has been reported.[24,25]

Another possibility is to run breeding tests, which is time consuming, costly, and requires adequate numbers of breeding animals to be accurate. In addition, correct identification of the animals is paramount. A ram can be progeny tested by breeding with females

VetBooks.ir

that produced spider lambs or his own daughters. The number required to be highly accurate is 16 normal offspring from mating with a known carrier's ewes or 32 normal lambs from breeding with his own daughters. However, for these numbers the probability the ram is a carrier is 1% or less of the cases.[26]

Differential Diagnosis Some of the lesions seen in SLS require differentiation from abnormalities produced by viruses, chemicals, and toxic plants. Infection with blue tongue and Akabane virus may result in arthrogryposis and hydrancephaly. Border disease can cause abnormalities of the nervous system, skin, fleece, and skeleton. Cache Valley virus and blue tongue can also produce such anomalies.[27] Benzimidazoles, antiparasitic drugs, have been implicated as a cause of skeletal deformities when used in pregnant ewes during specific periods.[28] Toxic plants such as locoweeds are known to cause limb deformities in utero.[29] Deficiency of vitamin D or phosphorus can cause skeletal deformities or rickets.[30]

Septic (Infectious) Arthritis and Osteomyelitis

Joanne Hardy

Incidence and Risk Factors Septic arthritis can result from extension of a periarticular wound infection, traumatic inoculation, iatrogenic inoculation, or hematogenous inoculation. The hematogenous route is the most common avenue of inoculation of organisms in a joint in foals, and bacteremia and septicemia are the most important risk factors for septic arthritis in foals. In one study, septicemia was the most common cause of death (30%) in foals younger than 7 days of age; septic arthritis was identified as the cause of death in 12.5% of foals aged 8 to 31 days.[1] In adults, articular wounds are reported to be the most common cause of joint infection, followed closely by iatrogenic intraarticular injection; postsurgical infection and idiopathic (unidentified cause) are also reported in association with septic arthritis in adult horses.[2-4] Although uncommon, hematogenous spread from a distant focus is possible in adult horses.[5]

Establishment of infection depends on several factors, including size of inoculum, host defense, virulence of the organisms, and local joint factors. In foals, host defense is mainly associated with passively acquired immunity. Failure of transfer of passive immunity (FTPI) is the greatest risk factor for development of septicemia in foals.[6] The incidence of disease resulting from FTPI has been reported to be as high as 78%. Organism virulence is related to the ability to establish infection. Attachment factors, ability to resist phagocytosis, and resistance to cell killing all contribute to the establishment of infection. Local joint factors that may predispose to establishment or maintenance of infection include low blood flow, particularly in end-loop capillaries, and poor blood supply, more prominent in bone. In adults, certain intraarticular medications (e.g., corticosteroids, hyaluronate, polysulfated GAGs) have been associated with a higher risk for septic arthritis, potentially by decreasing articular defense.[7,8]

In calves, septic arthritis is associated with FTPI and septicemia and with feeding of mastitic milk *(Mycoplasma)*.[9,10] In older cattle, direct spread from a perisynovitis is the most common cause, and the distal interphalangeal joint (DIJ) is most often involved.

Pathogenesis Articular blood supply is provided through a main arteriole that branches to the synovial membrane and epiphysis. Blood supply to the metaphysis is provided by the nutrient artery, but in young foals, transphyseal vessels exist that connect the metaphyseal and epiphyseal blood supply.[11] Experimental intravenous (IV) injection of bacteria results in rapid inoculation of articular and periarticular capillaries. Five types of hematogenous articular infection have been described: *type S* (synovial), where a septic arthritis results from inoculation of the synovial membrane; *type E* (epiphysis), where subchondral bone infection is present (Fig. 38-15); *type P* (physis), where infection of the physis occurs on the metaphyseal side of the growth plate (Fig. 38-16); *type T,* observed in premature foals, with infection of the small tarsal or carpal bones (Fig. 38-17); and *type I,* where joint invasion occurs after a periarticular soft tissue abscess (Fig. 38-18).[12] In young foals, functional transphyseal vessels allow communication of the metaphysis and epiphysis, such that bacteria localize preferentially in the synovial membrane and subchondral bone. Thus, young foals predominantly have infectious arthritis types S and E. Closure of transphyseal vessels occurs after about 7 to 10 days of age, such that localization of infection to the metaphyseal vessel loops occurs in older foals.[11] Although bone inoculation can occur simultaneously with synovial inoculation in young foals, determination of bone involvement can be delayed until radiographs identify the lesions. In foals the hock, carpus, and stifle are frequently involved in hematogenous joint infection, but it is important to remember that any joints, including those of the vertebral column, can be affected. In young foals, *Actinobacillus equuli, Salmonella* spp., *Escherichia coli,* and other Enterobacteriaceae are often involved; in older foals, *Streptococcus* spp. and *Rhodococcus equi* are common isolates. In foals with type P (physeal) involvement, *Salmonella* and *Rhodococcus* spp. are typically involved.

FIG. 38-15 Radiograph of a foal with type E septic arthritis, showing involvement of the distal femoral epiphysis *(arrows).*

In adults, inoculation of the joint from an articular wound is the most common cause of joint sepsis. The establishment of infection will depend on size of the inoculum, pathogenicity of the bacteria, and duration before treatment. In one study, 53% of horses examined within 24 hours of an open joint wound developed septic arthritis, versus 92% of horses examined within 2 to 7 days of injury and 100% of horses examined after 7 days.[13] However, two studies failed to find a relationship between interval before admission and outcome.[14,15] This suggests that there are many other factors that influence the prognosis following joint infection. Joints of the lower limb (fetlock, coffin joint) are often involved in open joint injuries because of the poor tissue coverage in those areas.[3,16] Organisms frequently

VetBooks.ir

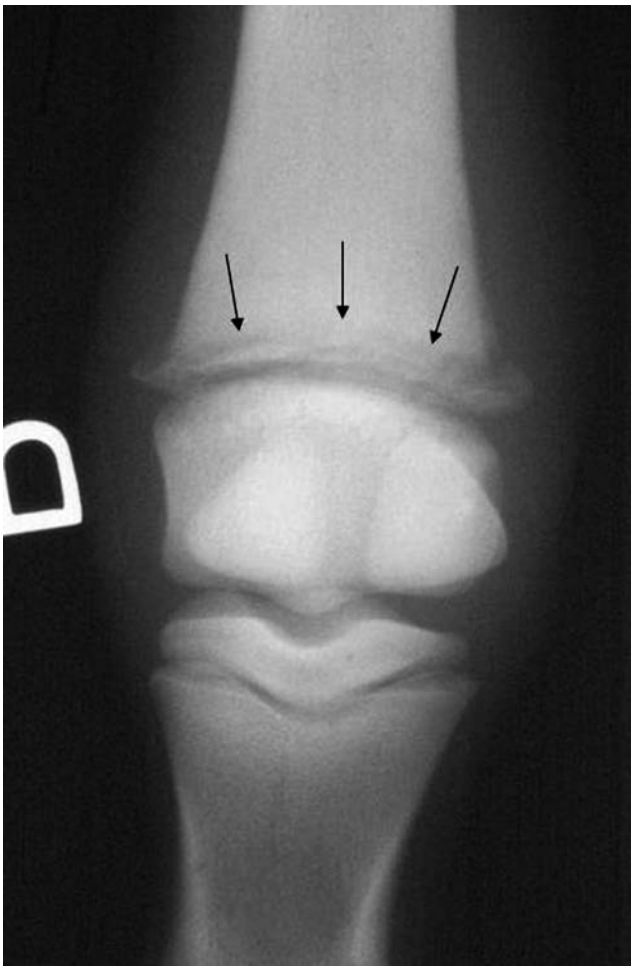

FIG. 38-16 Radiograph of a foal with type P septic arthritis, showing involvement of the distal metacarpal physis *(arrows).*

FIG. 38-17 Radiograph of the tarsus of a premature foal with type T septic arthritis, showing involvement of the distal tarsal bones *(arrows).*

FIG. 38-18 Photograph of a foal with Type I septic arthritis where a soft tissue abscess *(arrow)* dissected down into the coxofemoral joint.

encountered in open joint wounds include Enterobacteriaceae, streptococci, and staphylococci.[3,16] These injuries are also likely to have multiple bacterial infections. Wounds near the hoof are more likely to have anaerobic infection, and *Clostridium* is the most common isolate. Fungal organisms are a rare cause of septic arthritis in horses but should be considered if isolated in pure culture more than once.[5]

Iatrogenic joint injection is the second most common cause of septic arthritis in adults, followed by postoperative infection. The tarsus is the joint most often involved in septic arthritis after joint injection, whereas the carpus is the most common joint involved after surgery.[2,3] Staphylococci, particularly *Staphylococcus aureus,* are the most common organism isolated after iatrogenic joint injections or surgery. When *S. aureus* is isolated from a joint infection, care should be taken to determine the possibility of methicillin resistance.[17,18] The risk of septic arthritis after arthroscopic surgery is low, 8 of 627 joints (1.3%) in one study.[19] Interestingly in these horses, clinical signs did not develop until several days after discharge.

In adult cattle, common pathogens involved in septic arthritis include *Mycoplasma bovigenitalium, Mycoplasma mycoides, Brucella* spp., and *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), which is most often involved.[20] In sheep, goats, and calves, *Chlamydia psittaci* polyarthritis can occur as an endemic or epidemic disease and may be accompanied by keratoconjunctivitis.[21,22] In lambs, *Erysipelothrix rhusiopathiae* is also a cause of polyarthritis, gaining systemic entrance through the stump of docked tails or a castration site. Improving hygiene during these procedures helps prevent the disease.[21]

Diagnosis

Septic arthritis, osteomyelitis, or physitis should be ruled out in any lame foal. Foals with septicemia are at high risk of developing septic arthritis, which generally is noted clinically hours to days after the initial signs of septicemia. Although owners often complain of external trauma, septic arthritis is the most common cause of lameness in foals. In young foals with types S and E arthritis,

VetBooks.ir

inoculation of the synovial membrane is the first event, which the astute clinician can identify as periarticular edema. Joint effusion rapidly follows. Involvement of multiple joints is common, and identification of all affected joints is essential for successful management. Because effusion of the shoulder, elbow, or hip joints is more difficult to detect by palpation, arthrocentesis of these joints should be performed in foals with an unidentified lameness. In the stifle, femoropatellar joint involvement results in marked effusion, but femorotibial joint effusion is usually more difficult to discern. Because of the usual communication between the femoropatellar and the medial femorotibial joint, both are usually involved concurrently. Lateral femorotibial infection is more subtle to identify and can occur separately. Distention of the long extensor pouch is often present in lateral femorotibial infection and suggests involvement of that joint. In foals older than 7 days, physeal infection may be observed. With physeal infection, presence of concurrent synovial effusion depends on the intraarticular or extraarticular localization of the growth plate. For example, distal metacarpal physeal infection results in periphyseal edema, initially without joint effusion. The infection can break through the skin rather than involving the joint. In foals with septic arthritis, the CBC is consistent with an inflammatory response and includes a neutrophilic leukocytosis and hyperfibrinogenemia. In one study in foals, a plasma fibrinogen concentration of 900 mg/dL or higher (as measured by the heat precipitation method) was useful as an indicator of physeal or epiphyseal osteomyelitis, with a positive and negative predictive value of 84.2% and 98.2%, respectively.[23]

Adult horses usually show minimal changes on the CBC and little change in systemic signs, so development of or increasing lameness after a wound, joint injection, or surgery indicates the need for further examination. In one study, the mean and median times for readmission for septic arthritis following an elective arthroscopic procedure were 47 and 20 days, respectively.[19] In that study, the authors speculated that the delay in onset of septic arthritis following surgery was an indication that joint inoculation occurred in the postoperative period rather than intraoperatively, supporting careful joint closure and continued aseptic technique when changing bandages in these horses.[19] Because of their potent antiinflammatory properties, corticosteroids may delay the onset of clinical signs of septic arthritis after joint injection. In one study of experimentally induced septic arthritis, changes in synovial fluid were present before the onset of clinical signs, and clinical signs of lameness were delayed for 3 days in these horses.[24]

Arthrocentesis is the mainstay of diagnosis of septic arthritis.[24] Table 38-1 lists the characteristics of synovial fluid according to conditions in large animals. A high protein concentration (>2.5 g/dL) and high white blood cell (WBC [leukocyte]) count are observed. Classic counts diagnostic for septic arthritis in foals exceed 30,000 cells/μL, with greater than 80% neutrophils; cell counts above 10,000/μL may indicate early infection. Neutrophils are not always degenerate. Gram stain is a useful diagnostic tool because it may identify the etiologic agent in up to 25% of cases in which culture results are negative.[25] In foals with a separate physeal infection where the physis is extraarticular, sympathetic joint inflammation and effusion can occur.[26] This manifests as a moderate increase in WBC count, with less than 90% neutrophils. The presence of such cytologic findings should alert the clinician and practitioner to the presence of physeal sepsis. Several studies have examined the usefulness of synovial fluid markers to predict joint sepsis. In one study, synovial fluid D-dimer concentration was markedly increased in septic joints, and this was not influenced by the presence of septicemia.[27] However, inclusion criteria for the study included the presence of a synovial fluid analysis consistent with sepsis, so it is not known whether D-dimer concentration would be a useful marker earlier in the disease process or when results of synovial fluid analysis are equivocal. In another study, synovial fluid equine myeloperoxidase (MPO) activity was compared in different forms of joint disease. In cases of septic arthritis, MPO activity in synovial fluid was significantly increased compared to control. Although the study concluded that synovial fluid MPO may be useful as a marker of septic arthritis in horses, further studies are needed because horses were included in the study when they already had synovial fluid analysis indicative of septic arthritis.[28] Serum amyloid A (SAA) is an acute phase protein that is markedly increased (>1000 mg/dL) in horses with septic arthritis.[29] Interestingly, SAA concentration was not increased in synovial fluid collected after repeated intraarticular injections of amikacin in healthy horses.[30] Intraarticular injection of various substances such as antibiotics, saline, or therapeutic agents often cause a transient inflammatory reaction where total protein and nuclear cell counts are consistent with sepsis.[31] The use of SAA to differentiate inflammation from infection would definitely warrant further study.

In adult horses with a wound localized near a synovial structure, it is crucial to identify as early as possible whether there is synovial involvement. The most convincing evidence is demonstration of synovial communication with a wound by injecting a sterile solution into the synovial structure and observing fluid exiting the wound. For this purpose, a site remote from the wound and covered with normal skin should be prepared aseptically, and depending on the structure involved, 20 to 200 mL of a sterile solution (e.g., saline, balanced electrolyte) is injected after collecting synovial fluid samples using aseptic technique.[32] If synovial involvement is detected, therapy is immediately instituted.

Radiographs of all affected joints are essential. The presence of osteomyelitis may affect prognosis and dictate prolonged antibiotic therapy. Radiographs should be repeated weekly until resolution of clinical signs, or any time there is deterioration in the clinical condition. Radiographs are also indicated whenever a change in therapy is planned (e.g., from IV to oral antibiotics).

Nuclear scintigraphy has been used to diagnose infectious foci in odd localizations in foals. For example, vertebral and atlantooccipital involvements have been diagnosed using this imaging modality. It

FIG. 38-19 Computed tomography scan of a foal with septic arthritis of the left coxofemoral joint, showing osteomyelitis of the acetabulum *(arrows)* that was not radiographically evident.

must be remembered that local bone infarcts, which are often present in osteomyelitis, will result in areas of decreased rather than increased uptake. Scintigraphy using technetium-99m (^{99m}Tc)–labeled WBCs or ciprofloxacin labels has potential uses in foals with multiple-limb involvement and warrants further investigation as an imaging modality for septic arthritis.[33]

Computed tomography (CT) is a useful imaging modality to identify osteomyelitis (Fig. 38-19). It is particularly useful for imaging areas that are difficult to detail with radiography.[34] The main disadvantage is that it is currently limited by the size of the animal.

Magnetic resonance imaging (MRI) has been used in foals and adults with septic arthritis.[35,36] In a limited series comprising six foals with infectious arthritis, four of the six had infectious lesions on MRI indicative of osteomyelitis, and only four of 19 lesions were detected on digital radiographs. Osseous lesions in the T2-weighted, short tau inversion recovery (STIR), and proton density MRI sequences appeared as hyperintense foci.[36] In addition, joints with infectious arthritis had heterogeneous signals within the synovial fluid, whereas all nonseptic joints had homogeneous fluid signals.[36] In adult horses with septic arthritis, MRI findings included diffuse hyperintensity within bone and extracapsular issue on fat-suppressed sequences (Fig. 38-20). The study concluded that MRI may allow earlier and more accurate diagnosis of septic arthritis in horses, particularly when the clinical diagnosis is challenging.[35]

Identification of the organism should be attempted in all cases of septic arthritis. Gram stains, culture of synovial fluid in blood culture bottles, and culture of synovial biopsies have been suggested to increase the likelihood of identification of the organism. In general, the positive culture rate from synovial fluid samples is approximately 50%, and synovial biopsy culture has a low yield to increase this figure.[37] Appropriate culture techniques should be used for organisms such as *Chlamydia* or *Mycoplasma* spp., and special stains may be required. In foals, because bacteremia or septicemia precedes the local signs, blood cultures should be obtained. In addition, any other local sites of infection should be cultured. In cases of septic physitis, needle aspiration of the affected site under radiographic or fluoroscopic guidance can be performed. In the future, other techniques for early identification of synovial sepsis may become available.[37]

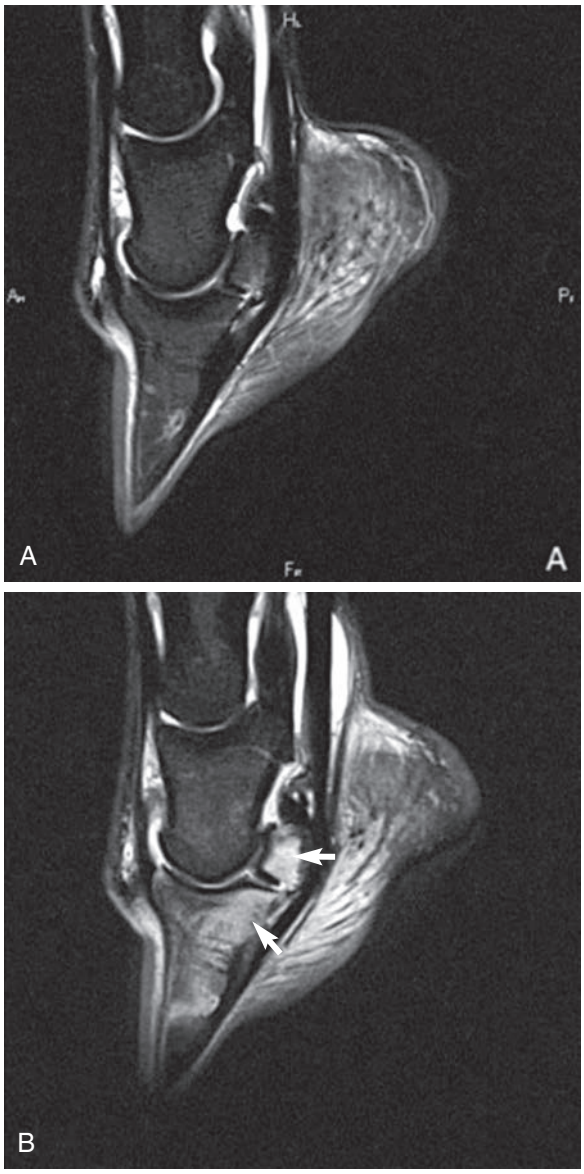

FIG. 38-20 Sagittal short T1 inversion recovery weighted magnetic resonance imaging sequence of the left **(A)** and right **(B)** feet of a horse with septic navicular bursa and septic navicular bone, showing severe hyperintensity of the navicular bone and distal phalanx *(arrows)*.

Treatment Septic arthritis is an emergency. Immediate assessment followed by institution of treatment should be done as soon as possible after problem identification. The principles of treatment of septic arthritis include systemic broad-spectrum antibiotics, local joint lavage and débridement, and local antibiotic delivery. Systemic antibiotics are best administered intravenously to ensure adequate tissue concentrations. Most often the combination of a β-lactam and an aminoglycoside or fluoroquinolone is used in adults; a β-lactam and aminoglycoside combination is most often used in foals because fluoroquinolones may have detrimental effects on articular cartilage in young animals. In open joint injuries, particularly if an anaerobic organism is suspected, metronidazole may be added to the antibiotic regimen. Gram-positive organisms can be isolated from blood cultures in up to 33% of foals with sepsis, so gram-positive coverage is also important.[38,39] In foals with physeal involvement, Gram stain and culture of a physeal aspirate are helpful to identify the causative agent. The most common organisms isolated from septic physitis are *Salmonella* spp. and *R. equi*. If *R. equi* is identified, appropriate therapy with erythromycin, azithromycin, or clarithromycin and rifampin should be instituted, keeping in mind that resistance to rifampin and erythromycin has been reported; obtaining susceptibility patterns may be warranted.[40] Intestinal uptake of clarithromycin is significantly impaired when administered in combination with rifampin, so use of that combination should be questioned.[41] The presence of osteomyelitis warrants an antibiotic combination that reaches effective bone levels; rifampin with another antibiotic is often used. Rifampin should not be used as the sole antimicrobial, because resistance is acquired rapidly with this antibiotic. Other antibiotics that reach effective bone concentrations include tetracyclines,

VetBooks.ir

chloramphenicol, fluoroquinolones, and cephalosporins. If cephalosporins are chosen, third-generation agents (e.g., ceftiofur, cefotaxime, ceftriaxone, ceftazidime) are preferred because they are more effective against gram-negative bacteria. In foals, fluoroquinolones should be reserved for organisms that are only susceptible to this class of drugs, because evidence shows cartilage lesions developing in immature animals with their use.[42,43]

Local lavage of the joint or synovial structure is an important component of therapy; removal of debris, fibrin, and inflammatory mediators helps minimize damage and eliminate the organism. In foals, joint lavage can be performed under heavy sedation or short-term general anesthesia. In adults, sedation and a regional block can be used or short-term general anesthesia. Joint lavage can be performed using through-and-through needle technique; use of a pressure bag or a pump will facilitate efficient lavage of several liters of fluids through the joint. This technique may be sufficient in joints where the diagnosis was made early, where the infection is not severe, and in simple joints (fetlock, carpus). If there is poor response to treatment after one or two sequential joint lavages, arthrotomies should be performed without hesitation. Often, fibrin accumulation in the affected joint precludes effective lavage and allows sequestration of bacteria. Once arthrotomies have been performed, the affected joint will have to be covered with a sterile bandage. During subsequent lavages, a teat cannula inserted in the arthrotomies may be used to lavage the joint. The arthrotomies are left to heal by second intention; the joint will have to remain bandaged until the arthrotomies are closed. Occasionally, delayed closure of the arthrotomies is necessary, particularly in arthrotomies localized over high-motion joints. In joints with multiple compartments (stifle, hock), in severe infection or osteomyelitis, in cases of longer duration, or in animals with poor response to joint lavage, arthroscopic débridement is indicated.[15] Arthroscopy has several advantages over simple needle lavage. It allows thorough débridement, removal of fibrin, and lavage of all compartments, evaluation and débridement of cartilage and underlying bone lesions, and in the case of wounds, identification and removal of foreign material. In one study, foreign material was identified on arthroscopy in 41 of 121 (43%) horses and 34% of joints with wounds involving synovial structures; these were predicted in only 15% of cases, suggesting that endoscopic evaluation is important diagnostically in wounds involving synovial structures.[15] In addition, arthroscopy may have prognostic value when radiographic lesions are equivocal. The arthroscopic portals can be left open for drainage and subsequent lavage but must be kept under a sterile bandage.

Local or regional delivery of antibiotics is advocated for the management of septic arthritis.[44] Delivery of local antibiotics to the affected joint can be achieved by intraarticular injection, isolated IV or intraosseous (IO) infusion, isolated retrograde venous injection, continuous antibiotic delivery, or implantation of antibiotic-impregnated biocompatible materials. Intraarticular injection is the simplest method but requires repeated injections. Aminoglycosides (gentamicin, amikacin) and ceftiofur have been shown to maintain levels above the minimum inhibitory concentration (MIC) for 24 hours after a single intraarticular injection.[45,46] Intrasynovial catheter placement and repeated antimicrobial injection was described successfully in one study where a modified over-the-wire catheter system was placed directly in the synovial structure and used for antibiotic injection and lavage of the synovial structure.[4] Continuous infusion of antibiotics can also be accomplished by placing a small catheter into the affected synovial structure and attaching it to an infusion system, providing constant rate infusion of the antibiotic.[47,48]

Isolated regional IV perfusion or IO perfusion techniques are also advocated for the treatment of septic arthritis.[49,50] Although the term *perfusion* is often used in the veterinary literature, the term *infusion* should probably be used because in most studies a single injection of the antibiotic is made at the start of the treatment period, whereas perfusion techniques establish an extracorporeal bypass system for the extremity or organ under treatment.[51] Isolated limb infusion techniques are based on isolating the area of interest with a tourniquet, followed by a single IV or IO injection of the antimicrobial. These techniques rely on transient pressure and concentration gradients to distribute a drug to the tissues. The type of tourniquet used is important; escape into the systemic circulation must be avoided during the treatment period. Wide rubber or pneumatic tourniquets are recommended.[52] An Esmarch tourniquet has also been shown to be effective.[51,53] Tourniquets should be 20% wider than the diameter of the limb on which they are used.[54] After tourniquet placement, a regional vein is catheterized using a 23-gauge butterfly catheter for isolated limb infusion. Alternatively, a long-term indwelling catheter can be placed in the vein to facilitate treatment and avoid repeated injection and possible damage to the vein.[55,56] The antibiotic is diluted in a volume of sterile fluid (20 to 120 mL have been reported) and is subsequently injected and the tourniquet left in place for 30 to 45 minutes. In theory, the increased volume serves to increase the vascular pressure and therefore antibiotic distribution, but it remains unknown whether distribution of the antibiotic is a result of a pressure gradient or a concentration gradient. The increased pressure generated after a single infusion of 60 mL returned to baseline after 10 minutes in one study.[51] For IO infusion, a tourniquet is placed in a similar manner, and an intraosseous screw is placed in the medullary cavity and used to inject the antibiotic. Alternatively, a sterile infusion line can be placed in a hole drilled into the medullary cavity. In one study, the IV infusion method had fewer complications than the IO route.[57] Several drugs have been used for IV infusion, including aminoglycosides, cephalosporins, erythromycin, enrofloxacin, vancomycin, and amphotericin B.[49,58-62] The irritating property of drugs like enrofloxacin makes their repeated use undesirable unless no alternative is available.[63]

Intravenous retrograde venous injection (ILRVI) was compared to isolated limb infusion (ILI).[51] The ILRVI technique was similar to that reported for regional limb perfusion in horses. The ILI consisted of catheterization of one digital artery and vein followed by application of a tourniquet. The antibiotic was then injected over 3 minutes, followed by circulation of infusate and blood from the venous to the arterial circulation in 5-minute aliquots for 25 minutes. In the ILI technique, high pressure within the venous system was sustained for the duration of treatment, compared to the ILRVI technique. There was no difference in pharmacokinetics of synovial fluid amikacin in the metacarpophalangeal joint between the two techniques, but significantly higher amikacin concentration was measured in the DIJ.[51] The authors concluded that either ILRVI or ILI may be used for antibiotic delivery, but the technically less demanding ILVRI technique may be more practical.[51]

Antibiotic-impregnated polymethylmethacrylate (PMMA) beads can also be used, although direct implantation into a joint can result in cartilage damage.[64-66] PMMA implants are fabricated by mixing the desired antibiotic with the powder before adding the polymerizer. Antibiotics evaluated for inclusion in PMMA include gentamicin, metronidazole, vancomycin, ceftiofur, cefazolin, and amikacin.[67-74] Antibiotic combinations have also been used, but combining antibiotics can change their elution properties. For example, cefazolin or amikacin elute at concentrations greater than MIC for 30 days in vitro, but the combination elutes above MIC for only 6 days.[73,74] Antibiotic-impregnated biodegradable implants include synthetic and natural carriers. The advantage of these implants is that a separate procedure for their removal is unnecessary.[75-77] Synthetic carriers are degraded by hydrolysis, which may affect the antibiotic prior to its implantation.[44] Although synthetic biodegradable carriers have been evaluated in an experimental model of synovial membrane sepsis, they are not currently clinically available.[75] Gentamicin-impregnated collagen sponges consist of highly purified cattle collagen; the gentamicin molecules are embedded within the pores of the collagen. No stabilizing agents or foreign substances are added. Clinical use of successful treatment of septic arthritis in horses and cattle has been reported.[77-79] However, a recent study performed in healthy horses failed to detect sustained antibiotic release beyond that obtained with a single intraarticular injection.[80]

As high levels of antibiotics are reached within the targeted tissues with these techniques, it remains unknown whether systemic

VetBooks.ir

antibiotics are still required. In addition, the best dosing interval between treatments is unknown; for example, with concentration-dependent aminoglycosides, there is a transient reversible adaptive resistance for some bacteria to a second dose of aminoglycoside up to concentrations 128 times MIC. These same bacteria revert to original susceptibility when exposed to drug-free media.[51,81] Another unknown is the potential interaction of aminoglycosides and β-lactam combinations, which depending on the drug combination, can be synergistic or antagonistic. Although inactivation of certain β-lactam antibiotics by certain aminoglycosides in vitro has been documented, several studies document in vivo synergism.[82,83] Significant postantibiotic effects were detected with several antibiotic combinations.[84]

With extensive physeal lesions in foals, curettage, autologous bone grafting, and external coaptation may be required.[85,86] The addition of tricalcium phosphate granules or bioresorbable paste may be considered.[87] Angular limb deformities may result from growth disturbances or collapse of the physis on the affected side. In adults with septic arthritis and osteomyelitis, curettage of the bone lesion followed by bone grafting and external coaptation may also be indicated.[88] Adjunctive therapies that may help alleviate inflammation include sodium hyaluronate, polysulfated GAGs, and dimethyl sulfoxide (DMSO). Sodium hyaluronate and polysulfated GAGs can be used systemically or locally, but local use should be reserved for when infection is under control, because these agents decrease joint defense mechanisms.[8,89] Although DMSO has significant antiinflammatory properties in joints, it should be used with caution because of its negative effects on cartilage metabolism.[90]

In addition to specific therapies, management of pain, stress, and other metabolic disturbances are indicated. Pain can be managed by judicious use of NSAIDs, using the smallest dose that will keep the animal comfortable. If a foal continues to show severe pain despite appropriate treatment, it is important to ensure that other joints in the limb are not involved. Other pain management modalities (e.g., opiates, fentanyl patches, epidural analgesia) can be used. It is important to remember that in foals, continued pain in one limb may result in development of a varus deformity in the contralateral weight-bearing limb owing to the tripod stance these foals acquire to maintain the weight-bearing limb under the center of gravity. Application of a lateral extension to the contralateral foot may help increase the weight-bearing surface and prevent development of this complication. Continued pain is a negative prognostic indicator in the affected foal. In adults, continued pain in one limb may result in the development of contralateral limb laminitis.[91] When continued pain in the treated limb is a problem, preventive measures (e.g., hoof support, therapeutic shoeing) should be undertaken.

Antiulcer agents are indicated in foals and adult horses that are in pain, stressed, and receiving high doses of NSAIDs. Omeprazole is currently the only medication that has been shown to significantly prevent formation of gastric ulcers and promote healing of existing ulcers in adult horses. Although evidence for its efficacy in preventing and treating NSAID-induced ulcers is lacking, omeprazole is still indicated when NSAIDs are used in stressed animals.

In cattle, facilitated ankylosis is a reasonable alternative when the disease is too advanced, and it is a particularly good option for involvement of the DIJ. Articulations of the distal limb in general are well suited to facilitated ankylosis. In brief, the involved joint is opened and débrided of all debris, all infected tissue is curetted and removed, and a cast is applied and maintained until ankylosis is achieved.[92] Alternatively, the digit may be amputated, although a reduced production life should be expected.[93]

Prognosis

In clinical studies, treatment is often limited by economic considerations, so the true long-term outcome of treatment is unknown. Outcome variables used in clinical studies range from discharge from the hospital to pasture soundness to racing potential. Owner expectations should be clear, keeping the animal's welfare in mind. The prognosis for septic arthritis should always be guarded, and owners should be informed of the high cost of treatment. In foals, factors that will influence prognosis are systemic condition of the foal, number of joints involved, localization of joint involvement, severity of the infection, early versus delayed identification and institution of treatment, presence of osteomyelitis, and virulence of the organisms. In one study, 73 of 93 (78%) foals survived to discharge, but only a third reached racing performance.[94] Isolation of *Salmonella* spp. and presence of multisystem diseases were negatively associated with survival and ability to race.[94] A multidrug-resistant *Enterococcus* sp. was associated with unresponsive septic arthritis in three horses.[95] In another study, 58 of 69 (84%) foals survived to discharge, although signs were present for less than 24 hours in 74% of foals, only five foals had more than one joint involved, and only one foal had osteomyelitis.[96] This population of foals therefore appeared less severely affected. Of the affected foals, only 40.5% started in one race, and of the affected foals that were discharged, only 48.3% raced versus 66.2% in the control (sibling) group. This study concluded that even if foals are successfully discharged from the hospital, they are significantly less likely to start in at least one race than their siblings. Furthermore, these foals took significantly longer to appear on the track than their siblings. In another study of foals with osteomyelitis of hematogenous origin, 87 of 108 (80.6%) foals were discharged from the hospital, and 79 of 87 reached racing age.[97] Overall 52 of 108 foals (48%) raced. Of the 21 non-survivors, only one died; the other 20 were euthanized, but none were euthanized for economic reasons. Factors associated with non-survival in that study included foals less than 30 days of age, critical illness, multisystem disease, multiple bone lesions, lesions of the proximal phalanx, concurrent septic arthritis, multiple septic joints, and involvement of the coxofemoral, stifle, hock, or navicular bursa. In that study, the bacterial isolate involved had no significant effect on short-term outcome.[97] In a study evaluating the factors associated with survival and racing performance in 423 neonatal Thoroughbred foals with bacteremia, the presence of septic arthritis increased the likelihood of non-survival by 4.54 times.[98]

In adults with open joint injuries, the prognosis can be favorable if the joint is contaminated but not yet infected, and if aggressive treatment is immediately started. However, with established infection, the prognosis should always be guarded. In one study of horses with open joint injury, 53% of those examined within 24 hours developed septic arthritis, and overall survival was 65%. In horses presented within 2 to 7 days of injury, septic arthritis developed in 92%, and survival was 38.5%; in horses examined more than 7 days after injury, septic arthritis developed in all, and survival was 50%.[13] In one study of 101 horses with heel bulb lacerations, those with involvement of synovial structures had worse outcomes then those that did not; 5 of 17 horses with synovial involvement were euthanized.[16] Horses with contaminated or infected synovial structures treated by arthroscopic débridement appeared to have a better long-term outcome, with 106 of 118 (90%) surviving and 96 (81%) returning to previous use.[16] In a study of horses with septic tenosynovitis, 40 of 51 horses (78%) were discharged, and 37 of 40 (73%) survived long term, with 21 (57%) returning to intended use.[99] Surgical technique did not influence outcome in this study. One study reported on the use of matrix metalloproteases 2 (prommp2) and 9 (prommp9) and WBC count to monitor treatment and predict outcome in horses with septic arthritis.[14] In that study, survivors had a significantly lower WBC count, prommp9, and ratio of prommp9:prommp2, with the latter being the best predictor for survival.

In cattle the prognosis for septic arthritis is generally better than in horses, probably because of the lack of expectation for athletic use. Prognosis depends on time of presentation, degree of bone involvement, and degree of extracapsular ankylosis. In two studies the success rate was reported as 72% and 85%; cattle with septic tarsi had a worse prognosis.[100,101] In another study, arthroscopic lavage and implantation of gentamicin-impregnated collagen sponges resulted in recovery in 12 of 14 cattle.[102] After arthrodesis of the DIJ, 85% success was reported.[93] For carpal arthrodesis, 87% success was reported if no carpal bone was removed, 72% success if one row of carpal bones was removed, and 35% if both carpal rows were

removed. Tarsal arthrodesis has a reported success rate of 87% in cattle.[93]

Mycoplasmal Polyarthritis in Goats

Piper Lambard Norton

Definition and Etiology There are numerous species of *Mycoplasma,* but not all are pathogenic. The contagious agalactia syndrome of sheep and goats causes mastitis in lactating does and septicemia in kids, leading to polyarthritis and keratoconjunctivitis. This syndrome was originally thought to be attributed to only *Mycoplasma agalactiae* but has also been attributed to *Mycoplasma capricolum, M. mycoides* subsp. *capri, M. mycoides* subsp. *mycoides* (caprine or large colony type), and *Mycoplasma putrefaciens* and has been documented in many different countries.[1] Each of these species has been described as causing septic arthritis in kids as well as mastitis in does.[1,2]

Of these species, *M. mycoides* subsp. *mycoides* is the most common in the United States.[3] Documented infected goats are usually housed at large U.S. dairies, and infection follows introduction of asymptomatic carrier animals into a herd.[4]

M. mycoides subsp. *mycoides* (small colony) is the etiologic agent of contagious bovine pleuropneumonia and was eradicated from the United States in 1892.[4] Since that time, goats in this country have been affected by mycoplasmas that are serologically indistinguishable from the bovine strain.[1] *M. mycoides* subsp. *mycoides* that affects goats is known as *caprine* or *large colony type* rather than the small colony type that affects cattle.

Clinical Signs and Differential Diagnoses The majority of cases of *Mycoplasma* spp. mastitis are observed during the spring, although one large U.S. outbreak was documented in the fall.[5] Adults may be asymptomatic carriers, have mastitis, or have more severe systemic infections like pneumonia. Does with mastitis may have clinical signs of an elevated temperature, anorexia, interstitial fibrosis of the mammary gland, and decreased milk production. Milk has the appearance of white liquid glue, progresses to being curdled and thick, and then becomes thin and watery.[5] In addition, goats may exhibit pneumonia (interstitial or fibrotic), arthritis or polyarthritis, conjunctivitis, lymphadentitis, peritonitis, abortions, pericarditis, or septicemia.[3] Differential diagnoses in adults with mastitis include a large number of other bacteria such as coliforms, *S. aureus,* fungal organisms, and other bacteria.

Goat kids most frequently demonstrate clinical signs of fever (102° to 107° F), polyarthritis, pneumonia, anorexia, and lethargy due to mycoplasmal septicemia.[6] Infections with *M. putrefaciens* may be less likely to be associated with temperature elevations in goat kids and adults.[5] Meningitis and sudden neurologic signs may also be observed in goat kids.[3] Experimentally inoculated kids demonstrate clinical signs of anorexia, lethargy, and painful enlarged joints within 3 to 5 days of inoculation.[7,8] Differential diagnoses in kids with septic arthritis include chlamydial infections and other bacterial etiologies secondary to septicemia.[4]

Clinical Pathology and Diagnosis Hematologic abnormalities in kids may include decreased red blood cell (RBC) counts, increased platelets, and increased fibrinogen. Neutrophilia may be observed, but the finding is inconsistent.[5] Chemistry panels may show decreased albumin levels.[3]

Arthrocentesis of effusive joints may be grossly hemorrhagic or dark yellow and turbid with increased total protein.[9] Mean total protein in normal joints was 1.8 ± 0.2 g/dL, whereas mean total protein in joints of affected kids was 3.2 ± 0.2 g/dL.[9] Cytologic analysis of synovial fluid may reveal increased neutrophil, lymphocyte, and erythrocyte counts in addition to decreased glucose concentrations.[9] Synovial fluid also has very poor mucinous precipitate quality (mucin clot test).[9] Culture of *Mycoplasma* requires special medium and up to 14 days of incubation.

Pathophysiology and Epidemiology Transmission of the organism from the infected doe to a kid is through infected colostrum.[3] The organism penetrates the gut wall and leads to septicemia. Transmission in adults has been speculated to be through direct contact, the milking process, venereal transmission, or through vectors such as ear mites or fleas.[3,10,11] Most sources say *Mycoplasma* is not very contagious if milk sources are not contaminated.

Chronic carriers of the bacteria have been noted following treatment for the disease, and asymptomatic carrier does and bucks have been documented.[10] In one outbreak of *M. putrefaciens,* clinical signs were documented to occur within 3 weeks of the introduction of new animals into the herd.[5] In another outbreak in Spain, a drought was implicated as a possible predisposing factor, suggesting environmental stress may play a role.[8,11] Recommendations should be made to ensure that sanitary milking, kidding, and housing environments are established to decrease the risk of contagion.

