Treating periodontal disease on a flock basis often may prove impractical. Dental treatment, drug therapy, and management change have been tried in sheep. One form of dental treatment, tooth grinding, consists of trimming the incisors to the level of the lower dental pad.[12] Two trials of the productivity effects of tooth grinding have been conducted. Neither has shown any positive benefit from the procedure.[30] An attempt to influence the development of periodontal disease in sheep by long-term treatment with tetracycline and metronidazole has proved ineffective.[21] In commercial sheep, surgical treatments could improve conditions such as periapical and gingival abscesses, but these treatments are not economically feasible.

Sheep can live without incisors provided that they do not have to graze too closely. Supplementary feeding or improved pasture usage for these sheep should provide a net gain to the owner. When premolar and molar teeth are involved, this approach is unlikely to be effective because of the inability to chew and ruminate efficiently.

Dentigerous Cysts

Dentigerous cysts have been described in ruminants, particularly sheep.[14,31] These are odontogenic cysts of unknown cause that manifest as localized, bony swellings. Radiographs demonstrate the cystic nature of the swelling and reveal one or more teeth in the cyst.[14,31] For valuable individuals, treatment is surgical.

Developmental Anomalies and Retention of Deciduous Teeth

Developmental anomalies have been reported in cattle.[5] Occasionally, tooth buds fail to develop. The fourth pair of permanent incisors is the set most often absent. The mandibular premolar on one or both sides also occasionally fails to form. The permanent incisor teeth have been observed to be rotated up to 180 degrees in the alveolus. Rotation of the first permanent mandibular premolar has been seen. The rotation was 90 degrees, and no cause could be detected. Retention of a deciduous premolar is common in 12- to 18-month-old cattle. This results in difficulty in masticating food and excessive salivation. The treatment consists of removing the deciduous premolar with a forceps.

Overgrown or Loose Molar Teeth

Overgrown molar teeth are found most commonly in old ruminants. The opposite tooth is often missing. Food accumulates between the affected tooth and the cheek, causing obvious swelling of the face. Interference with mastication often is noted. The offending tooth should be rasped regularly or removed. A power tool to grind cheek teeth works well. Premolar or molar teeth can become loose in advanced cases of actinomycosis affecting the jaw. It may be difficult to determine whether the loose tooth is a cause or result of the bony abnormalities. One cow with maxillary lymphosarcoma and loose teeth has been reported.[32]

Broken Teeth

Broken incisors are not common because of the loose alveolar attachment of these teeth. Broken premolars and molars are more common because these teeth are more solidly attached in their alveoli; breakage usually results from attempts to masticate hard objects. Most fractures usually involve only a portion of the tooth, do not involve the root, and are asymptomatic. A sagittal tooth fracture that includes the root causes pain and may result in reduced feed intake and loss of condition. (Treatment is described later, in the section Tooth Root Abscess.)

Dental Caries

Dental caries, or decay, creates areas of decalcification of the tooth.[3] Dental caries is rare in ruminants,[3] but it sometimes can be found in

VetBooks.ir

both temporary and permanent teeth and in both dentin and enamel.[5] Interference with prehension usually is not seen. On oral examination, an orange or black pigment is seen in the defective enamel or exposed dentin; these areas should be probed with a fine dental pick or needle. Caries may be filled or the tooth extracted. In rare cases the caries can reach down the pulp cavity to the root apex, causing periodontal abscesses. (See Tooth Root Abscess, later.)

Osteodystrophia Fibrosis

Osteodystrophia fibrosa is caused by resorption of calcium from bone and its replacement by connective tissue.[33] It is seen most commonly in the goat. Osteodystrophia fibrosa can result from calcium, phosphorus, or vitamin D deficiencies or from hyperparathyroidism. Usually a growing animal is presented with a bilateral, soft, nonpainful, swelling of the maxilla and/or mandible.[33] The diagnosis is based on radiographic evidence of poorly mineralized bone and inward rotation of the premolar and molar teeth. The treatment consists of supplementing the ration with adequate mineral levels while maintaining a ratio of calcium to phosphorus of 2:1.

Tooth Root Abscess

Dental repulsion is done preferably under general anesthesia with the affected tooth uppermost. A straight incision is made directly over the longitudinal axis of the tooth. Only the bone lateral to the tooth is removed. If necessary, a chisel is used to free the tooth of bone at its rostral and caudal surface, taking care not to disturb the neighboring teeth. A dental punch is placed on the tooth root, and dental repulsion is performed. The ventral aspect of the incision can be left open for drainage, or the alveolus can be packed with dental wax, gauze, or dental material, such as Optosil (Heraeus Kulzer GmbH, Hanau, Germany).[7] Abscessed maxillary cheek teeth often result in maxillary sinusitis. The sinus must be curetted at the time of surgery and flushed daily for 1 to 2 weeks following surgery. Antibiotics are administered for 1 week, according to culture antimicrobial sensitivity results. After removal of the affected tooth, the abscess and clinical signs usually will resolve, but chronic sinusitis may require a bone flap and extensive curettage.

Dental Fluorosis

Dental fluorosis is associated with continuous ingestion of small but toxic amounts of fluorine in the diet or drinking water. Most reported occurrences of fluorosis are in cattle. Sheep are less susceptible. Developing teeth are very sensitive to the ingestion of excess fluorides. Fluorides inhibit the action of ameloblasts and odontoblasts during tooth formation, resulting in failure of the tooth to accept minerals. Fluorosis results in striations or patches (yellow, brown, green, or black) in enamel. Some erosion of the permanent tooth can be seen. Cattles are susceptible to dental fluorosis during enamel matrix formation from approximately 6 months to 3 years of age. Severe dental fluorosis results in dental wear, inability to graze properly, and difficult mastication and food intake because of tooth pain. In addition to clinical signs, the diagnosis can be made by analyzing the fluorine concentration in the blood and urine. Normal cattle have blood levels of up to 0.2 mg fluorine per mg/dL of blood and 2 to 6 mg per kg in urine. Cattle with fluorine intakes sufficient to cause intoxication may have bloods levels of 0.6 mg per kg and urine levels of 16 to 68 mg/kg. Treatment is usually to remove the animals from the source of fluorine.

Salivary Gland Diseases

Guy St. Jean

The parotid, mandibular, and sublingual glands are the three largest salivary glands in ruminants.[1] In cattle the mandibular gland is larger than the parotid gland. The adult bovine produces 50 L or more of saliva in 24 hours. Saliva is secreted continuously, but the rate of secretion is increased by feeding, rumination, and the presence of coarse feed in the rumen.[1] The saliva provides a fluid medium for transport of ingesta during deglutition and regurgitation. It also maintains adequate phosphate for bacterial digestion of cellulose in the rumen and contains bicarbonate, which acts as a buffer to maintain ruminal pH above 5.5. Ruminant saliva contains approximately 80 mEq of bicarbonate per liter.

Excessive Salivation

Excessive salivation (ptyalism) is a sign of many pathologic conditions. The volume of saliva may be normal, but if it is not being swallowed, salivation can appear excessive. As a precaution against exposure to rabies, gloves should be worn to examine the mouth of any animal that is salivating excessively. Excessive salivation may be seen with dental disease, stomatitis, foreign objects in the mouth or pharynx, or esophageal obstruction. It also has been seen with ruminal disorders, in cows that have eaten spoiled silage, and with impaction of the abomasum. Ptyalism may be a clinical sign in rabies, pseudorabies, meningoencephalitis, and slaframine toxicity.[1,2] Mercury, iodine, lead, copper, and arsenic also can stimulate secretion by the salivary glands. Treatment depends on the underlying causes.

Sialocele

A sialocele develops when saliva escapes from a duct or salivary gland and enters the surrounding tissue. The saliva contains enzymes that irritate the tissue. The accumulation of saliva is surrounded by inflamed tissue, which gives the lesion a cystic appearance. A soft, fluctuant swelling usually is seen. Signs of pain may be observed during mastication. Trauma or foreign body usually is the cause of a sialocele. The diagnosis is based on the history, palpation, paracentesis ultrasound, and sialography. Needle aspiration may yield yellow mucoid saliva. Two treatments have been described.[3,4] The first involves removal of both the mandibular and sublingual glands and ducts.[3] Surgical extirpation of the mandibular salivary gland in the caudal area of the mandibular spaces has been performed successfully in cows, sheep, goats, and buffaloes.[1] Exposure of the tissue by opening the capsule of the gland facilitates the process of extirpation and prevents trauma of the surrounding nerves and blood vessels.[3] In the second treatment option the sialocele is opened, drained, and chemically débrided using a caustic agent like iodine or copper sulfate.[4]

Parotid Gland Carcinomas

In three cows at slaughter that had parotid gland carcinomas, the neoplastic cells appeared to originate from ductal and acinar epithelium.[5] Ocular squamous cell carcinoma may spread locally to the parotid or mandibular lymph nodes.[6]

Sialoadenitis

Inflammation of the salivary glands usually is caused by nonspecific infections, penetrating wounds, or plant awns. Diffuse swelling of the salivary glands may be observed, and the swelling may be hot and painful on palpation. Abscess formation is a common complication. The pain may interfere with mastication and swallowing. Treatment consists of systemic antibiotics and antiinflammatory and analgesic drugs. Abscesses should be drained when they localize. Salivary fistulas can be sequelae to salivary abscesses.

Actinobacillosis (Woody Tongue, Wooden Tongue)

Bradford P. Smith

Definition and Etiology *Actinobacillus lignieresii,* a gram-negative rod, is a normal inhabitant of the rumen and mouth of many cattle and sheep and probably goats. When the organism enters the soft tissues through a lesion, actinobacillosis results in a granulomatous abscessation. Ruminants of all ages can be affected, and the disease appears to have a worldwide distribution. The classic site of

VetBooks.ir

infection is the bovine tongue; because the condition causes a very hard, diffuse nodular swelling, it has been given the name "woody tongue" or "wooden tongue." The prevalence of woody tongue in bovines at slaughter is 0.7% to 3.6%.[1] Atypical actinobacillosis lesions of cattle can occur in the lips, nose, or lymph nodes of the head or neck or at other sites. Although the lesions normally occur sporadically, herd outbreaks with up to 73% morbidity have been reported.[1,2] Sheep are most commonly affected by hard swellings of the lips, often with fistulous tracts. Actinobacillosis has also been reported to cause tongue lesions in sheep and horses. These lesions appear to be rare in goats.

Clinical Signs and Differential Diagnosis Actinobacillosis lesions usually involve soft tissues. When the tongue is affected, the major clinical signs are inability to prehend food normally, excessive salivation, and sometimes a visibly enlarged tongue that protrudes from the mouth. The submandibular area often is enlarged and firm. On palpation the tongue is firm to very hard, painful, and nodular (Fig. 32-84). Nodular lesions often are slightly ulcerated. The base of the tongue is most frequently affected, but the shaft may also be involved. An ulceration filled with plant awns or stems often is seen in the sulcus lingualis at the junction of the base and shaft of the tongue. Because cattle use the tongue to prehend food, anorexia results when the tongue is painful and inflexible. Actinobacillosis must be differentiated from dental disease, oral foreign bodies, pharyngeal trauma, and other diseases that cause oral pain.

Atypical lesions in cattle involve sites other than the tongue.[3] Lymph nodes of the head and cranial cervical area are most frequently affected, but where any abrasion is present, granulomas or abscesses may develop, followed by licking or contact with pus draining from a lesion on another animal. Because plant awns and stems create entry sites for the organism in the mouth, most lesions are in the head. Granulomas in the nose and eyelids and needle puncture wounds over the left jugular vein have been reported. These granulomas may be confused with tumors, polyps, or cysts. Granulomas have been reported in the esophagus, pharynx, palate, flank, internal iliac lymph nodes, and testes; multiple subcutaneous lesions with regional lymph node involvement also have been reported. Three cases involving cutaneous lesions of the facial tissues were described as extensive swollen plaques under alopecic areas. Most granulomatous abscesses in a herd outbreak of actinobacillosis involved the tongue, muzzle, and lips and the submandibular, parotid, and cranial cervical areas. Generalized involvement or granuloma formation in internal organs may also occur.

Lesions in sheep typically involve the lips and face or parotid and submaxillary regions. The nasal cavity and internal organs occasionally may be involved. Soft tissues of the head may be infected through fight wounds. Lesions of the lips must be differentiated from those of contagious ecthyma, and granulomatous abscesses in other sites must be differentiated from caseous lymphadenitis lesions. Lesions of the tongue of sheep, essentially identical to those found in cattle, have been reported as a cause of green staining of the lips and "cud-dropping" in sheep.

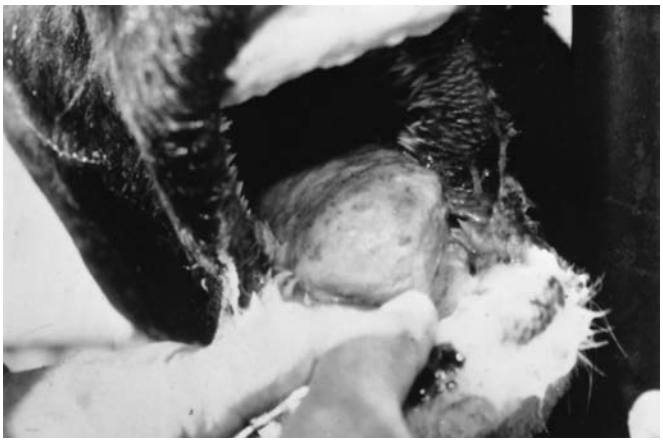

FIG. 32-84 Firm, enlarged bovine tongue typical of woody tongue caused by *Actinobacillus lignieresii*. Partly ulcerated areas of mucosa overlie hard nodules.

Clinical Pathology Diagnosis of actinobacillosis requires biopsy and culture of the lesion. The pus usually is not malodorous. Pus crushed between two glass slides shows "sulfur granules," "club-like rosettes," or "club colonies." Similar colonies may be found in actinomycosis and some staphylococcal infections. *A. lignieresii* are small, gram-negative rods. Definitive diagnosis relies on culture. No reliable serologic test is available for actinobacillosis, and the hematologic and clinical chemical findings may be normal or typical of a response to chronic infection.

Pathophysiology *A. lignieresii* is a normal inhabitant of the mouth of ruminants and can be found in many plant awns. When mucosal lesions occur as a result of plant awns (e.g., foxtails), thistles, or particularly stemmy coarse feed, actinobacillosis may occur. Cattle often have a small ulcer in the sulcus lingualis at the junction of the base and shaft of the tongue. Plant fibers are sometimes found in the granulomatous lesions of actinobacillosis. Once inoculated into tissues, the organism may cause a local lesion, lesions in draining lymph nodes, or both. Lesions elsewhere on the body may be contaminated by saliva or by pus from other draining lesions or directly by plant awns on which *A. lignieresii* resides.

Epidemiology Most cases of actinobacillosis are sporadic. Herd outbreaks may be associated with abrasive feedstuffs and crowded conditions in which the organism is spread rapidly to wounds on other animals by way of saliva. In one herd outbreak, 73% of a group of heifers (4 to 24 months of age) were affected 1 month after feeding of a coarse, stemmy haylage had begun.[2] Atypical lesions often are associated with a previous wound at the site, such as a nose lead wound, multiple needle punctures, or a head butting wound. Outbreaks of actinobacillosis in wounds of the head, neck, body, and limbs have been reported.

Necropsy and Biopsy Findings Actinobacillosis lesions typically are firm, pale, gritty, granulomatous abscesses. Grossly they are similar to exuberant granulation tissue and connective tissue, often appearing to have a yellowish granular (1 to 3 mm) surface. Masses contain multifocal necrotic foci, often filled with nonodorous, thick, yellow-white pus. On histological exam the lesion is a granulomatous abscess. An outer capsular region of connective and granulation tissue surrounds an area of leukocytes and rosettes ("club colonies"). Mononuclear cells, plasma cells, and eosinophils predominate. Many neutrophils are seen at the center of the lesion. Multinucleated giant cells or plant fibers, or both, may be seen.

Treatment and Prognosis Treatment usually is successful, and the condition has an excellent prognosis when only the tongue is involved. The prognosis may be only slightly less optimistic when internal organs and atypical sites are involved. Sodium iodide (70 mg/kg given IV as a 10% to 20% solution) is the treatment of choice. Intravenous treatment is given once and repeated at least one more time at a 7- to 10-day interval. In refractory cases intravenous therapy may be repeated more often (2- to 3-day intervals). In severe cases daily organic iodides can be administered orally at a rate of 60 mg/kg/day[4] in addition to the intravenous iodide. If signs of iodinism develop (excessive tearing, coughing, inappetence, diarrhea, and/or dandruff), iodine administration should be halted; the adverse signs normally disappear shortly thereafter.

The onset of therapeutic benefit of sodium iodide is remarkably rapid. Within 48 hours after treatment, the tongue is flexible enough to allow the animal to eat. Although the mode by which iodides exert their beneficial therapeutic effect in actinobacillosis is not well understood, it seems most likely that they exert some antiinflammatory effect on the granulomatous inflammation. Iodides have little in

VetBooks.ir

vitro bacteriostatic or bactericidal effect at the concentrations given,[5] yet the onset of action is very rapid. They probably act in some way other than by direct antimicrobial effect. The old belief that iodides cause abortion at the recommended dose has been cast into doubt by the author's clinical experience and by reports of others,[6] who gave one and one-half to two times the recommended intravenous dose without inducing abortion. Nevertheless, there are anecdotal reports of the association, and when products are labeled with a contraindication for use in pregnant cattle, due caution should be exercised. Iodides should be given slowly and with caution to horses because of the possibility of severe generalized adverse reactions to intravenous sodium iodide.

Most strains of *A. lignieresii* are sensitive in vitro to a number of antimicrobial drugs, including ceftiofur, ampicillin, penicillin, florfenicol, sulfas, aminoglycosides, and tetracyclines. Each isolate should be tested for antimicrobial sensitivity. Therapy with an antimicrobial drug to which the isolate is sensitive is recommended in severe, generalized, or refractory cases of actinobacillosis. Therapy should also include iodides.

Surgical debulking of lesions, particularly if they interfere with airflow, is also possible for atypical cases in which a large granulomatous mass is present and the mass has proved refractory to medical therapy. Hemostasis may be a problem after surgical debulking.

Prevention and Control Prevention relies mainly on avoidance of coarse, stemmy, scabrous feeds and pastures full of hard, penetrating plant awns (e.g., foxtails) or thistles. If an outbreak occurs, immediate change to a softer feed is advised, and affected animals should be treated individually. Rapid resolution of the outbreak can be expected once these steps have been taken. If atypical lesions occur, a cause of skin wounds in the area should be sought and resolved.

FIG. 32-85 Hard swelling on the distal mandible of a cow, typical of lumpy jaw caused by *Actinomyces bovis*. Loss of teeth and bone destruction, along with fibrosis and callus formation, are seen in this advanced case. The oral mucosa is secondarily ulcerated by trauma.

Actinomycosis (Lumpy Jaw)

Bradford P. Smith

Definition and Etiology Actinomycosis is caused by *Actinomyces bovis,* a gram-positive, nonencapsulated, branching, filamentous bacterium that is a normal inhabitant of the ruminant mouth. The disease occurs mainly in cattle but on rare occasions may affect sheep or goats, and one report of the disorder in a horse involving *Actinomyces viscosus* and *Actinomyces odontolyticus* was found.[1] It enters the tissues and bone through oral abrasions, openings, and punctures associated with dental or gingival disease, hard plant awns (e.g., foxtails), thorns, stickers, or dry, coarse, stemmy feeds. Lesions may begin as cavities (caries) in the dentin or dental pulp.[2] Lesions are sporadic and occur mainly in the mandible and less commonly in the maxilla. The preponderance of mandibular lesions, with the development of periosteal new bone and fibrosis, gives the disease its common name of "lumpy jaw." Lesions occasionally occur in soft tissues of the head, esophagus, forestomachs, and trachea. Occasionally *A. bovis* may cause granulomatous abscesses in other soft tissues. Most of the early reports of esophageal groove and forestomach involvement incriminate actinobacillosis rather than actinomycosis.

Clinical Signs and Differential Diagnosis Bovine actinomycosis typically causes a hard, immovable, painless, bony mass on the mandible (Fig. 32-85). The lesion is most common on the horizontal ramus. Initially it is nondraining (has no fistulous tracts), but it may develop fistulous tracts and involve tooth roots as the condition progresses. When teeth become involved, evidence of pain when chewing may be seen, and weight loss may result. A careful examination of the mouth is required to detect loose teeth, plant awns, or severe gingivitis and to rule out a pathologic fracture. If a fistula is present, it is useful to flush the tract with organic iodine and perform contrast radiographs to determine if it communicates with the mouth. The differential diagnosis includes tooth root abscess, fracture, tumors, and osteomyelitis caused by other organisms. A mandibular swelling that continues to enlarge despite therapy should be radiographed for evidence of a fracture or sequestrum. Atypical actinomycosis with lesions in soft tissue causes a variety of clinical signs, depending on the location.

Clinical Pathology and Diagnosis Hematologic and clinical chemistry findings may be normal or may reflect a chronic infection. Radiographs of the lesion are helpful in determining if there is dental involvement or a pathologic fracture. The radiographic lesion consists of multiple central radiolucent areas of osteomyelitis surrounded by periosteal new bone and fibrous tissue. If a fistulous tract is present, a contrast study done while flushing into the tract may help determine the extent of the fistula. Before flushing, material from the core of the lesion should be aspirated or biopsied. A Gram stain and culture of pus should be performed. The organism is gram-positive, filamentous, and branching. "Sulfur granules" similar to those described for actinobacillosis may be seen. Many authors report that they were unsuccessful at culturing the organism.

Pathophysiology and Epidemiology *A. bovis* appears to enter the bone through mucous membrane punctures caused by foreign bodies, plant awns, or coarse, stemmy feeds or through a diseased tooth or areas of gingivitis that allow oral bacteria access to the bone. Cases usually are sporadic.

Necropsy and Biopsy Findings Actinomycosis causes a granulomatous abscess. Scattered through the mass of tissue are basophilic clumps of bacteria surrounded by eosinophilic clublike projections. The bacteria are long, filamentous, branching rods. Surrounding them is cellular reaction composed of neutrophils, epithelioid cells, macrophages, and occasional multinucleated giant cells. In the outer fibrous tissue are plasma cells.

VetBooks.ir

Treatment and Prognosis Treatment of actinomycotic bone lesions usually results in arrest of the lesion, but seldom does the size of the hard mass regress significantly. The prognosis for arrest of the lesion with vigorous treatment is good. If the mass does not have any fistulous tracts and no affected teeth are loose, medical therapy alone may be sufficient. If the mass has fistulous tracts, it should also be vigorously curetted and flushed with povidone-iodine or other organic iodine. The lesion has a rich blood supply, and curettage can result in severe hemorrhage. If the cavity is large, it may be necessary to flush and pack with iodine-soaked gauze daily for several days, then less frequently as healing progresses. One paper reports on the successful treatment of three cases of actinomycosis by using repeat treatments consisting of curettage followed by cryotherapy with liquid nitrogen poured into the lesion. The authors repeated the treatment on day 2, day 9, and day 16.[3] If there is an open fistula into the mouth (as judged by vigorous flushing) or if teeth are involved, the affected tooth or teeth should be carefully removed or repaired endodontically.[2] Care must be taken to prevent mandibular fracture, and the animal must be sedated or anesthetized to allow for proper intraoral manipulation. The empty alveolus should be carefully packed with gauze or a dental acrylic to which a wire or umbilical tape is attached and pulled through the fistula. The wire is tied externally to a small gauze roll to keep the alveolar packing firmly in place. The wire should be untied daily and the tract flushed thoroughly with povidone-iodine until the wound is completely granulated. Once granulation begins, it may not be necessary to check and flush the lesion more than once a week. The alveolus will take several weeks to close, pushing the gauze or acrylic out as it does so.

Medical treatment of actinomycosis involves the use of sodium iodide, isoniazid, and penicillin or another antimicrobial drug to which the organism is sensitive. Sodium iodide is given IV at a dose of 70 mg/kg as a 10% to 20% solution. It can be given every 7 to 10 days or more often until signs of iodinism occur (i.e., lacrimation, cough, inappetence, diarrhea, and dandruff). If repeated intravenous treatments are difficult, oral organic iodides can be given at the rate of 60 mg/kg/day for 3 weeks. As with actinobacillosis, the beneficial therapeutic effects of iodides appear to lie in their ability to reduce granulomatous inflammation rather than in direct antimicrobial effects. Iodides do not appear to cause abortion and can be safely given to pregnant cows,[4] although care should be used because there are anecdotal reports to the contrary, and products are labeled with a contraindication for pregnant cattle.

Isoniazid (10 mg/kg/day given PO for 1 month) is effective at arresting actinomycosis of the mandible in cattle.[5] It is inexpensive and readily consumed in a small amount of grain. A prolonged withdrawal period before slaughter for human consumption is required. The drug appears to be nontoxic at this dosage, but it may cause abortion and should not be used in pregnant cattle.

Penicillin (10,000 U/kg IM twice daily) or another antimicrobial drug such as florfenicol or ampicillin can be added to the treatment regimen in cases involving valuable animals or when twice-daily treatment for 7 to 14 days is possible. Streptomycin was found effective in one study, but because of the prolonged persistence of tissue residues, aminoglycosides generally are considered unacceptable in food animals.

Prevention and Control *A. bovis* is a normal mouth inhabitant of ruminants; therefore the only possible means of prevention is to avoid feeding coarse, stemmy feeds, feeds with hard, penetrating plant awns, or feeds with other sharp materials. The recommendations in this regard are similar to those for actinobacillosis.

Pharyngeal Trauma and Abscess

Bradford P. Smith

Definition and Etiology Pharyngeal trauma occurs relatively frequently in cattle, resulting in cellulitis, abscessation, or hematoma formation. One case resulted in megaesophagus. Pharyngeal trauma is almost always associated with use of a balling gun, long dose syringe, speculum, paste wormer gun, rigid probe of calf esophageal feeder, or rigid stomach tube.[1] Occasionally a foreign body such as a sharp stick or wire can perforate the pharynx. Hematomas may result from unidentified blunt trauma. The puncture or laceration may be very small and usually is located in the area near the origin of the esophagus. The result is that feed and saliva enter the retropharyngeal area, and inflammation develops (also see Chapter 31, Retropharyngeal Lymph Node Abscessation).

Clinical Signs and Differential Diagnosis The clinical signs include anorexia, drooling of saliva, malodorous breath, extended head and neck, localized or diffuse pharyngeal pain, feed coming from the external nares, and forestomach stasis or bloat. Severe cases may involve obvious pharyngeal swelling, fever, easily elicited cough on laryngeal palpation, dyspnea, and aspiration pneumonia. Intraluminal submucosal pharyngeal abscesses with similar clinical signs have been reported. Differential diagnosis in cattle must include retropharyngeal abscesses (also see Chapter 31, Retropharyngeal Lymph Node Abscessation), pharyngeal foreign body, actinobacillosis, and lymphosarcoma or other tumor that involves the pharyngeal lymph nodes.

If megaesophagus occurs, it must be differentiated from diaphragmatic hernia with herniation of the reticulum into the thorax; other outflow obstructions involving the reticulum can result in frequent regurgitation and vomiting, as can a number of other diseases, including esophageal foreign body and esophageal diverticulum. Several toxins also cause vomiting (see Chapter 7). Rabies is easily differentiated, because the only clinical signs common to both are anorexia and salivation. Careful digital palpation of the pharynx often is diagnostic, although restraint is difficult because the area is painful and swollen, causing dyspnea and struggling. A well-lubricated stomach tube should be gently passed to relieve bloat and ascertain that no esophageal obstruction is present. Pharyngeal trauma is rare in sheep and goats, and retropharyngeal abscesses caused by *Corynebacterium pseudotuberculosis* (caseous lymphadenitis) are the most common cause of pharyngeal swelling.

Clinical Pathology and Laboratory Aids Endoscopy and radiography may be of great help in diagnosing the site of the lesion, the extent of cellulitis, and the presence of a foreign body. Endoscopy reveals a swollen, collapsed pharyngeal air space. The wound may be visible, and it may have exudate at its origin. Endoscopy can help rule out intraluminal masses and foreign bodies. Retropharyngeal cellulitis, abscess, or hematoma often can be visualized radiographically, and radiopaque foreign bodies can be seen (Fig. 32-86). Gas in the

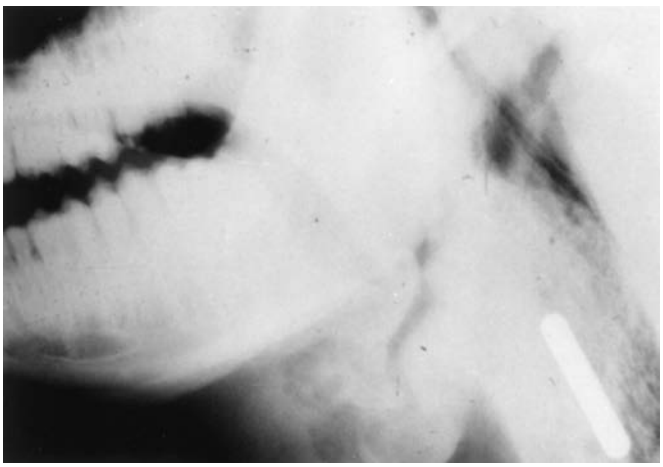

FIG. 32-86 Pharyngeal trauma in a 2-year-old bull caused by a magnet that was given forcefully with a balling gun 24 hours previously. The magnet is visible in the retropharyngeal tissues surrounded by cellulitis, with swelling and gas in the tissues. The area is swollen and painful.

VetBooks.ir

soft tissues or a discrete mass can be seen with cellulitis and abscess, respectively. Gas often can be seen in the lumen of the esophagus as well. Radiographs of the lung may be helpful if aspiration pneumonia is suspected. The results of hematologic analysis may reflect an infectious inflammatory process.

Pathophysiology Inflammation, swelling, and necrosis in the retropharyngeal tissues interfere with normal swallowing by causing pain when swallowing is attempted, physical interference with passage of a bolus, and neurologic involvement. The resultant dysphagia may predispose the animal to inhalation of feed and saliva.

If the retropharyngeal inflammation affects the pharyngeal branch of the vagus nerve on the dorsolateral surface of the pharynx, the esophageal and pharyngeal phases of swallowing and eructation are disturbed.[1] The resultant pharyngeal paresis may lead to reflux of feed through the nares. Involvement of the adjacent cranial laryngeal nerve makes the laryngeal mucosa less sensitive to foreign material and thus diminishes the cough reflex. Severe inflammation may involve the vagus nerve itself and cause forestomach stasis with bloat and laryngeal motor dysfunction.[1-3] Eructation also involves pharyngeal muscular activity, and the maneuver is likely to be quite painful when cellulitis is present in the area.

Treatment and Prognosis In spite of the fact that affected animals often are completely anorectic and febrile and look very ill, most cases of pharyngeal puncture or laceration resolve successfully if the animal can be vigorously treated with broad-spectrum antimicrobial drugs for 7 to 14 days, if aspiration pneumonia can be controlled by limiting access to feed, and if adequate supportive care can be given. Tetracyclines, sulfas, ampicillin, ceftiofur, trimethoprim-sulfonamide (TMS), and florfenicol or penicillin plus an aminoglycoside have been used successfully. NSAIDs should be given for analgesia and for their ability to reduce inflammation. Oral administration of boluses should be avoided.

The animal should have access to water; if it cannot drink, a soft stomach tube should be used several times daily to gently administer a total of 30 to 50 L (8 to 13 gallons) of water plus electrolytes daily. The most important electrolyte to administer is potassium: 60 to 100 g of potassium chloride should be given daily with the water. Once the animal can drink without coughing or nasal reflux, soft green grass or a soft mash should be offered. If this is well tolerated, it should be continued for 2 weeks, after which green pasture or soft, green, leafy alfalfa hay or other equally palatable feed should be gradually and carefully introduced into the diet.

If a discrete retropharyngeal abscess forms, it is best first to attempt drainage into the pharynx through the original laceration by pushing a finger into the healing wound until pus escapes. If this fails, a surgical approach to the area may be necessary. Surgery is rarely required in cases of pharyngeal trauma or laceration with cellulitis.

Prevention and Control Careful use of balling guns, paste wormer guns, and other equipment that can damage the pharynx is the best prevention. Adequate restraint of the head of any animal that is to be orally treated also helps prevent pharyngeal trauma.

Bluetongue

N. James MacLachlan • Christie E. Mayo

Definition and Etiology Bluetongue is an arthropod-transmitted viral disease of domestic and wild ruminants.[1,2] Clinical disease is largely restricted to sheep and certain wildlife, but other ruminants, including cattle, may show disease in some circumstances. Cattle are considered to be especially important amplifying reservoir hosts of bluetongue virus (BTV).

BTV occurs throughout tropical and temperate regions of the world, where different constellations of BTV serotypes are transmitted by different species of *Culicoides* midge vectors in relatively distinct global "episystems."[3,4] Whereas infection often occurs year-round in tropical climates, it is distinctly seasonal in temperate areas, occurring only in the late summer and fall months, and bluetongue is usually manifest only in the temperate areas at the upper and lower limits of the global range of the virus. The global distribution of BTV has altered recently, perhaps as a consequence of the impact of climate change on the *Culicoides* midges that serve as biological vectors of the virus.[5-7] In particular, since 1998 multiple BTV serotypes spread throughout the Mediterranean Basin and, in 2006, additional virus serotypes invaded and spread throughout extensive portions of northern Europe to precipitate an economically devastating epidemic.[8] Coincident with this invasion of multiple serotypes of BTV into Europe, at least 10 novel BTV serotypes have also appeared in the southeastern United States.[2,9]

Although BTV has now been isolated from ruminants and/or *Culicoides* midge vectors from all continents except Antarctica, the international movement of ruminants is highly regulated, and often severely restricted, for fear of importing BTV into free countries or regions.[10] The continuing occurrence of disease outbreaks globally, the wide host range, the potential for establishment of endemic infection (as has recently occurred in extensive portions of Europe that previously were free of the virus), and the similarity of some signs of bluetongue to those of vesicular diseases have all made BTV infection the subject of intense regulatory interest worldwide. Import regulations promulgated in reaction to the disease have been more of a threat than the disease itself to the livestock industries of some countries.[11]

BTV is the prototype virus in the genus *Orbivirus* within the family Reoviridae.[12] Other closely related viruses in this genus include epizootic hemorrhagic disease of deer and African horse sickness viruses. The genome of BTV includes 10 distinct segments of double-stranded RNA, each of which encodes at least one protein. The serologic classification of BTV into serotypes is based largely on the protein product of just one genomic segment (the *L2* gene that encodes the VP2 outer capsid protein), but virulence and other characteristics of individual virus strains may not be related to this protein. There is marked genetic variation among field strains of BTV, even viruses of the same serotype and from the same region.[13] The genetic diversity and heterogeneity of field strains of BTV arises as a consequence of both genetic shift and drift. Specifically, genetic shift occurs by reassortment of the individual viral gene segments during infections of cells with more than one virus serotype or strain. Individual genes also evolve by genetic drift during alternating replication in the insect and animal hosts of the virus.[14]

The genetic determinants of BTV virulence are uncertain. At least 26 BTV serotypes are recognized worldwide, but virus strains of the same serotype may have markedly different virulence even to highly susceptible ruminants.[1,2,10,15] For example, BTV serotype 8 is present in the Caribbean Basin where it has not been associated with major outbreaks of disease, whereas the strain of BTV serotype 8 that incurred recently into northern Europe was highly pathogenic and caused significant production loss and mortality in a variety of livestock species, including cattle.[3,8,15]

Clinical Signs and Differential Diagnosis Clinical bluetongue disease is manifested in two ways: (1) reproductive syndromes and (2) bluetongue per se, a systemic hemorrhagic viral fever that affects multiple organs but especially the upper gastrointestinal tract, skin, and lungs.[1,2,15] Sheep most commonly are affected, particularly European fine-wool breeds such as the merino and crosses thereof. Bluetongue also occurs in cattle, goats, and South American camelids, but less commonly than in sheep and only after infection with especially virulent virus strains.

In susceptible sheep, the first clinical signs of bluetongue appear after an incubation period of 3 to 7 days or sometimes longer. These signs include a transient fever (up to 41.1°C [106°F] or higher); edema of the face, lips, muzzle, and ears; excessive salivation; and hyperemia of the oral mucosa (Fig. 32-87). Affected sheep usually produce a profuse serous nasal discharge that becomes mucopurulent after a few days, leaving crusts around the nostrils and muzzle. The

VetBooks.ir

FIG. 32-87 Face of a sheep with severe bluetongue; note submandibular edema and hyperemia and cyanosis of the lips and tongue (bluetongue).

tongue may be cyanotic (hence the name), although this is a relatively infrequent manifestation. The oral lesions progress to petechial hemorrhages, erosions, and ulcers, which are especially prominent on the dental pad and the commissures of the mouth. The oral lesions can be sufficiently painful that animals will not eat, and severely affected sheep will stand over water without drinking. Lameness and stiffness caused by coronitis and myopathy can be severe, and the coronary band characteristically shows petechial hemorrhages and hyperemia. Hemorrhages also may be evident in the subcutis of nonhaired skin such as the inguinal region. Lameness may progress to "knee walking" or recumbency. The hooves may slough, and breaks in the wool are common. Diarrhea, with or without blood, can occur. Many sheep become depressed, are unable to rise, and die, but some severely affected sheep make a full recovery. Pulmonary edema is often marked, especially in fatal cases, and some cases appear to livestock owners to be pneumonia. Indeed, acute secondary bacterial bronchopneumonia is often superimposed on the characteristic pulmonary edema of bluetongue. Cardiac necrosis may result in sudden death at any time, even in an animal that appears to be recovering. Although the lesions and signs of bluetongue are characteristic, as is the seasonal occurrence of disease in temperate regions such as much of the United States, the differential diagnosis for sheep showing some of these signs includes sore mouth (contagious ecthyma), foot-and-mouth disease (FMD), peste des petits ruminants (PPR), and sheeppox.

The reproductive and teratogenic effects of BTV in sheep and cattle vary depending on the virus strain, the host, and other factors. Reproductive effects, including abortions, stillbirths, and weak but live "dummy lamb" births, were profoundly evident when live attenuated vaccine was administered to pregnant ewes in California in the 1950s.[16] In South Africa, where BTV infection has been recognized as endemic since the first descriptions of the disease before 1900, teratogenic effects have not been commonly linked to the virus despite the use of polyvalent live attenuated vaccines and nearly continuous exposure to the virus.[1] However, fetal infections were clearly documented in cattle after these same vaccines were introduced into Europe recently and, furthermore, it was unquestionably established that these vaccine viruses also circulated naturally after they were introduced into Italy.[17] With the notable exception of circulation of live attenuated vaccine viruses, abortion and teratogenic defects are uncommonly associated with natural BTV infection of livestock in endemic areas.[18] However, major outbreaks of abortion have occurred following the introduction of virulent BTV into immunologically naive populations of sheep. Furthermore, the strain of BTV serotype 8 that was responsible for the recent epidemic in northern Europe crossed the placenta in a substantial proportion of pregnant ruminants, including cattle.[8,15] Some have questioned whether this remarkable property of this northern European strain of BTV-8 might imply that it was, at some time in its history, propagated in cell culture, as is done with live attenuated vaccine viruses.

Clinical disease is uncommon among cattle infected with most virus strains, particularly in BTV-endemic areas.[1,2,10] However, as evidenced emphatically by the recent BTV-8 epidemic in northern Europe, disease certainly can occur in BTV-infected cattle. Severely affected cattle exhibit many of the same signs as do affected sheep. Excessive salivation may be the first clinical sign. Hyperemia and necrosis of the muzzle ("burnt muzzle") and a patchy dermatitis may also occur, along with necrosis of the skin of the teats. In cattle, depending on which signs are exhibited, the differential diagnosis should include mucosal disease (BVD), malignant catarrhal fever (MCF), vesicular diseases, rinderpest (RP), photosensitization, bovine papular stomatitis (BPS), and infectious bovine rhinotracheitis (IBR). Clinical disease in cattle can also be difficult to distinguish from FMD and vesicular stomatitis (VS), and appropriate regulatory officials should be notified in such outbreaks. Furthermore, recent outbreaks in the United States, North Africa, and the Middle East confirm that the related epizootic hemorrhagic disease virus can also cause a bluetongue-like disease syndrome in cattle that also mimics FMD.[19]

Ocular lesions occur in some BTV-infected ruminants. The syndrome was well characterized during the BTV-8 epidemic in northern Europe when calves infected transplacentally in late gestation developed transient corneal opacity (blue-eye) following ingestion of colostrum that contained BTV-8–specific antibody.[20] Similarly, non-African ungulates such as European bison at the Berlin zoo developed similar ocular lesions following BTV-8 infection.[21] "White eye calf" syndrome was described in Oregon in the 1970s and associated with BTV and/or epizootic hemorrhagic disease virus infection.[22] It may be that the lesions result from deposition of immune complexes in the eye, analogous to the immune complex–mediated uveitis that follows immunization of dogs with certain canine adenovirus vaccines.

Laboratory Diagnosis and Immunology Serologic diagnosis of BTV infection in livestock is routinely done by competitive ELISA that detects antibodies to the core VP7 protein of BTV. The test is highly sensitive and specific, and detects antibodies to most if not all BTV serotypes. These antibodies persist for long periods following natural infection, although it is not currently possible to distinguish animals that were naturally infected with BTV from those that were immunized with live attenuated vaccine. It is to be stressed that presence of antibody indicates only prior exposure to BTV and implies nothing about disease causality. Serotype-specific antibody is only assessed currently using laborious and expensive virus-serum neutralization assays.

Identification of BTV infection in animals is most readily accomplished using a group-specific quantitative polymerase chain reaction (PCR) assay. Such assays now are routinely available in diagnostic laboratories, and can identify all known serotypes of BTV. Furthermore, the amount of viral nucleic acid in the same can be quantitated, which can be useful in ascribing disease causality; specifically, acutely affected animals generally have large amounts of BTV nucleic acid in their blood and tissues, which is reflected by low cycle threshold (Ct) values on the assay. It is to be stressed that ruminants remain positive for BTV nucleic acid for up to 6 months or longer following infection, meaning that the mere detection of either viral nucleic acid by quantitative PCR or antibody to BTV by competitive ELISA is not proof of disease causality. Serotype-specific PCR assays can be used to serotype the virus present. The availability of these assays has largely obviated the need for virus isolation, which is cumbersome, laborious, expensive, and takes several weeks typically. Virus isolation also requires specialized laboratory facilities as some virus strains require initial propagation in embryonated chicken eggs before they will grow in cell culture systems.

The development of immune tolerance to BTV (in utero infection producing antibody-negative, virus-positive individuals), as happens in BVD infections, now is regarded as unimportant to the natural

VetBooks.ir

epidemiology of BTV infection although some controversy persists.[15] It is to be stressed that fetuses infected with BTV in late gestation are born viremic and, potentially, before they have had the time necessary to develop an immune response; the fact that these animals are born viremic (virus positive) and antibody negative should not erroneously be interpreted to mean that they are immunologically tolerant.

Pathophysiology Bluetongue is proposed to be a hemorrhagic viral fever analogous to viral hemorrhagic fevers of humans like Ebola.[15,23] Specifically, BTV replicates within the endothelium and mononuclear phagocytic cells of infected animals. Vascular injury, particularly to small vessels, is responsible for the manifestations of clinical bluetongue disease. Release of cytokine and vasoactive mediators from infected cells leads to capillary leakage and, subsequently, the edema and hemorrhage that is characteristic of fulminant cases. Direct virus-induced vascular injury leads to thrombosis and subsequent infarction of tissues, causing ulcers and manifestations such as the characteristic cyanotic (infarcted) tongue in some severely affected sheep. Teratogenic effects result from direct virus-mediated destruction of proliferating progenitor cells within the central nervous system of the developing fetus, following transplacental transmission of the virus in pregnant ruminants. Teratogenic defects occur only when the fetus is infected at critical stages of organogenesis, which is prior to midgestation (approximately 150 days in cattle and 70 days in sheep). Transplacental infection soon after conception can lead to early embryonic death and infertility.

Epidemiology The development of clinical bluetongue disease is the product of a complex interaction among host, virus strain, vector, and environmental influences.[1,2,10] For example, many of the virus strains that circulate in endemic areas such as California are mildly pathogenic for livestock in the region. Epizootics typically occur when a new virus strain or new animals are introduced into a previously stable ecosystem, as occurred, for example, with the introduction of a highly virulent strain of BTV serotype 8 into northern Europe in 2006.[8] In addition to sheep, this virus caused serious disease in cattle, South American camelids, goats, non-African wild ungulates such as yaks and European bison, and even some carnivore species.[21] Environmental alterations that favor the proliferation of midge vectors in a region also potentially can facilitate disease epidemics.

BTV infects wild and domestic animals primarily through the bite of the vector midge of the genus *Culicoides*. There are over 1400 *Culicoides* species globally; however, only a few have been identified as BTV-competent vectors.[1-6,10] In temperate regions of the world, *Culicoides* midges are abundant in midsummer to early fall, and outbreaks of bluetongue in livestock occur during this time when temperatures support both midge activity and BTV replication within the vector. Other routes of virus transmission are possible even during the interseasonal period in temperate regions (winter, spring, and early summer). For example, it has been shown that BTV can be spread to newborn ruminants via the ingestion of infective colostrum.[24,25] Lastly, although BTV can be transmitted sexually in infected semen and transplacentally from dam to offspring, the importance of these potential routes of virus transmission remains conjectural and they are unlikely to have any major role.[15] Specifically, animals infected in early gestation develop teratogenic brain defects and have cleared infectious virus by the time of birth. Those fetuses infected in late gestation can certainly be born viremic and potentially contribute to virus amplification and circulation. Embryo transfer currently is not viewed as a significant risk of BTV transmission provided that the embryo is washed at least 10 times. In summary, dissemination of BTV by vector *Culicoides* midges is by far the most common method of transmission in endemic areas.

In much of North America, the prevalence of bluetongue closely mirrors the distribution and abundance of *Culicoides sonorensis,* with lower rates in northern climates that are less hospitable to the midge and higher prevalence in California and other warmer southern regions.[3,4] However, the vector species in the southeastern United States where 10 additional serotypes of BTV recently appeared are less defined. Similarly, vector species other than *C. sonorensis* are important elsewhere in the Americas as they are in different regions of the world. In the absence of competent vector populations, animal-to-animal transmission appears to be incapable of maintaining endemic BTV infection; thus BTV serotype 8 has quickly disappeared from most of northern Europe.

It remains uncertain as to how BTV is maintained (over-wintered) in temperate areas where infection is highly seasonal.[2,10] Although viremia can be prolonged in both cattle and sheep, BTV infection is not persistent in domestic ruminants and insufficient to sustain the virus through the several months of the over-wintering period (approximately December through June in the northern hemisphere). Infection of vector midges is persistent and life-long; however, the lifespan of midges is relatively short so that it is unlikely that infected individuals could survive the entire over-wintering period. A plausible scenario is that a low-level cycle of infection between the animal and insect hosts of the virus or, alternatively, that vertical transmission of BTV occurs in vector *Culicoides* midges. There is no evidence to date that the latter occurs.

The severity of clinical signs in BTV-infected sheep varies by breed. Early in the history of the bluetongue investigation, it was noted that African breeds showed few if any signs of infection, whereas imported European breeds showed fulminant disease.[1,2] More recently, breed differences in immunologic response and susceptibility to disease expression following vaccination with live attenuated BTV vaccine have been reported.[26]

Necropsy Findings The lesions of bluetongue are characteristic, particularly in sheep.[1,15,27] These include ulcers and hemorrhage throughout the oral cavity, including the dental pad and tongue, which may extend from the esophagus into the forestomachs; coronitis; subcutaneous hemorrhages and edema, along with edema between the fascial planes of the neck and abdominal musculature; pulmonary edema; hemorrhages on the endocardial and epicardial surface of the heart and pulmonary artery; and necrosis of both skeletal and cardiac muscle. Especially characteristic lesions include gelatinous edema around the nuchal ligament (in addition to the other sites previously listed), subintimal hemorrhages in the pulmonary artery, and discrete focal areas of acute myocardial necrosis in the papillary muscle of the left ventricle. Microscopically, there is cuffing of inflammatory cells around small vessels in the affected skin and gastrointestinal mucosa with pronounced hypertrophy of the endothelium lining affected vessels, acute and focally extensive necrosis with the musculature of the heart and some skeletal muscles, and pulmonary edema.

Treatment, Prevention, and Control Treatment of bluetongue in affected ruminants is nonspecific and aimed at supportive and nursing care. Animals with severe oral lesions are reluctant to eat or drink. Valuable animals can be fed gruels of alfalfa pellets by stomach tube and can be encouraged to eat soft feeds or green grass. Muscle and coronary band pain may limit mobility; therefore water and shade must be close at hand. Sulfas or other relatively broad-spectrum antimicrobial drugs can be administered in an attempt to prevent or treat secondary bacterial pneumonia. NSAIDs, including aspirin and flunixin, are commonly used.

Elimination of *C. sonorensis* from the environment usually is not practical, but housing sheep indoors during the peak of activity (dusk, early evening) to minimize exposure to biting midges may be beneficial. Grazing wet areas such as irrigated pasture only during the heat of the day also may help, as most insects are not active in extreme temperatures. Midges that feed on ivermectin-treated cattle are killed, but the exchange of virus may be made before the insect's demise. *C. sonorensis* larvae develop in fine-grained mud with high organic matter content, such as around farm reservoirs, overflowing watering troughs, and shallow septic systems. Elimination of these breeding grounds combined with larvicidal treatments may help in some situations. Especially valuable animals can be housed in

VetBooks.ir

insect-protected enclosures to prevent any contact with vector midges during outbreaks, or they may be treated with repellants to minimize the likelihood of vector attack.

Both inactivated and live attenuated (modified live) BTV vaccines are available in some parts of the world, and these logically should be based on the local strains and serotypes.[1,2,28,29] Inactivated vaccines are inherently safer than live attenuated ones because the latter have the potential for transmission in nature, reversion to virulence, and the capacity to cross the placenta. There is little cross-protection between BTV serotypes, so animals need to be vaccinated against all serotypes of the virus circulating in a given region. Live attenuated vaccines to BTV serotypes 10, 11, and 17 are available in California from the California Woolgrowers' Association, but not to BTV serotype 13 that also is present in California.[25] These vaccines should be given at least 2 weeks before breeding season to avoid teratogenic effects, and vaccination should be done prior to the seasonal period of virus transmission (late summer and fall) to avoid infection of vectors and so minimize the likelihood of recombination of vaccine and field viruses. Pregnant ewes in late gestation may be vaccinated, but there is some risk of inducing abortion; vaccine should not be administered in early or mid-gestation because of potential teratogenic defects. Vaccinated breeding rams may have some risk of transiently decreased fertility. Vaccinated and naturally infected animals cannot readily be distinguished by current serologic diagnostic tests. New-generation BTV vaccines have been developed, including vectored recombinant vaccines, and in addition to being very safe, these vaccines also have the potential to distinguish vaccinated and infected animals (so-called DIVA).[30]

Contagious Ecthyma (Sore Mouth, Orf, Contagious Pustular Dermatitis, Scabby Mouth)

Bradford P. Smith*

Definition and Etiology Contagious ecthyma (CE) (sore mouth, orf, contagious pustular dermatitis, scabby mouth) is a common disease of sheep and goats that is transmissible to humans and has a worldwide distribution. The disease has a short 2- to 14-day incubation and tends to be more severe in goats, with Boer and Boer cross goats most likely to have severe generalized infections with proliferative dermatitis, chronic pneumonia, arthritis, and lymphadenopathy.[1] A good review of human lesions was published in 2005.[2] The colloquial name *sore mouth* describes the most common presentation of the disease in sheep and goats; the name *orf* (possibly from the old Norse term *hrufa,* meaning a crust or scab) is more commonly used for the disease in all species in England and for human disease in the United States. The agent is a DNA poxvirus of the parapoxvirus subgroup, which includes the closely related viruses pseudocowpox (another cause of orflike "milker's nodules" in humans), the agent of bovine papular stomatitis (BPS), parapoxvirus of red deer in New Zealand, squirrel parapoxvirus, and parapoxvirus of gray seals. Biological and genetic differences exist among strains of CE virus, so that cross protection may be limited and vaccines need to target the field strain. Wild ruminants (reindeer, musk ox, and others) and camels are also affected. A study demonstrated that the sheep orf virus does not cause lesions in camels, and vice versa, so it is likely that no infection is transmitted between camels and sheep or goats. The virus is epitheliotropic, usually creating proliferative lesions in the skin of the lips, nostrils, oral mucosa, teats, and occasionally the vulva.

Clinical Signs and Differential Diagnosis The most common presentation is of a young animal with crusting, proliferative lesions of the mucocutaneous junctions of the mouth and nose

*Paul G.E. Michelsen contributed to writing this chapter in previous editions. His contribution to this section is acknowledged.

FIG. 32-88 Typical scabby lesions of contagious ecthyma (sore mouth, orf) on the lips of a young goat. Lesions tend to be proliferative rather than ulcerative.

FIG. 32-89 Typical proliferative lesions of contagious ecthyma (sore mouth, orf) on the gums of a young sheep.

(Fig. 32-88). Proliferative lesions may be seen on the gums (Fig. 32-89). Older immunologically naive animals may be affected, and lesions may occur at the coronary band, on the tongue, interdigitally, on the conjunctiva of the eye, on the external genitalia, or on the udder or teats, with the last site affected especially in does or ewes nursing affected kids or lambs. The disease progresses through papular, vesicular, and pustular stages, which are rarely seen, before the characteristic presentation of proliferative, coalescing, scabbed lesions appears. One recent report described the characteristic proliferative scabs on the margins of healing burn wounds. Affected animals may be reluctant to nurse, eat, walk, or be nursed, depending on the location of lesions. Secondary bacterial infection or myiasis of affected parts may occur. The disease usually runs its course in 3 to 6 weeks, but chronic cases have been reported. Complete healing without scarring is the norm as scabs fall off. Severe infections may result in stunting of growth, particularly in goats. Overwhelming infection has been noted on rare occasions, with extension of lesions into the deeper respiratory or gastrointestinal tracts. Does and ewes with severe udder infection may develop mastitis from secondary bacterial infection. Sheeppox and goatpox may occasionally produce lesions similar to those of CE, but they are virulent diseases with systemic signs, including conjunctivitis, pyrexia, anorexia, and rhinitis. One report from China describes an outbreak in goats consisting of mixed infections with goatpox, orf, and *Mycoplasma capripneumoniae,* resulting in a 60% mortality rate.[3] Animals with bluetongue may have a crusted mouth and nose and eye lesions in the

VetBooks.ir

convalescent phase, but bluetongue is a disease with more evidence of oral erosive rather than proliferative lesions and systemic signs, including pyrexia, reluctance to move, lesions on the tongue, and conjunctivitis. Bluetongue has a seasonal incidence (late summer, early fall) that coincides with the activity of its insect vector. CE may be seen at any time but typically occurs in spring in the lamb or kid crop. Ulcerative dermatosis (lip and leg ulcer) is an uncommon disease caused by a virus similar to that of CE, but the lesions are crusted ulcers, to be distinguished from the crusted proliferations of CE. The author has observed a series of cases of what appeared to be mild CE of long duration (several years in one individual) in a family of Nubian goats; this was confirmed by an immunofluorescence assay. Smith and co-workers reported on five sheep, 4 months to 3 years of age, that developed severe refractory distal limb lesions resembling warts. Two also had lesions on the head. The sheep were from three different flocks; one was a Hampshire and four were Suffolk. Lesions were confirmed as orf by electron microscopy and immunohistochemistry.[4] A report from Texas describes severe multifocal persistent orf lesions in 16 Boer or Boer cross-bred goat kids 2 to 5 months of age, from two different farms. Some of the kids had been vaccinated with live-virus vaccine at 1 day of age, others at 2 weeks of age. Lesions were found on lips, nose, ears, body, legs, and feet.[5]

Laboratory Diagnosis The diagnosis usually is made in the field by recognition of the typical lesions in a naive flock or in a naive group (young lambs or kids) in a disease-endemic flock. Definitive diagnosis usually involves identifying the distinctive cross-hatched virus particles in typical early lesions with electron microscopy, PCR, immunohistochemistry, or inoculation into known protected or susceptible animals. Minced biopsy tissues have been used as a source of virus that is identified by fluorescent antibodies after it has been growing in embryonic ovine kidney cell cultures. Complement fixation (CF) tests to detect antibodies (using patient serum) or antigen (using vesicular fluid or a suspension of scabs) have also been used.

Pathophysiology The disease follows a similar time course in animals and human beings—approximately 6 weeks. Six stages have been described,[6] which begin after an incubation period of 3 to 14 days. Each stage lasts approximately 1 week.

1. *Maculopapular stage:* An erythematous spot becomes elevated. Histologically this stage shows vacuolization of cells in the upper one third of the epidermis with intracytoplasmic eosinophilic inclusions in the affected cells.
2. *Target stage:* A red halo of dilated blood vessels and inflammatory cell infiltrates surrounds a white ring of vacuolated epidermal cells with intracytoplasmic and intranuclear inclusions, which surrounds a red center of pyknotic epidermal cells.
3. *Acute stage:* The lesion is a red, weeping nodule. Microscopically there is reticular degeneration of the epidermis with vesicles. The dermis is infiltrated with macrophages and lymphocytes and is denuded of epidermis in places. The hair follicles are distended with pyknotic epidermal cells.
4. *Regenerative stage:* The nodule is now dry with small black dots (the pyknotic follicle cells, now extruded to the surface) in a thin yellow surface.
5. *Papillomatous stage:* The surface of the nodule is roughened with papillomas, which microscopically prove to be fingerlike, downward projections of epidermis through a full thickness of dermis.
6. *Regressive stage:* The lesion decreases in size and elevation above the surface, the papillomas regress, and several crusts may come off. Microscopically the papillomas and infiltrates regress, leaving normal architecture.

Orf virus encodes for a protein that is apparently homologous to mammalian vascular endothelial growth factors. This family of molecules mediates vascular permeability, angiogenesis, and endothelial cell proliferation, which may account for the swollen, proliferative nature of orf lesions.[7] Transient fever and lymphadenopathy are occasionally seen in humans. Lesions in humans that are not biopsied or excised heal without a scar.

Orf virus encodes a range of immunomodulatory genes that interfere with host antivirus immune and inflammatory effector mechanisms, allowing time for virus replication in epidermal cells.

Epidemiology The naturally occurring disease is primarily one of sheep, goats, and human beings, but it has also been reported in a variety of wild ruminants. Experimental transmission has been achieved in cattle, rabbits, horses, and monkeys. No naturally occurring clinical cases in these species have been reported. All ages and classes of sheep and goats are affected, and clinically normal sheep can infect naive individuals.[8] In herds and flocks in which the disease is endemic, it usually is seen in the lamb or kid crop and on the udders and teats of some of the nursing mothers. Animals that have had a bout of disease are solidly immune for 1 to several years, but morbidity is high (often 80%) among naive individuals. Humans are infected through contact with affected animals or fomites that have contacted affected animals (including one report of transmission by a pickup truck that had been used to haul sheep).[6] Effective disinfectants include hypochlorite, alkalis, Virkon, and glutaraldehyde. Human-to-human transmission can occur. Mortality is low among animals except when young individuals are severely affected and quit nursing or have mothers with severe udder lesions. Overwhelming infections are rare except in Boar or Boer cross goats, but some outbreaks are more severe than others.

The virus is quite resistant to many environmental conditions and persists from year to year on infected premises. Dried scabs allow the virus to persist for years, but wet conditions are less hospitable to it. Reports of persistently infected sheep point to another possible source of infection in wet climates.

Treatment, Prevention, and Control The infection usually is self-limiting and of minor consequence. Young individuals may need to be tube-fed if the lesions are severe enough to preclude suckling. Secondary infections, myiasis, or mastitis may be treated with topical disinfectants, antibiotics, or insecticides as appropriate. The hard crusts should not be removed, because doing so may delay healing and promote scarring. Also, humans should limit contact with affected animals and should wear gloves when handling them is necessary. Anecdotal reports, each consisting of one case, have claimed good results for treatment of human orf with intralesional corticosteroids, interferon (IFN), idoxuridine in DMSO, diethyl ether, or cryotherapy. An immunosuppressed human with a huge orf lesion on the finger was successfully treated with topical cidofovir antiviral cream. Similar good results were obtained in a group of 12 severely affected, bottle-fed lambs with painful intraoral lesions. The proliferative tissues were débrided and cauterized with a portable diathermy unit. The exposed submucosa was then frozen twice with liquid nitrogen spray. Healing occurred by second intention, with rapid recovery of affected lambs.

The infection is prevented by maintaining a virus-free herd or flock by not introducing or contacting infected individuals. Lesions often are not apparent on carriers.[8] Once established, the disease is persistent on the premises because of virus in scabs. Vaccination should be undertaken only if the infection is persistent, because the vaccine consists of virulent live virus. Vaccination can also be achieved with dried scabs from the previous year's outbreak because there are distinct antigenic differences among orf viruses[9]; the scab material is rubbed into scarified skin in an inconspicuous location (inner thigh, under the tail, in the axilla). A localized inflammatory reaction at the site 1 week after vaccination indicates a successful inoculation. Infected or vaccinated animals should not contact unexposed animals until the lesions have healed. Lambs born to immunized ewes may not be protected by colostral antibodies even though their levels of antibody postsuckling are high[10]; this points to the importance of cell-mediated immunity in protection from the disease. Lambs should be vaccinated at 6 to 8 weeks of age and are immune 3 weeks later. Yearly vaccination of the new lamb or kid crop

and new additions to the herd using farm-specific strains of orf should prevent devastating outbreaks on infected farms. At a minimum it appears that goat isolates should be used for kids and sheep isolates used for lambs.[9,10,11]

Bovine Papular Stomatitis (Proliferative Stomatitis)

Bradford P. Smith

Bovine papular stomatitis (BPS) is a disease principally of young cattle caused by a parapoxvirus closely related to CE and pseudocowpox. There are many similarities among BPS, CE, and pseudocowpox, and they may indicate a single virus adapted to different species.[1] There are as many antigenic differences among strains of BPS as among BPS, CE, and pseudocowpox.[1] Local strains therefore are recommended for vaccination. Infection usually is asymptomatic, but lesions consisting of raised papules may be noted on the muzzle, nose, oral mucosa (particularly the hard palate), or esophagus, where they are important differential diagnoses for lesions caused by VS, FMD, and BVD. In young feedlot cattle, 2- to 10-mm lesions of BPS are common for the first 4 weeks after arrival.[2] Morbidity may approach 100%. BPS may also occur as a chronic disease in young cattle.[3] It may be the same disease as proliferative stomatitis, muzzle disease, mycotic stomatitis, erosive stomatitis, ulcerative stomatitis, and necrotic stomatitis.

Ulcerative esophagitis caused by BPS virus in a 5-month-old, unthrifty calf was associated with a 20% morbidity rate in a group of 25 calves.[4] Outbreaks of severe disease associated with BPS with a mortality rate over 50% have been reported. Weight loss and diarrhea accompanied by papular lesions are commonly associated with the severe syndrome. Many lesions are erosions or shallow ulcers with elevated borders, whereas others are obvious raised papules. Lesions are found in the mouth, esophagus, and rumen. There are no lesions on the feet. BPS is commonly seen in calves 1 to 12 months of age and is rare in adult cattle, but outbreaks of confirmed BPS in Brazil and Japan involved the teats of dairy cows as well as the hands of milkers.[5,6] A confirmed case of severe esophageal lesions in an adult bull that died after 2 months has also been reported.[7] The disease is spread by animal contact and appears to be worldwide in distribution.

The first evidence of the disease is the appearance of 2- to 4-mm hyperemic foci, most commonly in the ventral margins of the nares. Similar lesions next appear in the mouth. Within 18 hours they become raised papules. Some lesions enlarge to form raised plaques over 1 cm in diameter. Lesions regress in 1 day to 3 weeks, leaving a yellow, red, or brown spot that persists for several weeks more.[8] Secondary lesions come and go, with some calves being visibly infected for 4 months.[8] Most animals have no fever or obvious clinical signs, and they continue to eat normally. Leukopenia was not seen in experimentally infected calves.[8] Secondary lesions appear to be spread through the blood; intravenous inoculation results in similar upper alimentary tract lesions.[9]

Histologic lesions consist of hydropic degeneration of the epithelial cells of the oral mucosa, hyperplasia of the papillae of the lamina propria, and eosinophilic inclusions in the cytoplasm of the degenerating epithelial cells. Lesions reaching the ulcerative stage show secondary necrosis, bacterial invasion, and sloughing of epithelium.

BPS has been associated with the "rat tail" syndrome of feedlot cattle.[10] Thirty-six of 84 Texas feedlots reported the problem, with a morbidity rate of 1% to 10%. The syndrome consists of diarrhea, salivation, poor weight gain, and loss of hair from the end of the tail. Sarcocystosis has also been mentioned in association with "rat tail" syndrome.

BPS is capable of causing painful proliferative lesions in human beings.[11] The lesions resemble those caused by CE or pseudocowpox. Most often the affected individual has a recent history of examining the mouths of cattle, often with cuts or abrasions on the hands. Lesions in humans apparently are limited to the primary site of inoculation on the hands.

Although ovine ecthyma vaccines are commercially available, no vaccine is marketed for protection against BPS. Local strains of parapoxviruses would be most likely to be more protective than commercial vaccine strains.

Diseases Caused by Bovine Virus Diarrhea Virus

Paul H. Walz

Definition and Etiology Infections with bovine virus diarrhea virus (BVDV) are endemic worldwide, and bovine virus diarrhea is recognized as one of the most important infectious diseases of cattle. Although the definition of the virus and its associated disease implies alimentary tract disease in cattle, BVDV is a pathogen capable of infecting other ruminants and pigs, and affecting multiple physiologic systems, including the reproductive, respiratory, circulatory, immunologic, integumentary, musculoskeletal, and central nervous systems.[1] Reproductive losses and respiratory tract disease are the most important economically, and infection of the reproductive system is critical to maintenance and transmission of BVDV within and among cattle populations through the generation of persistently infected (PI) offspring.[2] Infection of pregnant cattle prior to day 125 of gestation can result in the birth of calves that are immunotolerant to and persistently infected with BVDV.[3] PI calves are the most significant reservoir of BVDV and are at risk for the sporadically occurring, usually fatal mucosal disease.