Necropsy Findings Gross necropsy findings in does with mastitis include enlarged, firm udders with thick, chunky to putrefactive milk. Histopathology of the udder may show severe chronic mastitis with a mononuclear infiltrate and enlarged mammary lymph nodes.[5,12] Lungs may have a diffuse interstitial pneumonia or consolidation with areas of focal necrosis.[7,8] A thickened pleura may be observed, with fibrinous exudate in the thoracic cavity.[7,8] The arthritis is characterized by a fibrinopurulent polyarthritis.[8] Some animals may show ulcerated synovium with an infiltration of macrophages and neutrophils.[3]

Treatment and Prognosis Mortality rates in kids may surpass 90%, and mastitis may affect 25% to 33% of does in a herd, or more if unsanitary conditions are present.[3,5] Most sources state that there is no effective treatment for mycoplasmal infections, although many antibiotics have been tested in vivo and in vitro. It is important to recognize that individual isolates of *Mycoplasma* spp. may be more or less susceptible to certain antibiotics, and susceptibility patterns may be regionally dependent.[13] Mycoplasmal organisms lack a cell wall, making cell wall synthesis inhibitors ineffective as treatment, but they are generally susceptible to antibiotics that inhibit protein or DNA synthesis. Antibiotics used to treat this condition in goats include oxytetracycline, florfenicol, macrolides (tulathromycin), and tylosin.[13,14] Only antibiotics with established milk withdrawals should be used in dairy goats. Prognosis for response to treatment is poor, and oftentimes carrier animals persist despite treatment.[3]

Prevention and Control Maintenance of a closed herd is the simplest method of prevention.[3] Modification of milking practices and kid rearing is necessary to prevent mycoplasmal spread.[3] When does with mycoplasmal mastitis are identified, they should be culled or isolated from the remaining herd. Kids born to mastitic does should be isolated from infected does and raised on milk replacer or heat-treated milk.

Whole-herd milk culture can be used to identify *Mycoplasma* in a herd. Polymerase chain reaction (PCR) assay of milk, synovial fluid, or tissues can also be used to identify *Mycoplasma.* Asymptomatic bucks in a herd can be detected using cultures of ear swabs or semen.[10,15]

Caprine Arthritis-Encephalitis Virus

Kevin Washburn

Definition and Etiology Caprine arthritis-encephalitis virus (CAEV) is an RNA-enveloped lentivirus from the Retroviridae family that infects cells of the monocyte-macrophage lineage, with clinical manifestations ranging from subclinical disease to severe encephalitis. Time from viral infection to clinical disease may vary from months to years, and because infection is lifelong, efforts to eradicate

VetBooks.ir

VetBooks.ir

and control its prevalence and incidence are paramount to maintaining successful goat herds. Loss of productivity, death, and restrictions on the export of dairy goats are some of the economic impacts of this disease on U.S. herds and the goat industry.

Clinical Signs Only about 20% of CAEV-infected goats display clinical signs of disease during their lifetime, but recognized forms of disease include a leukoencephalomyelitis, interstitial pneumonia, chronic mastitis, and debilitating polysynovitis-arthritis.[1] Leukoencephalomalacia is observed primarily in kids 2 to 6 months of age, but reports have been noted in adults.[1] This form is characterized by an ascending paresis leading to paralysis, beginning in the rear limbs and sometimes involving the forelimbs. These signs may or may not be accompanied by a mild interstitial pneumonia. Goat kids may continue to be bright, alert, and appetent. The most severe manifestation of this form of CAEV infection is progressive paresis to paralysis to urinary retention and bloating. Chronic interstitial pneumonia with progressive weight loss and dyspnea is another recognized form of CAEV infection. Primary ruleouts for this form should include lung worms, pulmonary abscessation, and chronic bronchopneumonia. The mammary gland is a target organ for the virus, resulting clinically in a firm udder with decreased milk production. Although quantity of milk is reduced, there are no apparent gross abnormalities.

The most common form of CAEV infection is polysynovitis-arthritis, which can be recognized in goats as young as 6 months but more frequently is observed in mature goats. Lameness caused by this form is intermittent and insidious in onset, but eventually affected joints become painful and enlarged. Enlargement of the joints is most typically due to hyperplasia of the synovial tissues and their associated sheaths rather than increased volume of joint fluid. The carpus is most frequently involved, but the stifle, coxofemoral, atlantooccipital, and hock joints are also potential locations. Affected goats have a stiff, stilted gait and progress to walking on their carpus or recumbency. Range of motion (ROM) is greatly affected, contributing to chronic soft tissue contracture. This polysynovitis-arthritis form can be accompanied by a chronic interstitial pneumonia and weight loss and typically is also associated with some form of mammary involvement.[1]

Clinical Pathology and Laboratory Aids Arthrocentesis to confirm suspicion of the polysynovitis-arthritis form of CAEV infection usually yields a brown to red-tinged fluid with an increased cell count and decreased protein. Joint fluid cell counts in affected joints are dominated by mononuclear cells, differing from bacterial synovitis, where cells consist predominantly of neutrophils. This predominance of mononuclear cells in CAEV infection is also seen in the cerebrospinal fluid (CSF) of goats affected with the leukoencephalomyelitis form. Radiographs may be a useful diagnostic tool for CAEV polysynovitis-arthritis; early cases display soft tissue swelling dorsal to the carpus. As the disease progresses, mineralization can be observed in the periarticular tissue, tendon sheaths, joint capsules, and ligaments. Roughened bone proximal and distal to the joint becomes apparent, as does periosteal reaction. The U. S. Department of Agriculture (USDA) recognizes an agar gel immunodiffusion (AGID) test using ovine progressive pneumonia virus antigen as the official test for CAEV. However, an enzyme-linked immunosorbent assay (ELISA) has been developed for detection of whole virus, core, or envelope proteins. Both AGID and ELISA are considered reliable enough to be incorporated into prevention and control programs. The AGID test is reportedly more specific but less sensitive than the ELISA.[2] Detection of antigen in milk, tissue, and blood can be facilitated through PCR techniques. A positive AGID or ELISA in adults is synonymous with lifelong viral infection. Generally, time from infection to seroconversion ranges from 4 to 16 weeks, but some infected goats shed virus for long periods of time without seroconversion.[3] Goat kids may be transiently positive for the presence of antibodies during the first 8 to 16 weeks of life after consuming CAEV antibody–containing colostrum, but because of the nonprotective nature of maternal antibodies, such kids may seroconvert to true viral infection due to viral shedding from the infected dam.

Pathophysiology The characteristic granulomatous inflammatory pathology produced in affected tissues is thought to be due to immune complexes generated by the interaction of non-neutralizing antibodies produced by lymphocytes and associated virus-infected macrophages. Localization of such inflammatory lesions occurs where tissue-associated macrophages are found. Tissues of importance for CAEV localization include the synovium, mammary gland, and central nervous system (CNS), so the clinical manifestations of the disease are logical.

Epidemiology Transmission involves the transfer of virus-laden cells from one animal to the next. Transfer of CAEV to neonates through colostrum and milk is a highly efficient natural mode of transmission.[4,5] Transmission has also been reported through direct contact, so herd owners who do not practice segregation of seropositive animals continually have difficulty controlling and eradicating the disease.[4-7] Complete separation of kids from dams immediately following parturition and during the periparturient period is necessary; evidence exists that even kids not allowed to nurse become infected. Caprine arthritis-encephalitis virus proviral DNA has been recently detected in the caprine genital tract,[8] and experimental infection of goat embryos with CAEV has been reported.[9] Additionally, intramammary and in utero transmission have been described.[7,10] All the described means of acquiring the virus are potential explanations for continued transmission in herds where segregation and sound colostrum and milk management are practiced.

Maedi-visna virus (MVV), also known as *ovine progressive pneumonia,* is another lentivirus that together with CAEV is commonly referred to as *small ruminant lentivirus* (SLV). Although sheep are most likely to display clinical signs of MVV, and goats signs of CAEV, studies have shown that these viruses can be transmitted from sheep to goats and vice versa.[11] Therefore, eradication programs aimed at eliminating SLV from herds and flocks should not allow contact between sheep and goats.

A study examining the prevalence of antibody to CAEV in the United States found that 31% of all goats tested were seropositive, and 73% of herds had at least one seropositive member. Serum samples in this study were obtained from 28 states. Prevalence was highest in the western Pacific and northern plains regions on family-owned farms, and increased with age. Prevalence in this study was lowest in the Angora breed.[12]

Necropsy Findings Grossly, goats affected with the polysynovitis-arthritis form of CAEV have thickened, sometimes folded synovium consistent with synovial hyperplasia due to chronic inflammation. Microscopically, synovial hyperplasia is characterized by mononuclear infiltration of lymphocytes, plasma cells, and macrophages. Synovial spaces contain fibrin, and synovial villi and collagen are necrotic.[1]

No gross lesions are apparent in the CNS of goats affected with the leukoencephalomyelitis form of CAEV, but microscopically, perivascular infiltration of lymphocytes, macrophages, and plasma cells are observed. Perivascular infiltration is often accompanied by malacia of the brain and spinal cord, in addition to loss of myelin. Occasionally, degenerative lesions are seen in the gray matter.[13]

Treatment and Prognosis Prognosis for CAEV infection varies because most goats do not show clinical disease; once signs begin, however, rapid deterioration ensues. Arthritis and accompanying weight loss progress, and there is no treatment. Kids or mature goats affected with the leukoencephalomyelitis form do not survive and should be euthanized for humane reasons. Reportedly, a genetically determined predisposition for development of CAEV arthritis exists and can be identified with DNA fingerprinting.[14]

VetBooks.ir

Prevention and Control Prevention and control centers upon colostrum and milk management, but kids should also be prevented from any contact with the dam following parturition. Heat treatment of colostrum by holding it at 45°C (113°F) for 1 hour effectively inactivates the virus.[7] Kids can then be fed pasteurized milk until weaning. Unpasteurized goats' milk from seronegative dams is a risky substitute for heat-treated milk because some seronegative goats shed virus for long periods before seroconversion occurs. Pooling of colostrum increases the prevalence of disease in goat dairies, so this practice should be restricted. Kids should be tested serologically at periodic intervals to detect and remove infected individuals. Seronegative goats should be isolated from seropositive ones by a minimum of 6 feet.[7] Sharing of feed and water troughs should not be allowed, nor should use of common needles during routine vaccination or administration of medication. During breeding, seronegative does should not be housed with seropositive bucks, but they can be hand mated and quickly re-isolated. New additions to the herd should be tested and isolated until seronegative status is confirmed prior to entry into the herd.

Despite diligent prevention and control programs based on elimination of colostrum and milk transmission, isolation of seronegative goats, and serologic monitoring, obstacles to a CAEV-free herd are often encountered. Detection of virus has been reported in properly treated colostrum.[4] Overheating colostrum denatures immunoglobulin, thereby preventing effective passive transfer of immunity, but not heating colostrum long enough or at high-enough temperatures fails to inactivate the virus. Feeding overheated colostrum may also cause diarrhea in kids.[15] Attention to time and temperature details during heat treatment of colostrum and pasteurization of milk are of the utmost importance for effective colostrum and milk management. Some farms routinely feed cow colostrum, but neonatal isoerythrolysis has been reported in kids consuming cows' milk, and the lack of goat-specific immunoglobulin transfer is less than ideal.[15] Serologic monitoring can be complicated by the fact that viral shedding precedes seroconversion, so all goats should be tested a minimum of twice yearly to ensure any new cases are detected and managed accordingly. Unfortunately, no vaccine is currently available for CAEV.

Osteoarthritis

Melinda H. MacDonald

Definition The term *osteoarthritis* (OA) encompasses a large group of joint disorders characterized by progressive, permanent deterioration of the articular cartilage.[1-4] Cartilage damage is often accompanied by changes in the adjacent bone and soft tissue structures, including subchondral bone sclerosis, periarticular new bone formation, and synovial inflammation. Unfortunately, some confusion and debate surround the best term to use for this broad group of disorders. *Osteoarthritis, DJD, osteoarthrosis,* and *secondary joint disease* have been used almost interchangeably in veterinary medicine,[1,2] but *osteoarthritis* emphasizes the characteristic synovial inflammation detected in most patients, so this term is used here.

Interestingly, OA is one of the oldest documented orthopedic conditions. In fact, the fossilized remains of early dinosaurs suggest that OA predates the evolutionary development of mammals. Unfortunately, however, questions remain regarding the etiopathogenesis of OA, and this condition is still regularly diagnosed in most large animal species, including horses, cattle, and small ruminants. In goats, OA is frequently associated with CAEV (see previous discussion).[5,6] In pigs, OA is a common debilitating sequela of infectious arthritis or osteochondrosis.[7] Although not routinely diagnosed in sheep, OA has been reported to develop in individuals infected with ovine progressive pneumonia.[5] In contrast, joint disease is a common and expensive problem in the equine industry, and a wide variety of athletic injuries can progress to a common endpoint with stereotypic features of chronic OA.[1-3]

Etiology and Classification Many factors, including athletic performance, repetitive trauma, and age, are thought to influence cartilage homeostasis and contribute to degenerative changes in the joint. Contrary to the traditional view of articular cartilage as a passive bystander subjected to overexertion and traumatic wear-and-tear damage, it is now recognized that both resident and infiltrating articular cells have a critical role in the development of OA. Cartilage degeneration is an active process ultimately resulting from the inability of resident cells to maintain a normal balance between matrix synthesis and degradation. This occurs when chondrocytes and synovial cells are exposed to various nonphysiologic stimuli, including trauma and inflammation. Once the balance is disrupted, proteoglycans within the hyalin cartilage matrix are depleted and reduced in size, while the collagen meshwork progressively deteriorates. These changes in turn alter the mechanical properties of articular cartilage. A variety of different joint problems can initiate an imbalance between the rates of cartilage degradation and repair and, if left untreated, will ultimately progress to a common endpoint of OA.

Although a number of initiating and predisposing conditions have been identified, it is generally thought that trauma, either a single severe injury or low-grade repetitive damage, is the most important basis for the development of OA in large animal species.[1-3] In many cases the traumatic damage is augmented by abnormal weight bearing, poor-quality cartilage, or congenital joint instability, such as that seen with hip dysplasia in calves. In addition, OA frequently develops in joints that have unresolved or untreated osteochondrosis, subchondral bone collapse, or septic arthritis. In all these cases, the link between the cause and the end result of OA is a series of complex biochemical and metabolic events that are not yet fully understood. Regardless of the inciting etiology, advanced OA is characterized by fibrillated and ulcerated cartilage, eburnation and sclerosis of the subchondral bone, hyperplasia of the synovial membrane, and development of periarticular osteophytes.

Several classification schemes have been proposed to group clinical OA conditions in both human and veterinary medicine. One useful classification developed for equine OA defines three main categories of disease based on predisposing causes and clinical findings.[6] The categories include OA associated with synovitis and capsulitis (type 1), OA secondary to other identified injuries or disorders (type 2), and incidental or nonprogressive articular cartilage erosion (type 3).[2] For example, type 2 OA would include the chronic degenerative changes typically associated with intraarticular fractures, septic arthritis, osteochondrosis, and traumatic cartilage or ligament injuries. All three categories are routinely identified in equine athletes, but this simple scheme can easily be applied to other large animal species as well. Cattle most often develop type 2 OA as a consequence of septic arthritis, cruciate rupture, osteochondrosis, or nutritional deficiencies.[7]

A second way of classifying OA is based on the possible deleterious effects of biomechanical forces on normal and abnormal joints.[3] According to this scheme, the first of two major causes of OA is the concentration of abnormal forces on a previously normal joint. For example, OA can develop when there is increased weight bearing on one limb to protect a painful contralateral limb. The second major cause is the concentration of normal forces on an abnormal articulation, such as the joint damage that occurs when normal weight-bearing forces are applied to cartilage previously exposed to infection.

Pathology and Pathogenesis Despite the many pathways by which OA may develop, the resulting changes in the joint are essentially indistinguishable regardless of the initiating cause. By definition, this condition has a characteristic picture of cartilage damage with variable amounts of hypertrophic cartilage and bone remodeling. Pathologic features include different degrees of cartilage splitting and fragmentation, extending to complete erosion and loss of articular cartilage.[1-3] Typically the rate of disease progression and severity of OA are related to the nature and severity of the primary

VetBooks.ir

insult, the animal's age at the time, the joint location, and the animal's type and level of activity.

The pathogenesis of these changes is only partially understood. Several explanations have been proposed for the failure of resident chondrocytes to maintain the extracellular matrix. Mechanical trauma to the joint surface could initiate matrix damage, and repetitive microtrauma could damage chondrocytes and physically disrupt the joint surface. Leukocytes in an inflamed joint release destructive enzymes that can degrade the cartilage surface. Recent work has also demonstrated that various polypeptide mediators released in inflamed joints can stimulate chondrocytes to degrade their surrounding matrix. Regardless of the initiating factor, once the balance of chondrocyte-matrix turnover shifts toward degradation, proteoglycans are rapidly depleted from the extracellular matrix, and collagen fibers are exposed to direct traumatic and enzymatic breakdown. Unfortunately, hyaline cartilage has no effective intrinsic repair mechanism.

Articular cartilage damage is accompanied by changes in the adjacent subchondral bone (e.g., sclerosis), joint capsule (e.g., synovial hyperplasia, thickening of fibrous joint capsule), and joint margin (e.g., osteophyte formation, enthesophyte formation at joint capsule and ligament insertions).[3] Subchondral bone sclerosis may develop from an abnormal distribution of forces under damaged articular cartilage, or it may actually precede the cartilage damage. It is now known that bone remodeling and subchondral bone sclerosis occur in response to repetitive cyclic compression during exercise and, in certain cases, could result in trauma to the overlying articular cartilage and predispose to the development of OA (e.g., third carpal bone disease in horses). Joint margin changes occur as a result of progressive cartilage deterioration and subchondral remodeling (osteophytes) or joint instability (enthesophytes).

Clinical Signs

History and occupation are important for identifying animals at risk for developing OA. Typically the first sign an owner or caretaker recognizes in an affected animal is lameness or stiffness. Whereas the pain and dysfunction may develop insidiously, the owner will often report a sudden onset of clinical signs. Flexion and extension of an involved joint frequently exacerbates the lameness or elicits a pain response. Because articular cartilage is aneural, pain is thought to result from joint inflammation and secondary changes in adjacent tissues. Pain receptors are abundant in joint capsules, articular ligaments, and subchondral bone. Joint stiffness may be associated with guarding of a painful joint. Decreased ROM with joint capsule inflammation is also common. Osteophytes and enthesophytes may be palpable in chronic cases of bone spavin and ringbone. A postural deformity may be evident if articular degeneration progresses to ankylosis. It is also important to remember that OA may exist in the absence of any clinical signs.

Gait abnormalities compatible with OA include shortened stride length, limb abduction, and dragging the toe. Increased lameness after sustained flexion of a single joint suggests the joint is involved. Horses with OA often present early in the course of disease with a primary complaint of poor performance. These individuals can warm out of the lameness or temporarily improve with rest and are often difficult to diagnose. In contrast, food animals typically present in the advanced stages of OA. Rams and bulls may stand post-legged and appear weak in the rear when the hindlimbs are severely affected. In all species, the severity of signs varies with the joint affected, stage of disease, amount of inflammation, cartilage degeneration, and periarticular changes.

Diagnosis

Regional nerve blocks and intraarticular anesthesia can be useful for determining the origin of lameness. Unfortunately, standard synovial fluid analysis typically shows only minimal nonspecific changes. Although not useful for determining the severity of cartilage destruction, cytologic analysis is often useful for differentiating OA from other causes of synovial inflammation (e.g., septic arthritis). A variety of synovial fluid markers have been evaluated as possible diagnostic aids for evaluation of equine synovitis and joint disease (e.g., cytokines, eicosanoids, GAG concentrations, immune complexes, collagen type-specific antibodies and propeptides, cartilage wear fragments, free-radical oxidation products, polymerization of hyaluronate, chondroitin sulfate epitopes). Current detection techniques for cytokines and eicosanoids may prove useful diagnostically and prognostically.

After identification of an involved joint, radiographs are used to determine the severity and extent of disease. Articular cartilage is not visualized but may be indirectly assessed by evaluating joint space width. In contrast, the associated subchondral and periarticular bone reaction can be directly evaluated. Radiographic signs of OA develop gradually, affect opposing joint surfaces, and may include destructive as well as productive lesions. Changes typical of advanced OA include marginal osteophyte proliferation, periosteal new bone production at sites of joint capsules and ligamentous attachments (enthesophytes), narrowing or obliteration of the joint space, subchondral bone sclerosis, and occasionally subchondral lysis. Early in the disease, no bony lesions may be detected, and clinical findings from the entire examination must be considered. Radiographic changes associated with OA must be differentiated from similar bone reactions caused by active infection, fractures, osteochondrosis, and invasive tumors. Infectious arthritis classically causes rapid widespread osteochondral destruction. Minimally displaced fractures may mimic OA but are usually discrete isolated lesions. Knowledge of the characteristic site distribution and site-respective appearances of osteochondroses in each species is useful for differentiation from OA. The presence of OA in joints with osteochondrosis usually worsens the prognosis.

Scintigraphy is particularly valuable in early disease states when conventional diagnostic methods have not revealed bone or soft tissue changes. Increased scan activity is associated with soft tissue inflammation or increased bone remodeling, but alone it is not diagnostic for OA. Arthroscopy is the best method for gross evaluation of articular cartilage and is most useful when lameness has been localized to a specific joint but no bony changes are detected radiographically. This technique provides the added therapeutic benefit of simultaneous joint lavage. Although arthroscopy was initially promoted for diagnostic and therapeutic use in equine patients, these techniques are gaining popularity in food animal practice as well.[8]

Treatment

The choice and efficacy of treatment depend on the inciting cause of OA, stage of cartilage degradation, joint involved, and degree of active inflammation. In general the treatment of OA should be directed at eliminating any primary causes, reducing active joint inflammation, and treating articular cartilage loss or degeneration.[1,2,9] Early treatment of primary problems minimizes the extent of secondary joint damage. For example, fractures and osteochondritis dissecans can often be managed successfully with arthroscopic surgery; however, early intervention is essential to avoid the secondary changes of OA.

Many therapeutic options are designed to treat active soft tissue inflammation and prevent progression of articular cartilage damage. Rest is the simplest but often the most difficult recommendation to enforce, especially when dealing with elite performance horses. There are also valid concerns that complete rest may result in resorption of subchondral bone and predispose the horse to subsequent injury. Other treatments for soft tissue disturbances in the joint include physical therapy and controlled exercise, systemic NSAIDs (e.g., phenylbutazone, flunixin meglumine), joint lavage, and topical application of antiinflammatory products.

Numerous medications have been specifically designed and marketed for treating OA in human and veterinary patients. However, many of these products remain controversial in terms of their safety and efficacy in large animals. The most popular formulations include intraarticular corticosteroids, intraarticular and intramuscular (IM) polysulfated glycosaminoglycans (GAGs), intraarticular and IV hyaluronan, and oral GAG supplements.

Intraarticular steroids are the most potent antiinflammatory agents available, but they have been associated with progressive cartilage damage.[9,10] Nevertheless, investigations critically evaluating the

VetBooks.ir

effects of corticosteroids in equine joints suggest that when administered at physiologic doses, these drugs may have beneficial protective effects.[9,10] Current recommendations emphasize the need for appropriate caution and encourage use of low doses of steroids in conjunction with other antiinflammatory medications. Hyaluronan (sodium hyaluronate) is currently used both intravenously and intraarticularly to treat synovial inflammation and OA in the horse.[9,11] The intraarticular products vary in molecular weight and cost and include cross-linked hylans, which may prolong intraarticular retention. Clinical reports document the efficacy of hyaluronan for mild to moderate synovitis, and some research supports an inhibition of proteoglycan degradation and inhibition of synoviocyte release of various inflammatory mediators. Other studies failed to demonstrate beneficial effects in joints with significant articular cartilage damage or osteochondral fragmentation.

Intraarticular administration of polysulfated GAG has been reported to reduce progressive degenerative changes in articular cartilage, but is controversial in terms of its ability to augment the chondrocyte repair response.[9,12] IM use is advocated because intraarticular use has been associated with adverse reactions and potentiates the risk of iatrogenic joint infection.[9,12] Intraarticular regenerative medications (platelet-rich plasma and stem cell therapy) are currently under investigation and used in specific clinical cases, but clinical research data are lacking.

There is still great interest in the use of nutritional supplements to prevent and treat OA, with a proliferation of products promoted as beneficial to joint health and cartilage regeneration.[13] Among the most popular are oral glucosamine sulfate and chondroitin sulfate preparations. However, oral absorption of chondroitin sulfates has not been documented in the horse, and although clinical reports suggest a beneficial effect from these supplements, additional controlled studies are necessary to confirm these effects. Methylsulfonylmethane (MSM), a dietary derivative of DMSO, is also being used as a dietary supplement to control the inflammation associated with OA. Again, minimal documentation exists regarding its value in treating joint disease in large animals. Other compounds to treat OA include *S*-adenosyl-L-methionine (SAMe) and various vitamins known to provide antioxidant protection.

The most challenging aspect of OA management is treating existing articular cartilage degeneration and loss. Partial-thickness cartilage defects do not heal, and full-thickness defects heal with inferior fibrocartilaginous tissue. Some surgical techniques (e.g., curettage, subchondral bone drilling, microfracture) facilitate defect repair by enhancing fibrocartilage ingrowth from the underlying subchondral bone; however, fibrocartilage is biomechanically inferior to normal hyaline cartilage. Grafting cartilage defects with periosteum, perichondrium, and sternal cartilage has not been encouraging. More recent work focuses on transplantation resurfacing using chondrocyte grafts and growth factors to stimulate repair.[14]

Prognosis

Prognosis for animals with OA depends on the initiating factor(s), extent of the secondary disease, joint affected, and intended use of the animal. With early and aggressive treatment, many animals can return to soundness and athletic performance. In other cases, salvage in the form of surgical arthrodesis may provide the most favorable outcome.

Sprains, Subluxations, and Luxations

Will C. Jordan • Robin M. Dabareiner

Definitions

Sprains and luxations have been classified as type 2a traumatic arthritides.[1] These injuries have been categorized in three forms: mild, moderate, and severe. *Mild sprains* constitute injuries that involve the tearing or disruption of a minimal number of ligament fibers with no loss of integrity to the ligament. Hemorrhage and edema are typically present in the ligament. Injuries that involve a portion of the ligament, with loss of integrity, are considered *moderate sprains*. Laxity of the joint is often present with moderate injury, but complete separation of the ligament from the bone or complete separation of the body of the ligament is not seen. Significant hemorrhage and edema are present in the ligament. Injuries that involve tearing of the ligament, resulting in either complete separation from the bone or widening of the tendon fibers, are considered *severe sprains.* These injuries will result in some form of joint instability, especially when the affected joint is manually stressed.

FIG. 38-21 Dorsopalmar radiograph of a subluxated metaphalangeal joint after the joint has been manually stressed.

Luxations and subluxations are usually the result of severe sprains of periarticular or articular ligaments. *Luxations* represent the complete dislocation of the articular surfaces, with *subluxations* having only partial and incomplete disarticulation (Fig. 38-21).

Etiology and Pathophysiology

Sprains can be associated with acute injuries in which there is excessive strain on the ligament fibers, on ligamentous attachments, or secondary to repetitive actions on the ligament. The latter results when there are maximal or near-maximal loads repeatedly applied to the ligaments and associated structures, causing a degenerative type of lesion. Age can also be a contributing factor in these degenerative changes. Muscle fatigue can contribute to the weakening of adjacent structures, increasing the stresses applied to the supporting ligaments. Luxations and subluxations are usually of traumatic origin, such as stepping in a hole or entrapment of a limb in a gate or fence.[1]

Typically, hemorrhage and edema form within the ligament(s) surrounding the joint capsule, or in severe lesions the hemorrhage can be periligamentous or intraarticular. Inflammation ensues, and the ligamentous or capsular lesion heals through fibrosis, forming a scar, with the predominant production of type III collagen. Type III collagen contains smaller-diameter fibrils and has fewer cross-links than type I collagen, which is the predominant collagen type in normal tendons and ligaments. As the lesion matures, both fibril diameter and number of cross-links increase, in addition to the proportion of type I collagen. This will increase the strength of the injury, which can take weeks to months to heal but will ultimately be weaker than normal tissue.[2] Often the affected joint capsule and surrounding ligaments become fibrotic as healing occurs, resulting in decreased ROM in the affected joint. Secondary calcification of the affected soft

VetBooks.ir

tissue structures may occur and also adversely affect the joint's mobility.

Luxations of the coxofemoral joint in calves may be associated with calving injuries during dystocia or in cows being ridden while in estrus, or with a traumatic fall in the immediate postpartum period.[3,4] Shoulder joint luxations are usually the result of trauma.[5,6]

Clinical Signs and Differential Diagnosis Clinical signs vary depending on the severity of the sprain and time since the initial injury. The animal may have a history of mild lameness or decreased performance, as well as a history of a positive response to NSAIDs or stall rest. Patients with moderate to severe sprains will typically have a more pronounced, acute lameness or may be non–weight bearing on the affected limb. There may also be localized swelling, heat, increased joint effusion, or pain elicited on palpation or manipulation of the affected joint. Other signs may include abnormal limb positioning, decreased ROM, crepitus, and joint laxity. Injuries may present after an acute or traumatic insult as chronic lameness, or a chronic mild injury can present acutely with severe lameness if the collateral ligament completely ruptures. Chronic injuries are characterized by joint capsule thickening or enthesophyte formation at the origin and insertion of the affected collateral ligament.

Subluxations and luxations result in loss of joint function and mobility and may present with a varus or valgus deformity. Complete luxations in the horse are most common in the pastern, fetlock, and hock joints.[1] Luxations can occur in the shoulder, carpus, and coxofemoral joint, but these luxations are less common in horses. Coxofemoral luxations are the second most common type of luxation in cattle.[4]

Differential diagnoses vary depending on the region affected and duration of injury but may include soft tissue contusion, synovitis and capsulitis, osteoarthritis, bursitis, musculotendinous injuries, fractures, physeal fractures, septic arthritis, tenosynovitis, and flexural or angular limb deformities.

Diagnostic Tests A thorough history and physical examination should be performed at presentation. The exam should include assessment of pain, swelling, heat, joint effusion, and joint instability. Patients presenting with only mild lameness should have a thorough lameness examination including perineural anesthesia to localize the affected region or joint. The clinician should be cautious if there is any evidence of joint laxity or instability or severe lameness, since perineural anesthesia could exacerbate the extent of joint damage.

Radiographs should be obtained to assess the joint's bony structures because concurrent factures are common, with traumatic insults resulting in luxation. Stress views can be performed to assess the level of joint instability (see Fig. 38-21). One study reported on 17 horses with luxation or subluxation of the metacarpalphalangeal (MCP) or metatarsalphalangeal (MTP) joints.[5] All had rupture of at least one collateral ligament (CL) of the joint. In those horses, radiographs showed that 8 of 17 horses sustained fractures, 6 of which were avulsion fractures located at the origin of the CL. Other types of fractures identified in that study were splint bone fractures and small articular chip fractures. Fractures of the proximal or middle pastern bones can cause luxation or subluxation of the proximal or distal interpastern joint. Nuclear scintigraphy can also be used to evaluate insertional desmopathies that may not be radiographically apparent.

Ultrasonography is very useful in localizing and depicting the severity of ligamentous lesions and for confirming the association of fracture fragments identified radiographically. In acute cases, ultrasound evaluation often shows hemorrhage within the joint capsule (Fig. 38-22). MRI is becoming more readily available in the veterinary field and has been found useful in identifying and characterizing lesions in ligaments. In addition, there may be concurrent damage to adjacent structures of the joint or avulsion fractures that might not be ultrasonographically or radiographically detectable but that can significantly influence the prognosis.[3,7-9]

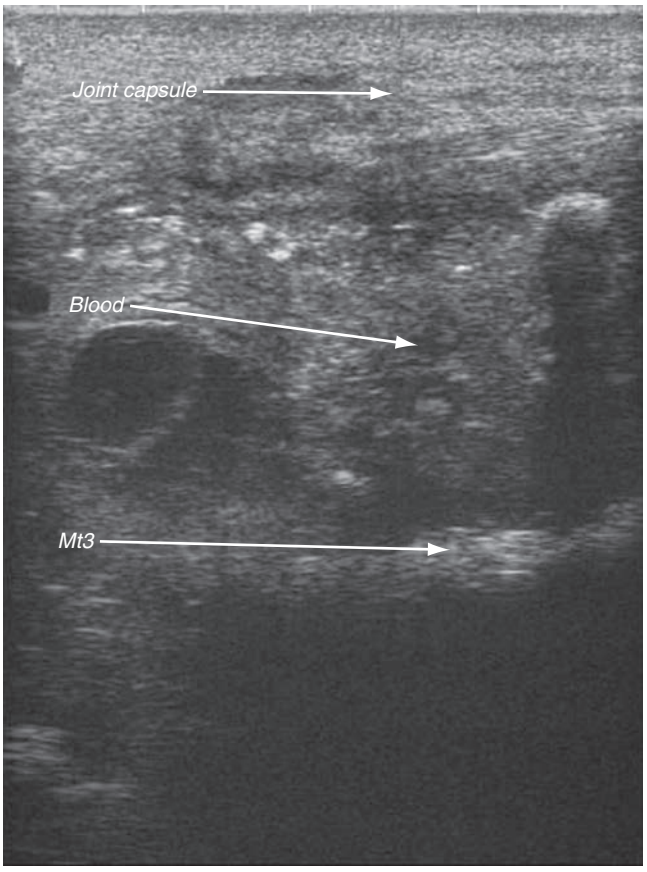

FIG. 38-22 Ultrasound image of a metacarpophalangeal joint from a horse with an acute sprain. Note the hemorrhage accumulation within the joint capsule. *Mt3,* Third metatarsal bone of fetlock joint.

Treatment Treatment is largely based on the severity of the lesion and the associated structures involved. Mild sprains can be treated conservatively with support bandages, NSAIDs, polysulfated GAGs, and rest for 3 to 4 weeks, followed by a controlled exercise program before returning to normal activity. Adjunctive physiotherapies may also be considered, such as hydrotherapy or shock wave treatment. Moderate sprains involving significant ligament damage may necessitate use of a cast or splint to provide joint stability during the initial healing process. Distal limb immobilization with a fiberglass cast and stall confinement was the initial treatment for 10 of 17 horses with MCP or MTP luxation and CL rupture. Duration of cast immobilization ranged from 14 to 132 days (mean, 71 days).[5]

In acute cases, hemorrhage is often present within the affected joint. This hemorrhage usually resolves after 7 to 10 days, but it can also subsequently form a fibrinous clot within the joint capsule, resulting in a chronic mild synovitis that can be treated with intraarticular medications such as sodium hyaluronic acid, triamcinolone, and amikacin antibiotic. Diagnostic arthroscopic surgery should be considered to evaluate articular cartilage integrity and remove persistent fibrin accumulation. If arthroscopic surgery is performed, a cast or splint should be applied to the affected limb during recovery from anesthesia to prevent luxation of the affected joint and further injury. Severe sprains may require some form of internal coaptation (surgical implants) or arthrodesis of the joint, depending on the degree of joint instability. Support of the contralateral limb should be considered for non–weight-bearing injuries.

Luxations of the coxofemoral joint in cattle can be repaired by open or closed techniques, and success depends on duration of the luxation, concurrent fractures or soft tissue injury, and age. Open reduction was reported as being more successful than closed reduction, although closed reduction should be attempted immediately after the injury if possible.[4] Shoulder joint luxations can also be

reduced by closed and open techniques.[5] Open reduction with internal stabilization seems to result in a better survival outcome for the animal.[5]

Prognosis Prognosis depends on the severity of damage to the intraarticular cartilage and surrounding soft tissue structures. Horses sustaining mild joint or ligamentous strains have a good prognosis for returning to previous athletic use. Horses sustaining moderate or severe sprains or joint luxations usually develop secondary DJD in the affected joint, which may require intraarticular medications and NSAIDs to return to previous use. The long-term prognosis for returning to athletic performance in many cases is poor. Eight of 17 horses with MCP or MTP joint trauma resulting in joint instability and rupture of the CL returned to riding and one returned to jumping activity after limb immobilization and stall confinement.[5] Simple shoulder luxations in large animals generally carry a guarded to poor prognosis. Simple coxofemoral luxations in cattle have a fair to good prognosis, with calves having a better prognosis than adult cows.

FIG. 38-23 Arthrogryposis as a result of Schmallenberg infection in a live lamb *(right)* in the United Kingdom. Its unaffected twin is on the left.

Arthrogryposis

Philippa Sprake

Arthrogryposis, or multiple congenital contracture, is a syndrome of persistent contracture present at birth.[1] In this condition, the limb cannot be straightened manually, and there is improper articular alignment or rotational deformity.[2] Arthrogryposis is one of the most common congenital defects of cattle and more commonly affects the forelimbs. It should be differentiated from other types of contractures, such as congenital tendon contracture or contracture secondary to articular fracture, ankylosis, septic arthritis, agenesis, or dysgenesis of joints.[2]

Etiologies for arthrogryposis include genetic, infectious, and toxic. A congenital syndrome comprising forelimb arthrogryposis, spinal dysraphism, and cleft palate has been documented in calves of primarily Charolais origin.[3] Arthrogryposis was documented to be part of the clinical findings in Holstein calves with the inherited complex vertebral malformation syndrome.[4] Various other congenital syndromes have been reported in cattle, including vertebral agenesis and arthrogryposis of the pelvic limbs in a Holstein heifer calf[5] and arthrogryposis in Herefords.[1] Arthrogryposis multiplex, or "curly calf syndrome," is an autosomal recessive defect in Angus cattle where kyphoscoliosis and decreased muscling are also observed.[6] While not as common as in ruminants, arthrogryposis has been reported in equines, including Norwegian Fjords[7] and a Thoroughbred foal.[8] Arthrogryposis has been documented as an autosomal recessive condition in Suffolk[9] and Corriedale sheep.[10] There are no documented case reports of arthrogryposis in camelids.

Viruses of the family Bunyaviridae have a common tropism for fetal tissues and result in abortion, stillbirths, and arthrogryposis.[11] The viruses include Akabane virus, primarily found in Australia, Asia, and the Middle East,[11] and Cache Valley virus in the United States.[12] Both wild and domesticated ruminants and horses are susceptible to the Akabane and Aino viruses.[11] Concurrent defects include hydranencephaly or microencephaly, cerebellar hypoplasia, and irregular neuromuscular development.[11,13,14] More severe defects are found with infection earlier in gestation.[11,14] In 2011, a syndrome consisting of fever, decreased milk yield, diarrhea, and abortion or stillbirth was reported in adult dairy cattle in northwestern Europe.[15] Abortions, stillbirths, and live births with congenital malformations were reported in calves, lambs, and kids (Fig. 38-23).[16] Congenital defects included arthrogryposis, brachygnathia inferior, spinal curvature, hydrocephalus, hydranencephalus, porencephaly, and cerebellar hypoplasia primarily. The syndrome was found to be caused by a novel virus of the Simbu serogroup of the genus *Orthobunyavirus,* and was named Schmallenburg after the town in Germany where it was first detected.[15] The virus is currently diagnosed by real-time polymerase chain reaction (RT-PCR).[15,17] No vaccine is currently available. In utero infection with bluetongue virus in cattle and sheep primarily presents with hydranencephaly, although arthrogryposis, prognathia, brachygnathia, and excessive gingival tissue have been reported.[18] The pestivirus causing border disease in lambs was shown to result in several congenital abnormalities when experimentally inoculated into pregnant ewes (arthrogryposis, tremors, brachygnathism, prognathism, and lateral deviation of joints).[19]

Arthrogryposis has been associated with ingestion of toxic alkaloids during pregnancy, including plants of the genera *Conium, Lupinus,* and *Nicotiana*.[20] All three have also been shown to result in cleft palate deformities when fed to goats during days 30 to 60 of pregnancy.[20] Arthrogryposis due to lupine toxicity has been termed "crooked calf disease." Congenital contractures have also been reported with the grazing of sorghum pastures in sheep[21] and feeding *Veratrum californicum* at day 29 of gestation in sheep.[22]

The pathogenesis of arthrogryposis is thought to be a result of denervation resulting in muscle atrophy with the functional opposing muscles resulting in contracture.[23] Reduced numbers of ventral horn cells have been reported in cases of multiple congenital contracture.[24] Restriction of fetal movement in utero has also been proposed.[24]

Animals with arthrogryposis may be aborted, stillborn, or born alive. The prognosis for survival, however, is poor. Treatment has been attempted by tenotomy of the ulnaris lateralis and flexor carpi ulnaris followed by stall confinement and bandaging.[25] In that study, a straight palmar carpal angle was achieved in 70% of treated limbs at 8-month follow-up. Outcome was improved in less severely affected limbs.[25] Arthrogryposis in aborted or near-term fetuses commonly results in dystocia, leading to the necessity for manual removal of the fetus by fetotomy or caesarian section.[2,14] Death of the dam has also been reported.[11] Severely affected animals commonly have secondary problems including sepsis and metacarpophalangeal deformities.[25] Surviving animals should not be retained in the herd as breeding animals.

Ankylosis

Ricardo Loinaz

Definition and Etiology *Ankylosis* refers to the abnormal fusion of bones in a joint, which can occur naturally or as a desired end result of treatment. *Facilitated ankylosis* refers to a medical fusion and thus is different from *arthrodesis,* or surgical fusion, of two or more bones into a single structure.[1] Naturally occurring ankylosis is often the result of disease or trauma to the joint and bones involved. Septic arthritis with subsequent DJD and associated prolonged

VetBooks.ir

therapy, including joint immobilization, are often the inciting factors for ankylosis. *Congenital ankylosis* is the absence of an articulation, and it is a rare condition in horses and cattle, often associated with other congenital abnormalities.[2] Congenital ankylosis of the DIJ in both hindlimbs, with concurrent dysplasia of the distal sesamoid bone in all four limbs, has been reported in a 2-year-old Arabian horse.[3] In calves and foals, congenital ankylosis may occur between vertebrae or in multiple joints of the limbs, resulting in dystocia related to musculoskeletal inflexibility.[2]

Joint fusion is initiated by biomechanical and biochemical factors, leading to instability and degeneration of cartilage and chondrocytes.[2] Periarticular contracture, joint capsule fibrosis, and chronic muscle spasm all contribute to joint immobility, which leads to synovitis and cartilage destruction. Ossification of periarticular soft tissues develops, resulting in partial bone bridging across the joint. The final stage of ankylosis is complete bone bridging with trabecular bone and joint obliteration.

Common sites of ankylosis in horses include the distal hock joints (distal intertarsal [DIT] and tarsometatarsal [TMT]), the thoracolumbar intervertebral articulations, and the PIP. These low-motion joints are more likely to achieve complete bone bridging without surgical intervention. In high-motion joints (antebrachiocarpal, midcarpal, metacarpophalangeal, scapulohumeral, and distal interphalangeal), naturally occurring complete bone bridging is rare, and the resulting cartilage degeneration leads to severe lameness. In these cases, surgical fusion or arthrodesis using internal fixation techniques is required if treatment is to be attempted.[4] Large animals with vertebral ankylosis may show neurologic deficits caused by bony impingement on the spinal cord or by dynamic compression leading to abnormal motion or spinal ligament hypertrophy.[2]

Clinical Signs and Differential Diagnosis Indications for ankylosis include stiffness of a joint and associated immobility, degenerative joint changes, decreased range of joint motion, and varying degrees of lameness. Decreased ROM is most obvious if high motion or multiple joints are involved. Degree of lameness can range from mild to severe, particularly in the acute phase where local inflammation contributes to the degree of lameness. Enlarged and thickened periarticular structures, conformational abnormalities, disuse atrophy of muscles or disuse osteopenia of bones, and gait stiffness may also be identified. Once bone bridging is complete and no articular cartilage remains, the condition is no longer painful and the articulation is immobile.

Differential diagnoses include soft tissue injuries or contracture, intraarticular or periarticular adhesions, joint luxation, neoplasia, arthrodesis, spondylosis, an intraarticular mass, osteomyelitis, and fracture. Diagnosis of ankylosis should be based on a complete physical and musculoskeletal examination, lameness evaluation, and radiography. Multiple radiographic views should be available for definitive diagnosis, but additional imaging techniques such as ultrasonographic evaluation of relevant soft tissues and joint spaces, CT, and MRI may be useful and provide more detailed information that may influence the treatment option elected.

Treatment and Prognosis Treatment in the acute phase focuses on providing comfort to the animal, because ankylosis is a chronic and progressive disease process. A complete treatment plan should be tailored to the specific case and is often determined by the presence or absence of infection or severe joint instability. Antiinflammatory medications (phenylbutazone, firocoxib, flunixin meglumine, intraarticular corticosteroids) are necessary in most cases. Additional oral joint supplements, hyaluronic acid, and polysulfated polysaccharides (Adequan) may also be beneficial as chondroprotectants. Although joint immobilization and a decrease in exercise are often necessitated, low-level exercise appears to be beneficial in some cases because it helps increase and stimulate development of new bone formation, promoting faster and more complete ankylosis.[2] Unstable joints or actively septic joints, however, require immobilization with splints or casts to allow the fusion to progress and improve the animal's comfort level. Animals that remain lame, have end-stage joint disease, or are not completing ankylosis naturally require surgical or chemical arthrodesis to improve the comfort level and chances of returning to performance activity.

Different methods of facilitated ankylosis can be used to promote joint fusion. The speed at which complete bone bridging occurs may be enhanced through the use of chemical chondrocyte destruction or surgical obliteration of the articular cartilage. Chemical methods of ankylosis include the use of sodium monoiodoacetate (MIA) and ethyl alcohol, but MIA has been associated with considerable morbidity and signs of severe pain.[1] In addition, postinjection soft tissue swelling, progression of osteoarthritis to adjacent unaffected joints, severe soft tissue necrosis, variable length of convalescence, and inconsistent outcomes are why MIA-mediated ankylosis can no longer be recommended.[5] Ethyl alcohol ankylosis works via nonselective protein denaturation and cell protoplasm precipitation and dehydration. One of the first controlled studies investigating the use of ethyl alcohol in horses found that 70% ethyl alcohol injected in the TMT joint of healthy horses with no radiographic evidence of joint disease resulted in a pain-free fusion by 4 months in 8 of 16 horses and complete fusion by 12 months post injection in 15 of 16 horses.[6] A recent study evaluated the safety and efficacy of ethyl alcohol–mediated ankylosis of the DIT and TMT joints in horses with lameness localized to those joints and found a significant reduction in posttreatment lameness in all treated horses but evidence of joint collapse and progressing ankylosis by 3 months post injection.[1] Another study looked at 24 horses that received ethyl alcohol injections in the distal hock joints, and 52% had improved lameness scores at 6- and 9-month follow-up, whereas 19% had deteriorated.[7] A recent study looked at 70% ethyl alcohol injection alone or in combination with lag screw placement for PIP fusion, and in both instances alcohol treatment failed to produce reliable fusion of PIP joints.[8] Another recent study looked at facilitated ankylosis of PIP joints using ethyl alcohol and reported that 50% of horses were sound and 34% were improved but not sound at time of follow-up.[9] The median time for horses to become sound enough to return to work in this study was 8 months, suggesting that ethyl alcohol–facilitated ankylosis may be more effective and work faster in DIT and TMT joints than in PIP joints.

Facilitated ankylosis via surgical débridement of articular cartilage and use of casts or transfixation casts is recommended in the initial treatment of septic PIP joints instead of surgical arthrodesis in the acute phase.[5] Laser-facilitated ankylosis using a neodymium:yttrium-aluminum-garnet (Nd:YAG) or a diode laser to destroy articular cartilage by superheating and vaporizing synovial fluid, resulting in chondrocyte death, can also be used for facilitated ankylosis. Experimental studies using laser-facilitated ankylosis in DIT joints found that partial ankylosis was achieved in 5 to 12 months.[5] Transarticular drilling has been used as a method for ankylosis of the DIT and TMT joints, alone or in combination with laser application, and estimates of outcomes suggest that this technique is 47% to 85% successful.[5]

Ankylosis may require 6 to 12 months for complete bone bridging after surgical or chemical treatment methods. This process can take several years if left to natural ankylosis. Prognosis depends on which joint is involved and the expectations for use of the animal. Low-motion joints have a good prognosis for returning the horse to soundness and athletic performance once the fusion process is completed. High-motion joints have a poor prognosis for return to use in horses.

Osteomyelitis

Justin Dominick McCormick

Definition and Etiology Osteomyelitis is an infectious inflammatory disease process of bone and its marrow cavity, causing bone destruction. Infection may be localized to a single region of

VetBooks.ir

bone or may involve several structures including marrow, cortex, periosteum, and surrounding soft tissue.[1,2] If only bone is affected, it is classified as osteitis. The majority of osteomyelitis cases, both acute and chronic, are bacterial in origin, though myotic infections have been reported. This disease process begins hematogenously, secondary to adjacent soft tissue infection, or by direct inoculation (e.g., trauma, internal fixation).

Clinical Signs and Differential Diagnosis Clinical signs will depend on the severity and duration of infection and the organism involved. Diagnosis is based on a complete history, physical examination, identification of microorganisms, and results of diagnostic imaging.

In the neonate, acute osteomyelitis is most commonly of hematogenous origin. Translocation of bacteria from the umbilicus or other sites of infection (e.g., respiratory or gastrointestinal) results in infection of synovial structures and bone.[3] In the foal, common anatomic locations of established infections have been described.[4] *S-type infections* only involve the synovial membrane. *E-type infections* are located around areas of growth (i.e., articular epiphyseal complex). A *P-type infection* is a primary infection of the long-bone physis. Early detection of acute osteomyelitis in young animals can be difficult. Clinical signs of S- and E-type infections include persistent lameness and joint effusion with fever. P-type infections present without synovial effusion, but edematous soft tissue swelling secondary to osteomyelitis of the metaphysis is often seen. The femoropatellar and tarsocrural joints are most commonly affected, followed by the carpal and fetlock joints. Persistent lameness that is unresponsive to antiinflammatory treatment often precedes diagnosis, but lameness can be subtle during the early stages of osteomyelitis and easily mistaken for musculoskeletal injury.[5] There is often a history of failure of passive transfer, pneumonia, septicemia, gastroenteritis, or omphalophlebitis.[6] Osteomyelitis in the neonate is typically localized to areas of growth near the distal femur, radius, tibia, and metacarpal/metatarsal regions (Fig. 38-24).[3] Joints of lame foals should be evaluated thoroughly to localize pain and swelling.

Osteomyelitis in adults is usually associated with traumatic infection (e.g., puncture wound or laceration) or open fracture reduction. In mature animals it is difficult to differentiate between infection and postoperative inflammation in cases of acute osteomyelitis. Lameness may be mild initially then progresses rapidly to non–weight-bearing lameness. Local swelling, painful response to digital palpation, fever, and inappetence are clinical signs often associated with acute osteomyelitis in the adult.[2] Clinical signs of infection related to injury or following orthopedic surgery may be present as early as 7 days or be delayed up to 3 to 4 weeks.[6] Chronic osteomyelitis becomes more localized as the disease progresses and often results in a firm swelling over the affected area. Persistent drainage from an incision or area of granulation tissue, mild to severe lameness, or a non-healing wound are also often seen with disease progression in chronic cases. Drainage may be persistent or intermittent and is generally characterized as purulent. Osteomyelitis in conjunction with septic arthritis or tenosynovitis may result in only mild lameness if the wound is open and able to decompress.

Osteomyelitis is difficult to diagnose with radiography in the acute stages. Soft tissue swelling with or without gas opacities adjacent to the area of infection may be the only abnormalities noted in early infections. Ultrasonography can aid in early diagnosis of osteomyelitis by detecting purulent fluid in soft tissues and irregular bone echoes near affected sites.[2] Osteolysis does not appear on radiographs until 30% to 50% of bone mineral is lost, which may take up to 10 to 14 days after infection is established.[6] Radiographic signs of chronic osteomyelitis include soft tissue swelling with bone destruction and new bone formation (Fig. 38-25).[8] Infection of bone may result in the formation of an *osseous sequestrum,* a piece of radiodense cortical bone that has lost local vascular supply.[9] The sequestrum is well defined by an outline of radiopaque productive new bone formation called an *involucrum,* which forms as the body attempts to wall off infection.[8] An opening to the sequestrum, the *cloaca,* is usually present and allows drainage of purulent exudate out to the skin surface.[9] Fistulography can be useful in determining the extent of draining tract communication with bone or joints.[8]

Advanced imaging modalities provide greater diagnostic capabilities than radiography and may help in the early detection of osteomyelitis. CT gives superior imaging of bone in three planes and can be used to identify purulent material in the medullary cavity, adjacent soft tissue abscesses, intraosseous gas, decreased bone density, and presence of foreign bodies.[2] CT can also provide additional

FIG. 38-24 Osteomyelitis and septic physitis of the distal radius of a 3-week-old foal. There is a large area of lysis over the distomedial radius involving the metaphysis, physis, and epiphysis with marked soft tissue swelling.

FIG. 38-25 Lateromedial radiograph of a horse with chronic osteomyelitis of the third metatarsus. A sequestrum is identified at the level of the proximal metaphyseal region. An involucrum is outlined by an area of medullary sclerosis. There is periosteal new bone formation over the dorsal cortex.

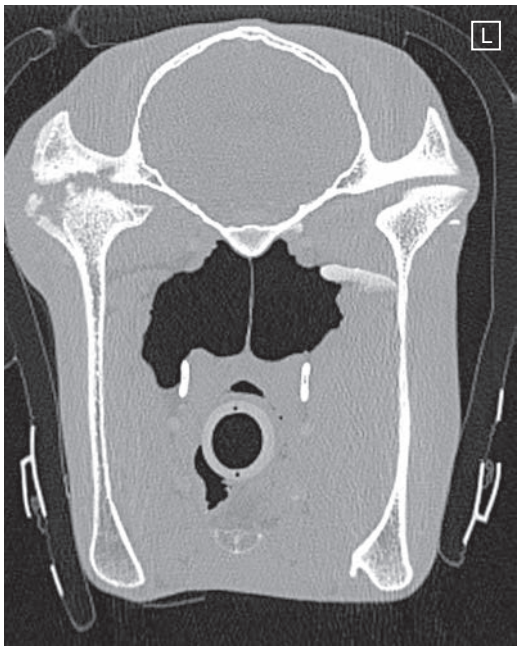

FIG. 38-26 Computed tomography image of a septic temporomandibular joint with osteomyelitis of the right mandibular and temporal bones. There are multiple small subchondral lytic lesions of the medial aspect of the condyle and temporal bone. Periosteal reaction is associated with the temporal bone at the level of the temporomandibular joint.

information in anatomic locations where images on radiographs and ultrasound are difficult to interpret (e.g., skull) (Fig. 38-26).[2] MRI is useful in determining lytic changes in the medullary cavity but less effective than CT in defining cortical bone involvement.[2]

Development of osteomyelitis following fracture repair decreases stability of the affected limb and increases healing time. Signs related to orthopedic infection are subtle in the acute stages, making primary recognition difficult. Fever, malaise, and a slight increase in lameness are nonspecific signs of immediate postoperative infection. Risk factors associated with orthopedic procedures include use of implants, length of surgery, location of injury, and the amount of soft tissue damage related to the initial injury.[2,10] Open reduction and internal fixation during fracture repair require extended duration of surgery, increasing the exposure time of soft tissues to air.[10] Early radiographic evaluation when infection is suspected is beneficial to ensure structural stability of the construct.[5] Bone lysis around implants with periosteal reaction unrelated to fracture healing can be seen later on radiographs (Fig. 38-27).[5] Implant loosening secondary to bone lysis increases motion across the fracture gap and decreases stability of the repair. Healing is prolonged or improbable when rigid internal fixation is lost. In addition, motion across the fracture together with osteomyelitis adds to patient discomfort and reluctance to bear weight on the affected limb. Overloading the contralateral limb increases the risk of laminitis or breakdown of the support limb.

Microbial culture and sensitivity testing should be performed to confirm a diagnosis of osteomyelitis. Ultrasonography can be useful in aspirating fluid samples proximal to suspected bone lesions. A WBC count should be performed to differentiate between serous and purulent aspirates.[2] Culture may also be performed on surgically removed sequestra, necrotic tissue from the area, biopsy of affected bone, and infected metallic implants. Samples should be collected aseptically and inoculated directly into culture media to improve chances of obtaining bacterial growth.[2] Swabs taken from an open draining sinus tract may include nonpathogenic microorganisms and yield misleading results.[1] Arthrocentesis is indicated to measure WBC count, cytology, and total protein in cases of septic arthritis and osteomyelitis.[2] Both aerobic and anaerobic culture testing should be performed on samples when osteomyelitis is suspected. Blood culture may be useful in isolating the infectious organism in the neonate.

FIG. 38-27 Dorsoplantar **(A)** and lateromedial **(B)** radiographic projections of implant-associated osteomyelitis and nonunion of a comminuted fracture of the third metatarsus in a horse. The fourth most distal screw of the lateral plate is retracting. There is increased lucency surrounding the screws involving the medial plate, suggestive of implant loosening and instability secondary to implant failure associated with osteomyelitis.

Clinical Pathology A peripheral WBC count is generally considered unreliable in determining the presence of osteomyelitis. In the acute stage, increased fibrinogen and a degenerative left shift in the leukogram should raise the index of suspicion that bone or synovial infection may be present.[3] In chronic cases of osteomyelitis, a leukogram is often within normal range.

Arthrocentesis is the preferred diagnostic test for septic arthritis in both the adult and neonate. Synovial sepsis should be suspected if the nucleated cell count is greater than 10,000 cells/dL or if the polymorphonuclear cell count is over 90%.[3] Gram stain of synovial fluid immediately following arthrocentesis can be useful in narrowing selection of antimicrobial treatment before results of culture and sensitivity become available. Nuclear degeneration and bacteria are

VetBooks.ir

not always observed on cytologic analysis of acutely infected joints. The absence of these markers should not be delay treatment if suspicion of joint sepsis high.[3] The most commonly isolated gram-negative bacteria from foals include *E. coli, A. equuli,* and *Salmonella* spp. Gram-positive isolates include *Streptococcus* spp., *Staphylococcus* spp., and *R. equi*.[7] Neonates exhibiting signs of lameness should be monitored closely for synovial sepsis until the definitive cause of clinical signs can be determined (e.g., musculoskeletal injury). In the adult horse, members of the Enterobacteriaceae family, *Streptococcus* spp., and *S. aureus* are the most commonly isolated microorganisms in cases of osteomyelitis, septic arthritis, and tenosynovitis.[13] In a retrospective of 192 cases of postoperative infections involving orthopedic implants for repair of long-bone fractures or arthrodesis, the most common gram-negative and gram-positive bacteria cultured were *Enterobacter cloacae* and gram-positive coagulase-negative *Staphylococcus,* respectively.[14]

Pathophysiology Development of osteomyelitis is related to host microbial factors.[1] Injured bone forms a sequestrum if the periosteum is damaged, local blood supply is disrupted, or soft tissue covering is lost, leading to compromise of normal defense mechanisms. As the body attempts to contain the infection, inflammatory cells are released into the area and engulf bacteria. Proteolytic lysosomal enzymes are released as phagocytic cells are lysed, resulting in damage to local tissues and bone.[2,11] If the host is unable to eliminate the infection, a purulent exudate begins to accumulate. As the infection persists, bacteria colonize adjacent periosteal, cortical, and medullary regions of bone. Bacteria attach to the surface of dead bone or implants through adhesins and produce a polysaccharide extracellular matrix known as *biofilm*.[2,11] Within this biofilm, microcolonies develop, mature, and continue to produce matrix material.[11] Inflammatory molecules, phagocytic cells, and antimicrobials are unable to effectively penetrate the biofilm matrix, providing a protective environment through evasion of host immune responses and effects of antimicrobial therapy.[2,11] Granulation tissue forms over the devitalized tissue, and new bone is laid down, forming an involucrum as the body attempts to isolate the infection.[9] As exudate accumulates, it may eventually form a draining sinus tract through the cloaca out to the skin.

Hemotogenous osteomyelitis is most often localized to the metaphyseal region in young, developing animals. The nutrient artery ends in the metaphysis, capillaries close to the growth plates make loops to enter large venous sinusoids, and blood flow subsequently slows.[12] The slowing of blood flow in this area allows bacteria to accumulate, leave the vasculature, and initiate an inflammatory response.[12] It has also been shown in the developing embryo that osteogenic cells and vascular endothelium are a continuous network, suggesting that the relationship between bone and circulation is closer in the developing animal than in the adult.[3] The metaphyseal capillaries in this region lack phagocytic cells, allowing further growth of microorganisms.[12] The inability of young animals to mount an adequate immune response against bacteria is a key factor in the development of hematogenous osteomyelitis in areas of bone growth.

Tremendous forces are sustained during fractures of long bones in large animal species, often leading to soft tissue injuries that compromise vascular supply to the wound. Reduced perfusion to the area increases oxidative damage to healthy tissues, decreases delivery of immunogenic and proinflammatory cells during the acute stages of healing, and increases the probability of developing infection. In addition, certain locations (e.g., distal limb) have limited soft tissue covering, making closure over implants difficult. Inadequate soft tissue covering over implants can lead to cast sores and if left undetected may cause exposure of implants.

Treatment Early diagnosis and aggressive therapy are critical in preserving normal function to the limb in neonates affected by osteomyelitis.[5] Left untreated, irreversible damage to the growth plate or articular cartilage may cause lifelong debilitating lameness in the affected limb. Antimicrobial treatment during the acute stages may resolve bone infection, but medical treatment is often unsuccessful once osteomyelitis is established, and surgical intervention is required.[9] Treatment goals are to physically remove bacteria, inflammatory debris, and devitalized tissue. Long-term medical therapy is directed at controlling inflammation in the area and preventing recurrence.[2] Supportive therapy should be considered to improve the overall systemic health of the neonate, especially in cases of failure of passive transfer. Broad-spectrum IV antimicrobials should be considered until culture results are available.[5] β-Lactams and an aminoglycoside provide activity against gram-negative and gram-positive bacteria.[5] Metronidazole can be added when anaerobic infection is suspected.[5] In cases of septic arthritis without osseous involvement, joint lavage, arthroscopic débridement of synovial proliferation and concurrent articular damage, arthrotomy portals to facilitate drainage, intraarticular antimicrobial administration, and IV regional limb perfusions should be considered, along with systemic antimicrobial therapy targeted against the causative organism.[3] Radiographs may be helpful in determining whether osteitis or osteomyelitis are present. Débridement of the bone defect is indicated if infection has been seeded in bone. Use of antimicrobial impregnated beads can facilitate sustained delivery of high concentrations of antimicrobials to infected tissues.[3] IV antimicrobials should be selected based on culture and sensitivity results and be continued for 1 week following resolution of lameness in the neonate, followed by at least 2 weeks of oral antimicrobials.[3]

Medical management, including parenteral antimicrobials and topical wound dressings, may reduce drainage and contain infection to a single area, but is rarely successful as a single treatment of osseous sequestra.[9] A sequestrectomy with effective débridement can resolve infection rapidly and decrease the duration of antimicrobial therapy.[5] The goal of surgical treatment is to increase efficacy of antimicrobial treatment and host defenses by breaking down the biofilm matrix, removing necrotic debris with infected tissue, promoting vascularization of compromised tissues, and in most cases, establishing drainage. A tourniquet placed proximal to the affected site at the time of surgery decreases hemorrhage and facilitates visualization between healthy and devitalized tissue.[5] Infusion of the sinus tract with diluted methylene blue or use of a metallic probe may help identify areas of sequestered bone when location is difficult to determine.[5] Successful treatment depends on removing necrotic tissue lining the draining tract, opening the cloaca to access and remove the sequestered piece of bone, and aggressive débridement of all infected bone and exudate. Cancellous bone graft or antibiotic-impregnated beads can be used to fill in large defects following sequestrum removal. Autogenous bone grafts provide structural support by filling in gaps and providing a large volume of viable cells and increased osteogenic potential.[15]

Local delivery of high concentrations of antimicrobials has been described using various methods. Choice of antimicrobial delivery methods should be based on results of culture and sensitivity testing and the antimicrobials chosen. Continuous local infusion (e.g., indwelling pumps) may be the best method of delivering time-dependent drugs, and concentration-dependent antimicrobials (e.g., aminoglycosides) can be given intermittently in high doses via IV regional limb perfusions.[5] Wound location and duration of antimicrobial treatment should also be considered when choosing the best method of delivery.

Regional limb perfusion of antimicrobials is an effective way to deliver a high dose of antimicrobials to an isolated area. For regional limb perfusion to be effective it is critical to have adequate venous access, appropriate tourniquet application, and control of limb motion during the procedure. The tourniquet should be placed just proximal to the area of infection, where adequate venous access can be attained. A pneumatic tourniquet or a broad rubber tourniquet have been shown to be the most effective at achieving vascular occlusion and adequate delivery of antimicrobial concentrations distal to the tourniquet site.[17] An indwelling or 25- to 27-gauge butterfly catheter is used to establish venous access distal to the tourniquet. A 4.5-mm hole drilled into the medullary cavity can be used to deliver

VetBooks.ir

a regional limb perfusion when venous access cannot be attained. Dosage of antimicrobials varies between one third and a full systemic dose, depending on drug selection.[5] Careful attention should be paid to ensuring the regional limb perfusion dose combined with the systemic dose does not exceed nephrotoxic levels, especially in the neonate. It has been suggested that in horses the dosage of antimicrobials should be diluted to a total volume of 60 mL when the tourniquet is placed above the carpus or tarsus, and 30 mL if the tourniquet is placed at the level of the distal limb.[5] The injection should be given over 5 to 10 minutes, checking periodically for blood-tinged back pressure to make sure venous access is maintained throughout the injection. The tourniquet is removed after 25 to 30 minutes once the infusion is complete, and pressure is applied over the injection site to prevent hematoma formation. The animal should be properly restrained (and sedated if necessary) to prevent movement during the procedure.

Antibiotic-impregnated biomaterial allows for sustained continuous release of antimicrobials to the area of bone and soft tissue infection. Antibiotic-impregnated polymethyl-methacrolate (PMMA) beads provide sustained delivery of antimicrobials up to 80 days at 200 times the concentration obtainable in a systemic dose.[16] Traditionally, gentamicin-impregnated PMMA beads were used for their broad-spectrum bactericidal coverage and water- and heat-soluble characteristics. However, additional antimicrobial PMMA bead choices have since been determined to have suitable elution rates.[2] Selection of appropriate drugs and withdrawal times depend on the species treated. Antibiotic-impregnated PMMA beads are routinely used in orthopedic procedures when dealing with open fractures, plate luting, and placement around orthopedic implants at the time of closure. When managing septic synovial structures, there is concern that using rigid implants like PMMA beads may cause cartilage damage or mechanical lameness if the implant moves to the joint surface.[2] Collagen sponges and indwelling synovial catheters may be viable options for managing septic synovitis without causing inflammation or damage to articular cartilage. Antibiotic-impregnated plaster of Paris biodegrades faster and is often used in the neonate to deliver high concentrations of antimicrobials for a short period of time.[5]

In the presence of infection, fractures can only heal if adequate stability is maintained through internal fixation, although healing is often delayed. Débridement of infected bone and tissue, in addition to implant replacement, can be performed in an attempt to resolve infection.[5] Antibiotic-impregnated PMMA beads placed around sites of orthopedic infection, along with regional limb perfusion and establishing dependent drainage, may slow the rate of infection and allow additional time for fracture healing, increasing stability before removing implants.[5] If infection persists, implant removal maybe indicated in addition to alternative methods of fracture management (e.g., transfixation casting, external fixator).[5] In cases of open contaminated fractures, external fixation is often necessary to keep animals comfortable until infection is resolved and internal fixation can be performed. Maintaining use of the affected limb is important in preventing support limb breakdown and should be considered when making management decisions while treating orthopedic infections.

Prevention and Control Early recognition and aggressive medical therapy are critical in preventing acute hematogenous osteomyelitis in high-risk neonates. Hyperimmune plasma and prophylactic antibiotics are indicated when failure of passive transfer is suspected. In open wounds, débridement of necrotic and avascular tissue, eliminating gross contamination, controlling ongoing infection, and reestablishing vascular supply are the foundations of preventing osteomyelitis. Sharp dissection of devitalized tissues to reestablish viable soft tissue margins and copious lavage of the wound can help reduce the level of contamination in open wounds. If availability of soft tissues is inadequate for closure, a bandage should be used to cover exposed bone until granulation tissue fills in the area. Osteostixis or curettage of superficial cortical bone can be performed to access endosteal blood supply to reestablish vascular supply to exposed bone in an attempt to prevent sequestrum formation.[9]

Risk of developing postoperative infection following open reduction and internal fixation of fracture repair is relatively high compared to other orthopedic procedures, so strict adherence to aseptic technique should be followed to reduce the possibility of this complication. Extended-period postoperative antimicrobial use is often warranted after long-bone fracture repair because of the increased risk of postoperative infection due to prolonged surgery times, use of metallic implants, and injuries to soft tissue structures at the time of fracture occurence.[10] In addition, orthopedic patients are often placed in a rigid cast following internal fixation, which prevents daily monitoring of the affected limb for subtle changes suggestive of implant infection. Antimicrobials are generally administered until the first cast change (i.e., 2 weeks), and daily regional limb perfusions can be given when indicated.

Navicular Disease (Palmar Foot Pain)

Robin M. Dabareiner

Roughly a third of all forelimb lameness in horses originates from the caudal third of the foot and has generally been associated with pain arising from the navicular bone and its related structures, although other foot structures can also cause lameness. Any one or a combination of the following should be considered when evaluating horses that exhibit lameness localized to the posterior aspect of the foot:

1. Injury to the navicular bone itself
2. Desmitis of the navicular suspensory apparatus, which includes the sesamoid impar ligament (IL) distally and the collateral suspensory ligament (CSL) proximally
3. Inflammation of the synovial membrane of the navicular bursa; navicular bursitis or inflamed tissue (adhesions) between the navicular bursa and deep digital flexor (DDF) tendon
4. Desmitis of the DDF at (a) the insertion, (b) palmar to the navicular bone, or (c) proximal to the navicular bone
5. Laminar tearing in the heel region
6. Solar bruising in the heel region
7. Pain arising from some aspect of the palmar region of the distal phalanx
8. Pain arising from synovial structures located in the distal interphalangeal (DIP) joint
9. Structural damage to the hoof capsule in the heel region (e.g., underrun heels, collapsed foot)
10. Desmitis of the distal digital annular ligament

Diagnosis The diagnosis of heel pain is not difficult when a horse's lameness resolves with a palmar digital nerve block. However, determining which foot structure is the source of pain and establishing correct treatment can often be challenging. It seems the more we learn about diagnostic anesthesia, the more clouded the picture becomes. Horses with navicular or heel pain can be a diagnostic and therapeutic challenge to the owner, clinician, and farrier.

Diagnosis is based on historical data, clinical findings, and both routine and advanced imaging techniques to localize the structure causing pain within the hoof capsule. Our approach to horses with lameness originating from the heel region is to determine which structure in the foot is causing the pain and then develop a therapeutic plan. Severity and duration of the lameness, the horse's activity, potential owner compliance, and the farrier's experience should be considered. The horse's hoof wall quality, conformation, environment, and occupation will all affect therapy.

HISTORICAL DATA. Common complaints reported by owners of a horse exhibiting chronic foot pain include intermittent unilateral or bilateral forelimb lameness and increased severity of lameness for several days immediately after shoeing or at the end of the shoeing

VetBooks.ir

period (when the toes are long). Occasionally the horse may point the affected forelimb, stumbling with a short, choppy gait and increased lameness when ridden on hard ground.

Horses sustaining acute injuries to soft tissue structures in the caudal aspect of the foot (e.g., impar or CSL of navicular suspensory apparatus, distal DDFT), laminar tearing, or severe bruising of the heel region may have a history of becoming acutely lame during or immediately after a performance event. Historical data are often overlooked but may suggest which foot structure is damaged.

Clinical Findings and Diagnostic Evaluation

Signalment can be helpful in the diagnosis of chronic heel pain. Middle-aged Quarter Horses and Thoroughbred and warmblood horses in general are often affected by navicular disease. Arabians, draft horses, ponies, donkeys, and mules are rarely affected with palmar foot pain. A hereditary predisposition may be related to the development of navicular disease. Many Quarter Horses are heavily muscled and have relatively small hoof size. Poor hoof conformation plagues many Thoroughbred and warmblood horses. Since 1978, Dutch Warmblood stallions with grade 4 classification on navicular bone radiographs (0 = excellent, grade 4 = poor) have not been certified for breeding. The incidence of grade 3 or 4 navicular radiographs decreased from 11% in 1997 to 3% in 2002.[1] Although hindfeet can be affected with navicular disease, it is predominantly considered a forelimb problem.

Observation of limb conformation, as well as hoof size and shape and hoof-pair asymmetry, can aid in the diagnosis and treatment of palmar foot pain. A broken back hoof-pastern axis is frequently seen in horses with navicular or heel pain, but a small subset of horses with navicular pain will have a broken forward or normal hoof-pastern alignment. In one report of horses diagnosed with navicular disease, 72% had a broken back hoof-pastern axis and 8% a broken forward axis.[2] Horses having a long toe/low heel hoof conformation or underrun heels (defined as >5 degrees difference between heel and toe angle of foot) accounted for 77% of a group of horses with chronic heel pain.[2] Atrophy of the frog and contracted heels (defined as frog width < two-thirds its length) can be seen in horses with palmar foot pain and have been attributed to lack of weight bearing in the posterior portion of the foot, which reduces the dynamic movement of the frog.[2] Hoof-pair asymmetry in which one foot is smaller, narrower, and has a higher heel length is also common in horses with navicular area pain. The smaller and more upright foot is usually the lamest limb.

A thorough musculoskeletal examination should include palpation and comparison of the digital pulses in the feet and assessment of the hoof capsule for increased heat. Of 23 horses diagnosed with navicular area pain, 97% had an increased digital pulse in the most severely affected limb.[3] Hoof-tester evaluation can be beneficial in determining pain location. Pain involving the navicular area is identified by application of intermittent hoof-tester pressure over the middle third of the frog, which results in persistent nonfatigable reflex withdrawal of the hoof from the examiner. It is important to assess whether the withdrawal reflex is due to real pain and not a whimsical reaction by the horse. Both front feet should be tested and results from each foot compared. A positive hoof-tester response over the wall of the foot across the ends of the navicular bone may occur in horses with radiographic evidence of proliferative new bone on the abaxial margins of the navicular bone. Horses that have sustained an injury to the impar ligament or insertion of the DDFT seem particularly sore with hoof-tester pressure near the junction of the middle and anterior thirds of the frog. Horses with underrun or bruised heels or damaged laminae in the heel area will often have more pain over the affected heel. It is important, if possible, to differentiate peripheral from central hoof pain with a thorough hoof-tester examination. Many horses with heel pain will land toe first and may bruise the sole in the toe region, resulting in pain from hoof testers in this area. The hoof-tester exam is a useful diagnostic tool, but horses can have navicular area pain and not respond to hoof-tester pressure. This will occur more often during periods of dry weather, when the horse's feet are excessively hard, or in horses with thick soles and hard frogs.

LAMENESS EXAMINATION. Horses with bilateral forelimb involvement have a stiff, shuffling, short-strided gait that owners often perceive as shoulder lameness. The horse should be observed at a slow trot in a straight line and circled in both directions. A smooth, hard surface is optimal. Lameness will often be exacerbated when horses with heel pain are trotted on hard ground. The severity of lameness should be assessed before and immediately after application of hoof-tester pain. Horses with navicular area pain may have increased severity of lameness when trotted after the hoof-tester application in the central frog area. Several tests may exacerbate lameness in horses with navicular pain, such as allowing the horse to stand for 60 seconds on a small block of wood centered over the frog before trotting, or elevating the toe with a block of wood. A 30-second lower-limb fetlock flexion test may also exacerbate lameness in horses with navicular area pain.

DIAGNOSTIC ANESTHESIA. Perineural anesthesia of the palmar digital nerves (PDNs) with 1 to 2 mL of mepivacaine placed axial and distal to the proximal limits of the medial and lateral collateral ligaments will desensitize the palmar half of the foot, entire sole, and palmar aspect of the coffin joint. This block is performed just below the proximal limits of the collateral cartilages to avoid desensitizing the dorsal nerve branches. One study demonstrated that lameness secondary to solar pain created by a setscrew-induced pain model was eliminated 10 minutes after anesthesia using 2 mL mepivacaine over each PDN.[4] In the past, coffin joint (DIP) anesthesia was thought to be helpful in diagnosing navicular area pain, but investigators have recently demonstrated a lack of specificity with this block. DIP anesthesia has been shown to eliminate lameness associated with pain in the navicular bone itself, navicular suspensory apparatus, navicular bursa, and sole of the foot, because the sensory nerves to the navicular area are close to the DIP joint, and passive diffusion of the anesthetic occurs to the PDNs. Solar pain in the toe region was eliminated before solar pain in the heel region after DIP anesthesia, and a maximum 6 mL of anesthetic was recommended for analgesia of the DIP joint. This suggests that horses with heel bruises or laminar tearing in the heel region should not improve after DIP analgesia using low-volume anesthetic and evaluating the horse after 10 minutes.

The navicular bursa is a thin synovial structure located between the navicular bone and distal aspect of the DDFT. Analgesia of the navicular bursa may be more specific for navicular area pain. A positive response to navicular bursa analgesia probably reflects pathology in the navicular bursa, navicular bone, or supporting ligamentous structures. The normal navicular bursa has a 3-mL capacity, which may be reduced in horses with inflamed tissue or adhesions between the navicular bursa and DDFT. Synovial fluid is obtained infrequently when performing navicular bursa analgesia.

Horses that improve but do not have total resolution of the lameness until after a high palmar digital or abaxial nerve block may have pain associated with a desmitis of the DDFT within the hoof capsule or desmitis of the DIP joint collateral ligament. Horses with DDFT desmitis may also improve after DDFT digital tendon sheath analgesia.

RADIOGRAPHIC EXAMINATION. A minimum of three high-detail radiographic views should be used to evaluate the navicular bone; additional views are needed to evaluate the entire foot. Latero-medial (LM), 60-degree dorsoproximal-palmarodistal oblique with grid (D60Pr-PaDiO), and palmaroproximal-palmarodistal oblique (Pa45Pr-PaDiO) views of the navicular bone are obtained. Some clinicians also include two oblique views of the navicular bone. Abnormal radiographic changes include variation in size and shape of synovial foramina on the D60Pr-PaDiO projection; cystic changes within the navicular bone; enthesophyte formation at the attachment of the CSL ligament on the LM projection; flexor cortex erosions and

VetBooks.ir

loss of corticomedullary distinction, best viewed on the Pa45Pr-PaDiO projection; calcification of the flexor surface and distal DDFT; and osseous fragments associated with avulsion of the impar ligament. Previous studies have shown that abnormal synovial fossae correlate poorly with lameness, rarely progress over time, and are inconclusive for the diagnosis of navicular disease. Radiographic abnormalities more strongly associated with lameness are flexor cortex defects, medullary sclerosis, proximal border remodeling, and loss of medullary trabecular pattern.

Although radiographic evaluation is important in the diagnostic work-up of a horse showing palmar foot pain, it is not very sensitive in defining the actual pathologic condition of the navicular bone. Radiographs often underestimate the extent of pathology seen on necropsy in horses with navicular lesions.

NAVICULAR BURSOGRAPHY. Administration of a 3-mL mixture of 1:1 contrast media and anesthetic into the navicular bursa, followed by a Pa45Pr-PaDiO radiographic view, is used to evaluate pathologic changes on the flexor surface of the navicular bone and adhesions or scarring of the DDFT. The advantage of this technique is confirming pathologic changes on the flexor surface of the navicular bone, which may not be apparent on survey radiographs, and injection of the anesthetic into the navicular bursa. Navicular bursography identified pathology in the flexor region of the navicular bone 60% more often than plain radiographs.[5] The disadvantages are that some horses are not very tolerant of needle penetration of the DDFT and insertion into the navicular bursa, and the procedure carries risks like trauma to the navicular bone, sepsis, acute synovitis of the bursa, and possibly DDFT damage secondary to needle penetration.

NUCLEAR SCINTIGRAPHY. Nuclear scintigraphy offers higher sensitivity than radiography but equal specificity for the diagnosis of navicular disease. For detecting abnormal bone activity within the hoof, nuclear scintigraphy is a sensitive but rather nonspecific imaging method; it detects increased ^{99m}Tc uptake in areas of active osteoblastic activity. However, because of the proximity of anatomic structures in the caudal third of the foot, specific structural location of the source of pain in a horse with palmar foot pain is limited. The reliability of scintigraphy in diagnosis of foot pain has been criticized because of common false-positive and false-negative results. Lateral bone-phase images were found to be less sensitive than palmar images, and views taken 1 hour after radioisotope administration were as diagnostic as those taken 2 to 4 hours after administration.