BVDV is the prototypic member of the genus *Pestivirus* within the family Flaviviridae.[4] The pestiviruses are enveloped, single-stranded, positive-sense RNA viruses. Currently, the genus *Pestivirus* contains four recognized species, which include the two genotypes of BVDV (BVDV-1 and BVDV-2), classical swine fever virus and border disease virus.[4] Genetically distinct pestiviruses that have not yet been designated as species are also described and include Giraffe virus, Bungowannah virus, Pronghorn virus, and HoBi-like viruses. The HoBi-like viruses, which are also referred to as BVDV-3 or atypical pestiviruses, have received considerable attention because of their recent emergence and spread across multiple areas of the world purportedly via contaminated fecal calf sera.[5] So far, the HoBi-like viruses only appear to infect ruminant hosts, specifically cattle and water buffalo.[5]

Similar to many RNA viruses, mutations can occur within BVDV genomes leading to genetic, antigenic, and pathogenic variation. BVDV exists as a quasispecies, which are different but closely related mutant viral genomes subjected to continuous competition and selection. Nucleotide sequence differences are the most reliable criteria for differentiation of BVDV species. Subgenotypes of BVDV are described within BVDV-1 and BVDV-2 species, 12 among BVDV-1 viruses (BVDV-1a through BVDV-1l)[6] and 2 among BVDV-2 viruses (BVDV-2a and BVDV-2b).[7] Within the United States cattle population, there are three major subtypes, BVDV-1a, BVDV-1b, and BVDV-2a, with the BVDV-1b subtype predominating from diagnostic laboratory submissions and PI prevalence studies, accounting for 78% of bovine persistent infections in one North American study.[8] Predominance of the BVDV-1b strains in North America is noteworthy because most vaccines licensed and marketed in the United States contain BVDV-1a and BVDV-2 strains.[9] Strains of BVDV can also be further subdivided into cytopathic (CP) or noncytopathic (NCP) biotypes based on their effect on cultured cells, with CP strains causing vacuolation and death of cultured cells. The effect of the virus in cultured cells does not correlate with virulence, as NCP BVDVs are associated with cases of severe clinical disease, and only NCP strains of BVDV have been demonstrated, both naturally and experimentally, to induce persistent infection.[10] The NCP biotype predominates in the cattle population, accounting for approximately 65% to

VetBooks.ir

VetBooks.ir

90% of BVDV isolates.[11] The NCP biotype is often the source for CP strains, which arise by mutations and recombination in the NCP strain.

Epidemiology

PREVALENCE. BVDV is distributed in cattle populations throughout the world as indicated by serologic surveys that test for the presence of neutralizing antibodies to the virus. Exposure to PI animals or vaccination against BVDV can result in a seropositive animal within a population. Prevalence of seropositive cattle varies among countries, ranging from 13% to 90% of cattle surveyed.[12] Differences in seroprevalence rates among countries largely depend on the management of cattle populations examined. Use of vaccines, open versus closed cattle production units, population densities, indoor versus pasture housing, communal grazing, and presence of PI animals will greatly influence prevalence of seropositive cattle. Surveys in North America have indicated overall seropositive rates of 40% to 90%.[13,14] In contrast, the prevalence of PI cattle is much lower and is generally believed to be between 1% and 2% of all cattle. In randomly selected beef herds in five U.S. states, an individual animal prevalence and a herd prevalence of BVDV persistent infection were 0.17% and 2.7%, respectively.[15] Other PI prevalence studies in beef cow-calf operations within more geographically focused areas within the United States have demonstrated rates between 0.09% and 1.7%[14,16,17]; however, not all studies used randomly selected herds and this factor can impact prevalence rates considerably. Surveys conducted on U.S. dairy operations have demonstrated individual animal prevalence rates of 1.9%[14] and 0.13%.[18] PI cattle can be found in clusters within groups of cattle as a result of BVDV exposure in pregnant cattle at similar gestation, and this can elevate the prevalence within a studied population.[15,18] Although it is generally believed PI calves have poor survivability, PI animals can survive to adulthood, become pregnant, and give birth to PI offspring. Of PI calves identified from randomly selected beef herds, 61% survived to weaning and thus were capable of providing a source of virus throughout the breeding season and early gestation.[15] The prevalence of PI calves arriving at U.S. feedlots has been demonstrated to be between 0.1 and 0.3%,[19,20] and this PI rate in feedyards is similar to the 0.17% reported for U.S. beef cow-calf operations.[15]

HOST RANGE. Cattle are considered the natural host for BVDV; however, BVDV does not possess strict host specificity.[21] Historically, pestiviruses were assigned according to the species from which they were isolated, with BVDV, classical swine fever virus, and border disease virus isolates being recovered from cattle, pigs, and sheep, respectively. Through serologic evidence, BVDV infections have been identified in more than 50 species within 7 of the 10 families of the mammalian order Artiodactyla.[22-24] Species other than cattle that have been reported susceptible to BVDV infection include pigs, sheep, goats, bison, captive and wild cervids, and Old World and New World camelids.[21] Of the heterologous hosts, sheep and goats are considered to have high potential for BVDV infections because they are phylogenetically most closely related to cattle, and sheep and goats can have close contact with cattle under certain management conditions such as subsistence agriculture and hobby farming. Recently, alpacas and white-tailed deer have received attention as heterologous hosts for BVDV infections because of the identification of PI animals. Several cases of PI alpacas have been reported in North America and Great Britain.[25,26] PI alpacas can survive for several months, but low birth weights, failure to thrive, and chronic respiratory and gastrointestinal infections are described in PI alpacas.[27] The BVDV-1b strain is most frequently isolated from PI alpacas[25,28,29] and could be the result of introduction and intraspecific spread and maintenance of BVDV-1b into North American alpaca populations or that unique BVDV-1b subgenotypes are able to establish transplacental infections in alpacas.[26] A prevalence study on BVDV infections in alpacas was conducted in the United States, and 25% of herds tested had seropositive alpacas, with 6% of alpaca herds possessing a PI alpaca.[30] Other seroprevalence studies have been performed for alpacas, with rates less than 20% reported in both North and South America.[31,32]

Infection of wildlife with BVDV has been demonstrated by several serosurveys and, less frequently, virus identification in individual animals. The livestock-wildlife interface is of great concern for a number of infectious diseases, including the related classical swine fever virus in wild boars. Wildlife may become infected with BVDV, but other factors, including shedding of the virus, intrapopulation maintenance, and amount of interspecific contact may influence the establishment of BVDV wildlife reservoirs. Persistent infections of white-tailed deer with BVDV have been demonstrated by both experimental and natural exposure.[33,34] Similar to cattle, the most dramatic effects of BVDV infections in white-tailed deer involve the reproductive system. Shedding of BVDV through nasal or rectal routes has been demonstrated in acutely infected and PI white-tailed deer, and shedding has resulted in transmission to other white-tailed deer.[35,36] Apparent prevalence rates of persistent infections in U.S. cervid populations were between 0.03% and 0.3% in tested populations.[37-39] Whether the source for BVDV infection in these populations was contact with cattle or the result of an endemic cycle is unknown.

Identification of heterologous PI hosts may have important implications for the epidemiology of BVDV, as these nonbovid PI animals may serve as reservoirs for BVDV. As reservoirs, nonbovid PI animals could threaten the health and well-being of other artiodactyls, including cattle, and adversely affect outcomes and the ultimate success of organized BVDV control and eradication efforts.[40]

TRANSMISSION. Methods of BVDV transmission can be classified into vertical and horizontal transmission. With BVDV, horizontal and vertical transmissions are closely related, as horizontal transmission to a pregnant cow can result in vertical transmission to the developing fetus (Fig. 32-90). As stated previously, PI cattle can reach adulthood. Calves delivered from PI dams will themselves be PI; however, most PI offspring are the result of an acute infection, or horizontal transmission, in the dam.[15] Horizontal transmission of BVDV can occur continuously by PI animals and briefly by animals during an acute infection. As with other viral diseases, factors controlling BVDV transmission in a susceptible population are the infectiousness of the virus, the contact rate between infectious and susceptible animals, the duration of infectiousness, and the proportion of the population that is naive and susceptible.[41] Cattle PI with BVDV shed large amounts of virus their entire life and are the major source of BVDV transmission both within and among herds. These PI cattle are capable of shedding virus from nasal secretions, urine, feces, milk and colostrum, uterine fluids, saliva, tears, and semen.[42] Direct contact with these body fluids from PI cattle is the most efficient method of horizontal BVDV transmission, with inhalation and ingestion being the most common routes for transmission. While heterologous PI hosts are capable of shedding equivalent amounts of BVDV in nasal secretions as PI cattle,[34] they are assumed to play a reduced role in BVDV transmission because contact rates are less between infectious heterologous hosts and susceptible cattle. Acutely infected cattle also have a limited role in BVDV transmission because levels and duration of virus shed are considerably lower; however, potential for transmission of BVDV following acute infection can be greatly influenced by the virulence of the acutely infecting strain of BVDV, the proportion of naive animals being exposed, and the immune cross protection acquired either through vaccination or exposure to field strains of virus. Acutely infected calves will shed greater levels of virus and for a longer duration following an infection with a highly virulent strain of BVDV,[43] theoretically providing a source of transmission. However, an experimental study demonstrated no spread of infection from acutely infected to susceptible animals even though they were in close contact, further emphasizing the importance of virus and host characteristics during transmission.[44] Following acute BVDV infection, virus can be found in nasal secretions usually only for a few days between 4 and 10 days after exposure.

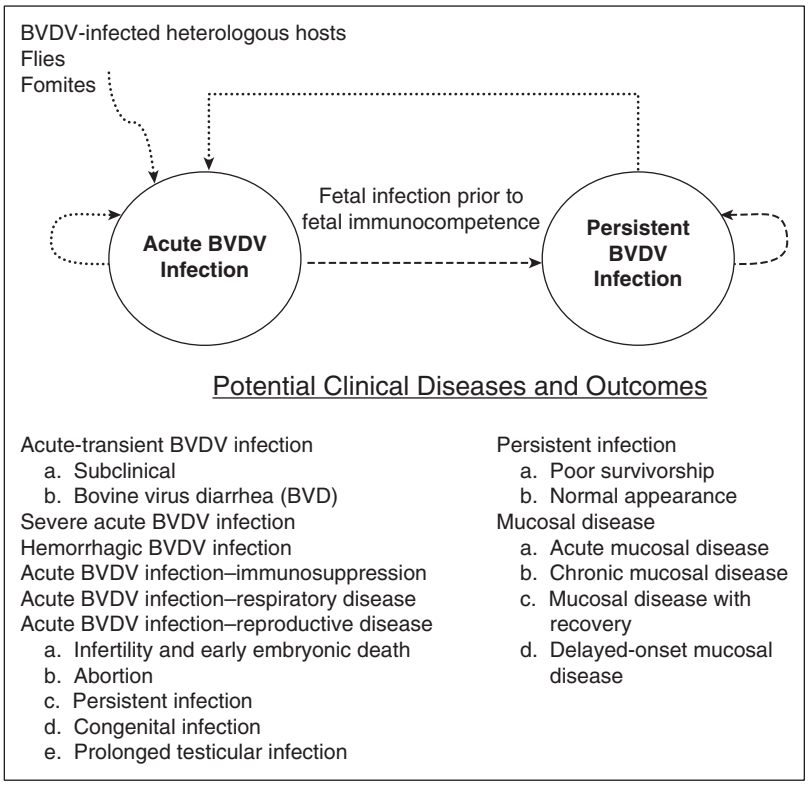

FIG. 32-90 Two forms of bovine virus diarrhea virus (BVDV) infection: acute and persistent. Routes of horizontal transmission are indicated by dotted lines (most important is from persistently infected [PI] cattle to naive cattle); routes of vertical transmission are indicated by dashed lines (most important is acute BVDV infection in pregnant cattle). Potential clinical diseases are not exclusive and multiple clinical forms can be observed in the same population of cattle.

Although contact with PI cattle is the most important source for BVDV transmission, infections with BVDV in the absence of PI cattle have been described in seronegative herds.[45] Spread of BVDV can occur in the absence of PI cattle as a result of direct contact with acutely infected animals, contact with heterologous hosts, or indirect contact. Being that BVDV is an enveloped virus, the virus is unstable at low or high pH and at high temperatures but can survive in a cool, protected environment for several weeks.[42] Temperature has a major influence on BVDV survival in manure slurry with virus infectivity remaining for more than 6 weeks at 5° C (41° F) but less than 2 weeks at 20° C (68° F).[46] On the basis of research with the related classical swine fever virus, BVDV is probably susceptible to common disinfectants such as chlorhexidine, phenols, iodophors, aldehydes, and hypochlorites.[47] Indirect transmission through contaminated needles and equipment and insect vectors has been demonstrated experimentally.[48,49] Insects such as stable flies, horse flies, and face flies can potentially serve as a source of BVDV infection[48,50]; however, the horn fly, which is a common fly species affecting cattle, was not able to transmit BVDV between PI cattle and BVDV-naive cattle.[51]

Bulls acutely and persistently infected with BVDV are capable of shedding virus in semen and have the potential for horizontal and vertical transmission.[52-54] The virus may survive cryopreservation and processing of semen for artificial insemination.[55] Although acutely infected bulls shed lower concentrations of BVDV in semen than do PI bulls, infection of artificially inseminated heifers may result from using semen from acutely infected bulls prior to seroconversion.[53] Prolonged, localized testicular infections have also been described following experimental BVDV infection of postpubertal bulls; however, their prevalence and epidemiologic significance are probably low.[56]

Herd-to herd transmission usually occurs through acquisition of PI cattle or pregnant cattle that are carrying a PI fetus. Cattle operations that have purchased cattle within the past 5 years are at highest risk for having PI animals.[57] Purchase of new cattle incubating an acute infection or exposure to other cattle through fence line contact, communal pastures, and animal exhibitions can also be a source of BVDV introduction into a herd.

Clinical Signs and Differential Diagnoses

BVDV infection in cattle may result in a complex spectrum of clinical manifestations ranging from subclinical to fatal disease. The virus is capable of infecting multiple organ systems, often with several organ systems involved concurrently.[9] Clinical manifestations are dependent on the interplay of host factors, environmental stress levels, and viral factors.[12] Host factors influencing the outcome of viral infection include immune status, pregnancy status, gestational age of the fetus at the time of infection, and whether the host is immunotolerant or immunocompetent. Viral factors include biotypic variation, genotypic variation, and antigenic diversity. When describing the clinical manifestations of BVDV infection in cattle, it is important to note that both BVDV-1 and BVDV-2 strains can be involved in the entire spectrum of clinical disease, including acute and persistent infections. Two states of infection (acute and persistent) are possible with BVDV infections in ruminants, and this will be the basis for discussion of clinical signs and pathogenesis within this text (see Fig. 32-90).

Disease Associated with Acute BVDV Infection

The terms *acute, primary,* and *transient* have all been used to describe BVDV infection in postnatal cattle, which possess the ability to respond immunologically to BVDV. Although postnatal cattle are able to respond immunologically to BVDV, immunosuppression induced by the virus is an important contribution to pathogenesis and clinical disease. For discussion of clinical disease states, acute BVDV infections can be further subdivided into six disease categories: acute-transient BVDV infection, severe acute BVDV infection, hemorrhagic BVDV infection, acute BVDV infection-immunosuppression, acute BVDV infection–respiratory disease, and acute BVDV infection–reproductive disease.[9,40]

ACUTE-TRANSIENT BVDV INFECTION. Acute-transient BVDV infection occurs in postnatal cattle. In most situations, the disease occurs in cattle considered naive to BVDV, but disease could potentially occur in cattle seropositive to BVDV that become infected with a heterologous BVDV strain. Most acute BVDV infections occur

VetBooks.ir

without clinical manifestations, with up to 90% of BVDV infections estimated to occur without clinical signs[12]; however, if cattle are observed closely, mild fever, leukopenia, and a decrease in milk production can occur. Exposed cattle develop BVDV-specific neutralizing antibodies. Even though BVDV infection may be subclinical, if the infected animal is pregnant, deleterious effects can be manifested in the fetus.

Bovine virus diarrhea (BVD) is the term used to describe the clinical form of BVDV infection in immunocompetent cattle and digestive tract disease manifested by severe diarrhea was part of the original description of BVD in 1946.[58] The incubation period for acute BVDV in naive cattle is 5 to 7 days. Following oronasal uptake, BVDV initially replicates in nasal mucosa and tonsils. Viremia will typically last for several days starting around day 3 after infection, but it can last for up to 15 days. During this period of viremia, spleen, thymus, lymph nodes, gastrointestinal epithelium, and the respiratory tract can become sites of further viral replication. Clinical signs of bovine virus diarrhea include depression, oculonasal discharge, anorexia, fever, oral erosions and ulcerations, diarrhea, and decreased milk production in lactating cows. A rapid respiratory rate may be observed, which may be interpreted incorrectly as pneumonia. Clinical pathologic changes such as leukopenia are observed in calves acutely infected with BVDV.[12] The major decreases in the total leukocyte count have been in the numbers of neutrophils and lymphocytes.

One of the most important determinants for the outcome of acute BVDV infection in susceptible animals is the virulence of the infecting BVDV strain.[59] Experimental infections with BVDV strains of low and high virulence reveal similar initial infection and spread but differing amounts of virus in tissues and speed of dissemination through the body.[60] Virulent strains of BVDV result in widespread distribution of virus in tissues, and BVDV strains that induce high levels of viremia result in more severe clinical signs.[43] Viral replication and antigen distribution can be detected in the thymus, lymph nodes, Peyer patches, tonsils, and spleen with all strains of BVDV. In contrast to low virulent strains of BVDV where antigen is only found outside of lymphoid tissues in the intestinal mucosa, antigen can be found in bone marrow, intestinal mucosa, respiratory tract, endocrine tissues, and nervous system tissues following acute infection with high virulent strains of BVDV.[60] The HoBi-like viruses have received considerable attention because of their recent emergence and detection in South America, Europe, and Southeast Asia, and natural descriptions and experimental reproductions of the infection have revealed very mild disease signs in cattle. Most descriptions of HoBi-like virus infection in natural settings relate the infection to either respiratory disease or reproductive disease, specifically abortion. During experimental reproduction of the disease, clinical signs associated with HoBi-like virus infection can be indistinguishable from low virulent BVDV infection.[5]

Disease associated with acute BVDV infection is often observed in seronegative cattle between the ages of 6 and 24 months. It is generally believed that maternally derived BVDV-specific antibodies have waned and acquired immunity is not yet formed, thus making calves as early as 4 to 6 months of age susceptible. Maternally derived BVDV-specific colostral antibodies are thought to be protective unless sufficient antigenic diversity exists between challenge strain and strain against which the maternal-derived colostral antibodies were developed. Disease as a result of acute infection can be observed in preweaned calves.[61] Acute disease in neonatal or preweaned calves can result in signs of pneumonia or enteritis, often occurring in association with failure of passive transfer. Studies have investigated the duration of maternal colostrum–derived antibodies against BVDV-1 and BVDV-2, and a major finding from these studies is the variability in duration between calves as a result of colostrum quality and consumption. Estimated mean time to reach seronegative status in dairy calves receiving maternal colostrum was 117.7 ± 37.7 days for BVDV-1 and 93.9 ± 61.9 days for BVDV-2.[62] Another study reported that the mean duration for colostrum-derived antibodies in beef calves was 185.6 ± 59.8 days for BVDV-1 and 157.8 ± 56.1 days for BVDV-2.[63]

Diarrheal diseases considered as differential diagnoses for acute BVDV infection in adults include salmonellosis, winter dysentery, paratuberculosis, intestinal parasites, malignant catarrhal fever, arsenic poisoning, and copper deficiency (molybdenosis). The differential diagnoses for acute BVDV infection for the neonatal period includes other causes of diarrhea in young calves such as rotavirus or coronavirus infection, cryptosporidiosis, enterotoxigenic *Escherichia coli* infection, salmonellosis, and coccidiosis. Other causes of calf pneumonia such as bovine respiratory syncytial virus, pasteurellosis, hemophilosis, or mycoplasma infection should also be considered.

SEVERE ACUTE BVDV INFECTION. In the late 1980s and early 1990s, an atypical and significantly more severe form of BVDV infection was recognized in Quebec,[64] Ontario,[65] the United States,[66] and the United Kingdom.[67] The disease had a peracute course, caused high morbidity, and resulted in substantial numbers of deaths in all age groups. In Quebec, mortality due to BVDV in veal operations was estimated at 25% of 143,000 calves for 1993.[64] The outbreak in Ontario involved 150 dairy, 600 beef, and 100 veal herds. The severity of disease varied among herds, with some herds experiencing 10% to 20% mortality rates in all age groups of cattle. Clinical manifestations of severe, acute BVDV infections include diarrhea, pyrexia, decreased milk production, and oral ulcerations frequently observed in older cattle. The presence of severe clinical disease combined with oral ulcerations made mucosal disease a primary differential diagnosis. Other differential diagnoses for diseases that cause oral lesions in cattle include malignant catarrhal fever, vesicular stomatitis, papular stomatitis, foot-and-mouth disease, and bluetongue. Abortions in cattle also were a common occurrence. These outbreaks of severe clinical disease were reported to be associated with recent introduction of cattle to the herd or history of inadequate vaccination programs.[65] Analysis of BVDV isolates from outbreaks in Canada and the United States was performed, and NCP isolates were obtained from affected cattle. Nucleotide sequencing of the RNA genome of these isolates revealed a distinct group of BVDV, which were designated as BVDV-2,[68] which then later became a separate species within the genus *Pestivirus*.

The outbreaks of severe BVDV infections clearly demonstrated that some BVDV strains can cause severe life-threatening disease in postnatal, immunocompetent cattle. Prior to 1993, it was believed that the majority of BVDV infections in immunocompetent adult cattle resulted in subclinical or mild disease. Although BVDV-2 strains were associated with severe acute BVDV infections, not all BVDV-2 strains will cause severe disease. Furthermore, it is likely that some BVDV-1 strains are capable of inducing severe clinical disease under unfortunate conditions involving host, agent, and environment factors.

HEMORRHAGIC BVDV INFECTION. The hemorrhagic syndrome, which is characterized by thrombocytopenia, is an additional form of severe acute BVDV infection in immunocompetent cattle.[69] The first descriptions of hemorrhagic syndrome included both calves and adult cattle naturally infected with BVDV, with severe depressions in platelet counts and high case fatality rates being reported.[70] Clinical manifestations of the hemorrhagic syndrome are primarily related to thrombocytopenia and include bloody diarrhea, epistaxis, petechial hemorrhages, ecchymotic hemorrhages, hyphema, and bleeding from injection sites or insect bites. Fever, diarrhea, rumen stasis and dehydration are also common. In addition to thrombocytopenia, leukopenia characterized by severe neutropenia and lymphopenia are clinical pathologic abnormalities. Thrombocytopenic BVDV infections have been experimentally reproduced, almost exclusively with NCP BVDV-2 strains[43,69]; however, hemorrhagic syndrome has been reported following experimental inoculation of colostrum-deprived calves with a BVDV-1b strain.[71] Platelet dysfunction has also been described with experimental BVDV infection[72];

VetBooks.ir

thus quantitative and qualitative platelet defects contribute to the hemorrhagic diathesis observed in infected cattle. Bone marrow infection and, specifically, BVDV infection in bone marrow megakaryocytes may be important in the etiology of BVDV-induced thrombocytopenia.[43,73] Diseases that can mimic hemorrhagic syndrome include septicemia with subsequent development of disseminated intravascular coagulation, sweet clover poisoning, and bracken fern poisoning.

ACUTE BVDV INFECTION–IMMUNOSUPPRESSION. Although the majority of BVDV infections in immunocompetent cattle are transient and self-limiting, it is apparent that when infection occurs in the presence of other microorganisms, BVDV can contribute to disease that becomes clinically evident. Numerous studies, under both natural and experimental conditions, have demonstrated the relationships between BVDV and other infectious agents. The virus has been reported to enhance the pathogenicity of bovine herpesvirus-1 (BoHV-1), actinomycosis, papular stomatitis, enteritis caused by *Salmonella* spp., colibacillosis, metritis, and mastitis. The role of BVDV in synergistic or mixed infections with other agents is most likely due to immunosuppression.[9] Mechanisms responsible for BVDV-induced immunosuppression are likely multifactorial; however, critical information on mechanisms of the suppression, the duration and extent of recovery, and the long-term effects are currently speculative.[40] The ability of BVDV to induce quantitative and qualitative defects in leukocytes could provide some contribution to immunosuppression. The defects involve immune system cells of both the innate and adaptive immune responses. A transient leukopenia occurs in most cattle acutely infected with BVDV which may be more severe with BVDV-2 than BVDV-1. Decreases in helper ($CD4^+$), cytotoxic ($CD8^+$), and gamma/delta (g/d) T lymphocytes, as well as B lymphocytes and neutrophils, have been reported and these decreases are often strain dependent.[74] Several possible explanations exist for the mechanism of leukopenia, and these include immune system removal of BVDV-infected immune cells, destruction of immune cells by BVDV, and increased trafficking of immune cells into tissue sites of viral replication. During acute infection, various levels of lymphoid depletion are observed in the thymus, spleen, lymph nodes, and gut-associated lymphoid tissues (Peyer patches).[75] The NCP BVDV strains are lymphotrophic, and lymphocyte apoptosis in lymphoid tissues results in cytolysis and lymphoid depletion.

Decreased functional responses in immune system cells have also been described during acute BVDV infection, and affected cells include lymphocytes, neutrophils, and monocytes and macrophages.[76,77] Dysfunction in both B and T cells has been demonstrated by poor culture response to phytohemagglutinin, pokeweed mitogen, and concanavalin A stimulation and by decreased production of IFN.[26,78] Infection of peripheral monocytes in vitro caused a significant decrease in the chemotactic responses to lymphokine.[79] Immunohistochemical and flow cytometric studies have demonstrated that BVDV infects and replicates in antigen-presenting cells.[80] Infection of monocytes with BVDV has been shown to stimulate the synthesis of cytokines that may be responsible for the reduced ability to stimulate T-cell responses to specific antigens and mitogens. A decrease in the secretion of tumor necrosis factor (TNF)–α from lipopolysaccharide (LPS)- or *Salmonella*-stimulated bone marrow–derived macrophages that had been infected with BVDV has been reported.[81] These abnormalities, combined with environmental and/or management stressors, contribute to immunosuppression and concurrent infection with other pathogens. Increased susceptibility to other secondary infections is a consequence of BVDV-induced immunosuppression.

ACUTE BVDV INFECTION–RESPIRATORY DISEASE. Substantial data exist demonstrating that BVDV infection is important in polymicrobial disease, and the bovine respiratory disease complex in feedlot animals and intensively housed calves is the best example of this type of disease process. In North American feedyards, bovine respiratory disease is the most frequently reported cause of morbidity and mortality. The role of BVDV in the bovine respiratory disease complex is debatable as to whether BVDV-induced immunosuppression or primary infection of the respiratory tract plays the major role, but BVDV can be isolated from pneumonic cattle more frequently than can other viruses.[82] Certain BVDV strains may be pneumotropic, as evidenced by some BVDV strains causing interstitial pneumonia in experimentally inoculated calves.[83] BVDV may play a secondary role in bovine respiratory disease complex through immunosuppression. Although BVDV is frequently isolated from cattle with pneumonia, it is often isolated with the other infectious agents typically associated with bovine respiratory disease complex. Reports from disease outbreaks and experimental studies have supported a synergistic role of BVDV with bovine herpesvirus type 1 (BoHV-1) and bovine respiratory syncytial virus (BRSV).[84,85] Calves experimentally inoculated with BVDV 7 days prior to inoculation with BoHV-1 developed more severe clinical disease, with dissemination of BoHV-1 into nonrespiratory tissues including intestinal and ocular tissues, as compared with calves inoculated with BoHV-1 alone.[84] Initial BVDV infection may impair the ability of calves to clear BoHV-1 from the lungs and to contain BoHV-1 at the local infection site. Synergism between BVDV and bacterial pathogens, specifically *Mannheimia haemolytica* and *Mycoplasma bovis* has also been described.[86,87] Viral-bacterial synergy in bovine respiratory disease complex likely is the result of BVDV compromise of the host defense mechanisms. Viral damage of nasal turbinate and tracheal epithelium alters mucociliary clearance of bacteria with subsequent bacterial attachment and colonization. The innate defenses of the lung are compromised with BVDV infections of macrophages and neutrophils, resulting in depletion, destruction, or impairment in function. Suppression of B- and T-cell–mediated immune responses can also occur as a result of BVDV infection.[9]

ACUTE BVDV INFECTION–REPRODUCTIVE DISEASE. Reproductive tract infections have been described for male and female cattle. The importance of BVDV on the male reproductive tract has not received attention equivalent to the effects on female reproduction for a number of reasons, but from a transmission standpoint, acutely infected bulls and PI bulls are capable of shedding virus in semen.[52] Acceptable or unacceptable semen quality may be observed in bulls acutely infected with BVDV. Although acute BVDV infections generally result in a transient viremia with subsequent clearance of the virus by the host immune system, a localized, prolonged infection of testicular tissue with NCP BVDV has been described under both natural and experimental conditions.[52,54] The original description of prolonged testicular infection with BVDV was identified in the testes of a seropositive, nonviremic bull at an artificial insemination center.[54] Despite absence of viremia, the bull continuously shed infectious BVDV in semen throughout his life, and the semen of this bull resulted in infection and subsequent seroconversion of an inseminated seronegative heifer.[88] Furthermore, this bull displayed a consistently high concentration of circulating serum antibodies that neutralized the specific viral strain that was persistently shed in the semen. Since that original description, prolonged testicular infections with BVDV have been reproduced in postpubertal bulls. Viral RNA has been detected in semen for 2.75 years following BVDV exposure, and infectious virus grown from testicular tissue has been detected up to 12.5 months after BVDV exposure.[52] Protection from a systemic immune response due to a blood-testes barrier is believed to be the mechanism for the localized, prolonged testicular infection. Uncertainty currently exists regarding whether bulls with a prolonged testicular infection may become viremic and infectious to other animals.

It is well established that BVDV infection can cause significant reproductive problems in nonimmune pregnant cattle, including fertilization failure, embryonic death, fetal death and expulsion, persistent infection, and congenital defects (Fig. 32-91). Transplacental infection is a common event in pregnant cattle exposed to BVDV, and in experimental studies, transplacental infection occurs with almost 100% efficiency.[89] As discussed previously, most acute BVDV

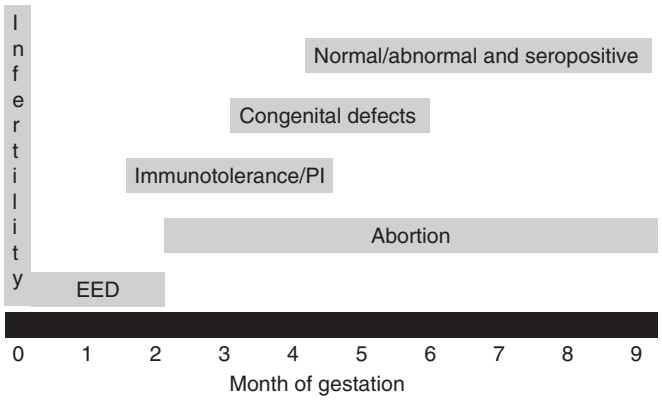

FIG. 32-91 Potential reproductive outcome after infection with BVDV during different stages of gestation. *BVDV,* Bovine virus diarrhea virus; *EED,* early embryonic death; *PI,* persistently infected.

infections are subclinical; yet, infection in pregnant cattle may result in significant disease. The economic damage caused by BVDV in susceptible herds is mainly associated with the outcomes of intrauterine infections. The outcome of fetal infection with BVDV is dependent on three main factors: (1) time of infection (i.e., gestational age of the fetus at the time of infection); (2) organ system involved in the infection; and (3) properties of the virus (i.e., biotype, virulence, and target cell range). It is important to note that BVDV-1 and BVDV-2, as well as CP and NCP strains, can result in reproductive disease, although only NCP strains are capable of inducing PI cattle.

Infertility and Early Embryonic Death. Infection of cattle prior to insemination can result in impaired conception rates.[90] This may be due in part to ovarian infection and dysfunction as a result of BVDV viremia. Viral antigen in macrophage-like cells and ovarian stromal cells and oophoritis have been described in cattle acutely infected with NCP BVDV,[91] and in cattle vaccine with modified live viral vaccines containing CP BVDV.[92] Of particular interest is that pathologic change and BVDV antigen were detected in some cattle up to 60 days after infection.[91] The first 45 days of gestation are the embryonic period, and conception and pregnancy rates are lower if cattle are exposed at the time of insemination and become viremic during the first 3 weeks of gestation. The zona pellucida has been demonstrated to prevent BVDV from infecting the embryonic cells.[93]

Abortion. Abortion may be observed at any time during gestation as a result of BVDV infection. Fetal resorption, mummification, or expulsion can occur following fetal death depending on the gestational age of the fetus at the time of infection.[2] Although fetal death and abortion are most common during the first trimester, mid- and late-term abortions and stillbirths should be examined for BVDV. Diagnostic laboratory surveys indicate that BVDV isolation prevalence from aborted fetuses in the United States is quite variable, with BVDV being isolated from as few as 0.1% to as many as 27.2% of submitted fetuses.[94,95] Following BVDV infection, expulsion of the fetus may occur shortly or may be delayed for several months after infection. As a result of delayed expulsion following fetal death, isolation of BVDV from aborted fetuses may not be successful. This has also been demonstrated experimentally, with abortion being observed 30 to 50 days after experimental infection at around days 100 to 120 of gestation.[96]

Persistent Infection. The fetal gestational ages between day 45 and day 125 are the period of fetal development during which fetal immunocompetence to BVDV occurs. The most outstanding outcome of infection during this period is the development of persistent infection. Immunocompetence to BVDV is not absolute at day 125 of gestation, and the dams of most PI calves were exposed at gestational ages prior to day 100. By definition, cattle that are persistently infected with BVDV are immunotolerant to BVDV. Biotype is important when discussing infection during this period of gestation. Fetal death and expulsion can occur with infection with both CP and NCP strains of BVDV; however, only NCP strains are capable of causing persistent infection.[10] The PI animal cannot recognize the infecting NCP BVDV as foreign. Immunotolerance is specific to the infecting NCP strain of BVDV, and postnatal, PI animals can respond immunologically to heterologous strains of BVDV. For this reason, PI animals may be seropositive to BVDV, and seropositive status cannot be used diagnostically to rule out persistent infection.

Congenital Defects. Congenital malformations are associated with BVDV infection during the gestational period of organogenesis, which occurs approximately between days 100 and 150 of gestation.[89] Congenital malformations that have been reported in association with BVDV infection include cerebellar hypoplasia, hypomyelinogenesis, hydranencephaly, alopecia, cataracts, optic neuritis, brachygnathism, hydrocephalus, microencephaly, thymic aplasia, hypotrichosis, pulmonary hypoplasia, and growth retardation. Congenital malformations may be due to the direct result of viral infection on developing cells or to the host immune response in destroying virally infected cells. During a point-source of exposure of BVDV into a bred population of cattle, congenitally malformed calves will be born just prior to the birth of PI animals, and this information can be useful to determine sampling of calves for BVDV.

BVDV Infection during Later Stages of Pregnancy. Fetal infections in the last trimester can occur, but at this stage of gestation, organogenesis is often complete and fetuses are considered immunocompetent to BVDV. Congenital infection during this period usually results in the birth of a calf that is seropositive on a precolostral blood sample. Detrimental effects of BVDV infection in late gestation seem to be less common; however, weak calves and abortions have been reported.[89] It has generally been accepted that infection in late gestation results in the birth of calves that are clinically normal; however, calves congenitally infected with BVDV may be at greater risk for increased morbidity and mortality postnatally.[97] The congenitally infected calves that are born with neutralizing antibody titers to BVDV have been shown to be twice as likely to experience a severe illness during the first 10 months of life as compared with calves born free of BVDV antibody titers.[97] The prevalence and importance of congenital infections remains to be determined.

Disease Associated with Persistent BVDV Infection

PI cattle are the main reservoir for BVDV. Cattle PI with BVDV are characterized by a wide distribution of BVDV throughout their organs as a result of lacking an immune response to the persisting BVDV strain. In PI animals, the virus is present throughout all organs and tissues; therefore BVDV is shed from multiple sites including nasal discharges, urine, semen, colostrum/milk, and feces. Some PI calves are born weak, stunted, and die shortly after birth[12]; however, many PI calves are born without any observable abnormalities and can survive for at least several months. This is important for beef cattle herds as these animals can survive into the start of the subsequent breeding period and thus become an important source for horizontal transmissions. PI cattle can have decreased survival rates, as evidenced by reports documenting a greater than 50% mortality rate in the first year of life.[98] This mortality may be due in part to the fact that PI cattle may have an impaired immune response, which makes them more susceptible to opportunistic pathogens. Vertical transmission is 100% as PI cows will give birth to PI offspring. PI cattle are at risk of developing mucosal disease.

MUCOSAL DISEASE. Mucosal disease is the most dramatic of BVDV-associated clinical disease due to the severity and characteristics of lesions. Mucosal disease occurs when cattle that are immunotolerant and PI with NCP BVDV become infected with a CP BVDV.[99] Because mucosal disease only occurs in PI cattle and PI cattle comprise less than 1% of the cattle population, it is characterized as a disease of very low morbidity and high mortality. Although the origin of the CP BVDV can be external, such as following the use of modified live virus vaccines, current theory holds that in the majority of cases of mucosal disease, the CP BVDV represents a

VetBooks.ir

VetBooks.ir

mutation of the NCP BVDV (the persistently infecting biotype).[99] There are multiple clinical forms of mucosal disease, with the variations being due to the antigenic relationship between the persistently infecting NCP strain and the superinfecting CP strain.[99] The multiple clinical forms of mucosal disease can be divided into acute fatal mucosal disease; chronic mucosal disease; chronic mucosal disease with recovery; and delayed onset mucosal disease.[99]

ACUTE MUCOSAL DISEASE. Acute mucosal disease occurs when the superinfecting CP strain shares close antigenic homology to the PI NCP strain. The CP strain may arise de novo by a mutational event from the NCP strain in the PI animal. The mutational event affects the viral biotype but does not affect the viral antigenicity.[100] The clinical findings associated with acute mucosal disease include pyrexia, depression, anorexia, decreased milk production, profuse diarrhea, ptyalism, mucopurulent oculonasal discharge, and oral erosions.[12] Oral erosions are present on the lips, gingival margins, tongue, dental pad, and the hard palate. Experimental reproduction of acute mucosal disease indicates an incubation period of 7 to 14 days.[99] Acute mucosal disease is considered to be 100% fatal.

CHRONIC MUCOSAL DISEASE. Chronic mucosal disease and mucosal disease with recovery are forms of mucosal disease in which the superinfecting CP strain is heterologous to the PI NCP strain. The likely source of the superinfecting CP strain is external, rather than a mutational event in the PI NCP strain. The clinical manifestations of chronic mucosal disease are anorexia, weight loss, diarrhea, chronic bloat, alopecia, erosive lesions on the mouth and skin, and lameness.[12] The lameness may develop as a result of laminitis, interdigital necrosis secondary to erosive lesions, and hoof deformities. Rarely, a PI animal may mount an immune response to the superinfecting heterologous CP strain and clear the superinfection, and this has been referred to as mucosal disease with recovery.[99] It is important to note that the animal remains PI with the NCP strain.

Necropsy Findings Pathologic lesions associated with BVDV infection can be quite diverse in types and degree and, like the clinical manifestations, are dependent on host and viral factors. Age of animal, immune status at the time of infection, and the presence of concurrent infections will greatly influence the pathologies observed. Many lesions observed are not specific to BVDV infection; thus laboratory testing becomes an important component in the diagnostic process. Occasionally, only microscopic lesions are present, and unless histopathology is performed, a lesion can be unnoticed and infection undiagnosed.

ACUTE BVDV INFECTION. Animals that die of acute BVDV infection have less severe lesions. In addition, lesions, when present, can often be nonspecific and subtle. Edematous intestines, occasionally with ecchymotic hemorrhages and mild reaction in mesenteric lymph nodes, can be observed. Occasionally, linear erosions in the alimentary tract and proximal colon are present along with atrophy of gut-associated lymphoid tissues (Peyer patch). Secondary bacterial infections such as enteritis, pneumonia, or mastitis are present and have contributed to death. Animals that die of hemorrhagic syndrome can have evidence of hemorrhage in many organ systems, including the gastrointestinal, cardiovascular, respiratory, and urinary systems. Petechial or ecchymotic hemorrhages are often apparent on mucosal surfaces, and significant hemorrhage in the gastrointestinal submucosa and Peyer patches may also be present. Lesions associated with cases of severe acute BVDV infection can be similar to lesions associated with mucosal disease. Because of this and the severe clinical signs observed, it is usually not possible to differentiate the two forms of disease without supporting laboratory testing.

MUCOSAL DISEASE. Postmortem examination of cattle dying of mucosal disease usually reveals gross abnormalities most prominent in the alimentary system. Animals that die of mucosal disease usually have severe necrotizing erosive or ulcerative lesions involving the mouth, tongue, esophagus, ruminal pillars, omasum, abomasum, intestines, and cecum.[101] Erosive lesions may extend onto the external nares and into the nasal cavity. Ulcers involving the esophagus typically are linearly elongated. The Peyer patches in the small intestine often are necrotic and hemorrhagic. Bowel contents are watery, hemorrhagic, and foul smelling. Pathologic gastrointestinal conditions may be absent or very mild in cattle with chronic mucosal disease, although histopathologic lesions usually are present with atrophy of gut-associated lymphoid tissues present. Skin lesions are often found and include patchy hyperkeratosis around the neck, shoulder, and perineal areas. Erosive lesions involving the perineal area, the prepuce, and the interdigital cleft and coronary band of the hoof may be present. Skin lesions are most apparent in cattle suffering from chronic mucosal disease.

ABORTIONS AND CONGENITAL DEFECTS. Pathologic criteria for the diagnosis of BVDV as a cause of abortion are not established. Fetuses aborted as a result of in utero BVDV infection often are autolytic when expelled. Lesions found in aborted fetuses and the accompanying placentas are nonspecific for BVDV. Under experimental conditions or when aborted fetuses are expelled soon after death, lesions observed include conjunctivitis, peribronchiolar and interalveolar pneumonia, and nonspecific myocarditis. A significant decrease in cerebellar mass may be evident in calves affected by cerebella hypoplasia as a result of in utero infection with BVDV during the second trimester of gestation. Other common congenital defects associated with BVDV infection that may be noted at necropsy include cataracts and thymic hypoplasia.

Diagnosis Numerous methods are available for detecting BVDV infection. The choice of test depends on the clinical problem, the availability of tests by different diagnostic laboratories, and financial considerations (Table 32-10). Because the clinical manifestations of BVDV are diverse, accurate diagnosis of BVDV infection relies on laboratory testing. Sample selection and handling for BVDV testing are critical because the starting test material will largely define success or failure of the diagnostic test.[102]

VIRUS ISOLATION. Virus isolation is a basic, reliable, and widely used method for diagnosis of BVDV infection, and remains the "gold standard" for BVDV diagnostics; however, many diagnostic laboratories use different cell culture systems, and sample handling and processing can have a major impact on results obtained. The BVDV may be cultured and isolated from many samples, including serum, whole blood, semen, nasal swabs, and various types of tissues.[103] Although time-consuming and expensive, mononuclear cells in the buffy coat from whole blood are an ideal sample for individual virus isolation where an acute BVDV infection is suspected, because BVDV is highly cell associated, and the virus isolation is not interfered with by neutralizing antibodies to BVDV in serum.[103] Sample handling is very important for virus isolation using mononuclear cells because they need to be viable when inoculating in the cell culture system.[102] The ideal tissue samples for virus isolation from deceased animals at postmortem exam include lymphoid organ–related tissues such as spleen, the gut-associated lymphoid tissue of the distal small intestine (Peyer patches), mesenteric lymph nodes, and thymus.[103] In addition, pooled tissues from the same animal can be applied to virus isolation. Detection of NCP BVDV strains and confirmation of CP strains as BVDV are performed using immunofluorescence or immunoperoxidase staining techniques or reverse transcription polymerase chain reaction (RT-PCR).

A microtiter virus isolation that has been referred to as the *immunoperoxidase monolayer assay* (IPMA) has been developed, but the test is not ideal for detecting acute infections, nor is it advisable to use this assay for testing calves less than 3 months of age, as these calves likely have colostral antibodies that would interfere with the test.[104]

TABLE 32-10

Diagnostic Testing for Bovine Virus Diarrhea Virus (BVDV)

Suspected Form of Infection or Purpose for Testing	Diagnostic Test	Specimen	Comments
Acute BVDV infection	Virus isolation PCR	Serum, whole blood, or nasal swabs	Whole blood preferred over serum Viremia may be too transient for successful virus detection Nasal swabs can be useful for establishing role of BVDV in bovine respiratory disease complex
	Serology (virus neutralization tests)	Serum	Pair sera 3 to 4 weeks apart Serology for both BVDV-1 and BVDV-2 should be performed
	Immunohistochemistry Virus isolation PCR Fluorescent antibody testing on fresh tissues	Postmortem tissues	Tissues of choice include ileum, mesenteric lymph nodes, spleen, thymus (calves), lung (pneumonia)
Reproductive tract disease (infertility and abortion)	Serology (virus neutralization tests)	Serum or fetal fluid	May need to establish serum bank on at-risk animals as seroconversion complete when reproductive problem noticed or compare titers of affected to unaffected cattle Serology for both BVDV-1 and BVDV-2 should be performed Presence of antibodies or BVDV in fetal fluid is suggestive but not definitive for BVDV as cause of abortion Absence of antibodies or BVDV in fetal fluids does not rule out BVDV as cause of abortion
	Virus isolation PCR Immunohistochemistry Fluorescent antibody	Fetal tissues	Tissues of choice include ileum, mesenteric lymph nodes, spleen, thymus, liver, lung
Persistent infection	Virus isolation (IPMA) Antigen capture ELISA PCR	Serum or whole blood	Should be repeated in 3 to 4 weeks to confirm persistent infection For virus isolation, buffy coats should be used on calves less than 6 months of age because of possible interference of passive immunity
	Antigen capture ELISA Immunohistochemistry Fluorescent antibody PCR	Skin biopsy	Should be retested in 3 to 4 weeks with blood sample to confirm persistent infection Pools of skin or blood may be tested initially by PCR
Mucosal disease	Virus isolation PCR	Serum or whole blood	Isolation of both CP and NCP-BVDV
	Virus isolation PCR Immunohistochemistry Fluorescent antibody	Postmortem tissues	Tissues of choice include ileum, mesenteric lymph nodes, spleen, thymus, liver, lung
Herd screening	PCR	Bulk tank milk samples Pooled serum, whole blood, or skin biopsies	Bulk milk tank screening only tests lactating cows; limit 300 cows per milk pool Pooling of skin biopsies, whole blood, and serum is controversial; request data on pooling performance from laboratory prior to testing
	Serology (virus neutralization tests)	Serum from sentinel cattle	Unvaccinated cattle 6 to 12 months of age Serology for both BVDV-1 and BVDV-2 should be performed

CP, Cytopathic biotype; *ELISA,* enzyme-linked immunosorbent assay; *IPMA,* immunoperoxidase monolayer assay; *NCP,* noncytopathic biotype; *PCR,* polymerase chain reaction.

BVDV ANTIGEN DETECTION. Direct antigen detection methods have been described for BVDV using blood and a variety of fresh, frozen, or fixed tissues. These methods include immunohistochemistry (IHC), antigen capture ELISA (ACE), and immunofluorescence. Viral antigens can be detected from BVDV-infected tissue, whole blood, serum, milk, or nasal swab samples.[103] These tests are advantageous in that they allow rapid and inexpensive detection as compared with virus isolation. In addition, there is no amplification of antigen so these tests are ideally suited for the detection of animals with considerable amounts of antigen, namely the PI carrier.

Detection of BVDV antigen through IHC or ACE methods on skin samples has become widely used and applied for the detection of cattle PI with BVDV.[105] Skin biopsies may be obtained easily and inexpensively. A major advantage of testing by IHC or ACE on skin samples is that sampling can be performed on young PI calves, which would test negative by virus isolation, microplate virus isolation, and ACE testing on serum because of inhibition by acquired colostral antibodies.[106] Both the IHC and ACE tests are ideally suited for the detection of PI animals, and reports indicate these tests do not detect acutely infected cattle.[107,108] However, a recent report indicates

VetBooks.ir

positive results may be observed for acutely infected cattle with IHC and ACE tests.[109] With IHC testing, PI animals can be differentiated from acutely infected cattle based on the location of viral antigen in the skin.[110] Cattle vaccinated with modified live viral vaccines do not cause a positive result when tested by IHC or ACE methods.[8,111]

REVERSE TRANSCRIPTION POLYMERASE CHAIN REACTION. Since sequences of BVDV isolates became available, molecular techniques have been developed for diagnosis of BVDV, and this method of BVDV diagnosis has gained widespread use as a routine diagnostic method.[105] Development of commercial kits, with rapid and simple viral RNA extraction techniques, has made molecular techniques ideal for detection of viral genomic nucleic acids from many types of samples including serum, whole blood, tissues, and bulk tank milk. The RT-PCR assay is a molecular diagnostic method that is a specific and sensitive technique for diagnosis of BVDV infection. The RT-PCR is more sensitive than virus isolation.[112] The high sensitivity of RT-PCR allowed it to be used for pooled testing, and pooling of whole blood, serum, or milk samples is an economical way to detect BVDV infection in herd screening assays.

SEROLOGY. Detection of antibodies to BVDV is another method to demonstrate virus infection; however, it is often difficult to distinguish antibodies produced in response to a natural infection, following vaccination, or as a result of transfer of maternal antibodies from dam to offspring. Interpretation of serology results is difficult without knowing important information of the herd being tested such as the vaccination history. Serologic testing may be used to assess vaccine efficacy and vaccine protocol compliance as well as determine if BVDV exposure has occurred in the herd.[103]

The BVDV-specific antibodies can be divided into two groups, neutralizing and nonneutralizing antibodies. Although there are several applicable methods, serum use, more appropriately called virus neutralization (VN), and ELISA have been most commonly used for serologic diagnosis of BVDV. Numerous technical and logistical challenges make the VN test less useful than the ELISA.[113]

Treatment and Prognosis

No specific treatment is available for animals showing clinical signs of BVDV infection. Owners should be informed that severely ill animals may have mucosal disease, which normally is fatal. The goals of therapy for cattle suspected of having acute BVDV infection are supportive care and prevention of secondary bacterial infection. Broad-spectrum antimicrobial agents, fluids, electrolytes, and vitamins may be indicated.

Prevention and Control

Control of any infectious disease relies on eliminating the reservoirs of the pathogen and limiting transmission from infected individuals to susceptible animals. The PI animal is the reservoir, and eliminating the potential for the birth of PI calves is key to prevention and control. The goal of BVDV control is to ultimately reduce production losses associated with BVDV infection. Development and implementation of herd health programs that involve vaccination and biosecurity to limit exposure of pregnant cattle to PI cattle are important for success of control. Therefore, when applying prevention and control to BVDV, three major areas should be instituted; these are (1) identification and elimination of PI animals, (2) enhancing immunity through vaccination, and (3) implementing strict biosecurity measures to prevent introduction of PI carrier animals into a population of susceptible cattle. Each of these three principles has been applied to BVDV control[114]; however, BVDV continues to be a major problem to the cattle industry worldwide. Some European countries have successfully eradicated BVDV,[115] and voluntary BVDV control programs have been implemented in the United States. Control and eventual eradication of BVDV can be possible in defined areas, even with large and dense cattle populations.

IDENTIFICATION AND ELIMINATION OF PI CATTLE. The primary source of BVDV is cattle PI with BVDV, because PI animals have a high and persistent viremia and shed BVDV from nearly all secretions throughout their lifetime. Identification and removal of PI animals ideally should occur in breeding herds. In beef cow-calf operations with a controlled breeding season, PI animals should be removed prior to entry of the bull into the breeding herd.[116] In this situation, all calves, replacement heifers, bulls, and nonpregnant dams without calves should be tested for BVDV PI status. Because PI cows always produce PI calves, a negative test result of a calf indicates a negative PI status for the dam.[117] For any calves that test positive, the dam will need to be tested for BVDV PI status. Most PI calves result from an acute infection in the dam, rather than the dam of the calf being PI. For dams that test negative, they may reenter the breeding herd, and they will possess high natural immunity to BVDV. In beef herds with a controlled breeding season, the BVDV status of all animals can be determined if all animals are not pregnant at the time of testing. If cattle are pregnant at the time of testing, those animals will need to be segregated and their calves will need to be tested and found negative prior to return to the breeding herd. In dairy herds and beef herds without a controlled breeding season, young calves should be tested and removed as soon as possible to avoid possible transmission to the breeding herd. Screening young calves for PI status is best accomplished using ACE or IHC methods on skin biopsy samples. The use of skin samples for testing young calves is advantageous over other methods in that it is relatively easy for nonprofessionals to collect the samples, samples may be taken from calves that possess circulating maternal antibodies, and a single positive test usually indicates PI status. Because the occasional acutely infected animal may be IHC or ACE positive, valuable breeding stock should be retested 30 days later using virus isolation or RT-PCR assays on blood samples.[109]

Screening all individuals in a herd for BVDV is very costly, especially considering the low prevalence of PI animals among cattle herds. Instead of whole herd testing, monitoring strategies may be initiated, and these include evaluation of production records, BVDV evaluation of aborted fetuses, use of sentinel animals, pooling strategies using RT-PCR testing, and BVDV testing on sick or deceased individuals within the herd.[116] Monitoring breeding records, calf morbidity and mortality rates, and weaning proportions are considered the minimal level of surveillance, and these involve the least expense, but this level of surveillance is not very sensitive for evaluating the presence of BVDV PI within a herd.[15,116] As an example of the difficulty in using clinical suspicion as a reason to perform herd testing, BVDV was isolated from cattle in 53% of herds where there was no suspicion of the infection,[118] and BVDV PI animals were not identified in 81% of herds where veterinarians suspected BVDV was present.[15] On the other hand, identifying BVDV in sick or dead animals or in aborted fetuses provides the justification for further whole-herd testing for BVDV PI animals.

Because of high sensitivity, RT-PCR assays using pooled samples have been developed and tested to screen populations of animals for BVDV-persistent infection.[112,119] Sample types that have been used in RT-PCR assays of pooled samples include serum, whole blood, bulk tank milk, and skin biopsy samples. With pooling whole blood samples, a single PI animal is detectable in pools of up to 250 negative samples. Recently, an RT-PCR assay has been developed and evaluated for testing pools of skin biopsy samples.[119] Pooled sample testing by RT-PCR is a rapid and cost-effective method for screening populations of cattle for BVDV PI animals. Subsequent testing of individuals within the positive pools may be performed using IHC, ACE, virus isolation, or RT-PCR methods depending on the class of animals being tested. When testing young beef calves, it is important to perform all testing prior to the breeding season to identify and eliminate BVDV PI animals that pose a risk for bred cattle.

ENHANCING IMMUNITY THROUGH VACCINATION. Many vaccines are commercially available for BVDV, and the majority of these USDA-licensed vaccines contains BVDV in combination with other bovine respiratory and reproductive pathogens including bovine herpesvirus-1 (BHV-1), parainfluenza type 3 (PI-3), bovine

VetBooks.ir

respiratory syncytial virus (BRSV), *Leptospira* spp., *Campylobacter* spp., *Mannheimia haemolytica, Histophilus somni,* and/or *Pasteurella multocida*. Historically, most BVDV vaccines contained only BVDV-1 strains, but because of antigenic diversity among BVDV-1 and BVDV-2, modified live and inactivated vaccines containing both BVDV-1 and BVDV-2 strains have been developed and are now widely available. Advantages and disadvantages of BVDV modified live viral vaccines and inactivated vaccines have been described.[120] One disadvantage of inactivated BVDV vaccines is that two doses are required for the initial immunization. A major problem with programs using inactivated vaccines is the widespread lack of compliance among producers who use inactivated vaccines.[121] Failure to give a booster during the primary series and failure to regularly administer annual boosters with inactivated vaccines are common.[121]

Vaccines are an important component to BVDV prevention and control, and their effectiveness has been to limit disease from BVDV infection. When discussing BVDV vaccination, it is important to discuss reasonable expectations following vaccination and to remember that *disease* and *infection* are not synonymous terms. Experimental and field data indicate vaccination with either inactivated or modified live BVDV vaccines is effective at reducing or obviating clinical disease.[65,122] In addition, modified live viral vaccines containing BVDV-1 strains are effective at limiting or preventing clinical disease when vaccinated animals are subsequently challenged with a virulent BVDV-2 strain.[123,124] Protection from clinical disease is important for stocker/backgrounder and feedlot operations, and immunity to BVDV has been demonstrated to be protective against bovine respiratory disease complex.[125] Preconditioning cattle by vaccinating cattle against BVDV prior to an expected exposure (commingling and shipping) reduces the effects of exposure of cattle to BVDV.

Protection against viremia is the true measure of BVDV vaccine efficacy. To be truly efficacious, vaccination against BVDV should protect against viremia to prevent dissemination of virus throughout the host, including preventing infection of target cells of the reproductive tract that result in fetal infection. In the past decade, the focus for vaccine efficacy has shifted from protection against clinical disease to protection against fetal disease or infection. Published studies indicate the protection against fetal infections following BVDV vaccination varies anywhere from 60% to 100%. This wide degree of variation depends on whether the vaccine is inactivated or modified live, the timing of challenge, and on the degree of homology between the vaccine strains and the challenge strains. Fetal protection studies have been performed evaluating commercial vaccines containing only BVDV-1 strains[126,127] and commercial vaccines containing both BVDV-1 and BVDV-2 strains.[128,129] From published studies, it would appear that protection is superior when animals are challenged with strains from the same genotype.[130,131] An extremely important observation regarding these fetal protection studies is that although protection may not be 100% against all strains of BVDV, the level of protection is far superior to that observed when proper vaccination is not used, as evidenced by very high rates of PI animals in unvaccinated cattle.

BIOSECURITY. Although BVDV prevention and control starts with identification and elimination of PI animals, strict biosecurity is essential to prevent reintroduction of the virus. Strict biosecurity is difficult for most cow-calf and dairy operations to achieve and is even more difficult or impossible for most stocker/backgrounder and feedlot operations to achieve. Biosecurity systems with isolation and testing of all incoming cattle are necessary to ensure that BVDV does not enter the farm. All purchased cattle should be isolated and tested for BVDV persistent infection prior to entry into the herd. In addition, isolation of new additions for 3 weeks prior to entry into the resident breeding herd should prevent transmission of BVDV from acutely infected animals. Most lapses in herd biosecurity involve purchasing cattle that are PI with BVDV or by purchasing pregnant cattle where the BVDV status of the fetus is unknown. If pregnant cattle are purchased, these animals should be isolated and their offspring should be tested to ensure that they are free of BVDV. Semen should be used only from bulls that have been tested for BVDV infection. For purebred herds marketing genetically valuable embryos and livestock, it is important to test embryo transplantation recipients to ensure that they are not PI with BVDV. Exposure of cattle to other cattle or small ruminants at exhibitions should be limited, and animals should be quarantined for 3 weeks prior to reentry into the breeding herd. Most biosecurity principles instituted for BVDV control will have the added benefit for disease control with other pathogens of cattle.

Malignant Catarrhal Fever (Bovine Malignant Catarrh, Malignant Head Catarrh)

Robert J. Callan

Definition and Etiology Malignant catarrhal fever (MCF) is a severe lymphoproliferative disease caused by a group of gamma herpesviruses collectively referred to as malignant catarrhal fever viruses (MCFVs).[1-4] Ten genetically and antigenically related viruses have been identified and make up the group of MCF viruses. Six of these viruses are associated with clinical disease and the remaining four viruses have not yet been associated with disease (Table 32-11). Each virus has a reservoir host where infection is typically asymptomatic. Clinical disease occurs in aberrant hosts and is characterized by acute onset of fever, inappetence, profuse ocular and nasal discharge, ocular signs including corneal opacity and conjunctivitis,

TABLE 32-11

Ten Antigenically and Genetically Related Viruses in the Malignant Catarrhal Fever Virus Group and Their Respective Reservoir and Clinical Hosts[3,4]

Virus	Primary Reservoir Host	Primary Clinical Host
Alcelaphine herpesvirus type 1 (AlHV-1)	Wildebeest (*Connochaetes* spp.)	Cattle and other domestic and wild ruminants
Ovine herpesvirus type 2 (OvHV-2)	Domestic and wild sheep	Cattle, American bison, and other domestic and wild ruminants
Caprine herpesvirus type 2 (CpHV-2)	Goats	White-tailed deer, Sitka deer, roe deer, moose
MCFV of white-tailed deer (MCFV-WTD)[11]	Unknown	White-tailed deer
Ibex-MCFV[49]	Ibex *(Capra nubiana)*	Bongo antelope *(Tragelaphus eurycerus)*
AlHV-2–like virus[50]	Jackson hartebeest *(Alcelaphus buselaphus)*	Barbary red deer *(Cervus elaphus barbarous)*
HiHV-1[51]	Roan antelope *(Hippotragus equinus)*	None identified
Oryx-MCFV[52]	Oryx *(Oryx gazekka)*	None identified
Muskox-MCFV[52]	Muskox *(Ovibox moschatus)*	None identified
Aoudad-MCFV[4]	Aoudad, Barbary sheep *(Ammotragus lervia)*	None identified

MCFV, Malignant catarrhal fever virus.

VetBooks.ir

alimentary erosions, enteritis, and enlarged lymph nodes. The disease is typically progressive and often fatal.

Clinical MCF is observed in cattle, deer, bison, buffalo, several other domestic and wild ruminants[5] (33 species to date), and pigs. It has worldwide distribution and can be a problem in zoos and game parks. There are two primary etiologic forms of MCF that are designated by the host reservoir of the virus. Wildebeest-associated MCF (WA-MCF) is caused by alcelaphine herpesvirus-1 (AlHV-1). The principal reservoir of AlHV-1 is the blue wildebeest *(Connochaetes taurinus)* and the black wildebeest *(Connochaetes gnou)*.[6] WA-MCF is seen primarily in Africa or in zoologic parks where other ruminants have contact with wildebeest. Sheep-associated MCF (SA-MCF) is caused by ovine herpesvirus type 2 (OvHV-2). Domestic and wild sheep and goats are asymptomatic reservoirs of the virus. SA-MCF is the primary form of MCF that is observed outside of Africa and primarily affects domestic and wild ruminants. MCF caused by OvHV-2 has also been identified in pigs.[7-9] Goats are a reservoir for caprine herpesvirus type 2 (CpHV-2),[10] which has been isolated from cases of MCF in white-tailed deer,[11] Sitka deer,[12] roe deer, and moose.[13] Both AlHV-1 and OvHV-2 can be experimentally transmitted to rabbits and hamsters, in which infection causes an acute, fatal lymphoproliferative disorder similar to natural MCF.[2]

Clinical Signs and Differential Diagnosis Cattle from 4 weeks of age to adulthood can be infected and develop clinical illness. After an incubation period of 2 to 30 weeks, the disease attacks vascular endothelium causing a lymphocytic vasculitis. The incubation period can be prolonged, and in at least one case the incubation period was 200 days. High fever, alimentary erosions, diarrhea, dysentery, corneal opacity, anterior uveitis, conjunctivitis, mucopurulent nasal discharge, thickened cracking skin, encephalitis, lymphadenopathy, and hematuria may be seen (Fig. 32-92). Oral and nasal erosions may be evident but are often too far back in the nasal or oral cavity to be observed externally. Ocular lesions are often present and consist of corneal opacity that originates in the periphery (centripetal) and progresses to the center. Corneal ulceration is generally not present and there is no uptake of fluorescein dye. Generalized weakness and dyspnea occur. Ropy saliva may be dropped from the painful mouth, and scabs may develop on the muzzle. Swelling and hyperemia of the coronary bands may be observed, characteristic of coronitis. The hoof or horns may be shed, and lameness may be pronounced. Hematuria often is present and caused by a hemorrhagic cystitis. Nonsuppurative arthritis can also be observed. Neurologic signs including ataxia or altered mentation may occur and are caused by a nonsuppurative encephalitis. Cutaneous lesions may be observed and consist of multifocal coalescing alopecia with dermatitis and necrosis. When particular signs predominate, the condition may be labeled the alimentary form, the encephalitic form, the head and eye form, or the skin form. One strain of virus can cause all forms, and animals with most of these signs can be seen in a given outbreak. Clinical signs in any single animal may progress rapidly or over a course of weeks. Disease in Sitka deer (and perhaps other species) may consist primarily of dermatitis and alopecia.[14]

FIG. 32-92 A yearling steer with malignant catarrhal fever. Note the corneal opacity, lacrimation, and mucopurulent nasal discharge.

The course of the acute disease is usually 3 to 7 days; some animals survive longer. Disease is generally more severe and progresses more rapidly in bison compared with cattle. The mortality rate is very high. Peracute deaths without any visible symptoms can also occur. A mild form, with transient fever and mild oral and nasal mucosal erosions followed by recovery, has been seen in experimentally infected cattle. Some animals survive clinical disease and in a few cases, may return to normal productivity. Case mortality is generally high and may exceed 90%. However, chronic and recovered cases are described, and in one report, recovery was seen in 50% of cases.[15]

MCF must be differentiated from bovine viral diarrhea mucosal disease (BVD-MD), rinderpest, bluetongue, vesicular stomatitis (VS), and foot-and-mouth disease (FMD). The last two diseases are not usually associated with diarrhea, and VS and FMD tend to have high morbidity and low mortality rates. Clinical bluetongue is rare in cattle and not usually associated with dysentery. Arsenic toxicity and chlorinated naphthalene toxicity have some clinical similarities to the intestinal forms of MCF. Ocular signs, including corneal opacity, conjunctivitis, and discharges, must be differentiated from bovine keratoconjunctivitis (pinkeye), in which the lesion starts at the center of the cornea and corneal ulceration is present. In contrast, the corneal opacity of MCF starts at the limbus and is caused by edema secondary to the loss of the internal endothelial layer of the cornea.[16,17]

Clinical Pathology and Serology Some affected animals show leukopenia caused by lymphopenia and neutropenia if sampled early in the course of disease, but this is an inconsistent finding in natural outbreaks.[18] Joint fluid is cloudy and may contain increased protein and mononuclear cell numbers. Cerebrospinal fluid may have elevated protein concentrations and elevated WBC counts with mononuclear pleocytosis in animals displaying neurologic signs. Serologic tests include ELISA, indirect immunofluorescence, complement fixation, and virus neutralization.[3] Virus isolation can be attempted for cases of MCF caused by AlHV-1. Serologic tests identify antibodies directed to a conserved MCFV glycoprotein and do not discriminate between the different MCF viruses. Serologic tests are best used to screen the infection status of reservoir animals or to identify asymptomatic infection in clinically susceptible hosts. Diagnostic PCR tests have been developed for AlHV-1 and OvHV-2.[3] PCR tests are best used to distinguish between AlHV-1 and OvHV-2 in animals with clinical MCF. PCR tests for the identification of other MCF viruses are available from specific research labs, including a multiplex PCR assay.[3]

A presumptive diagnosis is based on a history of exposure, clinical signs, and evidence of infection supported by serology or PCR. A definitive diagnosis can only be made by the presence of characteristic histopathologic lesions including lymphocytic vasculitis.[3]

Pathophysiology Natural infection occurs through inhalation of aerosolized virus or through direct or indirect contact with ocular or nasal secretions from reservoir hosts. The exposure dose plays a role in the likelihood of developing clinical MCF and the duration of the incubation period.[3,19-23] Experimental transmission studies in sheep and bison show initial replication of the virus in respiratory epithelium.[3,19,20,22,23] OvHV-2 DNA can be identified in the respiratory tract in 9 to 12 days post infection in bison experimentally infected by intranasal inoculation.[24] OvHV-2 infection of lymphocytes is observed by 14 to 21 days post infection. The incubation period for clinical MCF is highly variable and ranges from 14 to over 200 days. MCF virus infection causes infiltration of lymphocytes, particularly T cells, into tissues.[2] This T-cell proliferation is predominated by $CD8^+$ gammadelta T cells and to a lesser extent $CD4^+$ T cells.[25] There is also an increase in large granular lymphocyte

VetBooks.ir

(LGL) cells that appear to have cytopathic activity. It is believed that the fundamental pathology is caused by an autoimmune-like process involving dysregulation of cytotoxic T cells.[2,25,26]

Epidemiology WA-MCF remains an important disease in cattle and other ruminants that come in contact with wildebeest.[5] AlHV-1, unlike OvHV-1, can be isolated in cell culture and this has aided the ability to study the disease epidemiology and transmission. Wildebeest calves are generally infected with AlHV-1 in utero or soon after birth and shed the virus in ocular and nasal secretions to the age of 4 to 6 months.[6,27,28] As adults, the wildebeest become latently infected and transmit the virus to their offspring. Recrudescence and shedding of AlHV-1 in wildebeest can occur following treatment with corticosteroids. Cattle are infected with AlHV-1 when exposed to young, actively shedding wildebeest calves. The incubation period of WA-MCF under natural exposure conditions in cattle can range from 2 weeks to 6 months and perhaps longer. In general, the incubation period of WA-MCF is shorter than SA-MCF. Some cattle that become infected with AlHV-1 do not develop clinical MCF. Diseased cattle do not shed free infectious virus and thus are not a risk to contact animals.[5]

SA-MCF is the predominant form of MCF seen outside of Africa. The prevalence of OvHV-2 infection determined by PCR or competitive inhibition (CI)-ELISA in healthy adult North American domestic sheep is reported to be 99% and 94%, respectively.[29] Sheep serve as the primary reservoir of OvHV-2, although sheep do not show clinical signs of infection. Less than 5% of lambs are infected at birth.[30] The majority of lambs remain uninfected up to 2.5 months of age. After 3.5 months of age, the lambs develop infections through close contact with adult sheep approaching 100% prevalence by 5.5 months. Shedding and transmission of OvHV-2 is through nasal and ocular secretions.[31,32] Seroconversion and detection of OvHV-2 DNA in nasal secretions lags the detection of viral DNA in blood by several months.[30] Separation of lambs from adults at 2 months of age reliably produces OvHV-2–free sheep.[33] These findings indicate that newborn lambs are not a major source of virus infection for cattle. Peak nasal viral shedding occurs around 6 to 9 months of age and it is these infected adolescent lambs that pose the greatest transmission risk to other animals.[32]

Adult sheep continue to shed low numbers of virus throughout their life.[32] OvHV-2 shedding from adult sheep may be higher during the periparturient period or while on feed in feedlots, resulting in a higher risk to commingled cattle. OvHV-2 is readily transmitted between in-contact sheep; however, transmission by inoculation of whole blood or PBMCs is inconsistent.[34] This suggests that infectious virus is primarily produced and shed by nasal or ocular secretions and that infection of blood cells may be largely nonproductive.

Positive CI-ELISA tests have been identified in bison (2% to 23%), domestic goats (74%), elk (9%), mule deer (2%), white-tailed deer (3%), pronghorn antelope (25%), bighorn sheep (37%), muskox (40%), and mouflon sheep (62%). Black-tailed deer, llama, and mountain goats have been tested and were not found to be seropositive for MCF.[35,36] However, it is not clear if these species play any role as reservoir species.

The sheep-associated form of MCF can be acute or chronic, and animals may recover. Cattle and American bison *(Bison bison)* are the two primary species affected by SA-MCF. The disease usually occurs sporadically, with only one or a few animals affected, but many large outbreaks have been reported.[37-41] Transmission most likely occurs through direct contact, indirect contact, and aerosol of nasal secretions from sheep. In one report, exposure of bison to sheep for less than a day at an auction resulted in high mortality.[41] There is evidence of transmission from sheep to cattle or bison extending over distances of 70 m up to 5.1 km.[39,42,43] In one example of natural infection of bison, the incidence of disease and mortality was inversely related to the distance of exposure.[39] The incubation period following experimental or natural exposure ranges from 14 to 220 days.[21,24,37,40,41] Cattle and bison are considered dead-end hosts and do not spread the infection to other animals.[2,5,41]

Bison are more susceptible to developing clinical MCF than are cattle by both experimental inoculation studies and natural exposure.[19,21,40] In bison, OvHV-2 infection and clinical MCF is observed with intranasal nebulization at doses as low as 10^3 DNA copies of OvHV-2.[19,20] Cattle become infected with doses as low as 10^6 OvHV-2 copies but require at least 10^8 copies to become infected with clinical MCF.[21] In contrast, the minimum infectious dose for sheep is between 10^2 and 10^3 DNA copies but sheep require a dose of 3×10^9 copies to develop nonfatal clinical signs of MCF.[22,23] Several studies have shown that both cattle and bison can be infected with OvHV-2 and not develop clinical MCF.[35,36,38,42,44] These studies show that infection, morbidity, and mortality are related to species susceptibility, inoculation dose, and likely other factors not yet determined. Both asymptomatic and clinically affected cattle and bison do not shed infectious virus and are considered dead-end hosts.

Necropsy Findings The nasal mucosa is hyperemic may have hemorrhagic superficial erosions. The oral mucosa has necrotic papillae and large areas of necrosis and ulceration. Multiple focal ulcerations are seen in the esophagus. Parts of the forestomachs and intestines are thickened, edematous, and occasionally ulcerated and hemorrhagic. The lymph nodes, tonsils, and Peyer patches are enlarged, moist, and friable. Splenic lymphoid follicles are prominent, and the liver is swollen. The adrenal glands are hemorrhagic. The mucosal surface of the bladder has focal areas of hemorrhage. The eyes are hyperemic and show severe corneal edema. The brain may have intersulcal cloudiness and meningeal petechiation consistent with encephalitis. Joints may have swollen and reddened synovia with an increased quantity of cloudy fluid.[45]

Histologically, there is a marked lymphoid accumulation around blood vessels, as well as necrosis of the tunica media and intima in multiple tissues. There is generalized lymphoid hyperplasia and lymphoid infiltrates in subepithelial and intraepithelial locations, associated with epithelial necrosis and sloughing. Similar changes occur in all epithelial tissues.[45] Chronic cases develop chronic obliterative arteriopathy.[15]

Treatment and Prognosis There is no specific treatment for MCF beyond supportive care. Fluid therapy and nursing care may allow some animals to survive and recover from disease. Antimicrobial treatment to help prevent secondary bacterial pneumonia or septicemia may provide some benefit. Treatment with nonsteroidal antiinflammatory drugs may provide comfort but could increase the degree of alimentary erosions or decrease their healing. Gastrointestinal protectants such as Kaopectate or bismuth subsalicylate may provide support to the gastrointestinal tract and help maintain appetite. Maintenance of appetite seems to be one of the key prognostic indicators in clinical cases of MCF. Although some animals that exhibit mild disease may survive, close to 100% of those with severe clinical signs die.

In a recent report, the severity and progression of ocular lesions associated with MCF in cattle were evaluated relative to disease outcome.[16] The degree of corneal edema at presentation did not show prognostic value in predicting disease outcome (death vs. survival). However, improvement of corneal edema over the course of the disease was associated with a better outcome. In addition, animals where anterior uveitis worsened were more likely to die or be euthanized.

Prevention and Control At this time, the primary method of control is to reduce the exposure of susceptible hosts to reservoir hosts. Transmission is related to the distance between reservoir hosts and susceptible hosts so these groups of animals should be physically separated. This can be particularly difficult since transmission from sheep to bison over distances as far as 5 km have been reported.[39] Adult wildebeest and sheep pose a lesser risk of transmission than do neonatal wildebeest and adolescent sheep that shed higher amounts of virus from nasal secretions than the adults. Attempts to keep these younger groups of reservoir animals at a greater distance

VetBooks.ir

from susceptible hosts should be encouraged. Feedlot sheep from 6 to 9 months of age pose a significant risk. Natural transmission of OvHV-2 between feedlot sheep and dairy cattle or bison is reported and is likely related to the younger age of the feedlot sheep compared with adult breeding animals.[39,40,42]

Currently, there are no commercial vaccines available for prevention of WA-MCF or SA-MCF. Recently, an attenuated AlHV-1 vaccine showed protection against virulent AlHV-1 challenge in cattle for up to 6 months in a portion of the vaccinated animals.[46] Respiratory tract mucosal immunity appears to be critical in preventing initial infection and development of clinical MCF.[2,46-48] Further research identifying critical antigens and methods to induce strong, long-lasting mucosal immunity for both AlHV-1 and OvHV-2 will be necessary to develop effective vaccines for bison and cattle.

Vesicular Stomatitis

Bradford P. Smith

Definition and Etiology Vesicular stomatitis (VS) is a rhabdoviral disease of the genus *Vesiculovirus* that causes sporadic (cyclic) outbreaks in cattle, horses, donkeys, mules, and pigs and typically has a high morbidity but a low mortality rate. Cattle under 1 year of age rarely show clinical signs. Sheep and goats also rarely have clinical signs, and South American camelids are intermediate in susceptibility. VS is seen in the United States, Mexico, and Central and South America. Human beings have sometimes been infected with an influenza-like disease. Four distinct viruses are now recognized: VS Indiana (formerly called Indiana 1), VS New Jersey, Alagoas virus (formerly called Indiana 3), and Cocal virus (formerly called Indiana 2), with Indiana and New Jersey occurring in the United States.[1] Strains within each virus vary in virulence. Vesicles occur in the mouth, on the teats, and in interdigital areas, so the major differential is to eliminate foot-and-mouth disease (FMD) as a diagnosis. Lesions may occur only on the teats or only in the mouth. The vesicles rapidly turn to painful ulcerations that cause dysphagia and reluctance to eat, frothing at the mouth, drooling, agalactia, weight loss, mastitis, and lameness. Death is rare.

Epizootic waves of VS have tended to occur at about 10-year intervals, usually in the summer or fall, but since the major epizootic in 1982 and 1983 in the western United States, the NJ serotype has been identified in the United States each year. An outbreak occurred in 1995 in the western United States, in New Mexico, and Colorado.[2] More cases occurred in 1997 and 1998. From 2004 through 2006, 751 VS outbreaks caused by vesicular stomatitis virus serotype New Jersey (VSNJV) were reported in nine states of the southwestern United States, and overwintering of the virus was demonstrated.[3] Both migratory western grasshoppers and the plants they eat can be infected with VS virus,[4] providing another means of livestock exposure. It is hypothesized that VS virus may be a plant virus that strays into animals, where it causes disease.

Although the NJ serotype has at least 14 distinct genotypes, only a few of these have been found in recent outbreaks in the United States. The NJ serotype should be considered a collection of serologically related but genetically variant viruses. State and federal regulatory veterinarians should be contacted immediately when VS is suspected so that quarantine and disease identification measures can be used quickly to contain an outbreak.

Numerous outbreaks occur yearly from southern Mexico to northern South America. Outbreaks were seen in many parts of Mexico in 2008.[5]

Clinical Signs and Differential Diagnosis After a mean incubation period of 9 days (the range is 3 to 21 days), there is onset of fever and oral lesions that cause excess salivation and reluctance to eat.[6,7] From 5% to 60% of cattle on a farm may show clinical signs. Vesicles are only occasionally visible, because the epithelium rapidly necroses and many lesions quickly turn to ulcers. Lesions on the gums and tongue may coalesce to form large eroded areas (Figs. 32-93 and 32-94). Milk yield falls quickly. Teat lesions are common in dairy cattle, and small ulcers in the interdigital area and on the coronary band are occasionally seen. Recovery varies from 2 to 21 days, depending on the severity of the lesions and management factors such as the type of feed and milking sanitation.[6] Actual healing of the lesions may take 34 to 59 days.[7]

FIG. 32-93 Severe ulceration of the tongue of a dairy cow caused by vesicular stomatitis. A plaque of dying mucosa covered by fibrin is visible at the tip of the tongue, and excessive salivation is obvious. *(Courtesy Dr. Mark Thurmond.)*

FIG. 32-94 Tongue of horse with vesicular stomatitis (VS) demonstrating severe lingual erosions. *(Courtesy Dr. Skip Aaroe.)*

The major differential diagnostic consideration is FMD, which causes almost identical clinical signs. Other diseases of cattle that result in oral lesions (BVD, BPS, bluetongue) do not usually appear as epidemics but rather in one or a few animals (although BPS may have a high morbidity). Other causes of oral lesions such as bristle grass irritation and toxins should be ruled out.

Clinical Pathology and Laboratory Diagnosis The VS virus is difficult to isolate from blood, urine, feces, and oral swabs but has been isolated from tongue epithelium.[7] ELISA, PCR, CF, and a fluorescent antibody test are available for virus identification. Serum neutralizing (SN) titer rises rapidly after exposure and then gradually falls over the first year. SN titers that follow natural exposure may persist for years. Vaccination with inactivated virus results in a rapid rise in titer followed by a gradual decline for a year.[8] The presence of an SN antibody titer does not prevent reinfection or development of clinical signs. Hematologic and clinical chemistry findings generally reflect an acute to chronic inflammatory disease and are nonspecific in helping to make a diagnosis.

VetBooks.ir

Pathophysiology After a short incubation period of 24 hours, fever and viral invasion of the germinative layer of oral epithelial cells occur. Oral abrasions or trauma may increase susceptibility.[6] Contact of virus with teats or feet can result in lesions in these areas, especially if the teats are chapped or cracked or the feet are traumatized. The lesions progress rapidly from blanched macules to vesicles and soon rupture, leaving sloughed epithelium and ulcerated areas. Healing occurs quite rapidly if feed is soft and nontraumatic.

Epidemiology Older, higher producing dairy cows that have been in milk longer are more susceptible than herdmates to clinical disease caused by VS.[6] Because the virus cannot penetrate intact mucosa, cattle fed coarse feeds or hard pellets that traumatize the oral mucosa are at higher risk. Cows with chapped or cracked teats and those on farms with poor milking hygiene are more likely to get teat lesions.[6] Cow-to-cow contact is a major mode of transmission in outbreaks, and increased interpen movement of cattle, as well as shared feed and water troughs, unless cleaned frequently, increase the risk of development of VS. The virus is transmitted by milking machines and human hands during outbreaks. Insect vectors also contribute to the mechanical spread.

Outbreaks are often associated with the movement of animals from another area, but disease epidemics not associated with new animals do occur. The infection tends to be seasonal (occurring in the summer and fall in temperate areas and at the end of the rainy season in the tropics) and behaves like an arthropod-borne virus. The midge *C. sonorensis* was found in 2005 to be an efficient vector of VS virus. Other biological vectors include sand flies (*Lutzomyia* spp.) and black flies (*Simulium* spp.).[1] Other insects act as mechanical vectors. Antibodies have been found in a number of wild species of animals (deer, raccoon, bobcat, monkey), which may provide a virus reservoir. Active cases of VS occur in Mexico between U.S. epidemics, giving rise to the possibility that cattle from Mexico arriving in the United Sates may also act as sources of VS virus. Sheep and goats in contact often seroconvert, although clinical signs in these species are rare. The virus survives several weeks in cool soils but is inactivated by sunlight and is very resistant to pH changes. Cattle generally show a high morbidity rate and a low mortality rate (1% to 5%). Although many in-contact cattle do not show obvious clinical signs of disease, many more have oral lesions if closely examined, and most animals in the herd seroconvert.

The economic losses associated with an outbreak of VS can be severe, especially in dairy cattle. In the 1982 epizootic in California, losses on two dairies (principally decreased milk production and culling for mastitis) totaled $225,000 during 2 months.[9]

Necropsy Findings Deaths are rare and usually are attributed to secondary bacterial diseases, including environmental mastitis and pneumonia. Cattle become gaunt and weak as a result of dysphagia and resultant reduced food intake. Erosive and ulcerative lesions are usually confined to the mouth. The teats frequently are involved in lactating cows, and lesions on the coronary band and interdigital area occasionally may be seen.

Histologically, intracellular and extracellular edema, ballooning and degeneration of epithelial cells, and vesicle formation accompanied by neutrophilic infiltration are present. There are no inclusion bodies. The characteristic bullet-shaped structure of the VS virus sometimes can be seen with electron microscope examination of fresh lesions or vesicular fluid.

Treatment and Prognosis Mortality can be almost completely prevented if ill cattle are offered shade, fresh water, clean bedding, and soft feed. Offering soft feed hastens recovery and reduces the anorectic period. Debilitated cattle should be given broad-spectrum antibiotics in an effort to control secondary bacterial pneumonia. Cattle with teat lesions are at high risk for developing mastitis and should be carefully milked last and monitored closely for mastitis. The prognosis for survival is very good, but agalactia and mastitis may result in the culling of a large number of animals.

Prevention and Control The reader should use websites such as the World Organisation for Animal Health (OIE) and the U.S. Department of Agriculture (USDA) for the latest information on contagious illnesses. During an outbreak of VS, quarantine of the premises and isolation of sick animals are required. Regulatory officials will help organize and maintain a quarantine. Feed should be soft and fine, because coarse or hard-pelleted feeds increase the spread of the virus and prolong the recovery time. Leftover feed should be removed from feed bunks twice daily, and the bunks disinfected. Water troughs should be cleaned and disinfected daily. VSV is susceptible to numerous disinfectants including 1% sodium hypochlorite, 70% ethanol, 2% glutaraldehyde, 2% sodium carbonate, 4% sodium hydroxide, iodophor disinfectants, 1% formaldehyde and chlorine dioxide.[1] It is also inactivated by UV light, lipid solvents, or heat. Two hours of exposure to lye (2% NaOH) will *not* deactivate the virus.

Vaccination using killed[10] or live virus vaccines is rarely practiced preventively because the disease occurs as rare epidemics in small areas and because vaccination interferes with serologic testing and monitoring. Vaccination with a killed virus vaccine may be used by regulatory veterinarians in at-risk animals during an epidemic, as it has been shown to be an effective vaccine.[10] Owners and managers must consult state and federal veterinarians before considering VS vaccination.

Foot-and-Mouth Disease (Aftosa, Aphthous Fever)

Bradford P. Smith

Definition and Etiology Foot-and-mouth disease (FMD) is an acute, highly contagious viral disease of cloven-hoofed livestock characterized by vesicular lesions, erosions, and ulcers in the mouth and interdigital areas and on the muzzle, teats, and coronary band. Natural hosts include cattle, sheep, goats, swine, water buffalo, bison, deer, elk, antelope (all wild ruminants), bears, llamas, camels, giraffes, elephants, rats, yaks, capybaras, and hedgehogs.[1] Of these, cattle and swine are the most susceptible, and camelids have low susceptibility. Mature sheep and goats usually have mild signs, and horses are resistant to infection. Livestock of all ages are susceptible, but the mortality rate is higher in young animals because cardiac lesions occur. In rare cases, humans have contracted the disease. It is endemic in Asia, Africa, parts of Europe and the Middle East, and most of South America, where losses involve not only those caused by the disease itself but also the monetary losses that result because fewer animal products are available for export as a result of loss of foreign markets. Great Britain experienced a major epidemic in 2001, and China had one in 2009.[2]

The FMD virus is a picornavirus of the genus *Aphthovirus.* At least seven immunologically distinct types of FMD virus have been identified: A; O; C; SAT 1, 2, and 3; and Asia 1. Within the seven types, at least 60 subtypes have been recognized. African buffalo are the major maintenance host of SAT serotypes, and may harbor the virus for at least 5 years.[3] Vaccination against one subtype may not protect against another. This fact, together with the fact that immunity is generally short term, means that effective vaccination programs are difficult. The virus is rapidly inactivated by high or low pH, sunlight, and very high temperatures but is very resistant to normal environmental conditions and drying. Sodium hydroxide, sodium carbonate, chlorine dioxide, and acetic acid are effective disinfectants,[1] but many common disinfectants are ineffective, and the virus is resistant to iodophors, quaternary ammonium, hypochlorite, and phenol.

Clinical Signs and Differential Diagnosis FMD is clinically indistinguishable from vesicular stomatitis (VS) except that VS also affects horses. Clinical signs of FMD include fever, depression,

VetBooks.ir

anorexia, listlessness, occasional shivering, excess salivation, lip smacking, nasal discharge, and lameness. Agalactia may occur. In addition to VS, the differential diagnosis includes bovine papular stomatitis, bovine virus diarrhea, bluetongue, rinderpest, malignant catarrhal fever, and severe cases of infectious bovine rhinotracheitis. Teat lesions can be confused with those caused by bovine herpes mammillitis or parapoxviruses.

Vesicular lesions (blisters) 0.5 to 10 cm in diameter rupture within 48 hours, followed by a mucosal slough and large erosion. These lesions appear to be very painful, and affected animals are reluctant to eat or move. The morbidity rate is high, but the mortality rate is low. The disease is economically devastating because it spreads rapidly and causes weight loss, mastitis, loss of milk production, and frequent abortion. An outbreak of FMD in a country previously free of the disease can cost billions of dollars in trade losses over ensuing years. Deaths may occur in young calves, mainly from myocardial necrosis, and secondary bacterial pneumonia and foot infections are common.

Laboratory Diagnosis Because FMD is clinically indistinguishable from VS and other viral mucosal diseases, laboratory confirmation of the diagnosis is obtained through complement fixation (CF), virus neutralization, agar gel precipitation, enzyme-linked immunosorbent assay (ELISA), reverse transcription polymerase chain reaction (RT-PCR),[1] or fluorescent antibody tests. ELISA appears to be more sensitive and type specific than CF[4] and virus neutralization. When VS or FMD is suspected, state and federal authorities should be contacted immediately. In FMD-free countries, quarantine is practical to control spread. Slaughtered animals are burned and/or buried. All animals within 3 km may be destroyed during efforts to halt the disease.

Pathophysiology The usual incubation period is 2 to 14 days. The usual primary sites of infection and replication by the FMD virus are the pharyngeal and digestive mucosa and alveolar epithelium of the udder. The virus replicates in the cells of the stratum spinosum. It spreads locally and also enters the circulation and is carried to other susceptible tissues. Within 2 to 21 days a fever begins, and some vesicles appear. Vesicles develop in the mouth and on the ruminal pillars, and myocardial and skeletal muscle degeneration characterized by Zenker necrosis may occur in young cattle. The mucosal cell disruption results in separation of superficial epithelium from basal epithelium, which fills with tissue fluids. When these epithelial layers slough, erosions are left behind that take days to weeks to heal, depending on their size.

Epidemiology Transmission occurs primarily by means of aerosols, animal contact, and fomites such as shoes, tires, and equipment. The virus may be spread to farms 50 miles distant. Human beings can carry (and subsequently transmit) the virus on their shoes or clothing or in respiratory tract tissues for longer than 24 hours. Recovered cattle usually stop shedding the virus by 2 weeks, but some harbor it for 6 to 24 months and may act as sources of the virus at the start of an epidemic. The virus has been isolated from semen, and the possibility exists of sexual transmission from the African buffalo to cattle. African cape buffaloes can be lifelong carriers.

The virus exists in milk, and it may survive pasteurization. Uncooked or partly cooked meat products or garbage scraps, hides, or other tissues contaminated with the FMD virus from an endemic area of the world may transmit the disease long distances. The virus can persist in frozen meat for years. Besides actively infected animals, sources of infection include bedding, feed, milk, shoes and hands of humans, and equipment.

Necropsy Findings In addition to oral erosions and ulcerations, ulcers may be seen on the ruminal pillars. In young cattle myocardial and skeletal muscle degeneration and necrosis may be noted. Histologically the vesicles are characterized by ballooning, cellular degeneration, intracellular and extracellular edema, and separation of the basal epithelium. There are no inclusion bodies. Muscle lesions (skeletal and cardiac) are characterized by necrosis (Zenker degeneration).

Treatment and Prognosis Where FMD is endemic, quarantine, local eradication, virus typing, and revaccination of contact and at-risk cattle with the appropriate virus subtype should be considered. Good nursing care and administration of systemic antimicrobial drugs to limit secondary bacterial pneumonia and mastitis are recommended. Soft feeds such as chopped green grass (or soaked hay) are much more palatable than dry hay to sore-mouthed animals. The prognosis is good for survival, although many animals abort, lose weight, stop lactating, or have severe bacterial mastitis secondary to viral teat lesions and must be culled. The virus destroys mammary alveolar epithelium permanently.

Prevention and Control The reader should also consult the OIE and USDA websites for current status of this disease. In endemic areas, vaccination and quarantine are the basis for prevention and control. In FMD-free areas (Great Britain, the United States, Canada, Japan, New Zealand, and Australia), the method of choice is rapid identification of an outbreak, quarantine, and slaughter of all affected and exposed herds. Global strategies are also being studied.[5]

Vaccines must be type specific. Most European and South American countries use trivalent inactivated vaccines against types A, O, and C from cell culture virus. Vaccine-induced and naturally occurring immunity is short-lived, and vaccination usually must be repeated two or three times a year.[1] Newer, oil-adjuvanted vaccines may protect for up to 1 year. Because the protection is partial, infection usually results in subclinical or mild disease. Calves nursing immune dams are likewise partly protected by passive antibody for up to 5 months. Recent research examining subunit vaccines is promising.[2] In an outbreak the most effective vaccine is autogenous.

Rinderpest (Cattle Plague) and Peste des Petits Ruminants

Bradford P. Smith

Definition and Etiology Rinderpest and peste des petits ruminants are acute, highly contagious, and usually fatal diseases of ruminants. Rinderpest was officially declared by the World Organisation for Animal Health (OIE) to be globally eradicated in 2011, the second disease after smallpox to be eliminated.[1] Cattle and water buffaloes are most frequently affected, but the disease also occurs in yaks, gaur, sheep, goats, pigs, and other cloven-hoofed animals, in which it is usually less severe. It is rarer in camelids. Many wild animals in Africa are susceptible, including buffalo, lesser kudu, eland, giraffe, warthog, and wildebeest. Rinderpest virus (RPV) and peste des petits ruminants (PPR) are in the Paramyxoviridae family, genus *Morbillivirus.* There is only one known strain of RPV, and it is closely related serologically to the virus that causes PPR. The virus can remain viable for at least 1 year in frozen tissue, but it is killed by direct sunlight in 2 hours. Other morbilliviruses pathogenic for animals include canine distemper and the 1995 Australian morbillivirus, which occurred in horses and humans.

PPR is a closely related highly fatal virus of goats and sheep. It occurs in sub-Saharan Africa, the Middle East, and Asia. Morbidity can reach 100% and mortality can be between 50% and 100%. Cattle and pigs develop inapparent infections. The disease also occurs in wild species, including several gazelles, gemsbok, ibex, and wild sheep. Clinical signs of PPR in goats and sheep are similar to those of rinderpest in cattle. Bronchopneumonia is also common. The reader is referred to the OIE website[2] for current information.

Clinical Signs and Differential Diagnosis The incubation period in cattle is 3 to 15 days, which is followed by sudden onset

VetBooks.ir

of fever, depression, and anorexia. The nose is dry, and mucous membranes are congested. Within days oral erosions appear where necrotic foci have sloughed. Purulent lacrimation occurs. Diarrhea is severe and may be bloody. Dehydration and emaciation often lead to death. The disease in sheep and goats usually is mild or subclinical, but the PPR virus can cause outbreaks with high morbidity and mortality in small ruminants.

In endemic areas rinderpest is suspected when the signs described earlier occur in groups of animals. In nonendemic areas diseases that appear similar clinically are bovine virus diarrhea (BVD), malignant catarrhal fever (MCF), arsenic poisoning, severe coccidiosis, and severe fulminating infectious bovine rhinotracheitis, as well as FMD and VS. Other causes of severe gastroenteritis and diarrhea (e.g., salmonellosis) must also be considered. In small ruminants with PPR, bluetongue and Nairobi sheep disease must be ruled out.

Laboratory Diagnosis A rapid strip test for PPR can be applied in the field.[3] Laboratory confirmation of rinderpest and PPR can be accomplished by virus isolation, PCR, ELISA, detection of viral antigen by fluorescent antibody testing, virus neutralization, CF, or AGID; detection of rising antibody titer by ELISA or virus neutralization; and histopathologic evaluation, including immunohistopathology. Virus isolation is most successful in the first days of infection (often before the onset of diarrhea). Blood should be taken in heparin. The lymph nodes and spleen are reliable sources of virus, and tears and ocular discharges are also reliable sources. Lymph node biopsy after day 3 of infection is the most reliable means of diagnosis in a living goat. Tissues should be shipped frozen on ice to the laboratory for virus isolation or detection of antigen. Detection of a rising antibody titer can help diagnose the disease retrospectively. Leukopenia may be noted in the acute early states of rinderpest.

Pathophysiology The virus usually enters through the respiratory mucosa. Lymphoid tissue is the primary target of RPV. Lymphocytes are destroyed in the germinal centers of the lymph nodes, Peyer patches, tonsils, splenic corpuscles, and cecal lymphoid tissue. Immunosuppression occurs as lymphoid tissue is destroyed. The virus also attacks the alimentary tract mucosa; Peyer patches are the most severely affected. As alimentary mucosa is lost, diarrhea and emaciation become severe.

Epidemiology Rinderpest and PPR are highly contagious, spread mainly through airborne droplets, direct contact, feces, and contaminated fomites such as human beings. All secretions and feces of infected animals are contagious throughout the course of the disease. The virus is susceptible to most disinfectants. Wild ruminants frequently are a source of infection for livestock. The morbidity rate often approaches 100%, with a 25% to 90% mortality rate, making treatment unrewarding and the prognosis poor. Innate or specific resistance may protect individuals or herds from clinical signs after infection. Recovered animals do not appear to act as carriers for more than a few months. Valuable individuals may be helped by supportive therapy and hydration.

Necropsy Findings Lesions are found mainly in the alimentary tract and lymphoid tissues. Subendocardial hemorrhages may also be seen in animals that die of acute illness. Oral erosions, edema, and congestion of the abomasum are typically seen, and ulcers and hemorrhagic to necrotic Peyer patches occasionally are seen. The cecal and colonic mucosae are hemorrhagic, ulcerated, or necrotic. The lymph nodes are enlarged and have necrotic germinal centers.

Prevention and Control Because there is only one known strain of RPV and protection after infection usually is lifelong, vaccination of cattle at 6 months of age and older in endemic areas with a live cell culture attenuated virus is an effective means of controlling rinderpest.[4] Although there is some debate as to whether this vaccine causes immunosuppression, it has been used safely and effectively in millions of cattle in Africa and Asia. The vaccine does not produce adverse reactions, has a long shelf life, and produces solid immunity. Its major disadvantages are that the lyophilized virus has to be kept cold, and once a vial has been reconstituted, it must be used quickly before the virus dies. There is also a specific PPR vaccine available for goats and sheep.

Control of epidemics in areas where the disease is not endemic involves quarantine and slaughter of infected and contact animals, as well as other contact ruminants and swine. Disinfection of premises while under government quarantine is essential to controlling the disease. The virus is susceptible to most disinfectants and survives in the environment only for 2 to 3 days.

Choke and Esophageal Disorders

Bradford P. Smith • Charles L. Guard

Definition and Etiology *Choke* is the term used for esophageal obstruction. In ruminants it is most common in cattle because of their eating habits, but it has even been reported in a goat that ate thread with a needle attached.[1] If the obstruction is complete, the condition is rapidly fatal (except in neonates) because of the inability to eliminate the gases of fermentation produced in the ruminoreticulum. Partial obstruction produces dysphagia or anorexia. Obstruction may be caused by the ingestion of foreign objects or large chunks of solid feedstuffs such as apples, potatoes, beet tops, corn cobs, or even a mango.[2] It also may be the result of space-occupying lesions in or near the esophagus. Choke must be differentiated from diseases that cause dysphagia by means of pharyngeal lesions and resultant neuromuscular dysfunction. Congenital or acquired lesions of the esophagus, such as aortic arch anomalies and diverticula, may cause signs similar to those of esophageal obstruction.

Clinical Signs and Differential Diagnosis The earliest signs of complete esophageal obstruction from intraluminal objects are anxiety and ptyalorrhea (i.e., saliva dripping from the mouth because of an inability to swallow). The animal may violently swing the head from side to side and make repeated attempts to swallow. Staggering (which must be differentiated from ataxia caused by neurologic diseases) may be observed. Bloat develops soon after at a rate that depends on the nature of the ruminoreticular contents. Objects such as potatoes, apples, or beets may be swallowed whole or in chunks too large to pass the entire esophagus, especially in cattle. Dry grain, particularly in pellet form, may be consumed so rapidly that sufficient saliva is not produced to lubricate the passage of the feed boluses. This is more common in sheep than in other ruminants; spontaneous resolution usually occurs within minutes to hours.

Obstruction from intraluminal objects commonly occurs in the cranial part of the cervical esophagus, at the thoracic inlet, or at the base of the heart. In a 2-week-old calf with a cloth foreign body obstructing the distal esophagus at the cardia, regurgitation after drinking milk was observed.[3] External palpation may localize the site of obstruction in the cervical esophagus. With more slowly developing and incomplete obstruction, anorexia and dysphagia may be observed. Bloat may occur repeatedly and resolve spontaneously or after passage of a stomach tube. The underlying cause may result in signs severe enough to mask the esophageal problem. Cellulitis along the cervical esophagus may result in a reluctance to lower the head or bend the neck laterally. Possible causes of cervical cellulitis include perivascular injection of irritating substances, abscesses, and reaction to *Hypoderma lineatum* larvae.

Esophageal stricture may follow a previous episode of esophageal obstruction or inflammation in adjacent tissues. If no site of obstruction is externally evident, careful attempts to pass a stomach tube usually reveal the site of the problem. Radiography with barium contrast material may help identify the site of strictures, perforations, and diverticula. Endoscopy of the esophagus may also aid in identifying the specific nature of functional or structural abnormalities.

VetBooks.ir

Megaesophagus has been observed after pharyngeal trauma, as a congenital disorder, and with hiatal hernia. An animal with an esophageal stricture or a diverticulum may reflux boluses of feed mixed with saliva or regurgitate liquid ruminal contents. Failure to gain weight or progressive weight loss accompanies the failure to swallow feed successfully. Signs may be seen only when forage is consumed, whereas water and grain are swallowed normally.

Systemic diseases may lead to esophageal dysfunction. Rabies must always be considered when dysphagia is present, and appropriate precautions must be taken. Botulism also leads to esophageal transport failure, although dysphagia and a weak tongue are more prominent in the failure of affected animals to eat. Tetanus may be similar in appearance to esophageal obstruction because of the presence of bloat, dysphagia, and drooling. Several poisonous plants, including sneezeweed, larkspur, and milkweed, may cause excessive salivation, drooling, and bloat. Consumption of red clover infected with the fungus *Rhizoctonia leguminicola,* which produces the toxin slaframine, results in copious salivation. Pharyngeal trauma and subsequent cellulitis lead to dysphagia and drooling; severe bloat does not occur unless the swelling is sufficient to occlude the esophagus. However, mild bloat frequently accompanies pharyngeal trauma caused by associated vagal nerve inflammation and dysfunction.

Clinical Pathology Common features of long-standing choke are dehydration and metabolic acidosis resulting from continued loss of sodium bicarbonate and sodium phosphate in saliva. As sodium depletion develops, the composition of saliva shifts to include more potassium under the influence of aldosterone. Inflammatory diseases lead to predictable changes in the hemogram.

Necropsy Findings Animals that die of acute esophageal obstruction are bloated and may have saliva and feedstuffs in the upper airway. Postmortem examination of animals with protracted esophageal dysfunction may reveal focal dilations or stenoses of the esophagus. Esophageal perforation may have occurred because of pressure around an intraluminal foreign body or necrosis caused by extension of an adjacent septic process.

Treatment and Prognosis In cases of complete esophageal obstruction, relieving bloat is the first concern. Passage of a stomach tube may be attempted if the animal is not in respiratory distress. Trocharization of the rumen or installation of a temporary fistula may be required. Until the esophagus has been cleared, it is important to keep the muzzle level or pointed down to reduce the risk of aspiration of saliva. Sedative drugs such as acepromazine or xylazine may be useful to calm the animal and permit careful examination. Suitable precautions should be taken if rabies is remotely possible. The history and an examination of the environment should enable the clinician to anticipate the nature of the obstructing object. Palpation of the neck along the left jugular furrow may reveal the site of obstruction in lean or thin-necked individuals. A manual oral examination should precede probing attempts with a stomach tube. Gentle pressure on the stomach tube as it passes down the esophagus should allow localization of the obstruction. A small hand can reach into the cranial part of the esophagus and may retrieve some solid objects. If the object is solid (e.g., a potato), it may be possible to massage it into the pharynx by pressing in the jugular furrow on both sides of the neck. Specialized equipment, such as a probang, is available with a corkscrew-like or pincer-like end that can be used to grasp or engage a foreign body and expedite its retrieval. If a mass of grain is obstructing the esophagus, external massage, probing with the stomach tube, or pumping fluid against the mass through the tube may break it up.

If the choke is intrathoracic and probing with a stomach tube does not relieve the problem, several courses of action are possible. A small ruminal fistula can be inserted to prevent bloat, and the animal can simply be placed in a pen without bedding, feed, or water. Many masses consisting of grain or hay spontaneously pass within 24 hours, whereas solid objects rarely pass spontaneously. If the obstruction does not resolve in 24 hours, the animal can be heavily sedated, a cuffed endotracheal tube can be passed to prevent aspiration, and vigorous lavage with water through a stomach tube can be attempted. The head should be held lower than the body to minimize the risk of aspiration. If the obstruction still cannot be relieved or it is believed that the obstruction is a solid object, a rumenotomy can be performed. Access to the esophagus through the cardia should allow snaring of the object with a loop of stiff wire or breakup of a mass of grain.

The long-term prognosis after choke is good unless esophageal mucosal damage has occurred. Stricture formation may follow cellulitis or pressure necrosis at the site of the obstruction. Aftercare for the choked animal consists of a soft diet and antiinflammatory drugs to minimize tissue swelling. Well-soaked alfalfa cubes made into a mush may pass partly obstructed areas. Hay and grain should be moistened before feeding, and grain should be offered only in small amounts at each feeding. Broad-spectrum antibiotics should be given if mucosal damage is suspected. Maintenance of an indwelling nasogastric tube for feeding for up to 10 days after severe esophageal trauma may be helpful in preventing strictures during healing. Thick gruels made from soaked alfalfa cubes or pellets can be pumped into the rumen by a bilge pump designed for boats, or the animal can be fed and watered through a ruminal fistula. Surgical exploration may be required to determine the cause of esophageal obstruction from space-occupying lesions or strictures. Abscesses may be drained, and granulomatous lesions resected. Esophageal diverticula, aortic arch anomalies, and intrathoracic surgical problems may not be easily treated.

Esophageal Dilation (Megaesophagus) and Hiatal Hernia

Bradford P. Smith

Megaesophagus rarely occurs in ruminants. It has been reported in association with pharyngeal trauma and resultant inflammatory involvement of the vagus[1] and with hiatal hernia (diaphragmatic hernia with herniation of the reticulum into the thorax) in which there was a large megaesophagus (10 cm in diameter × 20 cm in length).[2] Vagotomy and hiatal hernia are recognized as causes of diminished esophageal pressure. A 4-month-old calf with megaesophagus lacked esophageal muscle cells and ganglion cells, and many fat cells were present.[3] The esophagus of a 12-month-old ram with megaesophagus was found to be heavily infected with *Sarcocystis arieticanis,* and eosinophilic inflammation and degeneration of muscle fibers were noted.[4] However, *Sarcocystis* spp. have been found in the esophagus of many sheep without megaesophagus, making the diagnosis difficult. An 18-month-old heifer with megaesophagus also had eosinophilic submucosal infiltration, but no sarcocysts were seen.[5] Megaesophagus in a goat due to unknown causes was also reported.[6]

The principal clinical signs of megaesophagus are regurgitation or vomiting, usually shortly after eating. Mild, recurrent bloat and discomfort when a stomach tube is passed are also observed. In other cattle with a hiatal (diaphragmatic) hernia or an esophageal diverticulum, regurgitation or vomiting and bloat have also been reported. Contortion of the neck while eating, apparently caused by pain, was seen in one cow and is reported in human beings with hiatal hernia. In some cases of herniation of the reticulum into the thorax, bloat and regurgitation are not seen; in others, diaphragmatic hernia resulted in chronic bloat.[7] Diaphragmatic hernias may be either congenital or acquired. It appears that acquired diaphragmatic hernias are most common.

A stomach tube should be passed to the rumen to rule out choke or an intraluminal mass obstructing the esophagus as a cause. If a tube can be passed freely to the rumen, plain and contrast radiographs of the esophagus should be taken. If this is not possible, surgical exploration of the abdomen for a diaphragmatic hernia and digital

VetBooks.ir

palpation of the cardia and terminal esophagus by means of rumenotomy should be considered.

Megaesophagus associated with pharyngeal trauma has a good prognosis,[1] whereas megaesophagus associated with hiatal hernia has a more guarded prognosis.[2] Supportive treatments and stomach tubing with fluids may be required for 1 to 2 weeks until the animal is able to drink unaided. Longer-term support can be given to a valuable animal by surgically creating a ruminal fistula fitted with a rubber cannula through which feed and water can be given until normal deglutition returns.

Ruminant Abdominal Ultrasonography

Betsy Vaughan

The key to diagnosing ruminant abdominal disorders is to conduct a thorough physical examination (see Chapter 1). A noninvasive and useful adjunct is the use of ultrasound.

Abdominal ultrasound provides a readily available, real-time, noninvasive method of imaging the abdomen in ruminants suspected of abdominal disease. Radiographic examination of the adult bovine abdomen offers limited information because of the large size of the patient and the need for expensive equipment with high milliampere-seconds (mAs) and kilovolt peak (kVp). Although radiographic examination of the small ruminant abdomen offers clinically useful information, it should be used in conjunction with abdominal ultrasonography to evaluate the abdominal organs and to further characterize radiographic abnormalities. Exploratory laparotomy is still commonly performed in cattle with unexplained illness referable to the abdominal cavity. Ultrasonographic evaluation of the ruminant abdomen has become an important part of the diagnostic workup in ruminants suspected of abdominal disease in combination with complete blood count (CBC), serum chemistry, peritoneal fluid analysis, urinalysis, and ruminal fluid analysis and can often provide valuable information that may preclude the need for exploratory laparotomy.[1,2] Abdominal ultrasound is indicated in patients with signs of abdominal pain, stasis, decreased motility, increased motility, lethargy, anorexia, bloat, regurgitation, fever of unknown origin, and suspected renal or liver disease. Ultrasound is also useful for diagnosing thoracic disorders.

Bovine patients should be restrained in a head gate and standing stocks. Squeeze chutes are not ideal because access to the complete abdomen is seldom possible. Small ruminants can usually be restrained with halters or collars. Bovine and small ruminant patients seldom need sedation for restraint during the examination. Patients should be prepared for complete abdominal ultrasound examination by surgical clipping of the left and right sides of the abdomen ventral to a diagonal line extending from the transverse processes of the lumbar vertebrae to the level of the elbow joint approximately at the level of the ventral lung margin. The entire ventral abdomen should be clipped from the xyphoid to the inguinal region (Fig. 32-95). If only one organ is to be examined, then the specific anatomic region should be clipped with wide margins. The clipped area should be washed thoroughly with water, degreased with soap or alcohol if necessary, and ultrasound coupling gel applied to the region. If clipping is not possible, alcohol saturation of the skin and hair may be adequate in patients with a short hair coat. The examination is performed with a low-frequency, curvilinear transducer (2.5 to 5 MHz) in large patients such as adult cattle, which provides penetration to a depth of 24 to 30 cm. A medium frequency (4 to 8 MHz) "microconvex" curvilinear transducer is ideal for evaluating calves and small ruminants. In large patients, superficial structures near the skin surface should also be evaluated using the medium-frequency transducer when image quality permits. This transducer is also useful for performing transrectal ultrasonography of the left kidney, urinary bladder, ureters, and urethra in cattle.

The examination should begin with detailed evaluation of the right paralumbar fossa region followed by evaluation of each intercostal space beginning at the ventral lung margin and scanning ventrally beyond the costochondral junctions. The ventral abdomen is then evaluated from the xyphoid to the inguinal region. The examination is repeated on the left side. The abdomen is evaluated for abnormalities of the kidneys, liver, gallbladder, spleen, rumen, reticulum, omasum, abomasum, duodenum, small intestine, cecum, and colon and for the presence and character of peritoneal fluid.

FIG. 32-95 Patient preparation for abdominal ultrasound examination. The region to be clipped for complete abdominal evaluation is shown, including the paralumbar fossa region, the intercostal spaces from the ventral lung margin to the costochondral junctions, and the entire ventrum from the xiphoid to the inguinal region.

Kidneys

NORMAL APPEARANCE (Fig. 32-96)**.** The right kidney is imaged from the right paralumbar fossa region and right eleventh to twelfth intercostal space at a scanning depth of 10 to 20 cm in cattle and 6 to 14 cm in small ruminants. The anatomic detail of the right kidney is greater than that of the left because of its more superficial location within the abdomen. In small ruminants the left kidney is routinely imaged in the right paralumbar fossa caudal to the right kidney at scanning depths of 8 to 14 cm. The left kidney in cattle can often be seen in this region as well though at greater depth. The left kidney cannot usually be visualized from the left side of the abdomen because it is obscured by the gas-filled rumen. Transrectal imaging of the left kidney should be performed in adult cattle suspected of having renal disease even when it is visualized transcutaneously, because it offers superior anatomic detail.

In cattle the normal right kidney has been reported to range from 8.1 to 11 cm in length and 4 to 7 cm in width.[3] Transrectally the left kidney has been reported to range in width from 4.5 to 7.5 cm in normal cattle. Transrectal length measurements of the left kidney were not reported, as it cannot be imaged in its entirety.[4] However, in the author's experience, normal bovine kidneys routinely measure up to 16 to 18 cm in length when measured transcutaneously. Normal bovine kidneys demonstrate a lobulated appearance with a relatively indistinct corticomedullary junction. Renal parenchyma should be less echogenic than hepatic parenchyma. The renal sinus demonstrates a hyperechoic appearance because of the presence of the renal calyces, adipose tissue, and connective tissue.[3,4]

In small ruminants, renal size can vary greatly depending on the size of the animal. In sheep the right kidney ranges from 7.1 to 8.9 cm in length and 3.4 to 5.5 cm in width, and the left kidney from 7.2 to 9.2 cm in length and 3.5 to 5.4 cm in width.[5,6] Small ruminants demonstrate smoothly marginated, oval kidneys. The renal capsule may be visible as a thin hyperechoic line. As in cattle, the renal parenchyma should be less echogenic than hepatic parenchyma. In contrast to cattle, the corticomedullary junction is clearly distinguishable. The renal pelvis demonstrates a hyperechoic appearance because of the presence of renal calyces, adipose tissue, and connective tissue.[5,6]

VetBooks.ir

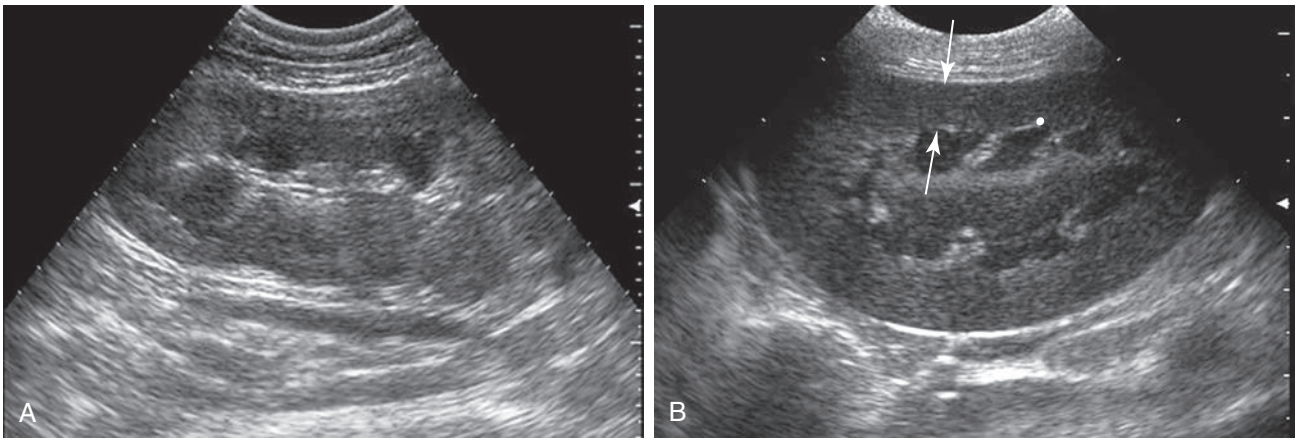

FIG. 32-96 **A,** Normal right kidney viewed from the right paralumbar fossa region in a 5-year-old Holstein dairy cow. Note the lobulated shape and indistinct corticomedullary junction. Image was obtained with a 2.5-MHz curvilinear transducer at a depth of 20 cm. **B,** Normal right kidney viewed from the right paralumbar fossa region in a 4-year-old castrated male Nigerian Dwarf goat. Note the smooth renal capsule, ovoid shape, and distinct corticomedullary junction *(arrows).* Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 7 cm.

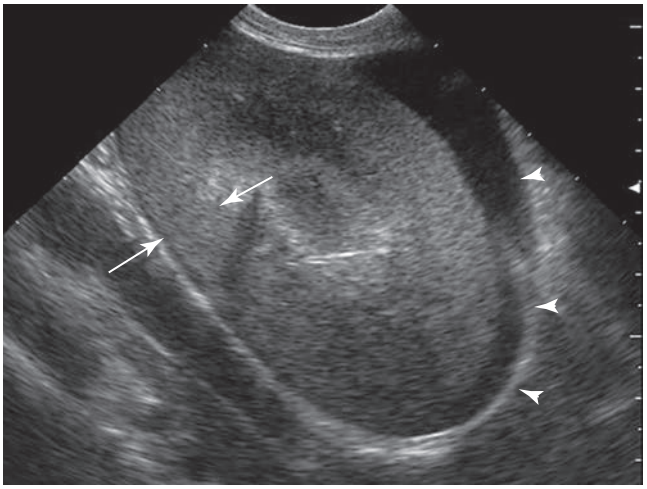

FIG. 32-97 Right kidney viewed from the right paralumbar fossa region in a 12-year-old Pygmy goat buck with acute renal failure. Note the increased cortical echogenicity and thickness *(arrows).* Perirenal edema *(arrowheads)* is seen surrounding the kidney. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 8 cm.

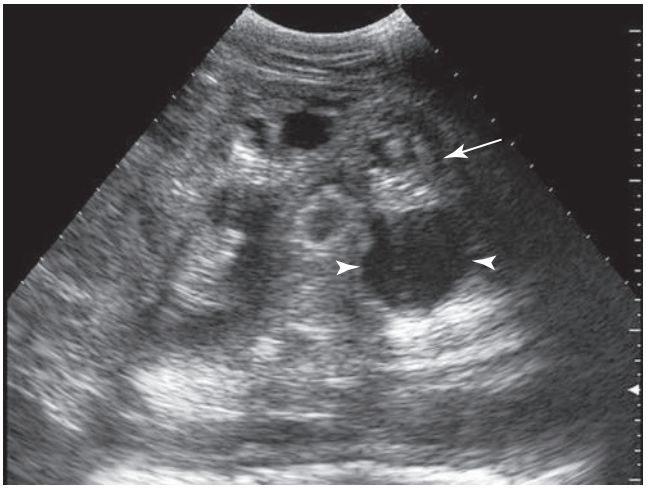

FIG. 32-98 Right kidney viewed from the right paralumbar fossa region in a 2-year-old Angus heifer with severe necrotizing pyelonephritis. Note the abnormal renal architecture with echogenic debris *(arrow)* within the distended renal calyces *(arrowheads).* Image was obtained with a 2.5-MHz transducer at a depth of 20 cm.

ABNORMAL FINDINGS. Changes in size, shape, architecture, and echogenicity are nonspecific ultrasonographic abnormalities that can be seen in ruminants with acute or chronic renal failure, amyloidosis, nephritis, and pyelonephritis. Abnormalities seen in patients with acute renal failure include renal enlargement, thickening of the renal cortex, and perirenal edema (Fig. 32-97). In cases of chronic renal failure, the kidneys are often smaller than normal and may be misshapen. Pyelonephritis is a common cause of fever, colic, and pyuria in cows, often occurring as an ascending infection after abortion or dystocia. Ultrasonographic findings include renomegaly, pyelectasia with echogenic to hyperechoic debris within the renal sinus, and ureteral dilation (Fig. 32-98).[7-10] Ultrasound-guided percutaneous biopsy can be performed safely and is commonly required to distinguish the specific cause of disease in patients with acute or chronic renal disease.[11]

Specific renal abnormalities include nephrolithiasis, hydronephrosis, renal neoplasia, and renal abscessation. Nephroliths are round or irregularly shaped hyperechoic structures within the renal sinus that cast strong acoustic shadows (Fig. 32-99). Associated dilation of the renal sinus or calyces may be seen with obstructive nephrolithiasis. Hydronephrosis is characterized by dilation of renal calyces with anechoic urine and may be seen with a postrenal obstruction (Fig. 32-100). Hydronephrosis is commonly seen in small ruminants with obstructive urolithiasis but can also be caused by extramural obstruction secondary to caudal abdominal masses. Transrectal evaluation of the ureters and urinary bladder is indicated in bovine patients with hydronephrosis or obstructive nephrolithiasis to evaluate for the presence of uroliths within the ureters or urinary bladder.

Congenital renal cysts are relatively common in cattle, sheep, and goats and should be readily recognizable via ultrasound.[10,12-15] Mass lesions within or obliterating the normal renal parenchyma can be seen with neoplasia or abscessation. Both renal abscessation and renal neoplasia are rare in ruminants.[13,14] Renal abscesses may be distinguished from neoplasia based on their ultrasonographic appearance. Renal abscesses are usually encapsulated and contain anechoic to echogenic fluid. Ultrasound-guided percutaneous aspiration can be used to obtain a sample for cytology and culture and to facilitate drainage in affected animals. Ultrasound-guided biopsy is necessary to identify specific neoplastic processes.[11]

Urinary Bladder and Ureters

NORMAL APPEARANCE. The urinary bladder is normally imaged from the right or left caudoventral abdomen in small ruminants at a scanning depth of 5 to 14 cm and appears as an oval or spherical structure with a thin wall containing anechoic urine

VetBooks.ir

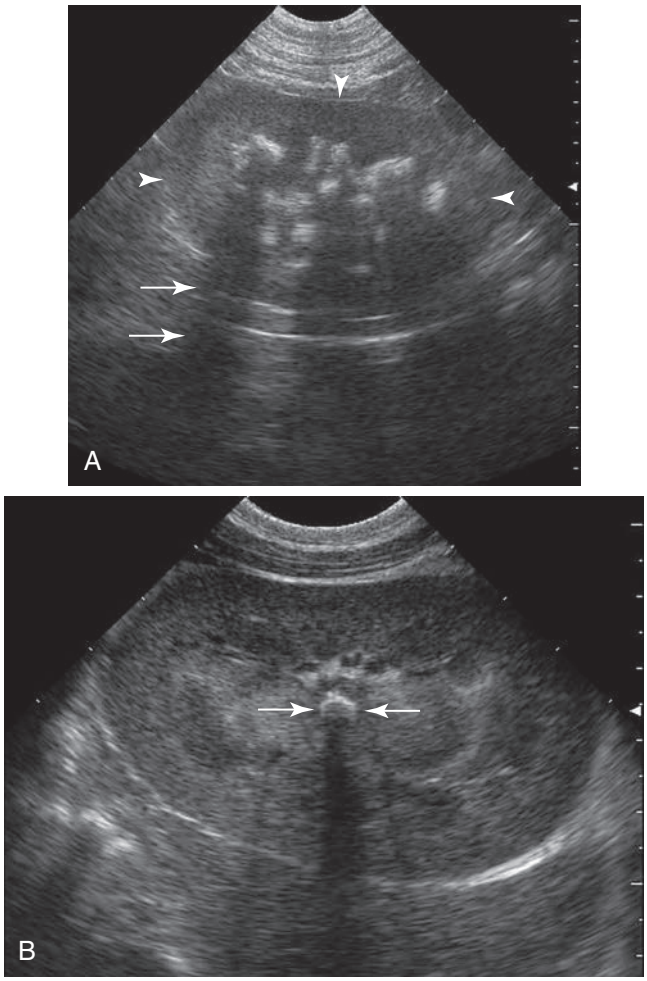

FIG. 32-99 **A,** Severe nephrolithiasis of the right kidney *(arrowheads)* in a 8-year-old Nubian doe. Note the strong shadows cast by the hyperechoic nephroliths *(arrows)*. Image was obtained with a 5.5-MHz transducer at a depth of 12 cm. **B,** Single right nephrolith in the right kidney of a 3-year-old Nigerian Dwarf doe *(arrows)*. No dilation of the renal pelvis is seen. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 8 cm.

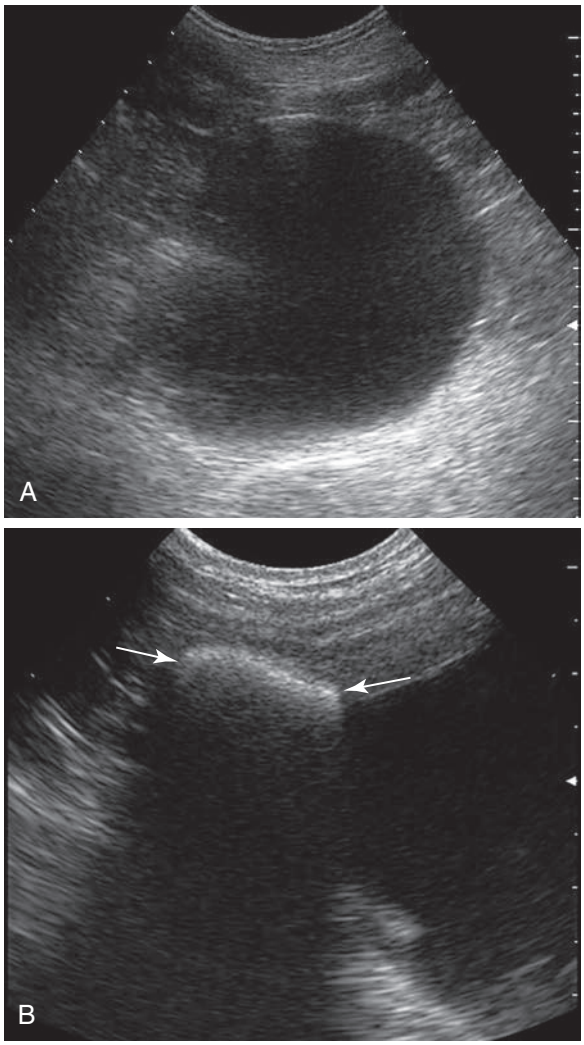

FIG. 32-101 **A,** Normal urinary bladder viewed from the left inguinal region in a 10-year-old Romeldale ewe. Image was obtained with a 3.5-MHz curvilinear transducer at a depth of 15 cm. **B,** Cystic calculi *(arrows)* in an 11-year-old Pygmy doe with urolithiasis. Image was obtained in the left inguinal region with a 7.5-MHz curvilinear transducer at a depth of 5 cm.

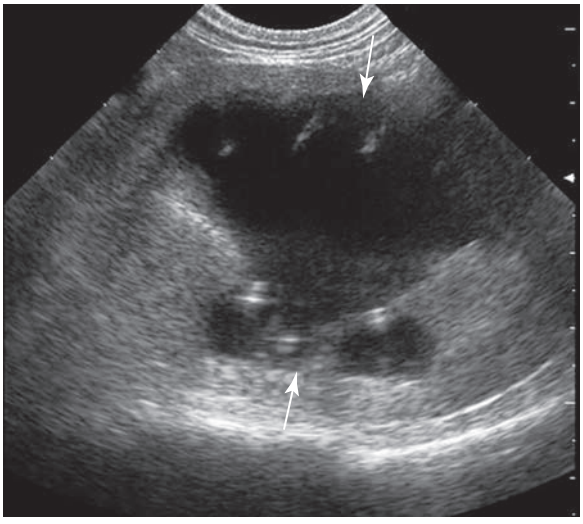

FIG. 32-100 Severe hydronephrosis of the left kidney viewed from the right paralumbar fossa region in a 10-year-old Pygmy doe. This doe had a uterine mass that was compressing the left ureter. Note the severe dilation of the renal pelvis *(arrows)*. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 7 cm.

(Fig. 32-101, *A*). The size and shape of the urinary bladder are dependent on its distention at the time of examination. The urinary bladder is often not visible transcutaneously in cows but can be evaluated transrectally along with the urethra and the distal portion of the right and left ureters.[4] The normal urethra is not visualized except at the onset of urination and appears as a thin anechoic line when distended with urine.[4] An attempt should be made to locate the ureters to the right and left of the urinary bladder at the trigone region. The ureters should then be followed cranially as far as they can be visualized.

ABNORMAL FINDINGS. Abnormalities of the urinary bladder include distention secondary to obstruction, thickening of the bladder (cystitis), cystic calculi, mass lesions, and rupture. Severe distention of the urinary bladder can be indicative of mechanical or functional obstruction. For this reason, transabdominal ultrasound examination is commonly used as a screening procedure for obstructive uropathy in small ruminants.[5,14,15] In affected animals the bladder will be markedly distended and may demonstrate multiple pinpoint echogenic or hyperechoic particles within the urine as well as cystic calculi.[5] Cystic calculi are seen within the bladder and can be hyperechoic or hypoechoic with a round or irregular shape. They may or may not cast strong shadows (see Fig. 32-101, *B*). Mass lesions associated with the urinary bladder wall include neoplasia and hematoma that may be difficult to differentiate ultrasonographically.

VetBooks.ir

Urinary bladder rupture may occur secondary to obstructive urolithiasis or trauma. Ultrasound examination reveals an increased amount of free anechoic fluid within the abdomen. Definitive diagnosis can be made by comparing the concentration of creatinine in abdominal fluid to the serum concentration.[10]

Ureteroliths may be seen on transrectal ultrasound examination in bovine patients and demonstrate the appearance of hyperechoic structures within the ureter that cast strong shadows. Marked ureteral dilation that appears as a tubular structure dilated with anechoic fluid is seen cranial to the ureterolith.[16] Thickening of the ureteral wall may occur secondary to inflammation. Ureteral rupture can occur secondary to obstruction and results in accumulation of anechoic fluid within the retroperitoneal space.[1,16]

Liver

NORMAL APPEARANCE (Fig. 32-102)**.** The right liver lobe is imaged from the right sixth to twelfth intercostal spaces at a scanning depth of 6 to 14 cm in small ruminants and 20 to 30 cm in cattle and demonstrates a homogeneous, echogenic appearance. The branching vasculature of the portal and hepatic veins can be seen in addition to fine vascular markings scattered throughout the hepatic parenchyma.

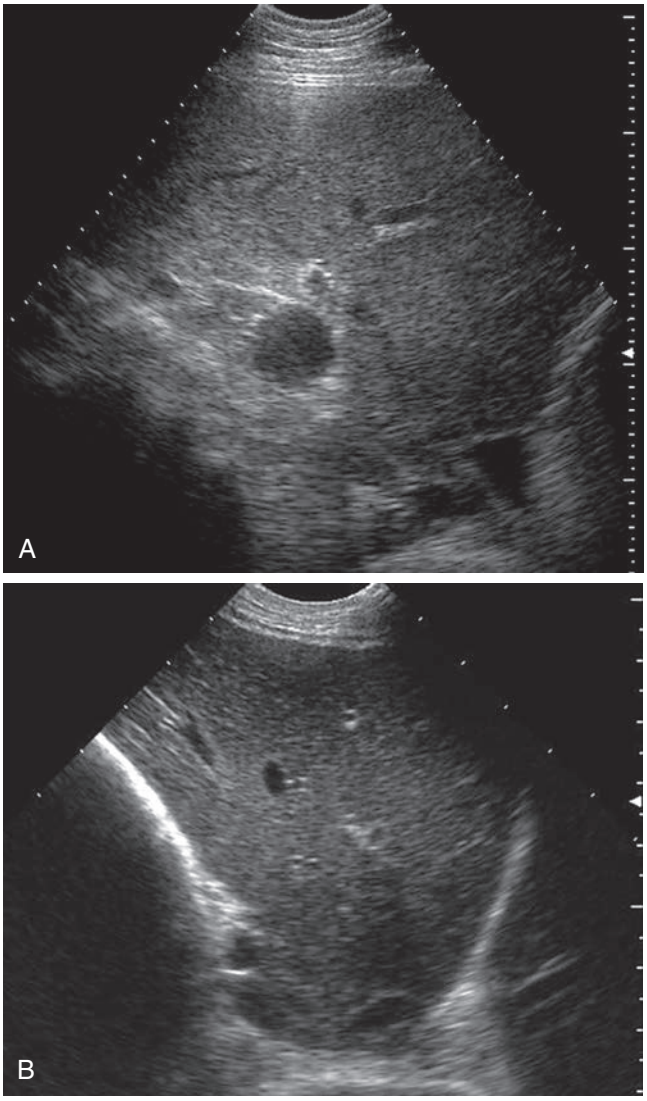

FIG. 32-102 **A,** Normal right liver lobe viewed from the right tenth intercostal space in a 5-year-old Holstein dairy cow. Image was obtained with a 2.5-MHz curvilinear transducer at a depth of 27 cm. **B,** Normal right liver lobe viewed from the right tenth intercostal space in a 12-year-old Pygmy buck. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 10 cm. Dorsal is to the right and ventral is to the left.