ULTRASONOGRAPHY. Diagnostic ultrasonographic images can be obtained for some structures in the foot region. Ultrasonographs of the collateral ligaments of the DIP joint are obtained by positioning a 7.5- or 10-MHz transducer on the firm part of the dorsolateral and dorsomedial aspects of the coronary band. The normal DIP joint collateral ligament for a large horse is about 0.66 cm.[2] The distal aspect of the DDFT can be visualized from between the heel bulbs in the palmarodistal aspect of the pastern joint. The frog of the foot can also be used as a window to image the DDFT and impar ligament near the flexor surface of the navicular bone. Before imaging, the frog should be trimmed to pliable tissue and the foot soaked in a water bath overnight. Limitations of ultrasound are that the images are restricted to the axial midline, and off-incidence artifacts can confuse image interpretation. If the frog is excessively hard or has deep sulci, poor contact between the frog and transducer may prevent propagation of the ultrasound beam. Variation in cross-sectional area and width of the DDFT and impar ligament both within and between limbs of normal horses also may make image interpretation difficult.

COMPUTED TOMOGRAPHY. CT is the best modality for detecting and evaluating bone pathologies in the cortex or trabecula and can also provide an accurate three-dimensional assessment of soft tissue structures of the foot. Although less expensive than MRI, CT is less versatile. Special contrast studies are needed to evaluate articular cartilage with CT, but not with MRI. One advantage over MRI is that CT can be used to assess accurate needle or scalpel placement for specific treatment options. One disadvantage for CT in horses is the need for general anesthesia and special equipment designed to accommodate the horse.

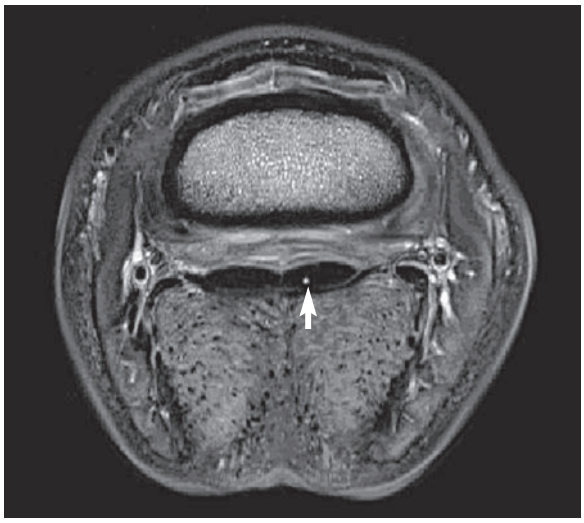

FIG. 38-28 Transverse magnetic resonance imaging section showing deep digital flexor tendon tear *(arrow). (Courtesy Dr. Chad Marsh.)*

MAGNETIC RESONANCE IMAGING. MRI offers a superior diagnostic tool to image soft tissue structures in the foot, and its use to evaluate equine lameness has provided valuable insight into the pathologic problems occurring in horses with palmar foot pain. MRI is particularly useful in the recognition of abnormally high signal (fluid) in structures such as the DDFT, IL, and collateral ligaments (Fig. 38-28). It can also detect navicular bone edema and articular cartilage damage in the navicular region. MRI can be performed under general anesthesia or in the standing horse, depending on the equipment available. In one study of 199 horses with lameness localized to the foot by clinical signs and perineural anesthesia, MRI was found to be superior to nuclear scintigraphy, ultrasound, or radiology in identifying the specific foot structure causing the pain. The most common injury was DDFT desmitis (59%), followed by desmitis of the DIP collateral ligament (31%); 17% of horses had injuries to multiple structures. Only 28% of horses with DDFT or collateral ligament injuries of the DIP joint returned to previous use.[6] A recent study evaluated 101 horses with clinical signs of navicular syndrome; the animals underwent MRI evaluation and had the navicular bursa (NB) medicated with 40 mg methylprednisolone and 10 mg hyaluronate at the time of the MRI.[7] Response to treatment was dependent on which specific structure(s) were damaged, supporting the value of MRI as a superior diagnostic tool in horses with foot pain.

NAVICULAR BURSOSCOPY. Endoscopic evaluation of the navicular bursa has recently been described in 92 horses.[8] This surgical procedure allows direct visualization of pathology within the navicular bursa and digital flexor tendon sheath. It is recommended for horses with lameness localized by regional anesthesia to the foot and absence of significant radiographic abnormalities.

Etiology

The exact etiology of navicular pain is unclear, but two theories exist. Initially, vascular occlusion of the navicular arteries was believed to result in ischemic necrosis of the navicular bone, but this theory lacks experimental support. The biomechanical theory suggests that the degenerative changes in the navicular bone result from abnormal forces exerted on the bone and its supporting ligaments. Compression of the navicular bone by the DDFT is an important aspect of this theory. Peak compressive forces of the DDFT

VetBooks.ir

on the navicular bone are about 0.77 times body weight during a slow trot and occur at approximately 70% of the stance-phase duration.[2] In addition, the navicular bone suspensory apparatus (IL and CSL) is under excessive tension and possibly compression when the horse has dorsopalmar hoof imbalance (broken back hoof-pastern axis or long toe/low heel hoof conformation). Faulty conformation and improper hoof balance resulting in abnormal biomechanical forces in the navicular area cause pathologic changes in the navicular bone that appear similar to those seen in clinical cases. Pain presumably results from interosseous pressure in the navicular bone or from strain of the supporting soft tissue structures. The biomechanical force applied to the navicular bone depends on hoof conformation and is negatively correlated ($P < 0.05$) to both the angle between the distal phalanx and the ground and the ratio between heel and toe length. Experimental studies seem to support the biomechanical theory.

Treatment

There are numerous treatment regimens for horses with palmar foot pain, and no one treatment can be recommended in all cases. Factors to consider in determining a treatment plan include prior treatment, duration of clinical signs, structure injured, severity of disease, use of horse, hoof conformation, and shoeing. Treatment options include variable periods of rest, therapeutic trimming and shoeing, antiinflammatory medications, intraarticular therapy, systemic osteoarthritis-modulating drugs, and surgery.

MEDICAL THERAPIES

Rest. Taking the horse out of work and confining it to a small area like a stall and small run allow it freedom of movement without opportunities to run and buck, which could exacerbate the lameness. Controlled exercise at a walk and trot for 15 minutes daily has been shown to increase blood flow to the feet by 15%. Although the duration of the rest period is variable, 3 to 6 weeks will allow soft tissue inflammation to subside and the horse to adjust to changes in trimming and shoeing. If the lameness has resolved after the rest period, a gradual increase in exercise is recommended before returning to normal use. An exception is the horse with an acute ligamentous injury to the navicular suspensory apparatus or distal DDFT injury. These injuries are usually severe and require 6 to 12 months of rest and confinement.

Although rest may be beneficial as part of the treatment regimen, the owner's situation may not allow for a rest period. Other treatments are then required to minimize the pain while allowing the horse to continue working, as often preferred by many professional horsemen.

Farriery. Therapeutic trimming and shoeing to reduce biomechanical forces on the navicular/heel area is the cornerstone of treatment for horses with palmar foot pain. Many horses respond to this without further need for medical or surgical therapy. Other horses improve after corrective shoeing but still require additional treatments. Horses with poor hoof conformation or inappropriate shoeing often respond best to corrective shoeing, whereas horses with good farrier management and good hoof conformation may show minimal or no improvement after therapeutic trimming and shoeing. The goals are to (1) restore hoof balance, (2) improve existing problems such as underrun heels, (3) reduce biomechanical forces on the navicular region, and (4) protect injured areas of the hoof. Although there is no standard shoeing technique for horses with heel/navicular pain, observing abnormalities in the hoof and lower-limb conformation and following basic principles can often accomplish these four goals. Proper trimming alone may restore correct hoof balance such that special shoes or pads are unnecessary; even with proper trimming, however, many horses still require special shoes or pads to achieve the desired hoof conformation. Many horses benefit greatly from therapeutic shoeing, but some have permanent structural problems that cannot be corrected. The veterinarian, farrier, and owner must work together and consider the horse's hoof shape and hoof wall quality, environment, conformation, use, and severity of disease.

Basic Principles for Proper Hoof Balance. The configuration of the hoof capsule reflects the stresses applied to the foot during the previous months. *Hoof balance* refers to both mediolateral and dorsopalmar balance. *Dorsopalmar balance* refers to proper hoof-pastern alignment. Ideally, when viewed from the side, a line drawn through the central aspect of the first phalanx should bisect the hoof capsule, and the toe angle and heel angle should be parallel to this line. A broken back hoof-pastern axis is common in horses with long toe/low heel conformation and results in increased stress on the phalangeal joint capsules, navicular suspensory apparatus, and distal DDFT and increases pressure between the navicular bone and DDFT.

Breakover (break-over point) of the foot is the terminal part of locomotion when the heel loses contact with the ground surface, followed by the toe. Tension of the DDFT over the navicular area and flexion of the coffin joint occur during breakover. A low hoof angle or long toe is associated with prolongation of breakover time. A high heel angle reduces breakover, causing a reduction of forces exerted on the caudal structures of the foot and limb (e.g., navicular suspensory apparatus, DDFT, suspensory ligament). Breakover should be made as easy as possible by decreasing toe length.

Corrective trimming is often more important but can be more difficult than corrective shoeing. The toe is shortened as much as possible, and the heels are trimmed back to the widest aspect of the frog. One of the most common problems we see in our practice is allowing the heels to grow forward, decreasing heel support and contributing to dorsopalmar hoof imbalance (Fig. 38-29). The heels lose mechanical strength and often collapse, and the bars of the hoof flatten out and lose support. Proper heel trimming back to the widest aspect of the frog increases the functional weight-bearing surface of the foot. The ground surface of the properly trimmed foot has a more

FIG. 38-29 Hoof with the heels allowed to run too far forward. The heels are located at the end of the pointer but should be back at the widest aspect of the frog.

VetBooks.ir

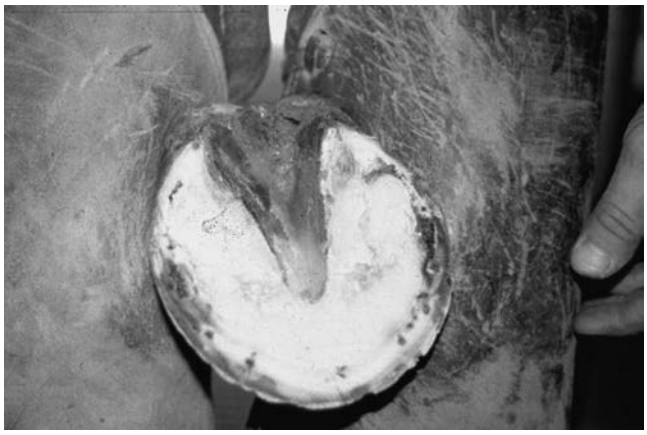

FIG. 38-30 Hoof from Fig. 38-29 after trimming the heels back to the widest aspect of the frog. Note the larger, rounder shape to the hoof and increased heel support.

rounded appearance (Fig. 38-30). Palmar hoof support is essential for horses with navicular/heel pain. Full-fitting shoes provide more support hoof by increasing the weight-bearing surface. Ideally, the shoe should fit about 1/16 inch wider than the hoof behind the last shoe nail to allow heel expansion. The nails should be placed in a line parallel to the ground approximately 1 inch (2.5 cm) proximal to the shoe, and no nails should be placed behind the widest aspect of the hoof.

Using a wedged shoe or pad to elevate the heels by 2 to 3 degrees after the foot is properly trimmed decreases tension in the DDFT, reducing pressure applied to the navicular region. The effect of raising the heels is helped by rolling or rockering the toe to quicken the breakover of the foot. The use of an egg-bar shoe is controversial. Although horses with long toe/low heel hoof conformation may gain caudal foot/heel support from the shoe, egg-bar shoes had no effect on reducing forces between the DDFT and navicular area.

When selecting a particular corrective shoe or shoe/pad combination, the horse's use is an important factor because the desired corrective shoe for the individual hoof conformation may not be suitable for the horse to perform its intended use. A compromise must be made between shoeing for the ideal and shoeing for athletic performance, taking into consideration such factors as weight of the shoe, traction, and interference of other limbs. Another important factor is hoof quality. The ideal shoe/pad selected for proper hoof balance may be impossible to apply if the hoof wall is thin or damaged. In these cases, a secondary shoeing regimen is selected that will accomplish similar results until hoof quality improves. Although no standard shoeing technique exists for horses with navicular pain, the following suggestions may be beneficial.

A *rim shoe* or *half-round shoe* has a rounded edge that will enhance breakover. The rim shoe has good traction and is useful in western performance horses (e.g., roping horses, barrel racers, cutting horses). The Natural Balance Shoe (Anvil Brand Shoe Co., Lexington, Ill.) has a rockered toe and, because of its design, artificially shortens the toe length and enhances breakover. It is made of aluminum or steel; owners of some western performance horses seem to prefer the steel shoe, which is thought to provide better traction than the aluminum shoe.

Acute ligamentous injuries involving the distal aspect of the DDFT or navicular suspensory apparatus require extended periods of rest. During the rest period, application of a 3- to 4-degree wedge pad to the shoeing regimen may decrease tension of these soft tissue structures. Controlled exercise is important in treating these injuries. Our group often begins with a 3- to 4-degree pad, depending on the horse's hoof conformation, and gradually decreases the quantity of heel elevation over time.

Different shoeing techniques will accomplish the same goals of easing breakover, supporting the heels, and protecting injured areas of the foot.

Nonsteroidal Antiinflammatory Drugs. Phenylbutazone is the most common NSAID used to treat navicular/heel pain. It reduces pain by inhibiting the enzyme cyclooxygenase and the subsequent cascade of prostaglandins. It also inhibits platelet aggregation, which may theoretically increase blood flow to the foot. Phenylbutazone can break the pain cycle and allow adjustment to new hoof angles and shoeing changes. The recommended dosage depends on individual horse needs and severity of disease. An initial dosage of 4.4 mg/kg once daily for 5 to 7 days seems appropriate to allow adjustment to shoeing changes. Many horses will require additional treatment during competition. Gastric and right dorsal colon ulceration has been associated with phenylbutazone administration in some horses.

Isoxsuprine Hydrochloride. This β-agonist, α-antagonist is a peripheral vasodilator working to increase blood flow to the foot. Its absorption after oral (PO) administration in the horse is erratic, and it usefulness is questioned. The recommended dose of isoxsuprine is 0.6 mg/kg PO twice daily for 3 weeks; if no response is seen, the dose is increased to 1.2 mg/kg PO twice daily for 3 weeks, then once daily for 3 weeks, then every other day for an additional 3 weeks. No adverse drug reactions have been reported. Isoxsuprine's efficacy appears to be horse-dependent.

Intraarticular Medications. Intraarticular medication of the DIP joint can be beneficial in horses with navicular area pain. Some horses fail to respond adequately to corrective shoeing, rest, and NSAID therapy, or the horse may have responded initially but no longer. If the lameness has been previously localized to the caudal aspect, intraarticular anesthesia of the DIP joint is performed at the recheck examination. If significant improvement is seen in the lameness, the client is offered intraarticular medication as a treatment option. Alternately, if the horse improves after PDN anesthesia in one limb and becomes lame in the opposite limb, anesthesia of the DIP joint is performed. If significant improvement is seen, medication of the DIP joint is offered as an initial treatment option. It is important to remember that DIP joint anesthesia is not specific for navicular area pain, as discussed earlier.

Selection of intraarticular medication varies with the clinician, severity of disease, and client. We usually inject 20 mg of sodium hyaluronate and 6 to 9 mg of triamcinolone (Vetalog), which often alleviates clinical signs of lameness for 6 to 12 weeks. In severe cases of navicular disease, 20 to 40 mg of methylprednisolone acetate (Depo-Medrol) in combination with the sodium hyaluronate may provide a slightly longer duration of effect. Hyaluronate is used for joint lubrication and to increase the hyaluronan content of synovial fluid. Corticosteroids interact with steroid-specific receptors in the cytoplasm of cells and inhibit inflammatory infiltration into the joint and neutrophil function by impairing lysosomal enzymatic release. Corticosteroids also inhibit phospholipase A_2, preventing both cyclooxygenase and lipoxygenase inflammatory pathways.

The two primary reasons not to use intraarticular corticosteroids in horses with joint disease are risk of sepsis and potential adverse effects on articular cartilage and subchondral bone. Using aseptic technique and combining intraarticular antimicrobials with the injection medication should decrease the risk of synovial infection. We prefer to use 50 to 100 mg of amikacin sulfate for joint injections. To minimize the negative effects of intraarticular corticosteroids, the lowest clinically effective dose is used. Minimal research has been performed in this area, so clinician experience and empirical information are often consulted. Both systemic and intraarticular corticosteroids have been associated with laminitis in horses. DIP joint medication is injected using a 20-gauge sterile needle placed approximately 1 cm dorsal to the hoof capsule on midline, penetrating the extensor tendon while entering the DIP joint. The angle of needle insertion is about 45 degrees from perpendicular to the ground surface. Synovial fluid is usually obtained.

About 30% of horses with pain localized to the navicular area either do not improve or may improve but remain lame after DIP joint anesthesia, which may be associated with different diffusion properties of the local anesthetic versus the intraarticular medication. Drug treatment of the navicular bursa may be beneficial in some

VetBooks.ir

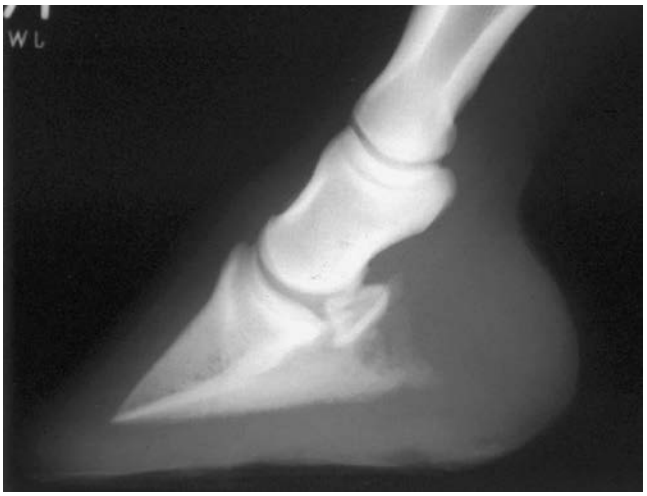

FIG. 38-31 Lateralomedial radiograph of foot, showing an enthesophyte at the proximal aspect of the navicular bone where the collateral suspensory ligament attaches. Horses with this type of radiographic abnormality usually respond better to navicular bursa medication than distal interphalangeal medication.

of these horses. We recently reported on 25 horses with pain localized to the navicular region that did not respond to corrective shoeing, phenylbutazone, or DIP joint medication.[3] These horses did improve after navicular bursa injection with 40 mg methylprednisolone and remained sound for a mean of 4 months. Most of the 25 horses had moderate to severe radiographic changes involving the navicular bone. About half had an enthesophyte located at the proximal aspect of navicular bone at the attachment of the CSL, possibly indicating chronic CSL desmitis (Fig. 38-31). The technique for navicular bursa injection has been previously described.[3]

A recent study evaluated 101 horses with clinical signs of navicular syndrome that underwent MRI evaluation and had the navicular bursa (NB) medicated with 40 mg methylprednisolone and 10 mg hyaluronate at the time of the MRI.[7] Seventy-six (75%) of 101 horses returned to their intended use for a mean of 9.6 months. Horses that had been lame less than 6 months before treatment had a significantly better chance of returning to intended use than horses that were lame more than 6 months before treatment. Horses with primary DDF tendinitis responded best to NB medication and 6 months rest. If the DDF tendinitis extended proximal to the navicular bursa in these horses, the digital flexor tendon sheath was also medicated with 100 mg methylprednisolone acetate and 20 mg hyaluronic acid. Horses with primary navicular bursitis returned to work within 2 days after NB medication. Horses with scar tissue and adhesions between the DDFT and CSL or horses with adhesions between the navicular bone and DDF tendon were treated with pressurization of the navicular bursa with 30 to 50 mg of hyaluronate to create high pressure within the bursa in an attempt to break down some of the adhesions.[7]

Navicular bursoscopy was performed in 92 horses with navicular area pain.[8] Injuries of the DDF tendon within the navicular bursa were evaluated and débrided. In addition, fibrillated fibrocartilage seen on the navicular bone was also débrided. Fifty-three of 92 (63%) horses returned to soundness.[8]

Systemic Joint-Modulating Drugs. Hyaluronan (HA) is a normal component of synovial fluid and functions as a joint lubricant. It also appears to have some antiinflammatory properties, but the exact mechanism is unknown. Exogenous HA inhibits chemotaxis and phagocytosis of granulocytes, reduces the stimulation of lymphocytes, and may decrease prostaglandin synthesis. The antiinflammatory properties of HA appear to be dose dependent, and HA with a molecular weight greater than 500,000 daltons may be more effective. Systemic HA may be more effective in horses with mild synovitis/capsulitis and less effective in horses with chronic osteoarthritis. The recommended dose is 40 mg HA IV once weekly for 3 weeks, then once monthly for maintenance. Some horses with mild navicular pain improve after systemic HA administration, but its use is usually combined with other treatments.

Polysulfated GAGs like Adequan are referred to as *chondroprotective agents* and are used to prevent, attenuate, or reverse morphologic cartilaginous lesions associated with osteoarthritis. Adequan is made from bovine lung and trachea extracts containing mainly chondroitin sulfate. Previous studies have shown that the antiinflammatory effect of GAGs involves inhibition of enzymes and cytokines associated with osteoarthritis, such as interleukin (IL)-1, a potent chemotactant agent, metalloproteinases (MMs), and prostaglandin E_2 (PGE_2). Both in vivo and in vitro equine studies have been performed, with conflicting results. More recently, a survey of 1522 equine veterinarians assessing the efficacy of systemic polysulfated GAGs resulted in the subjective conclusion that their use was more effective than HA for treatment of subacute DJD and less effective for acute synovitis. IM GAG administration was shown to improve lameness in horses diagnosed with navicular syndrome in one double-blind study.[9] The dose was 500 mg IM every 4 days for eight treatments. In our hospital we see many middle-aged western performance horses with chronic navicular problems. IM Adequan (500 mg) every 1 to 2 weeks subjectively seems to benefit these cases, although no scientific studies support the change in frequency of its use.

The oral chrondromodulatory nutraceutical Cosequin has been evaluated in the treatment of 10 horses with navicular syndrome.[10] The nutraceutical consisted of 9 g glucosamine, 3 g chondroitin sulfate, and 600 mg manganese ascorbate and was given PO twice daily for 60 days. The clinical impression from the owners was that the horses' lameness showed improvement. Glucosamine has been shown to reduce expression of MMPs and increase expression of natural inhibitors of MMPs in the joint when studied in vitro. The ability of the horse to absorb these oral nutraceuticals has been questioned, however, and recent work suggests that doubling the dose currently recommended by the manufacturer improves product efficacy, although 4 to 6 weeks of treatment is often needed before a response is seen. We have found that nutraceutical use is variable in horses with navicular area pain, with some showing improvement with daily administration and some showing no effect. Empirically, the benefit of oral nutraceuticals seems inferior to systemic administration of IV hyaluronan or IM Adequan.

Other Medical Treatments. Tiludronate, a biphosphonate, is used in human medicine to reduce bone resorption. It has been used to treat navicular area pain in horses with promising results.[11]

Investigated as a treatment for navicular disease in horses, extracorporeal shock wave therapy (ESWT) directs a pressure wave to a specific area of the body to increase osteogenic activity in bones and induce neovascularization at the tendon-bone junction. Human patients have variable duration of analgesic effect after treatment with ESWT. The equine study reported that a single ESWT treatment had no effect on horses with navicular disease.[12]

SURGICAL OPTIONS

Palmar Digital Neurectomy. Neurectomy of the palmar digital nerves is occasionally required to allow horses with chronic heel or navicular pain to remain athletically sound. Despite aggressive medical treatment with corrective shoeing, NSAIDs, and intraarticular/intrabursal injections, many horses fail to respond or only improve temporarily, which leaves palmar digital neurectomy as a final treatment option. Before surgery the horse should improve greater than 90% after palmar digital nerve perineural anesthesia. Palmar digital neurectomy resulted in improvement in lameness for a mean of 2 years in one study evaluating 59 horses with navicular disease. Diligent postoperative care is critical to achieve prolonged soundness. After surgery, a padded pressure bandage is applied to the limb and changed every 4 to 5 days for 2 weeks. The horse remains in a stall for 30 days, followed by 30 days of light riding and resumption of normal activity 60 days after surgery. The limited activity and diligent bandaging after surgery may reduce the inflammatory response and reduce scar tissue formation around the nerve stumps.

VetBooks.ir

Navicular Suspensory Desmotomy. This procedure has been recommended for horses with navicular syndrome in the past and applied to a number of cases, without favorable long-term results. Therefore, we are not currently using this procedure and believe it has fallen out of favor as a treatment for horses with navicular pain.

PROGNOSIS. Prognosis depends on which structure(s) are affected and severity of the damage. After NB medication, horses with primary DDF tendinitis and navicular bursitis had a good outcome, especially if lameness was present less than 6 months before treatment. Horses with adhesion of the DDF tendon to the CSL and horses with adhesions from the DDF tendon to the navicular bone had a better (60%) chance of returning to previous use. Horses with significant scar tissue in the proximal aspect of the navicular bursa or those with multiple lesions were less likely to return to intended use (25% to 50%).[7]

SUMMARY. No single treatment option is suitable for all horses with heel or navicular area pain. Each horse must be evaluated individually to determine which structure in the palmar aspect of the foot is injured, severity of disease, horse and hoof conformation, and horse use and level of performance expectation before a treatment plan can be developed. Many treatment options are available to help these horses to perform. Horses having the best outcomes are those that have an accurate diagnosis of which structure(s) are affected within the navicular region of the foot so that proper treatment can be recommended. MRI appears to be the best diagnostic tool in identifying specific structural damage, thus dictating treatment.

Spondylitis/Diskospondylitis

Sarah M. Reuss

Definition

Spondylitis is inflammation of the vertebral body, whereas diskospondylitis is an inflammatory lesion that includes the intervertebral disk and its adjacent vertebrae. The etiologic agent may be difficult to isolate, but infection is the most likely cause. Thus, *vertebral osteomyelitis* and *spondylitis* are often interchangeable terms, and if the disk is involved, *diskospondylitis* is the most appropriate term. Both spondylitis and diskospondylitis are rare in large animals but are potentially career and life threatening when they occur. Diskospondylitis is described in swine,[1] horses, cattle,[2] goats,[3] and sheep. Neonates of all species are especially at risk for spondylitis. Diskospondylitis in large animals is most commonly reported in adult horses and cows in the cervical vertebrae.[4-6] Lesions have been less commonly identified in the thoracic,[7,8] lumbar,[9] and sacral[10] regions.

Clinical Signs and Differential Diagnoses

The earliest signs of spondylitis may include fever, lethargy, stiffness, and localized spinal pain. Soft tissue swelling may be evident with paravertebral abscessation.[11] Muscle atrophy has also been reported.[8] Diskospondylitis most commonly affects the cervical and thoracic vertebrae, so neck pain and reluctance to lower the head to graze are common signs. Animals may develop an abnormal stance with one forelimb forward and the other back to graze.[7] Vertebral osteomyelitis may progress to spinal cord compression with variable degrees of ataxia, paresis, sensory and proprioceptive deficits, and recumbency. Neurologic signs are dependent on the vertebral section affected and the amount of spinal cord compression. Once present, clinical signs are usually progressive.

Clinical signs in ruminants are similar. Early signs include abnormal behavior, decreased appetite, and weight loss. Difficulty in extending the head and neck ventrally is often the reason for presentation to a veterinarian.[2] Varying degrees of neurologic deficits are reported, from occasional stumbling[2] to tetraparesis[12] and paraplegia.[3]

Differential diagnoses for spinal pain include spondylosis, vertebral fracture, muscle strain, dorsal spinous process impingement, vertebral subluxation, vertebral infarcts, and aberrant parasite migration.[13] Additional differentials for spinal cord ataxia in horses include cervical vertebral stenotic myelopathy, equine protozoal myeloencephalopathy, herpes myeloencephalopathy, and neoplasia.

Etiology/Pathogenesis

Both spondylitis and diskospondylitis are thought to be septic conditions, although etiologic isolation is not often successful. Even in cases where bacteria are not isolated, response to antimicrobials may indicate a bacterial pathogenesis.[7] Bacterial infection is more common than fungal infection, and the hematogenous route of infection is the most common. Spondylitis occurs most frequently in neonates, which may be due in part to failure of passive transfer leading to sepsis.[1] In general, spondylitis is often secondary to a preexisting focus of infection elsewhere in the body.[1] Tail docking wounds,[14] umbilical infections,[1,12] pneumonia,[10] and lung abscesses[1] are possible sources of infection. Septic thrombi embolize into the metaphyseal arteries of the vertebrae, where flow is sluggish and bacteria can colonize.[14] In adults, direct injury to the intervertebral disk and/or the vertebral endplate may contribute to the formation of diskospondylitis. The injury disrupts the vasculature, increasing susceptibility to infection. Diskospondylitis is also reported to occur secondary to spread of local infection[5] and traumatic injury.[4] Infection results in destruction and remodeling of affected bone. Inflammation of the disk and vertebrae leads to spinal cord compression and the associated neurologic dysfunction. The intervertebral disk may actually prolapse into the spinal canal.[5] Lesions are usually confined to one intervertebral space. The neurologic signs may also be secondary to the infection eroding into the meninges and causing a suppurative meningitis.

Pathogens that have been cultured from adult horses with vertebral osteomyelitis include *Brucella abortus,*[15] *Aspergillus* spp., *Streptococcus zooepidemicus,*[1] *Staphylococcus* spp.,[6,9] and *Mycobacterium bovis.*[16] Vertebral osteomyelitis isolates in foals include *R. equi,*[10,11,17] *Streptococcus* spp., *Actinobacillus* spp., *Eikenella corrodens,*[18] *E. coli, Salmonella typhimurium, Staphylococcus* spp., and *Corynebacterium pseudotuberculosis.*[13] Isolates from cattle with vertebral osteomyelitis include *Aspergillus fumigatus, Bacteroides nodosus, Clostridium perfringens, Streptococcus* spp., *Staphylococcus* spp.,[2] *E. coli,*[14] *Actinomyces pyogenes, Fusobacterium necrophorus,* and *Pseudomonas* spp.[19] *Staphylococcus* spp. and *T. pyogenes* (formerly *A. pyogenes*) were cultured from the intervertebral disk of a goat.[3]

Diagnosis

Diagnosis is based on clinical signs and imaging modalities. Clinicopathologic findings may include anemia, leukocytosis, neutrophilia, and hyperfibrinogenemia.[1] One retrospective study, however, found that 80% of affected horses had a normal WBC count.[20] Hyperproteinemia due to hyperglobulinemia may also be seen.[7] CSF is usually normal unless the osteomyelitis has progressed to meningitis. Blood and urine cultures should be obtained but are often not diagnostic.

Radiography is often the basis of diagnosis. Radiographic signs of spondylitis include bony proliferation, lysis, sclerosis, and localized soft tissue swelling.[1] Radiographic abnormalities in diskospondylitis include osteolysis of adjacent endplates, with surrounding sclerosis and collapsed intervertebral disk space[9] (Fig. 38-32). Contrast radiography may be used to delineate spinal cord compression.[9] Radiographic changes may lag at least 2 to 8 weeks behind clinical signs, hampering the ability to make an early diagnosis.[1] With vague clinical signs, the neuroanatomic location within the vertebral column may be difficult to identify, making targeted radiographs impossible. Nuclear scintigraphy may help localize the lesion to a specific vertebral section that can then be radiographed.[1] Scintigraphy may also allow earlier detection, owing to the lag time in radiographic changes. Ciprofloxacin and white cell–labeled scintigraphy may also prove useful in the diagnosis of vertebral osteomyelitis. Ultrasonography is becoming increasingly used as a diagnostic imaging modality. Abnormalities include irregular endplates or bone surfaces, wide or narrow disk spaces, vertebral step formation, and associated abscessation or muscle involvement.[9] Transrectal ultrasonography of the

VetBooks.ir

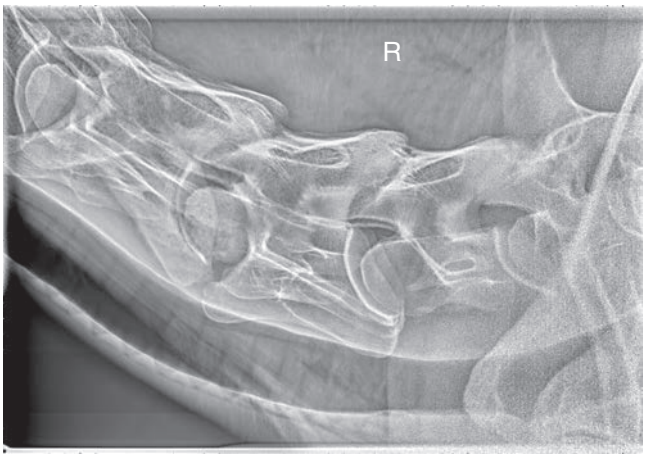

FIG. 38-32 Eleven-year-old Arabian cross gelding with fever and neck pain. The cortical margins of the caudal endplate of C5 and the cranial vertebral body of C6 are markedly thin and ill defined. Additionally, there is osteolysis and sclerosis associated with the cranial vertebral body of C5. The C5-C6 intervertebral disk space is narrow.

lumbar vertebrae may be performed, and transcutaneous studies can image the rest of the vertebral column. Advantages to ultrasound are that it can be done in the field, it can be used for needle-guided aspirates of potentially infectious lesions, and it can be used as a screening tool to localize lesions.[9] Depending on the size of the animal and availability of equipment, MRI and CT may also be considered because these modalities can be used to assess the vertebral endplates, disk, and spinal cord.[3] CT has been used in a goat to diagnosis diskospondylitis. Bone lysis, bone proliferation, mineral opacity within the intervertebral disk, and spinal cord displacement were seen.[3]

Treatment Long-term antimicrobial therapy is indicated for cases of vertebral osteomyelitis. Blood, urine, or tissue cultures and sensitivities may be used to guide antimicrobial choices. When that is not possible, broad-spectrum bactericidal antimicrobials should be used. Long-term treatment is necessary and may extend to 3 to 6 months.[10] NSAIDs can be used for pain control. In unresponsive cases, curettage of infected bone may be necessary.[6,10] This also provides an opportunity to collect material for bacterial culture.[10] In horses with instability and spinal cord compression, surgical decompression and stabilization may be indicated.

Prognosis The prognosis for horses with diskospondylitis is guarded. If there are no neurologic deficits, and thus presumably no spinal cord compression, the prognosis is more favorable. Early diagnosis and long-term treatment is essential. In one retrospective study, 13 of 19 adult horses survived to discharge, with 7 returning to their previous level of performance.[20] Foals may have a worse prognosis, with only 7 of 15 surviving to discharge.[21]

Spondylosis

Sarah M. Reuss

Definition Spondylosis is a degenerative condition of the intervertebral joints. In middle-aged and older horses and cattle, the thoracic and lumbar vertebrae are susceptible to chronic progressive development of enthesophytes within the ventral longitudinal ligament or the ventral margins of the anulus fibrosis. Osteophytes extend across the intervertebral space toward osteophytes on the adjacent vertebrae, resulting in partial bridging, where a lucent line persists between the two. Complete bridging, or *ankylosis,* can occur without significant loss of intervertebral disk width. A variety of terms are used in veterinary medicine to describe vertebral enthesophyte formation: *spondylosis deformans, vertebral osteophytosis,* and *ankylosing spondylosis.*[1]

Spondylosis in horses is most common in mature animals and reportedly in a higher proportion of mares.[2] The most common location in horses is from the tenth to fourteenth thoracic vertebrae, and most horses with spondylosis have lesions at more than one intervertebral space. In the thoracic region, the osteophytes are usually ventrolateral; osteophytes are more lateral when found in the lumbar region.[3]

Middle-aged and older bulls have a higher prevalence of vertebral enthesophytes than other cattle. Bulls used for artificial insemination are especially at risk, with over 49% of those 8 years and older having spondylosis.[4] Middle-aged bulls also have significant pathology, with 21 of 21 dairy bulls aged 65 to 90 months in one study having some degree of lumbar vertebral osteophytes; 13 had complete ankylosis of at least one intervertebral space.[5]

Etiology/Pathogenesis The exact cause of spondylosis is unknown but is apparently related to altered biomechanics and inflammatory mediators. One hypothesis is that spondylosis is a result of excessive dorsiflexion when the back muscles fatigue. There is then mechanical stress and tearing of the ventrolateral anulus fibrosus.[6] Chemical mediators act on the periarticular ligaments and joint capsules, leading to metaplastic change. Ossification occurs within the anulus fibrosis and ventral longitudinal ligament, leading to partial bridging. The cycle may continue until complete ankylosis and a continuous medullary cavity exists.[1] Partial or complete ankylosis at one site puts more stress on adjacent segments, so there is more active bone remodeling elsewhere in the vertebral column.[3] One study found that 60% (14/23) of horses with radiographic evidence of spondylosis had involvement of more than one site.[7] Secondary DJD of the dorsal articular facets may also develop as a result of the altered biomechanics.

The enthesophytes and then the ankylosed vertebral bodies are both at higher risk for fracture because of their inability to absorb normal forces; 3% of bulls at artificial insemination centers have vertebral fractures.[8]

Spondylosis in bulls is not related to force of ejaculatory thrust at service, frequency of semen collection,[9] or high-calcium diets. Despite previous thought, limited dietary calcium does not reduce the prevalence of spondylosis in bulls.[8]

Nerve roots may be compressed as they exit the intervertebral foramen, and spinal cord compression may occur if the bony proliferation extends dorsally into the vertebral canal. This results in neurologic deficits including progressive ataxia and paralysis.

Clinical Signs and Differential Diagnoses Spondylosis can be an incidental finding in animals with no history or clinical signs of back pain. Spondylosis can, however, account for acute, recurrent, and chronic back pain in some animals. Pain is due to inflammation, impingement, and fracture. Palpation of the spine may be resented. Horses may "guard" their vertebral column by using muscle contraction to not allow ventroflexion. Resentment of girthing and mounting may be noticed. Riders may report poor performance, vague lameness, or altered gait.[6] Spondylosis is rarely the cause of back pain, however; only 3.4% (23/670)[7] and 2.7% (8/443)[2] of horses presenting for back pain were found to have spondylosis in two separate studies.

Bulls with spondylosis will have a good appetite and be afebrile, but they may have difficulty rising, be reluctant to move, and have difficulty mounting.[1] Once clinical signs are present, they are slowly progressive. Lameness becomes more severe, and neurologic deficits may develop with nerve root impingement or spinal cord compression. Abnormalities include bilateral proprioceptive deficits of the hindlimbs with hoof dragging, excessive hindlimb flexion, and incoordination. Hindlimb ataxia can progress to paralysis in some animals, especially older dairy bulls.[5]

Differential diagnoses for spinal pain include muscle strain, vertebral fracture, diskospondylitis, dorsal spinous process

VetBooks.ir

impingement, vertebral infarct, and aberrant parasite migration. Additional differentials for cattle with hindlimb neurologic deficits include lymphosarcoma, encephalopathy, progressive degenerative myeloencephalopathy, and "downer cow" syndrome.[1]

Diagnosis Diagnosis is suggested by clinical signs. Palpation of the dorsum may elicit signs of pain. Rectal palpation may reveal ventral osteophytes if they are located on the caudal lumbar vertebrae. A thorough neurologic examination is indicated if there are hindlimb deficits. CSF is usually normal.

Standing lateral radiographs are the mainstay of diagnosis, but diagnostic radiographs can be difficult to obtain, given the depth of the vertebrae in the thoracolumbar region. If one suspects spondylosis, targeting radiographs to areas of predilection is helpful. Spondylosis in horses is typically in the midcaudal thoracic vertebrae, commonly T10-T14, but may also affect the lumbar vertebrae.[2] In bulls, the most common locations are C3-C5, T2-T6, and T11-L5. The largest osteophytes occur in older bulls at the thoracolumbar junction.[4,9] Radiographic changes include smooth bone that blends with the vertebral body and bridges apparently normal intervertebral disks. A grading system has been developed, with grade 0 being normal, grade 1 having an osteophyte from one vertebral body, and up to grade 5 having complete bridging of the intervertebral space.[7] The clinical significance of radiographic change must also be determined based on history and clinical signs, as spondylosis can be an incidental finding. Nuclear scintigraphy can be useful for determining the activity and potential clinical significance of a lesion based on the radiopharmaceutical uptake. Scintigraphy may also helpful in localizing the lesion for targeted radiography and is an option if diagnostic radiographs cannot be obtained owing to size constraints. Subjective assessment of scintigraphic images had 21.7% sensitivity but 95% specificity in a recent study using radiographic change as the standard.[7]

Treatment and Prognosis Treatment for clinical spondylosis consists of palliative care. Systemic antiinflammatories, cryotherapy (ice packs, cold hosing), and stall rest are recommended during the acute phase. Some horses may respond to intervertebral injection of corticosteroids and/or systemic chondroprotectants such as IM Adequan. Once complete fusion occurs, clinical signs should improve. However, if vertebral fractures or neurologic deficits are present, the prognosis is poor.

Laminitis

Michelle C. Coleman

Definition *Laminitis,* defined as inflammation of the laminae of the hoof wall, results in degeneration, necrosis, and inflammation of the dermal and epidermal laminae in the hoof wall of equids and ruminants.

Etiology and Pathogenesis Laminitis has a complex and multifactorial etiology ultimately resulting in lamellar degradation of the suspensory apparatus of the distal phalanx. Disease states thought to be associated with laminitis include sepsis and systemic inflammation, equine metabolic syndrome, pituitary pars intermedia dysfunction, and mechanical or traumatic overload. Septic processes including endotoxemia, gastrointestinal disease, pneumonia, and septic metritis are frequently associated with the development of laminitis. Laminitis has also been noted secondary to systemic inflammation resulting from an overload of carbohydrates, such as from overgrazing lush pastures or unrestricted access to concentrates. Excess weight bearing as a result of a contralateral limb lameness and trauma to the distal phalanx following exercise on hard ground can result in laminitis. Exposure to a water-soluble toxin in black walnut shavings[1] and administration of corticosteroids have also been associated with the development of laminitis.[2]

In cattle, overweight heifers fed excess concentrates and housed on concrete surfaces appear to be at higher risk.

Pathophysiology The pathophysiology of laminitis has not been fully elucidated, but it appears to involve a combination of events that lead to lamellar degeneration, impaired biomechanical function, and debilitating pain. There are several experimental models for induction of laminitis, including carbohydrate overload, fructan overload, black walnut extract administration, and hyperinsulinemia. These models support several similar and possibly interconnected theories on the pathophysiology of laminitis: digital hemodynamic events, enzymatic events, inflammatory events, endocrinopathic events, and mechanical/traumatic events.

Clinical signs of acute laminitis include bounding digital pulses and elevated temperature, supporting a vascular component of the disease. It is thought that increased capillary pressures secondary to venoconstriction of the digital microvasculature result in laminar edema, increased arteriovenous shunting, and capillary collapse.[3] Thrombi have been identified in laminar microcirculation of laminitic horses, with unknown effect on laminar ischemia. Through release of vasoactive and inflammatory mediators, leukocyte activation, and platelet-neutrophil activation in the lamella, platelets are likely involved in vascular disturbance and inflammation in the acute stages of laminitis.

The enzymatic theory postulates that increased digital blood flow results in delivery of cytokines to the digit, which induce production and activation of matrix metalloproteinase (MMP) enzymes. Active lamellar MMPs are important in the separation of lamellar cells from their basement membranes, resulting in separation of epidermal and dermal laminae. MMP-2 and MMP-9 have been isolated in increased quantities from lamellar tissue affected by laminitis,[4] and affected lamellar tissue has been shown to increase transcription of MMP.[5] MMP-9 has also been associated with neutrophil migration into the lamellae.[6]

Experimental models of equine laminitis have displayed a number of inflammatory events. In the early stages of laminitis, endothelial activation, leukocyte extravasation, inflammatory signaling, and activation of degradative enzymes like MMP occur.[7] These inflammatory events in the laminae of laminitic horses closely resemble inflammatory events that occur in human sepsis. Proinflammatory cytokines IL-1β and IL-6 have increased laminar expression in laminitis. There is also increased expression of IL-8, GRO-α, and MCP-1, which play a role in leukocyte activation and chemotaxis. Increased expression of inducible cyclooxygenase, COX-2, suggests that prostaglandins may play a role in laminar dysfunction.

The role of endotoxemia in the development of laminitis remains unclear. Although systemic inflammation is a risk factor for development of laminitis, experimental endotoxin administration fails to induce the disease. This could be explained by the fact that endotoxin does not act alone but in combination with several factors including bacterial toxins, necrotic cell products, and proinflammatory cytokines. Endotoxin has been detected in the blood of horses following experimental carbohydrate overload[8] and is known to affect digital vascular function and platelet activation. Recent studies have hypothesized that the proinflammatory state of carbohydrate overload models is driven by an immune response to the rapid overgrowth of gram-positive and gram-negative cecal bacteria.[9]

Several conditions in the horse that have been associated with insulin resistance are pituitary pars intermedia dysfunction (PPID), equine metabolic syndrome (EMS), and iatrogenic corticosteroid administration. To help better understand the underlying relationship between insulin resistance and laminitis, the metabolic profiles of laminitic ponies and a cohort of non-laminitic ponies were compared in one study.[10] Body condition score, measures of insulin resistance, and serum insulin concentration were predictors of development of laminitis in 11 of 13 ponies in that study. Laminitis can be induced in healthy horses by maintaining a high plasma insulin concentration with normal glucose,[11] but insulin at lower

concentrations has resulted in changes within the laminae that were suggestive of laminitis.[12]

Laminitis has long been associated with mechanical overload on the distal phalanx, such as excessive concussion (road founder) and supporting-limb laminitis. The mechanism of insult to the laminae is thought to be direct damage to the lamellae and/or altered blood supply.

These theories of the pathogenesis of laminitis are extremely complex and likely interconnected. Much research has been performed on experimental models, but the relationship of these models to the naturally occurring condition is unknown.

Clinical Signs Laminitis can affect all four feet but is most commonly noted in the front feet of horses (likely due to an increased load on the forelimbs) and the hind feet of ruminants. Supporting-limb laminitis occurs on the supporting forelimb or hindlimb opposite the non–weight-bearing limb. Clinical signs of acute laminitis include lameness, depression, and anorexia. The lameness may vary in severity from subtle to prolonged recumbency due to digital pain. Because of the variability in lameness, the Obel grading system was developed.[13] Grade 1, the least severe classification, is characterized by shifting weight with no apparent lameness at the walk but a short-stilted trot. Horses with grade 2 lameness are willing to walk but have a stilted gait and are willing to lift a foot off the ground. Grade 3 is characterized by reluctance to ambulate and resistance to having a foot lifted off the ground. The most severe classification is grade 4, in which the horse refuses to move.[13] Other clinical signs consistent with laminitis include bounding digital pulses, sensitivity to hoof testers over the sole at the toe, sensitivity to tapping of the hoof wall at the toe, heat over the dorsal surface of the hoof wall, swelling of the coronary band, and shifting of weight, often to the hindlimbs if laminitis affects the forelimbs. More severe clinical signs consistent with rotation or distal displacement of the distal phalanx within the hoof wall include palpation of a depression over the coronary band and a dropped sole.

Chronic laminitis results in lameness and deformation of the hoof capsule that vary with duration of disease and type of displacement. In these cases, the sole is flat or dropped, the white line is widened, and the hoof wall shows signs of uneven growth. Irregular rings of growth may be noted around the hoof wall, more widely spaced at the heels. The abaxial white line develops apparent hemorrhages, and fissures of the hoof wall may be noted parallel to the coronary band. In ruminants the sole softens and assumes a light yellow discoloration.[14]

Clinical Pathology and Radiology There are no clinical pathologic findings specific to acute or chronic laminitis. If clinical pathologic findings are present they may reflect an underlying disease process such as endotoxemia, enteritis, colitis, pleuropneumonia, or metritis. Changes may also be seen as a result of glucocorticoid and catecholamine release in response to pain and stress. One study showed that horses euthanized for chronic laminitis had higher WBC counts when compared to control horses and horses with less severe disease.[15] Baseline values for creatinine and total protein should be obtained because they are important parameters to monitor for NSAID toxicity.

Radiographic examination is critical for diagnosis of suspected cases, monitoring progress, and guiding appropriate therapy. Radiographs, including lateromedial and 65-degree dorsoproximal-palmarodistal views, should be taken of all suspected digits in acute disease to serve as a baseline for subsequent radiographic studies and to determine whether prior radiographic changes are present. Using a consistent technique is important to achieve a true lateral image and allow accurate evaluation of radiographic parameters for comparison of serial studies. For both views, the foot should be thoroughly cleaned and placed on a wooden block such that the x-ray beam can be centered on the solar margin of the distal phalanx. A radiopaque marker placed on the mid-dorsal hoof wall starting at the coronary band and extending distally can be useful in determining the position of the distal phalanx in relation to the surface marker.

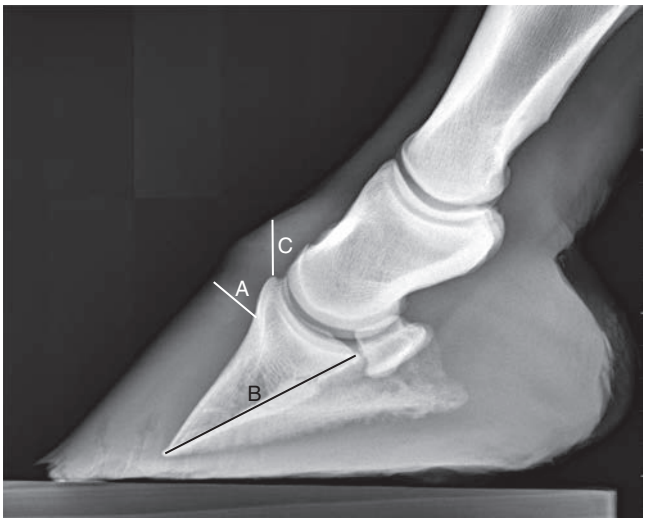

FIG. 38-33 Lateromedial radiograph of a horse with acute laminitis. *(A)* Distance from the dorsoparietal surface of the distal phalanx to the dorsal surface of the hoof capsule, *(B)* length of the palmar cortex of the distal phalanx, and *(C)* distance from the extensor process to the proximal aspect of the hoof wall distal to the coronary band.

Primary radiographic changes in acute laminitis include thickening of the dorsal hoof wall as a result of inflammation and separation of the laminae and separation of the distal phalanx from the hoof wall. When the suspensory apparatus of the distal phalanx fails, the distal phalanx rotates away from the hoof wall or displaces distally, increasing the distance between structures. This distance can be measured as a line vertical to the parietal surface of the distal phalanx and distal to the extensor process. In normal horses, this distance should be less than 18 to 20 mm (Fig. 38-33, *A*). The ratio between this dorsal measurement and the palmar cortical length of the distal phalanx measured from the dorsodistal tip of the bone to its articulation with the navicular bone (see Fig. 38-33, *B*) can be used to account for changes in magnification and size of the foot. This ratio should be less than 28% in normal horses and greater than 32% in horses with displacement of the distal phalanx. Sinking of the entire distal phalanx within the horny capsule can be assessed by measuring the vertical distance between the coronary band and the extensor process of the distal phalanx (see Fig. 38-33, *C*). Soft tissue swelling of the coronary band may be apparent. Palmar/plantar rotation of the distal phalanx away from the hoof wall greater than 5 degrees is indicative of capsular rotation (Fig. 38-34, *A*).

In chronic cases, a radiolucent line may appear between the distal phalanx and the sole or hoof wall; this is due to accumulation of serum between the dermal and epidermal laminae. The angle of the solar margin of the distal phalanx to the ground surface may be a more accurate assessment of rotation in chronic cases (see Fig. 38-34, *B*). Radiographic evidence of a previous episode of laminitis may be evident in clinically normal horses. Changes may include increased thickness of the dorsal hoof wall, a radiolucent line in the dorsal hoof wall, modeling of the toe of the distal phalanx, and/or uncorrected rotation of the distal phalanx.

Positive contrast venography is useful in identifying filling defects in the digital vasculature, including the lamellar vessels, circumflex area, and terminal arch. Venographic studies are most valuable in early disease and may reveal damage in the hoof before radiographic changes are evident.[16]

Epidemiology Epidemiologic studies into the risk factors for naturally occurring laminitis in horses are limited; a few studies report inconsistent results. A recent systematic review of publications assessing the risk factors for naturally occurring laminitis revealed

VetBooks.ir

VetBooks.ir

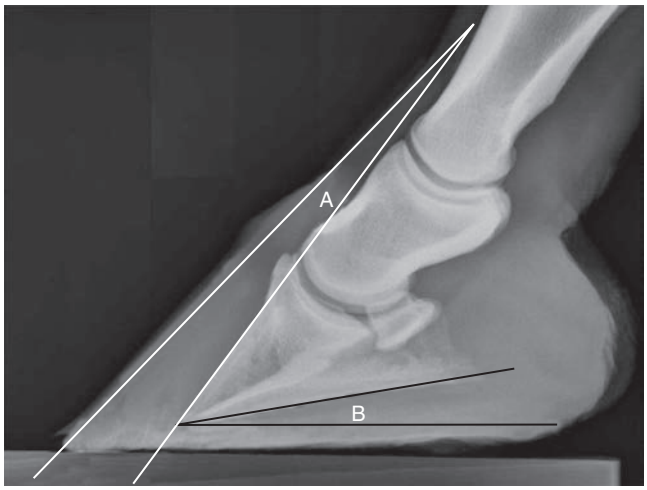

FIG. 38-34 Lateromedial radiograph of a horse with acute laminitis. *(A)* Measurement of the degree of capsular rotation, and *(B)* measurement of the angle of the solar margin of the distal phalanx to the ground surface of the foot.

only an association with chronic laminitis and increasing age. Results for other horse-level factors like gender, breed, and body weight were inconsistent. No consistent associations have been identified with other factors, including exercise and seasonality.[17] Associations between health conditions and laminitis have been investigated, with endotoxemia the only variable for which an association has been noted.[18] This finding has not been reproducible in experimental models.[19] Many studies describe concurrent pituitary pars intermedia dysfunction and laminitis, but no association has been identified.[18] Likewise, no scientific evidence of an increased risk of laminitis from a supporting limb has been identified despite widespread concern. Further evidence-based studies on the risk factors for development of laminitis are clearly indicated.

Necropsy Necropsy findings depend on the duration and severity of the disease. Separation of the primary epidermal laminae of the hoof wall and the collagen fibers of the corium occurs as a result of complete degeneration of the secondary epidermal laminae. The distal phalanx may sink, rotate ventrally, or penetrate the sole. Necrotic laminae are prone to abscessation. Severe changes include fractures of the solar margin, osteomyelitis, or resorption of the distal phalanx.[14]

Treatment Incomplete understanding of the pathophysiology and progression of laminitis limits our ability to successfully prevent and treat the disease and results in considerable controversy regarding appropriate treatment regimens. Therapy is often empirical and based on the clinician's experience. Advancement in our knowledge of the complex pathophysiology of laminitis may result in more effective preventive and therapeutic approaches. Acute laminitis should be considered an emergency, and therapy should be initiated before or immediately following the onset of clinical signs. General principles of therapy include minimizing or eliminating predisposing factors, decreasing pain and inflammation, promoting digital circulation, reducing tension on the laminae, and reducing platelet activation and coagulation.

ELIMINATING CAUSES. Predisposing factors to the development of laminitis should be minimized or eliminated. Following ingestion of large amounts of grain, laxatives or purgatives (e.g., mineral oil, activated charcoal) may be administered via nasogastric tube. Exhaustion, dehydration, and hypovolemia may be treated with appropriate IV fluid therapy. Appropriate therapy for endotoxemia and septic processes like colitis, enteritis, pleuropneumonia, metritis, and retained placentas should be initiated.

Preventive measures in suspect cases may include placing the horse in a deeply bedded stall, frog support, and corrective shoeing or trimming.

DECREASING PAIN AND INFLAMMATION. Antiinflammatory therapy is recommended to decrease lamellar inflammation, edema, and pain associated with laminitis. The most common NSAID used in horses is phenylbutazone at a dose of 2.2 to 4.4 mg/kg IV or PO q12h. The dose and frequency are tapered as quickly as possible. Flunxin meglumine can be administered at a dose of 0.5 to 1.1 mg/kg PO or IV q8-12h for its antiinflammatory effects, or at a dose of 0.25 mg/kg IV q8h to interrupt eicosanoid production associated with endotoxemia. Ketoprofen and firocoxib are also labeled for use in horses. DMSO is a free radical scavenger that aids in reduction of edema and may reduce ischemia-reperfusion injury. DMSO is typically administered at 0.1 to 1 g/kg IV diluted in a polyionic fluid to a concentration of less than 10% to avoid hemolysis. Pentoxifylline, a phosphodiesterase inhibitor, alters RBC membranes to improve blood flow. It has been shown both in vivo and in vitro in horses to have antiinflammatory effects,[20] and preliminary data indicate a decreased incidence of laminar failure in horses treated with pentoxifylline at the time of experimental carbohydrate overload.[21] In a recent study, the analgesic effects of tramadol hydrochloride administered in combination with ketamine hydrochloride were evaluated in horses with naturally occurring chronic laminitis. Tramadol provided little analgesic effect, but analgesia was enhanced by administration of subanesthetic doses of ketamine.[22]

PROMOTING DIGITAL BLOOD FLOW. Venous vasoconstriction is involved in the pathogenesis of laminitis, but several therapeutic agents that have been suggested for increasing blood flow to the digit (i.e., isoxsuprine, nitroglycerin paste) have not proven effective. Acepromazine, a phenothiazine tranquilizer, has been shown to increase digital blood flow in clinically normal horses, with a short duration of efficacy of about 30 minutes.[23] Acepromazine has been recommended at a dose of 0.03 to 0.06 mg/kg IM or IV q6-8h.

Continuous application of cryotherapy to the distal limbs for 48 hours effectively ameloriated induced acute laminitis during the developmental stages of experimental models.[24-25] Filling a 5-L fluid bag with ice and water was shown to be as effective as using wader boots at laminar and digital venous cooling.[26]

REDUCING TENSION ON THE LAMINAE. Because laminar deformity is likely due to tension placed on the suspensory apparatus of the distal phalanx, reduction of mechanical force and stabilization of the distal phalanx are essential in the treatment of acute laminitis. Horses should be confined to strict stall rest and not be exercised in the acute stages of the disease. The horse should be encouraged to lie down, and bedding in the stall (ideally sand) should be deep. Redistributing weight from the hoof wall to the bars, sole, and frog may decrease laminar tension. Various methods have been suggested, including silicone impression material (EquiFlex-Pak [Sound Horse Technologies, Unionville, Pa.]), styrofoam insulation board, Lily Pads (Nanric Inc., Lawrenceburg, Ky.), the Steward Clog (Equine Digit Support System Inc., Penrose, Colo.), and Soft-Ride boots (Soft Ride Inc., Vermillion, Ohio). Regardless of the method of weight redistribution, it is important to remember that once the distal phalanx displaces, increased pressure over the sole where the distal phalanx displaces may cause severely increased discomfort. Various methods of distal limb casts have also been used to improve stability to the distal phalanx.

Decreasing tension on the DDF tendon will also help decrease tension on the laminae. This can be accomplished by elevation of the heels with a wedge (i.e., the Redden Modified Ultimate Wedge [Nanric]) or transection of the DDF tendon to reduce caudal pull on the coffin bone.

Depending on the degree of rotation and/or distal displacement in chronic laminitis, various methods of hoof care and shoeing have

VetBooks.ir

been employed. More radical past approaches (e.g., hoof wall resection, coronary band grooving) offered varying efficacy.

ANTICOAGULANT THERAPY. Heparin has been recommended in the treatment of laminitis to reduce microthrombi and platelet-platelet or platelet-neutrophil aggregates that are thought to form. Heparin was recently reported to have potential antiinflammatory effects on equine endothelium exposed to neutrophil-derived myeloperoxidase.[27] When administered prophylactically, unfractionated heparin was shown to reduce the proportion of horses with proximal enteritis that develop laminitis,[28] and low-molecular-weight heparin reportedly reduced the incidence and severity of laminitis in postoperative colics.[29]

Prognosis

There is little evidence-based research on prognosticating laminitic horses, but it is likely the prognosis of laminitis depends largely on the severity of the pathology, type of displacement, clinical signs, and underlying diseases or conditions. Prognosis may also be influenced by financial constraints, owner expectations, and owner compliance. In general, rotation is considered to have a more favorable prognosis than distal displacement, which is considered to have a more favorable prognosis than unilateral displacement. The degree of rotation and distance from the proximal margin of the extensor process of the distal phalanx to the proximal margin of the hoof were reported to be important factors in return to soundness and prognosis for survival.[30] General guidelines based on degree of lameness and rotation and progression of clinical findings proposed by Redden in 1988 can be found in the previous edition of this textbook.[14] In one study, 75% of horses referred to a university veterinary hospital with acute laminitis did not return to athletic function, and a majority were euthanized within 1 year because of poor response to therapy or development of complications.[31]

Prevention and Control

Preventive measures are aimed at decreasing risk factors for development of the disease, but our poor understanding of the etiology and pathophysiology of the disease makes prevention challenging. In general, suspected risk factors such as uncontrolled grazing on lush pastures, unrestricted access to grain or concentrates, factors contributing to gastrointestinal upset including rapid changes in diet, and retained placentas should be avoided when possible.

Fluorosis

John Maas

Definition and Etiology

Ingestion of excessive fluoride by cattle, sheep, and horses can result in toxicosis. Acute fluoride toxicosis is relatively rare and is the result of accidental massive ingestion of fluoride compounds such as sodium fluoride or sodium fluorosilicate. Signs of acute fluoride toxicosis include restlessness, stiffness, anorexia, agalactia, salivation, vomiting or regurgitation, urinary incontinence, diarrhea, clonic convulsions, hyperemia, weakness, severe depression, and cardiac failure. Necrosis of the gastrointestinal mucosa and high concentrations of fluoride in plasma and urine are present in acute fluoride toxicities. Chronic fluoride toxicosis is most often referred to as *fluorosis,* a general term that includes osteofluorosis and dental fluorosis. Common sources of excess fluorides in the diet are (1) water with a naturally high fluoride content, (2) forages contaminated with fluorides from nearby (upwind) industrial plants (e.g., phosphate-processing plants, aluminum plants, and aluminum smelters), (3) mineral sources (nondefluorinated rock phosphorus) and feed supplements with excessive fluoride content, (4) forages contaminated by soil or water (particularly sprinkler irrigation water) with a high fluoride content, and (5) volcanic activity, which can deposit fluoride-containing ash on soil, plants, or in water used for agriculture.

Recent outbreaks of fluorosis have been attributed to environmental fluoride contamination by superphosphate fertilizer plants,[1] ingestion of a commercial mineral supplement containing a contaminated phosphorus source,[2] fertilizer-grade phosphorus supplements (containing large amounts of fluoride) fed to cattle for lameness attributed to a phosphorus deficiency,[3] and fluorosis in sheep and cattle attributed to water with excess fluoride used for irrigation and drinking water.[4]

Clinical Signs, Differential Diagnosis, and Pathophysiology

Clinical signs of fluorosis are usually first recognized as either dental fluorosis or osteofluorosis. Developing teeth are very sensitive to the ingestion of excess fluorides. The deciduous teeth rarely show signs of dental fluorosis because a partial placental barrier to the accumulation of fluorides appears to be present in the fetus. During tooth development, excess fluorides cause ameloblasts to reduce in size prematurely and the enamel epithelium to form an irregular matrix. This matrix does not calcify normally, producing defects in the mature teeth. Cattle are susceptible to dental fluorosis during enamel matrix formation, from approximately 6 months to 3 years of age. Excess fluoride intake after 3 years of age does not result in the typical fluoride-induced dental lesions. Changes in incisor teeth are observed most frequently and include chalkiness, mottling (striations or patches in enamel), hypoplasia (defective enamel), and hypocalcification. Clinical lesions can be graded from normal to excessive.[5] Factors that influence dental fluorosis include the amount of fluoride ingested, the animal's age, the duration and consistency (intermittent vs. continuous) of exposure to fluoride, and the source and chemical form of fluoride ingested. Although clinically important, dental lesions should not be used as the sole criterion to determine the degree of fluorosis.

Fluoride accumulation in bone occurs over a prolonged time; osteofluorosis can eventually develop if excessive fluoride is ingested. In cattle the first palpable lesions occur on the medial surface of the proximal third of the metatarsal bones. Later, lesions can be palpated on the mandible, metacarpal bones, and ribs. Radiographically, osteofluorotic bones are thickened with a chalky, roughened, and irregular periosteal surface.

The presence of osteoporosis, osteosclerosis, hyperostosis, osteophytosis, or osteomalacia depends on the amount of fluoride ingested and the duration of exposure to fluorides. The articular surfaces are not involved in osteofluorosis and can be used to differentiate osteofluorosis from osteomyelitis, osteoarthritis, and septic arthritis. The osseous lesions eventually cause intermittent lameness and stiffness, which may affect feed intake, body condition, milk production, and reproduction. Severe dental fluorosis causes reduced feed intake and efficiency, and affected animals are sometimes reluctant to drink cold water.

Clinical Pathology and Diagnosis

Diagnosis of fluorosis is difficult and complicated by many factors that affect fluoride intake and deposition. Fluorosis may be suspected by history, clinical signs, and physical examination. Radiographic findings of bone disease without evidence of joint involvement are highly suggestive of fluorosis in the live animal. The fluoride concentration in the urine of cattle may help to approximate recent fluoride exposure. The diagnostic value of urine fluoride analysis increases as the duration of excess fluoride ingestion increases. Normal cattle have a urine fluoride concentration of about 2 to 6 mg/L (2 to 6 parts per million [ppm]) or less than 10 mg/L (ppm).[6] Cattle exhibiting moderate fluorosis have urine fluoride concentrations of about 15 to 20 mg/L (ppm). Cattle with urine fluoride concentrations of 40 mg/L (ppm) or greater or a urinary fluoride/creatinine ratio of 0.025:1 or greater could be suspected of ingesting a diet with a fluoride concentration of 60 ppm or greater.[5,7] The concentration of fluoride in bone is also quite helpful in the diagnosis of fluorosis (Table 38-2). Fluoride content in cancellous bone (e.g., rib, pelvis) is greater than in cortical bone. In addition, fluoride concentrations may vary in different areas of the same bone.

TABLE 38-2

Fluoride Concentration in Bones of Dairy Cattle Fed Various Levels of Sodium Fluoride[8,9]

Fluoride in Feed (ppm*, Dry Matter Basis)	Fluoride in Bone (ppm*; Dry, Fat-Free Basis)		
	2 years	4 years	6 years
0-15 (Normal conditions)	401-714	706-1138	653-1221
15-30 (No adverse effects)	714-1605	1138-2379	1221-2794
30-40 (Borderline fluorosis)	1605-2130	2379-3138	2794-3788
40-60 (Moderate fluorosis)	2130-3027	3138-4504	3788-5622
60-109 (Severe fluorosis)	3027-4206	4504-6620	5622-8676

*ppm = mg/kg

TABLE 38-3

Long-Term Tolerances of Dietary Fluoride for Cattle[11]

Animal	Dietary Fluoride (ppm*, Dry Matter Basis)
Dairy or beef heifers	30-40
Mature dairy cows	40
Mature beef cattle	40-50
Feedlot cattle	100

*ppm = mg/kg

Fluoride concentration of bone is usually expressed as mg/kg (ppm) of dry, fat-free bone. However, some bone samples are ashed before fluoride determination, so it is critical to note precisely which bone was sampled, how it was prepared, and what part of the bone was analyzed. The metatarsus and metacarpus are typically analyzed for fluoride content. For all practical purposes, fluoride concentration is equal in either of these bones from the same patient.[8] Using sawdust from a longitudinal section of bovine metatarsus (dividing the bone into lateral and medial halves or dorsal and palmar halves) yields virtually the same fluoride concentration as the whole bone.[8] The fluoride concentration of the fourteenth coccygeal vertebrae (ash basis) is approximately twice that of the metacarpus (dry, fat-free weight basis).[9] This can be a practical tool for clinical diagnosis in the live animal.

Analysis of dietary fluoride is a valuable adjunct to the diagnosis of fluorosis. The upper safe limit of fluoride in water for livestock is 2 mg/L (ppm).[10,11] This safe limit may not protect against fluorosis in all field situations because of the large number of variables involved in the pathogenesis of fluorosis. Table 38-3 lists the long-term dietary tolerances for cattle. Under field conditions, the clinician must consider all possible sources of fluoride ingestion in evaluating total intake. Because fluoride intake may be intermittent, a low dietary intake at one time may not necessarily eliminate a diagnosis of fluorosis.

Treatment and Prognosis No specific treatment is known for ruminants with severe fluorosis, and the prognosis is poor for cattle lame from extensive bony lesions. Animals removed from the offending diet or water may lose 50% of the fluoride from bone within 2 to 5 years,[12] but severe dental damage is irreversible.

Prevention and Control Prevention involves avoiding feeds, water, and supplements with excessive fluoride concentrations. Feeding aluminum sulfate at 0.5% of the total diet reduces bone fluoride storage by 30% to 40%. However, additional phosphorus must be supplied in the diet, or osteoporosis and possibly spontaneous fractures may occur. Aluminum chloride or calcium aluminate also can be fed to cattle to reduce fluoride absorption. Calcium carbonate added to soils high in fluorides aids in reducing fluoride in forages. Cereal grains do not accumulate fluorides and thus can be helpful in reducing overall fluoride consumption. In circumstances of high fluoride concentrations in water, use of flood irrigation rather than sprinkler irrigation decreases the fluoride content of crops such as alfalfa hay.

The effects of varying levels of dietary protein on long-term fluoride exposure have been examined. In this study the feeding of low-protein diets (75% of recommended amounts) increased the bioavailability of fluoride, but there was no significant influence on the susceptibility to fluorosis by varying the dietary protein concentration from low (75%) to normal (100%) to high (125%).

Hypertrophic Osteopathy

M. Keith Chaffin • Robin M. Dabareiner

Definition and Etiology Hypertrophic osteopathy (HO), also known as *Marie's disease,* is an uncommon condition in horses and is characterized by symmetric proliferation of connective tissue and subperiosteal bone along the diaphyses and metaphyses of the bones of the distal extremities.[1-3] The skeletal manifestations of HO are usually secondary to a primary underlying disorder elsewhere in the horse's body, often involving a space-occupying mass.[1-4] Most often, intrathoracic disorders are the primary cause[2]; intraabdominal and intracranial lesions have been less frequently associated with HO.[2,4,5] In addition to horses, HO has also been described in humans, dogs, cats, cattle, deer, and fowl. In humans the term *hypertrophic osteoarthropathy* is used because the articular surfaces are usually affected; in animals, however, HO apparently does not frequently affect the articular surfaces.[1-3]

In the horse, HO has been associated with a number of primary intrathoracic disorders, including mycobacterial pneumonia,[2,6] lung abscess,[1,2] suppurative pneumonia,[1,2,7] granulomatous pneumonia, systemic granulomatous disease,[2,3] fibrosing pneumonia,[8] primary and metastatic lung neoplasia,[7,9-12] pulmonary infarction,[13] rib fracture,[14] pleural adhesion,[2] and pericarditis.[15] Recently a 5-year-old warmblood was diagnosed with HO secondary to equine multinodular pulmonary fibrosis.[16] Reported primary extrathoracic disorders associated with HO include ovarian neoplasia,[17-19] pituitary adenoma,[5] and gastric squamous cell carcinoma.[4] There is one report of HO in a mare that was thought to be associated with pregnancy; signs of HO developed during three different gestational periods and regressed each time after parturition.[7] In occasional cases, HO may develop in the absence of an identifiable underlying disorder.[2]

Pathophysiology The pathophysiology of HO is not completely understood. Initially, blood flow to the distal limbs is increased, followed by proliferation of connective tissue, then bony proliferation along the inner aspect of the periosteum.[1-3] The periosteal proliferation results in the bony enlargements seen clinically. The link between the primary lesion and the skeletal abnormalities is poorly understood. Proposed explanations include hormonal abnormalities, hypoxia, arteriovenous shunting, and neurologic mechanisms.[1-3] The neurologic theory is based on increased vagal stimulation, and the endocrine mechanism involves a variety of local and systemic hormones increasing the production of vascular endothelial growth

VetBooks.ir

factor (VEGF) and platelet-derived growth factors (PDGF), causing release of megakariocytes from the pulmonary circulation, resulting in platelet clumping in the periosteal capillaries.[16] No single theory offers a completely satisfactory explanation.

Horses of any age or breed and either gender can be affected with HO. Some evidence suggests that HO may be more common in male horses and large-breed horses.[2] Ponies, donkeys, cattle, and sheep can also be affected.[7,10] The condition appears to be most common in mature horses.[7]

Clinical Signs Common clinical signs of HO include lameness, stiff gait, and reluctance to move or trot.[1-3] Firm bony enlargements are present on the distal extremities. In some cases, there may be soft tissue swelling or edema adjacent to the bony enlargements. In some horses the limb swelling is warm and painful to palpation, whereas in others the swelling is cold and painless.[2] Pain can frequently be elicited by forced flexion of the major joints. Bony enlargements are usually bilateral and symmetric and often affect the cranial, lateral, and medial aspects of the affected bones.[1,2] All four limbs are usually affected.[2] The metacarpal and metatarsal bones are most often affected; other sites that can be affected include the phalanges, carpus, tarsus, radius, and tibia, as well as the maxilla, mandible, and nasal bones.[2]

Affected horses may or may not show signs related to the primary underlying disorder, such as cough, fever, weight loss, ventral edema, tachypnea, or colic.[2] Clinicopathologic features are highly variable and depend on the underlying primary disease process. Generally, there is increased serum activity of alkaline phosphatase, associated with increased osteoblastic activity at the sites of periosteal proliferation.[2,3]

Radiographically, the bony enlargements are characterized by periosteal proliferative new bone formation of the diaphysis and metaphysis of affected bones.[2] The periosteal reaction often exhibits an irregular palisade pattern of osteophyte formation.[1,2] The bony reaction may extend to the chondrosynovial junctions; the articular surfaces are usually not affected.[3] In a few cases, nuclear scintigraphy revealed focal areas of intense uptake of radiopharmaceutical at the sites of bony enlargement.[1,15]

Treatment and Prognosis The prognosis for horses with HO is guarded and depends on the underlying disorder. In one study, 71% of horses with HO were euthanized.[2] Gradually progressive limb swelling and pain are the typical clinical course in most affected horses for which an underlying cause is either not identified or effectively managed. Thus, management of HO should be directed at identification and treatment of the underlying primary disorder if possible. Common methods to help identify the underlying disease include hematologic studies, serum chemistries, fibrinogen, thoracic radiography, thoracic and abdominal ultrasonography, abdominocentesis, thoracocentesis, gastroscopy, and rectal examination. Successful management of the primary underlying disorder has resulted in partial or complete regression of the skeletal disease in a limited number of equine cases.[1,2,15,16] Regression of HO is characterized by a decrease in limb swelling and lameness, and a return to athletic performance is possible if bony lesions are not advanced.[1] In a few idiopathic cases in which an underlying disorder was not identified, bony reactions decreased with rest, phenylbutazone, or corticosteroid therapy.[2]

Fescue Foot

Eric W. Davis

Definition and Etiology Fescue foot is a toxicosis of cattle grazing pastures that contain tall fescue grass (*Festuca arundinaceae* Schreb). The condition is characterized by lameness, particularly of the rear limbs, progressing to dry gangrene of the feet and lower legs. The end of the tail and the ear tips occasionally may be affected.

Fescue pastures also cause three other syndromes. "Summer slump" is characterized by reduced gain and milk production, dull hair coat, and poor heat tolerance. Abdominal fat necrosis also has been reported in cattle on fescue pasture.[1] Equine reproductive problems, including prolonged gestation and agalactia, as a result of grazing tall fescue late in gestations have also been described.[2]

The earliest description of fescue foot appeared in 1949 in Australia. It has been reported in Europe, New Zealand, and the United States, particularly in the Southeast. The etiologic agents in fescue have not been definitely established, although several toxins have been identified.[1,3-7] Chemicals produced by the grass itself (e.g., loline, perloline, several organic acids) could be toxic agents contributing to fescue foot and other syndromes, but mycotoxins produced by endophytic fungi that infect tall fescue are generally accepted as being the most important agents. The endophytic fungus of tall fescue, *Acremonium coenophialum* (formerly *Epichloe typhina*), produces ergovaline, ergonine, ergosine, and lysergamide.[1,3,7] All these toxins are capable of producing vasoconstriction similar to that caused by ingestion of the ergot fungus *Claviceps purpurea.* In fact, the symptoms of fescue foot are identical to gangrenous ergotism. Pastures not infected with *Acremonium* produce none of the symptoms of fescue toxicosis in animals.[7]

Environmental factors also play a role in the development of fescue foot. Although the disease can occur over a range of seasons, symptoms usually occur during colder months. Another factor is the level of pasture fertilization. High levels of nitrogen in soil, regardless of the form applied, increase pasture toxicity. Certain strains of fescue, particularly Kj-31, seem to be more toxic.[8] Finally, because the endophyte imparts a selective advantage on the infected plant by increasing growth rate and disease resistance, the number of toxic plants in a pasture increases. The infestation rate of the fescue endophyte is high; more than half the forage samples from states in which fescue foot occurs are infected with *A. coenophialum.*[9]

Clinical Signs and Differential Diagnosis Clinical signs of fescue foot usually begin as hindlimb lameness. Affected cattle are underweight and have a dull, "rough" hair coat. The feet and pasterns become cold to palpation, and the coronary bands become reddened and swollen. Hair may be rubbed from the pastern area with the fingers, and limb edema may be present. As the condition progresses, the classic signs of fescue foot appear, including a sharp line of demarcation at the level of the pastern or fetlock, distal to which the skin becomes dry and gangrenous and eventually sloughs. The tips of the ears and tail also may necrose. Affected animals lose condition initially and eventually are unable to stand or to walk. Susceptibility to the toxin in animals on a given pasture seems to vary considerably. Generally, morbidity is low, although 20% to 30% of the herd may be affected in some circumstances.

The diagnosis is made on the basis of characteristic signs and gross lesions, as well as the presence of tall fescue in the pasture. As mentioned, gangrenous ergotism is clinically identical except that it occurs in the presence of the easily recognizable "ergot" fungus *C. purpurea,* which grows on rye grass. Similarly, chronic selenium toxicosis ("alkali disease") mimics fescue foot, except that this disease does not occur on fescue pastures, and affected animals have elevated tissue selenium concentrations. Both ergot and selenium poisoning affect animals other than cattle, whereas fescue foot has been described only in the bovine.

Early in the course of the disease, mechanical foot injury, foot rot, or laminitis can resemble fescue foot, especially because only a few animals in a herd are affected. Close inspection of the foot, however, reveals lesions that are typical of these diseases. Necrosis due to freezing may be difficult to distinguish from fescue toxicosis, because both occur at the same time of year.

Pathophysiology Pastures that contain tall fescue infected with *A. coenophialum* produce toxins responsible for vasoconstriction. Peripheral vasoconstriction causes blood stasis, endothelial damage, and thrombosis in peripheral vessels. Impaired circulation

VetBooks.ir

causes tissues of the distal extremities to become ischemic and gangrenous. By decreasing peripheral circulation, cold ambient temperatures exacerbate the condition.

Necropsy Findings At necropsy the principal finding is a characteristic line of demarcation between normal and gangrenous tissues. Generalized loss of condition is also found because of the animal's inability to ambulate and eat. Vascular thrombosis and necrosis of the tissues of the lower limbs are found microscopically.

Treatment and Prognosis When animals with fescue foot are recognized early in the disease course, they should be removed from pasture as soon as possible. Antibiotic treatment to prevent bacterial invasion of injured skin and hooves is valuable; recovery can occur in 2 weeks. Once the extremities have necrosed, however, treatment is unsuccessful, and euthanasia is recommended.

Control Unlike *C. purpurea,* which grows only on the seed head of grasses, the toxins causing fescue foot are contained in the leaves and stems. As a result, mowing contaminated pastures is not an effective control measure. Growing strains of tall fescue with low toxicity, mixed with legume forage plants, seems to be the best management technique for controlling fescue foot. In cold weather, feeding hay to cattle when the pasture contains tall fescue decreases the ingestion of toxins.

Interdigital Necrobacillosis (Foot Rot) in Cattle

Jared J. Janke

Definition and Etiology Interdigital necrobacillosis is an infectious disease of cattle that is a leading cause of lameness in feedlots and confinement dairies. The condition can affect cattle at any age, although most cases are in mature or weaned animals. Sporadic cases are encountered with pastured beef and dairy animals. A variety of names have been used to describe this condition, including "foul-in-the-foot," "foot rot," and "interdigital phlegmon" (phlegmona interdigitalis). The condition is characterized by inflammation and tissue necrosis of the soft tissues of the interdigital space.[1] Deep structures (e.g., tendons, ligaments, synovium, bone) may be involved in severe cases. *Fusobacterium necrophorum,* a gram-negative anaerobic rod, has classically been considered the etiologic agent associated with foot rot, but multiple anaerobic organisms are likely to be synergistically involved. Typical foot root lesions could be induced 5 days after inoculation of the interdigital cleft with *F. necrophorum* alone.[2] *Prevotella melaninogenicus* and *Porphymonas levii* (both previously classified in the genus *Bacteroides*) have been reported to play an important role.[1] The presence of *Dicylobacter nodosus,* the agent associated with contagious foot rot in small ruminants and interdigital dermatitis in cattle, may facilitate penetration of the skin with *F. necrophorum*. Wet, unsanitary conditions and rough environmental flooring are important factors in precipitating infection.