The liver parenchyma is normally more echogenic than renal parenchyma and less echogenic than splenic parenchyma. In contrast to horses, an anatomic window for direct comparison of the liver and spleen does not exist in ruminants. Subjective comparison between the spleen on the left side and the liver on the right side should be undertaken with caution because changes in image quality and machine settings may lead to a false assessment of echogenicity. Bile ducts are not normally visible ultrasonographically.[17,18] The ventral borders of the liver are usually sharp or mildly rounded and extend near or beyond the costochondral junctions. One proposed method of assessing hepatic size in cattle is to measure the thickness of the liver overlying the portal vein (normally 5.1 to 14.1 cm) and the caudal vena cava (normally 8.2 to 15.4 cm).[19] Cows with high body condition scores and milk production will have larger livers than thin cows with decreased milk production, making assessment of liver size somewhat subjective in cattle.[20] The portal vein and caudal vena cava should also be assessed during the hepatic ultrasound examination. The portal vein is round and is commonly seen deep to the liver in the right eighth to twelfth intercostal spaces, ventral and lateral to the caudal vena cava. The caudal vena cava is usually seen only in the right eleventh and twelfth intercostal spaces, dorsal and deep to the portal vein.[17-19,21,22]

ABNORMAL FINDINGS. Nonspecific ultrasonographic abnormalities of the liver, including hepatomegaly, changes in echogenicity, and a decreased number of fine vascular markings, can be seen with hepatopathies of numerous causes including pyrrolizidine alkaloid toxicosis,[23] hepatic lipidosis, and diffuse infiltrative disease.[17,24] Hepatic lipidosis, in particular, has been reported to result in an overall increase in hepatic echogenicity with decreased fine vascular markings (Fig. 32-103).[17,24]

Variable changes in echogenicity can also be seen during the parenchymal stage of fascioliasis.[25,26] Ultrasound-guided liver biopsies can be used to obtain a definitive diagnosis.

Hypoechoic or hyperechoic mass lesions within the hepatic parenchyma may represent abscessation or neoplasia. Hepatic abscessation is common in cattle and can occur with numerous disease processes, including cholangitis, traumatic reticuloperitonitis (TRP), or bacteremia secondary to rumenitis or omphalophlebitis. Hepatic abscesses demonstrate a variable appearance with a homogeneous or mixed echogenicity, hyperechoic or hypoechoic contents, and a variable degree of encapsulation (Fig. 32-104, *A*).[17,22,27,28] The appearance of the abscess can change throughout the course of disease. Early abscesses may demonstrate a hypoechoic appearance without visible encapsulation. More chronic abscesses are usually well encapsulated with more echogenic contents. Gas echoes within the abscess are

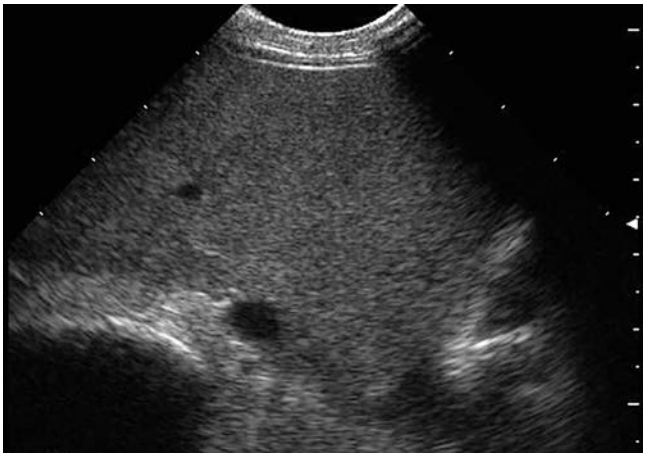

FIG. 32-103 Increased echogenicity and decreased fine vascular markings viewed from the right ninth intercostal space in the right liver lobe of a 4-year-old castrated male Nigerian Dwarf goat with hepatic lipidosis. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 8 cm. Dorsal is to the right and ventral is to the left.

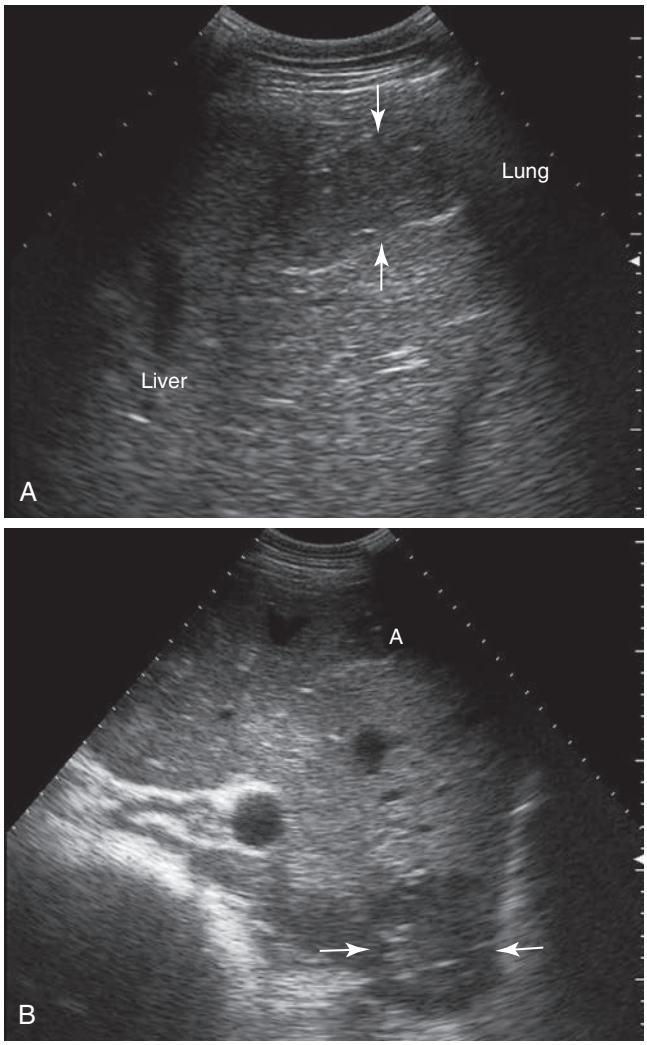

FIG. 32-104 **A,** Hepatic abscess measuring 5.6 cm × 3.1 cm *(arrows)* in a 2-year-old Holstein dairy cow that presented for fever, anorexia, and weight loss. View is from the right tenth intercostal space. Image was obtained with a 2.5-MHz curvilinear transducer at a depth of 15 cm. **B,** Thrombus of the caudal vena cava *(arrows)* in the same cow. Image was obtained in the right ninth intercostal space using a 3.5-MHz transducer at a depth of 27 cm. The *A* in the upper right indicates an abscess.

indicative of anaerobic infection. Ultrasound-guided percutaneous aspiration commonly yields fluid for culture and sensitivity.[17,27-29] Thrombosis of the caudal vena cava can occur secondary to hepatic abscessation. Affected cows show dilation of the caudal vena cava characterized by a change in shape from triangular to oval or round. Dilation of the hepatic veins may also be seen. Thrombi are uncommonly visualized ultrasonographically because they are typically located deep within the abdomen or in the thorax.[30-32] If seen, thrombi demonstrate a heterogeneous appearance (see Fig. 32-104, *B*).

Hepatic neoplasia is uncommonly reported in ruminants.[17,33] The ultrasonographic appearance of the liver is variable in these cases. The hepatic parenchyma may be diffusely affected, or discrete single or multiple masses may be seen. Metastatic lesions can be seen within the hepatic parenchyma or may distort the hepatic capsule along the serosal surface.[17,33] Ultrasound guidance is recommended when obtaining percutaneous biopsies to avoid sampling unaffected parenchyma.

Ultrasound can be helpful to diagnose obstructive cholestasis.[17,34,35] Ruminants with obstructive cholestasis will show changes consistent with extrahepatic or intrahepatic obstruction. Extrahepatic obstruction usually occurs at the level of the duodenal papilla. Ultrasonographic findings include dilation of the gallbladder with bile and echogenic sludge, dilation of the common bile duct, and

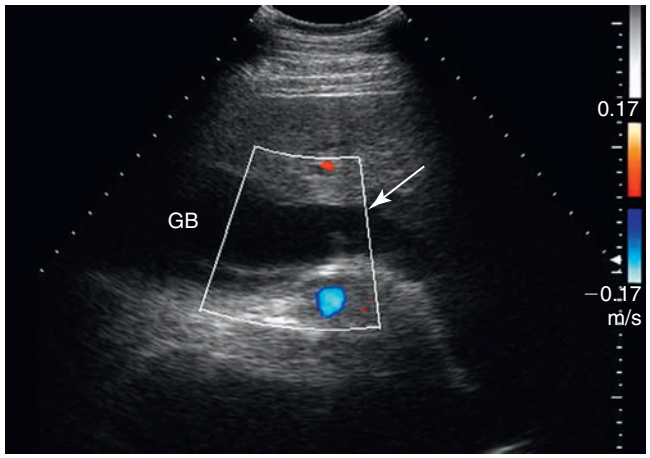

FIG. 32-105 Dilated cystic duct *(arrow)* viewed from the right ventral abdomen in a 3-year-old Holstein dairy cow with extrahepatic cholestasis. Color Doppler confirms the absence of blood flow in the cystic duct. Image was obtained from the right ventral abdomen using a 4.0-MHz curvilinear transducer at 21.5 cm. Dorsal is to the right and ventral is to the left. *GB,* Gallbladder.

dilation of the intrahepatic ducts (Fig. 32-105). Dilation of the intrahepatic ducts results in a "parallel channel sign" because intrahepatic ducts lie parallel to portal veins. The presence of gas echoes within the bile ducts is consistent with anaerobic suppurative cholangitis. The ductal phase of fascioliasis results in distention and tortuosity of the bile ducts.[25,26] Occasionally, moving echogenic forms can be seen within these bile ducts in infected sheep.[25] Mineralization of individual bile ducts can be seen in cases of chronic fascioliasis.[22,35] In contrast, ruminants with hepatocellular cholestasis may show ultrasonographic changes consistent with infiltrative disease or hepatic congestion or may have a normal hepatic ultrasound examination.

Gallbladder

NORMAL APPEARANCE (Fig. 32-106, *A*)**.** The gallbladder is visualized deep to the liver in the right ninth to eleventh intercostal spaces and is a thin-walled, round, or oval structure filled with anechoic fluid that is usually visualized in only one or two intercostal spaces. However, ruminants with anorexia have no reflex stimulus for emptying the gallbladder. This creates a distended appearance without obstruction (see Fig. 32-106, *B*).[18,19,21] The gallbladder is usually seen at a scanning depth of 6 to 10 cm in small ruminants and 12 to 18 cm in cattle.

ABNORMAL FINDINGS. Abnormalities of the gallbladder include biliary distention, wall thickening, sediment accumulation, or cholelithiasis. As mentioned earlier, it is important to differentiate gallbladder distention secondary to anorexia or fasting from distention secondary to cholestasis. Cholestatic obstruction is a serious condition that can lead to rupture if the obstruction is not resolved.[36] Wall thickening may be secondary to edema or inflammation. Choleliths appear as discrete hyperechoic structures that cast strong shadows. Sediment, on the other hand, demonstrates an amorphous echogenic to hyperechoic appearance and will have a dependent location (ventral in standing animals) within the gallbladder (see Fig. 32-106, *C*). Ultrasound-guided cholecystocentesis has been reported to be a valuable diagnostic technique in cases suspect for liver fluke infection *(Fasciola hepatica, Dicrocoelium dendriticum).*[17,37] Both transhepatic cholecystocentesis and transcutaneous aspiration can be performed safely.[17] Bile examination for detection of fluke eggs is superior to fecal examination because liver fluke eggs are stored in the gallbladder for weeks.[17,37]

Spleen

NORMAL APPEARANCE (Fig. 32-107)**.** The spleen is visualized in the left seventh to twelfth intercostal spaces between the rumen and body wall at the cranial extent of the rumen at a scanning depth

VetBooks.ir

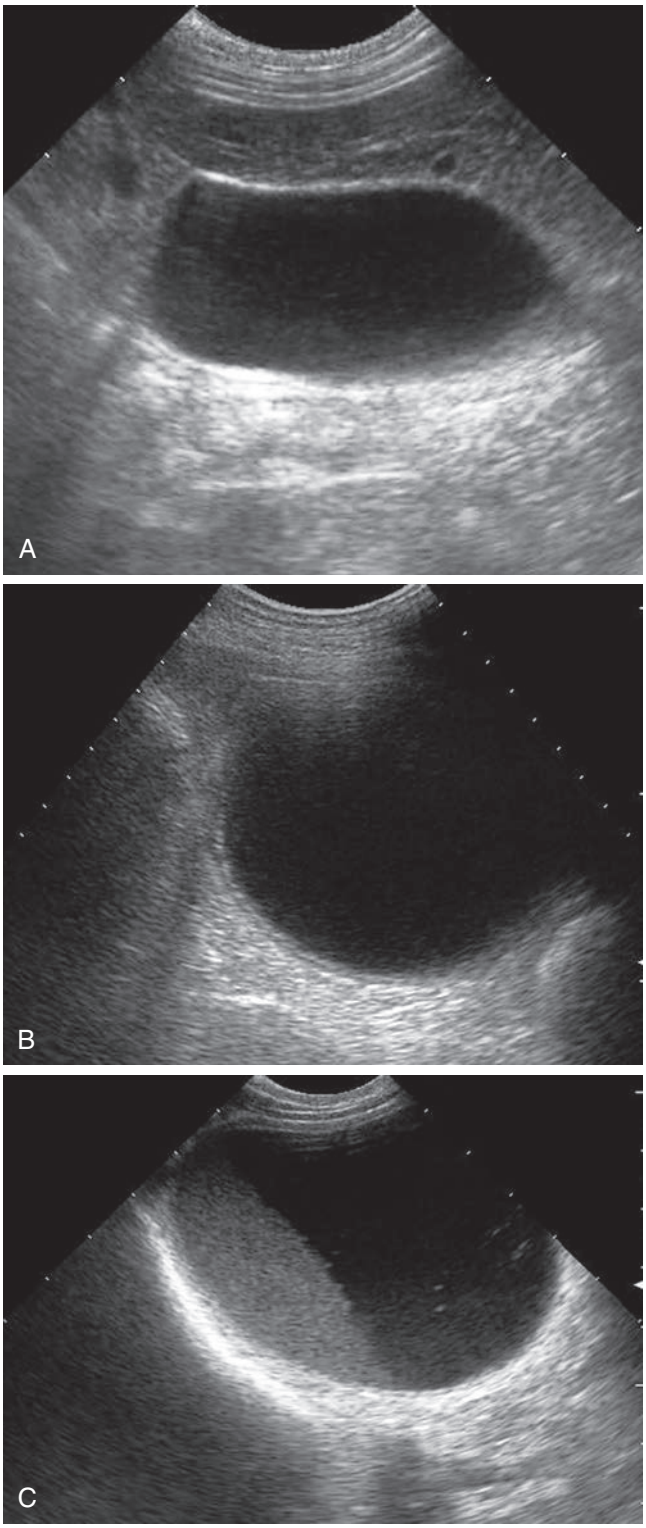

FIG. 32-106 **A,** Normal gallbladder in a 6-year-old Pygmy doe. Image was obtained with a 8.5-MHz curvilinear transducer at a depth of 8 cm. **B,** Distended gallbladder viewed from the right tenth intercostal space in a 3-year-old Holstein dairy cow that presented for anorexia. Image was obtained with a 3.5-MHz curvilinear transducer at a depth of 16 cm. **C,** Distended gallbladder with bile sediment viewed from the right twelfth intercostal space in a 12-year-old Pygmy buck. Image was obtained with a 7.5-MHz transducer at a depth of 10 cm. Dorsal is to the right and ventral is to the left.

of 6 to 14 cm in small ruminants and 16 to 28 cm in cattle. Splenic size is variable, and the spleen occasionally extends to the ventral midline in normal cows.[38] The spleen demonstrates a homogeneous appearance and appears more echogenic and less vascular than the liver. The splenic capsule appears as a thin hyperechoic line.[38,39]

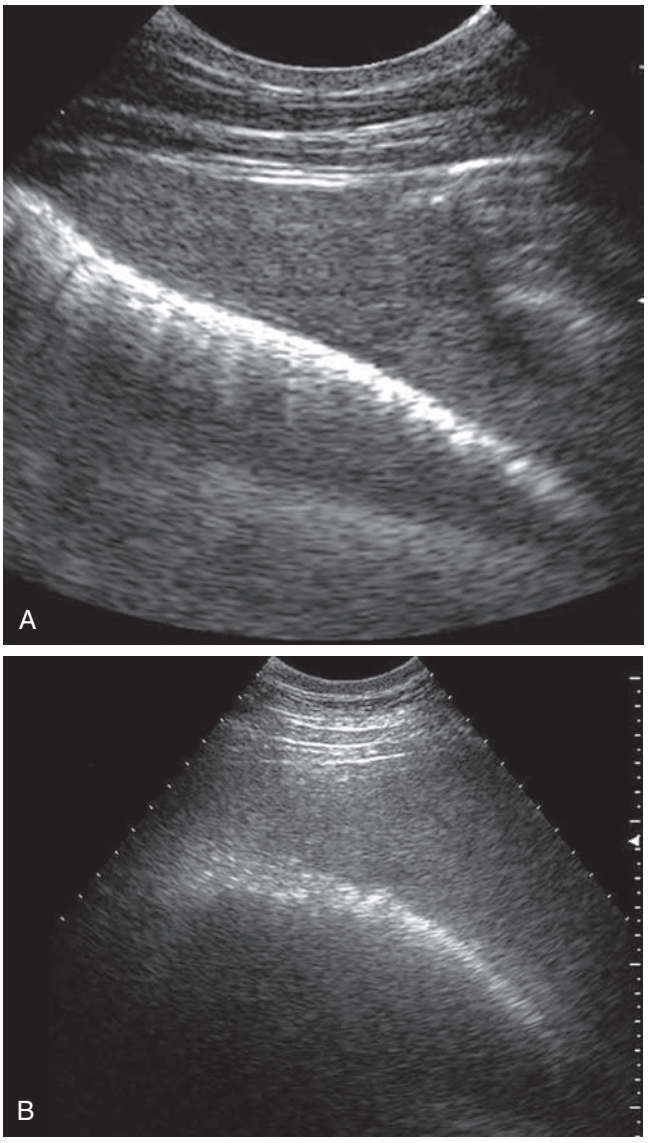

FIG. 32-107 **A,** Normal spleen viewed from the left ninth intercostal space in a 12-year-old Pygmy buck. Note that the spleen appears less vascular relative to the normal liver. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 4 cm. **B,** Normal spleen viewed from the left tenth intercostal space in a 4-year-old Holstein dairy cow. Image was obtained with a 2.5-MHz curvilinear transducer at a depth of 16 cm. Dorsal is to the right and ventral is to the left.

ABNORMAL FINDINGS. Splenic abnormalities may include changes in echogenicity indicative of diffuse parenchymal disease or discrete masslike lesions consistent with neoplasia or abscessation. Suppurative splenitis or abscessation can occur secondary to septicemia or TRP.[40] Splenic neoplasia has also been reported in ruminants.[38] Ultrasound-guided percutaneous aspiration or biopsy may provide definitive cytology, culture, or histopathologic diagnosis but should be undertaken with caution in compromised patients because of the risk of hemorrhage.

Reticulum

NORMAL APPEARANCE (Fig. 32-108, *A*)**.** The reticulum is seen in the cranioventral abdomen and both the left and right sixth and seventh intercostal spaces ventral to the spleen and cranial to the rumen at a scanning depth of 4 to 8 cm in small ruminants and 10 to 14 cm in cattle. The reticulum should be evaluated during the examination for normal biphasic contractions, which should occur approximately once per minute. Monophasic, triphasic and quadriphasic contractions have been reported in normal goats.[41] The reticulum contracts approximately 5 to 10 cm away from the abdominal

VetBooks.ir

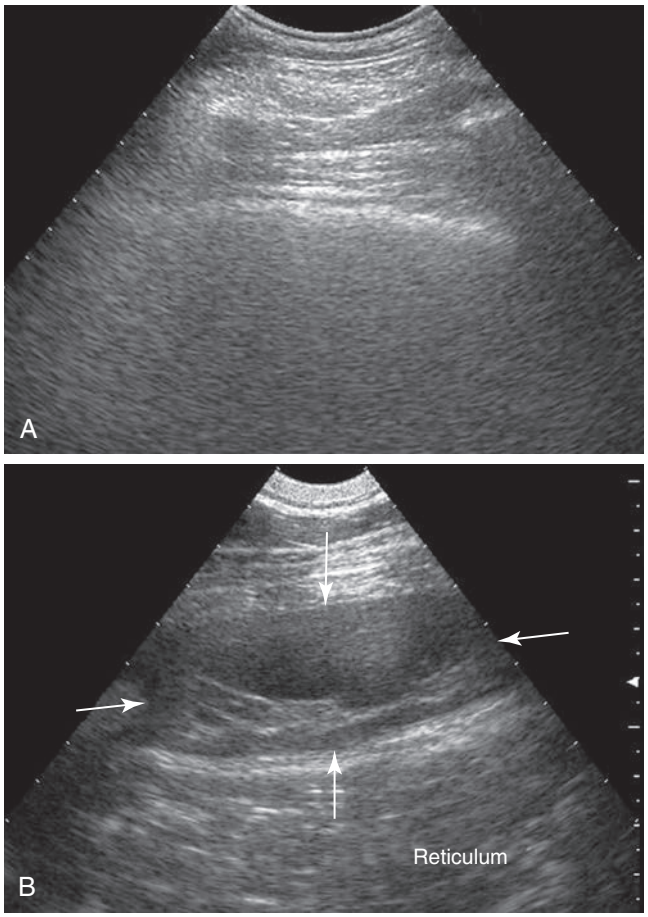

FIG. 32-108 **A,** Normal reticulum viewed from the left cranioventral abdomen in a 5-year-old Holstein dairy cow. Image was obtained with a 3.5-MHz curvilinear transducer at a depth of 14 cm. **B,** Small reticular abscess *(arrows)* viewed from the left seventh intercostal space in an 8-year-old Charolais beef cow suspected of traumatic reticuloperitonitis. A small wire was seen within the reticulum on abdominal radiographs. Image was obtained with a 5.5-MHz curvilinear transducer at a depth of 12 cm. Dorsal is to the right and ventral is to the left.

wall during the first phase of contraction and more than 17 cm away during the second phase of contraction in cattle.[42] When in a relaxed state the reticulum appears as a semicircular structure immediately adjacent to the ventral abdominal wall. Reticular contents cannot normally be visualized because of their gaseous composition. The honeycomb appearance of the reticular mucosa is not commonly distinguishable ultrasonographically.

ABNORMAL FINDINGS. Reticular abnormalities are primarily associated with TRP. Reticular abscesses caused by TRP can be seen between the reticulum and body wall, spleen, diaphragm, or liver.[2,43] These abscesses are usually well encapsulated with an echogenic capsule and may contain anechoic to echogenic contents (see Fig. 32-108, *B*). Abscesses adjacent to the body wall can be incised and drained transcutaneously with ultrasound guidance.[43] Other abnormalities associated with TRP include changes in the contour of the reticulum, echogenic fibrinous deposits on the reticular serosa, nonencapsulated fibrinous exudate between the reticulum and body wall, and adhesions between the reticulum and the peritoneum or adjacent organs.[2,40,43,44] Reticular contractions are often absent, reduced, or indistinct in affected animals and can be an indication of adhesions between the reticulum and body wall.[2,44] The causative foreign bodies are rarely identified ultrasonographically because of the gaseous composition of reticular contents and are better assessed via radiography.[2,44] Reticular hypermotility has been described in cows with reticuloomasal obstruction or stenosis.[45,46]

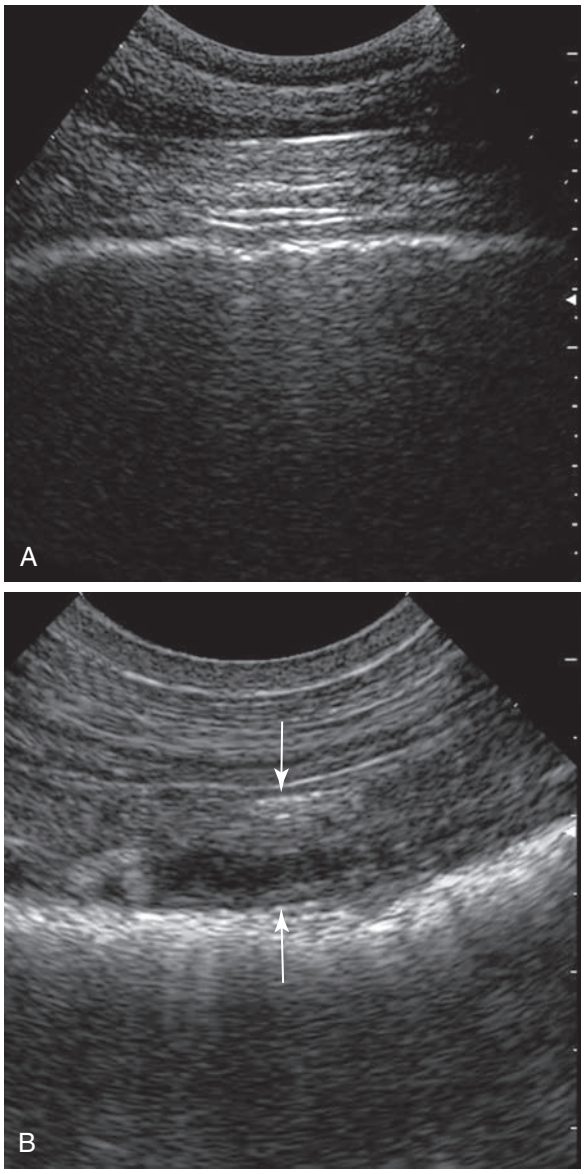

FIG. 32-109 **A,** Normal rumen viewed from the left paralumbar fossa region in a 5-year-old Holstein dairy cow. Image was obtained with a 2.5-MHz curvilinear transducer at a depth of 9 cm. **B,** Severely thickened ruminal wall measuring 14.9 mm *(arrows)* viewed from the left paralumbar fossa region in a 12-year-old pygmy buck that recently underwent rumenotomy. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 4 cm.

Rumen

NORMAL APPEARANCE (Fig. 32-109, *A*)**.** The rumen normally occupies the entire left paralumbar fossa region, the left eighth to twelfth intercostal spaces, and the left caudoventral abdomen and is seen directly adjacent to the body wall. The ruminal wall is seen as a smooth, thin hypoechoic line. Hyperechoic gas within the rumen creates a hyperechoic line immediately adjacent to the wall. Ruminal contents are not commonly visualized because of their gaseous composition; however, echogenic ingesta and hypoechoic fluid can be seen dependently in normal cattle. The wall of the craniodorsal blind sac, the ventral sac of the rumen, and the ruminoreticular groove are seen immediately caudal to the reticulum in the cranioventral left intercostal spaces.[2] Contraction of the craniodorsal blind sac of the rumen is commonly seen after the second reticular contraction.

ABNORMAL FINDINGS. Thickening of the ruminal wall may be seen in cases of ruminitis or secondary to ruminotomy or ruminal

VetBooks.ir

trocarization (see Fig. 32-109, *B*). Abscesses between the rumen and the left body wall may also develop secondary to surgical procedures performed in the left flank region.[47] Such abscesses are usually well encapsulated and contain anechoic to echogenic contents. Echogenic strands of fibrin or fibrinous deposits may be found in association with the abscess. Localized or generalized peritonitis may also occur secondary to abscessation. Abscesses adjacent to the body wall can be aspirated via ultrasound guidance for cytology and culture.

Omasum

NORMAL APPEARANCE. The omasum can be seen in the right sixth to tenth intercostal spaces dorsal to the abomasum and/or the reticulum. Although similar to the reticulum in appearance, the omasum can be differentiated by an increased wall thickness and the absence of visible contractions in cattle.[2,40,48] Active omasal contractions can be seen in goats and occur approximately 1 per minute.[49] Omasal contents and omasal laminae are seldom visualized because of intraluminal gas. Laminae are sometimes seen in ill ruminants with increased omasal fluid contents.[2,50]

ABNORMAL FINDINGS. Ultrasonographic abnormalities of the omasum are limited to changes in position associated with displaced abomasum, traumatic reticuloperitonitis and reticuloomasal stenosis. Increased fluid contents are usually secondary to abomasal reflux. Rarely, omasal motility is visible in cases of reticuloomasal stenosis.[2,50] Omasal impaction cannot be diagnosed reliably via ultrasound examination.[51]

Abomasum

NORMAL APPEARANCE (Fig. 32-110, *A*)**.** The abomasum is normally visualized in the cranioventral abdomen along the ventral midline and in both the right and left paramedian regions caudal to the xiphoid process. In general, the abomasum is situated more to the right of the ventral midline. The abomasum can be distinctly identified because of its visible fluid contents, which demonstrate a heterogeneous anechoic to echogenic appearance. The abomasal wall appears as a thin hyperechoic line. Abomasal folds are sometimes visible. Passive movement of the abomasum is seen during reticular contractions; however, abomasal contractions are usually not seen. The pylorus is rarely identified.[52]

ABNORMAL FINDINGS. Reported ultrasonographic abnormalities of the abomasum in cattle include left and right abomasal displacement, abomasal volvulus, and functional or mechanical pyloric stenosis.[1,2,40,52] In cattle with left abomasal displacement, the rumen is seen adjacent to the body wall ventrally; however, the abomasum is imaged between the rumen and the left body wall dorsally. The rumen is displaced medially at this level, deep to the abomasum. Fluid and ingesta are visible ventrally within the abomasum, and a gas cap is visible dorsally.[1,2,53] With right abomasal displacement and abomasal volvulus, the abomasum is imaged adjacent to the right body wall in the right intercostal spaces. In this case the liver is displaced medially, deep to the abomasum, and cannot be seen. Similar to left dorsal displacement, fluid and ingesta contents are visible in the ventral aspect of the abomasum, and a gas cap is visible dorsally.[1,2,40,54] In cases of pyloric stenosis, the abomasum is dilated but not displaced (see Fig. 32-110, *B*).[2] No gas accumulation is seen, and the abomasal contents demonstrate an anechoic or hypoechoic, fluid appearance. If the abomasal distention is a result of delayed abomasal emptying secondary to ileus, distended, amotile loops of small intestine will be visible in the right ventral abdomen.[40] Transmural thickening of the abomasal wall has been reported in cases of abomasal lymphoma.[55,56] Abomasitis and abomasal ulceration cannot be visualized with ultrasound.[2]

Small Intestine

NORMAL APPEARANCE (Fig. 32-111, *A*)**.** The descending duodenum is visualized from the right tenth intercostal space caudally to the right paralumbar fossa region. The ascending duodenum cannot be visualized because of its location deep within the abdomen. The cranial duodenum may be seen deep or ventral to the gallbladder in the right tenth or eleventh intercostal space. The descending duodenum is then visible deep to the liver in the right eleventh and twelfth intercostal spaces and becomes progressively superficial as it courses caudodorsally such that it is seen adjacent to the body wall in the right paralumbar fossa region. Duodenal contents are often visible and consist of a fluid, feed, and/or mucous mixture with mixed echogenicity. Occasionally, gaseous contents are seen within the duodenum. The descending duodenum can be differentiated from jejunum and ileum by its anatomic location within the abdomen.

The jejunum and ileum cannot be differentiated from one another in adult cattle and are usually seen in the right caudal intercostal spaces, right paralumbar fossa region, and right caudoventral abdomen. Loops of jejunum and ileum demonstrate a similar appearance to the duodenum, with anechoic to echogenic fluid and feed contents. Gaseous contents may also occasionally be seen in the jejunum and ileum. Loops may be seen both longitudinally and transversely and demonstrate consistent, active motility. The wall thickness of normal small intestine is 2 to 3 mm, and the normal diameter ranges from 2 to 4 cm in adult cattle.[2,57]

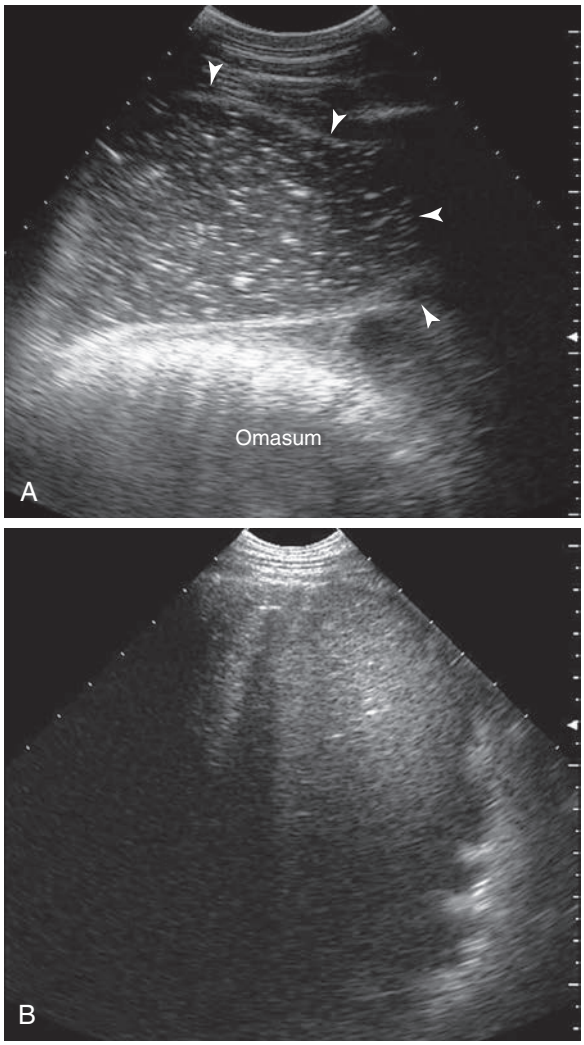

FIG. 32-110 **A,** Normal abomasum viewed from the right cranioventral abdomen in a 5-year-old Holstein dairy cow. Image was obtained with a 2.5-MHz curvilinear transducer at a depth of 9 cm. Note that abomasal contents and the walls of the abomasum are visible *(arrowheads)*. **B,** Severe abomasal distention viewed from the right ventral paralumbar fossa region in an 8-year-old Pygmy doe with severe bloat. Postmortem examination revealed marked pyloric stenosis. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 9 cm. Dorsal is to the right and ventral is to the left.

VetBooks.ir

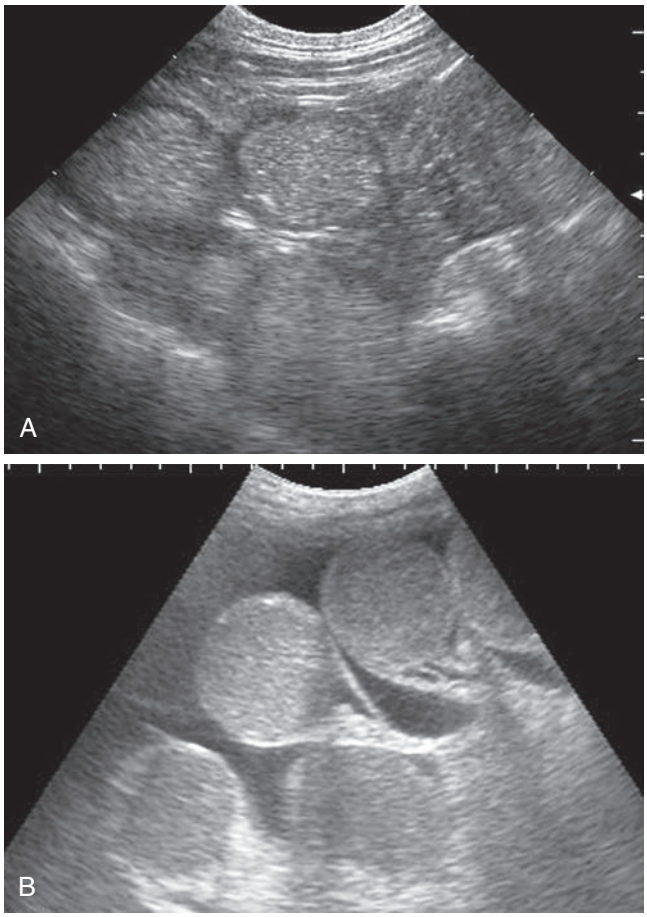

FIG. 32-111 **A,** Normal small intestine viewed from the right paralumbar fossa region in a 5-year-old Nubian buck. This small intestine demonstrated normal consistent motility. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 7 cm. **B,** Severe small intestinal distention with moderate peritoneal effusion viewed from the left ventral abdomen in a yearling Angus heifer with severe ileus secondary to peritonitis. Image was obtained with a 3.5-MHz curvilinear transducer at a depth of 25 cm.

ABNORMAL FINDINGS. Motility, distention, and wall thickness are the most important variables for evaluating small intestinal abnormalities via ultrasound. Ultrasonographic evidence of ileus, characterized by distended, hypomotile to amotile loops of small intestine, can be seen in patients with functional ileus, obstruction, strangulation or incarceration, volvulus, intussusception, and impaction of the small intestine. Small intestinal obstruction may be intraluminal, caused by foreign body, bezoar, impaction, or intraluminal mass or clot formation (hemorrhagic bowel syndrome [HBS]).[1,57-59,60-62] The ventral abdomen should be carefully evaluated in patients suspected of having small intestinal obstruction because affected small intestine is heavier than normal intestine and falls to the most dependent portion of the abdomen. Distended small intestine demonstrates the appearance of a static tubular structure filled with anechoic to echogenic fluid (see Fig. 32-111, *B*). Small intestinal intussusceptions demonstrate a characteristic appearance often described as a "target sign" or "bull's eye" created by a loop of bowel imaged within a second loop.[2,58,63] Extraluminal causes of small intestinal obstruction include compression from adjacent structures such as intraabdominal abscesses or masses or entrapment, which can occur secondary to adhesion formation, rents in the mesentery, extramural masses, or malposition of other abdominal organs.[64] Regardless of cause, small intestinal distention will be seen oral to the obstruction. Small intestinal thickening may also be seen oral to the obstruction owing to secondary hypertrophy. Fluid and feed contents may be seen flowing back and forth with little to no progressive motility. This movement should not be confused with normal peristalsis. Small intestine aboral to the obstruction may appear collapsed and hypomotile. Despite thorough evaluation of the ventral abdomen, the specific cause of ileus may be obscured by the presence of gas-filled bowel or may be too deep within the abdomen to be imaged.[2,58]

Cecum and Colon

NORMAL APPEARANCE. The cecum is normally imaged in the mid to dorsal portion of the right paralumbar fossa region adjacent to the body wall and demonstrates a smooth, curved appearance. Estimates of the diameter of the cecum vary depending on the amount of gas distention present at the time of examination and have been reported to range from 5.2 to 18 cm in normal cattle.[65] The proximal loop of the colon and spiral colon can be visualized dorsal to the cecum in the right paralumbar fossa region and the right twelfth intercostal space. The spiral colon has been described as demonstrating a "garland" appearance with segmental arched lines adjacent to one another.[2,65] Estimation of the diameter of the proximal loop of the colon also varies dependent on gas distention and has been reported to range from 3.1 to 15 cm. The diameter of the spiral colon is smaller, ranging from 2 to 4 cm. The proximal loop of the colon and spiral colon may be difficult to distinguish from gas-filled small intestine; however, the proximal loop and spiral colon seldom demonstrate visible motility or contractions.[65]

ABNORMAL FINDINGS. The diagnosis of cecal dilation is commonly made via rectal palpation but may be more challenging in cases in which dilation of the cecum is not palpable because of retroflexion.[66,67] In cows with cecal dilation, the cecum demonstrates a large radius of curvature and is seen to extend to the ventral portion of the right paralumbar fossa region and sometimes cranially into the right tenth to twelfth intercostal spaces. The proximal loop of the colon will also be dilated in and can be difficult to differentiate from the cecum. The liver may be displaced cranially in cows with severe cecal dilation. Torsion and retroflexion cannot be differentiated by ultrasonographic examination alone but may be diagnosed with a combination of rectal examination and ultrasonographic findings.[66]

Nongravid or Postpartum Uterus

Abnormalities of the uterus may be encountered during transabdominal ultrasound examination in ruminants and will be briefly addressed in the following sections. Evaluation of the gravid uterus and pregnancy diagnosis and monitoring are beyond the scope of this section.

NORMAL APPEARANCE. The normal nongravid uterus is seldom visualized during transabdominal ultrasound examination in ruminants. However, the involuting uterus may be encountered in females that have recently given birth.[68] Transrectal ultrasound is the method of choice to evaluate the bovine uterus.[69] However, abnormalities of the bovine and small ruminant uterus can be identified during transabdominal examination.

ABNORMAL FINDINGS. Abnormalities of the nongravid or postpartum uterus include metritis, pyometra, hydrometra, and uterine neoplasia. In ruminants with metritis or pyometra, the uterus is variably distended with fluid. This fluid may be relatively anechoic, echogenic, or hyperechoic depending on the nature of the debris and inflammatory material within the uterus[68-71] (Fig. 32-112, *A*). Hyperechoic gas echoes can be seen within the uterine fluid in cases of anaerobic or mixed infection. The uterine wall may also be thickened. Hydrometra, or pseudopregnancy, is most commonly reported in goats and is readily diagnosed via ultrasound.[68,72,73] The uterus appears distended with anechoic fluid in the absence of fetuses or placentomes. The dilated uterine horns may be curved or tortuous such that several cross-sections of the horn may be seen in any given scanning plane (see Fig. 32-112, *B*).[68] It should be mentioned that small pockets of fluid may be seen in the normal involuting bovine uterus for up to 4 weeks postpartum.[69,74]

VetBooks.ir

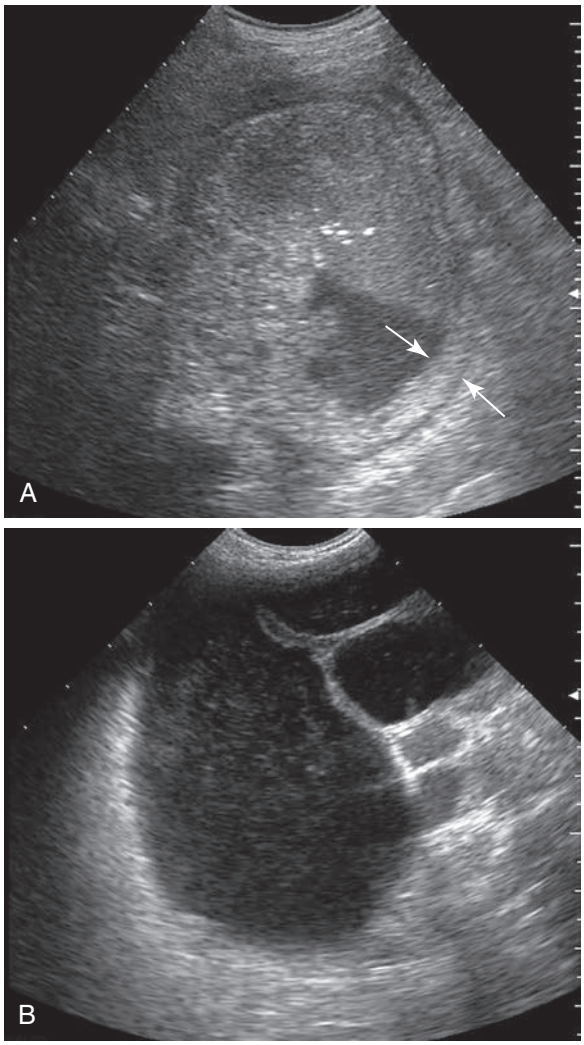

FIG. 32-112 **A,** Enlarged right uterine horn distended with echogenic fluid in a 5-year-old Holstein dairy cow with metritis. This cow had a history of aborting twins 4 days before presentation. Note the associated thickening of the uterine wall *(arrows)*. Image was obtained transabdominally in the right inguinal region with a 3.5-MHz curvilinear transducer at a depth of 18 cm. **B,** Enlarged uterine horn distended with relatively anechoic fluid in a 6-year-old Shetland ewe with hydrometra (pseudopregnancy). This ewe was reported to be 3 months pregnant. Image was obtained in the left flank region with a 7.5-MHz transducer at a depth of 9 cm.

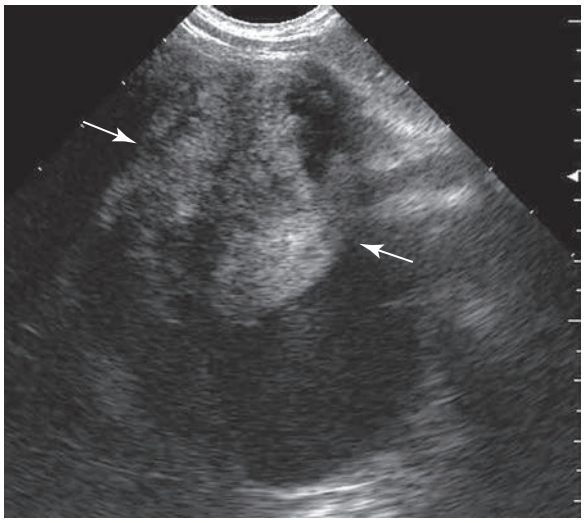

FIG. 32-113 Large uterine mass *(arrows)* viewed from the right ventral abdomen in an 11-year-old Pygmy doe diagnosed with uterine adenocarcinoma postmortem. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 10 cm.

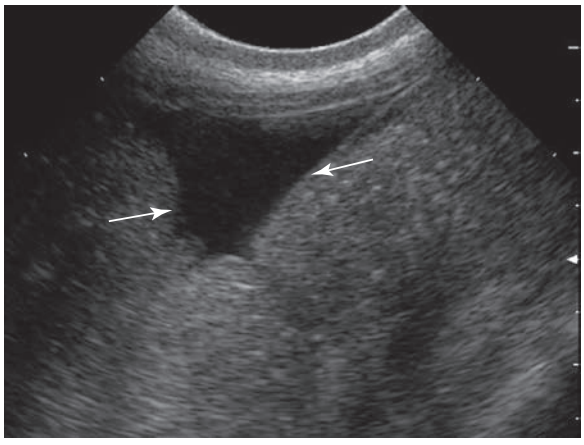

FIG. 32-114 Mild peritoneal effusion *(arrows)* seen between several loops of normal small intestine and the ventral body wall viewed from the right ventral abdomen in a 2-year-old Hampton cross ram. Image was obtained with an 8.5-MHz curvilinear transducer at a depth of 7 cm.

Uterine neoplasia is uncommonly reported in ruminants, but leiomyosarcomas, leiomyomas, carcinomas, chorionepitheliomas, fibrosarcomas, rhabdomyosarcomas, adenosarcomas, and multicentric lymphoma have been found.[75,76] Mass lesions visualized within the uterine wall or lumen are consistent with neoplasia. Masses may be single or multiple with variable echogenicity (Fig. 32-113). Diffuse infiltration of the uterine wall has been reported in cases of lymphoma.[75,76]

Peritoneal Cavity

NORMAL APPEARANCE. The peritoneal lining can be seen as a very thin, smooth hyperechoic line adjacent to the body wall. Minimal free abdominal fluid is seen within the peritoneal cavity. Retroperitoneal adipose tissue appears as a hypoechoic layer of varying thickness between the body wall and abdominal viscera and should not be misinterpreted as cellular peritoneal effusion. Adipose tissue may also be seen within the omentum and mesentery, demonstrating a similar appearance between or among the gastrointestinal viscera. This omental and mesenteric adipose tissue can often demonstrate an organized appearance with visible fine vasculature that can be mistaken for liver, especially in small ruminants.

ABNORMAL FINDINGS. Peritoneal fluid is readily identified on ultrasound as anechoic to echogenic fluid between the body wall and abdominal organs (Fig. 32-114). In cases of severe effusion, the abdominal organs and viscera appear to float within the free fluid. Fibrin deposits are commonly seen in ruminants with inflammatory peritoneal effusion and appear as linear strands extending between organs or between peritoneal surfaces and serosal surfaces of abdominal organs (Fig. 32-115).[1,47] Fibrin can also demonstrate a "shag carpet" appearance along the peritoneal and/or serosal surface. Localized peritonitis may also be seen and has been reported in cows secondary to left flank laparotomy.[47] Hemoabdomen appears as hypoechoic cellular-appearing fluid that swirls with ballottement, peristalsis, or respiration (Fig. 32-116).

Other abnormalities of the peritoneal cavity include mesenteric abscessation, mesenteric lymphadenopathy, fat necrosis, and neoplasia. Intraabdominal abscessation may be identified within the mesentery or associated with abdominal incisions. Abscesses are generally well encapsulated with anechoic to echogenic contents. Enlarged mesenteric lymph nodes can be seen within the small intestinal mesentery and are a nonspecific finding that has been seen by the author in cases of abdominal disease from numerous causes (Fig. 32-117).

VetBooks.ir

FIG. 32-115 Severe fibrinous peritonitis thought to be secondary to an intestinal rent viewed from the right paralumbar fossa region in a 3-year-old Holstein dairy cow. Note the hyperechoic fibrin strands creating a weblike appearance within the peritoneal cavity. Image was obtained with a 5.0-MHz curvilinear transducer at a depth of 27 cm.

FIG. 32-117 Enlarged mesenteric lymph node viewed from the left ventral abdomen in an 8-month-old Angora kid with disseminated *Rhodococcus equi* infection. Image was obtained with a 7.5-MHz curvilinear transducer at a depth of 5 cm.

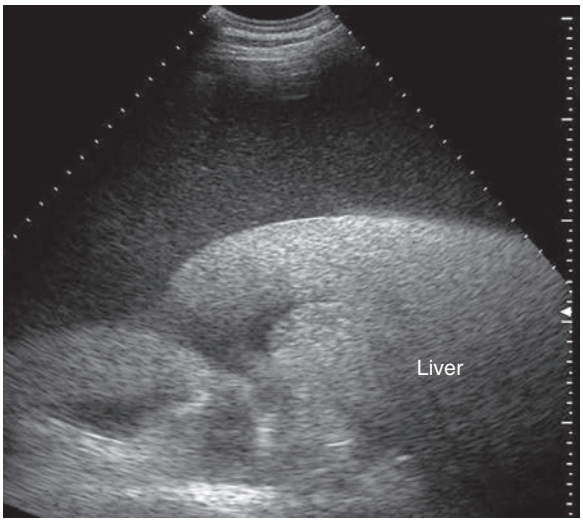

FIG. 32-116 Severe hemoabdomen viewed from the right cranioventral abdomen in a 2-year-old Shorthorn heifer with metastatic granulosa cell tumor. Note the very cellular appearance to the fluid within the peritoneal cavity. The liver is displaced from the body wall and appears to float in the effusion. Image was obtained with a 2.5-MHz curvilinear transducer at a depth of 27 cm.

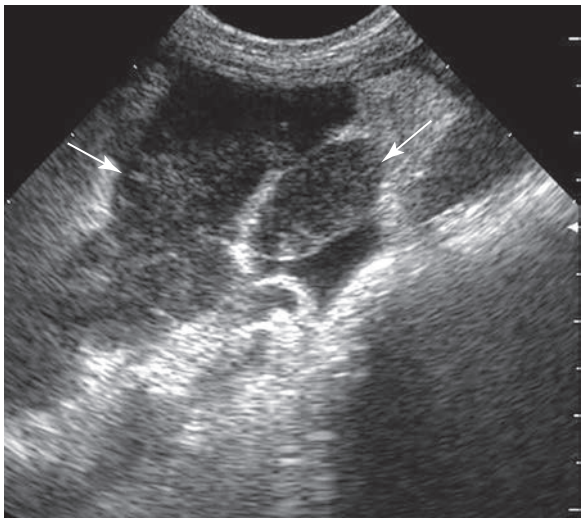

FIG. 32-118 Multiple peritoneal masses *(arrows)* between the rumen and body wall viewed from the left paralumbar fossa region in a 10-year-old Pygmy doe with mesothelioma. Image was obtained with an 8.5-MHz curvilinear transducer at a depth of 6 cm. Dorsal is to the right and ventral is to the left.

Hyperechoic masses surrounding the kidneys and small intestine or in the pancreatic and omental regions have been reported in cattle with abdominal fat necrosis.[77] Ruminants with neoplasia may demonstrate severe peritoneal effusion, most notably in cases of mesothelioma.[78,79] In cases of mesothelioma, multiple echogenic nodules are seen overlying the serosal surfaces of the peritoneum and abdominal organs (Fig. 32-118). Nodules can also be seen in the omentum.[78,79]

Indigestion in Ruminants

Franklyn Garry • Craig McConnel

Definition and Etiology

Indigestion is a general term for a group of diseases characterized by dysfunction of the reticulorumen. Some texts have limited the use of the term to a single, poorly defined entity that includes inappetence, decreased reticuloruminal motility, and abnormal feces, with a nonspecific cause that involves intake of abnormal feed.

The more generalized term applied here incorporates a pathophysiologic classification scheme of forestomach disturbances that has been devised by workers in Germany.[1] An absolute division of the pathologic processes is impossible because the various forestomach functions are interdependent; that is, abnormal motor function affects microbial fermentation by altered mixing or passage of ruminal fluid out of the forestomach chambers, whereas abnormal fermentation products secondarily alter motor function. Nevertheless, this classification provides a clinically useful diagnostic framework by emphasizing the underlying pathophysiologic mechanisms of different forestomach disturbances.

The primary indigestions include those diseases in which the reticulorumen is directly affected and responsible for the major

VetBooks.ir

BOX 32-5

Classification of Ruminant Indigestion

Primary Indigestions

Reticuloruminal Motor Disorders or Diseases of the Rumen Wall

Traumatic reticuloperitonitis (pp. 781, 805)
Frothy bloat (p. 810)
Free gas bloat (p. 780)
Reticulitis/rumenitis (p. 781)
Ruminal parakeratosis (p. 781)
Vagal indigestion (failure of omasal transport, failure of pyloric outflow, and free gas bloat) (p. 781)
Obstruction of the cardia (p. 784)
Obstruction of the reticuloomasal orifice (p. 784)
Diaphragmatic hernia (p. 784)

Reticuloruminal Fermentative (Microbial and Biochemical) Disorders

Inactivity of rumen microbial flora (caused by poor-quality roughage—rumen impaction) (p. 785)
Simple indigestion (p. 786)
Acute ruminal lactic acidosis (p. 786)
Subacute ruminal acidosis (p. 787)
Ruminal alkalosis (p. 788)
Putrefaction of ruminal ingesta (p. 788)

Secondary Indigestions (Secondary to Systemic Illness)

Secondary reticuloruminal motor inactivity (p. 779)
Secondary reticuloruminal microflora inactivity (p. 784)

disease signs (Box 32-5). These problems can be divided into two categories:

1. Abnormal motor function of the reticulorumen, including disease of the reticuloruminal wall, its innervation, or impedance to the passage of ingesta
2. Abnormal contents of the reticulorumen, with dysfunction of microbial and biochemical fermentation

Secondary indigestions are the sequelae of systemic problems or disease in other organ systems. For example, problems such as endotoxemia, fever, or depression can produce anorexia, secondary ruminal hypomotility, and decreased microbial fermentative function. Primary abomasal disease can depress ruminal function, inhibit ruminal outflow, and reflux abomasal contents back into the rumen.

With the exception of penetrating foreign bodies and sporadic infections of the forestomach wall (e.g., actinomycosis, mucormycosis), indigestions are physiologic abnormalities. In the adult ruminant one or more of the homeostatic processes of the fermentative environment are disturbed (e.g., an excessive carbohydrate intake generates an excessive amount of acid product; abnormal neural regulation of the ruminal motility pattern disturbs the mixing or aboral passage of ingesta). In the young ruminant the forestomachs are actively developing, and indigestions can result from disturbances of the developmental mechanisms. The forestomach diseases of young ruminants generally have received little attention, but they can be recognized and appropriately treated within a classification scheme similar to that for adult ruminants.[2]

Pathophysiology Digestion of feedstuffs in the reticulorumen is accomplished by microbial fermentation. The mucosal epithelium absorbs and exchanges products of fermentation but performs essentially no secretory function. Appropriate forestomach fermentation depends on the coordination of processes that provide a fairly constant reticuloruminal environment. The requirements include addition of appropriate amounts and types of feed substrate and water by ingestion; buffering of substances from the saliva to counteract the acid nature of fermentation products; eructation of the gaseous products of fermentation; coordination of reticuloruminal motility to provide mixing; rumination and remastication; aborad passage of ingesta; temperature maintenance; and exchanges of electrolytes and volatile fatty acids (VFAs) across the ruminal wall. Because these functions are intimately interrelated, abnormalities of any one of them can lead to digestive disturbances.

Disorders of Reticuloruminal Motor Function

Normal Motor Activity

The two reticuloruminal contraction sequences function independently. The primary cycle of contraction occurs approximately once a minute but more often during feeding and rumination. It consists of a biphasic contraction of the reticulum followed by a contraction that runs caudally across first the dorsal and then the ventral ruminal sacs. At the height of the second reticular contraction the omasal orifice relaxes and fluid, mostly composed of reticular ingesta, passes into the omasum. This reticuloruminal motility pattern directly influences ruminal fermentation by mechanically mixing the ingesta to provide contact with the microbes and to macerate the particulate matter. The mixing function prevents local accumulations of substrate or end products of fermentation, distributes the buffering saliva for neutralization of acids, and provides increased contact of the fluid with the ruminal wall to promote VFA absorption. The coordinated sequence of contraction of various parts of the ruminal wall maintains a stratification of fluid and particulate matter that selectively sorts the ingesta by particle size. The sorting function serves to retain large particles for further digestive breakdown while promoting passage of small particles (smaller than 6 mm) into the omasum and lower gastrointestinal tract.[3-5]

The secondary contraction cycle does not involve the reticulum. It begins in the caudal blind sacs, and a wave of contraction runs cranially across the dorsal rumen, pushing the gas cap into the cardia region. Eructation ensues, eliminating the gases generated by fermentation. Typically one secondary cycle contraction follows two primary cycles, so that three contractions occur every 2 minutes.[6] Two additional special contractions have been identified in sheep: primary-secondary contractions and prosecondary contractions.[7] These contractions appear when intraruminal pressure becomes elevated and function as secondary contractions by expelling ruminal gas. The primary-secondary and prosecondary contractions appear to help minimize free gas bloat when gas production is high.

Maintenance of the motility patterns requires well-coordinated neural control. The pathophysiologic mechanism of the first group of primary indigestions (i.e., diseases of the reticuloruminal motor function) involves disturbance of the mechanisms of normal ruminal motility, which secondarily affects ruminal fermentation.

The ruminal contraction sequences described rely almost completely on motor nerve activation arising from the medulla oblongata, in contrast to the intrinsic segmental and peristaltic movements of the intestine. Gastric centers in the medulla integrate sensory input and generate motor impulses, both of which are carried in the vagus nerves. The gastric centers have neither spontaneous activity nor an inherent rhythm. Generation of motor impulses relies on a greater excitatory than inhibitory input from the sensory nerves to determine the rate, magnitude, and duration of primary cycle contractions. During the quiescent period between the primary contractions, while the medulla collects the sensory information, there are no tonic vagal motor impulses.[8,9]

The splanchnic nerves also affect reticuloruminal motility by direct innervation and by neurohumoral effects of adrenal secretion. These nerves are not required for generation of normal contractions. The effect of splanchnic stimulation is inhibition of reticuloruminal motility. Splanchnic sensory nerves innervate sensory receptors in other areas of the gastrointestinal system, and some abnormalities such as intestinal distention or surgical manipulation produce reticuloruminal inhibition by means of reflex from splanchnic afferent activity.[9]

VetBooks.ir

Primary Cycle Activity

A decrease or absence of normal primary cycle activity (i.e., ruminal hypomotility or stasis) implies either a decrease of vagal motor discharges originating from the gastric centers or an ineffective motor response after motor impulse, as in cases of hypocalcemia. Causes of decreased motor discharges can include the following:

1. Decreased excitatory input to the gastric centers
2. Increased inhibitory input to the gastric centers
3. Depression of the gastric centers
4. Defective vagal transmission of motor impulses
5. Other factors

DECREASED EXCITATORY INPUT. The three most important excitatory inputs to the gastric centers are from (1) low-threshold tension receptors in the reticulum, (2) buccal receptors in the mouth, and (3) acid receptors in the abomasum (Table 32-12). The tension receptors are located in the musculature of the medial wall of the reticulum. They are stimulated by mild distention during the resting phase and thereby influence contraction frequency. They are further stimulated by the tension generated during contraction and thus increase amplitude and duration of the primary cycle contraction. This mechanism is probably responsible for the increased motility seen after feeding or during incipient bloat. Any cause of anorexia leading to decreased ruminal fill decreases this excitatory input, leading to ruminal hypomotility. Feeding mechanically stimulates buccal sensory receptors, providing a potent stimulus to both primary and secondary contraction cycles. This reflex can double the rate of primary contractions but is short-lived and declines as soon as chewing activity ceases. Thus anorexia effectively eliminates this potent excitatory input. Abomasal acidity increases as the abomasum empties and this too provides excitatory input to the gastric centers. The resultant increased reticuloruminal motility leads to increased flow of ingesta to the abomasum, diluting the abomasal acid and maintaining normal filling of the abomasum. Certain types of abomasal disease diminish this stimulus to forestomach motility.[8-10]

Less well-defined stimuli of reticuloruminal motility include the physical and chemical characteristics of the ruminal ingesta. Fiber and water content, as well as the normal chemical products of fermentation, are important for normal ruminal contraction. The exact mechanisms through which these factors enhance ruminal motility have not yet been clearly defined,[11] but low levels of any of these ingesta characteristics impair normal function, causing decreases of both rumination and primary cycle activity. That these excitatory stimuli are decreased or absent under some feeding regimens and with some of the diseases attributable to abnormal fermentation may account for the impression of hypomotility observed clinically.[12]

INCREASED INHIBITORY INPUT. Inhibitory inputs to the gastric center arise from (1) high-threshold tension receptors in the reticulum and cranial ruminal sac, (2) tension receptors in the abomasum, (3) epithelial receptors that detect high concentrations of nondissociated VFAs in the rumen, and (4) pain elicited at any site in the body (see Table 32-12). The high-threshold tension receptors are sensory nerve endings below the epithelial basement membrane of the reticulum and cranial ruminal sac. They respond to extreme distention of the wall and serve to modify the end stage of reticuloruminal contraction. With severe bloat or gross ruminal distention from other causes such as overfilling with indigestible fibrous roughage, they can be continuously activated producing ruminal stasis. Abomasal distention can inhibit primary ruminal contraction cycles presumably through tension receptors in the abomasal wall.[13] In normal circumstances this activity would serve to decrease the flow of ingesta to the abomasum when it is full. With abomasal displacement or impaction, this reflex may partly account for the observed ruminal hypomotility. Epithelial receptors in the reticulum and cranial ruminal sac are sensitive to increased concentrations of nondissociated VFAs. Inhibition of forestomach contractions occurs when conditions of excessive fermentation or acidosis increase the concentrations of these substances. Pain can reduce forestomach motility by increasing sympathetic nervous and adrenal secretory activity and by inhibiting the gastric centers. Although painful stimuli in the abdominal viscera are particularly potent, pain from anywhere in the body can inhibit or abolish reticuloruminal motility.[8-10]

DEPRESSION OF THE GASTRIC CENTERS. Depression of the gastric centers reduces vagal motor activation of forestomach motility and can be induced by central nervous system depressant drugs and anesthetics. Endotoxemia, fever, and possibly blood pH and electrolyte abnormalities can induce ruminal hypomotility or stasis through central effects on the gastric centers. These factors may also inhibit ruminal motility by increasing sympathetic nervous activity. In addition, some toxins or other abnormal fermentation products reduce ruminal motility. These substances may act locally at the ruminal epithelial receptors to generate inhibitory impulses, as do increased VFA concentrations, or they may act centrally after absorption into the blood. For the most part the nature of the substances capable of chemically suppressing ruminal function is unknown,

TABLE 32-12

Factors Influencing Vagal Motor Discharge from the Gastric Centers of the Medulla*

Input	Location	Stimulus
Excitation of the Gastric Centers (Causes Increased Rumen Motility)		
Low-threshold tension receptors	Reticulum, medial wall	Mild distention; tension generated during contractions
Buccal receptors	Mouth	Feeding (only during chewing)
Acid receptors	Abomasum	Increased acidity as abomasum empties
Tension receptors†	Medial wall of cranial rumen sac	Increased rumen gas pressure
Inhibition of the Gastric Centers (Causes Decreased Rumen Motility)		
High-threshold tension receptors	Reticulum and cranial rumen sac	Bloat or other severe ruminal distention
Tension receptors	Abomasum	Abomasal distention
Chemical receptors	Reticulum, rumen	Increased concentration of undissociated volatile fatty acid with rumen acidosis; also locally activated by some toxins
Pain receptors in body increase sympathetic tone and adrenal secretory activity	Anywhere in body; can act directly and through medullary gastric centers	Pain, especially abdominal
Gastric centers	Medulla	Anesthesia, depressant drugs, toxins, endotoxins, fever, acidosis
Hypocalcemia	Reticuloruminal smooth muscle	Hypocalcemia

*There is no inherent reticuloruminal motility such as that found in the intestines.

†Secondary cycle activity; independent of primary cycle activity.

TABLE 32-13

Causes of Rumen Tympany (Bloat)

Mechanism	Cause	Disease Examples
Obstruction of eructations	Esophageal obstruction	Choke, tetanus, thoracic inflammation or neoplasia with swollen mediastinal lymph nodes
	Cardia obstruction	Papilloma, fibroma, actinobacillosis
	Failure to clear cardia of fluid or ingesta	Lateral recumbency, reticulorumen overfilled with ingesta (as in vagal indigestion, ruminal microbial inactivity with poorly digestible roughage, obstruction of the reticuloomasal orifice)
Ruminal motor dysfunction	Gas trapped in stable foam	Frothy bloat
	Failure of smooth muscle contraction	Hypocalcemia
	Weakened muscle contraction	Chronic ruminal distention with indigestible roughage, outflow obstruction, or vagal indigestion; hypokalemia
	Abomasal distention	Displaced abomasum (especially in calves)
Chemical inhibition	Vagus nerve damage	Thoracic inflammation (especially in calves, neoplasia)
	Ruminal stasis	Rumen acidosis, rumen alkalosis, abnormal fermentation products with simple indigestion

but abnormal fermentation end products are the likely cause of ruminal stasis in indigestion associated with abnormal ruminal contents.[3,8,12,14]

DEFECTIVE VAGAL INNERVATION. Failure of vagal nerve transmission of motor impulses has been implicated as the cause of a reticuloruminal contraction abnormality that leads to failure of aborad flow of ingesta (hence the name vagal indigestion). The left and right vagi in the thorax divide into dorsal and ventral branches that unite to form dorsal and ventral vagi as the nerves enter the abdomen. The ventral vagus innervates the cranial and medial parts of the reticulum, the omasum, and the abomasum. The dorsal vagus innervates the rumen and parts of the other segments of the ruminant stomach. Sectioning of more than 50% of the vagal nerve trunks leads to impaired motility function, but most cases of vagal indigestion show much less nerve involvement. The importance of vagal nerve lesions in the pathogenesis of forestomach disease has been a subject of considerable debate and is discussed more fully later in this chapter.[8]

OTHER FACTORS THAT AFFECT THE PRIMARY CYCLES. Other influences on forestomach motility have been identified. Hypocalcemia inhibits motility by preventing contraction of the musculature after motor nerve discharge. This may explain the reduced ruminal motility seen in early cases of milk fever.[15] Low environmental temperatures[16,17] and milking[18] have been shown to increase ruminal motility mildly, whereas some drugs,[19-21] hyperglycemia,[22] and gastric hormones[23] are effective in decreasing reticuloruminal primary cycle contractions. These factors are not discussed further in this text.

Secondary Cycle Activity

The secondary cycle activity responsible for eructation is elicited independently of the primary cycles. An increase in ruminal gas pressure excites tension receptors in the medial wall of the cranial ruminal sac. This triggers relaxation of the cardia and eructation of the gas accumulated in the cardia region by the secondary contraction cycle. Receptors that apparently distinguish gas from fluid or solid matter inhibit opening of the cardia if it is covered by material other than gas. This reflex inhibition of cardia opening is responsible for bloat in cases in which abnormal ingesta cover the area, such as in recumbent animals, in frothy bloat, and when abnormal motility or overfilling of the rumen precludes clearing of the cardia. Under such circumstances and when ruminal distention is not yet extreme, both primary and secondary cycle contractions may increase in frequency. In other forms of bloat, hypomotility is a prominent feature, and the gas accumulates as a result of the poor motility function. This is the most probable cause of bloat in some of the disturbances of fermentative function.

Gross overdistention of the ruminal wall may inhibit motility by stretching the musculature beyond its ability to contract forcefully. If the process leading to the distention develops slowly, the high-tension receptor inhibition of motility appears to adapt, and complete inhibition of motor impulses does not seem to occur. Rather, in these cases motility is present but weak and relatively ineffective. This motility disturbance is likely when poorly digestible roughage accumulates in the forestomach. Patients with this condition often have mild to moderate chronic free gas bloat, which may result from poor ability of the weakened rumen to clear the cardia and dispel the gas.[1]

Free Gas Bloat

Accumulation of free gas in the dorsal rumen should not be considered a primary disease entity but rather a sign of disease (Table 32-13). However, because free gas bloat often is the most prominent sign and because it accompanies several different forms of indigestion, its pathogenesis is reviewed briefly here.

Ruminal microbial fermentation and neutralization of salivary bicarbonate continually produce gas as an end product (primarily methane and carbon dioxide) in proportion to the rate of fermentation. Normally the ruminant can eructate volumes of gas that exceed the amount produced even at maximum rates of fermentation.[24] Thus an excessive production of gas is not the cause of bloat. Bloat develops either because the evacuation of gas is hindered by a physical obstruction or because the mechanisms that expel the gas are inhibited.[25]

As in choke, physical obstruction of the esophagus by a foreign body can produce dramatic and peracute bloat. Other forms of esophageal occlusion (which may additionally involve inflammation of nerves or ruminal muscle malfunction) include muscular spasm (e.g., tetanus), swollen mediastinal lymph nodes (e.g., chronic pneumonia, thymic lymphosarcoma), and tumorous or inflammatory swellings of the cardia region (e.g., papilloma, actinomycosis). These problems tend to show bloat of a slowly progressive or chronic nature, although the degree of bloat may be marked.

Bloat is a common feature of indigestions caused by microbial fermentative disorders. When ruminal hypomotility occurs, the fermentative rate may decline, but weak ruminal contractions may be inadequate to move the gas layer and to clear the cardia preparatory to eructation. Thus dietary, microbial, or metabolic factors that affect the excitability of the gastric centers or the reticulorumen can result in bloat. Ruminal stasis can result in bloat because eructation occurs only with ruminal contraction. Bloat also accompanies indigestions that produce gross distention of the reticulorumen with fluid or solid ingesta (i.e., vagal indigestion, ruminal acidosis, and microfloral inactivity caused by indigestible roughage). The cause of bloat in these cases may be a combination of ruminal stasis, weakening of

VetBooks.ir

the ruminal wall caused by the gross distention, and failure to clear the cardia.

As is the case in adult cattle, it appears that free gas bloat in calves has numerous causes, including fermentative indigestions, ruminal wall disturbances, and esophageal involvement in an intrathoracic inflammatory process.[26,27] Chronic bloat in calves has also been attributed to a form of vagal nerve damage resulting from mediastinal inflammation. Distinguishing between vagal nerve impairment and esophageal compression or inflammation as the cause of free gas bloat requires a thorough assessment of ruminal motor function, as described under the section on clinical signs.

Reticulitis and Rumenitis

The most important inflammatory problem is reticuloperitonitis caused by sharp foreign body punctures (traumatic reticuloperitonitis [TRP], hardware disease); this disease is discussed elsewhere in Chapter 32. The localized infection established by reticuloruminal perforation causes inflammation of the forestomach wall and adjacent peritoneal cavity and pain in the anterior abdomen, inhibiting forestomach motility, appetite, and aborad flow of ingesta. Other causes of ruminal wall inflammation can cause acute or chronic forestomach dysfunction.

Most infections of the ruminal wall follow primary mechanical or chemical damage to the mucosa. The secondary invaders colonize the damaged areas and may gain access to the circulation and invade other tissues as well. The ruminal wall may be the niche for some of these microorganisms, and isolates from the ruminal wall have been matched with those isolated from liver abscesses.[28] Probably the most common cause of the initial mucosal injury is acute ruminal acidosis produced by grain engorgement. Chemical damage resulting in ruminal ulcers also occurs in oak or acorn toxicosis and with ingestion of caustic chemicals. Common secondary ulcer invaders include *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *Fusobacterium necrophorum,* and several mycotic species.[28,29] Mycotic rumenitis can follow ruminal acidosis and septic diseases, especially after the use of oral antibiotics. It also can occur after feeding spoiled and moldy feeds and without apparent predisposing causes.[30,31] Diseases that cause anorexia plus abomasal reflux of gastric acids may predispose an animal to mycotic rumenitis and omasitis. Mycotic rumenitis can be severe, with vascular thrombosis and infarction and mural necrosis and gangrene sufficient to cause death. Less frequently occurring specific infections of the ruminal wall include actinobacillosis, actinomycosis, and tuberculosis. These infectious inflammatory diseases of the ruminal wall may be distributed widely throughout the forestomach, depending on the initial site of mucosal injury, but they tend to localize in the ventral regions of the reticulorumen. The granulomatous inflammatory lesions of actinobacillosis and actinomycosis are most commonly found in the cranial forestomach in the area of the esophageal groove.

Neoplastic growths in the rumen have also been identified. These uncommon lesions include papillomas, myxomas, fibromas, carcinomas, and lymphosarcomas.[32] These lesions are most commonly localized in the reticulum and cranial rumen near the cardia and esophageal groove.

The importance of these inflammatory reticuloruminal lesions depends on their extent and location. Acute and extensive lesions have been associated with signs similar to those of reticuloperitonitis caused by foreign body puncture, including pain, inappetence, impaired forestomach function, and in some cases death. The more chronic cases may cause forestomach motility disturbances and signs of vagal indigestion. Pedunculated masses especially, but not exclusively, may obstruct the cardia or reticuloomasal orifice and lead to bloat or reticuloruminal outflow disturbance.

Reticuloruminal inflammation can also result from certain generalized infections. These include bovine virus diarrhea, foot-and-mouth disease, malignant catarrhal fever, and rinderpest. In these cases the forestomach problems are unlikely to be the most important clinical manifestation.

Ruminal Parakeratosis

In parakeratosis the papillae are darkly colored, enlarged, thickened, and clumped together. Histologic changes of the epithelial cells include a thickened, cornified layer with abnormal retention of nuclei in the cornified cells. These morphologic changes appear to represent a reaction to persistently high concentrations of volatile fatty acids. The changes occur predominantly in animals on pelleted or very finely ground rations, especially when the ration contains a high amount of energy. These rations tend to increase the proportions of propionate and butyrate, reduce the proportion of acetate generated by microbial fermentation, and produce a lowered ruminal fluid pH. The growth of the ruminal papillae is promoted by contact with the VFAs, especially butyrate, and secondarily propionate.[3] It appears that a disproportion of the concentrations of these VFAs may be the cause of an excessive change in the epithelium of the papillae.[33-35] Initial changes in the epithelium under these conditions appear to increase the absorption of the volatile fatty acids, but in severe cases the absorption decreases. This disease of the ruminal wall is not usually diagnosed as a primary problem. Although it may lead to impaired performance of the animal, the disease signs that lead to its discovery are usually those of chronic acidosis, a disease with which it often coexists. Parakeratosis can predispose to other injuries of the ruminal wall, however, because the abnormal papillae are more easily traumatized, leading to chronic inflammatory disease of the wall as discussed previously. In calves the problem is also associated with the development of hairballs (trichobezoars) because of the propensity of calves on the rations associated with parakeratosis to lick their hair coat.[35]

Vagal Indigestion

Vagal indigestion syndrome (vagus indigestion, Hoflund syndrome) comprises a group of motor disturbances that hinder passage of ingesta from the reticulorumen or abomasum or both. The pathogenesis of the disease has been debated for years and has yet to be completely clarified because many investigations have yielded conflicting information.[36-43]

The name *vagus indigestion* was introduced by Hoflund, who experimentally produced motor defects and disease signs similar to those seen in clinical cases by transecting various branches of the abdominal vagal nerve.[37] On the basis of his experimental results, he defined four types of functional disturbance, with obstruction of ingesta flow at two sites:

1. *Omasal transport failure* (anterior or proximal functional stenosis, reticuloomasal stenosis) impairs flow of ingesta through the reticuloomasal orifice and occurs with (a) atony of the reticulorumen (often associated with chronic recurrent bloat) or (b) normal to increased ruminal motility.
2. *Pyloric outflow failure* (posterior or distal functional stenosis, pyloric stenosis) impairs flow through the pylorus and occurs (a) continuously or (b) in an intermittent, recurrent pattern (incompletely).

Hoflund's description of the syndrome is convenient for explaining the observed functional defects, but its presumed pathogenesis is not supported by the findings of later investigators.[36] The use of the term *stenosis* has also led to some confusion, although it was appropriate in its original context. The term *functional stenosis* suggested that the defect was a functional one that mimicked a stenosis at the site of outflow. However, vagal denervation does not produce a true stenosis, but rather a paralysis and relaxation of either the reticuloomasal orifice or the pylorus. The paralysis can be appreciated in both experimental and clinical cases.

FAILURE OF OMASAL TRANSPORT. Failure of omasal transport with hypermotility of the rumen is the most common naturally occurring form of the disease. Accumulation of ingesta in the reticulorumen leads to gradually progressive distention of the forestomachs, whereas the omasum and abomasum remain relatively empty. The animal's appetite diminishes as the rumen becomes overfilled,

VetBooks.ir

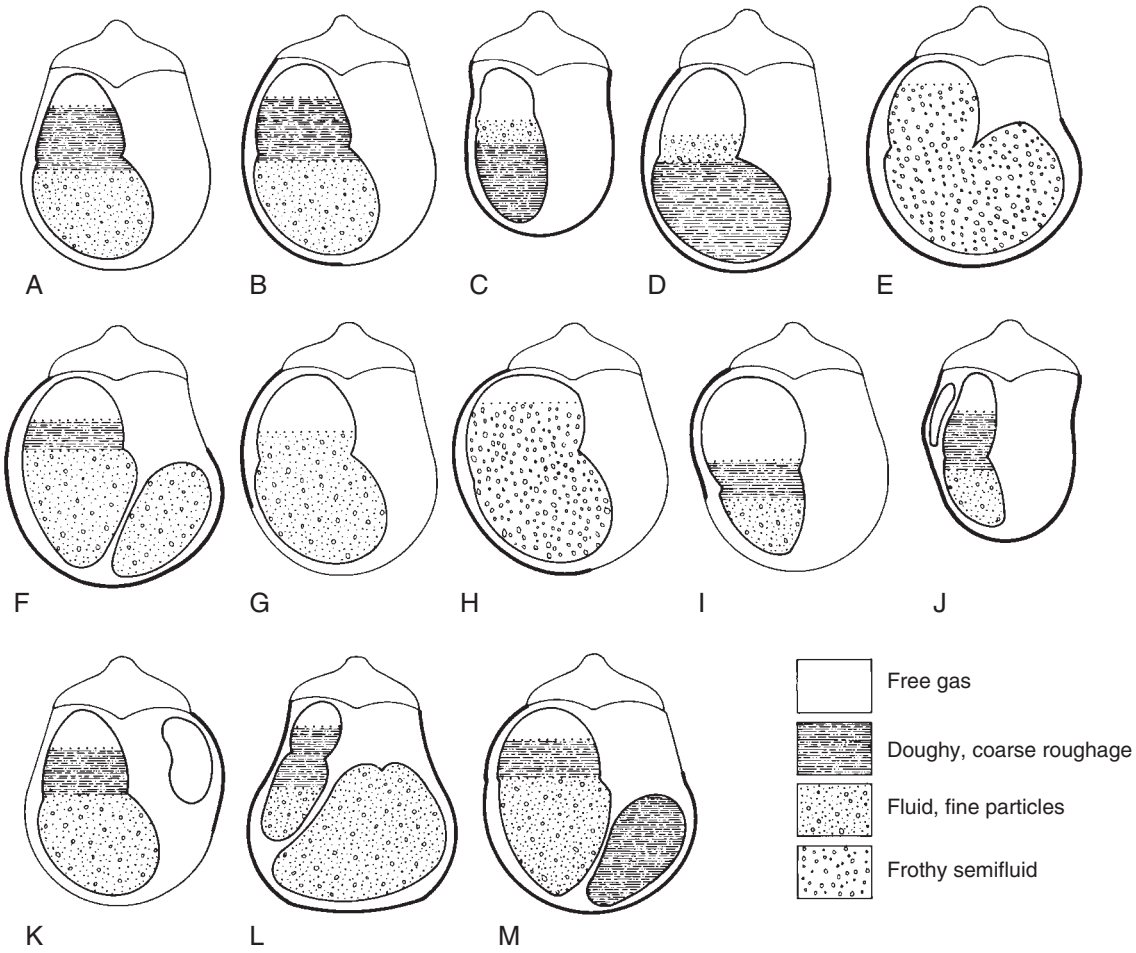

FIG. 32-119 Abdominal contours (viewed from the rear) and abdominal palpation findings characteristic of cattle with various types of indigestion and other abdominal diseases. A thin line for the abdominal contour indicates the normal configuration. Bold lines indicate areas of the abdominal contour that typically deviate from normal in affected animals. **A,** Normal. **B,** Acute onset of rumen stasis with simple indigestion, traumatic reticuloperitonitis (findings: mild ruminal distention with normal layering of rumen content). **C,** Prolonged rumen stasis, anorexia. The most common result of subacute or chronic disorders such as microbial or fermentative indigestions, traumatic reticuloperitonitis, and secondary indigestions (findings: reduced rumen fill, "tucked-up abdomen," firm, doughy contents that gravitate ventrally). **D,** Rumen inactivity with indigestible roughage (findings: rumen distended with firm, doughy contents that accumulate ventrally; recurrent free gas bloat often present). **E,** Omasal transport failure (findings: L-shaped rumen with gross accumulation of frothy ingesta; rumen hypermotility often present; free gas accumulation varies). **F,** Pyloric outflow failure (findings: fluid accumulation in abomasum; abomasal reflux to rumen common; doughy rumen content that usually accumulates dorsally until rumen stasis or anorexia is prolonged; abdominal contour similar to that for omasal transport failure). **G,** Acute rumen acidosis (findings: rumen distended with fluid; some free gas bloat common). **H,** Frothy bloat. **I,** Free gas bloat or chronic free gas bloat (findings: accumulation of gas in dorsal sac; layering or rumen contents usually normal; with chronicity, rumen fill often decreased; associated with some microbial or fermentative disorders and with esophageal and cardiac disorders). **J,** Left displaced abomasum (findings: gas-filled abomasum that often causes slight bulge of paralumbar fossa; rumen fill usually reduced). **K,** Right displaced abomasum, abomasal volvulus, cecal torsion (findings: distention of right flank with gas-filled viscus; rumen fill and consistency usually normal). **L,** Hydrops (findings: ventral abdomen distended with fluid-filled uterus: rumen fill usually decreased). **M,** Abomasal impaction (findings: abdominal contour similar to **E** and **F;** abomasum filled with firm ingesta).

producing one of the most characteristic signs of the disease: inappetence with gross distention of the rumen in the left flank. Continued dilation of the rumen eventually leads to a marked and almost pathognomonic overfilling of the ventral ruminal sac. The rumen assumes an L shape because the ventral sac occupies both the right and left ventral quadrants of the abdomen. The resultant characteristic abdominal contour often is called a "papple" shape (Fig. 32-119, E) because the left side of the abdomen is distended and assumes the appearance of an apple, whereas the right side assumes the contour of a pear. The diminished passage of ingesta passage results in reduced fecal volume. The normal ruminal process of selective retention of fibrous material is disturbed, leading to large particle passage and feces with increased fiber length and a greasy or pasty consistency. Some cases show firm feces with large particle size.[38,39] Affected animals often continue to drink water, but absorption from the rumen is poor, and the water accumulates in the forestomach while the animal becomes mildly dehydrated. Vigorous contractions of the rumen can be palpated in the left paralumbar fossa in most affected animals, although some display almost complete atony. The contraction pattern does not produce the typical stratification of material in the forestomach, but rather it churns the ruminal contents into a uniform frothy fluid.[39,41]

The signs just described, with abnormal flow of ingesta and normal or increased forestomach contractions, can be experimentally reproduced by sectioning the ventral vagal trunk at the cardia and the dorsal trunk just distal to the branching of the ruminal nerves.[37] The forestomach distention, empty omasum and abomasum, and stasis of the forestomach with resultant free gas bloat can be reproduced by sectioning both abdominal vagal trunks along the esophagus. The paralysis produced by vagal denervation can explain the failure of ingesta flow into the omasum by two mechanisms. First, the lower end of the esophageal groove is formed by two muscular lips. These overlap in a manner that allows a passive valve effect that blocks flow into the omasum when they are relaxed or paralyzed. Second, it appears that the flow into the omasum is accomplished by an active pumping motion of the omasum that reduces pressure and draws fluid through the reticuloomasal orifice. Paralysis of the omasal musculature after denervation would eliminate this effect.

VetBooks.ir

Decreased reticular motility caused by adhesion or paralysis may contribute to the changes in ruminal content and the alteration in particle passage.[39,41]

The most common predisposing cause of naturally occurring omasal transport failure (anterior or proximal functional stenosis) is TRP. Other causes of anterior functional stenosis include abscesses, adhesions, and peritonitis at the reticulum (especially the right side of the reticulum) or reticuloomasal area without identification of an offending foreign body; hepatic abscesses; diffuse peritonitis; neoplasia of the ruminoreticular fold and esophageal groove; inflammatory disease of the reticular and ruminal walls; papilloma or other mass at the reticuloomasal orifice; or herniation of the reticulum through a diaphragmatic defect. Foreign bodies that obstruct the reticuloomasal orifice cause a syndrome indistinguishable from vagal indigestion except by exploratory rumenotomy.[32] To reconcile the experimental findings with those from clinical cases, the development of omasal transport failure has been explained as involvement of the vagal trunks in the inflammatory process at the reticulum. Several findings make this an unlikely explanation in most clinical cases[8,36]:

1. Although sectioning the vagus nerves as described reproduces the syndrome, disturbing only one of the two trunks still allows normal cyclic contractions in most cases. For a clinical lesion to produce disease development, massive involvement of the vagal nerves would be required. By contrast, less than a third of examined cases reported show actual lesions in the nerve branches.
2. The ratio of sensory to motor nerve fibers in the abdominal vagi is approximately 9:1, suggesting the important sensory role of the nerve.
3. Inflammatory lesions of the reticuloruminal wall reported in cases of vagal indigestion are predominantly in the same areas as the important tension receptors that send afferent excitatory impulses to the gastric centers. Induration of the right (medial) wall of the reticulum and in the esophageal groove region may affect intramural nerves and ganglia and reduce the tension receptor activity and therefore the drive for primary cycle activity.

These considerations allow an explanation of some of the inconsistencies found in various cases. Anterior functional stenosis may occur with insufficient vagal sensory excitation, which in turn reduces excitatory input to the gastric centers, diminishes primary cycle motor drive, and results in paralysis of the omasum and reticuloomasal orifice. Alternatively, substantial reticular adhesions that develop after TRP could prevent normal delivery of small particle ingest, with fluid consistency, to the reticuloomasal orifice.[41] Because this reduces or abolishes flow into the omasum, both the omasum and abomasum would remain relatively empty, a common finding in these cases. The hypermotility observed in these cases may be the result of secondary rather than primary cycle contractions.[43] Distention of the cranial ruminal sac would still be able to induce the secondary contractions if this region is not involved in the induration. Without normal primary cycle activity, the typical stratification of the ingesta would be disturbed, as is usually observed. The existence of hypermotile secondary contractions with absence or severe reduction of primary contractions can be detected clinically. Damage to the thoracic or abdominal vagi by inflammatory or neoplastic lesions may lead to the occasional cases that show both anterior functional stenosis and atony of the forestomachs, with resultant free gas bloat. This would be similar to the experimental sectioning of both vagal trunks.

Pyloric Outflow Failure. Failure of pyloric outflow (posterior or distal functional stenosis) causes accumulation of ingesta in the abomasum and omasum. Advanced stages of this form of the syndrome also display gross distention of the reticulorumen. Generally the motility of the forestomach is not markedly affected in the early stages, and normal stratification of ingesta is maintained. Overfilling of the forestomach as a result of reflux of ingesta from the abomasum (internal vomiting) may occur, causing the chloride content of the ruminal fluid to increase (normal is less than 30 mEq/L). In contrast, the ruminal fluid of animals with anterior functional stenosis has a normal chloride content.[38,41] With severe distention forestomach motility is reduced, and the ruminal contents become more fluid.[43] Failure of ingesta to flow into the intestinal tract, combined with sequestration of chloride-rich fluid in the stomach chambers, can cause both marked dehydration and hypochloremic metabolic alkalosis. However, in cases with a gradual, prolonged development such as in anterior stenosis, any dehydration tends to be mild and body fluid electrolyte concentrations do not show remarkable abnormalities. Fecal production in these cases tends to be even less than with the anterior stenosis form of the syndrome.[41]

Failure of pyloric outflow can be experimentally reproduced by sectioning the ventral vagus trunk at the cardia and the continuation of the dorsal trunk as it crosses the omasum.[37] This mimics the usual clinical form of the disease, which is characterized by complete inhibition of flow from the abomasum. Combinations of more distal resections of the nerves produce the syndrome of recurrent atony of the abomasum as it occurs in natural clinical cases. Again, the term stenosis is a misnomer, because a true stenosis or spasm of the pylorus is not identified. Rather, the experimental vagal nerve resection and the naturally occurring cases show a flaccid paralysis, and ingesta accumulates as a result of failure of propulsive activity. The dilation of the abomasum is in the fundus and body and not in the pyloric part.[37]

A common predisposing cause of pyloric outflow failure syndrome is volvulus of the abomasum. Other abomasal disturbances, including right and left displacements of the abomasum and abomasal ulceration, can cause the disease as well. After surgical correction of a volvulus, the abomasum remains atonic, and the disease may develop within several days. Clinical signs compatible with vagal indigestion may arise from gross distention and twisting of the abomasum and lesser omentum resulting in potentially coexisting but distinct injury to the vagal nerves or structural damage to the gastric wall, with or without peritonitis. Although focally extensive vagal nerve lesions have been associated with concomitant vascular damage, indicating that even with nerve regeneration there may not be a return to normal function, the damage appears reparable in some cases as a return to normal function has been observed.[40]

Inflammation and adhesions involving the abomasal fundus and reticulum have been associated with posterior functional stenosis in some studies.[41] Inflammation of the reticular wall may account for the reticular atony reported in some cases. This form of vagal indigestion may be more frequently associated with true vagal nerve impairment than appears to be the case in anterior functional stenosis. Alternatively, reticular adhesions may prevent normal motility, alter the flow of ingesta to the omasum and abomasum, and lead to abnormal filling of the abomasum because of decreased fluidity of abomasal contents.[41]

Another predisposing cause of pyloric outflow failure is advanced pregnancy with a large fetus. An exact pathogenesis has not been clearly defined. Presumably the large, gravid uterus distorts the positioning of the abomasum or physically compresses and obstructs the anterior small bowel, preventing outflow of ingesta from the abomasum. In these patients the gravid horn typically occupies most of the space in the omental sling. In support of these conclusions, the problem can be resolved by inducing delivery of the calf or performing a cesarean section. Supportive care may be required for severely affected cows, but the gastrointestinal system returns to normal function, suggesting that it was secondarily affected by the pregnancy. This problem is referred to as a form of vagal indigestion because it appears as a pyloric outflow failure. Some patients have such severe obstruction of ingesta passage that they may be diagnosed as having an anterior bowel obstruction. This disease has been called *indigestion of late pregnancy*.

Animals affected with any form of vagal indigestion for a prolonged time lose body condition because the failure to pass ingesta into the intestinal tract produces a state of starvation. The weight loss may be overlooked because of the impression of full body size produced by the abdominal distention.

VetBooks.ir

CHRONIC RECURRENT BLOAT. Chronic recurrent bloat is commonly identified with vagal indigestion in any of its forms. It is mild to moderate in severity, commonly waxes and wanes, and adds to the visual impression of gross abdominal distention. The pathogenesis of this ruminal tympany varies from case to case. Experimental resection of both abdominal vagal trunks stops eructation by causing complete forestomach stasis. In naturally occurring cases in which lesions of the vagal nerve truly inhibit motor impulse transmission, bloat may arise from this mechanism. When vagal nerve damage does not appear to be involved, other mechanisms may explain the bloat (see Table 32-13). Overfilling of the reticulorumen with frothy ingesta, a common finding, can inhibit the cardia dilation reflex that is a prerequisite of eructation. Gross distention of the forestomach can also weaken the contractile ability of the rumen, so that the contractions are not strong enough to clear the cardia before eructation.

Bradycardia is often identified in association with vagal indigestion but can also occur with other forestomach diseases. The finding that atropine administration can abolish the bradycardia of vagal indigestion suggests increased cardiac vagal tone as the direct cause. However, the origin of the vagotonia is unclear. When vagal nerve lesions exist distal to the cardiac innervation, reflex excitatory discharges may effect bradycardia. Experimental resection of the vagal nerves causes bradycardia as a striking feature in most cases, although advanced cases show increased heart rates. By contrast, naturally occurring vagal indigestion shows bradycardia as a feature in only a third or fewer of the cases.[38] These variations may exist because the experimental and natural cases have different causes or because the disease varies in duration. Once the forestomach has become severely distended, the heart rate tends to be elevated, probably as a result of deterioration of hydration and cardiovascular parameters.

Obstruction of the Cardia or Reticuloomasal Orifice

True mechanical obstruction of the forestomach is an uncommon occurrence. The obstruction can be either full or partial and occur at either the cardia or the reticuloomasal orifice. The inflammatory and neoplastic conditions described previously can appear to be obstructive disease when the tissues are sufficiently distorted and lesions involve one of these orifices. Papillomas are most prone to causing an obstruction when they become pedunculated. A variety of foreign bodies create obstruction. In calves, trichobezoars are most commonly the cause, occurring predominantly in animals on a low-roughage diet that consequently lick their hair coats vigorously. In adult cows, ingestion of the placenta occasionally results in an obstruction. Curious ruminants, especially goats, sometimes consume plastic bags or discarded rectal palpation sleeves. These and other nondegradable materials can lead to obstruction even after considerable time has passed.

Cardia obstruction leads to the signs typical of esophageal obstruction, with free gas bloat as a prominent, perhaps life-threatening development. Obstruction of the reticuloomasal orifice produces the same consequences as some forms of vagal indigestion. Failure of ingesta flow beyond the rumen results in accumulation of fluid material in the forestomach and diminished or no passage of ingesta through the intestines. The degree and duration of obstruction determine the severity of associated problems such as dehydration, depression, elevated heart rate, forestomach stasis, colic, and muscular weakness. Only rumenotomy can effectively differentiate these obstructive diseases from other problems with similar signs.

Diaphragmatic Hernia

Defects in the diaphragms of cattle are uncommon. Most cases involve a tear through which the reticulum can herniate. Other abdominal organs may also be involved if the rent is large. The diaphragmatic defect may be congenital or an acquired lesion caused by a local inflammatory process (TRP), sudden external trauma (fighting, hanging up on a fence), or internal pressure (parturition, acute tympany).[44] Entrapment of the reticulum may lead to acute changes in intrathoracic pressure and cause sudden dyspnea, tachycardia, and poor venous return to the heart. Generally, however, this reticular problem causes signs identical to those of vagal indigestion with anterior functional stenosis.[1] Failure of flow through the reticuloomasal orifice may result from vagal nerve damage, or the anatomic distortion alone may explain the motility defect. Entrapment of the reticulum hinders normal reticular movements and distorts the esophageal groove and reticuloomasal orifice. Reticular ingesta can be heard moving inside the thorax; therefore complete reticular paralysis is unlikely. Motility disturbance is reflected by hypermotility of the rumen, generation of frothy ingesta, persistent or recurrent moderate tympany, and overfilling of the rumen. Signs of pain may also be present, as in cases of TRP. Rumination usually is impaired, and large volumes of ingesta may be vomited, especially after eating.

Disorders of Reticuloruminal Fermentative Function (see Box 32-5)

Forestomach Microbial Population

The continuous culture system of the rumen involves an ongoing selection of microorganisms best adapted to grow in a variety of ecologic niches that are in a dynamic state. Numerous control mechanisms govern the environment and the resultant microbial population. Some of these mechanisms are related to the animal itself, such as salivation, mixing and rumination, removal of substances by absorption or diffusion, outflow through the reticuloomasal orifice, and eructation. Others are related to the diet, including nutrient quality of the substrate (feed), balance of required elements, solubility, particle size, presence of inhibitory substances, nutrient quantity, and rate of delivery to the rumen. Control of fermentation also results from microbial interactions such as competition and symbiosis: cross-feeding between species, removal of inhibitory end products, and maintenance of the oxidation-reduction potential. The complexity of the system tends to promote an overall stability. Changes in the controlling factors create selective pressures that lead to population changes in the rumen.[3,45]

The rumen contains large numbers of bacteria, ciliated protozoa, anaerobic ruminal fungi, and bacteriophages.[45] Ruminal bacteria are predominantly anaerobes, with some coexisting facultative anaerobes. Although the facultative organisms are not important in normal ruminal function, they may be in some forms of ruminal dysfunction. Some microbes ferment the primary nutrients in the feed such as cellulose, hemicellulose, pectin, starch, and simple sugars. Other species ferment the products of the primary group such as pentoses, glucose, lactate, succinate, and formate. Many species are very specialized and have numerous growth requirements that may be supplied by the general fermentation. The last group is important for its role in removing end products and cycling essential factors back to the other organisms.[3,46,47]

Effects of Feed Characteristics

The concentrations and proportions of the microbial species vary with the composition of the diet (Table 32-14). An abundant supply of a certain substrate tends to favor a microbial population with a predilection or high capacity for using that material. The most important factors in the rate of digestion are the properties of the carbohydrates and protein in the feed. High-protein diets favor proteolytic organisms, whereas high-starch, low-fiber diets favor starch users. Cellulolytic bacteria are prominent in a high-fiber diet, but their numbers also depend on the fiber size as this factor determines the rate of passage or retention in the forestomach; thus, cellulolytic species can be abundant with a high-concentrate diet if some long-stemmed roughage is included because the retention time of the fiber is prolonged. Diets with readily fermentable carbohydrates and low fiber favor species capable of rapid metabolism and tolerant of low pH. Acid production is rapid and high, and populations of microbes less tolerant of such changes decline.[46,48,49]

The microbial population is also influenced by the limits of supply of certain feed substrates.[50] High rates of fermentation and microbial

VetBooks.ir

TABLE 32-14

Effects of Feed Characteristics on Ruminal Digestion and Health

Feed	Rumen Content	Effect on Health
Primary forage of high quality, long fiber length, crude fiber > 18% of dry matter; with concentrate supplement at 20% to 50% of total intake, moderate protein level	pH 5.5-7, VFA 60-120 mmol/L, acetic > propionic > butyric acid	Normal, healthy, productive
Excessive forage of low nutrient value (late cut) with little concentrate or protein supplementation	pH 6.5-7, VFA decreased, microbial activity decreased	Poor production or growth, microfloral inactivity and rumen impaction, malnutrition caused by protein, energy, mineral, and vitamin deficiency
High level of concentrate feeding (>60%) with decreased forage and/or fiber length	pH 5-6.5, VFA increased, microbial activity increased	High production, rapid growth; possible chronic rumen acidosis, milk fat depression, chronic laminitis, ketosis, ruminal parakeratosis, excessively fat condition
Extremely high level of concentrates (especially with sudden exposure to ration), low intake of forage	pH 4-5.5, VFA increased, lactic acid increased	Acute ruminal acidosis
Normal levels of forage intake, concentrate with very high protein or NPN supplementation	pH 6.5-7.5, VFA decreased, ammonia increased	Ruminal alkalosis, possible urea toxicity

NPN, Nonprotein nitrogen; *VFA,* volatile fatty acid.

growth on the abundant substrates depend on sufficient amounts of the more limited nutrients. Optimum carbohydrate use requires adequate sources of nitrogen, sulfur, and essential mineral nutrients.[51] When any essential nutrient is deficient, the rate of digestion and thus the digestibility of the feedstuff decrease. Whether the affected animal shows signs of nutrient deficiency or forestomach dysfunction with microbial and forestomach inactivity depends on the limiting nutrient and relative requirement of the host and bacteria for the nutrient. Substances and conditions that inhibit fermentation further reduce digestibility.

The feed material also affects ruminal fermentation by influencing the rate of passage from the reticulorumen. Fine grinding and pelleting of feed increase the rate of passage of the particulate matter from the rumen. Very finely ground rations also reduce the stratification of fibrous material in the rumen. This affects the ability to sort material in the rumen selectively by particle size and density, so that larger particles less thoroughly fermented pass more readily into the lower bowel. Microbes associated with the feed particles are passed out of the rumen with the feed. Thus a faster rate of passage influences the bacterial population because it competes with the generation time of the organisms. Populations of slower growing microbes tend to be most influenced by changes in the retention or passage times. Slow-growing cellulolytic bacteria decline in numbers as the passage rate increases (transit time decreases). High passage rates usually produce faster digestion rates. Although these factors are primarily important to the feed efficiency of the animal, they also affect ruminal function and the adaptation of microbes to feeding changes.[3]

Adaptation of the microbial flora to dietary changes requires a week or longer. The abruptness of a dietary change determines the degree of alteration of the ruminal microbial population and fermentation pattern and the potential for digestive disturbances. With abrupt and dramatic shifts to higher carbohydrate diets, the facultative species may overwhelm the more normal flora by producing excessive acid and lowering the pH. The importance of microbial adaptation to a particular diet is evidenced by the reduction in forestomach disturbances seen when the rumen is inoculated, before a feeding change, with fluid from animals already adapted to the new ration.[52,53]

The end products of microbial fermentation influence not only the microbial population but also ruminal function. High concentrations of nondissociated volatile fatty acids (VFAs) excite sensory epithelial receptors that reflexly inhibit ruminal motility. If a sudden increase in concentrate feeding induces lactic acid fermentation, the ruminal pH suddenly declines and a greater proportion of the VFAs shift to the nondissociated state, inducing ruminal stasis.[54] A consistently high level of concentrate feeding produces rapid fermentation, a high concentration of VFAs, and low pH, and the nondissociated VFA level may reach the threshold for stimulation of the inhibitory epithelial receptors. The ruminal stasis reduces the fermentation rate. Mild cases of ruminal acidosis may show spontaneous recovery of ruminal functions as the absorption of VFAs reduces the concentrations to a noninhibitory level. With more severe ruminal acidosis the generation of acid continues despite the ruminal stasis, giving rise to more severe complications of the disease.

In some instances the effects of ruminal microbial metabolism and microbial end products extend beyond impacts on nutritional status and digestive system function. Several ruminant diseases represent rumen-generated toxicities. These have extremely variable manifestations and include toxicoses from ammonia, nitrate and nitrite, 3-methylindole, dimethylsulfide (*Brassica* spp., onion toxicity), and sulfur-associated polioencephalomalacia.[55-58]

In summary, excesses, deficiencies, or rapid changes of feed substrate can cause imbalance in the microbial population and the fluid milieu. The result can be bacterial overgrowth and overproduction of microbial end products or insufficient microbial growth and fermentation. The effects of these abnormalities on the animal range from ruminal motility dysfunction, to poor growth and performance, to outright toxicity and organic damage.

Inactivity of Ruminal Microbial Flora (Caused by Poor-Quality Roughage, Haybelly, or Ruminal Impaction)

In ruminal microbial flora inactivity, the microbial populations and their metabolic and fermentative processes are diminished as a result of deficiencies of one or more nutrients. This occurs most commonly with poor-quality roughage deficient in protein and readily digestible carbohydrates (late cut, highly lignified hay or straw). Microfloral inactivity can also occur when specific mineral nutrients are deficient or it can be due to inhibitory substances such as antibiotics or some plant products.[3] Microfloral inactivity also occurs with prolonged anorexia, which abolishes the intake of all nutrients and is the primary pathogenesis of many cases of secondary indigestion.

When microbial digestive processes decline, the breakdown of ingested feedstuffs is prolonged. Failure to reduce the particle size of the ingesta leads to a prolonged retention in the forestomach and gradual accumulation of the undigested feedstuff. Gradual distention of the reticulorumen is commonly observed (haybelly). In extreme cases this can mimic the signs of vagal indigestion. Forestomach distention can result in weak contractions and moderate recurrent tympany. Ruminal hypomotility alters the normal stratification of the ruminal contents, and the fibrous components are found mixed in the fluid or compacted ventrally on the ruminal floor. Abnormal passage of ingesta from the forestomach results in decreased fecal

VetBooks.ir

passage, and the feces usually are dried and contain undigested plant fibers. Other effects on the animal are those of generalized or specific nutrient deficiencies (e.g., decreased growth or production, ketosis, emaciation, and a poor hair coat). When anorexia is the cause of the microbial inactivity, the ruminal fill decreases and the lack of normal distention also induces ruminal stasis.[1]

Simple Indigestion

Simple indigestion is the most common sequela of an abrupt change in the ration. Such feed changes present the ruminal microflora with nutrient substrates (1) to which they are not metabolically adapted, (2) to which they are adapted but in lesser quantities, or (3) that contain inhibitory substances or produce inhibitory substances on fermentation. The result is an imbalance in the microflora and its fermentation products. The difference between this problem and some of the other fermentation disorders is mostly a matter of degree. Generally the disease is relatively mild and self-limiting. Most affected animals show anorexia for 1 to 2 days, break with diarrhea in about 24 hours, and return to feed without treatment when the ruminal fermentation has stabilized and inhibitory substances have been eliminated. Ruminal motility is reduced but usually not absent, the filling of the rumen is not remarkably altered, and if bloat occurs, it is mild. In some cases the ruminal fluid pH may change, but usually not dramatically. Mild acidosis or alkalosis of the ruminal fluid may develop, depending on the nature of the causative feedstuff and its resultant fermentative degradation. Signs of ruminal microfloral inactivity are common. Simple indigestion is an acute problem, in contrast to the microfloral inactivity discussed in the previous paragraphs, in which deficiencies produce microfloral inactivity over time.

Feeds commonly implicated as causes of simple indigestion include moldy or overheated feeds, frosted forages, and partly fermented, spoiled, or sour silages. This form of indigestion also occurs in animals fed high-quality feed, usually after an increase in the rate of feeding or after a change of one of the feed constituents. Thus these mild forms of indigestion can range from a mild acidosis, to an excess of VFAs, to the generation of some bacterial inhibitory products. Because the rumen and its fermentative bacteria are very adaptable, the ways, if any, in which animals given a certain feed experience the problem vary considerably. Often only one or several animals from a group on the ration may have signs.

Acute Ruminal Lactic Acidosis (Grain Overload, Toxic Indigestion)

Acute ruminal acidosis is the most dramatic of the forms of ruminal microbial fermentative disorders and in some cases is lethal in less than 24 hours. It has also received the most research attention; therefore the events in its pathogenesis are more clearly defined than those of the other forestomach disorders. The condition has been named *lactic acidosis, acute ruminal impaction, ruminal overload, acid indigestion, toxic indigestion, grain engorgement, grain overload*, and *D-lactic acidosis*.

This problem is the result of excessive consumption of readily fermentable carbohydrates, which causes a rapid fermentation with production of lactic acid and a decrease in ruminal pH to physiologically inappropriate levels. This occurs when animals consume an excess of concentrate feeds (e.g., if animals are suddenly exposed to the feeds without prior adaptation; if animals already on such feeds suddenly consume an excessive quantity because of accidental access; or if animals that have been off feed return to feed and are offered unrestricted access to concentrates). The problem is more common when animals are grouped than when they are separate, probably because the psychology of competition induces them to overconsume. In general the feeds involved include the cereal grains commonly used in high-production rations and fruit and root crops (e.g., feed beets, sugar beets, potatoes) where they are available. Starch and soluble sugars promote an overgrowth of bacteria that produce glucose and organic acids. The acid end products increase ruminal acidity and osmolality, inhibit or destroy other ruminal microbes, and cause forestomach dysfunction and metabolic disturbances.[54,59-61]

Specific characteristics of the feedstuffs contribute to acidification of the ruminal fluid. Cereal grains inherently possess less buffering capacity than the fibrous forages. Low structured fiber content and decreased forage particle size induce less salivation at the time of ingestion and less rumination subsequently; therefore salivary buffering declines when concentrate feeds are consumed. Some silages contain both high carbohydrate and lactic acid and thus introduce more acid at both ingestion and fermentation.[33,60,62]

Feeding regimens that include significant fibrous roughage limit carbohydrate availability and rates of microbial fermentation and growth. Carbohydrate fermentation efficiency relative to the amount of adenosine triphosphate (ATP) derived from each sugar provides competitive survival value. Slower growing cellulolytic bacteria use substrate most efficiently. When starch or sugar is available in excess, the faster growing species such as *Streptococcus bovis* metabolize carbohydrate faster and produce more ATP per unit time, even though they are less efficient in ATP production per carbohydrate molecule. Under these conditions they can overgrow, producing lactic acid as their end product.[60]

The severity of ruminal acidosis and disease signs vary considerably, depending on the amount and type of carbohydrate-rich feed consumed and the degree of prior ruminal microbial adaptation to the carbohydrate substrate. The disease can range from a mild form of indigestion to an overwhelming toxemia that may be difficult to distinguish from other acute toxicities or various diseases with endotoxemia.

If consumption of fermentable carbohydrate is only mildly excessive, *S. bovis* proliferation decreases when the carbohydrate has been fermented, pH rises toward normal, and the efficient fermenters reestablish dominance. If the carbohydrate source is abundant and its supply is not exhausted, the acidosis becomes more severe. Continued production of lactate by *S. bovis* reduces the fluid pH to the range of 5 to 5.5, and the ruminal fluid osmolality rises concurrently. Both these factors inhibit or kill the ruminal protozoa, which normally use starch and small sugars and help to limit increasing lactic acid levels. There are also numerous species of lactate-using bacteria, of which *Megasphaera elsdenii* and *Selenomonas ruminantium* are the primary examples. These bacteria, which increase in numbers when animals slowly adapt to a high-concentrate diet, are eliminated by abrupt changes and generation of excessive acid; therefore lactate use decreases when the acid is generated too quickly.[52,60]

The lactobacilli are the major group of lactic acid producers in the rumen. The increasing acidity of the fluid enhances the growth of these organisms. Because the lactate-using bacteria are killed off before the lactobacilli overgrow, their diverse end products are unavailable as substrate for other bacteria. The lactobacilli are left as the predominant organisms to use the available carbohydrates. Even the *S. bovis* organisms that began the lactic acid production are inhibited below pH 4.5, leaving the lactobacilli, as the most acid-resistant species, to generate more lactic acid.[54,63]

The acidification of the fluid milieu enhances the lactic acid production by altering microbial metabolism.[60] The loss of the fluid bicarbonate buffer and the increase in available hydrogen ions block the conversion of lactate to propionate even before the lactate users die off. Also, when the pH is above 5 but declining, ruminal fluid amylase activity increases and liberates more free glucose from starch. However, glucose use is reduced, and ruminal glucose accumulates. Apparently the lactate-using bacteria such as *S. ruminantium* degrade less lactate to acetate in the presence of increased glucose concentrations. Thus not only does the microbial population change, but the characteristics of the fluid accelerate the lactic acid production when the available carbohydrate is excessive.

The effects on the animal from the ruminal fluid changes are numerous and detrimental. In the early stages of the acidic fermentation, the VFAs are produced in abundance. Although VFA production decreases as the microbes are increasingly inhibited, VFA concentrations remain elevated in advanced acidosis. The VFAs are

VetBooks.ir

much weaker acids than lactic acid; thus, as pH drops they accept hydrogen from lactic acid and serve as buffers in the fluid, so that a greater proportion of the VFAs exist in the nondissociated state. This form is more readily absorbable than free ions through the ruminal wall. During absorption some VFAs undergo metabolism by the ruminal wall epithelium, resulting in the release of lactate and ketone bodies into the circulation. Excessive absorption of the volatile fatty acids leads to systemic acidosis, and circulating lactate and VFAs may also directly damage the liver. In addition, the high concentration of nondissociated VFAs at the ruminal epithelium provides a strong inhibitory effect on reticuloruminal motility and leads to ruminal stasis. This effect tends to protect the animal, because it reduces the absorption of detrimental fermentation products from the rumen.[55-58,60,61]

The osmotic pressure of the ruminal fluid increases as lactic acidosis develops.[33,60,61] In a normal animal, ruminal osmolality remains relatively constant at approximately 280 mOsm/L, but osmolality may double in some cases of acute acidosis. Lactic acid accounts for a major fraction of the increase, but some of the components of this change remain unidentified. The increased osmolality inhibits and kills some of the microflora and draws fluid into the rumen, mostly from the extracellular compartment. This accounts for the increased ruminal fluid volume, ruminal distention, and severe dehydration observed clinically. The loss of circulating fluid volume leads to circulatory impairment, decreased renal blood flow and glomerular filtration, and in some cases eventual anuria. Poor peripheral circulation results in hypoxic metabolism and contributes to systemic acidosis.

Although it has been assumed that the systemic acidosis that develops with this disease is attributable to ruminal lactic acid absorption, such absorption does not appear to occur readily.[60] Lactate is absorbed from the rumen at a much slower rate than are the volatile fatty acids because it is highly ionized at a pH near physiologic normal, which tends to inhibit absorption. At lower pH the rumen becomes static, thereby also inhibiting absorption. The hypertonicity of the ruminal fluid further limits absorption of lactate and other substances.[59] It appears that the peak entry of lactate into the circulation occurs in the early phases of the disease. Some lactate may be absorbed from the intestinal tract from fluid passed before the onset of complete stasis. Many experimental trials do not show the development of severe systemic acidosis in the early phase of the disease. It may be that a large component of the later severe systemic acidosis is attributable to circulatory insufficiency rather than to absorption of lactic acid.

Some absorption of the lactic acid does occur, however, as evidenced by the appearance of D-lactic acid in the circulation. Microbes produce both the L- and D-form of lactic acid, whereas animal tissues produce only L-lactic acid.[54] The animals' pathways for metabolism of D-lactic acid are not as efficient as those for L-lactic acid; therefore absorption of both forms leads to an accumulation of predominantly D-lactate in the animal's system. The lactate is eliminated by oxidation, gluconeogenesis, and renal excretion. The animal's hydration status, liver and muscle metabolism, and renal function determine how readily it can eliminate excess lactate. Animals that survive ruminal acidosis often have metabolic alkalosis after the acidotic phase, as a result of lactate metabolism and production of bicarbonate.

Lactic acid is a strong corrosive agent that can destroy the ruminal epithelium, giving rise to the name *toxic rumenitis*. The increased ruminal fluid osmolality also damages the epithelium as extracellular water influx across the epithelium occurs in response to osmotic pressure imbalance and disturbed Na transport.[59] The effects of epithelial destruction can be far-reaching, because the damage persists after resolution of the acute acidosis.[33,64] Some yeast and fungi that are resistant to the high acidity readily colonize the damaged sites, invade the vasculature, and cause thrombosis or spread to the liver and other organs.[30] Ruminal acidosis is considered one of the primary causes of mycotic rumenitis (discussed earlier under Reticulitis and Rumenitis) and mycotic omasitis, although other predisposing causes have been identified.[30,31] Bacterial rumenitis can also result from the chemical damage and may lead to abscess formation, diffuse cellulitis, or perforation and peritonitis. If the animal survives the acute acidosis, it may succumb to secondary ruminal damage.[30] Alternatively, the rumen may heal uneventfully, leaving scars in the ruminal wall, but bacterial access to the circulation through these chemical lesions can result in hepatic abscessation, a common problem of animals fed high-concentrate rations.[65,66]

In addition to lactic acid, several toxic factors have been implicated in acute ruminal acidosis.[54,60] The altered metabolism of the ruminal microflora has been shown to generate increased quantities of histamine, ethanol, methanol, tyramine, and tryptamine. These may play a role in the pathogenesis of the disease, but conclusive evidence is lacking. Histamine has been implicated as an agent in the development of laminitis that sometimes accompanies ruminal acidosis. However, histamine is poorly absorbed from the rumen, especially at diminished pH levels. The destruction of ruminal gram-negative bacteria has been suggested to release large quantities of endotoxin for absorption through damaged mucosal surfaces. Endotoxin would contribute to most of the signs of the disease such as ruminal stasis, poor tissue perfusion with cardiovascular deterioration, weakness, and depression. Increased ruminal and blood concentrations of endotoxin and increased blood arachidonic acid metabolites have been found in cattle with experimentally induced ruminal acidosis, but their importance in naturally occurring disease is not clear.[67-70] With liver impairment or ruminal wall damage, toxin absorption and clearance are likely to be altered. Premature delivery and retained placenta may occur in pregnant animals after acute ruminal acidosis, possibly resulting from the effects of these circulatory toxins and metabolites.[71]

Subacute Ruminal Acidosis

Like acute ruminal acidosis, subacute ruminal acidosis (SARA) is caused by feeding of excessive quantities of concentrate with low levels of well-structured fibrous roughage; however, SARA results from continued ingestion of these feeds over a prolonged period rather than sudden exposure without adequate adaptation. Beef feedlot cattle may be chronically exposed to a ruminal pH between 5.0 and 5.5 from the start of the feeding period until slaughter. Dairy cattle are more likely limited to short periods of low ruminal pH typically between calving and approximately 5 months postpartum.[72,73] In early lactation dairy cattle may be exposed to energy-dense rations too rapidly, whereas the high feed intake of cows in mid-lactation makes them particularly susceptible to sudden ration changes or faults in feed delivery or composition.[74] The ruminal microbial population adapts to a high grain ration, and large numbers of lactate-using and lactate-producing organisms are found. The proportion of cellulolytic bacteria decreases, whereas the starch- and glucose-fermenting species proliferate. The overall effect of the adaptation is development of a microbial population that rapidly ferments the ingested feedstuffs. Lactic acid does not accumulate because it is further metabolized by the bacteria. The increased rate of fermentation instead produces high concentrations of VFAs and results in moderately acidic ruminal fluid with pH values usually ranging from 5 to 5.5,[75] although pH values between 5.5 and 5.8 may suggest cows at risk of SARA.[74] Ruminal buffering of the increased acid load is impaired because the fine particle size of the high-energy rations induces less chewing and less saliva production. As the name implies, the effects on the animal are chronic and insidious.

Along with the high concentration of volatile fatty acids and the low pH, a shift occurs in the proportions of the VFAs in the ruminal fluid. The proportions of butyric and propionic acids increase, and acetate decreases. Butyric and propionic acids stimulate proliferation of the ruminal papillae epithelium. When this process is exaggerated, it can progress to parakeratosis. The ruminal papillae develop an excessively keratinized epithelium and clump together. The parakeratotic changes are associated with decreased absorption of the volatile fatty acids and increased susceptibility to trauma and inflammation.[64] Epithelial damage and the acidic nature of the ingesta appear to be

VetBooks.ir

responsible for inflammation of the deeper tissues of the ruminal wall in some cases. The ruminal wall lesions allow penetration by bacteria with dissemination to the liver. This commonly results in liver abscessation in affected animals. Liver abscesses usually have no pathognomonic signs. Affected animals tend to show reduced productivity and may have signs of a chronic inflammatory response.[33,57,65,72,74,76]

The diagnosis of SARA is made on a herd level rather than on an individual cow basis. Cattle afflicted with SARA may demonstrate numerous clinical signs including reduced appetite and ruminal hypomotility.[73] High ruminal VFA concentrations can inhibit ruminal motility by stimulating the inhibitory receptors in the epithelium. The finely ground ingesta also induces less active ruminal motility because it lacks the physical bulk of high-roughage diets that stimulate strong and sustained contractions. Although the bacterial population is metabolically very active, the number of species of bacteria is reduced.[77] Likewise the protozoal population is inhibited when the pH remains in the lower end of this range. The microfloral environment is less stable when fewer species are present and is thus more susceptible to sudden changes in the diet.

A continual high acid load may also reduce metabolic efficiency and overall animal performance. High-concentrate diets have been associated with poor use of dietary protein.[46] Other pathologic conditions have been attributed to SARA, including chronic laminitis[78] and cerebrocortical necrosis. These conditions may be induced by some of the toxic by-products of acidic ruminal fermentation, such as endotoxins and hydrogen sulfide.[57,58,67-70,76]

Ruminal Alkalosis

An alkaline ruminal fluid pH occurs most commonly when microbial fermentation is reduced while the animal continues to ingest saliva. A ruminal fluid pH between 7 and 7.5 is found with prolonged anorexia, microfloral inactivity caused by poorly digestible roughage, and some cases of simple indigestion. The low rate of fermentation does not generate enough acid to neutralize the alkaline pH of the saliva. In addition, the absorption of VFAs through the ruminal epithelium proceeds with the generation of bicarbonate in the ruminal fluid. Acetate absorption is associated with greater generation of bicarbonate than is absorption of the other VFAs, and acetate is the predominant VFA produced during fermentation of roughage. Although the fermentation rate is low, the VFA absorption contributes to the ruminal alkalinity. Ruminal alkalosis occurring with these diseases is not the primary problem; therefore, these entities are discussed separately.

Ruminal alkalosis can occur with the generation of excessive ammonia. Ammonia concentrations rise when high-protein diets are fermented. The pH usually does not increase above neutral because these diets also contain sufficient readily fermentable carbohydrate to maintain a slightly acidic pH.

More dramatic elevations in the ammonia concentration, with a ruminal fluid pH above 7.5, occur with overfeeding of nonprotein nitrogen sources such as urea, biuret, and ammonium phosphate (see Chapter 54). Accidental ingestion of some common fertilizers that contain ammonium salts can produce the same results. For the purpose of this discussion, it is important to realize that some of the signs of urea poisoning involve ruminal dysfunction. Severe cases of urea poisoning result in generalized signs such as muscle tremors, incoordination, weakness, tachypnea, and central nervous system excitation, and affected animals die quickly. Signs of forestomach dysfunction such as ruminal hypomotility, bloat, vomiting, and abdominal pain are also present. In milder cases, diminished appetite, ruminal hypomotility, recurrent tympany, and diarrhea may be the most prominent signs, along with muscular weakness and incoordination. Thus the disease may appear as a form of forestomach disease. The ruminal fluid shows an alkaline pH between 7.5 and 8.5 and has a strong odor of ammonia.[55]

Putrefaction of Ruminal Ingesta

Putrefaction of ruminal ingesta infrequently results from overgrowth of a microflora that decomposes feed material in a putrefactive manner. The existence of a high ruminal fluid pH, such as occurs with high-protein feeds, and repeated inoculation with abnormal bacteria allow the development of the putrefactive decomposition. Fermented feeds undergoing spoilage, feed and water contaminated with feces, and spoiling, contaminated concentrates supply the offending microflora, which includes the coliform group and *Proteus* spp.[1] This type of abnormal decomposition is normally inhibited by the existence of an active physiologic microflora. Thus most cattle are remarkably resistant to aberrant digestive patterns even when spoiled feeds are ingested. Cattle affected with this form of indigestion typically follow a chronic course of disease. Ruminal motility declines, appetite is poor, and recurrent tympany develops, sometimes with the generation of frothy ruminal contents. The ruminal fluid characteristically has a blackish green color, a foul, putrefactive odor, poor protozoal and bacterial activity, and a pH in the neutral to alkaline range of 7 to 8.5. The cause of the forestomach hypomotility may be inhibitory products generated by the abnormal fermentation. In cases of prolonged duration, animals lose weight and display a poor hair coat, probably as a result of dietary deficiencies in the abnormal fermentation products.

Forestomach Diseases of Calves

Normal forestomach development and diseases of the forestomachs of calves have been reviewed.[3,79] The newborn ruminant has the same anatomic division of the stomach into four compartments as the adult ruminant. The abomasum is functional as a secretory digestive organ, like the stomach of monogastrics, and has a capacity approximately twice that of the other compartments. The remaining stomach compartments are small and do not perform digestive functions in the first days of neonatal life. The reticulorumen may not develop an adult-type function until 4 months of age or older and does not completely develop proportional dimensions similar to those of the adult until 9 to 12 months of age.[1-3,79,80]

The preruminant calf has been viewed as a functionally monogastric animal, and little importance has been assessed to diseases of the forestomachs. Under most management conditions, however, the forestomachs have begun to develop their digestive function within the first week or two after birth. During the development process the calf's forestomach is susceptible to problems different from those of the adult. After the rumen has developed a functional status similar to that of the adult, it is susceptible to the diseases discussed previously. Typically the feeding management of maturing young stock includes pasture or a mainly forage diet and does not predispose to digestive disturbance.

Esophageal (Reticular) Groove Function

Liquid feed bypasses the reticulorumen in the young ruminant, flowing directly into the abomasum through the esophageal groove. The groove consists of two lips that extend from the cardia to the reticuloomasal orifice. These lips close together, forming a tube to shunt liquid material to the abomasum when the soluble proteins and salts of milk stimulate a reflex through the glossopharyngeal nerve. Other salt solutions and even water can stimulate the reflex in very young animals, but the reflex weakens with age, especially after weaning. The response to stimuli varies among individuals, but generally milk produces the strongest response and plain water the weakest. Both nipple and bucket feeding stimulate closure in very young calves, but beyond 12 weeks of age closure is weak unless stimulated by nipple feeding. In older, weaned animals the reflex can be stimulated weakly for short durations by orally administered strong solutions such as copper sulfate or sodium salts. Intravenous vasopressin can induce more profound closure of the groove and has been advocated to aid ruminal bypass of orally administered treatment.

Milk replacers that contain nonmilk protein appear to stimulate a weaker closure of the esophageal groove than do whole milk or milk replacers containing real milk protein. Likewise unpalatable fluids and spoiled milk do not seem to induce normal closure of the groove.

VetBooks.ir

Even in healthy calves that consume unspoiled whole milk, some overflow into the forestomach may occur. Failure of esophageal groove closure allows these fluids to pass into the rumen rather than bypassing it. Milk or other fluid administered through a stomach tube or esophageal feeder does not contact the pharynx; therefore, the reflex closure is not stimulated and the fluid deposits in the forestomachs. Under normal conditions fluid in the forestomach of neonatal calves less than 2 weeks old overflows into the abomasum when more than 400 mL has accumulated.

Reticuloruminal Milk Accumulation (Ruminal Drinking)

Milk can gain access to the reticulorumen by several means. Failure of esophageal groove closure, just discussed, is one possibility. In addition, if calves are maintained as preruminants for longer than 3 to 4 months, groove closure weakens and may allow greater escape of fluid to the reticulorumen. Fluid can also accumulate in the forestomach from abomasal reflux (Fig. 32-120). Overfeeding fluids beyond the capacity of the abomasum (about 2 L in the newborn, 35-kg calf) promotes backflow into the reticulorumen. Certain fluids affect abomasal motility and emptying times, prolonging their retention in the organ. These include acidic and hypertonic fluids and severely heat-treated skim milk powder. Nonmilk protein does not curd in the abomasum, as does casein, when it contacts the abomasal enzyme renin. Prolonged fluid retention and failure of curd formation in the abomasum may promote backflow into the rumen, especially when more fluid feed is consumed. Abomasal inflammation or ulceration may also inhibit normal emptying and promote abomasal reflux.

Some amount of milk reflux from the abomasum appears to be a physiologically normal occurrence. In fact, this route supplies some of the inoculum for ruminal microfloral development and strongly influences the species distribution of the microbial population. But prolonged, repeated, or excessive retention of milk in the forestomach can lead to the development of abnormal fermentation patterns. Although amounts of fluid greater than 400 mL do not normally accumulate in the forestomach of the neonate, more fluid can accumulate when the abomasum is already filled and when ruminal size has increased during the development process. In some cases milk flow into the rumen accumulates significantly over prolonged periods.

The predominant organisms comprising the forestomach microflora of the 1- to 4-week-old ruminant are the coliforms and lactobacilli. These lactose-fermenting, facultative anaerobes tend to maintain the ruminal pH in the acidic range before the adult-type, anaerobic, cellulolytic flora becomes established. The high fat and protein content of milk in the rumen can predispose to a flora that decomposes these constituents and produces spoiled and rancid ruminal ingesta. Problems associated with ruminal milk accumulation are compounded when the milk or other fluid ingested is already contaminated or spoiled. The abnormal microflora established under these circumstances does not supply the young animal with the necessary digestive end products, and signs of dietary insufficiency develop. Affected animals fail to grow normally, show a poor hair coat potentially with widespread alopecia, and may have a depraved appetite. The stimuli for normal forestomach development are also deficient; affected animals have a potbellied appearance, and the rumen is distended with fluid and clots of milk. Ruminal motility is poor, and recurrent bloat is a common sequela. The ruminal fluid pH may be alkaline as a result of the proteolytic formation of ammonia, but in most cases the ruminal pH is acidic (below 6) due to an accumulation of volatile fatty acids and lactic acid from bacterial fermentation, and the fluid has a putrid, foul odor.[81] An enteric imbalance also seems to occur, and the feces are commonly pasty or fluid in consistency. Ruminal "drinking" appears to compound problems in calves with infectious enteritis and diarrhea, and affected calves frequently develop systemic acid-base and fluid balance disturbances.[82,83]

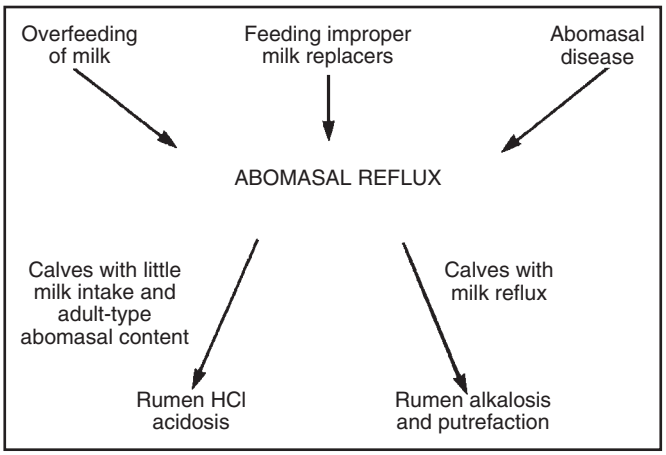

FIG. 32-120 Abomasal reflux in calves.

Problems in Ruminal Development

The age at which the calf has reticuloruminal digestion depends largely on its diet. A plentiful supply of milk delays the time until the calf consumes significant quantities of dry feed. Veal calves maintained without access to solid feed do not have forestomach development. The nervous reflexes that drive ruminal motility, eructation, and regurgitation are already functional before birth, awaiting only the drive of normal stimuli to begin operating. Dry feeds pass into the rumen, and bacterial inoculation from the environment or from abomasal reflux stimulates fermentation to begin. This process can be initiated as early as 1 week of age when calves are encouraged to consume dry feeds.[84]

The increase in the size of the forestomach results from the bulk effect of ingestion of bulky, fibrous feeds.[85,86] Mild distention stimulates ruminal motility and the development of the muscular wall. Mucosal development is stimulated by the presence of volatile fatty acids in the ruminal fluid, resulting from microbial fermentation. Butyrate and propionate are most effective in this regard, whereas acetate is less stimulatory. The thickness of the mucosa increases with proliferation of the ruminal epithelium and elongation of the papillae.[34] These changes serve to increase the ability of the mucosa to absorb the VFAs. Dietary excesses or deficiencies affect the developing rumen by altering the balance of these stimuli.