Clinical Signs Early in the course of foot rot, symmetric swelling and heat of the interdigital space are noted, progressing to the coronary band and possibly extending proximally to the level of the fetlock. The claws begin to spread as a result of severe cellulitis, leaving a widened interdigital space. Soft tissue swelling leads to necrosis and fissure formation within a few days,[3] starting at the dorsal interdigital space and spreading toward the heels. The edematous skin margins protrude and roll outward (Fig. 38-35). Exudation and pseudomembrane formation are seen, but significant purulent drainage is not evident. A characteristic foul odor accompanies the necrotic lesion. Acute and progressive lameness in one limb is typical, with the hindlimbs more frequently involved than the forelimbs.[4,5] Septic synovitis, osteomyelitis, or tendon involvement is more likely to result in non–weight-bearing lameness and limb carriage. Mild to moderate elevation of the body temperature (39.4° to 40°C [103° to 104°F]) may be recorded. The associated pain leads to reduced ambulation, feed intake, and milk production, as well as weight gain. Affected animals may spend a significant amount of time lying down, predisposing them to injury from herdmates. Systemic effects of inflammation and infection can result in reduced fertility in breeding bulls. Differential diagnoses for lameness of the foot include trauma, interdigital dermatitis, verrucose dermatitis, and laminitis.[6]

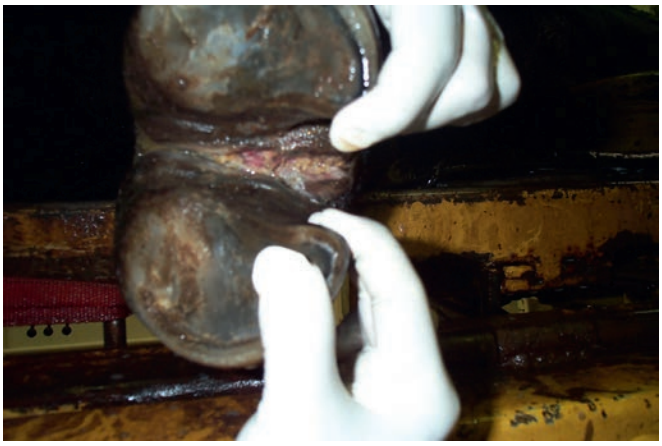

FIG. 38-35 Bovine foot rot lesion present in the interdigital space. *(Photo courtesy Dr. Kevin Washburn, Texas A&M University.)*

A previously described severe form of foot rot is peracute in onset and refractory to conventional treatments.[4,7] Severe interdigital swelling is noted in multiple limbs and most often in the hindlimbs. The condition is rapidly progressive, leading to recumbency and a rapid extension to deeper structures. Euthanasia may be warranted on animal welfare grounds.[8] Penicillin/sulfonamide-resistant *F. necrophorum* has been isolated from several cases.[7] Concurrent infection with bovine viral diarrhea (BVD) virus and the resultant immunosuppression have been suggested as an etiology.[9]

Clinical Pathology Laboratory analysis of blood is not typically done, although a normal or inflammatory leukogram may be encountered. Serum haptoglobin levels were found to be increased in foot rot–infected cattle, but this finding is not specific to foot rot. Researchers also noted a decrease or normalization within 1 to 5 days after treatment.[10] Collection of samples for microbial culture is seldom done because of the ability to diagnose the condition through typical clinical findings. Lesional swabs or biopsy samples may be submitted for bacterial culture. A mixed population of environmental and fecal contaminants is likely, but isolation of *F. necrophorum* and other anaerobes suggests true foot rot. Microscopic evaluation of biopsy samples may identify spirochetes, although this is not a consistent finding. Serodiagnosis has been reported with indirect ELISA (rL-ELISA) for the detection of leukotoxin A (lktA) antibodies using the recombinant protein PL2, yielding relatively high sensitivity and specificity.[11]

Pathogenesis The mechanisms of interdigital necrobacillosis are complex and incompletely understood. Compromise of the skin barrier is critical for invasion of the offending pathogens. Chronic exposure of feet to wet and dirty conditions leads to softening and maceration of the skin. Exposure to sharp gravel and stones, excessive stubble, irregular concrete, and other forms of mechanical trauma can result in significant abrasions and damage to the interdigital skin, particularly in wet environments. The combination of these two factors can result in penetration of the offending pathogens and resultant infection. Initial microbial flora may reduce tissue oxygen tension, allowing anaerobes and ideal environment to proliferate.[6,12] Once the organisms colonize the subcutaneous tissues, multiple

VetBooks.ir

mechanisms likely promote growth and evasion of the host defense systems.

The two subspecies of *F. necrophorum* currently recognized are biotypes A and B. Biotype A appears to be more virulent and is more frequently isolated.[13,14] Others have described differentiation of virulent strains by colony morphology,[15] and PCR differentiation of strains is available.[16] New Zealand researchers evaluated lktA PCR analysis of foot rot lesion swabs from cattle, sheep, and goats and found a lack of evidence for lktA strain variability within the same animal. This is contrary to the strain variability that is common with *Dicylobacter nodosus* in small ruminant foot rot cases.[17]

Although *F. necophorum* is also a human pathogen, differences exist between human and animal strains.[13] *F. necrophorum* is a normal inhabitant of the gastrointestinal tract of ruminants, although isolation from the feces is generally rare.[13,18] Oral administration of some antimicrobials has been shown to increase fecal shedding of *F. necrophorum*.[19] The increased number of organisms in exudate from necrotic lesions may provide an important source of transmission to other animals. Major virulence factors associated with this organism are a high-molecular-weight leukotoxin and lipopolysaccharide (LPS).[20,21] The leukotoxin is cytotoxic to ruminant neutrophils and, when combined with LPS, may protect the organism from phagocytosis.[13]

Findings suggest that *P. levii* did not stimulate a significant chemotactic response in bovine macrophages in vitro, and suppression of phagocytosis occurred when the organism was present in low numbers.[1] These properties of *P. levii* may facilitate a local tissue environment that allows other anaerobic organisms, including *F. necrophorum,* to colonize and evade host defense mechanisms.

Epidemiology Interdigital necrobacillosis has been recognized worldwide for centuries.[22] Wet and humid climates predispose to disease, and foot rot has been associated with rainy seasons.[12,23] The risk of the disease is higher in management systems that expose animals to traumatizing ground underfoot, such as concrete confinement with water and excrement accumulation, irrigated pastures, muddy lots, high stocking densities, and stony walkways. As noted, cattle of any age are susceptible, but mature animals account for most cases. *Bos indicus* breeds appear to be have a lower incidence than *Bos taurus,* and Jersey cattle may be overrepresented in the dairy breeds.[23]

Necropsy Findings Postmortem examination is rarely performed. Characterization of the lesions reveals subcutaneous and soft tissue necrosis, with suppurative inflammation of the foot. In severe cases, evidence of osteomyelitis, tenosynovitis, and septic arthritis may be identified.

Treatment and Prevention Most animals are responsive to parenteral antimicrobial therapy. Local treatment (e.g., topical preparations, wound care, bandaging) is probably not necessary for minor cases identified early, although local therapy may reduce the number of infectious organisms spread to the environment.[10] The organisms are typically susceptible to a variety of antimicrobials.[4] Procaine G penicillin (22,000-44,000 IU/kg IM once or twice daily) has been used successfully when infection is detected early.[10] These dosages of penicillin are considered off-label, and the clinician must take appropriate steps to ensure meat- and milk-withdrawal periods. A number of drugs have been approved to treat foot rot in the United States,[4,8] including amoxicillin (6.6 to 11 mg/kg IM or subcutaneously [SC] for 5 days), oxytetracycline (10 mg/kg IM or SC), sulfadimethoxine (55 mg/kg PO or IV loading, then 27.5 mg/kg PO or IV daily for 5 days), erythromycin (2.2 to 4.4 mg/kg IM daily for 3 to 5 days), ceftiofur hydrochloride/sodium (1.1 to 2.2 mg/kg SC or IM daily for 3 to 5 days), tylosin (18 mg/kg IM daily for up to 5 days), sulfamethazine (30 g/100 kg PO, repeated in 72 hours), florfenicol (40 mg/kg SC once), and tulathromycin (2.5 mg/kg SC once).[4,6,8,10] A comparison of ceftiofur crystalline free acid (6.6 mg/kg SC in the base of the ear once) and ceftiofur sodium daily for 3 consecutive days revealed no statistical difference in recovery rates; however, the ceftiofur sodium resulted in more labor and time required for multiple administrations.[24]

Early recognition and treatment can produce clinical improvement in 2 to 4 days.[4] The antimicrobial of choice can be tailored to suit the needs of the farm in terms of withdrawal times, number of treatments, route of administration, and familiarity with the product. Investigators found that 5 mg/kg of off-label tilmicosin SC at the onset of lameness resulted in a 74% cure rate, significantly higher than with placebo.[25] Antiinflammatory therapy, including flunixin meglumine or aspirin, may reduce fever and provide analgesia, resulting in improved appetite and ambulation.[8]

When topical therapy is warranted, wound cleansing and curettage of the necrotic tissue are beneficial. A variety of topical antimicrobial or astringent preparations can be placed under a foot bandage. The main objectives of bandaging are to keep the wound clean and prevent further contamination from fecal organisms for several days. Moving treated animals to clean, dry areas is recommended.[6] Dressing the foot to prevent further spreading of the digits helps protect the interdigital space. Bandaging infected feet may also reduce the amount of exudate that could infect herdmates.[10]

Spontaneous recovery is possible, although the risk of complications is increased and recovery may take several weeks.[6] Animals with significant deep structure involvement may require prolonged therapy and repeated wound management. Animals with evidence of septic arthritis of the digital joints or other synovial structures may require amputation of the digit to allow drainage. Claw amputation has been described.[8,26]

Metaphylaxis, or the mass treatment of animals, may be warranted in some circumstances. Methods to mass-treat animals include topical treatment in the form of footbaths or the addition of feed-grade antimicrobials and supplements to diets. It is prudent to inform owners that no feed additives are currently approved for the prevention or treatment of foot rot.[27] Off-label use of feed additives, as governed by the Animal Medicinal Drug Use Clarification Act, is strictly prohibited.[4,27] The only food-additive antimicrobials approved for nonenteric disease are chlortetracycline and oxytetracycline.[27] Ethylenediamine dihydriodide (EDDI) has been used to reduce the severity and incidence of foot rot,[28] although high doses are toxic in cattle. EDDI used for this purpose is prohibited, based on the present regulation of feed additives.[4,27]

Footbaths are an appealing alternative for many producers, but proper use is important. Contact time and efficacious ingredients are sometimes difficult to ensure. Footbath additives often are rapidly contaminated with organic material, eventually leading to inactivation.[27] Antibacterial agents and astringents have been traditionally used, including 3% formalin, 2% copper sulfate, oxytetracycline, and lincomycin-spectinomycin formulations. Dry footbaths have also been reported and include 10% copper sulfate and slaked lime.[6] Practitioners must check state and local laws that may prohibit use of some substances that could cause environmental contamination and might be unsafe for handlers.

Vaccination against *F. necrophorum* has been available for some time, but firm evidence of its efficacy in peer-reviewed publications is limited.[4] One study evaluating the incidence and severity of hepatic abscess and foot rot suggested a positive response to vaccination of feedlot cattle compared with controls, although the significance was evident only in the free-choice forage program. The same positive result was not evident when the analysis included all the cattle, particularly the limit-feed grain program. The benefit of vaccination may not overcome the challenge of diets that promote rumenitis.[29]

Infectious Foot Rot in Sheep and Goats

Jared J. Janke

Definition and Etiology Infectious foot rot is a highly contagious foot disease of sheep and goats and the leading cause of

VetBooks.ir

infectious lameness in these species.[1,2] The essential pathogen is the anaerobic bacterium *Dicylobacter nodosus*.[1-12] Synergistic activity with other microbes, primarily *F. necrophorum,* plays an important role in pathogenesis.[1,4,5,12] Equally important are the roles environmental moisture and climate play in transmission from animal to animal.[1,4-6,10,12] The infection has been reported in a variety of species including cattle, horses, pigs, deer, and mouflon but is generally considered a sheep- and goat-specific disease.[8]

Epidemiology Foot rot accounts for significant economic losses in sheep-producing countries[3,5,7,8] and has often resulted in government control programs.[2,6] Reduced body and fleece weight and increased costs of management, treatment, and culling make control of this disease important. Infectious foot rot is found worldwide wherever sheep and goats are reared, although it is primarily a problem in warm, humid climates.[1,4-6,10,12] Sheep raised on improved pastures in arid regions may also develop the disease.[5] Prolonged periods of moisture are required to facilitate transmission; short periods of heavy rainfall do not lead to significant increases in clinical disease.[1,4,5]

Consistent temperatures above 10° C (50° F) are considered favorable for disease transmission.[1] Incidence rates are likely to correspond with the seasons that favor these conditions and may vary between geographic regions. Using pastures with ground cover that promotes trauma to the foot is likely to increase the risk of disease. The natural herding behavior of sheep and goats is likely to propagate the spread of the organism within a flock. Traditionally, routine hoof trimming was thought to reduce the incidence by improving general foot health, but others have not made this association and have actually proposed trimming as a risk factor.[1,2,5,10]

Sheep are the primary species of concern, although other ruminants can be infected. An association with increased severity in lambs from aged ewes has been suggested.[5] The Merino breed appears to be the most susceptible, whereas British breeds demonstrate less severity.[4,5] Clinical disease is more often diagnosed in adults, although lambs may also be affected. Age and breed have been identified as risk factors, with an increase in incidence with age. Breed genetics and heritability may play important roles in resistance to disease, and reducing matings from chronically infected sheep may be an important step in propagating less susceptible breeding lines.[2,5] Introduction of the organism to a native flock is almost exclusively by the addition of asymptomatic chronic carrier animals that may harbor the organism on their feet for years.[4,5] Animals exposed to pastures or housing facilities immediately contaminated by infected feet are at risk of contracting the organism. *D. nodosus* is an obligate parasite of the hooves and survives only a short time in the environment, but it may remain viable for up to 2 weeks in favorable conditions.[4,5] Chronic subclinical infections of the interdigital skin or small cryptic lesions within the hoof can allow for persistence of the organism within the flock for months.[12] This finding is a critical point when considering flock biosecurity.

Pathogenesis and Clinical Signs The interdigital skin is typically an adequate barrier to infection. In prolonged wet conditions, however, the skin becomes macerated and weakened. Initially, *F. necrophorum* invades the skin and superficial soft tissues, resulting in ovine interdigital dermatitis (OID). This organism may produce a local tissue environment that promotes invasion of *D. nodosus*. These two organisms work synergistically to allow *F. necrophorum* to invade into deeper tissues and allow bacterial proteases produced by *D. nodosus* to eventually cause horn separation. Both organisms are essential for true foot rot to occur.[1] The lesion associated with foot rot is characterized as exudative inflammation and necrosis of the epidermal tissues of the foot.[8] A characteristic foul odor is almost always present.[3,5] Both claws of multiple limbs are typically involved. The interdigital skin becomes moist and swollen, and the soft horn is pale, pitted, and may be separated from the skin.[4]

Disease associated with *D. nodosus* infection is highly dependent on the virulence of the organism, resistance of the animal, and environmental conditions. All these factors are extremely variable; a relatively low virulent strain in wet conditions may contribute to more severe disease than a highly virulent strain in dry weather. Virulence is associated with the keratinolytic ability of a strain and occurrence of type IV fimbriae.[1,3,5-8] The fimbrial subunit gene fimA appears to be essential for virulence.[5] Heat-stable protease production is characteristic of virulent strains. Infectious foot rot is categorized into two clinical syndromes, benign or virulent, based on the clinical severity and the ability to transmit through the flock. Some have included a third, intermediate syndrome for cases that are clinically more involved than the benign form but are not associated with the appreciable production losses that occur with the virulent form.[1] Foot rot accounted for a 10% decrease in body weight and wool production in one report.[8] It may be difficult to clearly define each case early in the disease process; what appears to be benign may be the early onset of the more virulent form. Benign foot rot may progress into separation of the soft horn from the underlying hard horn, but it does not progress beyond this point. Virulent foot rot is characterized by severe interdigital lesions, with separation of the soft and hard horn from the sensitive laminae. Separation of the axial surfaces of the heels progresses in a dorsolateral direction.[4,5] Underrunning of the sole occurs, and in the most severe cases, the entire hoof may be sloughed. When confronting acute multiple-limb lameness in several animals in a flock, a practitioner should strongly consider virulent foot rot.

The spread from animal to animal is generally rapid, and multiple stages of the infection are present within the flock. Inspection of the flock is indicated to categorize the severity of the infection. In some flocks, only a small portion needs to be examined to determine the classification of the disease, whereas evaluation of the majority of the flock is required in other cases. If uncertainty exists, 2 weeks is usually adequate to allow lesions to progress to a stage that will accurately allow classification of the clinical syndrome.[1] Affected animals may graze on their knees to relieve the foot pain or remain recumbent in severe cases. Systemic signs of infection may include fever, anorexia, and weight loss.[4] Complications of the foot wounds include blowfly strike and secondary bacterial infection.[4,5] Although susceptible, the clinical course in goats is often less severe. Interdigital dermatitis is a more prominent clinical finding than separation of the horn in this species.[4]

Differential diagnosis for foot rot include traumatic injury, laminitis, foot abscesses, OID, and contagious ovine digital dermatitis (CODD). The presence of interdigital dermatitis increases the risk of the development of foot rot, and the prevalence may be high in the early stages of foot rot infection. It may be impossible to clinically distinguish between interdigital dermatitis and benign foot rot.[1]

Identified in the United Kingdom in the mid-1990s, CODD was initially thought to be a severe form of virulent foot rot. The disease shows clinical similarity to infectious foot rot, but initial involvement of the interdigital space is usually absent with CODD. Ulcerative lesions involving haired skin adjacent to the coronet are more common. This condition responds poorly to traditional foot rot treatment strategies. The complete pathogenesis of CODD is unclear, but one report isolated *D. nodosus* in 74% and a spirochete in 70% of affected feet. The spirochete was from the genus *Treponema,* which has been associated with similar lesions in cattle.[11]

Clinical Pathology, Diagnostic Tests, and Necropsy Findings Samples collected by swabs or lesion material can be submitted for anaerobic microbial culture. The mixed bacterial population present and the fastidious growth of *D. nodosus* make isolation difficult and time consuming.[3,8] Collection of samples in anaerobic transport containers and rapid submission to the laboratory are required. One report found that *D. nodosus* could not be isolated from field samples if they remained longer than 3 hours in transport.[3] Routine growth media found in most laboratories is not usually sufficient to grow this organism; selective media and techniques are helpful in isolating this microbe.[3] Microscopic examination of

VetBooks.ir

D. nodosus organisms by Gram stain reveals large, barbell-shaped, gram-negative rods.[4,8] Some investigators have reported colony morphology and correlation with virulence, but others have been unable to make this correlation.[3]

Biochemical testing for elastase activity and thermal stability of bacterial proteases has been used to differentiate benign from virulent strains. Thermal stability of bacterial proteases can be measured by the gelatin gel test,[5,6,7] although false-positive results have been reported. Advanced molecular techniques, including PCR and DNA sequencing, have recently become available for detecting gene sequences that encode for virulence, particularly fimA.[3,6,7] These advanced techniques have expanded the classification and number of strains and serotypes identified[3,6,7] and allow a rapid and sensitive diagnostic tool for use in control programs.[5] Serum antibody detection using an ELISA is available, but its specificity may be lacking.[5] Serology may be helpful in determining flock involvement. Infectious foot rot is usually diagnosed on clinical findings, and postmortem examination is not typically necessary.

Treatment and Prevention Once *D. nodosus* infection is identified in a flock, treatment to control and potentially eradicate the organism should be initiated. Eradication may not be possible in all flocks, and the severity of the disease, management practices, strain virulence, and environmental factors likely play a critical role. Separation of animals confirmed to have lesions could reduce transmission to uninfected flockmates, but this may not be possible under some management strategies. When possible, planning pasture rotation to allow 2-week dormancy periods enables producers to have infection-free zones. Improving pastures to prevent areas of standing water, excrement, and mud will theoretically reduce the potential for transmission. Routine flock hoof trimming has been a mainstay in the prevention of foot rot, although supportive clinical data are lacking.[1,2] Regions having consistent problems with foot rot have discontinued this practice because of the lack of evidence and the increase in time and labor.[2] However, judicious hoof trimming for the treatment of foot rot is probably beneficial on an individual basis and when topical treatments are employed.[2,4,5] Researchers found an increase in prevalence of foot rot following routine hoof trimming in one study, leading to concerns that excessive foot paring should be avoided.[12] Meticulous paring of the hoof may be necessary if the disease has produced overgrown and misshapen feet that promote hiding places for *D. nodosus*. Disinfection of knives and shears between each animal is important to reduce iatrogenic transmission. Treatment is typically more successful during dry periods of the year, when transmission is reduced.

Medical treatment methods for foot rot include topical therapy, including footbaths and topical medications, and parenteral antimicrobials. Although bandaging individual feet may increase the contact time of medications and reduce the spread of infectious material, this is not practical and does not allow the foot to dry. Topical 5% oxytetracycline tincture has been used successfully.[5] Chemicals used in footbath solutions include 5% copper sulfate, 3% to 5% formalin, and 10% zinc sulfate.[1,4,5] When used properly, these agents are usually highly effective, but caution must be used with each chemical to prevent adverse effects. All these agents are potentially toxic to varying degrees if ingested, and copper sulfate will stain the fleece. Comparison of formalin and zinc sulfate in footbath preparations yields similar results.[5] Formalin is more resistant to contamination by organic material, but higher concentrations and frequent application are extremely irritating to the skin. Additionally, considerable human health concerns and government health regulations may prevent formalin use in some flocks. Efficacy and improved safety make zinc sulfate an ideal agent for use in footbaths. Improved chemical penetration of the hoof can be achieved when the surfactant sodium lauryl sulfate is combined with the footbath solution, reducing the need for hoof trimming before treatment. The use of footbaths requires facilities and construction (6 to 12 m [20 to 40 ft] long) that ensure all feet on each animal are treated. The ideal contact time has not been established in clinical studies, but brief walk-through or soaking for up to 1 hour has been shown to be successful.[1] The frequency of treatment is also not clearly defined and may be dictated by the contact time. Because of its irritating properties, formalin should not be used more than once a week.[5] Although the response is likely multifactorial, cure rates of 50% to 80% have been reported with foot bathing. Separate footbaths for infected and noninfected animals reduce the risk of inadvertent transmission. Washing the feet by walking animals through a plain-water bath and allowing the feet to dry 2 hours before and at least 1 hour after treatment is ideal.[1] Once treated, the groups should be immediately moved to clean, dry pastures or lots that have not held livestock for at least 2 weeks.

No antimicrobial drugs in United States are presently labeled for use against infectious foot rot in sheep, so use is off-label. One-time treatment without hoof trimming can produce similar results to foot bathing. Parenteral antimicrobials have produced recovery rates of 85% after one dose when sheep were kept on dry floors for 24 hours after treatment.[1] Although *D. nodosus* has been reported to be sensitive to many antimicrobials in vitro, this gives no indication of sensitivity when used clinically.[5] Medications used successfully have included penicillin procaine G (20,000 to 30,000 IU/kg IM twice daily),[4] long-acting oxytetracycline (20 mg/kg SC once, or repeated in 72 hours),[4,5] erythromycin (10 mg/kg once, or 3 to 5 mg/kg IM twice daily),[4,5] florfenicol (20 mg/kg IM, repeated in 48 hours),[4] and linomycin (5 mg/kg SC once) in combination with spectinomycin (10 mg/kg SC once).[5] Maintaining dry footing for 24 hours, yielding meat- and milk-withdrawal times, and the potential of reinfection are important considerations when using parenteral antimicrobials.[1] In an observational study, producers that treated with parenteral antimicrobials and topical antibacterials early in the course of disease had a lower prevalence of lameness and increased profitability when compared to later treatment with hoof trimming and topical antibacterials.[13] Parenteral and topical oxytetracycline therapy yielded a 75% recovery in 5 days in a randomized clinical trial, while those animals receiving foot trimming and topical oxytetracyline had the longest recovery times.[14]

Recent work has found an association with decreased whole blood selenium levels and foot rot in sheep. Clinical cases receiving parenteral selenium as a component of their control program recovered more rapidly and demonstrated a more robust immune response.[15,16] Flunixin meglumine may be administered for analgesia, but there was no significant effect on recovery in one study.[14]

Vaccination against *D. nodosus* is available, and its use to treat and control foot rot has been reported.[1,2,4,5,9] A reduction in disease severity and quicker response to treatment may be evident when this is used as a treatment modality. Several strategies have been used for classifying *D. nodosus* strains based on fimbrial types, and at least 10 serogroups with 19 serotypes have been identified.[1,3-5,7,8] Fimbrial gene variation undoubtedly plays an important role in vaccine efficacy.[5] The currently available commercial vaccine contains 10 serotypes, and antigenic competition is likely to impede additional serotypes.[1,5] Identifying the most prominent strain or fimbrial type in a geographic region or flock may facilitate vaccine selection and development. Eight strains of *D. nodosus* have been reported to infect one foot.[5] Response to vaccination appears to be strain specific, with poor cross-protection between strains. Successful resolution of clinical signs by using autogenous vaccine without other treatments has been reported.[9] The use of adjuvants in killed vaccines is required to produce an adequate antibody response, and the addition of adjuvants, particularly oil based, has led to a high incidence of injection site reactions.[1,4,5] The response to vaccination is likely short lived (≈8 to 12 weeks[1]) and requires multiple doses. A split-flock randomized treatment trial revealed a significant increase in recovery (92% vs. 82%) and reduction in new infection rates (12% vs. 27%) at 9 weeks in the vaccinates versus the non-vaccinates. In that study, both groups received concurrent parenteral antimicrobial therapy.[17] Vaccination of animals during the dry period, several weeks before the optimal transmission period, is likely beneficial in a control program.

VetBooks.ir

Control and eradication can potentially be achieved in regions where the climate allows a break in the transmission period, but the investment in labor and cost of medical therapy may be high. A combination of topical treatment, parenteral antimicrobials, and vaccination is likely to be employed. Careful observation for early signs of infection and quarantine of any new animals are critical to controlling or preventing a flock outbreak. Some researchers have indicated aggressive culling practices may be necessary in an eradication program.[12] Using a weekly zinc sulfate footbath for 2 to 4 weeks, along with vaccination and culling of severe and unresponsive cases, has been suggested.[4] Based on the evidence of resistance heritability, careful breeding programs should be explored.[2,5] Complete eradication from a farm can be achieved if the entire flock is removed, the facilities are left dormant for at least 2 weeks, and the flock is repopulated with noninfected animals.[1]

Other Infectious Conditions of the Foot

Robin M. Dabareiner

Infections involving the foot of horses and cattle are common and almost always caused by contamination from the environment gaining access to the soft tissue or bony structures of the foot within the hoof capsule. Typically the animal has an acute, progressive lameness such that the animal is almost non–weight bearing on the affected limb or will bear weight on the toe region of the foot but resist putting the heel on the ground. Other clinical signs include increased digital pulse pressure, heat, and sensitivity to hoof-tester pressure over the affected area. Regional nerve blocks can be used to localize the lameness to the foot but frequently are unnecessary. Because the foot is encased in a shell of horny tissue, exudate from an infectious process often accumulates between the soft tissue and horn. The exudate then spreads or dissects along that plane until it reaches a soft tissue surface like the coronary band, especially near the bulbs of the heels, where rupture and drainage can occur.

Problems Associated with Horseshoe Nails ("Nail Prick")

History and Clinical Signs *Nail prick* ("quicking") refers to penetration of the sensitive hoof structures, usually the sensitive laminae, by a driven horseshoe nail. The horse will usually react as the farrier drives or clinches the nail by jerking the foot from the farrier. In some cases, blood may appear on the nail or leak from the nail hole. It is important to realize that nail pricks occur for many reasons and are not always caused by a misdirected nail. Poorly made shoes, nails that are too large, poorly placed nail holes, and faulty nails can also result in a nail prick. Horses with poor hoof quality, thin hoof walls, or flaring hoof walls can be difficult to nail and thus are at greatest risk. Fractious horses and young horses not previously shod may lean on the farrier or repeatedly pull the foot from the farrier, making nail driving difficult. Damage from an improperly driven nail can vary from minimal to serious infection.

Diagnosis Diagnosis of a misdirected nail warrants great diplomacy from the veterinarian, because many owners become unjustifiably upset with the farrier. Some horses will repeatedly stomp the affected foot or paw the ground immediately after shoeing. Others may point the affected limb after shoeing. Lameness may not be apparent immediately after shoeing and may occur days later when the nail hole becomes infected and the trapped pus begins to exert pressure. The horse usually becomes acutely lame and worsens over time unless treated. Some infected nail holes will travel up the lamellae (white line) and create an abscess or soft spot at the hairline of the coronary band. The abscess will be directly aligned with the hoof wall tubules, leading to the infected nail hole, which is an important diagnostic aid. Hoof-tester examination, paying particular attention to pressure over the driven nails, is an essential diagnostic tool to locate the offending nail. Using a hammer to strike the outside hoof wall may also elicit a painful response over the nail. Increased digital pulse and heat may be present.

Treatment Pricks from nails can be potentially serious and require immediate treatment. If the nail prick is discovered by the farrier at the time of shoeing, the nail is removed. The nail should be examined for moisture or blood. The nail hole can be irrigated with DMSO, povidone-iodine (Betadine) solution, or hydrogen peroxide. The nail hole is packed with iodine-soaked cotton and the nail hole left open. Often the nail is redirected, and no further treatment is needed. If the horse's immunization status is not current, a tetanus vaccine is given.

If the offending nail cannot be localized or the nail hole is infected, the shoe is removed. Hoof testers are then used to localize the painful nail hole. Frequently the pressure from the hoof testers will cause black, malodorous liquid pus to exit from the hole. The basis of treatment is to establish drainage. The infected nail hole often requires enlargement with a loop hoof knife or curette. Ideally a cone-shaped hole is made, with the larger opening at the bottom of the hoof. The hole is irrigated or the entire foot soaked in an Epsom salt/Betadine footbath for 20 to 30 minutes twice daily until the infection is gone. It is important to protect the foot from the environment (e.g., mud, dirt) by keeping the foot bandaged between foot soaks. Additional medications are usually unnecessary unless involvement is extensive. Antiinflammatory medications may be beneficial to decrease pain. Once the infection has cleared, the shoe is replaced. The affected nail hole can be packed with iodine-soaked cotton and the horse reshod with a plastic pad covering the sole. Alternately, a hole can be drilled into the shoe over the affected nail hole and the shoe replaced, leaving access to the infected area for daily irrigation and povidone-iodine packing.

Prognosis Prognosis is usually good provided that minimal damage occurs to vital structures of the foot. Establishing drainage for sepsis is important to avoid potential complications, such as third phalanx osteomyelitis or coffin joint sepsis.

Subsolar Abscess

Subsolar abscess is one of the most common causes of lameness in the horse and cow, but it is relatively rare in sheep and goats. In one study in cattle, 88% of cases of lameness were caused by problems in the hoof.[1] Most often, lameness is caused by a hole or crack in the horny sole, which then becomes packed with dirt, and eventually contamination extends to and is trapped within the sensitive soft tissue beneath the sole. Animals that are housed in filthy or muddy conditions and that have inadequate hoof care or overgrown feet are more prone to this problem. Horses taken from a very dry to a very wet environment, and vice versa, also tend to have a higher incidence of sole abscesses, apparently because of the sudden change in the moisture content of the hoof and the resultant cracking of the sole. Cattle with "corkscrew claw" (a hereditary condition) or other growth deformity in the claw are more prone to sole abscess. Puncture wounds or any form of trauma that introduces contamination to the soft tissue of the sole also may result in abscessation.

History and Clinical Signs Subsolar abscess is a common cause of acute lameness seen in all horses. There is no signalment or breed disposition. "Gravel" is a lay term describing the assumed etiology in which a piece of gravel migrates proximally from the white line to coronary band, leaving an infected tract. Subsolar abscesses may originate from a penetrating wound in the white line, a nail hole, or a deep subsolar bruise. Lameness is usually acute and severe (grade 3 to 4 of 5) and may worsen over time until drainage

VetBooks.ir

is established. The horse will often point and may not bear full weight on the affected limb. Distal limb swelling often accompanies a subsolar abscess that has not had drainage established. Systemic signs of infection (fever, lethargy) usually are not associated with subsolar abscesses unless deeper structures are involved. The infected tract may migrate and open at the coronary band. Before breaking open, a soft painful area can be located by digital palpation of the coronary band.

Diagnosis Digital pulses are usually increased, and the hoof capsule may radiate heat. A focal painful area can usually (but not always) be located with careful hoof-tester examination. Careful paring of the sole and frog may be helpful in locating the abscess, but the clinician must be careful not to damage good healthy tissue looking for the infection site. Foot poultices and hot-water footbaths with Epsom salts will eventually help to localize the affected area. Gray or black malodorous liquid will leak from the infected tract (Fig. 38-36). Radiographs are useful to rule out other causes, such as third phalanx and navicular bone fracture. In some cases a gas or fluid pocket can be identified on radiographs.

Treatment Treatment is aimed at establishing adequate drainage. If an opening in the tract is present at the solar surface, it should be enlarged just enough for good irrigation and drainage. This may or may not require sedation or peripheral anesthesia of the foot. If pink tissue or blood is encountered, débridement is discontinued. Large holes should be avoided to prevent solar corium protrusion, which can be a painful sequela to overzealous hoof paring. If drainage occurs at the level of the coronary band and solar surface, through-and-through lavage is beneficial. Débridement at the coronary band level should be minimal to prevent iatrogenic coffin joint contamination. Once drainage is established, a foot bandage can protect the foot from the environment and recontamination. Continued foot soaks in warm-water povidone-iodine and Epsom salt footbaths should be continued until sepsis and inflammation are eliminated. The shoe is replaced when the affected area is dry and cornified. Large areas may require a plastic pad under the shoe for solar protection. Antibiotics and NSAIDs are rarely needed except in severe cases or if penetration of deeper structures has occurred. The patient's tetanus immunization should be checked and a booster injection administered if needed.

Prognosis Prognosis for simple subsolar abscess is excellent but worsens if complications develop in which deeper structures of the foot become involved.

FIG. 38-36 Horse's hoof with a recently opened subsolar abscess, demonstrating gray exudate.

Deep Penetrating Injuries to the Sole

History and Clinical Signs Most animals' environments are filled with sharp objects that can penetrate the sole, causing severe damage to structures deep within the hoof capsule. All puncture wounds should be considered potentially serious, but those involving the solar white line or caudal frog area require special attention because of potential navicular bursa, digital tendon sheath, DDF tendon, or distal phalanx involvement.

The clinical signs of a penetrating wound to the sole vary with the anatomic structure involved and chronicity of the injury. The animal may show minimal lameness initially at the time of injury, but severe lameness once sepsis is established days later. Animals with penetrating wounds to the podotrochlear bursa or DDF tendon attachment to the third phalanx are in considerable pain and are reluctant to bear weight on the heel region.

Diagnosis If owners find a foreign body in the bottom of the animal's foot, they usually should be instructed to leave the object in the foot unless there is danger of further penetration. A radiograph is taken immediately to determine depth of penetration. Digital pulses are increased, and the foot is usually warm to the touch. Hoof testers are useful to determine the focal point of pain, but often the entire surface of the foot is reactive. Systemic sedation and peripheral anesthesia using an abaxial sesamoid nerve block may be needed to thoroughly examine the penetrated foot. Light paring of the sole and frog areas with a hoof knife may reveal a black spot indicating the penetration site. Often, however, the entry is not discovered because of the elastic nature of the hoof structures and collapsing of the penetration site. Regional IV anesthesia (Bier block) using a tourniquet is the method of choice for producing local anesthesia in cattle. Paring should be performed carefully so the solar corium is not injured with the hoof knife. Because the corium represents the horn-producing epithelial covering of the foot, injuries to it heal the same way as skin injuries. If an entry wound is discovered, the foot is scrubbed and prepared for further diagnostic testing. A sterile flexible probe can be gently inserted into the hole and a radiograph taken to determine its depth and direction. The clinician must take care that inadvertent force or horse movement does not cause the probe to penetrate previously unaffected structures. Alternately, a less invasive and preferred method is to catheterize or place a sterile teat cannula into the hole and inject sterile radiopaque material to determine which structures are involved (Fig. 38-37).

If sepsis of the podotrochlear bursa, DIJ, or digital tendon sheath is suspected, paracentesis and joint fluid cytologic analysis and culture and microbial sensitivity should be performed. Synovial fluid with an abnormal color, viscosity, elevated number of degenerative neutrophils, and high total protein concentration should suggest sepsis. If distal limb swelling is present, arthrocentesis should be delayed until the cellulitis subsides.

A series of radiographs should be taken to include a lateromedial, 60-degree dorsopalmar view of both the navicular bone and the third phalanx, and flexor (tangential) view of the navicular bone. Repeat examination 1 to 2 weeks after the original injury may be necessary because bony lysis takes time to develop and may not be apparent at the initial radiographic examination.

Treatment Broad-spectrum systemic antibiotics, antiinflammatory medications, and tetanus prophylaxis are administered if penetration of deep hoof structures is suspected. Depending on the severity of the lameness, the animal may require an NSAID such as phenylbutazone (4 mg/kg twice daily in horses; 10 mg/kg once daily in cattle) to reduce pain and lameness in the initial stages. Antibiotic therapy should be continued for 2 weeks after resolution of clinical signs of infection in most cases. Preferably, antibiotics are initiated after a culture and microbial sample has been obtained. Establishment of drainage, copious lavage with sterile ionic fluid, and débridement of all necrotic tissue are indicated. Involvement of the podotrochlear bursa warrants use of navicular bursoscopy and

VetBooks.ir

FIG. 38-37 Radiograph of a foot after injection of contrast dye to determine the path of the penetrating wound. Note dye in the navicular bursa and digital flexor tendon sheath.

aggressive medical therapy consisting of daily lavaging of the bursa under general anesthesia and local treatment using antibiotics instilled within the bursa and regional limb perfusion. Surgical treatment such as the "street nail" procedure, which opens a window through the central frog and DDF tendon in the bottom of the foot to reach the navicular bursa, is a drastic and aggressive method of therapy. This is usually a salvage procedure and reserved only for animals not responding to aggressive medical therapy.

If the DDF tendon is involved (septic tendinitis), débridement and removal of frayed and infected tendon fibers may be performed in the standing, sedated horse using a tourniquet and peripheral anesthesia, or under general anesthesia, depending on horse temperament and owner financial constraints. After débridement, placing the horse in a 4- to 8-degree wedge shoe decreases weight-bearing forces on the DDF tendon and provides some pain relief. The wedge shoe angle is gradually decreased over several months as the DDF tendon begins to heal and strengthen. The bottom of the foot requires protection with a bandage or hospital plate until the surgical site granulates in and cornifies.

Deep penetrating wounds to the sole, especially the solar/white line junction, can result in infectious osteitis of the distal phalanx. The horse usually presents with a chronic recurrent draining tract at the coronary band or solar surface and varying degrees of lameness. Infection of the distal phalanx often results from undetected soft tissue infection or dissecting subsolar abscesses. Septic pedal osteitis may also be a sequela to laminitis secondary to recurrent abscessation and ischemia at the toe region. As the bone infection progresses, blood supply to the area is compromised, and the area of avascular bone separates from the parent bone, forming a sequestrum. Localized third phalanx septic osteitis and sequestrum formation may not become radiographically evident for weeks after the initial penetration injury. Radiology often reveals a radiolucent area within the margins of the third phalanx, with or without sequestrum formation.

FIG. 38-38 Treatment (hospital plate) for medicating an open wound in the bottom of a horse's foot.

Débridement and curettage of all soft and necrotic bone can usually be performed in the standing, sedated animal if its temperament permits. The foot is desensitized with peripheral anesthesia, cleaned with a hoof knife and steel brush, then prepared for aseptic surgery using standard techniques. Hemostasis is achieved by wrapping a roll of Vetrap firmly around the fetlock joint to compress and occlude the palmar digital arteries. Access to the infected bone is made by removing sequential layers of sole using either a motorized Dremel tool or a Galt trephine with a retractable pilot bit.[2] The infected bone is usually discolored and soft and should be curetted to healthy bone margins. The infected bone should be cultured and undergo microbial sensitivity testing. A postoperative radiograph should be taken to ensure complete débridement. After surgery the site is packed with sterile gauze sponges soaked in antiseptic or antimicrobial solutions, and then the foot is bandaged. Disposable diapers and duct tape are inexpensive materials for a waterproof foot bandage. The bandage is changed every 1 or 2 days for the initial few weeks. Application of a bar shoe and hospital plate provides solar protection and decreases the labor and cost of daily bandage changes (Fig. 38-38). The bolts and metal plate are removed so that the surgical site can be cleaned and treated, and then the hospital plate is bolted back in place.