Calves fed concentrate diets to the exclusion of forages or mixed diets with the hay pelleted or finely ground may experience ruminal parakeratosis as a result of a lack of feed abrasion[87,88] and the excessive production of the stimulatory VFAs: butyrate and propionate.[34] These calves can have a form of chronic ruminal acidosis that results in a reduced growth rate and poor body condition. Ruminal contents are typically fluid with an acidic pH, ruminal hypomotility occurs, and recurrent free gas bloat is common. Affected calves often display a craving for fibrous materials. Hair coat licking is common in these individuals, and hairball formation in the reticulorumen is a common sequela. The hairballs may not be deleterious, but occasionally they cause obstructive disease or abrade the parakeratotic papillae or the abomasal mucosa, predisposing to ulcers and inflammatory lesions. Acute ruminal acidosis is not typically recognized in the young, developing ruminant, probably because feed consumption is limited and because the predisposing adult-type ruminal microflora has not yet developed.

An opposite extreme can occur when the young calf is fed dry forage to the exclusion of more readily digestible carbohydrates. Concentrates and grass contain soluble carbohydrates and are well digested by the developing ruminant. Hays contain much less soluble carbohydrate and an abundance of the structured, slowly digestible forms. These substances are not as well digested by calves because the appropriate cellulolytic microflora is not fully developed. With moderate hay intake and the supply of other sources of nutrition, problems are rarely encountered. When dry roughage is the only available

VetBooks.ir

feed, especially when the hay is of poor quality, adequate breakdown of the fiber is prolonged. The low availability of nutrient substrate that results from delayed digestion of the structured carbohydrates decreases microbial proliferation and fermentation. Inadequate fermentation of the feedstuff deprives the animal of required nutrients as well and results in poor performance and growth. When the only available feed source is the hay ration, the calf continues to consume while the long undigested fiber accumulates in the rumen. The rumen continues to expand as a result of the increased filling, eventually becoming grossly distended. Recurrent bloat is common in these animals because of the overfilling and poor ruminal contractility. This phenomenon is a frequent occurrence under some management conditions and has commonly been called "haybelly." Affected animals display a typical abdominal contour, with gross distention of the abdominal wall that is more prominent on the left side. The ruminal contents are very firm, the fluid has a pH around neutral and shows little microbial activity or odor, ruminal motility is poor, and despite the full abdomen, the animal is thin. This form of microfloral inactivity is more common in calves than in adults because the young ruminant is less able to ferment fibrous roughage.[1,2]

Recurrent Bloat (Ruminal Tympany)

Moderate gas distention of the rumen is a common sign of disease in calves, usually as a result of free gas accumulation, whereas frothy fermentation is very uncommon in the young ruminant. The pathogenesis of free gas bloat has been discussed, and the same principles hold for the young ruminant. The differences between free gas bloat in the adult and in the young calf are more a matter of chronicity and frequency of occurrence than cause. Digestive disturbances of the adult rumen tend to develop more rapidly and are more readily identified than those of the calf. Because of the involvement of ruminal developmental processes in the pathogenesis of calf indigestion, in young ruminants the diseases are often more chronic than acute in nature. In most cases the calf continues to consume feed, and the abnormal ruminal function and development may be easily overlooked.

Ruminal tympany seems to accompany indigestion in calves more often than in adult cattle and also assumes a more prominent appearance in calves than adults. These factors may be reflections of the juvenile anatomy and the incomplete development of adult function. It is worth noting, for instance, that although left-sided abomasal displacement is an uncommon occurrence in young calves, it almost invariably is accompanied by marked ruminal tympany. In contrast, the disease is common in adult cattle, but ruminal tympany is an infrequent sign of the disease.

Purulent lung infections appear to be a common cause of bloat in calves, probably as a result of intrathoracic compression or irritation of the esophagus or possibly the vagal nerves. However, other causes of bloat that are associated with abnormal ruminal function are also common in calves with indigestion. They include overdistention of the rumen, insufficient clearing of the cardia, and inhibition of motility by abnormal fermentation products. Thus a thorough examination is required to determine the underlying cause of the individual case.

Abomasal dilation and tympany in calves (acute bloat syndrome) is often associated with forestomach distention as well. Although the exact pathogenesis is unknown and appears multifactorial, large amounts of fermentable carbohydrate in the abomasum along with fermentative enzymes likely lead to gas production and bloat.[89-91] This syndrome is discussed in detail elsewhere (see Chapter 20). One presumed cause of bloat in calves that is not a cause of adult bloat is sudden filling of the abomasum by milk feeding during weaning. Calves not yet completely converted to a diet of solid feed still consume milk eagerly. In some cases acute free gas bloat occurs immediately after the milk feeding. Because the esophageal groove directs the milk into the abomasum but the abomasum is already partly filled by ingesta from the developing rumen, acute overdistention of the organ can occur and reflexly inhibit forestomach motility. Feeding smaller milk meals or discontinuing the milk feeding resolves the problem in these cases, lending support to the presumed cause.

Clinical Signs and Differential Diagnosis of Indigestion (Table 32-15)

GENERAL SIGNS. A general physical examination allows the practitioner to recognize signs of reticuloruminal problems and to assess whether a disease that could induce reticuloruminal dysfunction as a secondary phenomenon is present. General signs common to all forms of indigestion include a reduction or absence of appetite, dullness or depression, and decreased animal productivity. The most common signs of ruminal dysfunction are a decrease, absence, or abnormality of ruminal contraction sounds in the left paralumbar

TABLE 32-15

Clinical Signs Typically Associated with Primary Indigestions

Signs	Associated Problems
Fever	Traumatic reticuloperitonitis, reticuloruminitis
Decreased ruminal filling	Fermentative indigestions and secondary indigestions (especially with chronic anorexia) in which passage of material from the rumen is not impeded
Abdominal distention	See Fig. 32-119
Excessive fluid (or froth) in the rumen with loss of normal ingesta stratification	Acute ruminal acidosis, vagal indigestion, frothy bloat, anterior intestinal obstruction
Excessive firm, fibrous material in rumen	Ruminal inactivity caused by poor-quality roughage
Firm, doughy ingesta in ventral rumen with decreased ruminal filling	Prolonged ruminal stasis caused by chronic disease with anorexia
Ruminal hypermotility	Early cases of frothy bloat, some cases of vagal indigestion
Abdominal pain present or can be elicited	Traumatic reticuloperitonitis, abomasal ulceration, reticuloruminitis
Abnormal feces	Traumatic reticuloperitonitis, omasal transport failure, ruminal inactivity with poor-quality roughage, also dental disease and some abomasal disease
Decreased quantity, firm, dry, with increased fiber length	Acute or chronic ruminal acidosis
Feces with abnormal amounts of whole cereal grains	Pyloric outflow failure, abomasal displacement
Greasy consistency with very fine particle size	Acute ruminal acidosis
Foamy, fluid, yellowish color, acidic odor	Fermentative indigestions, enteritis
Pasty to fluid consistency with foul odor	Anorexia (various causes), acute indigestions before later developing abnormalities
Decreased quantity, dry, otherwise unremarkable	Ruminal overdistention with vagal indigestion, inflammation of reticulorumen, reticuloomasal orifice obstruction, diaphragmatic hernia, some intoxications (differentiate from esophageal disease)
Vomiting (rare)	

VetBooks.ir

TABLE 32-16

Differentiation of Types of Bloat through Nasogastric Intubation

Results of Intubation	Probable Causes of Bloat
Tube does not pass	Esophageal obstruction
Tube passes with resistance and releases ruminal gas	Esophageal compression caused by thoracic inflammatory or neoplastic disease
Tube passes easily and releases ruminal gas	Distortion of the cardia caused by inflammation, neoplasia, or abnormal anatomy such as abomasal displacement
	Ruminal stasis caused by reticuloruminal fermentative disorder, hypocalcemia
	Obstruction of cardia with ingesta (overfilling of rumen) or pedunculated mass
	Rumenitis (reticulitis)
	Weakened ruminal contraction caused by chronic overdistention with ingesta (vagal indigestion, indigestion with poorly digestible forage)
Tube passes easily but does not release gas or releases small amount of foamy ingesta	Frothy bloat
	Frothy ruminal contents caused by abnormal motility in some forms of vagal indigestion

fossa or an abnormal left-sided abdominal contour. The left abdominal wall may show gauntness and decreased filling or display gross distention. It is often the failure to detect signs of another primary disease as the cause of ruminal dysfunction that directs attention to the forestomach as the possible primary site of disease. Indigestion in calves effectively produces a state of malnutrition, and additional signs in these growing animals include poor growth rate and long, rough hair coat. The acuteness of onset and the severity of these signs depend on the inciting cause of the indigestion. Specific abnormalities in the ruminal motility pattern are discussed in more detail, but most indigestions are marked by decreased or absent ruminations (regurgitation and cud chewing) and depressed ruminal contractions. Only early cases of frothy bloat and some cases of vagal indigestion display increased ruminal motility.

Body temperature usually is within normal limits because the causes of indigestion are mainly physiologic abnormalities. Exceptions include TRP and occasional cases of rumenitis with significant inflammation. Disturbances of heart rate, respiratory rate, and body fluid vary tremendously among different forms of indigestion and different cases of any one form of indigestion. For example, an acute onset of severe ruminal bloat can produce severe embarrassment of the cardiovascular and respiratory systems, whereas mild or chronic bloat may produce no remarkable change in these systems. Rapid accumulation of fluid in the forestomach chamber in severe ruminal acidosis with grain overload can induce severe dehydration, systemic acidosis, and increased heart and respiratory rates, whereas slow fluid sequestration in some cases of vagal indigestion may not induce marked changes in these parameters.

The anamnesis is important, especially with regard to the animal's feeding. Characteristics of the feed determine the type of fermentation pattern to be expected. Knowledge of the nutrient content thus allows an assessment of the biochemistry of microbial digestion. Consumption of a high-concentrate, low-fiber ration or legume pasture may lead to frothy bloat. A ration of poor-quality hay or straw may result in low microbial fermentative activity and accumulation of impacted indigestible roughage. Overeating of carbohydrates or sudden access to concentrate feeds without adequate adaptation time can induce chronic or acute ruminal acidosis. The feeding history should agree with the findings from inspection of the ruminal contents, or the history should be suspected to be inaccurate. The amount and consistency of the feces should also provide supportive evidence of the type and amount of feed intake.

ABDOMINAL CONTOURS AND ANIMAL STANCE (see Fig. 32-119)**.** Visual inspection of the abdominal contours allows assessment of the degree of abdomen filling. Indigestions can be characterized by decreased, normal, or excessive filling of the reticulorumen. Most primary and secondary indigestions are associated with ruminal hypomotility and anorexia. Thus the rumen usually shows no obvious distention and may have less filling than normal, especially when the duration of the disease is prolonged. Forms of indigestion in which abnormal ingesta or abnormal ruminal motility prevents effective forward flow of ingesta (overfeeding of poor-quality roughage, vagal indigestion) or in which fluid is actively sequestered in the reticulorumen (acute ruminal acidosis) typically cause some degree of forestomach distention (see Fig. 32-119).

A left-sided or bilateral ventral abdominal wall distention indicates ventral ruminal dilation, although advanced pregnancy and hydrops conditions must be considered. Distention of the dorsal left flank results from ruminal tympany with or without distention of the ventral rumen. Abomasal displacement to the left can produce mild distention of the dorsal left flank under the caudal ribs and extending into the paralumbar fossa, but the abdomen usually is gaunt and empty when viewed from the side or the rear. Occasional cases of left displaced abomasum appear to inhibit eructation and produce gross ruminal tympany as the primary sign. Release of free ruminal gas through a stomach tube and reexamination for abdominal pings reveals this cause of secondary ruminal dysfunction. Frothy bloat in ruminants is discussed further elsewhere in this chapter. Free gas accumulation often occurs secondary to the causes of ruminal motility inhibition and is important as a sign of indigestion (Table 32-16). Right-sided abdominal distention suggests the various conditions of dilation, displacement, and obstruction or ileus of the intestines and abomasum. The diseases that cause obstruction and reflux of abomasal ingesta into the rumen may result in reticuloruminal distention. Both prolonged cases of gastrointestinal obstruction at any site and generalized peritonitis can produce gross bilateral dorsal and ventral distention of the abdomen.

The animal should be studied for signs of pain. A pain-filled expression, reluctance to move, an abnormal, stilted gait, an arched back with a tucked up abdomen, and an extended neck are typical signs of anterior abdominal pain. These signs may indicate TRP, abomasal ulceration, or another source of pain. A similar stilted gait and reluctance to move are typical of laminitis, a common sequela of acute ruminal acidosis.

PALPABLE FINDINGS (see Fig. 32-118)**.** Deep palpation of the left side of the abdomen is used to determine the consistency of the ruminal contents and thus the nature and volume of the ingesta. In normal animals the organized contraction sequence produces a layering effect.[3] Ventrally a fluid consistency can be palpated, whereas dorsally the consistency is firm and doughy. The doughy layer consists of the fibrous portion of the feed. Generally an animal fed a high-roughage diet has a more prominent layer of doughy ingesta. The ruminal contents of an animal fed concentrate feed are softer. In sheep and goats the normal dorsal rumen is softer than that of cattle no matter what the feed. In the normal condition a small layer of free gas is present in the most dorsal region. Distention with gas or foamy feed produces a taut, elastic tension. With free gas bloat the doughy layer can still be appreciated ventral to the gas accumulation, but in cases of frothy bloat the doughy layer is much less prominent. Most cases of vagal indigestion and some cases of high intestinal

VetBooks.ir

obstruction cause a grossly dilated rumen filled with fluid or foamy contents that may fluctuate on ballottement.

Overfeeding of indigestible poor hay or straw with resultant inactivity of ruminal microbial fermentation leads to accumulation of more fibrous material than normal that barely yields to deep palpation. With prolonged or severe ruminal stasis, as may occur in TRP, the lack of ruminal motility leads to failure to maintain the normal layering of the contents. In these instances the ventral portion of the forestomach is firmer than the area above. During severe ruminal acidosis, fluid accumulates in the forestomach. This can lead to some degree of abdominal distention, and on palpation the ruminal contents are fluid and may even splash with ballottement.

The rumen should also be palpated per rectum; a comparison of these findings with those obtained externally may be revealing. Moderate degrees of free gas accumulation are often more easily detectable per rectum. Palpation per rectum is also useful in distinguishing the presence of an L-shaped rumen, in which the ventral sac of the rumen is grossly distended in cases of vagal indigestion. It is important to differentiate an L-shaped rumen from either abomasal distention or impaction, which can display a similar external abdominal contour. It is also important to palpate for the size of the lymph nodes in the longitudinal groove of the rumen. These can enlarge to prominent size when rumenitis is present. The organs in the right half of the abdomen should be assessed as sources of abdominal problems.

Rectal examination is impossible in small ruminants and calves. External palpation using both hands can be valuable in these animals. In calves and goats it is the best method for detecting bezoars or clotted clumps of milk in the rumen and for palpating intussusception, umbilical abscesses, or grossly abnormal kidneys.

Palpation of the left paralumbar fossa reveals the presence of ruminal contractions. In a normal animal, three contractions should occur over a 2-minute period. One of these contractions should be associated with an eructation of gas, which can be appreciated both visually and audibly. The rate of eructation increases or decreases in proportion to the fermentative production of gas. Most indigestions produce decreased ruminal motility or ruminal stasis. Early cases of frothy bloat and some forms of vagal indigestion can result in prominent hypermotility. The motility pattern is characterized by changes in both frequency and strength, and weak contractions can also be detected by palpation. Some cases of secondary indigestion, in which the decreased ruminal function is a result of inappetence rather than an inhibition of ruminal motility, show a normal contraction frequency but decreased contraction strength. The duration and strength of ruminal contractions are primarily determined by the nature of the forestomach contents, whereas the frequency relies on medullary gastric center control. Decreased ruminal fill, decreased fiber content of the ingesta, or overdistention of the ruminal wall musculature results in reduced strength and duration of the contraction sequence. These distinctions can be important in determining the cause of decreased ruminal motility.

AUSCULTABLE FINDINGS. Auscultation of abdominal sounds is performed over several sites in the left flank and rib areas. Initial auscultation assesses the nature, frequency, and strength of ruminal sounds. This information can be compared with the assessment of ruminal motility gathered on palpation. The sounds represent the friction of fibrous ingesta rubbing against the ruminal wall as the ruminal sacs contract and mix their contents. In healthy cattle on a roughage diet, the normal rustling sound is prominent and prolonged with each contraction cycle. The ruminal contents of animals fed a high-concentrate diet produce less sound because very low fiber rations induce weaker contractions and less fibrous material is in contact with the ruminal wall.

As with palpation, both the frequency and the nature of the sounds yield information about reticuloruminal motility. The ruminal motility pattern is disrupted in vagal indigestion. Although contractions are present and may be more frequent than normal, their lack of normal coordination can lead to a churning of the ingesta without the usual progression of transport. This disrupts the normal stratification of the contents and produces abnormal sounds that are heard as a rumbling, bubbling, or splashing. When stratification is disrupted because of a hypoactive rumen and more fluid is present in the dorsal area of the rumen, contractions produce splashing sounds. The accumulation of gas under these circumstances may produce ringing tones as the fluid moves, similar to the pings found with a displaced abomasum.

Some circumstances require a distinction between primary and secondary contraction cycles, and they can be differentiated by ausculting for reticular contractions. Holding the stethoscope at the seventh intercostal space at the level of the costochondral junction, the examiner can detect a tinkling fluid sound as the reticulum contracts. A hand held in the paralumbar fossa can detect the tensed bulging of the dorsal sac as it contracts, allowing the examiner to determine if the ruminal contraction is associated with a reticular contraction. Reticular contraction and motility can also be assessed by transabdominal ultrasound.[5,92] Hyperactivity of primary cycles associated with feeding or the immediate postprandial period is normal. Mechanical stimulation of buccal sensory receptors can lead to an approximate doubling of the primary cycle rate. Hypermotility that results from excessive secondary contractions, without the normal mixing and propulsion of primary contractions, is abnormal and represents ruminal dysfunction.

Combining the auscultation with percussion or ballottement allows assessment of gas or fluid accumulations. The sounds heard in the left flank should be compared with those in the left rib area and right side of the abdomen. High-pitched pings and fluid tinkling sounds suggest a viscus filled with gas and fluid. In the left flank this may represent a displaced abomasum, gas-forming abscess, pneumoperitoneum, or static rumen. Careful comparison of the sounds heard at different sites, combined with the results of rectal palpation, should allow localization of the source. Generally the rumen can be ruled out as the source of pings if palpation reveals normal doughy ruminal contents, no ruminal tympany is felt per rectum, and sounds of normal ruminal contractions are heard in the paralumbar fossa. Prolonged anorexia associated with infectious or inflammatory diseases such as pneumonia or mastitis can result in a static, underfilled rumen, and occasionally a prominent ping can be ausculted in the left flank, where a filled rumen normally would be found. This condition has been called "ruminal collapse," and careful evaluation is required to distinguish it from left displaced abomasum. Ballottement of the rumen may reveal splashing fluid sounds without a high pitch in cases in which the rumen has accumulated significant fluid. This occurs frequently in cases of severe ruminal acidosis. It may also occur in cases of marked inactivity of the ruminal flora with loss of the normal stratification of ruminal contents.

PAIN ELICITATION. Tests of pain sensitivity in the anterior abdomen (percussion, deep palpation, withers pinch, xiphoid pressure) are performed to examine for localized peritonitis caused by TRP or abomasal ulceration. The same procedures, especially percussion or application of pressure to a localized area in the ventral abdomen, can be used to localize pain associated with rumenitis or ruminal abscessation or perforating abomasal ulceration.[93]

FECAL ABNORMALITIES. The rectal examination presents an opportunity to assess the volume and nature of the feces. The feces are abnormal in most cases of forestomach dysfunction. In adult cattle, passage of ingesta through the digestive tract requires 1½ to 4 days. Changes in the feces caused by acute diseases thus are often delayed by a day or longer beyond the first appearance of other clinical signs. Mature cattle typically pass a total of 30 to 50 kg of feces per day divided into 10 to 24 defecations. The color and consistency of feces are influenced by the feed and should be assessed in light of the feeding history.

Diseases that reduce the flow of ingesta from the rumen to the lower gastrointestinal tract typically result in feces of reduced volume that are firm and dry. These findings are also present with reduced feed or water intake. Assuming that normal intestinal function is

VetBooks.ir

present, a decreased flow of ingesta from the forestomach allows longer retention in the bowel with greater resorption of water. In severe instances the feces form into firm disks or balls with a dark, shiny mucous covering. These findings are typical of vagal indigestion and forestomach diseases that produce ruminal stasis without a grossly abnormal fermentative pattern. Indigestions with abnormal fermentation may produce decreased quantities of dry feces initially but usually result in other fecal abnormalities as the abnormal ingesta passes into the lower tract. Intestinal obstructions also decrease fecal passage to the point of absence, but usually the material passed also presents other gross abnormalities such as blood, melena, or discolored mucus.

The particle size of fecal material depends on the frequency and duration of rumination, the activity of the ruminal flora, and the function of the rumen in appropriately sorting out material for passage through the reticuloomasal orifice. Abnormalities of these digestive functions lead to passage of ingesta of inappropriate particle size. Plant fibers in normal bovine feces measure up to 0.5 cm. Particles with inadequate breakdown may measure 1 to 2 cm or longer. This long particle size may be seen in the feces of cattle with TRP, some cases of vagal indigestion, and poor-quality roughage with insufficient microfloral activity.[38,39] Similar findings occur with tooth disease and some cases of abomasitis or cellulitis at the cardia or esophageal groove, in which rumination or activity of the reticuloomasal orifice is inhibited. Whole cereal grains (especially whole corn) may pass in the feces of normal cattle, but excessive amounts of grain should raise suspicion of excessive intake and acute ruminal acidosis. Feces with an abnormally fine particle size and greasy-pasty texture are associated with delayed passage from the forestomach. These are common findings in most cases of vagal indigestion and abomasal displacement.

The odor of bovine feces is relatively inoffensive in healthy individuals. Foul odors are the result of abnormal fermentation or decomposition. Thus abnormal odor typically occurs when the ruminal fermentation pattern is altered, as in simple indigestion caused by abnormal feed, ruminal acidosis, ruminal alkalosis, or ruminal content putrefaction. A repugnant odor is also typical of enteritis when blood products, inflammatory products, or tissues decompose in the intestinal tract (e.g., *Salmonella* enteritis). Foamy, fluid feces with a yellow-brown color and acidic smell are typical of ruminal lactic acidosis in adult cattle. Abnormal ruminal fermentation not only produces feces with abnormal odor but also typically leads to a pasty or fluid consistency. Exceptions occur in acute cases, when ruminal stasis or the delay in the passage of ingesta from the forestomach can result in normal or firm feces during initial stages of the disease.

ACUTENESS OF SIGNS. The various forms of indigestion may be manifested as acute, subacute, or chronic illness. In general they do not appear as critical emergencies with fulminating systemic signs and life-threatening conditions. The exceptions to this are frothy bloat and acute ruminal lactic acidosis or grain engorgement.

Cattle examined a few hours after engorgement of grain may yet be alert but anorectic with a mildly distended rumen, weak ruminal contractions, and mild signs of colic. If the acidosis is mild, affected cattle show the signs of indigestion discussed in previous paragraphs and with or without treatment may show return of appetite within a few days. The severe form of indigestion leads to severe systemic involvement, with depression, severe dehydration, weakness, recumbency, profuse diarrhea, and eventually death. The temperature usually is normal to subnormal. The heart rate elevates with the progression of dehydration and systemic acidosis, with rates above 100 beats/min usually associated with a poor prognosis. Respiration generally is increased (60 to 90 breaths/min) and shallow. The rumen accumulates fluid. Animals capable of rising may show a staggering gait and appear blind. The pupillary light reflex may be slower than normal. Recumbent animals usually lie quietly and may be stuporous. As the cardiovascular system becomes more severely affected with increasing dehydration and acidosis, the extremities become cool, and mucous membranes dry. Anuria may follow poor renal perfusion. Rapid progression of signs leading to recumbency bespeaks a poor prognosis, and animals may die within 24 to 72 hours. Therefore if the progression of signs is rapid, emergency therapeutic measures are mandatory.

In cattle with intermediate degrees of ruminal acidosis, other signs may develop secondarily. Acute or chronic laminitis is a common complication.[94] The damage to the ruminal mucosa can lead to mycotic rumenitis or ruminal wall abscessation or can disseminate infection through the bloodstream to other organs, most notably the liver, resulting in the formation of hepatic abscesses.[65]

HEART RATE. Bradycardia of 40 to 60 beats/min is frequently associated with certain types of indigestion. This sign suggests reflex vagotonia to the heart and has been considered indicative of vagal indigestion. The bradycardia can be alleviated by subcutaneous administration of 30 mg of atropine, differentiating increased vagal nerve tone from a primary cardiac conduction disturbance. The atropine test is not especially useful because only a minority of vagal indigestion cases show bradycardia.[38] Advanced cases with severe abdominal distention or fluid imbalances (or both) frequently show elevated heart rates (over 80 beats/min). In most cases the other physical signs are more reliable for establishing the diagnosis. Further, bradycardia may accompany other forms of indigestion when ruminal hypomotility is prominent and no significant abnormalities of fluid or electrolyte balance are present. Even in normal cattle, postfasting heart rates may drop below 50 beats/min.[95] Therefore recognition of bradycardia in association with other signs of ruminal dysfunction is probably most useful as evidence that stimuli for an increased heart rate, such as inflammatory, infectious, or fluid balance disturbances, are not prominent factors in the individual disease occurrence.

VOMITING. Vomiting is uncommon in ruminants, but when it does occur, it generally reflects forestomach disease. Regurgitation from the abomasum frequently occurs with abomasal or intestinal disease. Abomasal reflux is not manifested externally and is discussed elsewhere because it relates to forestomach disease. Small-volume regurgitation and remastication are routine and normal ruminant functions that do not result in expulsion of material from the mouth. Explosive vomiting of fluid ingesta in large quantity occurs when the reticulorumen is irritated and occasionally when it is overdistended. Vomiting may accompany diaphragmatic herniation of the reticulum, inflammation of the reticulorumen caused by actinobacillosis, vagal indigestion, or obstruction of the reticuloomasal orifice. Animals are more prone than normal to vomiting around an orally passed stomach tube when they have almost any indigestive disturbance. Vomiting also occurs with certain intoxications, most notably azalea, rhododendron, and sneezeweed toxicity and some organophosphate toxicities.

Clinical Pathology

RUMINAL FLUID ANALYSIS. Evaluation of ruminal fluid characteristics is an essential procedure in establishing the cause of the indigestions of abnormal fermentation.[60,96] Several important determinations can be made at cowside in an ambulatory practice. Acquiring an appropriate sample is simplified by using proper equipment. The advantages of various collection techniques and devices have been discussed.[97,98] Needle puncture of the ventral ruminal sac (ruminocentesis) may yield a satisfactory fluid sample, and studies demonstrate that ruminocentesis samples provide the most reliable evaluation of ruminal fluid pH for field evaluation of subacute ruminal acidosis.[97-99] Oral or nasal passage of a collection tube produces more fluid volume with no risk of peritoneal contamination but with an increased risk of saliva contamination. An adequate tube for aspiration of a ruminal fluid sample should be at least 2.3 m long to reach the ventral ruminal sac and should have an internal diameter of 1 cm or larger to reduce the incidence of plugging with ingesta. A plastic stomach tube passed orally or nasally can be adapted for use

VetBooks.ir

by cutting multiple holes into the ruminal end of the tube. A digital examination glove can be placed over the end during passage to limit saliva contamination of the sample and then is forcefully blown off before sampling. The sample can then be withdrawn by a dose syringe. This technique is successful when ruminal fluid is accessible in the dorsal rumen, but the flexibility of the tube is disadvantageous when a prominent layer of fibrous feed is present. Several instruments with a flexible steel outer tube are commercially available and have the advantage of enough stiffness and weight to penetrate the overlying firm layer of ingesta.

Ruminal fluid samples collected in an expeditious manner yield the most useful results. When the animal strongly resists sampling and a prolonged time is required from introduction of the tube until the fluid is obtained, saliva contamination of the sample increases. This contamination alters the pH and consistency of the sample. The specially designed ruminal fluid collection tubes reduce this problem. If the sample must be collected with a standard nasogastric tube, passing the tube nasally avoids the presence of a device in the mouth. This reduces the amount of struggling (once the tube has passed the pharynx) and thus reduces excessive salivation.

The sample should be evaluated as soon as possible after collection to minimize the effects of cooling and air exposure on protozoal activity and pH. The more elaborate chemical tests such as chloride, acid, and ammonia concentrations can be delayed up to 9 hours on a room temperature sample and up to 24 hours on a refrigerated sample and still yield reliable results. Ruminal fluid collected for therapeutic transfaunation also retains its beneficial activity for a similar duration.[100] The ruminal fluid parameters important in a clinical examination are listed in Table 32-17.

Color, Consistency, and Odor. The color, consistency, and odor of aspirated fluid are assessed immediately after collection. Normal color varies, depending on the nature of the feed. Animals fed a hay ration have olive to brownish green ruminal fluid, those on grass show a deeper green color, and cattle fed grain or silage a yellowish-brown color. Fluid from cattle with acidosis tends toward a milky gray. Ruminal fluid from animals with prolonged stasis or decomposition of the ruminal ingesta (or both) is a darker greenish black, and fluid from calves with milk sequestered in the rumen as a result of abomasal reflux or esophageal groove failure is gray and may contain clots of milk.

Normal ruminal fluid has a slightly viscous consistency. The fluid becomes more watery when the microflora is inactive. Saliva contamination causes greater viscosity; therefore, the results from a highly viscous sample should be evaluated with care, and it may be best to discard such samples. Ruminal fluid has a typical odor that has been called "aromatic." The odor is less prominent when the microflora is inactive. Abnormal odors include the acidic smell of lactic acidosis, the putrid, foul odor of protein decomposition or spoiled milk with putrefaction of ruminal ingesta, or the ammonia smell of urea poisoning.

TABLE 32-17

Diagnostic Ruminal Fluid Analysis

Parameter	Normal
Color	Olive, brownish-green
Consistency	Slightly viscous
Odor	Aromatic, strong
pH	6-7 on roughage 5.5-6.5 on grain diet
Sedimentation/flotation	4-8 min
Redox potential (methylene blue reduction time)	3-6 min
Protozoal activity	Multiple forms, active motion
Gram stain	Predominant gram-negative bacterial population
Chloride concentration	<30 mEq/L

Ruminal Fluid Ph. The pH of ruminal fluid fluctuates within a broad range of normal values, varying considerably during the course of a day with shifts of 0.5-1.0 pH unit common during a 24-hour period.[72,101] The pH measured in a given fluid sample depends on the type of feed and fermentation pattern and the interval since the last feeding. Physiologic ruminal fluid pH typically ranges between 6 and 7 in animals on a mostly forage diet but is lower, at 5.5 to 6.5, in animals fed mostly grain.[61,72,98] The lower pH develops with the faster rate of amylolytic versus cellulolytic fermentation. Immediately after feeding the pH tends toward the high end of normal with the addition of feedstuff and saliva, the production of which is determined by the duration spent eating, ruminating, and resting.[102] Over a 2- to 4-hour period the pH decreases to the lower range as the feed undergoes fermentation. With no further feed consumption, fermentation declines and the pH rises with salivary buffering and acid end product absorption. In animals held off feed the ruminal pH rises above 7 within 12 hours after a hay meal and within 24 hours after a high-grain meal. Thus consideration of the most recent feed consumption is important to the interpretation of the ruminal fluid pH measurement.

Saliva contamination of the sample falsely elevates the measured pH value. Because it is impossible to exclude saliva completely from samples collected by tube, a minor false elevation of the pH likely occurs in all such examinations.[98] This can be minimized by expedient collection of a large fluid volume (more than 100 to 200 mL). If the collected volume is small and the sample viscosity is high, the pH measurement will be inaccurate. Modest contamination (5% to 10%) raises the measured pH by approximately 0.1 to 0.2 pH units, whereas excessive contamination with approximately 50% saliva may increase pH by 1 pH unit. Ruminocentesis of the ventral ruminal sac below the left paralumbar fossa is preferred by some clinicians for preventing saliva contamination. This is particularly advantageous for samples collected to monitor ruminal pH for balancing rations and minimizing chronic ruminal acidosis. A sampling strategy that incorporates ruminocentesis and ruminal fluid pH measurement in groups of cows in a herd has been developed to optimally identify cow groups with feeding problems that lead to subacute ruminal acidosis.[97,98]

Ruminal pH values of 7 to 7.5 are common in animals with anorexia and in those that have ingested feed that is not suitable for fermentation (e.g., simple indigestion and inactivity of microflora caused by indigestible roughage). Even higher pH values may be measured with ruminal alkalosis caused by urea ingestion or putrefaction of ruminal ingesta. Low pH values result from engorgement with readily digestible carbohydrates and generation of ruminal lactic acidosis. In extreme cases values occasionally decline to 4 to 4.5. It is important to remember that prolonged anorexia and continued saliva ingestion result in rising pH values in these cases as well and that the ruminal pH of a cow with ruminal acidosis can be normal if a sufficient period of anorexia precedes the ruminal fluid analysis. Conversely, a ruminal pH of 5.5 to 6 is abnormal for a cow fed a roughage diet and may be indicative of unobserved access to grain and resultant lactic acidosis. Subacute or chronic ruminal acidosis usually is accompanied by a ruminal pH in the range of 5 to 5.5.[60,61,72,98] Abomasal reflux into the reticulorumen caused by abomasal disease, vagal indigestion, or intestinal obstruction can cause mild decreases in ruminal pH because of the acidic nature of abomasal contents. However, ruminal pH measurement is a poor means of detecting abomasal reflux because the pH will remain within the wide range of normal values. Abomasal reflux is better assessed by measurement of the ruminal chloride concentration.

Sedimentation. The sedimentation activity time, or sedimentation/flotation test, provides a quick evaluation of microfloral activity. It must be conducted promptly after collection of the sample. The aspirated fluid is allowed to sit in a tube, and the time for completion of sedimentation and flotation of the solid particles is measured. Normally the finer particles settle to the bottom and the coarser particles float, buoyed by the gas bubbles of fermentation. Some of the finer particles sink and then rise again when the fermentation is

VetBooks.ir

very active. The normal time for completion of this activity is 4 to 8 min. Grossly inactive fluid shows very rapid sedimentation, and none of the material may float. This occurs with ruminal acidosis, prolonged anorexia, and inactive microflora caused by indigestible roughage. When the ingesta is particularly frothy, as in cases of frothy bloat or some cases of vagal indigestion, there may be no appreciable sedimentation or flotation. This test provides a crude evaluation of microfloral activity but does not differentiate well among the different forms of indigestion.

Redox Potential. The redox (reduction-oxidation) potential of ruminal fluid is a biochemical characteristic that reflects the anaerobic fermentative metabolism of the bacterial population.[3] An indirect determination of the redox potential can be achieved by measuring the time required by ruminal fluid to decolorize methylene blue dye. A mixture of 1 mL of 0.03% methylene blue with 20 mL of ruminal fluid at normal body temperature is observed in a tube and compared for color with another unaltered tube of the fluid. With a highly active microflora from an animal fed a hay and grain diet, the initial dark blue color of the mixture decolorizes within 3 minutes, leaving a narrow ring of blue color at the top of the decolorized sample. Fluid from a diet of hay alone requires 3 to 6 minutes and from a mostly grain ration requires as little as 1 min for methylene blue reduction. Reduction times up to 15 min and longer occur with diets of indigestible roughage, in anorexia of several days' duration, and after ruminal acidosis.[96] Thus the methylene blue reduction time provides an assessment of the degree of bacterial fermentative activity.

Microscopic Examination. Evaluation of the number and activity of protozoa in the ruminal fluid provides a sensitive indicator of the normalcy of the sample.[3] This is easily accomplished by examining a drop of fresh, warm fluid under a microscope. The examination requires only low magnification (×40 to ×100) and no special stains. In very active fluid samples the largest protozoa can be seen with the naked eye. They are detectable in a tube as small gray specks of material in active motion in the fluid, and they tend to localize above the sedimented particulate matter. Microscopically both ciliate and flagellate forms of varying sizes and shapes can be observed, with ciliates usually outnumbering the flagellates. The protozoa are normal inhabitants of a healthy ruminant's ruminal fluid, although their specific function is not completely clear and their presence does not appear to be a prerequisite of normal digestive activity. The importance of the protozoa from a clinical viewpoint is their sensitivity to abnormalities in the fluid milieu. The normal animal should show a wide variety of sizes of protozoa, in large numbers that are easy to see, and with active motility. Reduced numbers occur in inactive fluid samples. The larger species are more susceptible to abnormalities; thus a predominance of only small protozoa would suggest a mild indigestive disturbance. All protozoa are killed off when the ruminal pH drops below 5. Thus a recent bout of acidosis results in lack of protozoal activity, even if the pH has subsequently risen back into the normal range. Fluid from such an animal should also show other abnormalities of color and consistency. Very recent disturbances of the fluid may result in the observation of a large number of dead protozoa.

Although elaborate isolation methods for evaluating ruminal bacterial growth are not clinically applicable, examination of an air-dried, Gram-stained smear of ruminal fluid can be useful in diagnosing ruminal acidosis. Normal ruminal fluid should contain a variety of morphologically distinguishable bacterial forms, with a predominance of gram-negative organisms. After the overconsumption of readily digestible carbohydrate (grain engorgement), a population of streptococci and lactobacilli proliferates as ruminal lactic acidosis develops. This shift in the bacterial population can be distinguished microscopically, and a predominance of gram-positive cocci and rods are seen. The findings are best confirmed by comparing a smear from a herdmate.

Ruminal Fluid Chloride. The chloride concentration in ruminal fluid can be determined from the supernate from a centrifuged sample using standard chloride titration devices. A delay in measurement does not appreciably affect the value. Saliva contains concentrations of chloride similar to those of normal ruminal fluid, so that saliva contamination has minimal effect on the results. The normal ruminal fluid chloride concentration is less than 30 mEq/L, with elevated values demonstrating reflux of abomasal ingesta into the rumen or administration of chloride in the feed or as therapy. Accurate assessment of measured values requires information about possible previous administration of electrolytes via the rumen. In the clinical evaluation of forestomach dysfunction, elevated ruminal chloride suggests secondary indigestion caused by abomasal disease or obstruction of intestinal flow. This test can be very helpful in differentiating abomasal reflux from ruminal lactic acidosis as the cause of low ruminal pH and abnormal fluid accumulation in the reticulorumen. With vagal indigestion a high ruminal chloride suggests that the failure of aborad flow is posterior at the pylorus rather than anterior at the reticuloomasal orifice.[41] Generally cattle with elevated ruminal chloride also have hypochloremia and metabolic alkalosis as a result of the chloride sequestration in the forestomach, although very slow development of the sequestration may allow the animal to maintain normal plasma levels by altering other excretion rates.

Numerous other tests of the ruminal fluid have been described for the evaluation of digestive activity of the ruminal microflora. These include cellulose digestion, glucose fermentation, nitrite reduction, and measurements of titratable acidity, volatile fatty acids, lactic acid, and ammonia concentration. These procedures can more clearly define the nature of the ruminal fluid but are not generally used in a clinical setting.

HEMATOLOGY. Hematologic abnormalities are not generally a significant feature of the indigestive disorders. The primary exceptions are TRP or rumenitis, in which neutrophilia and hyperfibrinogenemia are routine findings. This feature of the disease can aid in its differentiation from other forestomach diseases. An inflammatory leukogram can also be observed in some cases of vagal indigestion when inflammatory disease is responsible for dysfunction of vagal innervation and forestomach motility. Chronic bronchopneumonia in calves and TRP in adult cattle are commonly implicated as causes of vagal dysfunction. A hematologic reflection of an inflammatory response may also be seen after ruminal acidosis if the ruminal wall and other organs suffer secondary pathogen invasion, and likewise in the occasional cases of primary rumenitis or reticulitis.

The more common hematologic abnormalities associated with indigestion are reflections of fluid disturbance or stress response. Hemoconcentration is routine and may be severe in ruminal acidosis. Mild dehydration may also accompany the other forms of indigestion, especially when the disease shows a protracted course. A stress leukogram would be anticipated in cases of indigestion that are acute or distressing, such as acute bloat. The hematologic response in secondary indigestions depends on the primary disease.

When indigestion is chronic, especially in calves, in which the indigestive disturbance may go unrecognized or undiagnosed for a long time, a state of malnutrition may develop. In these instances a mild to moderate anemia may develop that may be attributable to micronutrient or macronutrient deficiencies.

BIOCHEMICAL ABNORMALITIES. Most of the primary forestomach diseases do not induce remarkable changes in the biochemical profile. In lactating or heavily pregnant animals, anorexia may induce a secondary form of acetonemia, which is detected by the presence of urine ketones. The animal must be carefully examined to differentiate ketosis with secondary anorexia and decreased ruminal activity from primary indigestion with secondary ketosis. Mild to moderate hypocalcemia and hypokalemia are commonly identified abnormalities in many cases of indigestion, especially when anorexia has been prolonged.

Dramatic alterations of the blood biochemical characteristics may accompany severe ruminal acidosis. Usually the laboratory findings correlate with the degree of severity assessed on physical examination. Affected animals have metabolic acidosis with decreased blood pH and plasma bicarbonate. Blood lactate levels rise with the

VetBooks.ir

acidosis. The urine pH falls into the acidic range as the kidneys excrete some of the excess acid, but eventually severe dehydration results in renal failure and anuria, eliminating this route of acid excretion. Decreased renal function is reflected by elevated serum creatinine and urea nitrogen concentrations. Other findings commonly include increased serum phosphate concentration, possibly caused by massive cellular destruction, and mildly decreased serum calcium concentration, presumably the result of decreased gut absorption. Other serum electrolyte abnormalities, such as changes in the sodium and chloride concentrations, may reflect fluid balance changes in response to ruminal fluid hyperosmolality.[59] Concentrations of serum enzymes of muscle and liver origin rise when acidosis and dehydration produce cardiovascular impairment with poor tissue perfusion, increased recumbency, and cellular destruction. Portal bacteria and toxins from the damaged ruminal mucosa contribute significantly to the increased serum liver enzymes: aspartate aminotransferase, sorbitol dehydrogenase, orthinine carbamoyltransferase, and γ-glutamyltransferase.

Vagal indigestion may cause no significant blood biochemical abnormalities or can result in severe disturbances of fluid and electrolyte homeostasis. Measurement of the serum electrolyte concentrations provides important clues about the site of obstruction of ingesta flow and is useful in adjusting fluid therapy. When the primary problem is failure of flow through the reticuloomasal orifice, the rumen fills and grossly distends with fluid, but significant abomasal reflux does not occur. These patients generally show mild or no serum electrolyte abnormalities. When ingesta fails to pass from the abomasum, reflux of the high-chloride abomasal contents into the rumen results in elevated ruminal chloride concentrations and associated hypochloremic, hypokalemic metabolic alkalosis. In some instances these abnormalities can be dramatic. Prolonged or severe hypochloremia and hypokalemia may also result in the paradoxic aciduria associated with avid renal sodium resorption in the face of low concentrations of chloride and potassium. Some slowly developing cases may accumulate significant fluid in the reticulorumen but have minimal blood electrolyte changes.

Treatment and Prognosis

Ruminal Wall and Motor Function Disorders

Signs such as ruminal tympany, ruminal hypomotility or stasis, and forestomach distention can all result from a number of causes. Eliminating the underlying causative problem more effectively resolves the disease than treatment directed at the disease signs. Ruminal hypomotility, for example, is commonly a physiologic response to problems such as abnormal ruminal contents, a ruminal wall lesion, pain, or overdistention. In many cases the ruminal motility disturbance serves as a protective role for the animal. Former treatments that were directed at stimulating ruminal motility without addressing the causative disturbance included rumenatorics (i.e., nux vomica, ginger, tartar emetic) or parasympathomimetics (i.e., neostigmine, carbamylcholine). Such agents are not indicated under these circumstances. Likewise the treatment of indigestions with alkalinizing agents such as magnesium hydroxide is indicated only when the pH of ruminal contents is low.

FREE GAS BLOAT. When ruminal tympany is a prominent sign, it requires very critical assessment. Frothy bloat and free gas bloat can be differentiated by a thorough physical examination and knowledge of the feeding history. Passage of a stomach tube to help in this differentiation is very important and may alleviate the acute problem if free gas is present (see Table 32-16). Evidence of respiratory or cardiovascular distress indicates that the bloat is an acute, life-threatening problem that requires emergency treatment. With the exception of cardia or esophageal obstruction, the free gas bloat associated with indigestive disturbances is mild to moderate in severity and chronic or recurrent in nature. It does not represent a major threat to the animal and can be handled by treating the primary forestomach disturbance. Chronic free gas bloat does not respond to the antifermentatives or surfactants commonly used for frothy bloat. Only the restoration of physiologically normal reticuloruminal function corrects this type of bloat. Inhibition of eructation caused by lesions of the cardia region can usually be confirmed only by exploratory rumenotomy. This approach also determines whether the lesion is surgically correctable. Inflammatory lesions may respond to long-term administration of broad-spectrum antibiotics. This is also the treatment of choice when purulent lung infections appear to be the cause of the bloat. Failure to respond within about 3 weeks suggests that the treatment is not effective, and slaughter should be recommended after an appropriate withdrawal time. Detection of abnormal forestomach ingesta should direct treatment to the primary fermentative or feeding disorder.

The various causes of chronic or recurrent bloat usually require chronic treatment for correction. It follows that the bloat will also not completely resolve until the underlying disturbance is corrected. Repeated relief of the bloat may be accomplished by passage of a stomach tube during the treatment regimen. In many cases this proves too tedious or too traumatic for the animal, and the most viable alternative often is the establishment of a temporary ruminal fistula. Several devices are manufactured for this purpose, or the fistula can be created by suturing the rumen to the skin. Release of the fermentative gas in this manner is important for the reestablishment of normal forestomach motility, which is inhibited if distention is extreme. When free gas bloat is the result of an obstruction of eructation or another gastrointestinal tract disease such as abomasal displacement, surgical treatment of the primary problem may be necessary. The tympany responds rapidly in these cases, and ruminal fistulation is not required.

LESIONS OF THE RUMINAL WALL. Diseases of the ruminal wall may be suspected on the basis of the physical examination findings and results of a complete blood count, abdominocentesis, and ruminal fluid analysis. In most cases exploratory laparotomy is required to confirm the diagnosis. Rumenitis or reticulitis may respond to antibiotic therapy, but the prognosis in these cases is guarded. Not only is the forestomach inflammation difficult to resolve, but the hematogenous spread of infection to other organs often causes intractable multiple organ system disease. Parakeratosis is best treated by correcting the causal feeding error (reducing the amount of concentrate and increasing the feeding of long-stemmed forage). The ruminal papillae can grow or regress in a period as short as 3 weeks when the feed is changed from low- to high-concentrate content or vice versa. Exactly how long it takes for parakeratotic papillae to return to normal is not certain, but it probably depends on the degree of change of the diet. The prognosis of this problem is good if inflammation of the ruminal wall is not also involved.

RUMINAL DISTENTION. Vagal indigestion is a chronic and insidious problem that generally warrants a guarded to poor prognosis. The syndrome of abdominal distention with an L-shaped rumen and possibly ruminal tympany has several different causes. Exploratory laparotomy and rumenotomy are essential for establishing an accurate assessment (see Fig. 32-119). Diaphragmatic herniation and masses that obstruct the reticuloomasal orifice cause signs indistinguishable from those of vagal indigestion that result from inflammatory lesions of the reticulum. Surgical correction of a diaphragmatic hernia involving the reticulum can be attempted but has usually proved unrewarding, especially if the lesion is chronic, involves a large defect, or is accompanied by inflammatory reaction. Removal of pedunculated masses or foreign bodies at the reticuloomasal orifice can promptly correct such problems.

The two most common causes of vagal indigestion syndrome are inflammatory lesions of the reticuloomasal region and abomasal diseases that involve gross distention, twisting, or vascular impairment of the organ. Vagal indigestion caused by abomasal disease carries a poor prognosis, whereas the prognosis for cases with reticular involvement is more variable. Animals in either category may respond favorably with appropriate therapy[40,41] (Box 32-6). Surgical

VetBooks.ir

BOX 32-6

Principles of Treatment of Vagal Indigestion

1. Determine likely cause, often by means of exploratory laparotomy.
2. Administer specific therapy (e.g., antibiotics, antiinflammatory agents, removal of foreign body or relief of obstruction, drainage of abscesses) for causative lesion.
3. Relieve forestomach distention; often this must be repetitively performed.
4. Limit feed and water intake; feed palatable, high-fiber ration.
5. Transfaunate.
6. Fistulate rumen if chronic bloat is a problem.

BOX 32-7

Principles of Treatment of Fermentative Indigestions

1. Determine and resolve initiating cause; adjust feed regimen.
2. Correct ruminal pH.
3. Correct systemic acid-base and electrolyte abnormalities through parenteral fluid therapy (especially Ca^{++} and K^{+}).
4. Remove grossly abnormal ruminal ingesta.
5. Correct ruminal fill (overdistention or emptiness).
6. Transfaunate repeatedly.
7. Resolve inspissation or impaction of ruminal contents when present.
8. Provide oral and parenteral mineral and vitamin supplementation when indigestion or anorexia is chronic.

exploration not only allows an assessment of the cause of the problem but may also allow repair. When abscesses are identified at the reticulum or liver, surgical drainage may help resolve the forestomach motor disturbance.[41] Identification of adhesions and active inflammation indicates that broad-spectrum antibiotic therapy may be beneficial, it being essential that aggressive antimicrobial therapy be administered prior to and following the surgical correction of a right-sided abomasal displacement or volvulus.[40] Gross abomasal distention, indicating pyloric outflow failure, usually warrants a poorer prognosis, as does the presence of granulomatous or neoplastic processes or generalized peritonitis and adhesion formation.[41] When the presence of a large gravid uterus appears to be the inciting cause of outflow failure, induction of parturition or cesarean section usually resolves the problem completely.

The evaluation of animals with vagal indigestion with a large fluid-filled rumen should include assessment of the fluid and electrolyte status. Abnormalities such as dehydration, hypocalcemia, hypochloremia, and hypokalemia should be addressed with supportive fluid therapy. Treatment should be administered parenterally, because oral treatments are ineffective or deleterious. The forestomach should be emptied of the excessive ingesta accumulation either at surgery or with a large-bore stomach tube. This procedure may have to be repeated if the recovery period is prolonged. Relief of persistent forestomach distention is *critical* to the reestablishment of normal motility. Limited feed and water should be offered to prevent repeated accumulations in the reticulorumen, and intravenous fluid therapy should be continued until reticuloruminal motility is reestablished and oral fluid intake can be allowed at normal levels. Once the ruminal distention has been alleviated, several liters of ruminal fluid transfaunate from a healthy donor should be administered.[103] The limited diet must be palatable and should consist primarily of long-stemmed hay or green feed for maximum stimulation of the normal forestomach motility pattern. A temporary ruminal fistula may be indicated if tympany is a prominent sign.

Response to treatment of vagal indigestion usually is a slow process and may require several weeks. Favorable signs include a return of the normal primary and secondary contraction patterns, improvement in appetite, maintenance of normal forestomach dimensions, weight gain, and increased fecal production. Repeated development of forestomach distention, continued scant fecal output, poor ruminal motility, and recurrent bloat are indications that the animal is not responding to treatment and the prognosis is grave.

Fermentative Disorders

With the exception of severe acute ruminal acidosis, the disturbances of reticuloruminal fermentation generally are not fatal unless the disease is undiagnosed for a prolonged period, leading to extreme debility. Treatment of fermentation disorders centers around restoring a normal ruminal fluid environment that allows normal microbial metabolism. Identification of ruminal fluid parameters (see Table 32-17) and the nature of the forestomach ingesta direct the appropriate treatment (Box 32-7).

FEEDING. The first and most important step in treatment of nutritionally related indigestions is correction of the specific causal feeding error. Because the imbalance may have gone on for weeks, especially in cases of calf indigestion, correction of the problem may also take some time. The evolutionary development of the ruminant has adapted it to be a grassland grazer. Economic pressures in the animal industry have caused managers to institute feeding practices that diverge widely from a pasture setting. Fresh green grass, however, remains one of the best means of stimulating normal forestomach digestion and motility. The second best type of diet includes a balance of palatable and digestible sources of energy, protein, fiber, and mineral nutrients. Fiber requirements should be determined by considering both the physical effectiveness of fiber and the production of fermentation acids.[104] The content of structured roughage should not fall below 10% of the ration dry matter, and a crude fiber component above 17% is desirable for any ration.

ALTERATION OF RUMINAL CONTENTS. When the viability or activity of the ruminal microflora is in question, as in the primary fermentative disorders and most cases of secondary indigestion, ruminal transfaunation is indicated.[103] This should be obtained from a healthy individual that preferably is adapted to a ration similar to the one the patient is expected to consume. The fluid can be obtained from an animal with the rumen fistulated, by removal with a stomach tube, or from a local abattoir. After the large particulate matter has been strained from the fluid (cheesecloth or large stockinette can be used), it can be administered through a stomach tube. The transfer from donor to recipient is best accomplished immediately, but fluid that contains active and healthy microflora remains viable for up to 9 hours at room temperature or 24 hours under refrigeration.[100] In calves inoculation with 1 L is appropriate, whereas 3 L is minimal in an adult cow, and 8 to 16 L is more desirable.

Many animals with indigestion exhibit decreased ruminal fill. As discussed, one of the primary stimuli for active ruminal contraction is mild forestomach distention. In addition to the administration of ruminal transfaunate, it usually is beneficial in these cases to administer enough oral fluid to produce mild ruminal distention. This can be accomplished with water warmed to body temperature, and 20 to 30 L of fluid administered through a tube may be required to achieve the desired effect. The addition of salt (sodium and potassium chloride) in amounts sufficient to produce an isotonic solution (about 2 teaspoons per liter) supplements deficiencies and promotes rapid turnover of the fluid from the rumen to the lower tract. Cathartic agents such as magnesium sulfate have been used and may be beneficial but do not serve to supplement the common electrolyte deficiencies.

Correction of pH abnormalities to the normal range of 6 to 7 is important when ruminal acidosis or alkalosis is detected. Alkalinizing agents such as magnesium hydroxide and sodium bicarbonate are indicated for treatment of acidosis at an initial dose of 1 g/kg. Magnesium hydroxide is commonly used by some as a routine treatment for any animals in which ruminal hypomotility has been identified.

VetBooks.ir

This practice is not justifiable in most cases of ruminal hypomotility because the fluid pH is commonly at or near neutral. The use of magnesium hydroxide in such settings may induce a mild systemic alkalosis, and the agent is better reserved for true cases of acidosis. Ruminal alkalosis can be corrected with the infusion of acetic acid (vinegar, initial dose of 2 mL/kg, up to 12 L). All of these agents are best administered in several liters of warm water to ensure good distribution through the ruminal fluid.

Overdistention of the ruminal wall may be a primary inhibitor of forestomach motility in some cases of indigestion caused by abnormal fermentation. Treatment of free gas bloat has been discussed. When the distention is caused by accumulation of abnormal ingesta, normal contractions do not return and the ruminal tympany is not resolved until the distention is relieved. This situation is best exemplified by cases of microfloral inactivity caused by poor-quality roughage and is the underlying problem in calves with haybelly. One approach to this problem is to restrict the animal to small quantities of readily digestible feed given several times a day. Between meals the animal can be kept in an unbedded stall or muzzled. This process is continued until the accumulated ingesta has passed out of the forestomach. Repeated transfaunations during this time help reestablish a more normal microflora. This approach relies on motility and microbial activity sufficient to break down the ingesta and pass it to the lower tract. An alternative approach is to remove the accumulated ingesta by means of rumenotomy, after which the animal is transfaunated and allowed access to moderate amounts of feed until normal motility is restored. Emptying the rumen surgically is the treatment of choice when spoiled milk, putrefactive ruminal ingesta, or severe ruminal acidosis is detected. Prolonged cases of microbial inactivity or anorexia (or both) with ruminal hypomotility can result in loss of the normal stratification of forestomach ingesta. The fibrous, floating layer sinks to the ventral ruminal sac in these cases, forming a dense, firm mass. Return of normal forestomach motility will be delayed unless this accumulation of material can be eliminated. This can be accomplished during the process of microfloral reestablishment by massaging the mass through the lateral and ventral body wall. Dissolution and passage of the material can be enhanced by the administration of mineral oil (4 L), or dioctyl sodium sulfosuccinate (DSS) (4 to 6 ounces in 2 to 3 L of water). Because DSS kills ruminal protozoa when given in amounts greater than required to saturate the fibrous matter, at least one ruminal transfaunate should be given 1 to 2 days after the last application of this agent.

Animals with prolonged anorexia caused by a depressant or febrile disease that produced secondary indigestion may not return to feed or have normal ruminal motility even after normalcy of the ruminal contents has been restored. Chewing activity is one of the strongest stimulants for ruminal motility, and these individuals sometimes benefit if palatable hay or grass is placed forcefully into their mouth by hand. An alternative is to give such individuals access to pasture. Both the ruminant and its ruminal microflora have trace mineral requirements that are often not met by the types of diets that may induce microfloral inactivity. The ruminal microflora is also responsible for supplying the animal with its vitamin B requirements. The stunted, poor body condition of calves affected by chronic indigestions may reflect these deficiencies, as well as protein energy malnutrition (see Chapter 9). Oral supplementation of minerals and parenteral supplementation of the B vitamins may be helpful until normal ruminal digestive function is established. Adult cattle, especially lactating animals with high metabolic demands, may also benefit from B vitamin supplementation when ruminal function is impaired.

Intraruminal administration of antibiotics has been used to kill undesirable populations of ruminal microflora. A 2- to 3-day course of treatment with a broad-spectrum antibiotic that is not readily absorbed is only useful when an overgrowth of undesirable bacterial species is present and should be followed by transfaunation. Drugs used for this effect have included neomycin or tetracycline for ruminal alkalosis or urea toxicosis, and chlortetracycline or erythromycin for ruminal acidosis. Feeding changes and ruminal transfaunation are also effective in inhibiting the undesirable population and inoculating the desirable population. When spoiled milk, putrefactive ingesta, or extremely acidic ruminal contents are found on ruminal fluid analysis, rumenotomy, removal of the contents, and flushing of the rumen seem the more desirable treatment.

ACUTE RUMINAL ACIDOSIS. Therapy for cases of mild to moderate or chronic ruminal acidosis can follow the guidelines outlined previously. The prognosis in these cases is usually good, although ruminal inflammation and hematogenous dissemination of infection to other organs can produce chronic problems with a poorer prognosis.

Severe grain overload requires prompt and aggressive treatment. Animals showing severe depression, an unresponsive condition, apparent blindness, and gross ruminal distention warrant a grave prognosis. Immediate slaughter should be considered for animals with similar signs but still able to stand.

Emergency rumenotomy and removal of the acidic ruminal contents may be lifesaving if the procedure can be performed before significant amounts of ingesta have passed into the lower gastrointestinal tract. An alternative treatment in less severe cases is repeated flushing of the rumen with warm water through a large-bore stomach tube. Administration of magnesium hydroxide into the rumen and sodium bicarbonate solution (5%) intravenously is necessary to counter the acidosis. Intravenous fluid therapy should be continued until the animal has recovered to provide support against hypovolemic shock. Other treatments that may be considered include nonsteroidal antiinflammatory drugs and intraruminal antibiotics. The other therapeutic measures discussed such as transfaunation and dietary adjustment should be continued during the recovery phase.

SUPPORTIVE TREATMENTS. Indigestion often is accompanied by varying degrees of dehydration and electrolyte imbalance. When these abnormalities are only mild or moderate, the animal's fluid homeostasis may correct as the normal digestive processes are restored. More rapid recovery is achieved if these problems are addressed during the initial treatment, and animals must be treated if the imbalance is severe. Restoration of normal fluid balance improves attitude and appetite and normal gastrointestinal motility.

When laboratory facilities are available and the specific electrolyte imbalances can be assessed, fluid therapy can be tailored to the individual case. Empiric treatment with a balanced electrolyte solution administered intravenously is sufficient in most cases, because gross disturbances of the body fluid electrolytes are uncommon in most indigestions. The greatest exceptions to this are cases of severe ruminal acidosis or vagal indigestion with pyloric outflow failure and sequestration of abomasal chloride. These problems should be identified during the examination.

Hypocalcemia and hypokalemia are routinely present in many cases of indigestion. Low serum concentrations of these elements can produce muscular weakness and impair gastrointestinal motility. Both calcium and potassium should be included in the administered fluids. As an alternative, calcium salts should be administered subcutaneously if intravenous fluid administration is not elected. When anorexia has been prolonged, an additional oral dosage of potassium chloride (120 g/day) may be required even after adequate hydration has been achieved and fluid therapy has been discontinued.

Prevention

Some of the sporadically occurring diseases of the forestomach wall such as granulomatous infections, neoplastic invasions, and diaphragmatic herniation cannot be foreseen or prevented. The most common cause of vagal indigestion syndrome is inflammation of the reticular area caused by TRP. Prevention of this disease by keeping metallic foreign bodies out of the feed or by prophylactic administration of a ruminal magnet is the best prevention of vagal indigestion as well.

The microbial-fermentative forestomach disorders are best prevented by proper feeding management. A well-balanced diet of palatable feeds with an adequate amount of well-structured roughage (not

VetBooks.ir

finely ground or pelleted) prevents most problems. Dietary changes should be introduced slowly (over 2 to 3 weeks) to allow adaptation of the microbial flora to the new substrate. Calves undergoing ruminal development and cattle fed high-production diets or changing between production groups are at risk of oversights in proper feeding management. Some feed additives have proved effective in preventing the overgrowth of the high acid-producing ruminal microflora. Feed-grade buffers are widely used in both dairy and beef cattle production, in which high-concentrate diets are fed to maximize production. These buffers stabilize the ruminal pH and alter the mechanics of ruminal fluid outflow, thus decreasing the chances of overgrowth of the lactate-producing organisms. Commonly used "buffers" include sodium bicarbonate, sodium sesquicarbonate, sodium bentonite, magnesium oxide, and calcium-magnesium carbonate, of which only the sodium carbonates are truly buffering agents in the chemical sense. The other agents do tend to stabilize ruminal pH, however, and all of these have shown some benefit in reducing the disease problems associated with heavy grain feeding and diets that are low or marginal in effective fiber. The ionophore antibiotics (e.g., lasalocid, monensin) and some other antibiotics (e.g., the sulfur-containing peptide antibiotic thiopeptin) have also proved effective in reducing lactate production in animals fed high-grain diets. The effect of these agents is to suppress the lactate-producing organisms while not appreciably affecting the lactate users. The ionophores are in common use in feedlot cattle and dairy heifer rations because the selective effects of these antibiotics on the ruminal microbes alter the ruminal metabolism in a manner that promotes increased animal weight gain. In 2004 the FDA approved the use of the ionophore, monensin, for lactating cattle in the United States. Although approval was based on increases in milk production efficiency, ionophore use may also reduce the risk of ruminal acidosis and ketosis.[105]

Acute Abdomen in Ruminants

David Francoz • Gilles Fecteau • André Desrochers

Abdominal emergencies in ruminants are both a therapeutic and a diagnostic challenge for the veterinary practitioner. Some of them will require immediate surgical treatment, and others can be treated medically (Fig. 32-121). They are associated with numerous conditions that affect the abdominal cavity and can also be mimicked by diseases of extraabdominal origin (Fig. 32-122).

Four important questions should be addressed while dealing with an acute abdomen in ruminants: (1) Where does the pain originate? (2) Is it a medical or surgical problem? (3) Is medical treatment indicated before surgery? (4) What is the likelihood for survival and productivity? To answer these questions, the clinician should use a systematic approach based on adequate signalment and history, complete physical examination, and judicious choice of ancillary tests. Prognosis should be based on past experiences of others as well as one's own experience.

Even though a precise diagnosis facilitates the institution of appropriate treatment and helps to better predict outcome, emphasis should not be placed solely on the diagnosis. Precise information is not yet available for accurately making a prognosis on the outcome of an acute abdomen in ruminants.

A Concise but Precise Evaluation of the Animal

An animal with acute abdomen may need immediate medical assistance. Therefore the clinician should identify life-threatening problems and take appropriate action rapidly. Acute abdominal emergencies are often associated with either hypovolemic or septic shock.[1] Hypovolemic shock is characterized by increased heart rate, pale mucous membranes, slow capillary refill time, and dehydration.[1] Increased heart rate and dehydration are also observed in case of septic shock, but mucous membranes are hyperemic or bluish in color, and scleral vessels are engorged and dark.[1] Intensive fluid therapy is the treatment of choice for both hypovolemic and septic shock.[1] Consequently, an intravenous catheter should be placed and fluid therapy instituted immediately. However, a complete history and meticulous physical examination should be performed before emergency medical therapy if the condition of the patient is stable.

History

SIGNALMENT. Signalment may identify an animal at higher risk of particular diseases. Age, sex, breed, and production stage are important parameters to take into consideration when elaborating the differential diagnosis. For example, abomasal volvulus develops more frequently in dairy cows than in beef cattle.[2,3] Similarly, uterine torsions are essentially observed at the time of parturition or in the last trimester. Colic in a wether or a buck goat should be considered a result of urolithiasis until proven otherwise.

MANAGEMENT-FEEDING PROGRAM. Feeding management system (feeding cows with silage or a total mixed ration [TMR]), herd size (dairy farms with more than 100 cows), and high-intensity milk production are risk factors associated with the development of hemorrhagic bowel syndrome (HBS).[4] Use of wire on hay bales is associated with higher incidence of TRP. Struvite urolithiasis in cattle occurs more frequently in bulls or steers fed with high-grain diets.