After surgery the horse is confined to a small area until the hole granulates in and cornifies, usually 4 to 6 weeks. If granulation tissue becomes excessive at the surgical site, application of 2% tincture of iodine will hasten healing. If severe infection is present, the site can be packed lightly with antibiotic-impregnated beads for continued antibiotic release at the infected site. Regional limb perfusion with antibiotics is also beneficial in severe cases.

In cattle, simple sole abscesses may heal quite satisfactorily without bandaging. In cows, use of a wooden block on the unaffected claw of the affected foot elevates the affected claw to a non–weight-bearing level and greatly reduces lameness. The block is attached with an epoxy such as Technovit and allowed to wear off over a period of weeks.

VetBooks.ir

Prognosis Prognosis depends on severity of injury, structures involved, and chronicity of the problem before initiating treatment. Horses with acute penetration wounds that receive immediate and aggressive treatment have a good chance of returning to athletic use. Penetration injuries that have an established infection involving the podotrochlear bursa, digital tendon sheath, or DIJ have a poor prognosis. In one study, only 12 of 38 horses with sepsis of the navicular bursa had a satisfactory outcome.[3] Chances of survival increased if treatment was started within a week of the penetration injury. Osteomyelitis of the navicular bone and DDF tendon rupture are common complications of a septic navicular bursa.

Prognosis for infectious osteitis of the distal phalanx is good if sepsis is not caused by laminitis. In one study, up to 24% of the distal phalanx was removed, and the horse returned to athletic soundness.[4]

Thrush

Definition and Etiology Thrush is a bacterial infection characterized by an accumulation of black, malodorous, necrotic material usually originating within the central or collateral sulci of the frog of the hoof. This degenerative condition may spread to involve deeper structures of the foot, such as the digital cushion, hoof wall, and heel bulb region of the foot, causing inflammation and breakdown of these structures.[5] Many keratolytic organisms may be present, but *F. necrophorum* is often isolated. Thrush is most often caused by poor environmental conditions; animals standing in soiled stalls, deep mud, swampy land, or wet pastures are at risk for developing thrush, especially if the feet are not cleaned daily. Another predisposing factor is poor hoof conformation. Saddlebreds, Tennessee Walkers, and other gaited horses have long feet with naturally deep frog sulci and are at risk of thrush.[6] Horses with sheared heels or acquired frog deformity are also predisposed. Horses shod with full pads may develop thrush secondary to moisture and dirt collection under the pad. Other well-kept, clean horses can develop thrush for no apparent reason.

Clinical Signs and Diagnosis Lameness may or may not be present, and severity can vary. Diagnosis is based on the presence of black, malodorous discharge, most often within the frog sulci. The central frog sulcus is often malformed and very deep. A painful response may occur when the affected sulci are cleaned, because the degenerative process may extend to sensitive structures of the foot. If structural damage has occurred, the heels may move independently of each other, causing pain on manipulation. Horses with mechanical instability of the heels may show caudal heel pain.

Treatment The basis for treatment is removing the predisposing cause of the thrush. The horse should be moved to a clean, dry environment and have the feet cleaned daily. Any necrotic debris and undermined tissue are carefully débrided and cleaned using a hoof knife. Foot bandages may be necessary if the débridement is extensive. Systemic antibiotics may be necessary in severe cases that involve deep or more proximal tissues. Infection is usually managed by topical medication. Several caustic materials have been recommended, including a combination of phenol, tincture of iodine and 10% formalin, Kopertox solution, or methylene blue. Others have recommended soaking the foot in chlorine bleach (1 oz bleach per gallon water). If poor hoof conformation is the cause, proper farrier management should be pursued to correct existing problems. If heel instability is present, a bar shoe may be necessary to stabilize the caudal aspect of the foot. Exercise is important to strengthen the caudal aspect of the foot and will naturally clean the feet. The best treatment for thrush involves prevention by educating the client on proper hoof hygiene.

Prognosis Prognosis is favorable if the cause of thrush can be identified and eliminated and if the condition is treated before extensive hoof damage has occurred.

White Line Disease ("Seedy Toe")

History and Clinical Signs The white line, visible at the sole, is created by the junction of the insensitive laminae of the hoof wall and the horn of the sole. White line disease has historically described the separation of the hoof wall from its laminar attachments. A crack or opening occurs within the white line, allowing a bacterial or fungal infection to invade the stratum medium close to the laminae, causing cavities to develop between the laminae and outer hoof wall. In environmental conditions with too much moisture (continuous wet pastures) or in drought conditions producing excessively dry feet, animals are at risk of developing a crack or opening in the white line. Horses with poor-quality hoof walls that split or crack may develop white line disease. In addition, horses with chronic laminitis having a thickened or stretched white line in the toe region ("seedy toe") are predisposed (Fig. 38-39).

The hoof wall separation is usually a chronic condition beginning weeks or months before presentation. Horses with white line disease often show little or no lameness and therefore are not perceived as an immediate concern by many owners. Hard ground may exacerbate any lameness seen.

Diagnosis Visual examination of the white line, assisted by a probing instrument, will reveal a cavity with separation of outer hoof wall from the laminae. Radiographic evaluation will determine the full extent of hoof wall separation. Often the cavity is either dry or filled with necrotic debris, which may involve a bacterial or fungal infection. The cavity is usually not painful to probing.

Treatment Treatment begins with removal of the separated outer hoof wall using a hoof nipper, hoof knife, and motorized tools. It is important to remove any unattached or loose hoof wall to reveal cracks or crevices that could harbor bacteria. The Dremel tool burr is useful to smooth any cracks in the insensitive laminae that are exposed after hoof wall removal. After thorough débridement, large

VetBooks.ir

FIG. 38-40 Hoof with white line disease after the undermined hoof wall has been removed.

FIG. 38-41 Horse's hoof with an infected collateral cartilage.

defects usually exist in the hoof wall and require protection (Fig. 38-40). A heart-bar shoe redistributes weight-bearing forces to the frog and caudal region of the foot and away from damaged and weakened areas. The hoof wall defects prevent normal nailing procedures, and shoe clips can help secure the shoe to the hoof. After hoof wall removal, the exposed laminae may still have an active infectious component. With the heart-bar shoe in place, the owner is instructed to keep the horse in a clean, dry stall and topically treat the exposed laminae with iodine or methiolate daily for 10 days or until the exposed laminae are dry and inactive. At this point, the horse may be a candidate for prosthetic hoof wall repair using a product such as Equilox. The plastic acrylic is trimmed and shaped to the horse's natural hoof wall at the next shoeing. The owner should keep the hoof dry to avoid losing the acrylic patch. The horse may return to normal activity once the prosthetic patch is in place.

Prognosis Prognosis depends on response to treatment and cause of the original white line problem. Horses with poor hoof quality or seedy toe will often have disease recurrence. If the horse responds to original treatment and environmental conditions improve, prognosis is good.

Quittor

Quittor is a term used to describe chronic infection of the medial or lateral collateral cartilage of the distal phalanx in the horse. This condition is characterized by local inflammation and necrosis of the affected cartilage, with subsequent formation of draining tracts proximal to the coronary band. The infection is usually caused by a wound, and the horse often presents with moderate to severe lameness and a history of chronic or recurrent drainage. Obtaining a dorsopalmar radiographic view after injecting contrast dye into the draining tract helps demonstrate the infected collateral cartilage (Fig. 38-41).

Although this condition occasionally responds to medical therapy, the treatment of choice is surgical débridement with the horse under general anesthesia, the foot in full extension, and a tourniquet around the pastern. An elliptical section that includes the draining tract should be incised above the coronary band and discarded. All underlying infected soft tissue and necrotic cartilage should be excised. If the case has not become chronic and only a small amount of cartilage has to be removed, the wound may be packed and partially sutured. The pack can be removed in 24 to 48 hours and the wound flushed twice a day until it has healed. If the condition is chronic with extensive cartilage necrosis or multiple draining tracts, the infectious process usually extends below the level of the coronary band. In this case it is best to trephine a hole in the hoof wall at the lowest point of the infection. This procedure provides better drainage, facilitates débridement of the necrotic cartilage, and allows for complete closure of the surgical incision above the coronary band. The wound should be packed through the trephine hole and treated as an open wound until it heals. In cases with extensive cartilage necrosis, care should be taken to avoid accidental opening of the coffin joint. If débridement is complete, the prognosis for the return to soundness is fair to good.[7]

Fistulous Withers

Sarah M. Reuss

Definition Fistulous withers is a chronic inflammatory condition of the supraspinous bursa and associated tissues in horses, mules, and donkeys. The supraspinous bursa is located dorsal to the dorsal spinous processes of the second through fifth thoracic vertebrae. The normal bursa may extend laterally to the scapular cartilage, and it may be asymmetric. Normal bursal volumes range from 30 to 90 mL.[1]

Clinical Signs Affected horses may show nonspecific signs that include lethargy, fever, and generalized muscle stiffness. These may progress to the more specific signs of pain, heat, and swelling of the withers and cervical area. Over days to weeks, these swellings mature and rupture at one or more locations, releasing serous or mucopurulent drainage. The classically described discharge is yellowish-brown with white, yellow, or red flakes ("rice bodies").[2] Fistulous tracts may extend to the dorsal spinous processed of the vertebrae, as well as to the scapula, ribs, and occasionally the thoracic cavity. Lesions and drainage may wax and wane.

Etiology/Pathophysiology There are two forms of fistulous withers: idiopathic (or typical) and traumatic (or atypical). The more common idiopathic form results from the spread of inflammation and infection of the supraspinous bursa to surrounding structures like the nuchal ligament and/or dorsal spinous processes. Organisms reported to be the primary cause of fistulous withers include *Brucella abortus, Actinomyces bovis,* and *Onchocerca cervicalis*. *B. abortus* has a predilection for synovial structures and is often associated with septic supraspinous bursitis in addition to septic atlantal bursitis ("poll evil"). In 1937, *B. abortus* was isolated from 80% of fistulous withers cases; 92% of affected horses had contact with cattle, and 65% were from farms with *Brucella*-positive cattle.[2] Geographic variability is evident. In New York, where the prevalence of *B. abortus* infection in cattle is low, *B. abortus* is rarely isolated from equine cases of fistulous withers. In 1988, the prevalence of *B. abortus* in horses presented to the New York State College of Veterinary Medicine had

VetBooks.ir

apparently decreased, with only 2 of 14 horses (14%) having positive titers.[3] However, in Texas, where seropositive cattle are still prevalent, 9 of 28 (37.5%) horses with fistulous withers were seropositive for *B. abortus,* and these horses were more likely to be pastured with seropositive cattle.[4] Researchers have also experimentally produced fistulous withers via injection of *B. abortus* and *A. bovis* into the supraspinous bursa.[5] *O. cervicalis* has also been proposed as an etiology for fistulous withers, especially in Australia. This parasite migrates through the nuchal ligament and causes inflammation that can extend to the supraspinous bursa. Fibrous and calcified tracts develop around dead and viable parasites, causing necrosis and degeneration of the nuchal ligament.[6] *Streptomyces* spp. have also been incriminated as the etiology of fistulous withers in donkeys.[7]

The traumatic form of fistulous withers is preceded by an open wound or blunt trauma to the withers and then secondary infection. Infection may result from external contamination or from hematogenous spread to devitalized tissue. Secondary contamination of open wounds with *Streptococcus equi* subsp. *zooepidemicus*[3] or environmental microorganisms is reported.

Diagnosis A careful history that includes duration and severity of clinical signs and response to previous treatment must be obtained. Physical examination with careful palpation over the withers may reveal pain, swelling, or draining tracts. CBC may show leukocytosis due to neutrophilia, as well as hyperfibrinogenemia, indicating chronic inflammation.

If the swelling is encapsulated and not draining, needle aspiration should be performed to obtain a sample for culture and sensitivity. Once tracts are open and draining, secondary bacterial contamination will make the validity of cultures questionable. Negative cultures can also be misleading because *B. abortus* is difficult to grow in culture and may be overgrown by other bacteria. Biopsy of inflamed tissue may also be obtained for culture and histology. Blood cultures may also be diagnostic in febrile animals.

Because of public health implications, serologic testing for antibodies against *B. abortus* should be performed in all animals with fistulous withers. The plate agglutination test is more sensitive and specific than the card test. *Brucella* titers are considered negative when they are less than 1:50. Ideally paired titers should be performed, with any rise in titers 2 weeks apart indicative of current infection.[8] Chronic infections may not show a paired titer increase, so a single high titer with compatible clinical signs should be considered diagnostic. Animals should be isolated while awaiting test results, and public health officials should be contacted if *Brucella* is suspected.

Radiographs should be obtained to determine the extent of the lesions, presence of osteomyelitis of the dorsal spinous processes, and/or presence of a foreign body. There may also be swelling or granular opacity of the soft tissue in the withers region.[3] Horses with positive *B. abortus* titers are more likely to have radiographic evidence of osteomyelitis of the dorsal spinous processes than seronegative horses.[4] A positive-contrast fistulogram may help determine the extent of any draining tracts. Ultrasonography can also help delineate draining tracts or foreign bodies.

Treatment Medical treatment may be attempted but is often unsuccessful alone. Antimicrobial selection should be guided by culture and sensitivity results. In the absence of a culture, systemic broad-spectrum antimicrobials may be used and should be combined with lavage of the draining tracts. Systemic antiinflammatories are also indicated to control pain.

Brucella vaccination with the S19 strain has been reported in *Brucella*-confirmed cases as an effective off-label treatment in horses. The vaccination regimens described varied from single-dose SC injection to a series of three SC injections 10 days apart. Success rates of 70% have been reported in horses treated with strain 19 vaccine.[2] However, SC injection reportedly causes severe local and systemic reactions, including fever, depression, and local abscessation.[8] IV administration of strain 19 vaccine has also been reported, but it resulted in death in 3 of 4 horses.[4] At this time, there are no approved vaccinations for use in horses, and the RB51 vaccine has not been used in equids. The apparent decline in frequency of *Brucella* infection in fistulous withers now makes vaccination of questionable value.

Medical management alone is rarely effective and usually has to be combined with aggressive surgical débridement. Reportedly, 80% of traumatic fistulous withers treated conservatively will have recurrent lesions.[9] Standing drainage and débridement has been performed, but general anesthesia and aggressive débridement is the preferred treatment.[3] Ostectomy and curettage of the dorsal spinous processes may be necessary. Primary closure is difficult to achieve but will provide a better cosmetic result and quicker healing time. Wounds left open to heal by second intention may take months to heal.[3]

Prevention and Control *B. abortus* infection, if present, carries great public health implications. Horse owners and veterinary staff must be notified of the possible exposure and take appropriate precautions. Brucellosis in humans may cause acute fever with pneumonia, spondylitis, orchitis, or pyelonephritis, and chronic brucellosis causes a transient fever.[1]

Parasite control is an important aspect of prevention of fistulous withers. Horses should be kept separate from *Brucella*-positive cattle. Proper saddle and harness fit will also decrease the incidence of traumatic fistulous withers.

Flexural Limb Deformities

A. Berkley Chesen

Definition Flexural limb deformities are defined as hyperflexion or hyperextension of a limb. Flexural deformities are described by the joint involved and occur in the sagittal plane, typically the DIJ, metacarpophalangeal/metatarsophalangeal joint, carpus, and rarely the tarsus. Although commonly referred to as "contracted tendons," the tendons themselves are not truly contracted but functionally short relative to the adjacent bone. Flexural limb deformities can be classified as either congenital or acquired and are very common in horses and cattle. Small ruminants and camelids are much less commonly affected.

Pathogenesis Congenital flexural deformities (present at birth) are likely due to a multitude of factors. Although intrauterine positioning has been suggested, it is probably an uncommon cause of flexural limb deformities. Disease and teratogenic exposures of pregnant mares are more likely causes of congenital flexural limb deformities. Evidence behind an absolute inciting cause is lacking, but the following have been implicated in contributing to flexural limb deformities: transient glycogen branching enzyme deficiency in Quarter Horse foals, ingestion of locoweed and hybrid Sudan grass, equine goiter, defective cross-linking of collagen and elastin formation from lathyrism, neuromuscular disorders, and viruses.[1-5] Foals with congenital flexural deformities commonly have other anatomic abnormalities like spinal deformities, which may result in dystocia.

Acquired flexural deformities are seen typically from 4 weeks to 4 months of age and in yearlings to 2-year-olds. These deformities have been implicated as part of the developmental orthopedic disease complex. Two general theories explain how acquired flexural deformities occur. The first is that the tendon unit is unable to passively elongate relative to the bone.[6] In the case of the DIJ, the rigid DDF tendon and its accessory ligament causes a palmar rotation of the foot (clubbed foot) (Fig. 38-42). Flexural deformities in the metacarpophalangeal joint often occur during rapid growth in the distal radius, leading to a functional shortening superficial digital flexor (SDF) tendon unit. The second theory is that longitudinal bone growth cannot create a functional shortening of tendons and that increased tension within the tendon induces pain, leading to the deformity.[7]

VetBooks.ir

FIG. 38-42 Flexural deformity of the distal interphalangeal joint (clubbed foot).

FIG. 38-43 Flexural deformity of the metatarsophalangeal joint.

Acquired deformities often have a very acute onset (24 hours), adding validity to the latter theory. Pain may initiate the deformity, but this can become a permanent condition if not addressed promptly, and contracture can occur. Contracture results from fibrodesis of the joint capsule and periarticular structures.[6]

Diagnosis

CONGENITAL DEFORMITIES. Digital hyperextension deformities in neonates are due to lack of tension in the flexor muscles. These deformities typically correct without intervention after a few weeks. In severe cases, the palmar or plantar surfaces of the foal's pastern and fetlock area may become ulcerated from contact with the ground if not protected.

Contractural deformities may involve one or a combination of the SDF tendon, DDF tendon, or suspensory ligament and most commonly affect the carpus and metacarpophalangeal/metatarsophalangeal joint (Fig. 38-43).[8] Flexural deformities of the DIJ and the tarsus occur less frequently. In some pony breeds and Miniature Horses, lateral luxation of the patella results in the stifle showing a flexural deformity. This is usually due to a hypoplastic trochlear groove. Depending on the severity of the deformity, if the metacarpophalangeal joint is affected, the foal may or may not be able to stand.[6] Although not truly a flexural deformity, rupture of the common digital extensor tendon results in a similar appearance. This can result secondary to flexural deformities. These foals have a characteristic swelling on the dorsolateral aspect of the carpus and often bow at the carpus owing to the lack of support over its lateral aspect.[2,9] More importantly, foals with ruptured common digital extensor tendons should be checked for incomplete ossification of cuboidal bones; these conditions often occur together.[6]

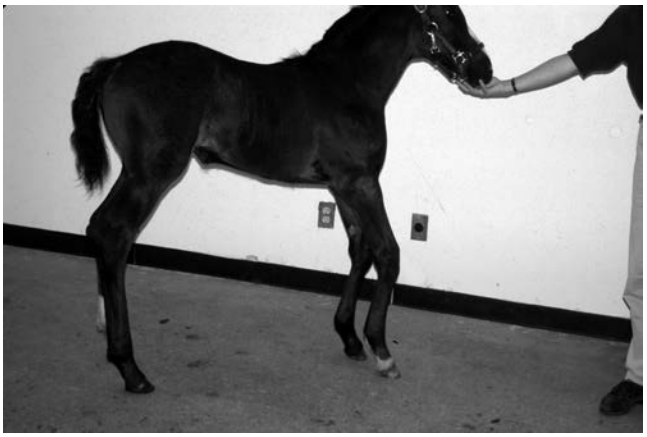

FIG. 38-44 Bilateral mild carpal flexural deformity.

ACQUIRED DEFORMITIES. The most common acquired flexural deformity involves the DIJ and typically occurs within the first 4 months of life. The affected limb will have a more vertical hoof wall angle and a shorter toe than the unaffected limb, but the condition is often bilateral. The heel will get longer on the affected limb, the metacarpophalangeal joint will concurrently begin to hyperextend, and the toe will undergo more wear, potentially causing issues with the white line. Two stages have been described for flexural deformities of the DIJ: *stage I* is defined as an angle of less than 90 degrees between the dorsal hoof wall and the sole; *stage II* is defined as a dorsal hoof wall that exceeds vertical.[10]

Early detection of flexural deformity of the metacarpophalangeal joint is characterized by a straight fetlock angle, or upright conformation. More severe deformity of this joint is evident by buckling at the fetlock. By placing pressure in a dorsopalmar direction on the fetlock, the flexor tendons are stretched, allowing the practitioner to determine which structure is tightest, which is important for selecting an appropriate treatment.[6] It is also important to palpate the limb while the animal is not bearing weight to detect any adhesions.

Carpal flexural deformities tend to occur within the first 6 months of life. These foals tend to be fast-growing, heavier foals (Fig. 38-44). Although not as common, flexural deformities of the PIP also occur; they are usually bilateral and affect the hindlimbs.[6] The exact mechanism is unknown, but it is thought that as the musculotendinous unit of the DDF complex shortens, the SDF tendon becomes more lax.[11] This can lead to a dorsal subluxation of the joint. Often a clicking sound is appreciated when the foal walks. This condition is most often seen in weanlings with a high growth rate.[6]

Flexural deformities also occur after foals or horses are non–weight bearing for a period of time. These deformities can be permanent if the joint undergoes contracture or fibrodesis (fixed without osseous ankylosis).[6]

Treatment

CONGENITAL DEFORMITIES. Hyperextension deformities require exercise to hasten recovery, but excessive exercise is contraindicated because it leads to fatigue and possible injury. Treatments include swimming, corrective shoeing, and light bandaging when indicated. Swimming allows muscle tone to increase without bearing weight on the limbs. If the foal's toe lifts off the ground when weight bearing, glue-on shoes with a heel extension may be indicated. It is important that glue-on shoes not be left on a growing foal for an extended period, because they may prevent the foot from expanding normally; changing them every 10 days is indicated. Bandaging is only necessary to prevent ulcerations of the skin in cases where the palmar/plantar surface of the pastern or fetlock is in contact with the ground; bandages should not be supportive of the structures. Excessive bandaging and support will only cause more laxity and should be avoided.

VetBooks.ir

Treatment for congenital flexural deformities should include pain management by judicious use of NSAIDs (e.g., phenylbutazone, 2.2 mg/kg daily, or flunixin meglumine, 1.1 mg/kg daily). Use of gastroprotectants such as omeprazole (4 mg/kg PO daily) is strongly suggested to help avoid the ulceragenic effects of NSAIDs.

Oxytetracycline at a dose of 44 mg/kg diluted in physiologic saline given slowly IV has been used for many years in foals with flexural deformities.[12] Renal function of the foal should be taken into consideration prior to administration of oxytetracycline. There are many proposed mechanisms for how oxytetracycline works to achieve a decrease in the angle of the metacarpophalangeal joint. One mechanism proposes the chelation of calcium, resulting in muscle contraction.[12] Oxytetracycline has been shown to be a neuromuscular blocking agent, but this mechanism does not explain why other muscle groups are unaffected.[12] An in vitro study showed that oxytetracycline also works through matrix metalloproteinase (MMP)1 mRNA expression to inhibit tractional organization of collagen fibrils by myofibroblasts; this interaction may cause relaxation of the musculotendinous unit.[13] Regardless of the mechanism of action, foals treated with oxytetracycline should also undergo forced exercise to make the improvement permanent. Without exercise, the angle of the metacarpophalangeal joint tends to return to its previous value within 96 hours.[14]

Toe extensions benefit the foal in two ways: they help protect the toe from being overworn, and they lengthen the breakover of the foot, adding strain to the flexor tendons, potentially helping stretch them. Toe extensions may be made using acrylic hoof products or glue-on shoes with built-in extensions. In severe cases, the dorsal hoof wall should be incorporated into the shoe to prevent excessive strain at the toe and separation of the white line. Shoes and extensions should be removed within 2 weeks because they can prevent the hoof from growing and expanding naturally in a young foal; typically, 2 weeks is enough to achieve correction. For foals with deformity of the DIJ, frequent rasping of the heels will help stretch the DDF tendon.

Splints and casts have been used to treat flexural deformities by giving support to the limb, thereby allowing the muscle-tendon unit to relax. When using splints, it is vital to use plenty of padding on the limb and change the padding every time the splint is changed to ensure pressure sores are not developing. Pressure sores can be very serious and even life threatening. Splints are made from a variety of materials, but the most common is polyvinyl chloride (PVC) pipe that has been cut an appropriate length and width; commercially made splints are also available. Splints are applied by placing the splint over the padding on the palmar or plantar surface of the limb. If the flexural deformity involves the DIJ, the splint should touch the ground. If the deformity is in the carpal region, the splint should end at the fetlock. Splints are left in place from several hours to 2 or 3 days, depending on the individual patient's condition.[6,8] One major advantage of splints over casts is that they may be removed every few hours if desired. Casts used for the lower limb are typically half-limb casts that incorporate the foot. The exception is the carpal region, where a tube cast ending at the fetlock is more appropriate. Casts should never be left in place longer than 2 weeks at a time in rapidly growing foals. Cast sores are a very serious complication and a legitimate disadvantage to using them.

A combination of conservative treatments should be considered when treating foals with flexural deformities. If nonsurgical management does not correct the problem, surgical intervention may be necessary, but foals with severe congenital contractural deformities have a poor prognosis. Surgery is more often attempted for foals with carpal contracture. Other congenital contractural deformities usually respond to nonsurgical treatments. Surgical correction for contractural deformities in the carpal region involves transection of the tendons of the flexor carpi ulnaris and ulnaris lateralis, as well as transection of the palmar carpal fascia.[6,8] The prognosis for mild to moderate congenital flexural deformities is good for an athletic future if the foal improves over the first 2 weeks and is able to stand and nurse.[8] Flexural deformities that can be manually straightened have a better prognosis than those that cannot.

Foals with ruptured common digital extensor tendons are best treated nonsurgically. Affected foals should be confined to stall rest, and a well-padded splint should be applied.[9] The splint will provide support to the limb and help protect immature cuboidal bones, which often accompany this condition.[6]

ACQUIRED DEFORMITIES. Conservative management for acquired flexural deformities is very similar to that for congenital flexural deformities. Other conservative therapies include dietary restrictions, including early weaning. Surgical management is selected for those cases unresponsive to nonsurgical treatments.

For flexural deformities of the DIJ, desmotomy of the accessory ligament of the DDF tendon is indicated. This surgery has an excellent prognosis for full athletic potential for stage I horses. For more severe flexural deformities of this joint (stage II) a tenotomy of the DDF tendon may be necessary.[15] This procedure is not performed to promote an athletic career. It is acceptable for pasture soundness, breeding animals, and for some, light riding. Gradual rasping of the heels should be combined with any treatment for flexural deformities of the DIP joint.

Acquired flexural deformities of the metacarpophalangeal joint are treated nonsurgically with a combination of NSAIDs, corrective shoeing (raising the heel with or without using a vertical bar shoe with rubber dorsal tubing), and splints. Physical therapy has been used to help stretch the tendons by having the horse hop on one leg while the other is held up in a flexed position, moving in a lateral direction toward the down limb.[6] If surgical correction is needed, it is important to first determine which structure is creating the tension. Most commonly, the SDF tendon is involved, but the DDF tendon and even the suspensory ligament may also be involved. For treatment of contracture of the SDF tendon, desmotomy of the accessory ligament of the SDF tendon is performed. If the DDF tendon is the most taut, desmotomy of the accessory ligament of the DDF tendon is completed. Both accessory ligaments may be cut when indicated. In very severe cases, the suspensory branches may be transected, but this procedure is done for salvage because it usually leads to subluxation of the PIP.[6]

Carpal flexural deformities are treated with splints and controlled exercise. Early weaning should be considered in these foals. If surgery is necessary, a tenotomy of the flexor carpi ulnaris and ulnaris lateralis in addition to splints may yield good results.

Flexural deformities of the PIP are not as common but can be very serious to the future athletic potential of the horse. Over time, the soft tissues around the joint will fibrose, and the PIP may undergo DJD. At this stage, a pastern arthrodesis may be necessary to achieve a pain-free and potentially sound limb. Desmotomy of the accessory ligament of the DDF tendon, as well as the tendon of the medial head of the DDF tendon (level of the chestnut), may benefit affected horses early in the disease process.[6,11]

Tendinitis

Elizabeth J. Davidson

Definition and Etiology Tendinitis is one of the more common musculoskeletal injuries in athletic horses. Of the two flexor tendons, the SDF tendon is more commonly injured than the DDF tendon. SDF tendon injuries occur in the forelimb far more frequently than the hindlimb, and most injuries are in the midmetacarpal region. The prevalence of SDF tendinitis in Thoroughbred racehorses ranges from 7% to 43%.[1] SDF tendon injury also occurs in Standardbred racehorses, upper-level event horses, and is less commonly diagnosed in other performance horses. DDF tendinitis is typically diagnosed in older (aged 9 to 10 years) English sport horses, and injury to the distal portion of the DDF tendon is a major contributor to lameness in horses with foot pain.[2] DDF tendon injury

VetBooks.ir

also occurs in the fetlock or pastern regions within the digital flexor tendon sheath (DFTS) and infrequently in the metacarpal/metatarsal region.[3,4] Desmitis of the accessory ligament of the DDF tendon[5] and the accessory ligament of the SDF tendon[6] are unusual injuries in performance horses.

The function of a tendon is to transfer activity from its associated muscle to its bony attachments on the opposite side of a joint. This allows for joint movement and locomotion. During normal weight bearing, the palmar/plantar situated digital flexor tendons act to support the fetlock joint. During locomotion, the elastic properties of tendons give them the ability to act like a spring, storing and releasing energy during movement. To withstand high tensile forces during exercise, tendons contain a high proportion of type I collagen, and its fibers are longitudinally aligned. When loaded, these fibers deform elastically by stretching. Substantial elongation, up to 20% increase in length, has been reported.[7] Tendon injury occurs when fibers are stretched beyond physiologic limits, which can be due to cumulative fatigue failure or a single sudden overloading event. In Thoroughbreds, normal SDF tendons have strains reaching up to 16% when galloping,[7] suggesting that at maximal exercise the SDF operates close to its physiologic limit, which may explain the high incidence of injury. Tendon injury also appears to be related to age and exercise matrix deterioration. Other factors like hard ground or a rider's weight can also contribute to tendon injury by increasing the peak load of the SDF tendon. Landing from a jump, for example, increases the peak forces in the SDF tendon[8] and accounts for the higher incidence of SDF tendinitis in Grand Prix jumpers and event horses than in those competing at lower levels.

Response to tendon injury is similar to other tissue healing and includes inflammation, repair, and remodeling. During the acute inflammatory phase, hemorrhage and edema occur, and the degree of the response is determined by severity of the injury. Angiogenesis quickly follows, and recruited fibroblasts produce new type III collagen. A fibrinous scar of weak, haphazardly arranged collagen fibrils is formed. At this stage, the tendon is prone to reinjury. Scar tissue remodels over several months, converting type III collagen to type I collagen. Controlled loading of the tendon promotes this conversion and alignment of the collagen fibrils in the direction of force (longitudinally). In a severely injured tendon the entire process can take 12 or more months. The healed but scarred tendon is stiffer than its original state; reinjury is common.

Clinical Signs The classic appearance of metacarpal/metatarsal SDF tendinitis is a convex or bowed profile of the tendon when viewed from the lateral aspect. In acute injury, swelling and heat of the tendon and peritendinous tissues can be noted but may be mild in the earliest stage of injury. A painful response to direct digital palpation is often appreciated and is best performed by holding the leg and palpating the tendon between thumb and forefinger. Unless the injury is severe, most horses with SDF tendinitis are not lame.

Horses with DDF tendon injuries within the DFTS are moderately lame and more lame after distal limb flexion.[3,4] Most horses have DFTS distention and thickening, making accurate palpation of the DDF tendon difficult. Injuries are usually unilateral and occur more commonly in the hindlimbs.[3,4] Horses with DDF tendon injuries within the hoof capsule have unilateral or bilateral lameness without any palpable abnormalities.[2] Horses with desmitis of the accessory ligament of the DDF tendon have obvious swelling and are acutely moderately to severely lame.[5] Thickening and effusion in the carpal canal may be noted in horses with desmitis of the accessory ligament of the SDF tendon.

Diagnosis Ultrasonography is the technique of choice to confirm the diagnosis and assess the severity of the injury. The entire palmar/plantar area of the metacarpus/metatarsus should be examined in transverse and longitudinal planes. The commonly measured variables include cross-sectional area, echogenicity, and fiber alignment. The severity of the injury is determined by the length of the lesion, cross-sectional area of the tendon, cross-sectional area of the lesion, lesion echogenicity, and fiber alignment of the lesion.[9,10] The severity rating score has been correlated with successful outcome. The most common type of SDF tendon injury is a central core lesion, which appears as an anechoic lesion.[9]

Diagnostic analgesia may assist the clinician in localizing the tendon injury if clinical signs are subtle or absent. This is particularly true for DDF tendon injury within the hoof capsule. Pain from DDF tendon injury in the distal metacarpal/metatarsal region usually improves after intrathecal analgesia of the DFTS.[4] Antebrachial or proximal metacarpal analgesia alleviates pain from the accessory ligament of the SDF tendon.[6]

MRI, either with the horse under general anesthesia or in a standing horse, offers the best method of diagnosing DDF tendinitis within the hoof capsule.[2,11,12] Injury types include core lesions, sagittal tears, and fibrillation along the dorsal border; most lesions occur at or near the navicular bone.[2] Transcuneal (through the sole) ultrasonography[13] has been reported but is not easy. Successful imaging requires meticulous foot preparation and clinician expertise.

Treatment Proper treatment of tendinitis includes assessment of the injury using ultrasonography, control of the acute inflammatory episode, controlled return to function, and adjunct medical and/or surgical therapy. In acute injury, a combination of systemic NSAIDs (e.g., phenylbutazone, flunixin meglumine) and topical therapy (e.g., cold water hydrotherapy, poultice, distal limb bandage) are recommended. DMSO and antiphlogistically impregnated gauze bandages may also be beneficial. Box stall rest is essential during the acute phase of injury.

A variety of intratendinous and peritendinous injections have been advocated. Intralesional corticosteroids dramatically decrease the swelling and pain but cannot be recommended due to delayed tendon healing and the risk of continued injury and catastrophic injury in horses that remain in training. Historically, intralesional β-aminoproprionitrile fumarate (BAPTEN), a plant-derived toxin that temporarily blocks collagen cross-linking, improved tendon healing and postinjury performance, but there is currently no commercially available source of BAPTEN, and its use has largely ceased in North America. For metacarpal/metatarsal DDF tendon injuries, intrathecal injections of sodium hyaluronon into the DFTS are beneficial.[14] Intralesional sodium hyaluronon for SDF tendinitis has been advantageous,[15] but other reports failed to document any significant improvement.[16,17] IM polysulfated GAG has a positive effect on tendon healing in a collagenase-induced model,[18] but no difference in return to racing or recurrence of SDF tendinitis has been demonstrated with intralesional and/or IM polysulfated GAG.[16] The therapeutic role of regenerative medicine (e.g., stem cells derived from fat or bone marrow and platelet-rich plasma) in equine tendinitis is not fully understood. Marketing and availability of such products are ahead of evidence-based research, and long-term clinical efficacy has yet to be determined, but early clinical results are encouraging.

Surgical treatments include tendon splitting,[19] desmotomy of the superior check ligament,[20-23] and desmotomy of the palmar/plantar annular ligament.[23] Tendon splitting is believed to enhance revascularization and has a tendency to improve tendon repair. It is used in horses with core lesions to decompress areas of hemorrhage. Disadvantages of tendon splitting include the risk of damaging normal tendon fibers, so this procedure can no longer be recommended. Superior check desmotomy may improve the likelihood that horses return to racing and is clearly beneficial in Standardbred racehorses.[20,21] In Thoroughbred racehorses, postoperative success was initially promising, but no difference between horses treated conservatively and horses treated with desmotomy has been reported.[22] In addition, desmotomy may predispose horses to desmitis of the suspensory ligament.[21,22] Annular desmotomy has been successfully performed in horses with signs of annular ligament constriction and is usually combined with superior check desmotomy.[23] Immediate decompression and improved gliding function are presumed benefits. Complications of annular ligament desmotomy include DFTS sepsis and subsequent tendon sheath adhesions.

VetBooks.ir

Other therapies for SDF tendinitis include therapeutic ultrasound, low-power laser treatment, and extracorporeal shockwave therapy. Counterirritation (internal or external blisters) and pin firing in combination with controlled exercise or turnout in a large pasture are time-honored treatments, but their effects on tendon healing have been questionable. These practices can no longer be recommended.

Controlled exercise in combination with the treatments described guides the repair process in hopes of producing a functional tendon or tendon substitute. If exercise is excessive, fibrous tissue is produced rather than remodeled. If no stress is applied, the tendon is more adapted to pasture exercise than to performance. Therefore, a controlled incremental exercise program is advocated. The program should be flexible and adjusted based on the severity of injury and the quality of healing. Typically, stall rest coupled with gradually increasing amounts of hand walking and trotting are recommended. Horses are monitored by regular clinical and ultrasonographic assessment until they have returned to their previous athletic function or have failed to do so. As the tendon heals, its echogenicity increases, and short linear echoes are detected. With continued healing, longer linear echoes and improved fiber alignment appear. Decrease in cross-sectional area is good indication that the tendon is healing and remodeling. Ideally, complete repair will occur, and the tendon will no longer have a discretely visible area of injury because it has filled in with tissue that is isoechoic with normal tendon, and fiber alignment is parallel to normal.

Successful treatment of DDF tendon injuries within the foot remains a challenge. Long-term follow-up indicates a high rate of recurrent lameness despite prolonged periods of stall rest and corrective shoeing.[2] Other treatments include surgical débridement via navicular bursoscopy,[12] CT-guided intralesional injections,[24] and navicular bursa injection with corticosteroids and hyaluronan.[11]

Prognosis Prognosis for horses with SDF tendinitis depends on lesion severity and the type of athletic work performed. In Thoroughbred racehorses, only 60% will return to successfully race, and reinjury rates are high.[25] Standardbreds and English sport horses have a better prognosis. Most horses treated with superior check desmotomy returned to racing, but recurrence and suspensory desmitis may develop.[21,22] Horses with DDF tendon injuries remain problematic; prognosis is fair to poor.[2-4,11,12,24] Prognosis for horses with desmitis of the accessory ligament of the DDF tendon is good.[5] Prognosis for horses with uncomplicated desmitis of the accessory ligament of the SDF is fair, but horses with concurrent injuries are likely to suffer recurrent lameness.[6]

Suspensory Ligament Desmitis

Elizabeth J. Davidson

Definition and Etiology The suspensory ligament (SL), also known as the *interosseous muscle,* is a strong, flat, tendinous band that contains a variable amount of muscle fibers.[1,2] The SL originates from the palmar carpal ligament and the proximal palmar aspect of the third metacarpus (MCIII) and in the hindlimb from the proximal plantar third metatarsus (MTIII). Coursing distally, it descends between the second and fourth metacarpal/metatarsal bones and divides into the medial and lateral branches before inserting on the abaxial aspect of the proximal sesamoid bones. The suspensory apparatus continues distally as the straight, oblique, cruciate, and short distal sesamoidean ligaments, which originate from the base of the sesamoid bones and insert in the palmar pastern. Similar to tendons, the SL acts like a spring, storing and releasing energy during locomotion. Its main function is to prevent hyperextension of the fetlock joint.[1,2] Its branches also help stabilize the rotational forces on the joint.[2] Injury to the SL occurs when it is overloaded with stress (overstretched) and its structural integrity is compromised. Like tendons, the repair process is characterized by inflammation (desmitis) and fibroplasia. Healing occurs over many months, and repaired tissue is subject to reinjury. SL desmitis is a common injury in all breeds of performance horses. Both forelimb and hindlimb injuries occur, and bilateral desmitis is not uncommon. Desmitis of the SL can be divided into three regions of interest: the proximal (origin) portion, the body, and the branches. Proximal SL desmitis is likely due to hyperextension of the carpus/tarsus in conjunction with severe overextension of the fetlock joint.[1] Straight hock conformation, hyperextension of the fetlock joint, and a long toe/low heel conformation may be predisposing factors in the hindlimbs.[2] Jumping and/or working horses in deep soft footing may also increase risk of injury.[1,2] Avulsion fracture, bone sclerosis, and/or enthesophyte formation in the proximal palmar/plantar MCIII/MTIII can also occur. Proximal SL desmitis occurs most frequently in sport horses, racehorses, and western performance horses.[1,2] Injury to the body of the SL is less common and occurs predominantly in racehorses, specifically Standardbreds.[1,2] Desmitis of the SL branches is most common in Standardbreds and jumping horses.[1] In the SL branches, injury is frequently associated with fetlock lameness, which suggests that the twisting motion of the fetlock predisposes horses to injury.