HISTORY AND CLINICAL SIGNS. Previous history of surgery can be associated with the development of adhesions and colic. Recent calving and obstetric manipulations may cause a full-thickness uterine tear and subsequent peritonitis. Paralytic ileus associated with hypocalcemia is reported to occur during estrus.[5] Pleuritis, pleuropneumonia, or rib fractures may mimic abdominal pain. Previous treatments, especially those that can modify clinical signs or the interpretation of laboratory results, should also be noted. Administration of analgesics such as NSAIDs may partially control abdominal pain, attenuate signs of colic, and decrease the heart rate.

Description of the clinical signs observed by the owner and the chronologic sequence of events are of particular interest. Intussusception in cattle is characterized by an acute onset of anorexia, decreased fecal output (often with dark feces containing blood) and milk production, as well as colic. However, even though the abdominal pain eventually becomes less severe, the depression progresses.[6,7] Torsion of the mesenteric root has an acute onset with severe colic and rapid deterioration.[6,8,9] Fecal output, consistency, and appearance are relevant information. Stranguria manifested by unsuccessful micturition efforts is associated with urolithiasis.

Complete Physical Examination

A thorough and complete physical examination is the most important step when approaching an acute abdomen.

VISUAL EXAMINATION. The animal's abdominal profile or silhouette should be observed from the rear and both sides to detect and characterize abdominal distention. Bilateral ventral distention is associated with small intestine disorders, whereas distention in the right paralumbar fossa is associated with cecal and/or colon disorders. In cases of abomasal volvulus, the distended abomasum can be observed caudal to the last rib in the right paralumbar fossa. Gas in the rumen causes a distended upper left abdomen, whereas some forms of vagal indigestion have a "papple" shape (pear on the right and apple on left). Lateral views of the abdomen help to determine whether the distention arises primarily from the paralumbar fossa or extends cranially under the ribs. An arched back may be observed in cases of cranial abdominal pain, sole abscesses, or laminitis (sore feet).

Abdominal pain is an important criterion in deciding if surgery is necessary. Severe colics are classically associated with some surgical intestinal conditions,[6,10] although some animals with severe jejunal distention secondary to acute enteritis may have a similar clinical

VetBooks.ir

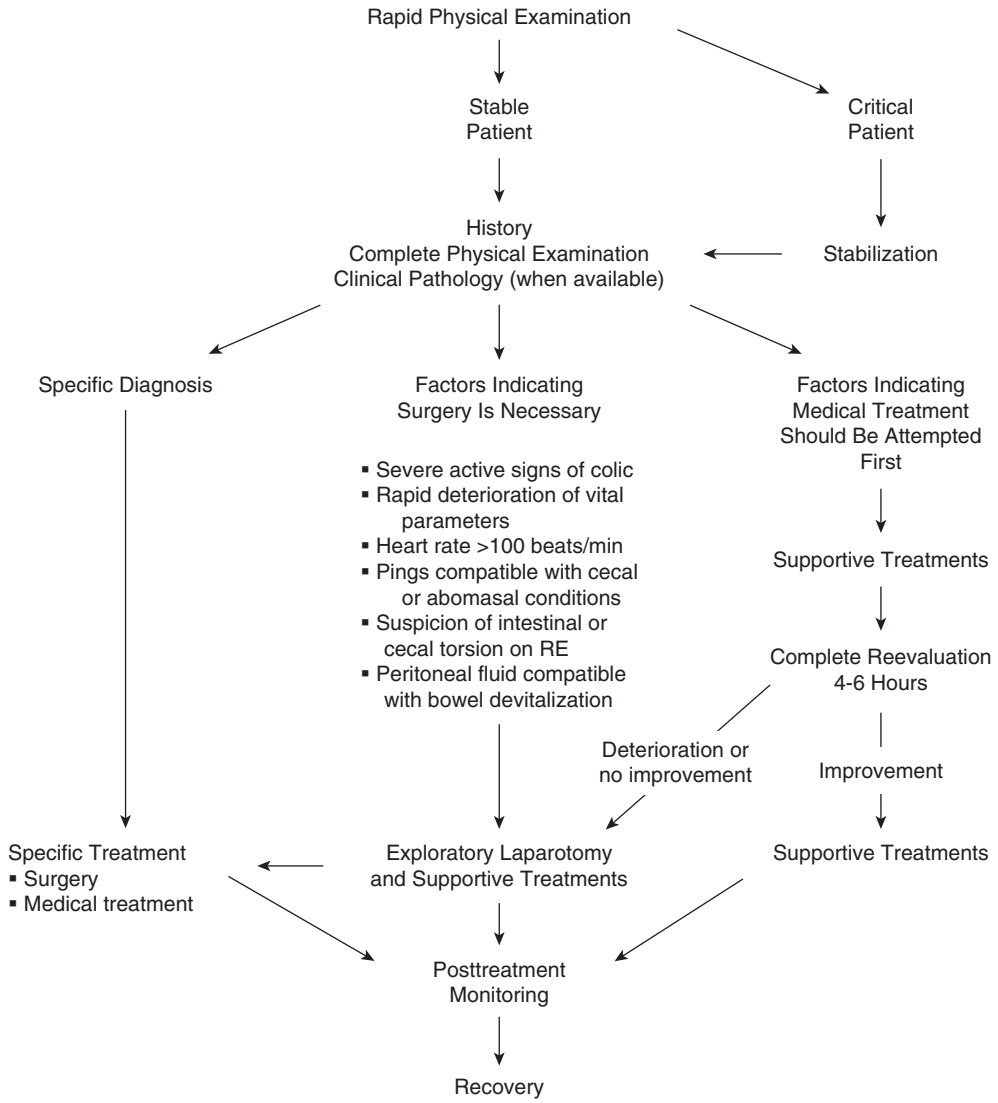

FIG. 32-121 Suggested decision tree for cattle with an acute abdomen. *RE,* Rectal examination.

presentation. Abdominal pain may be a consequence of excess distention of a hollow viscus (excessive intestinal distention), spasms of intestinal smooth muscles, stretching of the mesenteric supporting structure, intestinal ischemia, or chemical irritation of the visceral or parietal peritoneum.[11] Abdominal pain is classified into 2 main categories: visceral pain (hollow viscera and solid organs) and parietal pain (parietal peritoneum, abdominal muscles, rib cage).[11] Although the task is often difficult in animals such as cattle that have unpredictable behavior in response to pain, differentiation between visceral and parietal pain should be attempted in order to identify the cause of abdominal pain.

Pain sensation from the parietal peritoneum travels through the peripheral spinal nerves and usually localizes over the affected area.[11] Because parietal pain is exacerbated by pressure and tension modification, the patient is reluctant to move and has a tonic reflex contraction of the abdominal muscles.[12] No active clinical signs of colic are present. This is typically observed in cases of peritonitis. While reluctant the move, the animal has a splinted abdomen and is responsive to external palpation,[6] such as a positive xiphoid grunt test or not dipping the back when pinched over the withers.

Some pain fiber endings are located in the submucosa and muscle layers of hollow viscera (intestines, bladder) and in the capsule of solid organs (kidney, liver). Consequently, distention, forceful contraction, or traction will produce pain in a hollow viscus. Capsule stretching will create pain in solid organs. Visceral pain is typically recognized by active manifestations of colic: kicking at the abdomen; treading with the rear feet; lying down, standing, and stretching out and grinding the teeth. Goats may also vocalize. The animal is anxious and has an apprehensive attitude. Contrary to parietal pain, visceral pain is transmitted via sensory fibers in the autonomic nerves.[11] Visceral pain is often diffuse and difficult to localize.[11]

EVALUATION OF VITAL PARAMETERS. Assessment of cardiovascular status is essential in the evaluation of an animal with an acute abdomen. Hypovolemic and septic shocks are associated with increased heart rate, pale or hyperemic mucous membranes, slow capillary refill time, and dehydration. Normal to moderately elevated heart rate and adequate hydration status are considered good prognostic indicators regarding the outcome of abomasal volvulus.[13] Circulatory insufficiency, secondary to hypovolemia and caudal vena cava compression, is a complication of abomasal volvulus. Dehydration and acid-base abnormalities are principally caused by fluid accumulation in the abomasum and are associated with a high mortality rate.[13] Heart rate is increased secondary to hypovolemia, compression of the caudal vena cava, and sympathetic nervous system stimulation in response to distention and twisting of the abomasum.[13] Determination of rectal temperature, pulse or heart rate, and respiratory rate (TPR) should always be performed first, as manipulations performed during the physical examination of an abdominal emergency can elicit pain, modifying the heart rate.

VetBooks.ir

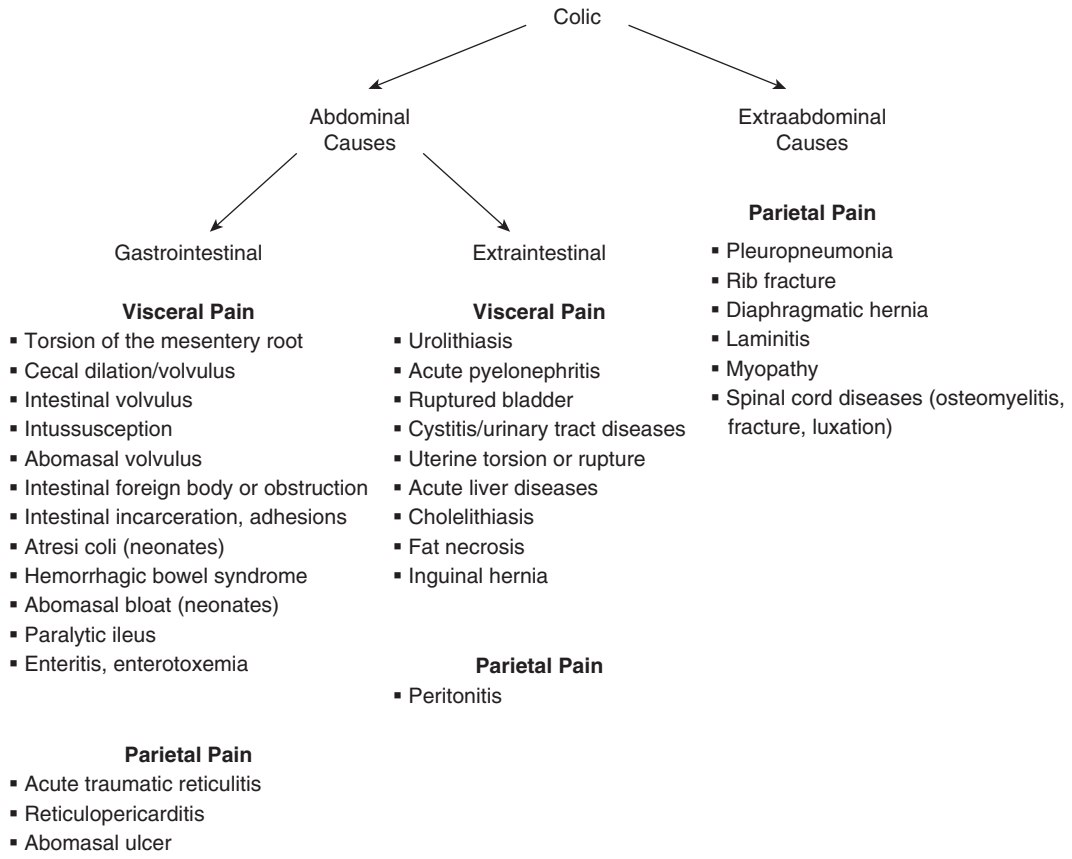

FIG. 32-122 Causes of colic (abdominal pain) in ruminants.

The TPR and amount of pain exhibited may also be used to monitor the evolution of the condition and the response to the initiated treatment.

EXTRAABDOMINAL EXAMINATION. Once vital parameters have been evaluated and the animal appears hemodynamically stable, a thorough complete physical examination of all body systems is performed. Examination of the thorax (pleuropneumonia, rib fractures) and the musculoskeletal system (laminitis, myopathy) are important in eliminating diseases that mimic abdominal pain.

ABDOMINAL EXAMINATION. Abdominal examination is performed by auscultation, percussion, ballottement, and succussion of the abdomen. Pings are tympanic resonance caused by a gas-fluid interface in a distended organ and can be detected by simultaneous auscultation and percussion. Because rectal palpation may create an area of increased resonance on the right dorsal part of the abdomen, detection of pings should be performed before rectal palpation. On the right side of the abdomen, many organs may be responsible for pings. Location, pitch characteristics and variability of the ping are essential to establish a differential and precise diagnosis. Pings localized from the thirteenth rib cranially to the ninth rib are typical of abomasal volvulus or a right-displaced abomasum.[6] Cecal dilation or volvulus creates a ping in the right paralumbar fossa and caudal quadrant,[6] often extending to the hip. Abomasal volvulus will be more likely to have a high-pitched ping, whereas animals affected with peritonitis may have a bilateral low-pitched ping in the upper paralumbar fossa. In normal animals, a monotone pinging area of 15 to 20 cm centered just under the last rib corresponds to gas in the spiral colon (see Chapter 1, Fig. 1-3). Moving or constantly contracting viscera will have changing pitch of their pings, like gas in the descending duodenum, or proximal colon. For this particular reason, it is important to auscultate and percuss for a certain period of time to notice ping variation.

On the left side, pings are principally associated with left abomasal displacement, ruminal collapse, and pneumoperitoneum. Left abomasal displacement typically creates pings dorsally from the eighth to the thirteenth ribs. Pings associated with gas in the rumen, ruminal collapse, and pneumoperitoneum are localized dorsally in the left paralumbar fossa and extend cranially to the eleventh rib. Illustrations and details are presented in Chapter 1 of this textbook. Simultaneous auscultation and ballottement (succussion) of the abdomen may permit detection of fluid-filled viscus with an interface of gas like rumen or abomasum. The location of the fluid splashing sounds on auscultation-succussion may help to confirm and differentiate among auscultation-percussion findings. Tense abdominal muscles, secondary to parietal peritoneum inflammation (parietal pain), may also be detected during succussion.

Cattle with cranial abdominal pain are reluctant to move; they stand with elbows abducted and back arched.[6] During examination, bruxism (grinding of the teeth) may be present.[6] Pain can be elicited by pinching over the withers or applying forceful movement with the knee or upward pressure with a bar or pole over the xyphoid area or anterior abdomen. In response, the animal in pain may grunt or kick and be reluctant to dip the back when the withers is pinched.[6] Sensitivity of this test may be increased by simultaneous auscultation of the trachea. Cranial peritonitis, secondary to TRP or abomasal ulcers, is an important cause of cranial abdominal pain. A complete cardiorespiratory examination may help to differentiate this from thoracic pain.

RECTAL PALPATION. Per rectum abdominal palpation of cattle is an essential part of the acute abdomen physical examination. However, the size of the abdomen limits the systems or organs that can be palpated.

Cecal disorders are clearly diagnosed per rectal palpation. Moreover, cecal dilation or retroflexion can often be differentiated by location of the apex. Based on these findings, medical treatment can be

VetBooks.ir

started if the caecum is only dilated and the apex is mobile. A firm mass palpated in multiple, dilated, turgid small intestine loops is a typical finding of intussusception[7] or HBS.[4] Adhesions between the kidneys and the rumen, the intestinal convolutions, and decreased rectal mobility in the posterior abdomen are characteristics of a chronic peritonitis. Uterine wall integrity may be evaluated during rectal palpation, although examination per vagina may be necessary to confirm a full-thickness laceration in the early postpartum cow. Feedlot steers with urolithiasis will have a pulsatile pelvic urethra and a distended bladder at rectal palpation. In cases of pyelonephritis, enlargement of one or both ureters may be palpated. Normally, only the left kidney can be palpated per rectum: If infected, it will be painful to the touch, larger, and lobulation less obvious. Pathologic right kidneys are exceptionally reached per rectum especially if hydronephrotic. In small ruminants, urolithiasis is manifested by pulsations in the pelvic urethra that may be felt by digital rectal examination. Distended bladder or enlarged kidney can be detected by deep abdominal palpation and vocalization will be elicited on palpation of the distended bladder.

Presence and macroscopic appearance of feces can be evaluated during rectal examination. Decreased, or absence of, feces is principally associated with intestinal stasis or obstruction, which may occur secondary to a direct mechanical obstruction (requiring surgical treatment) or to gastrointestinal ileus (requiring only medical treatment). However, feces may be present in the first few days following an intestinal obstruction.

Ancillary Tests

PACKED CELL VOLUME AND TOTAL SOLIDS. Shock, sepsis, and toxemia cause hemoconcentration and dehydration and are associated with an increase of PCV and total solids. On the other hand, increased PCV and decreased total solids are observed during the formation of a third compartment filled with a protein-rich fluid such as in generalized peritonitis.[14] In one study, the serum total protein concentration was significantly lower in cows with septic peritonitis when compared with cows suffering from nonseptic peritonitis.[15]

BLOOD GAS ANALYSIS AND ELECTROLYTES. Blood gas analysis as well as determination of electrolyte imbalance may be useful before initiation of treatment. Most adult ruminants with acute abdominal diseases suffer from metabolic alkalosis.[16] Metabolic alkalosis is often associated with abomasal volvulus, intussusception, cecal disorders, abomasal ulcers, peritonitis, renal diseases, and reticuloperitonitis.[16] Hypochloremia and hypokalemia are frequently combined with metabolic alkalosis.[17] Metabolic acidosis may be observed if urinary tract disease, small intestinal strangulation or obstruction, or enteritis with severe diarrhea is present.[16]

Serum chloride concentration, anion gap, and base excess have been proposed as preoperative prognostic indicators in dairy cattle suffering from abomasal volvulus. Poor short-term prognosis was associated with serum chloride concentrations less than 79 mEq/L,[18] base excess values of −0.1 or less,[19] and anion gap values of more than 30 mEq/L.[20] However, a prospective study on the outcome of abomasal volvulus reported that serum base excess and anion gap values did not differ between productive and nonproductive animals.[13] In this study, serum chloride concentration was significantly lower in nonproductive animals, but this prognostic test had numerous false-negative results.[13]

Blood gas analysis and electrolyte measurement results are helpful in the institution and monitoring of fluid therapy.

BLOOD LACTATE CONCENTRATION. Blood lactate concentration is frequently used to assess a compromised cardiovascular or respiratory system, to monitor the response to treatment, and to establish a prognosis for survival. Portable analyzers are now available, making this diagnostic test easily available. In cattle, blood lactate concentrations have been reported to be higher in animals with abomasal volvulus in comparison with animals with left abomasal displacement.[21] Elevated blood lactate was associated with a poor outcome for right abomasal displacement/volvulus in one study,[22] whereas Constable and co-workers did not find any association in their study.[23] In humans,[24,25] and horses[26] blood lactate concentrations are an important indicator of adequate response to treatment and reperfusion of ischemic tissues.

COMPLETE BIOCHEMICAL PROFILE. Evaluation of specific enzyme activity (e.g., hepatic enzymes, BUN, and creatinine) combined with physical examination and other ancillary tests may be useful in establishing a diagnosis and assessing progress.

WHITE BLOOD CELL COUNT AND DIFFERENTIAL. Hematologic findings are rarely specific to a condition and reflect the underlying inflammatory process. In most cases a minimal to moderate inflammatory process characterized by a neutrophilic leukocytosis is observed. Hematologic findings may also provide information about the acuteness of the disease and the severity of the sepsis and toxemia associated. Severe sepsis is associated with neutropenia, degenerative left shift, toxic changes of neutrophil morphology, and lymphopenia. Hematology is also an important ancillary test to monitor the response to treatment.

FIBRINOGEN. In ruminants, increased fibrinogen concentration is an early indicator of inflammation. Studies in cattle report that fibrinogen concentration may increase within 1 to 2 days after induction of inflammatory conditions.[27] Consequently, increased fibrinogen concentration may be observed in some cases of acute abdomen. Normal fibrinogen concentration despite severe visceral involvement should be observed only in peracute cases (within a few hours) (e.g., torsion of the root of the mesentery). Moderate to marked increased fibrinogen concentration is also the signature of chronic active localized inflammatory condition such as reticuloperitonitis, liver abscesses, or pyelonephritis.

URINALYSIS. Urinalysis is helpful in differentiating between colic of urogenital origin versus gastrointestinal disorders. Urinalysis can be rapidly performed using a urinary dipstick (Chemstrip 9, Roche Diagnostics Corporation, Indianapolis, IN) and gross morphologic examination. Renal diseases are associated with proteinuria (>1+), glucosuria, and positive blood reaction. In case of acute urethral obstruction, hematuria and proteinuria are consistently observed. Determination of urinary specific gravity before fluid may help to characterize azotemia.

ABDOMINOCENTESIS. Abdominocentesis is considered an essential ancillary test in the approach to acute abdomen in many species[1,28] including cattle.[6] Because of the ability of cattle to wall off and localize infections in the abdomen, a four-quadrant method of abdominocentesis is suggested by some authors.[6] Ultrasonography can be used to find abnormal fluid location or quantity, improving the precision of the abdominocentesis site. Fluid can be evaluated macroscopically for color, volume, odor, and turbidity. Normal values are reported in the section of this chapter on peritonitis. Peritoneal fluid changes to cloudy yellow, then blood-tinged with fibrin, and finally to black in color as bowel necrosis and hemolysis of extravasated RBCs occur. In case of generalized peritonitis, fluid is abundant, cloudy, and sometimes foul-smelling. Occasionally, digestive fibers can be observed macroscopically if rupture has occurred.

Different parameters may be evaluated in peritoneal fluid. D-dimer, lactate, glucose, alkaline phosphatase and pH of the peritoneal fluid concentrations have been reported to be indicators of intestinal ischemia and peritonitis in horses.[29,30] In one cattle study, decrease in peritoneal fluid glucose concentration was a sensitive and specific marker of septic peritonitis.[15] D-dimer is also elevated in cases of ischemic and inflammatory abdominal conditions.[15,21] L-lactate measurement could also be a useful diagnostic tool for the evaluation of various abdominal ischemic conditions in cattle.[21]

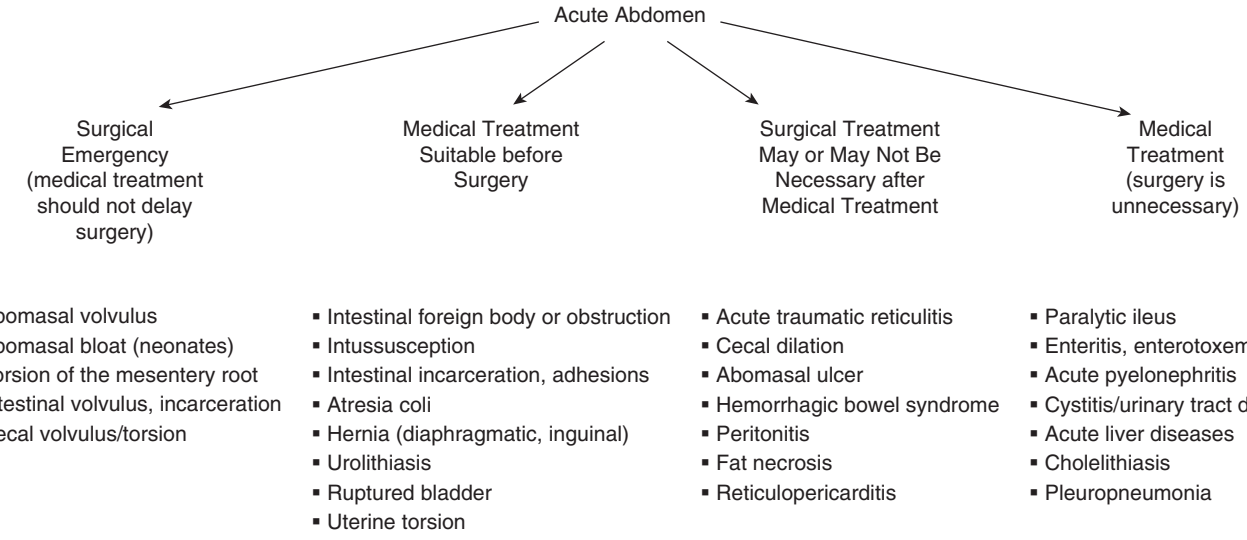

FIG. 32-123 Classification of abdominal causes of acute abdomen based on the need for surgical exploration or medical treatment.

Diagnostic Imaging

ULTRASONOGRAPHY. With the advance of multifrequency abdominal transducers, ultrasonography is used more frequently in ruminant medicine. Information on ultrasound of the ruminant abdomen is available in this chapter.

RADIOGRAPHS. Radiographic images in adult cattle are obtained with powerful machines only available in referral centers. They are one of the most helpful ancillary examinations for the diagnosis of reticuloperitonitis.[31,32] Abdominal radiographs were used for the diagnosis of intestinal atresia and intussusception in calves.[6]

A lateral view of the abdomen of small ruminants may help for the diagnosis of urolithiasis since stones in the urethra or in the bladder may be detected.

Medical or Surgical Decision

A differential diagnosis list and a decision for surgical or medical treatment should be established based on clinical signs and ancillary tests results (Fig. 32-123). If a precise diagnosis is made, adequate treatment can be instituted. When a precise diagnosis cannot be established, attempts should be made to differentiate surgical and medical cases (see Fig. 32-119). Any animals with elevated heart rate, distended organ on rectal palpation, and lacking feces are surgical candidates even if a definitive diagnosis cannot be established. Among surgical cases, intestinal obstructions are those requiring immediate surgery. A mechanical obstruction may be suspected when there is a suspicion of intestinal or cecal torsion on rectal examination, pings indicating a right abomasal displacement or volvulus, peritoneal fluid indicating bowel devitalization, or severe signs of active colic or rapid deterioration.[10] If an intestinal mechanical obstruction is not suspected during the first examination, exploratory surgery may be delayed for up to 36 hours.[33] However, frequent monitoring should be performed and appropriate medical treatment provided to the animal.

SURGERY. Most abdominal surgeries in adult cattle are performed with the animal standing under sedation and local or regional anesthesia. Cattle can tolerate intestinal resection and anastomosis standing if adequate local anesthesia and systemic analgesia are provided. However, some animals will be reluctant to stand because of the primary condition or secondary to electrolyte imbalance. Any traction on the mesentery is painful enough to make an animal go down during the procedure. Surgery should be performed with the animal in recumbency if it is extremely painful or weak and likely to lie down. Because a right paralumbar fossa celiotomy provides the best exposure to the intestinal tract, left lateral or sternal recumbency should be favored. Other than the general status of the animal, the suspected affected organ, presence of aggressive behavior, surgeon preferences, and facilities should be considered in the choice of doing the surgery with the animal standing or in recumbency. If the animal is dehydrated and/or manifests signs of shock, preoperative fluid therapy and analgesics are recommended. For the prevention of surgical infection, appropriate preoperative antibiotic administration is also recommended.

MEDICAL AND SUPPORTIVE TREATMENT. The goal of therapy in an animal with acute abdomen is to initially correct the hemodynamic and metabolic imbalances associated with hypovolemic or septic shock, to control pain, and to correct or treat the primary cause of the disease, when identified. Consequently, medical treatment is based on fluid therapy, NSAIDs, and antimicrobial drugs.

Fluid Therapy. Crystalloid solutions (0.9% NaCl, Ringer's solution) are indicated initially to replenish fluid loss and improve the circulating blood volume. To resuscitate critically ill neonatal patients, recommended intravenous fluid administration rates of isoosmotic crystalloid solution are 80 to 90 mL/kg of body weight per hour.[34] However, such rates are difficult to achieve through a catheter in adult ruminants. Studies demonstrated that perfusion rates of 40 and 80 mL of an isoosmotic crystalloid solution per kilogram of body weight per hour can be used safely in adult ruminants and dehydrated calves, respectively.[35-37] If the animal is not critically ill, fluid and electrolyte deficits should be corrected over 2 to 8 hours. The maximal flow rate usually achieved through a catheter in an adult is 15 to 20 mL/kg/h.

Hypertonic solutions (7.2% or 7.5% NaCl) are also an alternative. Intravenous administration of hypertonic saline provides rapid resuscitation in dehydrated or endotoxemic ruminants.[38] A rate of 4 to 5 mL of hypertonic solution per kilogram should be administered IV through the jugular vein over 8 to 10 minutes. Animals should be provided with a supply of fresh water immediately after the treatment, or an intravenous infusion of an isotonic crystalloid solution should be instituted. Cattle not observed to drink within 5 minutes should have 20 L of water pumped into the rumen.[38] An administration rate for a hypertonic solution of over 1 mL/kg/min should be avoided because it induces a potentially fatal hypotension coupled with a decrease in cardiac contractility.[38]

Correction of Acid-Base and Electrolyte Imbalances. Correction of electrolyte imbalances should be based on laboratory results when available. Previous treatments should be considered (e.g., intravenous calcium, orally administered magnesium hydroxide) to initiate the most appropriate fluid therapy if no laboratory

VetBooks.ir

VetBooks.ir

results are available.[17] Most animals with acute abdominal diseases suffer from metabolic alkalosis, hypochloremia, and hypokalemia.

Calcium homeostasis is in a precarious balance in postpartum dairy cattle. Hypocalcemia is common in ruminants with gastrointestinal disorders or simply anorexia, particularly in lactating cows.[16,34] Moreover, metabolic alkalosis, frequently observed in cases of acute abdomen, is strongly associated with subclinical hypocalcemia.[5,39] Calcium ions are of particular importance in gastrointestinal motility. First, in the gastrointestinal smooth muscles, the channels responsible for generating action potentials are calcium-sodium channels.[40] Second, gastrointestinal smooth muscle contraction occurs in response to the entry of calcium into the muscle fiber.[40]

Based on these considerations, the intravenous solutions used for the medical treatment of acute abdomen, secondary to a suspected digestive disorder, should contain Na, Cl, K, and Ca.

The Ringer's solution containing 8.6 g of NaCl per liter, 0.3 g of KCl per liter, and 0.3 g of $CaCl_2$ per liter, yielding 147 mEq/L Na, 155 mEq/L Cl, 4 mEq/L K, and 4 mEq/L Ca, is the commercially available solution of choice. In our clinics in Quebec, we use a beneficial homemade solution composed of 7.5 g of NaCl per liter, 1.5 g of KCl per liter, and 5.75 g of Ca^{2+} per liter (25 mL of 23% calcium borogluconate per liter), yielding 128 mEq/L Na, 148 mEq/L Cl, 20 mEq/L K, and 26 mEq/L Ca, for adult cattle. We usually begin our fluid therapy with rapid administration of a 0.9% NaCl solution (15 to 20 mL/kg/h, which is the highest rate possible through a catheter) for rapid correction of dehydration and then administer this homemade solution with an infusion rate of approximately 4 to 5 mL/kg/h.

Control of Pain and Inflammation. Pain and inflammation are important causes of gastrointestinal hypomotility (see Fig. 32-122). Gastrointestinal pain increases sympathetic tone, causing general inhibition of the gastrointestinal tract.[40-42] Numerous inflammatory mediators are released during disease of the gastrointestinal tract, leading to alteration of intestinal motility.[41,43] Peritoneal inflammation or irritation and associated pain are well-recognized initiating factors of ileus in multiple species.[41,43] Release of proteinases, vasoactive substances, free oxygen radicals, and endorphins secondary to ischemia and reperfusion injury, or to endotoxemia, impairs cardiovascular function and decreases gastrointestinal motility.[43] Inflammatory mediators lead to a pain response and modulate the intensity of noxious stimuli.[41,42] Consequently, analgesic and antiinflammatory drugs appear essential in the management of acute abdomen. These drugs must be used with caution. NSAIDs may induce abomasal ulcers, particularly in an anorectic patient. Analgesics may mask clinical signs (pain, fever) and compromise adequate case management by delaying surgery.

NSAIDs are the most commonly used drugs for gastrointestinal pain management in cattle. There is no information comparing the efficacy of the different NSAIDs available in food animal medicine related to their use in the management of acute abdomen. Some authors report that, based on clinical observations, flunixin provides an excellent visceral analgesia.[44] Preoperative administration of flunixin was demonstrated to have a positive impact on animal recovery after left abomasal displacement surgery.[45] Ketoprofen and flunixin appear to have similar activities in endotoxic calves.[46] Consequently, no single NSAID can be recommended based on scientific evidence for the management of abdominal emergencies in cattle. The choice of NSAID becomes a matter of previous experience, comparative medicine, legislation, and cost. In our experience, flunixin and ketoprofen are both adequate for the management of acute abdomen in cattle. In equine gastrointestinal pain, a poor or short duration response to NSAIDs indicates a need for surgery.[42] This principle can be applied to cattle with caution because of their different behavior in response to pain.

α_2-Agonists that function as sedatives and analgesics, such as xylazine, detomidine, and medetomidine, could also be used to relieve pain in cases of acute abdomen. All are considered to be strong analgesics that can alleviate most visceral pain, at least temporarily, in equine medicine.[42] There are few data on the use of α_2-agonists for the management of acute abdomen in cattle. In a cow with a large intestinal obstruction, signs of abdominal discomfort disappear immediately after the administration of a single dose of xylazine (0.05 mg/kg IV) for at least 1 hour.[47] Different side effects must be considered before the administration of α_2-agonists. Xylazine is reported to have significant effects on the gastrointestinal tract in cattle, decreasing reticuloruminal and intestinal motility.[48] Because of the hemodynamic changes associated with the administration of α_2-agonists, these drugs must be used with caution in hypotensive patients and/or those suffering from shock.[49] α_2-agonists can mask surgical pain and delay the decision for surgery. This is particularly critical with the use of detomidine.[42] Finally, dose and administration of α_2-agonists should be used with care if standing surgery is planned, as they may encourage the animal to lie down.

Opioids, morphine or butorphanol can also be used alone or in combination for the control of abdominal pain. Information on their use in this way in cattle is lacking. To our knowledge, opioid usage was studied in cattle in castration, dehorning, and preoperative analgesia but never for abdominal pain control. In our clinic, following the diagnosis of a nonsurgical process or correction of a surgical process, we use morphine (0.1 mg/kg, IM or SC), or butorphanol (0.05 to 0.1 mg/kg, IV, IM, or SC) or a continuous rate infusion of a combination of ketamine (0.2 mg/kg/h) and butorphanol (0.02 mg/kg/h).

Finally, lidocaine may be used for their analgesic effect as well as their potential motility modifier effects. As described in horses, a continuous IV administration of lidocaine at a rate of (3 mg/kg/h) after an initial dose of 1 mg/kg (IV, over 15 min) can be administered. However, no data are actually available of its effect on the control of pain and on the gastrointestinal motility in cattle.

Antimicrobial Drugs. Bacterial translocation from the intestines can occur in cases of mechanical or functional ileus secondary to bacterial overgrowth, inflammation, and impairment of barrier function of the intestinal wall.[43,50] A systemic broad-spectrum antibiotic treatment should be instituted when a septic process is suspected, until bacterial culture results become available. This initial antibiotic therapy should be effective against gram-negative, gram-positive, aerobic, and anaerobic pathogens. The choice of antibiotic should also take into consideration legal aspects and the cost of the treatment. β-Lactams, tetracyclines, and trimethoprim-sulfadoxine appear to be good choices. In cattle there is no accepted recommendation for the duration of treatment. In human medicine, prolonged broad-spectrum antibiotic therapy in cases of surgical acute abdomen does not appear beneficial.[51] Prevention of infective complications was not affected by prolonging the course of antibiotic treatment.[51] In human medicine the current recommended dose is a single prophylactic antibiotic administration when there is no or minimal evidence of contamination, and 5 to 7 days when pus or contamination, either localized or diffuse is present.[51]

Other Treatments. The use of purgatives (magnesium hydroxide, mineral oil, liquid paraffin) in cases of suspected gastrointestinal obstruction or ileus in cattle has no therapeutic basis. Moreover, these treatments may exacerbate the condition. Because the intestines are already filled with gas and fluid, purgatives only impose additional distention. In human medicine, laxatives are frequently used for the treatment of postoperative ileus (POI); however, no study could demonstrate their actual benefit.[52] Braun and colleagues reported that the use of purgatives for the treatment of cecal disorders delayed the time to first defecation.[53] Moreover, magnesium hydroxide may be responsible for detrimental effects such as decreased potassium absorption, metabolic alkalosis,[54] sedation caused by hypermagnesemia,[54] increased ruminal pH,[55] and decreased ruminal microbial activity.[55]

Motility-modifying agents may be used in the management of gastrointestinal disorders. In most cases intestinal motility is restored when pain is relieved and electrolytic imbalances are corrected. Steiner[48] and Constable and colleagues[56] reviewed the different prokinetics that can be used in ruminant medicine and their

VetBooks.ir

clinical implications. In cattle, based on their reviews, erythromycin (10 mg/kg, IM, bid for 2 days, Erythro-200[48] or 8.8 to 10 mg/kg IM[56]) is the most effective drug for the treatment of abomasal hypomotility and can be used for the postoperative treatment of abomasal displacement or torsion. Bethanechol (0.07 mg/kg, SC, tid for 2 days, not approved for food animal use in the United States) alone or in combination with metoclopramide (0.1 mg/kg, SC or IM, tid for 2 days, not approved for food animal use in the United States), increased the contractility of abomasal smooth muscles, but no data on in vivo efficacy are available.[48,56] Metoclopramide alone is ineffective in cattle and sheep for the treatment of abomasal hypomotility.[48,56] Bethanechol (0.07 mg/kg SC tid for 2 days; not approved for food animal use in the United States) can be used for conservative or postoperative treatment of cecal disorders and treatment of paralytic ileus.[48] Contrary to cattle and sheep, in goats metoclopramide (0.5 mg/kg IM or IV; not approved in the United States) has been reported to significantly increase myoelectric activity of the duodenum.[48] Continuous infusion of neostigmine (87.5 mg in 10 L of sodium chloride-glucose infusion at 2 drops/sec per cow) was successfully used for the conservative and postoperative treatment of cecal disorders.[53] In this clinical report, this protocol was preferred to those previously reported (neostigmine SC every hour over 2 to 3 days in doses that gradually decreased from 12.5 mg to 2.5 mg.[53] Drug administration was easier and involved fewer disturbances for the animal.[53] However, no control group was included in this study. Also, neostigmine has been reported to have a pronounced effect on intestinal contractility, causing uncoordinated spikes to become more frequent, thereby compromising the potential beneficial effect.[57]

No prokinetic drug is reported to directly increase ruminal motility. In cases of prolonged anorexia or acute indigestion, ruminal flora can be disturbed and reduced. Transfaunation may help to rapidly reconstitute the ruminal flora and hasten return to normal function of the rumen and the digestive tract. The technique for and beneficial effects of transfaunation (reduction of ketonuria, increased feed intake, and higher milk yield) have been reported in the postsurgical treatment of left abomasal displacement.[58]

Follow-Up

When a definitive diagnosis cannot be made, close monitoring of the animal may be indicated. Follow-up must also be performed secondary to surgery to ensure adequate response to surgical treatment and to allow possible adjustment of treatment. In a referral hospital the animal should be reevaluated every 4 to 6 hours. In field practice, vital parameters, rectal examination, presence and consistency of feces, and pain may be reevaluated every 6 to 12 hours. A significant reduction of heart rate was observed 4 and 6 hours after the initiation of treatment in cases of cecal dilation.[53] Feces are usually passed within 4 to 6 hours after surgery in cases of intestinal volvulus or cecal disorders. Failure to defecate for 24 hours or more is abnormal in cattle and therefore indicates persistence of intestinal obstruction and may adversely affect the prognosis. Deterioration or persistence of clinical signs despite the initiation of supportive treatment is also an indication for surgery. Surgical exploration is indicated if the following clinical signs are observed: persistence of colic, development of abdominal distention, heart rate over 100 beats/min, scant feces, typical abomasal or cecal pings, or paracentesis indicating bowel devitalization.

The decision for surgery or medical treatment remains challenging in cases of acute abdomen in ruminants. Optimal management of acute abdomen prevents any unnecessary delay in cases requiring surgery and avoids unnecessary surgery. Knowledge of diseases associated with signs of acute abdominal pain is important, but no clinical signs are specific for a particular problem, and a specific diagnosis cannot be established postoperatively in many cases. Based on a systematic approach to clinical examination and a judicious use of ancillary tests, the clinician may be able to identify cases that require immediate or delayed surgery, avoid unnecessary surgery, and establish a cost-effective management plan.

Traumatic Reticuloperitonitis (Hardware Disease, Traumatic Reticulitis)

David Francoz • Charles L. Guard

Definition and Etiology Traumatic reticuloperitonitis (TRP), also called hardware disease, is a common disease of cattle but is rarely seen in small ruminants. It is the most common cause of anterior abdominal pain in cattle. The ingestive behavior of cattle predisposes them to the accidental swallowing of metal foreign objects that settle in the reticulum. Ingestion of a foreign body may also be associated with diseases that cause pica, such as phosphorus deficiency. Subsequently, the foreign object may enter the reticulum and (1) attach to a magnet and prevent any clinical disease; (2) penetrate the reticulum wall only with intramural inflammation; (3) perforate the reticulum wall, penetrate into the peritoneal cavity, and create a localized peritonitis; or (4) migrate into the peritoneal and thoracic cavities.[1] The diaphragm, pericardium, and heart muscle are located just cranial to the reticulum, with the liver positioned medially and dorsally and the spleen laterally and dorsally. These organs may sometimes be penetrated by foreign bodies and become involved in the inflammatory process.

Clinical Signs and Differential Diagnosis TRP in the most severe, acute form is characterized by fever, anorexia, decreased or absent ruminal contractions, and evidence of cranial abdominal pain. Pinching of the withers or upward pressure on the xiphoid region may elicit a grunt on expiration. Affected cattle may stand with an arched back and resist ventral flexion of the back when pinched over the withers (normal cattle flex ventrally). Some cattle grunt spontaneously when forced to move or when defecating or urinating. Lactating cows show a sudden decrease in milk production. Some cows regurgitate ruminal fluid, especially if the oropharynx is mechanically stimulated. Tachycardia, reluctance to move or lie down, mild bloat, constipation, or abducted elbows may also be seen. These typical signs often abate within the first day or two, making diagnosis more difficult. Sudden death has occurred as a result of the laceration of a coronary blood vessel or puncture of the heart by the foreign body.

Less severe or more long-standing cases may have signs that are more subtle and confusing. Cows in early lactation may have ketosis; however, a distinguishing feature of hardware disease is the abrupt onset of anorexia and hypogalactia. Fever may be absent. Weight loss, rough hair coat, diarrhea, or generalized lameness, along with cranial abdominal pain that is difficult to localize, may be the only signs.

If the pericardial sac has been seeded with bacteria, pericarditis usually develops. Clinical signs of pericarditis are presented in detail in Chapter 30. In addition to the clinical signs previously described for TRP (decreased appetite, fever, tachycardia, signs of pain), muffled heart sounds, jugular vein distention, and edema of the submandibular region, brisket, and ventral abdomen are typically observed.[2]

The foreign body may penetrate the liver or spleen, leading to abscess formation. These abscesses as well as reticular adhesions may be responsible for ruminoreticular outflow problems and may lead to vagal indigestion.[3]

TRP must be differentiated from other causes of cranial abdominal pain. They mainly include abomasal ulcers, hepatic abscesses from other causes, and pleuritis. More information about the differential diagnosis of abdominal pain is presented in the section on acute abdomen in cattle. When thoracic structures are involved, TRP must be differentiated from primary pneumonia or pleuritis, diaphragmatic hernia, and heart diseases such as endocarditis, lymphosarcoma of the heart, and cor pulmonale. Finally, TRP must be differentiated from others causes of ruminal distention and vagal indigestion (although TRP is a leading cause of vagal indigestion).

VetBooks.ir

Clinical Pathology The white blood cell (WBC) count and differential, as well as the determination of plasma proteins and fibrinogen, may indicate an acute or chronic inflammatory process depending on the stage of the TRP. Neutrophilia and a left shift, as well as hyperfibrinogenemia, are expected in acute cases. However, in more chronic cases, changes are less pronounced, and WBC count as well as differential may be normal,[1] but modification associated with chronic inflammatory diseases such as erythrocytopenia, thrombocytopenia, and hypohemoglobinemia may also be noted.[4,5] Gokce and colleagues[4] also reported longer activated partial thromboplastin time, prothrombin time, and thrombin time in cattle affected by TRP in comparison with a control group of healthy cattle.

High total plasma proteins, primarily reflecting high globulin levels, are expected in chronic cases of TRP.[4,6] Higher concentration of total plasma proteins has been observed in cases of TRP compared with other abdominal disorders.[7,8] Plasma protein concentration cutoff points of 87 to 100 g/L have been proposed in these studies. High fibrinogen concentration may be observed in acute (2 to 3 days after the beginning of the disease) and chronic cases. Studies in referral centers have demonstrated highest plasma fibrinogen concentration compared with other abdominal disorders.[7-9] Cutoff points have also been reported in these studies for the differentiation between TRP and other abdominal disorders. Jafarzadeh and colleagues[8] proposed a value of 6.91 g/L (with a sensitivity and specificity of 81% and 72%, respectively) whereas Nazifi and colleagues[9] suggested a value of 5.7 g/L (with a sensitivity and specificity of 32% and 100%, respectively). However, other inflammatory disorders can induce the same modifications, and absence of these abnormalities does not rule out TRP. Consequently, other diagnostic tests (diagnostic imaging) must be performed to confirm the diagnosis. Serum amyloid A (SAA) and haptoglobin concentrations have also been reported to be increased in case of TRP.[7,9,10] Cutoff points for the differentiation between TRP and other gastrointestinal disorders of 0.67 and 0.74 g/L for haptoglobin and 68 µg/mL for SAA have been reported. [7,9] These two parameters seem to be more accurate than plasma fibrinogen or protein concentrations for the differentiation between TRP and other gastrointestinal disorders.[7,9]

Biochemical profile and blood gas analysis are usually within normal range but may reflect anomalies associated with ileus and vagal indigestion such as hypochloremic metabolic alkalosis, hypokalemia, and hypocalcemia.[5,6] Other abnormalities reported include increases in specific and nonspecific indicators of liver damage (such as AST, ALP, LDH, and bilirubin),[1,4,5] and increases in specific and nonspecific indicators of skeletal or cardiac muscles (such as CK [CK-MB], LDH, AST, and cardiac troponin).[4-6]

Radiography and ultrasonography of the reticulum are very useful for the diagnosis of TRP. Radiographs of the reticulum are limited to referral to a location where powerful equipment is available. They are performed on standing animals and allow the detection of a metallic foreign body and the determination of its location in or outside the reticulum. Different parameters may be observed on radiographs for the diagnosis of TPR; they include presence or absence of a foreign body, position of the foreign body, presence of focal gas shadows or gas-fluid interface near the reticulum, and the shape, size, and location of the reticulum.[11-13] Of these parameters, location of the foreign body is the most reliable indicator for the diagnosis of TPR.[11,13] Ultrasonography of the reticulum is presented elsewhere in this chapter. Ultrasonography and radiography are complementary methods that provide different and useful information for the diagnosis and management of TPR.[14] Ultrasonography is also the most useful complementary examination for the diagnosis of pericardial effusion.[2]

Abdominocentesis and pericardiocentesis may be performed blind or with ultrasound guidance. Abdominal fluid analysis and its limitations in cattle are discussed in the section on peritonitis. Pericardiocentesis may be performed at the level of the point of the elbow in the fifth left intercostal space. Aseptic preparation of the skin and local anesthesia of the region to be punctured are required; pulling the left forelimb forward may be helpful. A 5- to 10-cm spinal needle or intravenous catheter can be used; the length required depends on the size of the animal and the amount of subcutaneous fat. Previous ultrasonographic examination is helpful for the choice of the needle. Caution is advised when advancing the needle to prevent laceration of the myocardium. Ultrasound-guided centesis prevents trauma to the myocardium. Visual inspection of the fluid obtained is usually adequate to confirm the diagnosis of pericarditis; it is cloudy and foul smelling. The fluid may be examined bacteriologically and cytologically.

If ileus occurs or vagal indigestion develops, analysis of the ruminal fluid may reveal elevated chloride ion concentration as a result of reflux from the abomasum and omasum (internal vomiting).

Pathophysiology The indiscriminant eating habits of cattle lead to accidental consumption of foreign bodies. Those that are of high specific gravity initially settle to the bottom of the ventral sac of the rumen. Subsequent contraction cycles of the forestomach move those objects from the rumen into the reticulum. If the object is large enough and sharp enough, it can be pushed, most often through the cranial wall of the reticulum, by the forceful, normal reticular contractions. Normal forestomach bacteria leak through the hole thus created and may establish infection locally along the foreign body. Infection also may spread as in the pericardium or locally during abscess formation. The pain and inflammation associated with the trauma and infection lead to decreased appetite and ruminal hypomotility or stasis. Agalactia is abrupt because of the acute anorexia and subsequent failure to absorb precursors for milk synthesis.

Rehage and colleagues[3] demonstrated that the disturbances of digesta through the forestomachs and the abomasum in cows affected with TRP develop in three phases. The first one, characterized by poorly comminuted feces, occurs secondary to virtual immobilization of the reticulum caused by pain and inflammatory adhesions. With extension of the adhesions, additional impairment of reticulum motility develops. At this time, stratification of the food particles in the reticulorumen is lost, volume of these two forestomachs is increased, and ruminal outflow is inhibited. Finally, the consistency of ruminal contents is changed to a pasty mass with high viscosity. Increase in viscosity of ruminal outflow leads to inhibition of the transpyloric outflow. At this time, abomasal volume increases and internal vomiting occurs.

Epidemiology There are few data available on the frequency of TRP in cattle. In one study in Denmark, TRP was diagnosed by veterinarian in 1621 cows of 222,490 in the year prior to slaughter and identified in 1521 of these cows at slaughter. It is interesting that only 48 of these cows had been diagnosed to have a TRP by a veterinarian premortem, and agreement between premortem and postmortem diagnosis of TRP was low.[15] Gröhn and Bruss[16] reported a similar prevalence (0.6%) of TRP diagnosis in dairy cattle in 1990. Data from England and Wales indicated that 141 of 2709 adult cattle carcasses submitted to the Veterinary Laboratories Agency from January 2004 to May 2008 had a diagnosis of TRP.[17] In western Canada, TRP was the most frequent of postmortem findings (8%) in beef cows and replacement heifers where tissues were submitted for histopathologic examination.[18] Most cases are sporadic, but outbreaks have occurred when such things as multistranded cable have been chopped up by a forage harvester and ensiled or when cattle have chewed nails containing charcoal from burned buildings.

The ingestive techniques of cattle allow sharp nonfood items to be prehended and swallowed. Ingestion of such items by sheep or goats is extremely rare. The disease affects confined cattle where mechanical processing of forages or construction activities increases the chances that wire or nails will be included in the feed.

Necropsy Findings Cattle that die peracutely may have a lacerated myocardium with resulting hemorrhage or cardiac

VetBooks.ir

tamponade. Diffuse peritonitis characterized by copious, foul-smelling peritoneal fluid with an obvious reticular defect may be seen in acute cases. More chronically affected animals may have extensive pericardial effusion with a thick epicardial layer of fibrin if the pericardium was penetrated. If only localized peritonitis with adhesions occurs, then the animal is unlikely to die from this. The penetrating foreign body generally is still present in the wall of the reticulum or pericardium.

Treatment and Prognosis Conservative treatment generally is attempted first and includes the administration of a forestomach magnet, parenteral antibiotic therapy, and confinement. Often the animal is confined to a stanchion or box stall. Many cattle recover after such a course of therapy with resumption of forestomach motility and appetite within 1 to 3 days. Different drugs have been used to enhance the chance of the magnet to enter the reticulum cavity. The effects of premedication with atropine, scopolamine, or xylazine and of standing the cow with its forelimbs 30 cm lower than its hindlimbs on successful administration of a magnet (i.e., adequately located in the reticulum cavity) have been evaluated in healthy cows.[19] Adequate location of the magnet was controlled radiographically 1½ hours after the administration of the magnet. None of the procedures increased the chance of the magnet being successfully placed in the reticulum. Moreover, in all groups (treatment groups and control groups) only 57% of the magnets were adequately located in the reticulum.[19] Braun and co-workers[20] demonstrated that foreign bodies that have penetrated the reticulum wall or that have clearly perforated the reticulum had about a 54% and 32% chance, respectively, to become attached to the magnet. Animals that have not significantly improved by the third day may require a rumenotomy to remove the foreign object. Ideally, radiography combined with ultrasonography is recommended at this time to verify the diagnosis and objectively assess the response to treatment,[20] but ultrasonography alone is most feasible in most practices.

During rumenotomy, abscesses that are tightly adhered to the reticulum may be drained into the lumen of the reticulum. In some instances reticular abscesses may also be drained through an ultrasound-guided transcutaneous incision,[21] ultrasound-guided insertion of a chest trocar, or insertion of a trocar during ventral laparotomy.[1] Treatment of peritonitis requires systemic antibiotic therapy and possibly drainage of the affected area; surgical correction of the inciting cause is discussed in the section on peritonitis.

Prognosis The prognosis of TRP depends mainly on the location of the foreign body and the other organs affected. The prognosis is fair to good when TRP is associated with localized peritonitis and when only the spleen or the liver is also affected. In most cases, as inflammation diminishes, the reticular function can return to normal.[22] The prognosis is poor to guarded in TRP associated with pericarditis, pleuritis, or diffuse inflammatory adhesions in the abdomen.[1,2,22]

Prevention and Control Eliminating sources of sharp foreign objects in the feed supply prevents TRP. Installation of large magnets on feed handling equipment and prophylactic administration of forestomach magnets to all animals at 6 to 8 months of age prevent almost all cases caused by magnetizable objects.

Peritonitis in the Ruminant

Gilles Fecteau

Despite the frequency with which peritonitis is suspected, it remains a frustrating disease for all food animal clinicians. A presumptive diagnosis is often based on clinical signs and history and rarely confirmed by ancillary tests. If response to therapy is satisfactory, the clinician may never confirm the diagnosis or the precise cause.

Review of the Peritoneal Cavity

Histology

The peritoneal cavity is lined by a serous membrane composed of two layers called the *peritoneum*. The deeper layer (subserosa) is composed of loose connective tissue containing collagen, fat cells, reticular cells, and macrophages. Covering that layer is a single-surface layer of mesothelial squamous cells (serosa). On the surface of the diaphragm, special lymphatic collecting vessels are located under the mesothelial basement membrane. Small stomata are found between mesothelial cells. They act as channels for lymphatic drainage from the peritoneal cavity to the thoracic duct.

Normal Peritoneal Fluid

The peritoneum acts as a bidirectional semipermeable barrier to the diffusion of water and low-molecular-weight solutes between the blood and the peritoneal fluid. Peritoneal dialysis uses this principle to treat renal failure. Normal peritoneal fluid provides lubrication for the movement of abdominal organs and apposed peritoneal surfaces. It is formed and resorbed constantly. Normal fluid movement is achieved by movement of the viscera and contraction of the diaphragm during respiration. A normal animal has no more than 1 mL of peritoneal fluid per kilogram of body weight.[1] In acute severe peritonitis, the inflammatory process may induce a net flow of liters of proteinaceous fluid (80 mL/kg/day in humans), leading to hypoproteinemia, hypovolemic shock, or both.[2]

Several authors have described normal peritoneal fluid values.[3-10] Without a systematic review with a meta-analysis, it appears hazardous to present the wide range of reported normal values. Each study should be appraised for its strengths and weaknesses and conclusions drawn accordingly. Later, in the diagnostic section, the author will share his personal experience with interpretation of peritoneal fluid in cattle.

Pathophysiologic Mechanism of Diseases in the Peritoneal Cavity in Response to Injury

Healing

Peritoneal regeneration and healing can occur by reperitonealization or creation of an adhesion with an adjacent nearby mesothelial surface. This adherent type of healing occurs more frequently if the inflammation is severe, with presence of bacteria and/or foreign material.

Host Defenses against Peritoneal Infection

The first mechanism of defense is physical removal of the bacteria. The second mechanism of defense relates to the response to noxious stimuli. This intense acute inflammatory response includes degranulation of peritoneal mast cells with release of vasoactive substances. This creates a net influx of fluid rich in complement and serum opsonins that can bind to the bacteria. Third, the omentum contributes to the defense mechanism by adhering to an infected and/or damaged area to wall off the problem site. Finally, the rapid movement of neutrophils, and later, macrophages, is also an important mechanism of control of infection.

Adhesions

Adhesions are defined as fibrinous or fibrous bands that create an abnormal attachment of two or more surfaces that should be moving freely against each other. Formation of adhesions is part of the healing process and should be interpreted as an effort to control an injury. The omentum is often involved in adhesions and acts as a natural sealing device to control the acute phase of inflammation. Whole blood potentiates adhesion formation by providing more fibrinogen. Adhesion may or may not be reversible, depending on the amount of organization that takes place in the process. Adhesions that are cut or broken usually rapidly reform. As the fibrin deposition process is replaced by capillaries and fibroblasts, the adhesion

VetBooks.ir

becomes solid fibrous tissue. The three major elements responsible for dissolution of the fibrinous adhesions are (1) adequate oxygen and nutrient supply for the mesothelium, (2) liberation of plasminogen-activating substance by mesothelial and submesothelial cells, and (3) control of the inflammatory process.[2] Mechanical obstruction to the normal flow of ingesta and subsequent development of bowel obstruction are major undesirable side effects of formation of adhesions.

Peritonitis

Definition and Etiology Peritonitis is an inflammatory process involving the peritoneal cavity and its serosal surface, the peritoneum. Peritonitis is not a true synonym of intraabdominal infection because the latter is defined as an inflammatory response of the peritoneum to microorganisms and their toxins that results in purulent exudates in the abdominal cavity. Peritonitis should be considered as the localized equivalent of the systemic inflammatory response syndrome (SIRS), whereas intraabdominal infection is the localized equivalent of sepsis. Intraabdominal abscess is an intraabdominal infection confined within the abdominal cavity. Because most often in farm animals peritonitis is caused by bacteria, the two terms are often used as synonyms. The peritoneal inflammation may result from trauma, surgery, or vascular damage associated with an intestinal obstruction and/or accident or from gastrointestinal ulceration (Box 32-8). Peritonitis is a serious and complex process that is often accompanied by various degrees of abdominal pain, changes in gastrointestinal motility, progressive signs of hypovolemia and septicemia, and/or endotoxemia.

BOX 32-8

Causes and Examples of Peritonitis in Approximate Order of Frequency

Traumatic Perforation

Traumatic reticuloperitonitis
Septic abdominal surgery
Vaginal perforation in heifer during coitus
Penetrating wound

Visceral Rupture

Perforated abomasal ulcer
Perforated ulcer in other part of gastrointestinal tract (oak toxicity of other cause)
Abomasal rupture after torsion
Small intestinal rupture after volvulus, strangulated hernia, intussusception
Ruptured bladder secondary to urolithiasis
Spontaneous uterine rupture during gestation or dystocia

Abscess Formation and Possible Intraabdominal Rupture

Reticuloperitonitis, localized
Liver
Umbilicus
Perimetritis
Pyelonephritis

Iatrogenic

Intraperitoneal injection of irritant solution or contaminated solution
Uterine rupture during dystocia
Perforation of the uterine wall with a pipette
Rectal tear secondary to palpation

Miscellaneous

Hematogenous with systemic infection: tuberculosis, septicemia
Fat necrosis

Classification Peritonitis may be classified according to the clinical presentation and/or the cause. Clinically relevant classifications include acute versus chronic, septic versus chemical, localized versus generalized, and primary versus secondary. Although it is useful to classify types of peritonitis, it is imperative to recognize that it is a dynamic process. An apparently localized nonseptic peritonitis can evolve toward a more diffuse septic process if the primary cause is not resolved.

Pathophysiology After peritoneal injury or contamination, mesothelial cells initiate an inflammatory response, modifying the permeability of the peritoneum and its vascular supply. Several blood constituents are then able to move into the peritoneal cavity. Macrophages and polymorphonuclear cells, humoral opsonins, natural antibodies, serum complement, and a protein-rich fluid are the most important. The inflamed peritoneum also becomes more permeable to toxins, allowing them to be absorbed into the bloodstream. Although this initial response is beneficial to the organism, it induces several systemic abnormalities that the clinician must recognize and treat adequately.

Hypovolemia, hypoproteinemia, bacteremia or septicemia, and toxemia are commonly observed in acute diffuse septic peritonitis. The major adverse effects of peritoneal contamination are (1) rapid clearance of bacteria, producing endotoxemia and/or bacteremia; (2) rapid influx of fluid rich in protein, leading to hypovolemia and hypoproteinemia; (3) deposition of fibrin, occluding lymphatic drainage, contributing to abdominal distention, and enhancing the chance of abscess formation; (4) ileus; and (5) adhesion formation, which may lead to obstruction.

Clinical Signs and Diagnosis Clinical signs are often nonspecific but suggestive of gastrointestinal dysfunction. Severity of clinical signs ranges from mild recurrent discomfort caused by a localized abscess to an acute severe onset of toxemia and hypovolemia leading rapidly to death after the sudden rupture of a viscus. Cattle suffering from acute peritonitis tend to show more characteristic signs. As the condition becomes less acute, the ability of the bovine to seal the infection will attenuate the clinical signs. Chronic but active peritonitis remains to this day a very difficult diagnosis to make without ancillary tests. Abdominal rigidity and tenderness, abdominal distention, scleral injection, fever, anorexia, and sudden reduction in milk production are classic but not pathognomonic findings of acute peritonitis. In the acute stage, abdominal pain and the release of catecholamines often lead to a complete gastrointestinal stasis and ileus. The rumen is then completely atonic. Feces are abnormal in quantity and quality. In the acute stage, feces are present in small amounts and often dry. In more chronic cases, feces are present with a tendency to be diarrheic. Pain, decreased plasma volume, and endotoxemia often result in persistent tachycardia. Anterior abdominal pain, evaluated by the withers pinch test, may be difficult to interpret. This procedure is based on the normal reflex of the bovine to drop its back when the withers and back are pinched (ventroflexion). Cattle with anterior abdominal pain may be reluctant to ventroflex on withers pinch. The sensitivity of this test can be increased by simultaneous auscultation of the trachea during the manipulation. Production of an expiratory grunt is considered a sign of pain during ventroflexion. Cranial ventral pressure with the fist, knee, or some other external force (transverse pole under the abdomen) just behind the xiphoid can help identify the presence of pain (expiratory grunt) and even localize it in some cases. It is my impression that one of the most reliable clinical signs of abdominal discomfort in cattle is reluctance to move. Scleral injection, fever, tachycardia, gastrointestinal stasis, and distention are the clinical signs that should be monitored to evaluate peritonitis.

Ancillary Tests Hematologic findings associated with peritonitis range from a completely normal hemogram to severe leukopenia with degenerative left shift and presence of toxic neutrophils, depending on the severity of the peritoneal contamination. In severe

VetBooks.ir

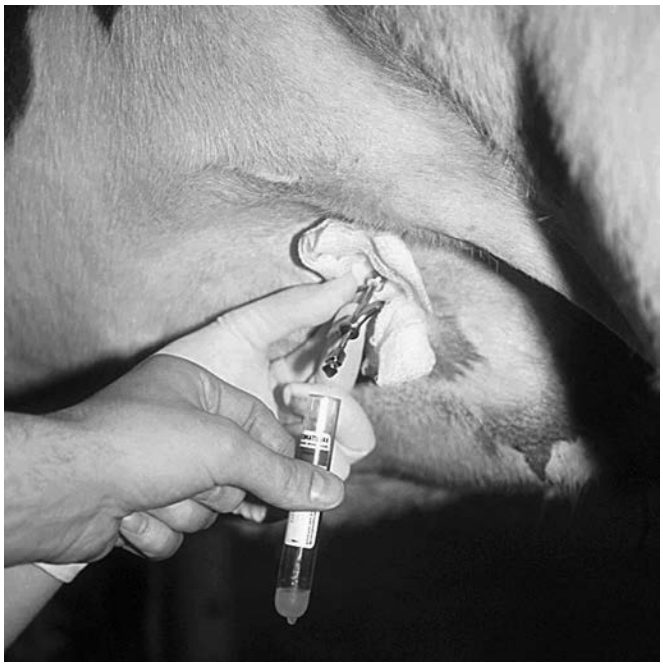

FIG. 32-124 Site of caudal abdominocentesis.

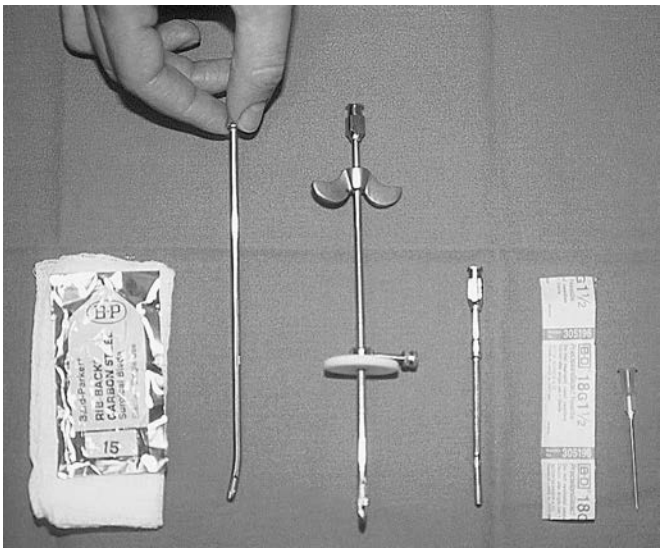

FIG. 32-125 Material used to perform abdominocentesis of the bovine.

cases variations observed reflect the degree of sepsis and toxemia. Packed cell volume (PCV) tends to increase as proteins decrease. In less severe cases, a neutrophilic leukocytosis and hyperfibrinogenemia are often present. Hematologic analysis has been a useful tool to monitor response to therapy after a diagnosis has been made by other ancillary tests. Plasma fibrinogen concentration is also used to monitor the progress of a particular case.

The blood chemistry profile is rarely altered by peritonitis in a way that is diagnostically useful. Chronic inflammation causes a marked increase in serum proteins, particularly the globulin portion. In acute severe cases, secondary findings may include increased serum urea nitrogen and creatinine, mildly increased liver enzymes, reduction in total CO_2, and strong ion difference and reduction in serum albumin. Ileus and upper gastrointestinal stasis may result in marked hypochloremia and alkalosis.