Catastrophic traumatic disruption of the suspensory apparatus occurs almost exclusively in the forelimbs of Thoroughbred racehorses and is the most common cause of breakdown injuries.[3] Fatigue and high speed are components of this career-ending injury. Degenerative suspensory ligament desmitis (DSLD) is a disorder characterized by progressive degeneration and enlargement of the SL, resulting in excessive fetlock hyperextension (dropping). Affected horses are generally dropped in both hind fetlocks. The condition occurs sporadically in many breeds, usually older horses and broodmares.[1,2] Peruvian Paso[4] and Andalusion horses may be at risk and often are affected in all four limbs. The pathogenesis is unknown.

Clinical Signs Horses with proximal SL desmitis frequently have no localizing clinical signs. Heat, swelling, and edema are transient or absent, and lameness is variable. Horses with bilateral injury, especially in the hindlimbs, may have subtle gait abnormalities that are only apparent when ridden or at speed. Lack of impulsion, resistant behavior, and loss of action are frequent complaints. In horses with desmitis of the body and branches of the SL, heat, pain, ligamentous enlargement, and lameness are common. Associated fetlock effusion and concurrent distal splint bone fractures may also be noted. Acute severe traumatic disruption of the suspensory apparatus results in obvious swelling, grade 4 to 5 lameness, and a hyperextended fetlock. Affected horses require first-aid treatment by application of a splint for weight-bearing stability. DSLD is characterized by bilateral chronic lameness, painful and enlarged SLs, dropped fetlocks, prolonged periods of recumbency, and reluctance to move.[1,2,4]

Diagnosis Perineural analgesic techniques help localize the site of lameness pain to the SL. For proximal SL desmitis, analgesia of the lateral palmar nerve[1,2,5] or lateral plantar nerve just distal to the tarsus[1,2,6] will alleviate lameness in the forelimb or hindlimb, respectively. Desmitis of the SL body and branches is localized using low palmar/plantar analgesia.

Ultrasonography is the imaging modality of choice. Lesion severity is assessed by obtaining cross-sectional and longitudinal views of the ligament and cross-sectional area measurements. Ultrasonographic changes include cross-sectional area enlargement, focal or diffuse areas of hypogenicity, core lesions, loss of normal fiber pattern, and periligamentous thickening. Mild injuries to the SL may be difficult to identify because of the wide variation in its normal ultrasonographic appearance. This is especially true in the proximal SL, since its origin is more heterogeneous than other tendons and ligaments owing to variable amounts of muscle tissue. Comparison between the affected and nonaffected limb in the same horse are recommended because of individual variations and the large variation between breeds.[1,2]

Radiographic examination should be performed to identify concurrent bony lesions. Subchondral sclerosis, avulsion fracture, and

VetBooks.ir

enthesophyte formation have been identified in the proximal palmar/plantar MCIII/MTII regions of horses with proximal SL desmitis.[1,2,7,8] Axial exostosis along the second and fourth metacarpal/metatarsal bones[9] or fractures can contribute to SL body desmitis. Sesamoiditis and sesamoid fractures may be noted in horses with desmitis of the SL branches. In acute traumatic disruption of the suspensory apparatus, comminuted fractures of both sesamoid bones is common.

Nuclear scintigraphic findings are normal in the majority of horses with SL desmitis.[1,2,10] Increased radiopharmaceutical uptake associated with the proximal palmar/plantar MCIII/MTIII can be identified in horses with avulsion fractures and other stress-related bone injuries seen in complex SL desmitis.[7,8] MRI is not necessary but should be considered if no ultrasonographic abnormality is identified. MRI has identified fibrous adhesions between the SL and the small splint bones.[9]

Treatment Treatment of acute SL desmitis is aimed at reducing inflammation with systemic NSAIDs, local cold hydrotherapy, limb bandages, and controlled exercise. Initial clinical signs dissipate quickly even when there is significant SL fiber disruption, so it is strongly recommended to assess the ligament using ultrasonography. In uncomplicated desmitis, a controlled graded exercise program is recommended. The duration of rehabilitation will depend on the extent and severity of the desmitis. Fractures of the small metacarpal/metatarsal bones or sesamoid bones should be removed prior to rehabilitation. Horses are confined to a stall and hand walked daily. Ligamentous healing should be monitored every 60 days using ultrasonography. Ideally there should be a progressive reduction in cross-sectional area, improved echogenicity, and fiber alignment. Gradual increase in exercise can be prescribed depending on healing. The reparative process is slow, and return to competition or racing may not be possible for 12 months.

Damaged SLs have been injected with a wide assortment of corticosteroids, iodine compounds, sodium hyaluronate, and polysulfated GAGs in an effort to reduce inflammation and promote a more rapid return to function. Pin firing, blistering, and cryotherapy with liquid nitrogen have also been used. Although these therapies may treat the initial inflammation, they do not restore normal fiber architecture and can put the SL at increased risk from overuse of the horse, based solely on reduction of clinical signs. Extracorporeal shockwave therapy[1,2,11] and surgical splitting of the branches[1,2] may be beneficial. The effects of intralesional platelet-rich plasma[12] and autologous stem cells[13] are currently under investigation, and clinical results are promising. These regenerative medicine therapies could be the recommended treatment of the future, but their long-term effects and clinical efficacy have yet to be proven.

Successful treatment of proximal hindlimb SL desmitis is particularly challenging. Plantar metatarsal neurectomy,[1,14] desmotomy,[15] and fasciotomy[13-15] may be beneficial in these horses. Fasciotomy surgery allows decompression of the compartment-like syndrome that occurs when the damaged proximal SL becomes edematous and swells within the surrounding retinaculum. The accessory plantar nerve within the damaged SL becomes inflamed and damaged, so a neurectomy of this nerve is performed at the same time as the fasciotomy surgery.

For horses with acute traumatic suspensory desmitis, it is crucial to place the affected limb in a protective splint that aligns the metacarpus with the phalanges in a straight column to prevent fetlock bending. Surgical management involves fetlock arthrodesis using dorsal plating. Treatment for horses with DSLD is palliative. Restricted activity and extended-heel or large egg-bar shoes may improve comfort. Humane euthanasia is recommended for affected horses with deterioration of clinical signs despite treatment.

Prognosis Prognosis of SL desmitis depends on the location and severity of the injury. Uncomplicated cases with minimal disruption of the ligament can recover and resume preinjury athletic function; 90% of horses with acute proximal SL desmitis in the forelimb will return to full athletic function.[2] Complicated, chronic, or recurrent desmitis has been associated with a worse prognosis; only 14% of horses with hindlimb proximal SL desmitis treated conservatively return to full work.[2] Adjunctive medical and surgical treatments can improve prognosis in these problematic horses. Most horses with traumatic disruption of the SL can be salvaged for breeding after surgical repair. Prognosis for horses with DSLD is extremely poor.

Fractures

Tamara M. Swor

The ability to treat fractures in large animals depends largely on rapid and correct diagnosis, appropriate first-aid treatment and stabilization of the injured limb, and safe transportation to a referral surgical center. Emergency treatment administered by a veterinarian in the field is crucial to provide the most treatment options and enhance the prognosis. Accurate knowledge of available treatment options and the prognosis for various fracture types is critical during discussions with clients. The surgeon receiving a patient with a fracture should be contacted early and involved in the decisions regarding limb stabilization, transportation, and owner financial commitments. Treatment options are discussed in this section; specific surgical principles related to fracture repair can be found in surgical textbooks.

Definition and Etiology A *fracture* is defined as a break or rupture of a bone. In large animals, fractures are usually classified as complete or incomplete, articular or nonarticular, displaced or nondisplaced, open or closed, simple or comminuted, and transverse, oblique, or spiral. Classification by location is also common and includes terms such as *physeal, metaphyseal,* and *diaphyseal.*

Fractures in large animals are typically associated with an acute traumatic event followed by sudden severe lameness. Horses may have a history of falling or running into a solid object, receiving a kick from another horse, being hit by a car, or flipping over backward (typically young animals). In another common scenario, the owner hears a loud pop or cracking sound while the horse is being lunged or is participating in an athletic activity.

Stress fractures may also occur and are often a result of cyclic loading over time, with corresponding fatigue leading to bone microfracture. Intensive training schedules create a high number of loading cycles with insufficient time to remodel and repair local areas of stressed bone (e.g., racehorse training). Specific locations of stress fractures include the distal end of the scapular spine, caudoproximal humeral head, craniodistomedial aspect of the humerus, medial humeral diaphysis, caudal aspect of the radius, dorsal middiaphyseal and distodorsolateral third metacarpal, caudal border of the ilial wing and adjacent to the pubic symphysis, proximolateral tibia, and caudal diaphysis of the tibia.[1]

Less common causes of large animal fractures include nutritional deficiencies, neoplasia, and infectious causes leading to pathologic fractures. Fractures related to difficult parturition events are seen in neonatal foals and calves.

Clinical Signs and Differential Diagnosis An animal with a long-bone fracture will typically present with an acute non–weight-bearing lameness of the affected limb. Moderate to severe soft tissue swelling and inability to control the limb often accompany other clinical signs of distress, agitation, and pain. Because of the horse's "fight or flight" reaction to traumatic situations, the patient will often continue attempts to place weight on the fractured limb. Fractures in locations with limited soft tissue coverage are often open (e.g., third metacarpal). Severe hemorrhage or laceration of large vessels is uncommon but may occur.

Complete catastrophic fractures are often easily identified based on limb instability and soft tissue trauma or swelling. Proximal limb fractures may be difficult to palpate but have adjacent severe soft tissue inflammation and edema, crepitus, and difficulties in limb

VetBooks.ir

function. Nondisplaced or incomplete fractures may be associated with a wound or may be painful to manual palpation. Focal pain on palpation, a corresponding lameness, and a history of trauma or being kicked by another animal warrants radiographic evaluation in search of an incomplete fracture. An unrecognized incomplete fracture may progress to a complete fracture with time and exercise. Physeal fractures should be considered in young animals.

Stress fractures often present with a history of acute severe lameness followed by a rapid decrease in the degree of lameness. There may also be reports of intermittent lameness that improves with stall rest. Palpation of the limb often reveals a focal area of pain, heat, and swelling. The horse may resist manipulation of the limb.

Differential diagnoses should include hoof and sole abscesses, joint subluxation, joint luxation, nerve damage, soft tissue injury, and septic synovial structures.

Clinical Evaluation A complete physical examination should be performed on initial evaluation. Animals that are not immediately identified as having a fractured limb may be in need of systemic support. Fluid therapy, pain control, antiinflammatory medications, and antimicrobials should be used as necessary.

Definitive diagnosis is made by taking multiple radiographic views; nuclear scintigraphy, ultrasonography, CT, and MRI may also be used. Information from imaging studies will provide fracture configuration details essential for determining prognosis. The bone involved, degree of comminution, articular involvement, physeal involvement, and condition of the bone fragments all affect potential repair attempts and long-term prognosis. Incomplete fractures may not be readily identified at the time of injury, and radiographs should be repeated in 10 to 14 days if a fracture is suspected.

Stress fractures are also diagnosed using radiographic evaluation and may be identified as an incomplete cortical fracture, endosteal callus, or periosteal callus.[2] As with incomplete fractures, it may be difficult to identify a stress fracture by conventional radiography in the acute stages. Radiographs should be repeated in 10 to 14 days if a fracture is suspected. Other imaging modalities, especially nuclear scintigraphy or CT, may be useful in stress fracture identification.

Emergency Treatment The goals of emergency treatment include preventing further soft tissue damage, stabilizing the injured limb to decrease the patient's anxiety, minimizing further damage to the fractured bone ends, keeping the fracture closed, and preventing further injury and stretching to the surrounding vessels and nerves.[3] A large animal with a fractured limb should be immediately restrained and calmed. Sedatives and tranquilizers should be used with caution, however, because the desired result may be difficult to achieve if the animal is agitated or in shock. The goal of sedation should be to allow manipulation of the limb and placement of external coaptation. Common sedatives should be used with caution to avoid creating additional ataxia; butorphanol should not be used if the horse has sustained a front limb fracture, because it will make the horse lean onto the forehand. If a soft tissue wound is present, the clinician should assume the fracture is open. The wound should be cleaned, topical antimicrobials used, a bandage placed to prevent further contamination, and the animal started on systemic antimicrobials. Antiinflammatory medications should be used as necessary.

Appropriate external coaptation and stabilization of the fracture for transport can greatly influence the options available for fracture repair and the prognosis for success. Table 38-4 outlines specific emergency splints for different fractures in bones.[3,4] Splinting techniques are designed to be placed on the standing horse and attempt to neutralize forces acting on the fractured limb. Splints should be made of a strong, lightweight material like PVC pipe or wooden boards. Bandages over fractures should be placed tightly over the injured area to decrease soft tissue swelling and minimize slippage. A layer of cotton padding should be followed by a layer of gauze or a self-adhering bandage. Multiple layers can be placed if needed (e.g., Robert Jones–type bandage). The splint should not end at the level of the fracture. In general, splinting techniques can be divided into categories based on fracture location.

DISTAL LIMB FRACTURES (PHALANGES, DISTAL METACARPUS/METATARSUS). A light cotton bandage should be placed on the affected limb from the carpus to the ground. A splint is then positioned on the dorsal aspect of a forelimb or the plantar aspect of

TABLE 38-4

Emergency Splinting Techniques for Fractures in Large Domestic Animals

Location	Species/Age	Splint
Distal phalanx	Horses, foals Cattle, calves	No splint needed
Middle phalanx	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint to proximal metacarpal/tarsal 3 and cast material, Kimzey splint*
Proximal phalanx	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint to proximal metacarpal/tarsal 3 and cast material, Kimzey splint*
	Cattle, calves	No splint needed
Distal sesamoid (navicular)	Horses, foals	No splint needed
Proximal sesamoids	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint and cast material, Kimzey splint*
Metacarpal/tarsal 3	Horses, foals	Bandage with dorsal (front limb) or plantar (rear limb) splint and cast material, Kimzey splint* if fracture distal
Metacarpal/tarsal 3 & 4	Cattle, calves	Bandage with dorsal (front limb) or plantar (hindlimb) splint and cast, cast
Metacarpal/tarsal 2 & 4	Horses, foals	No splint needed
Olecranon/ulna	Horses, foals	Robert Jones–type bandage with caudal splint to lock carpus in extension
Radius	Horses, foals Cattle, calves	Robert Jones–type bandage with lateral splint to withers, second caudal splint if needed
Humerus	Horses, foals Cattle, calves	No splint needed
Scapula	Horses, foals Cattle, calves	No splint needed
Tibia	Horses, foals	Robert Jones–type bandage with lateral splint to tuber coxae
Femur	Horses, foals Cattle, calves	No splint needed
Pelvis	Horses, foals Cattle, calves	No splint needed

*Leg-Saver splint, Kimzey Inc., 164 Kentucky Ave., Woodland, CA 95695 (530-662-9331; fax 530-662-9178); www.kimzeymetalproducts.com.

VetBooks.ir

a hindlimb. The toe is pointed toward the ground to align the dorsal cortices and minimize stretching of the palmar/plantar vascular and nerve structures. A second splint should be placed on the medial or lateral side of the limb if any instability is present in those directions. The splint should be secured with inelastic tape. For additional stability, several rolls of fiberglass casting tape should be placed around the entire bandage and splint structure, incorporating the hoof into the cast.

MIDLIMB FRACTURES (MIDMETACARPUS TO DISTAL RADIUS, MIDMETATARSUS TO PROXIMAL METATARSUS). A Robert Jones–type bandage should be placed on the limb from the ground to the elbow in a forelimb, or the ground to the calcaneal tuber in a hindlimb. The bandage should be less extensive in the hindlimb to facilitate splint placement. In the forelimb, splints should be placed on the lateral and caudal aspects of the limb from the ground to the elbow. In the hindlimb, splints should be placed on the lateral and caudal aspects of the limb from the ground to the calcaneal tuber. The splints are secured using inelastic tape, followed by several rolls of fiberglass casting tape around the entire structure.

UPPER LIMB FRACTURES (MIDDLE AND PROXIMAL RADIUS, TARSUS, TIBIA). A Robert Jones–type bandage should be placed on the limb from the ground and extend as far proximal as possible. In the forelimb, a splint should be placed on the lateral aspect of the limb from the ground to the withers. For increased stability, a second splint may be placed on the caudal or cranial side from the ground to the proximal forearm if necessary. Horses with olecranon fractures that disable the triceps muscle benefit from placement of a caudal splint to reestablish carpal extension. In the hindlimb, a splint should be placed on the lateral aspect from the ground to the tuber coxae. Splints placed high in this fashion will help minimize abduction of the limb.

HIGH LIMB FRACTURES (PROXIMAL TO ELBOW JOINT, FEMUR). Fractures in these locations are covered by extensive muscle, and attempts at splinting are usually unsuccessful and unhelpful to the animal. If triceps muscle function is disabled, a splint on the caudal aspect of the carpus, locking it into extension, is beneficial.

TRANSPORT. Transportation of horses with long-bone fractures can be difficult. They should be trailered in a manner that allows them to lean on dividers for support, and be tied loosely to prevent them from turning around in the trailer but still able to use their heads for balance. When possible, horses with forelimb fractures should be transported with the head facing the rear of the trailer, and those with hindlimb fractures should be transported with the head facing the front of the trailer. These positions allow the horse to control its weight most easily with the uninjured limbs during deceleration of the trailer.

Pathophysiology of Bone Healing

Healing of a fracture terminates in the return of the injured bone to its original form.[5] The process of fracture healing involves several biological steps that overlap and interact with each other. Typically, three phases are recognized: inflammatory, reparative, and remodeling.[5,6] The *inflammatory phase* occurs in the initial 2 to 3 weeks after bone fracture, and chemical mediators cause chemotaxis, migration of leukocytes, and vasodilation to the injured area. These mediators protect the injury from infection and stimulate angiogenic factors. Cytokines from platelets aid in angiogenesis and mesenchymal cell growth.[5] Granulocytes and macrophages destroy invading bacteria and stimulate cell repair through the release of growth and angiogenic factors. If the inflammatory phase is impaired, fracture healing may be compromised.[5]

The *reparative phase* overlaps with the inflammatory phase and may last up to 12 months. This phase attempts to reestablish bone union. Interfragmentary stabilization by periosteal and endosteal callus formation begins if the fractured ends are not immobilized.[6] Bony union develops as a result of endochondral and intramembranous ossification.[5,6] In the reparative phase, interfragmentary motion may greatly influence fracture healing.

The *remodeling phase* takes place both during and after the reparative phase. Osteonal remodeling allows for replacement of necrotic regions of bone. When the bone is loaded, the negatively charged concave surface will attract osteoblasts to add new bone, and the positively charged convex surface will attract osteoclasts to remove bone.[5,6] The result is the ability of a fractured bone to straighten itself by creating new bone formation on the concave surface and removing bone from the convex surface.

Repair of a fractured bone with the use of rigid internal fixation will inhibit naturally occurring callus formation and encourage bone to heal through haversian remodeling. *Haversian remodeling* requires that a fracture be rigidly fixed, have adequate reduction, and have an adequate blood supply.[5,6] Haversian remodeling then functions to revascularize necrotic bone at the fragmented ends of the fracture and bridge interfragmentary gaps. This form of remodeling begins 2 to 3 months after injury.

Fractured bones are often described as healing by primary (direct) or secondary (indirect) intention.[2,5,6] Primary bone healing only occurs with complete anatomic reduction and rigid stability. In large animal fracture repair, this is difficult to achieve because of the size of the animal and micromotion at the repair site.[2] Secondary bone healing utilizes endosteal and periosteal callus formation, and new bone formed at the fracture site develops after initial formation of fibrous tissue or fibrocartilage.[5,6]

The rate of bone healing may be decreased if blood supply is inadequate, infection is present, soft tissue damage is extensive, or stability of the bone fragments is inadequate.

Treatment and Prognosis

Treatment options for fractures in large animals include conservative therapy with stall rest and external coaptation (casts, splints), and surgical stabilization with open reduction and internal fixation. It is important to recognize incomplete and stress fractures to manage them appropriately with conservative therapy, preventing progression to a catastrophic fracture. The majority of fractures require some form of stabilization for the best chance of a successful outcome. Most horses require surgical stabilization for successful fracture repair. Ruminants are more amenable to successful fracture repair with nonsurgical options.[2]

Conservative therapy with stall rest and external coaptation may be successful in some foals and calves with complete nondisplaced fractures. Young animals have a greater and faster ability to heal bone in a reasonable amount of time, and their body weight is much less than that of a mature animal. In foals and calves, fracture configurations tend to be simpler, and the surgical implants available for repair are of a suitable strength for the animal's size. Complications in young animals include closure of a physes with fractures in these areas, infection, and angular limb deformities from overuse of the contralateral limb.

Severely comminuted fractures are more common in adult animals because of the greater force required for bone breakage. Proximal limb fractures in an adult horse often defy successful treatment because severe comminution of the bone occurs, implants are not strong enough to support the bone until it is healed, these horses are less likely to protect the limb, and laminitis formation in the contralateral limb is a common complication. Stall rest with external coaptation alone is rarely associated with a good outcome; most horses need some form of internal fixation for success. Horses are often required to be athletes, and fracture repair resulting in survival but not soundness may be unacceptable. In general, ruminants have a better prognosis for survival than horses because of their less excitable temperament, and complete soundness is often unnecessary for a successful outcome. In ruminants, external fixation may be more successful than external coaptation because it provides increased stability and costs less than internal fixation.[2] Open fractures in horses greatly decreases the prognosis for survival and may delay the ability

	Nonarticular	Medical	Guarded to good

*Foals, calves, and small ruminants.

to perform internal fixation. In ruminants, open fractures are less common but also carry a poorer prognosis.

Implants used for surgical open reduction and internal fixation methods vary based on the specific bone involved, the animal's age, the strength of the bone fragments used in the repair, and the surgeon's preference. Common implants used in large animals include intramedullary interlocking nails, dynamic compression plates (DCPs), locking compression plates (LCPs), limited-contact DCPs, screws, wires, pins, and dynamic condylar screw plates. Table 38-5 lists specific treatment options and prognoses.[4]

HUMERUS. The humeral fracture is often in a spiral or long oblique configuration. In ruminant and equine species, both conservative and surgical treatments have been used. In foals, surgical repair may include the use of intramedullary interlocking nails, DCPs, or intramedullary nails. Prognosis for a closed fracture in a foal is fair to good and depends on configuration, age, and weight.[7,8] Humeral fractures in adult horses are not reparable at this time. Recent reports of horses with deltoid tuberosity or greater tubercle fractures of the humerus indicate some successful treatment results.[9,10] Conservative treatment may be successful in adult horses with nondisplaced fractures and has been used in small ruminants and foals with acceptable outcomes. Ruminants have a better prognosis in general than equine species.[2]

RADIUS. Survival rates for ruminants with radial fractures repaired by external or internal fixation have been reported as 86%.[11] Radial fractures in foals repaired with internal fixation have a good prognosis, but in adult horses the success rate is poor.[12] Animals with incomplete fractures that do not progress have a good prognosis for a full recovery.

OLECRANON. There are several different fracture configurations, and the olecranon fracture may be articular or nonarticular. These fractures are common in both young and older horses. Surgical and conservative treatments have been used with success, although internal fixation is the preferred treatment method.[13,14] Typically the fracture is repaired with a DCP or LCP applied as a tension band. The prognosis with surgical repair is good, with 75%, 81%, and 87% of horses returning to athletic use, depending on the fracture type.[13,14,15] Conservative treatment has been reported to result in a 73% return to soundness.[16]

FEMUR. Diaphyseal fractures are more common in calves, whereas proximal physeal fractures are more common in foals. Femoral fractures in calves may occur during parturition events. In young calves, these fractures have been repaired by internal fixation and femoral head and neck osteotomies with success. A recent study found calves treated surgically for femoral diaphysis fractures had fewer complications than those treated conservatively.[17] In foals, fracture repair with internal fixation gives the best chance of survival, and the use of intramedullary interlocking nails has shown positive results.[18] Femoral fractures in adult horses are not reparable at this time.

TIBIA. Tibial fractures in ruminants have been repaired using splints, external fixators, transfixation pin casts, and DCPs. Fractures repaired with external fixation in adult cattle had a 64% success rate, whereas conservative therapy yielded 44% success.[19] Internal fixation is the repair method of choice in horses. Foals have a fair to good prognosis for survival. Adult horses have a poor prognosis for survival because tibial fractures are often open, have limited blood supply, and are often severely comminuted.

METACARPUS/METATARSUS. In cattle, these fractures are common and have a good prognosis when treated with internal fixation, casts, or transfixation pin casts. Calves may incur distal physeal fractures after forced extraction during a dystocia, and these may be

VetBooks.ir

casted with good success. In horses, cannon bone fractures are frequently open because of a lack of soft tissue coverage. Treatment options include internal fixation with DCP/LCPs and screws, or transfixation pin casts. A recent study evaluating outcomes in mature horses and foals with complete diaphyseal third metacarpal/metatarsal fractures treated with internal fixation found that 62% survived, although the survival rate was much higher for foals.[20] Another study reported a 67% success rate with surgical repair.[21]

PHALANGES. In ruminants, fractures of the proximal or middle phalanx are treated with reasonable success by applying a block to the uninjured claw or by cast application. In horses, proximal and middle phalangeal fractures have been treated by internal fixation with screws and DCPs. Prognosis for survival is good, but return to athletic function depends on the degree of osteoarthritis that develops after fixation. A recent report of proximal phalanx fractures in non-racing horses found that those treated with internal fixation had a better outcome than those managed conservatively.[22] One review of proximal phalangeal fractures in racehorses reported that 61% to 75% were able to race.[23] Prognosis for comminuted middle phalangeal fractures repaired with PIP arthrodesis is 50% for forelimbs and 80% for hindlimbs.[2] Severely comminuted fractures may also be treated successfully with transfixation pin casts or the Nunamaker external skeletal fixator.[24] Fractures of the distal phalanx in horses may be successfully treated with surgical fixation, hoof casts, or modification in shoeing, depending on fracture configuration. A recent study found that 77% of horses had a successful outcome but did not find that immobilization of the hoof influenced outcome.[25]

SUMMARY. Animals identified with incomplete fractures should be treated conservatively with stall rest and should be tied to prevent them from lying down if the fracture is at risk of becoming complete (e.g., radius). Animals with stress fractures should be treated conservatively with stall rest and a careful rehabilitation program, with ongoing radiographic evaluation.

Many fractures in large animals can be repaired and allow survival of the animal. Prognosis in general is better if the animal is young and weighs 500 pounds (225 kg) or less, the fracture is closed, appropriate emergency stabilization is implemented, and prompt reduction and stabilization are performed.

Spontaneous Fractures in Ruminants

Kara Schulz

Definition and Etiology A spontaneous (or pathologic) fracture occurs when bone is weakened by underlying disease to the degree that nontraumatic forces applied to the bone result in bone failure. Commonly affected bone structures include the long bones, vertebrae, ribs, scapula, pelvis, and mandible.

Clinical Signs and Differential Diagnosis Clinical signs of lameness, postural or angular limb deformities, and swelling may be observed in the absence of historical trauma. Additional chronic fractures may be noted with careful physical examination. The primary differential diagnosis is a fracture of normal bone that is due to traumatically applied force.

Pathophysiology, Epidemiology, and Clinical Pathology In ruminants, the underlying conditions that can lead to weakening of the bone's composite structure and subsequent fracture include neoplastic bone lesions, osteomyelitis, osteodystrophy associated with rickets in young animals, osteomalacia associated with nutritional imbalances in adults, and osteoporosis associated with copper deficiency.

Both neoplastic bone lesions and osteomyelitis can lead to pathologic bone fracture from resultant decreases in bone mineral matrix. Lymphosarcoma and a variety of less commonly reported tumors such as hemangiosarcoma, liposarcoma, osteogenic sarcoma, and osteoma among others have caused spontaneous bone fractures in ruminants.[1-3] Lesions may have an osteolytic, osteoblastic, osteoporotic, or mixed roentgen sign depending on the tumor or infectious agent involved.[4] Localized bone infection can be traumatic or hematogenous in origin.[5] Reported cases include osteomyelitis of the sternum, distal sesamoid bone, and mandible, as well as osteitis of the third phalanx.[6-9] *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) is the most common bacterial isolate,[5,6] although other diseases processes like actinomycosis may be involved.

Development of osteodystrophy in young ruminants and osteomalacia in adult ruminants is commonly due to nutritional deficiencies or imbalances and can occasionally lead to spontaneous fracture. Primary (simple) deficiency implies dietary lack of a nutrient, and secondary (complex) deficiency involves reduced nutrient absorption. Primary deficiencies of minerals such as calcium, phosphorus, copper, and vitamin D (1,25-dihydroxycholecalciferol) are commonly associated with bone disease, owing to their integral role in bone mineralization and collagen cross-linking. Secondary deficiencies of these minerals occur when increased consumption of minerals like iron, manganese, magnesium, zinc, sulfur, and molybdenum impede their absorption.[10]

Hypophosphatemia is a common cause of osteodystrophy in young animals and osteomalacia in adult animals. In young animals, development of rickets due to phosphorus or vitamin D deficiency can occasionally result in spontaneous bone fracture.[11] In adults, the pathogenesis of osteomalacia-associated disease is similar but also leads to osteoporosis when mature osteoid is replaced by poorly mineralized bone matrix. Clinical signs of pica, lameness, joint enlargement, poor body condition, and estrus cycle abnormalities may be noted.[12] Primary phosphorus deficiency can occur in ruminants when low levels of phosphorus are available in forage, and secondary phosphorus deficiency can result when significant imbalance exists between calcium and phosphorus concentrations in the ration.[13] Serum phosphorus levels may not adequately reflect a deficiency until severe hypophosphatemia is present and can vary based on age and lactation status, so timely diagnosis may be hampered.[13-14] Gross postmortem findings may include brittle, porous bone and enlarged chronic fracture site scars on ribs.

Primary and secondary deficiencies of copper have been reported to cause osteoporosis and fracture in ruminants.[15] Clinical signs of pica, poor body condition, and anemia are reported.[16] Molybdenosis (molybdenum-associated copper deficiency) occurs when there is a relative excess of sulfate and molybdenum in the diet or water, leading to formation of insoluble copper thiomolybdenate compounds and reduced copper absorption. Although the exact mechanism of copper-induced osteoporosis is unknown, copper is a cofactor for lysyl oxidase, which enzymatically promotes collagen cross-linking. Abnormalities in bone collagen and decreased recruitment of osteoblasts may cause the resultant osteoporosis.[17] In cattle, copper deficiency can be diagnosed through measurement of plasma copper levels (<9 μm/L) or ceruloplasmin levels (<15 IU/L).[18]

Chronic fluoride toxicity, or fluorosis (see earlier section), has been associated with spontaneous fracture in ruminants. These animals present with ill thrift, lameness, and severe dental disease due to abnormalities in tooth wear and mandibular bone, as well as generalized osteomalacia of bone and periarticular structures.[19] Pedal bone fracture has been reported with severe fluorosis.[20] Osteogenesis imperfecta in Holstein-Friesian calves and inherited rickets in Corriedale sheep are two specific conditions that have been associated with spontaneous fractures in ruminants. Genetic conditions like these usually entail abnormalities in bone collagen formation or bone matrix mineralization.[21-22]

It is important to note that this is not an all-inclusive list; other management and nutritional issues may contribute to abnormal bone composition and lead to spontaneous fracture. A detailed history, physical examination, and diagnostic work-up can help identify underlying conditions.

VetBooks.ir

Treatment and Prevention Treatment of spontaneous fractures is similar to routine fracture fixation and will likely involve some type of coaptation, immobilization, or rest depending on the structure affected and the inherent stability of the fracture and surrounding bone. Resolution of the underlying cause is essential to the success of fixation. The prognosis is dependent on the severity of the underlying condition, with an understandably guarded to grave prognosis for many of the listed conditions. However, it must be noted that many of the nutritional imbalances leading to osteodystrophy, osteomalacia, or osteoporosis-associated fractures have been successfully treated. As with many other conditions, prevention of the underlying cause is the most effective means for reducing the incidence of spontaneous fractures in ruminants.

Bucked Shins and Stress Fractures of the Metacarpus in the Horse

Justin Dominick McCormick

Definition and Etiology The third metacarpal bone can be painfully affected by bucked shins or stress fractures, also known as *dorsometacarpal disease,* and cause variable lameness in the racehorse.[1,2] Dorsometacarpal disease is a well-recognized problem in young Thoroughbred and Quarter Horse racehorses and has been described in Standardbreds as well. Bucked shins occur mainly in 2-year-olds in response to high strains sustained during the repetitive loading experienced during the first year of training. Periostitis develops over the dorsal cortex in response to stress remodeling as speed is first introduced in early training.[2] Short oblique stress fractures are the result of an imbalance between bone fatigue and failure of bone remodeling. The mid-distal dorsolateral cortex of the left third metacarpus is the most common site of pathology, but periostitis can develop anywhere along the dorsal cortex and affect the right metacarpus as well.[1,3] Stress fractures typically develop in 3-year-olds as training continues and previously developed pathology progresses.[3-5]

Clinical Signs and Differential Diagnosis Bucked shins and stress fractures occur in young horses early in training, and less commonly in older horses that have not been appropriately conditioned before racing. Bilateral forelimb involvement is most common, with the lead limb most severely affected.[2] Heat and swelling develop acutely over the dorsal metacarpus. As training continues, soft tissue thickening becomes evident several weeks after development of the initial clinical signs.[2] The degree of pain and lameness depends on the severity of the condition and is most noticeable following intense work. Lameness typically resolves after several days of rest and recurs when training resumes. Poor performance at high speeds and reluctance to train are evident as disease progresses if exercise continues at the same intensity. Radiographic changes are often subtle in horses with acute bucked shins. Microfractures secondary to cyclic fatigue may result in periosteal and endosteal reactions that are difficult to detect radiographically.[6] Thickening of the dorsomedial cortex and periosteal proliferation may be seen in chronic cases (Fig. 38-45).[2] A complete radiographic exam, including multiple oblique views to highlight the dorsal cortex, is indicated at the time of initial onset of clinical signs to determine whether fissure lines are present. Increased focal uptake of technetium-99m (^{99m}Tc) on nuclear scintigraphy in the dorsal cortex is suggestive of disease when radiographic abnormalities are inconclusive.[6]

Differential diagnoses for pain and swelling localized to the metacarpal region are traumatic or infectious in origin and include cellulitis, periostitis, osteitis, and osteomyelitis. A thorough history, complete physical exam, and close examination of the area should be performed during initial work-up to identify any evidence of external trauma or local infection in the dorsal metacarpal region. Older horses or horses not involved in race training are unlikely to develop bucked shins, so other causes of clinical signs should be investigated.

FIG. 38-45 Lateromedial radiograph of the third metacarpal bone of a horse with chronic bucked shins. Note the dorsal cortical thickening and endosteal and periosteal response.

Failure of dorsal metacarpal bone remodeling in response to strain during exercise results in stress fractures. The majority of stress fractures occur on the dorsolateral surface of the mid-diaphysis of the left third metacarpus, but bilateral fractures can occur.[7] These stress fractures are usually observed in 3-year-olds but have been reported in older horses.[2] Similar to bucked shins, lameness is variable and exacerbated with exercise. Pain may be elicited on digital palpation over a discreet area of swelling that hardens with periosteal callus formation.[2] Clinical examination is usually sufficient for diagnosis of bucked shins or stress fractures of the third metacarpus. Median and ulnar perineural anesthesia or local anesthesia of the proximal metacarpus with a ring block may be performed to confirm the source of pain.[2]

Fissures or nonspecific linear lucencies are suggestive of incomplete fractures. They are often seen radiographically in the dorsal cortex of the third metacarpus (Fig. 38-46, *A*). The most common fracture configuration courses distoproximal at a 30- to 40-degree angle from the mid-distal dorsolateral cortex. These fractures either extend 60% to 70% through the dorsal cortex or curve back to the dorsal cortex in the form of a saucer fracture.[3] The presence of marked periosteal and endosteal proliferation on radiographs strongly suggests the presence of a cortical stress fracture. Radiographic evidence of periostitis may be delayed up to 2 weeks following the onset of clinical signs.[6] Additional radiographic examination may be indicated 7 to 10 days later if stress fractures are suspected but not evident initially.[2] Multiple fractures in the same limb have been reported.[6]

Pathophysiology The effect of race training on the growth and development of the maturing metacarpal bone appears to be directly related to the development of bucked shins.[1] As the horse enters training during its 2- or 3-year-old year, the third metacarpal bone is subjected to new strains and remodels in an attempt to adapt to the bending forces experienced during repetitive loading during exercise.[8] Cyclic fatigue during high strain decreases bone stiffness. New bone is formed over the surface of the dorsal medial cortex in response to deformation of bending forces localized to that region of the third metacarpus.[8] As cyclic loading during training continues,

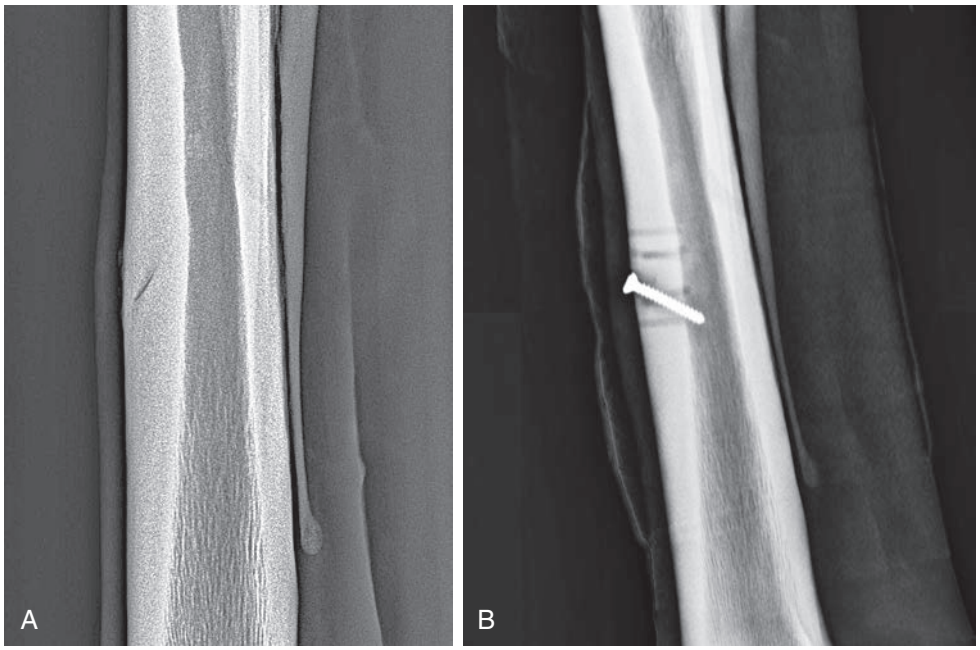

FIG. 38-46 **A,** Preoperative radiographic projection of a cortical stress fracture of the dorsolateral third metacarpal bone. **B,** Postoperative lateromedial radiographic projection of position screw placement through the fracture line, with surrounding osteostixis holes.

production of woven and lamellar bone is exhausted. Fiber-type bone is formed, which appears radiographically as periosteal proliferation.[9] As cyclic loading continues, the bone continues to lose stiffness and begins to fatigue, resulting in failure or microdamage.[2]

Incomplete stress fractures are commonly localized to the dorsolateral cortex of the third metacarpus and are observed within 1 year following the onset of dorsocortical pain.[9] Evidence suggests that cortical bone is unable to appropriately remodel during periosteal bone formation. As bucked shins develop, the dorsolateral cortex loses stiffness and becomes more vulnerable to high-stress cyclic fatigue and stress fractures.[8] The forces exerted on the limb differ during race speeds (compared to training speeds), so racing may shift stresses to areas less adapted to high-speed cyclic loading.[4]

Epidemiology The incidence of bucked shins varies with region, ranging between 30% to 90%, and is mostly seen in 2-year-old Thoroughbred racehorses during the first 6 months of training.[1] Prevalence of stress fractures is unknown, but a reported 12% of horses that buck their shins later develop stress fractures,[10] and a greater number of horses developed bucked shins and stress fractures during prolonged fast workouts while on dirt surfaces.[4,5]

Bucked shins primarily develop in the Thoroughbred, less commonly in Quarter Horses and Standardbreds.[2] Thoroughbreds are trained to race longer distances at greater speed, subjecting them to higher cyclic loading and greater risk of fatigue failure compared to other racing breeds.[10]