In our experience, abdominocentesis followed by cytologic examination of the peritoneal fluid is a useful aid in making a definitive diagnosis of peritonitis. The technique is simple and without complications. The right side just cranial to the udder is the preferred site (to avoid stomach and omentum) (Fig. 32-124). A needle, a blunt teat canula, or a bitch catheter and scalpel blade may be used with success (Fig. 32-125). The heavy fascia of bulls makes a needle preferable. It is imperative to remember that failure to secure fluid is common and should be interpreted with caution (because fibrinous peritonitis with fluid loculation is common). More than one site should be attempted if no fluid is secured on the first attempt. Interpretation of values and what is considered normal appears difficult when the entire literature is searched.[3-5,11] Recent publications have tried to establish better reference values for cattle.[10] Unfortunately, the range seems extremely wide even in the normal cattle population. Here are some of the criteria we have been using over the years based on some older literature and personal experience. Normal fluid is clear and often in small quantity. Easily collecting a large amount of fluid should arouse suspicion. A sanguineous fluid leads to suspicion of a compromised bowel problem (e.g., intussusception). A cloudy fluid leads one to lean toward peritonitis. Any foul smell is enough to conclude that septic peritonitis is occurring. Cytologically, the total number of cells is not as important as the differential. More than 50% neutrophils is suggestive of a septic process. The protein concentration should be less than 30 g/L (recent publications move the cutoff value higher than this number). No bacteria should be visualized. After exploratory celiotomy and omentopexy on normal cattle, peritoneal fluid has increased specific gravity, total protein, and white blood cells (WBCs) for at least 6 days, even without any peritonitis.[12] One should remember that because of the bovine's ability to deposit fibrin and seal areas of the peritoneal cavity, the interpretation of peritoneal fluid analysis applies only to the immediate area that was sampled. The clinician can be misled to conclude that a nonseptic process is occurring on the basis of a caudal tap, when in fact a septic process has already been sealed by the fibrin deposition in the cranial abdomen.

Abdominal radiographs using a high-power unit are extremely useful in cases in which traumatic reticuloperitonitis (TRP) is suspected. They have limited value in other causes of peritonitis. Ultrasound examination is useful for assessing the size and anatomic relationships of lesions, particularly when considering drainage, aspiration, or surgical exploration of a mass surrounding vital structures (see the section on ultrasound in this chapter). Knowledge of the underlying anatomy is important to prevent misinterpretation. Recognition of free abdominal fluid is easily accomplished by ultrasound examination, and it is also useful to guide a peritoneal tap. Areas that should be scanned include the caudal lower flank area (right and left), right perirenal area, liver, abomasum and pylorus, and right paramedian area. During exploratory surgery, ultrasound can be used to image an internal mass or a viscera appearing abnormal. Intraoperative ultrasound is performed by placing the probe in a sterile sleeve filled with ultrasound gel.

Surgical exploration is often used to confirm or rule out an intraabdominal problem. Information obtained from physical examination and laboratory data is often indicative of a diagnosis but does not provide a specific cause. Cattle are particularly amenable to exploratory surgery, as the procedure is performed when they are standing and is not often associated with complications. Recent advances in minimally invasive surgical technique in cattle are promising. Laparoscopy can be used to diagnose acute and chronic peritonitis, which is otherwise difficult to identify with ultrasound or abdominocentesis. It is easier to evaluate the extent of the lesions with the organs in situ.

Treatment

The basic elements of therapy are support, antibiotics, and surgery.

SUPPORTIVE THERAPY. Depending on the severity of the process, the patient may be in shock. Large volumes of isotonic intravenous fluids and correction of any acid-base deficit are indicated. Electrolyte abnormalities (hypokalemia and hypocalcemia) should

VetBooks.ir

be identified and corrected. If the animal is hypoproteinemic, plasma or whole blood transfusions may be beneficial. Nonsteroidal and/or steroidal antiinflammatory drugs may be of importance to prevent the synthesis of more inflammatory mediators. Pain control is also important. Transfaunation with normal rumen fluid may be beneficial in cases of prolonged anorexia.

ANTIBIOTIC THERAPY. Systemic antibiotic therapy should be instituted as soon as a decision to treat is made. Until results of culture and antimicrobial susceptibility become available, a broad-spectrum antibiotic should be used. The choice should take into consideration the following: cost of treatment, permitted use in and withdrawal period in food animals, spectrum of activity, and treatment regimen (frequency and route). Tetracycline or a β-lactam antibiotic (third-generation cephalosporin or a synthetic penicillin) appears to be a good choice. Diffusion into the peritoneal cavity is not a major limiting factor, because the permeability of the peritoneum is always increased in peritonitis. However, when fibrin becomes organized and forms multiple small pockets of infected peritoneal fluid, diffusion becomes more problematic. Duration of therapy is empirical in the bovine. In our clinics, we normally recommend at least one week of intravenous therapy followed by another week of intramuscular therapy. Some clients elect to have the 2 weeks of therapy in our hospital and we then maintain them on intravenous antimicrobials.

SURGICAL THERAPY. Surgical control of peritonitis includes peritoneal débridement, irrigation, and drainage. Using ultrasound guidance, it is possible to safely establish drainage from the abdominal cavity. A thoracic chest trocar can be used temporarily until all fluid has been removed.

The concept of abdominal lavage during surgery was adopted by human surgeons around the turn of the century and has been accepted as a part of the treatment of peritonitis since then with fluctuating support.[13] Although the principle of removal of any gross contamination is not in question, the level of aggression with which clinicians should institute abdominal lavage during surgery is still open to debate in human and veterinary literature. There is evidence of a negative effect of lavage on the mesothelial cells, the peritoneal defense mechanisms, and the risk of spreading the infection.[13] The solution used to irrigate is also under debate. There is no significant advantage to adding antibiotics to the lavage solution, and controversy exists regarding the possible advantages of adding an antiseptic.[13] In the bovine, large amounts of fibrin may be deposited in a short period of time; in combination with the omentum, this makes drains plug and become rapidly ineffective.

Prognosis The ultimate outcome of a bacterial peritonitis episode is determined by many factors, some of which are controlled by the clinician. The early decision on treatment (medical and surgical), correct choice of antimicrobials, and adequate supportive therapy contribute to the success or failure of a therapy. The owner's delay in seeking therapy, the primary cause of peritonitis, and the patient's age are important factors beyond the clinician's control. When aggressive therapy is economically possible, survival rates will be good, but long-term sequelae may compromise a complete recovery.

Miscellaneous Conditions

Ascites

Ascites is a collection of serous fluid in the peritoneal cavity. It must be considered as a secondary sign rather than a primary diagnosis. In that regard the primary cause must be identified in order to treat the patient adequately. Common causes of ascites in ruminants include severe liver disease and congestive right-sided heart failure. Young cattle with mesothelioma have remarkable ascites. Ascites remains an uncommon condition that needs to be differentiated from septic causes of peritonitis and from urine accumulation with ruptured bladder.

Pneumoperitoneum

Pneumoperitoneum is commonly observed postsurgically in the bovine. Presence of air in the abdomen can be recognized by simultaneous percussion and auscultation. A low-pitch resonance can be auscultated in the upper flank on both sides of the abdomen. Presence of pneumoperitoneum normally resolves in the week after surgery. No clinical signs seem associated with the presence of pneumoperitoneum, although some clinicians describe abdominal pain associated with no other cause than the presence of air in the peritoneal cavity. Pneumoperitoneum not associated with surgery is indicative of bacterial peritonitis and the presence of gas-producing bacteria (see Box 32-8).

Retroperitoneal Abscess

Retroperitoneal abscess is a particular condition occurring in cattle after a flank laparotomy. Animals are often presented several days after surgery. They are mildly febrile, not performing adequately, and showing clinical signs compatible with peritonitis. The skin wound is often unremarkable, but some pain may be elicited while the flank area is palpated. A substantial mass may be palpated per rectum, localized in the upper quadrant of the side of the previous surgical approach. The mass will be firm, smooth, unmovable, and close to the previous flank incision, and may have adhesions attached to it. Transabdominal or rectal ultrasound examination reveals a large amount of fluid located between the peritoneum and the rectus abdominis or the internal oblique of the abdomen. More superficial abscesses can also occur. A needle aspiration allows visual inspection of a thick, opaque, foul-smelling fluid. Treatment is aimed at establishing drainage and systemic antimicrobial therapy. A large volume of purulent and fibrinous material (up to 40 L) can be removed from the abscess. Rapid decompression may provoke hypovolemic shock, and intravenous fluids should be administered before a large abscess is drained. Prognosis is good, but the recovery phase is extremely long because of the large cavity left after drainage. Early closure of the drain is often observed, necessitating reopening. Some clinicians effectively use Penrose drains as they close a contaminated flank wound, to prevent serum accumulation in the wound and stave off the development of an abscess.

Frothy Bloat

Gilles Fecteau • Charles L. Guard

Definition and Etiology Frothy bloat results from the formation of stable foam in the rumen. Ruminal tympany is synonymous with bloat. The condition may be fatal if the distention is extreme enough to compromise ventilation by compressing the thoracic viscera. Cattle are more susceptible than sheep, but the disease does occur in small ruminants.

Clinical Signs and Differential Diagnosis The degree of forestomach enlargement varies from that producing an even filling of the left paralumbar fossa to that causing a uniform, extreme abdominal enlargement when the animal is viewed from the rear. With intermediate degrees of distention, the left paralumbar fossa bulges beyond the contours of the last rib and the tuber coxae. Clinical signs of colic may be seen, including kicking at the abdomen, treading, frequent lying down and rising, and vocalizations. Some animals adopt a stretched stance with the rear feet placed far back. Sheep with heavy fleece may be significantly bloated without the changes in abdominal contour being obvious. As the forestomach enlarges and compresses the diaphragm, breathing becomes more labored. Open-mouth breathing, cyanosis of mucous membranes, and collapse leading to death may occur within a few minutes if the animal becomes frantic from the abdominal pain and respiratory

VetBooks.ir

distress. Other conditions to consider in the diagnosis of frothy bloat in ruminants include other causes of ruminal enlargement: free gas bloat and vagal indigestion. Many systemic conditions influence the motility of the forestomach and thus may produce mild bloat coincidentally.

Clinical Pathology Clinical pathologic measurements are not necessary for the diagnosis and management of most cases of frothy bloat in ruminants. Evaluation of a sample of ruminal contents may provide useful information for prescribing treatment and prevention. The presence or absence of froth and the pH are critical features relating to the cause that influence the choice of therapy. The normal pH of the rumen varies with time after feeding but should be between 5.4 and 6.8.

Pathophysiology Regardless of the cause of forestomach distention, the process may become self-perpetuating because of reflex inhibition of motility. Low-threshold stretch receptors in the ruminal wall augment cyclic forestomach contractions when stimulated. However, stimulation of high-threshold stretch receptors leads to inhibition of motility. Thus, beyond a certain degree of stretching of the ruminal wall, further contractions that may relieve the distention through eructation are prevented.[1]

Frothy bloat is caused by the retention of gases of fermentation within the mass of ingesta that fail to rise and coalesce into a dorsal gaseous layer. This condition can arise from diets of lush legumes or winter wheat pasture or may be seen with high-concentrate finishing rations in the feedlot. In the case of legume-induced disease, bloat has occurred after grazing or feeding of fresh-cut forages or the feeding of alfalfa hay. The structure of stable froth in the affected ruminal contents is not true foam. The ingesta in the septa between adjacent bubbles form a complex structure that prevents coalescence. The viscosity of the fluid may prevent gravitational flow through the septa that would lead to the bubbles' rising and coalescing. Frothy ruminal fluid is higher in chloroplast membrane fragments, soluble protein, and very fine particles than is nonfrothy ruminal fluid.[2] The presence of the resulting frothy ingesta at neural receptors believed to be near the cardia prevents the reflex relaxation of the cardia during the secondary contractions of the forestomach that ordinarily lead to eructation.[3] In addition, the viscosity of the frothy ingesta is such that the cardia may become plugged during attempts to eructate.

Risk factors associated with the occurrence of frothy bloat can be categorized as animal risk factors, plant characteristics (species and maturity), and weather conditions.[2] Individual cattle have been classified as having either high or low susceptibility to legume bloat. Highly susceptible cattle have been shown to have larger ruminal volumes and specific salivary proteins in consistently different proportions compared with bloat-resistant cattle. There is a relationship between plant factors associated with bloat and the rapidity with which leaf structure is disrupted after ingestion.[2] Bloat-inducing plants are more readily macerated, thus providing quicker bacterial access to the inner leaf cells. Less bloat-predisposing cultivars of the main bloat-causing species, such as alfalfa *(Medicago sativa),* red clover *(Trifolium pratense),* and white clover *(Trifolium repens),* have a thicker leaf cuticle, smaller stomata, and a more fibrous leaf structure. Ionophore antibiotics such as monensin inhibit ruminal protozoa that normally ingest chloroplasts, leading to a reduction in the bloat potential of some forages.[4,5]

Grain bloat occurs in a manner similar to that caused by legumes; a stable froth is produced from high-concentrate rations. Particle size and the rate of fermentation are thought to be the determining factors in the froth production. A mucoprotein slime composed of bacterial by-products stabilizes the froth.[4,6] This material tends to be stable at a lower pH than is found in non–grain-fed ruminants, so grain feeding promotes slime accumulation by lowering ruminal pH. Animals (such as dairy cattle) that are fed grain and then legumes may be particularly susceptible to frothy bloat because all the factors leading to froth production and accumulation are present. Both legume bloat and grain bloat may resolve spontaneously if the animal stops consuming the bloat-producing feed and microbial digestion eliminates the froth-stabilizing factors.

Acute distress, often appearing as abdominal discomfort, is caused by overdistention of the forestomach that stimulates pain receptors in the ruminal wall. As the abdominal distention increases, the ability to achieve normal respiratory movements of the diaphragm and rib cage is impaired. This exacerbates the anxiety and distress. Death from asphyxia ultimately results as the lungs are compressed by the cranially expanding diaphragm, and venous return via the posterior or caudal vena cava is compromised.

Epidemiology Frothy bloat often occurs as an epidemic. Pasture bloat may occur wherever alfalfa, red clover, or white clover is grazed. Environmental conditions that produce rapid, early growth lead to a higher incidence of bloat. Frothy bloat also occurs when stocker cattle are grazed on winter wheat pastures in the southern Great Plains of the United States. Death losses at pasture range from 0.5% to 2.5% of cattle at risk on an annual basis. The incidence of feedlot bloat has been estimated at about 1%, with death losses of about 0.1%.[2]

Necropsy Findings The finding of tenacious froth in the rumen, along with other evidence of bloat, is grounds for a presumptive diagnosis of frothy bloat. The challenge for the diagnostician is to determine if the bloat occurred before death; this may not be possible if the animal was not observed before death. The increase in intraabdominal pressure prevents venous return from the hindquarters and may lead to obvious edema in the intermuscular areas. Unfortunately this is not a consistent finding; other evidence of impaired circulation or a differential degree of edema between fore and hind parts must be used to make a diagnosis.

Treatment and Prognosis Passage of a stomach tube is indicated to determine the cause of the ruminal distention and possibly initiate treatment. A sample of the ruminal contents for pH measurement should be obtained at this time. Care must be taken to exclude saliva from the tube by blowing into the rumen, flushing water through the tube, or using a ruminal sampling device that carries the tip of the stomach tube down into the liquid ingesta. If no gas can be released with a stomach tube, the tube should be withdrawn after suction has been applied and examined for the presence of froth. If the animal is not in respiratory distress or extremely colicky, surface-active agents should be administered by means of a stomach tube. Poloxalene or mineral oil can be used.

Some cattle are in violent pain with bloat but not in respiratory distress. Sedation with xylazine may be necessary for further examination and treatment. Animals with extreme distention of the forestomach and in respiratory distress require immediate surgical intervention. A trocar introduced through the left paralumbar fossa after local anesthesia relieves bloat caused by free gas accumulation but may not be adequate for frothy bloat. An emergency rumenotomy may be necessary to evacuate frothy contents.

Prevention and Control Prevention of frothy pasture bloat relies on the general principle of decreasing the rate of rumen fermentation. To significantly modify the rate of rumen fermentation, grazing management strategies and controlling pasture yields and quality remain the most common methods applied to a population. Cattle could be fed other feeds before being turned out and could be allowed limited access to the problem forages. Accurately predicting when forages are safe has not been reliable. Strip grazing is another option allowing cattle a reduced amount of new forage every few days. The choice of forages and the stage of growth are also to be considered. Agronomists are selecting cultivars of the bloat-producing forages for slower rates of initial fermentation. These are likely to become more widely used in the regions in which bloat is a regular occurrence. When grazing strategies and pasture management are not enough, then as an alternative, cattle at risk have been treated

VetBooks.ir

with supplemental surface-active agents such as poloxalene or oil. In Australia and New Zealand, oils and tallows have been drenched daily, sprayed on fields, and smeared on the flanks to be later licked off, to prevent pasture bloat. Although poloxalene has proved effective, it is more expensive than oils. It can be fed in molasses blocks or individually administered. Ionophore antibiotics such as Rumensin (monensin; 1 mg/kg daily) greatly reduced the incidence of legume bloat. Beginning treatment before exposure to the bloat-inducing feed was more effective than waiting until bloat occurred.

Providing adequate fiber in feedlot rations and slowly introducing higher proportions of concentrates, particularly corn, barley, and soybean meal, permit ruminal adaptation that helps prevent bloat.

Abomasal Displacement and Volvulus

Gilles Fecteau • Charles L. Guard

Etiology Although the precise cause of displacement of the abomasum remains unknown, general agreement exists in veterinary literature that it is a multifactorial syndrome and that abomasal hypomotility is an absolute prerequisite. Abomasal motility can be decreased in many ways. Numerous common disorders of postpartum dairy cattle have been incriminated as possible triggering events to abomasal dilation and displacement. Among the most important, ketosis, low serum calcium, hyperinsulinemia, and reduced insulin sensitivity have been studied and reported in recent publications.[1-6]

Prevalence and Incidence Abomasal displacement occurs either to the right or to the left side of the abdomen when gas accumulates within this viscus. Left-displaced abomasum (LDA) is the more common, accounting for most of the cases. By far the highest incidence is in adult dairy cattle in the early postpartum period, but cases have been seen in all other classes of cattle. LDA is probably a worldwide problem. The prevalence among dairy herds is variable depending on multiple factors such as geographic location, climate, management practices (confinement vs. pasture), and feeding practices.

Pathophysiology After abomasal atony, distention with gas produced by microbial fermentation occurs and most likely precipitates the displacement. It has been hypothesized that the displacement will be oriented (left or right) according to the size of the rumen. If the rumen is small and empty (as in the early postpartum period), the abomasum can move to the left and LDA can occur (Fig. 32-126). A large and filled rumen will make the left displacement less likely, and the abomasum will dilate and in some cases twist to the right (Figs. 32-127 and 32-128).

Surgical Therapy Numerous surgical techniques exist with advantages and disadvantages.[7] All techniques have a common objective to create a permanent attachment usually by suturing either the abomasum or the greater omentum to the abdominal wall. This prevents reoccurrence. The techniques may be classified into three different broad categories: blind technique, surgical (open) technique, and laparoscopic technique. Another way to look at the different options is to classify the techniques as performed on a standing animal or in recumbency. Multiple factors influence the technique used or recommended for a particular case. Cost and preference of the surgeon are very important. Recently, laparoscopic technique has been described and studied.[8-11]

All techniques have been successful when performed adequately. Recently, the less invasive techniques have been studied to evaluate the possible advantages over the more invasive open techniques. The advantages are time to perform the surgery, less frequent use of antimicrobials, a shorter interval from calving to first service, and a faster abomasal emptying.[12-15] Understanding the limitations of each technique will allow the clinician to best serve the patient and client

VetBooks.ir

in all situations. Success rates and possible economic advantages of having the procedure performed by herd personnel have been discussed in the literature.[16,17]

Left Displacement of the Abomasum

Clinical Signs and Differential Diagnosis Cattle with simple LDA have a reduced appetite (complete anorexia, reduced consumption of concentrates, or alternating periods of normal appetite and anorexia). Milk production is reduced. Ketosis is usually present, either as a predisposing factor or as a consequence. Feces are often normal to softer than normal but reduced in volume. Rectal temperature is normal, unless a concurrent infectious problem is present (metritis, mastitis). Pulse and respiration rates are normal or slightly above normal, unless a concurrent or secondary problem is present. Ruminal contractions are decreased to absent and difficult to hear because the abomasum interferes with transmission of the sound. It is not unusual to observe the animal ruminating despite the displaced abomasum. The last one or two ribs on the left are sprung, but the abdomen is sunken in the paralumbar fossa. Gurgling or tinkling rather than normal scratching sounds may be heard on auscultation in the left paralumbar fossa. Simultaneous auscultation and percussion reveal a ping over the gas-filled portion of the abomasum. With LDA the area of ping may be anywhere from the lower third of the abdomen in the eighth intercostal space to the paralumbar fossa (see Chapter 1, Physical Examination). Attention should also be given to the cranial and lower aspect of the flank because in some cases the ping will be audible only in this area. On rare occasions, during rectal examination the clinician may be able to palpate the abomasum to the left of the caudodorsal blind sac of the rumen or at least perceive that the rumen is displaced medially.

Ruminal tympany, pneumoperitoneum, and collapsed rumen may all produce pings on the left side of the cow. Physometra (air in the uterus) and dilation and displacement of the cecum to the left of the rumen (which is rare) may also produce left-sided pings. Having an assistant blow on the stomach tube passed into the rumen while auscultating over the left side differentiates the rumen from other structures. Percutaneous needle aspiration of fluid or gas from the suspected abomasum aids in correct identification. A pH of less than 4.5 as determined with wide-range pH paper or the odor of abomasal gas (slightly acrid or burned almonds) confirms the presence of LDA. Ultrasound examination could also be helpful in determining the position of the pylorus and to compare the position with the actual normal variation.[18]

Clinical Pathology The most important abnormalities detected by clinical chemical evaluation usually are the serum electrolyte, acid-base levels, and liver metabolism and integrity. Sequestration of the hydrochloric acid secreted into the abomasum or by means of reflux in the ruminoreticulum may occur and lead to metabolic alkalosis. The blood pH and bicarbonate concentration are slightly elevated, with a concomitant small decrease in the blood chloride concentration. Ketosis is frequent and liver enzymes are often elevated, reflecting a degree of hepatic lipidosis.[6,19,20] The serum calcium level may be below normal as a result of decreased intake and absorption. Hypokalemia may develop as a consequence of both the metabolic alkalosis and reduced intake and absorption. Cattle with LDA tend to be hypophosphatemic.[21]

The complete blood count (CBC) analysis may reveal a mild dehydration and a stress leukogram. If LDA is combined with bleeding abomasal ulcers, it may produce severe anemia. The presence of a concurrent disease may lead to specific changes (e.g., left shift with acute coliform mastitis). The peritoneal fluid of cows with abomasal displacement reveals changes compatible with ischemia and inflammation.[22]

Epidemiology Cows in early lactation (particularly the first month) are at greatest risk of developing LDA. The overall incidence is highly variable among herds and related to nutrition program and related problems. Retained placenta, metritis, and increased serum concentration of β-hydroxybutyrate (BHBA) were associated with a greater risk for LDA.[3] Cows identified with subclinical ketosis early in lactation (3 to 5 DIM) were 6.1 times more likely to develop an abomasal displacement compared with cows identified later in lactation.[1] Serum BHBA above 1200 μmol/L in the first week following calving were associated with an increased risks of subsequent abomasal displacement (OR = 2.6).[2] On a herd basis, in one study in Sweden, large herd size, high maximum daily milk yield, keeping dry cows in one group, and not cleaning the feeding platform daily appear to be important risk factors for a high incidence of abomasal displacement or clinical ketosis.[23] The same research group also identified that high-incidence herds have a lower metabolic index and a higher incidence of ketosis than low-incidence herds.[5] The metabolic index used was the revised Quantitative Insulin Sensitivity Check Index (RQUICKI). Genetic factors may also play a role in the predisposition to LDA. Fox suggested that body depth had increased in dairy cattle since 1945 and that this may provide more room for the relatively empty abdominal viscera to move about at parturition.[24] More recently, cows selected for large body size had significantly greater health cost, related mostly to the greater incidence of LDA.[25] Also, the depth of the abdomen and the vertical distance between the ventral abdomen and the descending duodenum were greater in cows with a previous history of LDA ($n = 44$) than in the controls.[26] Some evidence exists to support a genetic basis for predisposition to LDA, and perhaps this is mediated through body size or conformation.

Treatment and Prognosis Treatment for LDA involves returning the abomasum to its normal anatomic location and preventing reoccurrence ("pexy"); treating the electrolyte, acid-base abnormalities, and energy metabolism problems (ketosis and hepatic lipidosis); and providing therapy for concurrent disease conditions. Prognosis for LDA is good but is influenced by the severity of the concurrent disease. Cattle with severe hepatic lipidosis and LDA should be given a guarded prognosis, as their recovery is often slow and incomplete. Also, some cattle will develop LDA as a consequence of gastrointestinal malfunction. As an example, LDA could be diagnosed in an animal suffering chronic indigestion. The prognosis of this group of cattle is poor because the primary disease is often more serious than the LDA per se.

Prevention and Control The incidence of LDA has been reduced in problem herds by dietary manipulation that reduces the likelihood of forestomach and abomasal atony caused by high-concentrate rations. This includes slow introduction of concentrates after calving, prepartum introduction of ensiled and concentrate feeds, and increase in the particle size of the forage. Maintaining serum calcium concentration around parturition and reducing subclinical ketosis early in lactation are of particular importance. Dietary cation-anion difference (DCAD) is a reliable method of controlling hypocalcemia in dairy cows (see Chapter 41).

Right Displacement of the Abomasum

Simple right displacement of the abomasum (RDA) occurs at approximately 10% to 15% the frequency of LDA.

Clinical Signs and Differential Diagnosis The general systemic state of the cow with a simple RDA is the same as that of the cow with LDA. On the other hand, as the simple RDA evolves toward the volvulus, the systemic changes observed in cattle with abomasal volvulus progressively appear. An area of tympanitic resonance is heard on the right side with simultaneous auscultation and percussion. The ping usually is confined to an area under the last five ribs in the upper half of the abdomen. The condition must be differentiated from other causes of right-sided pings, such as cecal distention (with or without volvulus), gas in the spiral colon,

VetBooks.ir

pneumorectum after rectal examination, pneumoperitoneum, physometra (gas in the uterus), and abomasal volvulus. Cecal and rectal pings usually are detectable in a linear pattern just below the transverse processes of the lumbar vertebrae extending to the tuber coxae (see Chapter 1, Physical Examination). Rectal examination identifies the gas-filled structure. Pings heard with gas in the spiral colon typically have a variable pitch, depending on the location over the cranial paralumbar fossa and last three or four ribs. Generally the spiral colon may be palpated per rectum as a laterally flattened, mildly distended viscus adjacent to the right body wall. Gas in the uterus can be detected per rectum. Pneumoperitoneum creates a ping that is distributed all along the dorsal portion of the abdominal cavity and is usually heard on both sides.

Abomasal volvulus is the most difficult to differentiate from RDA. Determination of the difference by physical diagnosis in an early case of abomasal volvulus is probably impossible. With time the cow becomes progressively more dehydrated and more severely ill with volvulus than is usual with RDA. Heart rate (above 100 beats/min), ruminal motility (totally absent), and fecal output (almost none) are clinical signs in favor of a diagnosis of abomasal volvulus. Advanced cases of volvulus also have a ping that has an arched dorsal border and a horizontal ventral border caused by the fluid level in the abomasum. This fluid is auscultable on succussion of the abomasum. Even using ultrasound to determine position of the liver, omasum, small and large intestine, the two conditions could not be distinguished from one another.[27]

Treatment and Prognosis Surgical treatment is required to correct RDA. Because of the difficulty of differentiating RDA from early volvulus, intervention should be as prompt as possible. The prognosis for a successful recovery after surgery is comparable to that for LDA if no other concurrent disease is present.

Abomasal Volvulus

Abomasal volvulus, or right torsion of the abomasum, leads to complete obstruction of the flow of ingesta into the duodenum and therefore is a surgical emergency. The condition occurs in all classes of cattle. Although RDA is thought to precede its development, unknown factors lead to abomasal volvulus.

Clinical Signs and Differential Diagnosis The systemic effects of the gastrointestinal obstruction that results from abomasal volvulus progress to a much more severe degree than in LDA or RDA. Sunken eyes and loss of skin turgor accompany the dehydration that develops. The heart rate increases above 100 beats/min, and the pulse is weak and thready. Abdominal distention is marked bilaterally. Complete ruminal stasis develops, leading to bloat, and the abomasum greatly enlarges on the right. Despite the severe degree of gastric distention, colic rarely develops in cattle with abomasal volvulus; it is much more likely with cecal distention. The skin is cool to the touch. Feces are absent or watery but scant. A large area of tympanitic resonance with uniform pitch throughout is detectable on the right, extending from the eighth rib to the middle of the paralumbar fossa. The ventral border of the ping is a horizontal line reflecting the fluid level in the greatly distended abomasum. Borborygmi are absent. Splashing fluid sounds can be heard when the abomasum is ballotted (succussed) behind the last rib.

Other causes of proximal intestinal obstruction and torsion of the intestinal mass around the root of the mesentery must be differentiated from abomasal volvulus. On rectal examination the abomasum can usually be palpated with abomasal volvulus. With intestinal obstruction or intestinal volvulus, distended loops of small intestine can be palpated. Pings caused by gas in the intestines have a variable pitch over the area involved. Cecal distention with rotation can produce a similar degree of abdominal distention high on the right, but the abdomen usually is less filled cranioventrally on the right. A ping extends to the tuber coxae, and the cecum can be palpated per rectum. Diffuse peritonitis leads to complete atony of the gastrointestinal tract, and the abdomen may become distended with gas in all parts of the tract; there is no discrete ping extending over a large area of the right side. As abomasal volvulus progresses, cattle become recumbent and depressed. Death occurs within hours of this stage, which occurs 1 to 3 days after the development of the volvulus.

Clinical Pathology The serum biochemistry profile will show much more dramatic changes with abomasal volvulus than with RDA or LDA. Clinicopathologic consequences include hypovolemia, dehydration, hemoconcentration, metabolic alkalosis, hypochloremia, hypokalemia, and paradoxic aciduria. Hyperglycemia, hypocalcemia, and hyponatremia may also be observed. Later in the condition a superimposed metabolic acidosis is also present. Anion gap gradually increases with the severity of the disease. Systemic shock eventually causes fatality. Reduced fluid intake and sequestration of large quantities of chloride-rich fluid in the stomachs (third space problem) leads to dehydration and hypovolemia. Hyperphosphatemia was also observed, possibly as a consequence of decreased renal blood flow.[21]

Under the influence of carbonic anhydrase, hydrogen ions are normally pumped into the abomasal lumen. A chloride ion follows into the lumen, whereas bicarbonate and sodium remain in the blood. Under normal circumstances the HCl leaves the pylorus, where the hydrogen ions are neutralized by pancreatic and intestinal secretions and the chloride is resorbed. When abomasal volvulus occurs, the HCl is sequestered in the abomasum and regurgitated into the omasum and rumen (internal vomiting). Ruminal chlorides increase. The animal becomes alkalotic and hypochloremic. Because of shifts between intracellular and extracellular compartments, potassium moves intracellularly as hydrogen ions move extracellularly in response to the metabolic alkalosis. This, plus the total anorexia, leads to severe hypokalemia. The hallmarks of abomasal volvulus are metabolic alkalosis, hypochloremia, and hypokalemia.

Paradoxic aciduria occurs in the face of metabolic alkalosis, when the cow should be retaining hydrogen ions. The overwhelming renal physiologic drive appears to be sodium retention. Dehydration and reduced cardiac output result in falling blood pressure. The animal must respond by volume expansion; thus sodium is resorbed in the renal tubules. Chloride is also resorbed. Because there is hypochloremia, the electrical gradient that must be corrected is high; if 140 mEq/L of sodium is resorbed and only 60 mEq/L of chloride is available, there is a net of 80 mEq/L (140 − 60) of cations that must be secreted back into the tubules. This is normally accomplished by secretion of potassium. Because hypokalemia is severe, hydrogen ions are paradoxically secreted to retain electrical neutrality so that blood pressure can be maintained by means of maximum sodium resorption.

Peritoneal fluid (PF) of cattle with abomasal volvulus was studied recently (n = 15).[22] Cows suffering from abomasal volvulus when compared with cows with a diagnosis of LDA had significant PF parameters. Total protein, albumin, L-lactate, CPK, ALP, LDH, and D-dimer were increased while fibrinogen was decreased. Also, a higher percentage of apoptotic and necrotic neutrophils was detected despite the fact that total leukocyte count was not significantly different. At least in one study, evidence of abnormal coagulation profile reflecting possible disseminated intravascular coagulation (DIC) was present in a small proportion of cattle studied (3 of 10). Hemostatic dysfunction could be present in advanced stages of the disease.[28]

Pathophysiology At least some of the factors predisposing to LDA or RDA probably contribute to the development of abomasal volvulus. Whether true RDA precedes abomasal volvulus is not known. Dissection of naturally occurring cases of abomasal volvulus demonstrated that the structures involved in rotation can vary from the reticulum to the omasum at the orad end. The rotation probably occurs most frequently at the reticuloomasal junction. The duodenum is looped around the omasum, regardless of the degree of volvulus. The ensuing displacement leads to a counterclockwise rotation of the abomasum and omasum as viewed from the right side and the

VetBooks.ir

rear. The duodenum is pulled medial to the body of the omasum and wraps around the neck of the omasum in the final configuration. The continued hydrochloric acid secretion of the abomasum and the gas produced in the omasum and abomasum further stretch and occlude the duodenum. The abomasal blood vessels and the ventral vagal trunk are compromised near the site at which the duodenum wraps around the omasum in long-standing cases. Thrombosis of vessels may occur.

The acid-base and electrolyte abnormalities of early abomasal volvulus are the same as those of LDA. In cases of severe distention of the abomasum and omasum with vascular compromise, systemic cardiovascular insufficiency develops. Reduced perfusion of peripheral tissues may lead to metabolic acidosis terminally. Hemoconcentration develops, although bleeding into the abomasum may occur from devitalized mucosa, leading to a low hematocrit. These changes are compounded by the developing necrosis of the abomasum. The abomasum may physically leak contents through a weakened, overstretched wall. Endogenous inflammatory mediators and bacterial toxins may diffuse from the abomasum to viable surrounding tissues, where absorption occurs. In either case, the viability of the abomasum is lost, and death follows shortly. At least in a sheep model of abomasal volvulus, ischemia and reperfusion injury occur.[29]

Treatment Immediate surgical intervention usually is necessary to save the animal's life. At the same time, fluid, electrolyte, and acid-base abnormalities need correction. For early cases of hypokalemic, hypochloremic alkalosis and dehydration, intravenous fluids consisting of 20 to 80 L of 0.9% sodium chloride with 25 to 100 mEq/L potassium chloride added are administered. Intravenous potassium should not be given at a rate greater than 1 mEq/kg/h to prevent cardiotoxicity. If the serum potassium level is unknown, it is best to stay with an IV rate under 0.5 mEq/kg/h. For advanced cases with metabolic acidosis, balanced electrolyte solutions such as Ringer's solution are indicated. Broad-spectrum antibiotics are appropriate if the integrity of the abomasal mucosa is questionable. NSAIDs are indicated to control pain, inflammation, and shock. Both standing right-sided and recumbent right paramedian approaches have been successful for correcting abomasal volvulus. There may be less cardiopulmonary compromise if the animal remains standing, especially if reperfusion injury is suspected to occur.

Prognosis Establishing an accurate prognosis before surgery would be optimal because at that time salvage remains a possibility and little expense has been incurred. It is not a simple task. A second critical time is shortly after surgery in cows suspected to not fully recover. The decision will be whether to continue to treat (cost) or salvage, if that still is an option.

Preoperative assessment is difficult. In our experience, assessment cannot be based on a single clinical observation or serum biochemistry value. The best published studies looked at two different classifications of outcome: death versus survival and productivity versus nonproductivity. A logistic regression model, looking at heart rate, base excess, and serum chloride level, was developed as a preoperative predictor of death or survival.[30] The study by Constable and colleagues found that four presurgical variables (hydration, heart rate, duration of inappetence, and PAL level) could be used to best predict cattle as productive or nonproductive after surgery.[31]

Assessment of outcome following surgery has been investigated. The overall success rate of surgery varies between 61.5% and 86.3%.[32-35] The number of forestomachs involved in the twist has been found to adversely affect survival and productivity. Wallace found only 20% success in cattle with reticuloomasal-abomasal volvulus.[35] Another study reported success in 55% of cattle with omasal-abomasal volvulus and 87% success in cattle with only an abomasal volvulus.[31] Edema of the abomasum carries a guarded to poor prognosis.[35-37] Edema around the proximal duodenum was associated with a poor outcome in Pearson's study, but Fubini and co-workers found no association with outcome.[36,38] Purple discoloration of the abomasal serosa tends to bode poorly for long-term outcome, as does total distention of this organ, abomasal necrosis, and thrombosis of the gastric veins.[30,35] The measurement of intraluminal pressures of greater than 16 cm Hg also carries a poor prognosis because of mucosal damage.[31] A logistic regression model using some of the surgical findings did not predict outcome any better than with the preoperative model.[30]

After surgical correction, cattle with abomasal volvulus often have diarrhea for 24 hours. Feces then firm up to normal consistency. Postoperative clinical signs associated with a poor prognosis include melena, anorexia, persistent tachycardia, and dehydration.[33,37,39] In our experience, even if appetite and general attitude are initially good (24 to 48 hours after surgery), persistence of a loose low-volume stool 72 hours after surgery may indicate complications.[40] Once clinical signs compatible with chronic indigestion develop, the survival rate is only 11.5% to 20%.[35,41] Prolonged treatment seems irrelevant. Prokinetics and their possible benefit in postoperative care was recently studied and reviewed.[42,43] Erythromycin (10 mg/kg) given preoperatively ameliorates abomasal motility in cattle suffering from abomasal volvulus.

Necropsy Findings Cattle that die of abomasal volvulus are grossly dehydrated, and the abomasum is greatly distended or ruptured. The omasum often is also greatly distended when torsion occurs at the reticuloomasal junction. Cattle that die or are euthanized after developing postoperative complications have one or more of the following postmortem lesions: gastric compartment dilation, peritonitis, abomasal wall necrosis or ulcer, vascular thrombosis, or vagal nerve lesions.[40]

Prevention and Control Because factors predisposing to atony of the forestomach and abomasum probably are important in the genesis of abomasal volvulus, prevention should be similar to that outlined for LDA.

Abomasal Ulcers

David Francoz • Charles L. Guard

Definition and Etiology Abomasal ulcers occur in cattle of all ages and rarely in sheep and goats. Signs of loss of gastric epithelium may range from no clinical signs, to hemorrhage and subsequent melena, to peritonitis if the erosive processes penetrate all layers of the abomasum. The exact cause of abomasal ulcers is still obscure and may be multifactorial. In calves, development of abomasal ulcers has been proposed to be associated with mineral deficiencies (mainly copper),[1,2] stress,[3] proliferation of microorganisms (*Clostridium perfringens* type A or D, *Escherichia coli,* Sarcina-like spp., fungi, or others),[3,4-8] and/or abrasion of the abomasal mucosa by roughage, geosediments, or trichobezoars.[9] However, all of these hypotheses have failed to demonstrate alone their involvement in the development of abomasal ulcers.[3,6,10] In adult cattle, the disease is associated with stress such as recent parturition, peak milk production or presence of concurrent diseases (mainly those of the peripartum period), and with diets high in starch.[11,12] Lymphosarcoma of the abomasum may also lead to clinical signs of ulcer disease. Finally, abomasal ulcers are an adverse effect of antiinflammatory drugs.

Clinical Signs and Differential Diagnosis Smith and colleagues[13] have classified abomasal ulcers into four types: (1) nonperforating, (2) nonperforating with severe blood loss, (3) perforating with local peritonitis, and (4) perforating with diffuse peritonitis (Table 32-18). These classifications are useful for describing the various clinical pictures that may be observed when examining an animal with abomasal ulceration.

The mildest form (type 1) is caused by nonperforating ulcers that do not result in extensive hemorrhage. Affected animals may have mild or no clinical signs. The signs are mild abdominal pain, shown by partial anorexia, decreased ruminal motility, and mild ruminal

VetBooks.ir

TABLE 32-18

Abomasal Ulcers

Type	Lesions	Clinical Signs
Nonperforating	Mucosal and some submucosal tissue loss; focal mural thickening; local serositis	Partial anorexia; decreased ruminal motility; positive fecal occult blood
Nonperforating with severe blood loss (bleeding)	Penetration of mucosa and submucosal blood vessel; hemorrhage into abomasums	Partial anorexia; decreased ruminal motility; anemia; pale mucous membranes; melena; tachycardia; cool extremities
Perforating with local peritonitis	Penetration from mucosa to serosa; leakage of abomasal contents; localized peritoneal reaction with adhesion formation	Total anorexia; low-grade fever; decreased to absent ruminal motility; localized abdominal pain; very similar to traumatic reticuloperitonitis
Perforating with diffuse peritonitis	Penetration from mucosa to serosa; widespread contamination of the peritoneal cavity with abomasal contents; significant exudate in peritoneal cavity; fibrin deposition of all serosal surfaces	Total anorexia; fever early, then hypothermia; ileus of entire gastrointestinal tract; tachycardia; shock; terminally recumbent with grunt on respiration

tympany. There is usually no febrile response. Manure may be normal or reduced in amount and stale because of prolonged transit. In some cases abdominal pain may be evident on manual pressure on the right ventral abdomen. Traumatic reticuloperitonitis (TRP) or indigestion may be suspected. In one study, about two thirds of such cows had a positive test finding for fecal occult blood.[14]

In cattle with ulcers that erode into major gastric blood vessels (type 2), blood loss can be sufficient to cause signs of anemia and hemorrhagic shock. These animals have dark blood clots in their manure or tarry, black feces with the characteristic smell of partly digested blood. The mucous membranes may be pale, tachycardia and a pounding heart may be pronounced, and the respiratory rate may be elevated. There are other possible sources of proximal gastrointestinal hemorrhage in cattle, but abomasal ulcers are by far the most common cause. Among them, bleeding abomasal ulcers must be differentiated from melena sometimes seen with intussusception or hemorrhagic bowel syndrome (HBS; see Diseases Caused by *Clostridium perfringens* Toxins, in this chapter). The packed cell volume (PCV) usually is increased with intussusception,[15] normal or increased in HBS,[16-18] and decreased with a bleeding ulcer.[19] Total anorexia and rumen stasis usually are present. The rumen may have a fluid consistency, and if the animal is able to stand, abdominal pain sometimes is evident.

Abomasal ulcers that perforate the serosal surface may lead to localized peritonitis (type 3) from contamination with abomasal contents. If the lesion is small or the local inflammatory reaction sufficiently swift, localized peritonitis results. This condition is most like TRP in presenting signs. The animal may be moderately febrile and partly or totally anorectic, and milk production may decrease acutely. There is evidence of abdominal pain, usually localized to the right ventral quadrant (positive withers pinch test). Ruminal motility may be absent, and mild bloat may be present. As with hardware disease, the signs usually abate over the course of a few days if the infection is successfully contained. In some cases the infection is confined to the omental bursa, where extensive fluid and pus may accumulate. The course of omental bursitis is much more prolonged than that of simple localized peritonitis and usually results in a guarded prognosis.

Major leakage from a perforating ulcer leads to acute diffuse peritonitis (type 4). The course of the disease usually is rapid, with signs of septic shock developing within 24 hours of the onset. Total anorexia and ruminal stasis are accompanied by tachycardia with a weak, thready pulse and a heart rate over 100 beats/min. Pain may be evidenced by grinding of the teeth or groaning. The extremities are cool, and the animal usually becomes recumbent. Abdominal enlargement may be evident as a result of both ruminal tympany and the accumulation of peritoneal fluid. Dehydration is detectable by skin pinch or by observation of the position of the eye in the orbit. Septic shock from other causes may be difficult to distinguish from that caused by perforated abomasal ulcers in the terminal stages of the disease. Diffuse peritonitis from uterine, cecal, or intestinal ruptures have the same final course. Abomasal volvulus of more than a day's duration has similar characteristics but can be differentiated by the right-sided ping and fluid in the abomasum.

Clinical Pathology Antemortem diagnosis of abomasal ulcers may be challenging, particularly in cases of nonperforating and non-severely bleeding ulcers. Fecal occult blood test may be helpful. The test is inexpensive and can be performed during the physical examination. Testing multiple samples may increase its sensitivity.[20]

Serum pepsinogen concentration has been reported to be increased in one study in cases of severe abomasal ulceration.[21] Since serum pepsinogen concentration can also be elevated in other abomasal diseases such as nematode infection, this test is not specific.[21,22] Serum gastrin concentration has also been reported to be increased in cases of type 2 ulcers in comparison with healthy cows.[12] However, the sensitivity and specificity of this test are not known.

Abdominocentesis confirms diffuse peritonitis (a large quantity of abdominal fluid is obtainable); centesis fluid may contain leukocytes with phagocytosed or free bacteria and even feed particles. In localized peritonitis the results of abdominocentesis may be normal.

Abdominal ultrasonography is also useful for the diagnosis and the evaluation of peritonitis (see section on abdominal ultrasound). Braun and colleagues reported that percutaneous ultrasound-guided abomasocentesis can be safely performed for the evaluation of abomasal fluid.[23] According to the authors, the presence of blood or hemoglobin is principally associated with abomasal ulcers.

If peritonitis is present, leukocytosis usually is present, with neutrophilia predominating in many cases. The plasma fibrinogen is increased (over 700 mg/dL) in most cattle with peritonitis. This may be evaluated in the field with a glutaraldehyde coagulation test on whole blood. The hematocrit is normal or elevated with peritonitis, but plasma protein levels may be decreased as a result of protein accumulation in the peritoneal cavity or increased if dehydration is severe. If blood loss is severe, the PCV is decreased. Cattle over 5 years of age with a bleeding abomasal ulcer should be tested for bovine leukosis virus. Results of a complete biochemistry profile or blood gas analysis are nonspecific. In most cases, they reflect a digestive stasis (hypochloremic metabolic alkalosis), but in animals in shock a metabolic acidosis may be observed. Blood urea nitrogen (BUN) may be increased. This can be a result of blood degradation in the intestine or hypovolemia and prerenal azotemia. The utility of BUN in the diagnosis of abomasal ulcers by identifying digestive hemorrhage remains to be determined.

Pathophysiology The specific events leading to erosion and ulceration of the abomasal mucosal epithelium are unknown but probably are similar to those in other species. Cytoprotective mechanisms include a mucous barrier, cloudy mucus containing bicarbonate ions to neutralize back-diffusing hydrogen ions, and high

VetBooks.ir

submucosal rates of blood flow to remove back-diffusing hydrogen ions. When these mechanisms are disturbed, gastric (abomasal) ulcers can occur. Stress, concurrent diseases, corticosteroids, and NSAIDs are among factors known to contribute.

Epidemiology Abomasal ulceration occurs in cattle of all ages. At slaughter many healthy veal calves are found to have clinically inapparent abomasal erosions and ulcers, with prevalence reported ranging from 32% to 76%.[24-27] Abomasal ulcers were observed on gross postmortem examination and histologic examination in 3.9% and 18.9% of beef calves that died between the fourth day after birth and weaning.[28] In clinically affected calves, perforation with peritonitis (rather than hemorrhage) usually develops. In clinically normal slaughter cows, 20.5% had type 1 ulcers.[29] In adult cattle with abomasal ulcers causing illness, approximately one third of clinical cases in a referral population had significant hemorrhage.[30] Of these, half had lymphosarcoma and, for the most part, were older than 6 years of age. The age of the cattle with nontumor-associated bleeding ulcers was generally younger (7 of 12 were less than 5 years old). In the remaining two thirds of the cattle, ulcers had perforated, with about half having diffused and half having localized peritonitis.[31] Most adult cattle with abomasal ulcer disease are in the first month after calving and have a concurrent disease. Many cows have been discovered to have an abomasal ulcer at surgery for displaced abomasum. Metritis, mastitis, and ketosis are the other diseases commonly seen with abomasal ulcers.

Necropsy Cattle with bleeding abomasal ulcers resulting in death are very pale and may have blood or bloody fluid throughout the distal gastrointestinal tract. The lesion in the abomasum is typically small and involves an abomasal blood vessel in the submucosa. Most bleeding and perforating ulcers were found in the fundic portion of the abomasum in the region of the proper gastric glands. The most ventral portion of the abomasum in its normal position is frequently affected.[19] Most animals have a single bleeding ulcer, but approximately 60% have one or more additional ulcers or erosions.[19] Cattle with diffuse peritonitis have many liters of foul-smelling fluid in the peritoneal cavity. Fibrin usually covers the serosal surface of all abdominal organs. The defect in the serosal surface of the abomasum is usually nearly round and 3 to 6 cm in diameter. Abomasal fluid freely enters the peritoneal cavity. Omasal bursitis may be present, with the omental recess filled with purulent to fibrinous fluid. In these cases the remainder of the abdomen may not be grossly affected. Asymptomatic abomasal ulcers (often 50 to 200) may be found coincidentally in cattle that die of septic metritis or mastitis. These ulcers generally show no signs of hemorrhage and go undetected until necropsy.

Treatment and Prognosis Treatment is aimed at correcting dietary problems, reducing stress, ameliorating concurrent disease problems, and initiating specific therapy for the clinical problems caused by the ulcer. Removal of high-energy feedstuffs and replacement with good-quality hay plus confinement to a stall are beneficial.[32] The buffer effect of food is very important for the control of abomasal pH. Consequently, the return to a normal appetite is the main goal of the treatment of abomasal ulcers.[33]

Blood transfusions may be necessary for cattle that have lost enough blood to lower the hematocrit to 14% or below. Usually 4 to 6 L given once is adequate, but repeated transfusions occasionally may be necessary. Crossmatching usually is not necessary for cattle unless repeat transfusions are performed over a period of more than 3 days. Broad-spectrum antibiotics are administered to cattle with signs of peritonitis. Principles and details on the treatment of peritonitis are described in the section on peritonitis in ruminants. Intravenous or oral fluids may be necessary to treat dehydration and metabolic or acid-base disturbances that occur concurrently. Animals with diffuse peritonitis must be given intravenous fluids with caution because of the risk of pulmonary edema associated with the low colloid oncotic pressure (COP) of their plasma.

Numerous studies have been performed to evaluate the effect of different therapeutic agents on abomasal pH of healthy calves. Results of these studies have been summarized by Constable and colleagues.[33] The therapeutic agents studied in normal calves included oral administration of an antacid agent containing aluminum hydroxide and magnesium hydroxide (25 mL and 50 mL, tid), oral administration of specific H_2-antagonists (cimetidine, 100 mg/kg and 50 mg/kg, tid; and ranitidine, 10 mg/kg and 50 mg/kg, tid), and oral administration of the proton pump inhibitor omeprazole (4 mg/kg q24h). All these extralabel treatment regimens induce an increase in mean 24-hour abomasal luminal pH. Oral administrations of the antacid agent induced a dose-dependent increase in luminal pH and were more efficacious when administered postprandially. Because some deleterious effects were observed when this antacid was administered at the dose of 50 mL tid, this should be considered the maximal dosage rate in calves.[33] Cimetidine (100 mg/kg tid) was the most effective. However, ranitidine (50 mg/kg tid) was the most cost-effective in these studies. Interestingly, the effect of omeprazole on abomasal pH decreased over the time (decreased effect observed on day 5 of daily treatment).[34] Results of these studies need now to be confirmed in ill calves. In adults, oral administration of these therapeutic agents is of doubtful benefit because of dilution in the rumen and slow release into the abomasum. Oral medications administered after stimuli that induce reflex esophageal groove closure would be more likely to have the desired effect. Traditional stimuli have included copper sulfate solutions and 10% sodium bicarbonate solution. Vasopressin (0.25 IU/kg IV) was shown to induce reliable abomasal deposition of materials given by drench to adult goats.[35] Intravenous administration of H_2-antagonists at lower doses may be efficacious, but their use by this route is cost-prohibitive ($100 to $200 USD per day) or reserved for very high-value animals. In our clinic in Quebec, we use ranitidine 1 to 1.5 mg/kg IV tid for high-value animals; our clinical impression is that this is effective.

The prognosis is good for ulcers that are neither bleeding nor perforated. For those animals that stop bleeding and those with localized peritonitis, survival and eventual return to normal function can be expected. Many dairy cattle stop lactating during the acute course of the illness and do not return to milk until the next lactation. Because abomasal ulcers generally occur within the first month after calving, most of these animals are salvaged for slaughter. Most cattle with diffuse peritonitis die despite aggressive specific therapy. Early recognition and immediate surgery followed by antibiotic and fluid therapy may save some valuable individuals. Cattle with ulcers that occur secondary to lymphosarcoma should be euthanized or slaughtered.

Prevention and Control Because the exact cause of development of abomasal ulcers is unknown, prevention is difficult. Dietary management that reduces other abomasal diseases likewise reduces the incidence of abomasal ulcers. Avoiding abrupt changes in rations and including adequate fiber sources of sufficient particle size to facilitate normal ruminal function also promote normal abomasal function. Minimizing stress caused by overcrowding, excessive competition, adverse environmental conditions, and minimizing mastitis and metritis should also reduce problems with abomasal ulcers. Elimination of animals infected with the bovine leukosis virus from the herd eliminates lymphosarcoma as a cause of abomasal ulcers. Judicious use of corticosteroids and NSAIDs is also important.

Abomasal Dilation and Emptying Defect of Suffolk Sheep

David Francoz • Charles L. Guard

Definition and Etiology A syndrome of abomasal dilation and mechanical transport failure has been described in adult Suffolk sheep.[1] The condition resembles but is uniquely different from

VetBooks.ir

abomasal impaction of cattle wintering on very poor-quality roughage. It has been mainly reported in Suffolk sheep but a similar syndrome has been described in two Hampshire,[2] one Dorset,[3] and one Texel sheep.[4] No hereditary pattern of disease has yet been found.[1,5] An abomasal emptying defect syndrome has also been reported in Toggenburg goats, which could suggest that this syndrome may therefore occur in goats.[6]

Clinical Signs and Differential Diagnosis The disease is manifested primarily by anorexia and weight loss. Most patients eventually die. Animals described in reports from several teaching hospitals were adults of both sexes.[1,5] Not all animals had all of these signs, but the following have been reported: watery green diarrhea or normal feces; ruminal tympany; pear-shaped abdominal distention; increased, normal, decreased, or absent ruminal contractions; a palpable (by ballottement) firm mass in the right lower abdomen; mild abdominal pain; tachycardia; duration of observed signs from days to months; partial to total anorexia; dullness and depression; marked to undetectable weight loss; ketonuria.

Wasting diseases of sheep include malnutrition, parasitism, dental problems, Johne's disease, caseous lymphadenitis, other chronic infections, and neoplasia. Abomasal emptying defect is distinguishable by the palpable abomasum in advanced cases and the exclusion of other possible problems. Other causes of abomasal enlargement or impaction resembling those reported in cattle must also be considered. However, when a mature Suffolk from a well-nourished flock shows weight loss and a palpable abomasum, this syndrome must be considered highly likely. Confirmation should involve response to therapy but may require necropsy or exploratory surgery.

Clinical Pathology Reports on cases seen in North America have found hematologic and blood chemical determinations of little benefit in the diagnosis. The hypochloremic metabolic alkalosis common in cattle with abomasal problems has not been consistently observed in affected sheep. Elevated ruminal chloride ion values have been the most consistent laboratory findings in published reports.[5] The normal ruminal chloride level in sheep is 8 to 15 mEq/L; affected sheep have had values ranging from 34 to 130 mEq/L due to internal vomiting. Mild hypocalcemia was observed in all cases in one report.[5]

Pathophysiology The mechanisms underlying the dilation of the abomasum and the failure to transport ingesta to the intestines are unknown. None of the problems commonly associated with abomasal impaction and dilation in cattle have been identified in affected Suffolk sheep. It has been advanced that abomasal emptying defect of Suffolk sheep may be an acquired form of dysautonomia.[1]

Epidemiology The disease has been reported mainly in sheep of the Suffolk breed and has been seen mostly in winter months in association with lambing and feeding of concentrates. Both rams and ewes have been affected. Most cases are sporadic, but at least two outbreaks have been reported.[1,5] The incidence in one report was 13 of 92 mature ewes affected in the flock during one winter.[5] In the other, 5 ewes of the same flock (200 ewes) were submitted for necropsy the same day.[1] In both studies, pedigree analysis of affected sheep in these flocks showed no hereditary pattern. One report from a diagnostic laboratory in England described abomasal impaction in a Texel ewe and in a Suffolk ram that were simultaneously diagnosed as having scrapie.[4] It remains to be seen if any causative connection exists between the two diseases. Because no antemortem tests exist for the diagnosis of scrapie, this relationship will be difficult to establish. In one study, six sheep were immunohistochemically tested for scrapie; five were negative, and one was positive and presented equivocal microscopic lesions.[1]

Necropsy Findings The abomasum is greatly distended in sheep that die of this condition. The contents are either dry or liquid but most often have resembled normal ventral ruminal sac contents. The pylorus has always been patent. Normal ingesta have been observed throughout the remainder of the intestinal tract. Incidental findings have included aspiration of ruminal contents and subsequent pneumonia, abomasal ulcer with local peritonitis, passive congestion of the liver, megaesophagus, and esophageal ulcers. Reports of histopathologic findings include no lesions other than thinning of the abomasal muscle layers (presumably as a result of stretching),[5] mononuclear cell infiltration of the main muscle layers of the abomasum,[7] and one case of myxomatous changes in the abomasal branches of the vagus nerve.[8] Chromatolytic and necrotic neurons without signs of inflammation within the celiacomesenteric ganglia were found in six of six sheep examined.[1]

Treatment and Prognosis Medical therapy alone with cathartics and laxatives has been of limited benefit. Mineral oil, dioctyl sodium sulfosuccinate, and magnesium sulfate have all been used. Neostigmine and calcium gluconate were not useful.[7] Abomasotomy has led to death from complications in many affected sheep, but those that have survived more than 2 days and have been treated with metoclopramide (dosage not reported) have shown varying degrees of recovery. Metoclopramide is a dopamine antagonist that has been used in ruminants to facilitate abomasal emptying. However, experimental studies in cattle and sheep have failed to demonstrate any beneficial effect of metoclopramide on abomasal emptying.[9,10] On the other hand, erythromycin, a motilin agonist, has been shown to increase abomasal emptying rate in cattle.[9,10] Its utility in sheep remains to be determined. Despite these successes, most affected sheep die of cachexia. Because of the expense, poor response, and risks associated with abomasotomy, this treatment is reserved for valuable breeding stock.

Prevention and Control Until more is known about the pathogenesis of this specific defect in abomasal function in Suffolk sheep, no useful recommendations for prevention can be made.

Abomasal Impaction

David Francoz • Charles L. Guard

Definition and Etiology Abomasal impaction is the accumulation of firm ingesta in the abomasum with failure of aboral transport. Depending on the cause, abomasal impaction can be classified as primary or secondary. In primary abomasal impaction, no underlying cause can be identified and the impaction is considered idiopathic. On the other hand, secondary abomasal impaction can be the result of feeding poor-quality, coarse roughage as the sole feed. Several animals in a herd may be affected over a short period. Calves may also have impaction of the abomasum caused by eating bedding or indigestible objects when fed low-quality milk replacers. The distended abomasum is filled with a firm mass of fibrous ingesta. Animals on low-fiber diets may consume wood or baling twine. Hairballs occasionally accumulate in the abomasum of calves. Indigestible material creates a mechanical outflow obstruction. Abomasal distention may occur with normal diets after correction of abomasal volvulus, secondary to reticuloperitonitis, or secondary to the development of adhesions between the abomasum and the rumen and/or the abdomen. Lymphoma involving the abomasum or other space-occupying lesions adjacent to the pylorus may lead to abomasal distention. These conditions are referred to as *vagal indigestion*. Abomasal emptying defects of Suffolk sheep were addressed in the previous section.

Clinical Signs and Differential Diagnosis Beef cows with abomasal impaction develop abomasal and ruminal enlargement over a period of days to weeks. Closely monitored animals have reduced feed intake and a reduced volume of firmer than normal feces. The animal may have bilateral ventral abdominal enlargement and bulging of the left paralumbar region. Ruminal contractions are

VetBooks.ir

of normal or increased frequency but are often reduced in amplitude. In the later stages of the disease, ruminal motility often is absent. Cattle with advanced abomasal impaction may be recumbent and groan with each respiration. The consistency of the ruminal ingesta, as judged by ballottement, may be more fluid than expected on the basis of the coarse diet. Other animals have a uniformly firm and distended rumen. The pulse and respiration are usually normal until the animal is near death, at which time tachycardia develops. The abomasum may be palpable as a firm mass following the right coastal arch. Rectal examination reveals a distended rumen; often the ventral sac extends to the right body wall (L-shaped rumen). The pyloric part of the distended abomasum may be palpable in the right ventral quadrant. Wintering beef cows usually are pregnant, and therefore the uterus prevents palpation of the abomasum. Feces are absent or very scant and dry. Mucus may be all that clings to the clinician's sleeve after rectal examination. Adult dairy cows have a consistently decreased appetite, but other signs are inconsistent.[1] In calves the abomasum may fill most of the abdomen and be doughy or firm on external palpation. The body condition of affected animals is invariably poor because negative energy balance precedes and is amplified by the impaction. If the abomasum ruptures, signs of generalized peritonitis occur. Death usually follows within hours of rupture.

In dairy cows, abomasal impaction should be considered in the differential diagnosis of nonspecific clinical signs of decreased milk production and appetite.[1] Conditions that cause dehydration and bilateral abdominal distention with absence of feces must be considered in the diagnosis. In many of these cases exploratory celiotomy is necessary to arrive at a definitive diagnosis.

Clinical Pathology

The hypochloremic, metabolic alkalosis typical of upper gastrointestinal obstruction in ruminants does not always develop in abomasal impaction.[1] Initially some fluid ingesta may pass through the abomasum, preventing chloride sequestration. However, some cattle have metabolic alkalosis with chloride accumulating in the rumen to a level greater than 30 mEq/L (internal vomiting). Terminally a metabolic acidosis from starvation may mask the metabolic alkalosis. Anemia and leukopenia can accompany the cachexia of chronic abomasal impaction in poorly fed animals. If abomasal rupture has occurred, profound hemoconcentration and leukopenia are present. Abdominocentesis generally is not useful in diagnosing abomasal impaction, because peritoneal fluid is abnormal only after abomasal rupture.

Pathophysiology

Animals fed roughage that is poorly digestible and incapable of meeting their energy requirements consume as much as the rumen will physically permit. The flow of ingesta from the forestomachs to the abomasum normally contains only small, finely digested particles of forage material. With chronic engorgement of highly lignified, poorly digestible forage, larger particles escape the forestomach and accumulate in the abomasum. Once a mass of fiber forms in the abomasum, further accumulation of particulate material is enhanced. With time, the mass fills the abomasum. Additional ingesta distend the abomasum to several times normal size. Also, abomasal secretion may be inhibited by the cachexia and chronic distention of the organ.

Abomasal transport failure after correction of abomasal volvulus is typical of vagal indigestion syndrome. Abomasal wall and vagal nerve damage, as well as peritonitis occurring secondary to the volvulus, prevent the return of normal abomasal muscular activity.[2] Vagal tone sometimes increases, and bradycardia is observed. Hypochloremic, metabolic alkalosis does develop frequently, with chloride accumulating in the ruminoreticular contents (>30 mEq/L). The abomasum distends moderately, presumably as a result of atony.

Pyloric obstruction caused by foreign bodies or occlusion caused by lymphoma leads to mechanical outflow obstruction and must be considered. Chloride escapes back into the rumen, and metabolic alkalosis develops. The abomasum retains motility, but it is ineffective in moving ingesta into the duodenum.

Necropsy Findings

Emaciation and a firm, grossly enlarged abomasum are consistent with primary abomasal impaction. In Holstein cows, a syndrome has also been described in which the impaction affected only the pyloric part of the abomasum.[1] The abomasal contents resemble normal, dry ruminal contents. The rumen is also enlarged but either filled with homogeneous, watery ingesta that lack normal stratification or impacted with dry ingesta, similar to the abomasum. The abomasum is dilated, flaccid, and filled with fluidy ingesta if secondary to an abomasal volvulus. Intraluminal foreign body or tumor involvement of the abomasal wall is self-evident.

Prognosis

Because most cases of abomasal impaction are quite advanced when brought to the attention of the veterinarian, treatment usually is unrewarding. In dairy cows the short-term prognosis was reported to be good (93%) for impaction that affects only the pyloric antrum and guarded (50%) for impaction involving the entire abomasum.[1] The clinician must weigh the severity of the metabolic disturbances and the likelihood of recovery. Salvage by slaughter is often the most economic recommendation. If therapeutic measures do not resolve the impaction, death usually occurs within a few days of the onset of severe signs.

Treatments

Medical management includes correction of fluid and electrolyte abnormalities. Early cases may be resolved with easily digestible feeds, aggressive fluid therapy, and oral administration of laxatives such as mineral oil (4 L daily). The use of prokinetic drugs may be indicated in order to increase abomasal emptying rate and the passage of ingesta through the pylorus. However, no data are available on the efficacy of the administration of prokinetic drugs in the specific treatment of abomasal impaction. Constable and colleagues[3] published a comprehensive review on the data available for the recommendation of the use of prokinetic drugs in abomasal disorders. They conclude that, to date, (1) erythromycin (8.8 to 10 mg/kg IM bid), is the most effective drug to increase abomasal emptying rate; (2) based on in vitro studies, bethanechol (0.07 mg/kg SC tid) is potentially effective but there are actually no controlled clinical trials demonstrating its effectiveness; and (3) finally, metoclopramide is an ineffective prokinetic drug in cattle to promote abomasal emptying rate and cannot be recommended. Pregnancy may be terminated by induction of parturition with corticosteroids and/or prostaglandin, leading to improved comfort.

Different approaches have been proposed for a surgical treatment of abomasal impaction. Rumenotomy, followed by installation of a nasogastric tube inserted into the abomasum through the omasum, can be performed. Through the indwelling tube, laxatives and emulsifiers may be given during the postoperative days to aid in softening and removing the abomasal contents. Mineral oil (8 mL/kg/day), dioctyl sodium sulfosuccinate (50 mg/kg/day), magnesium hydroxide (1 g/kg/day), and magnesium sulfate (2.5 g/kg/day) have each been recommended. Right paralumbar fossa, right paracostal, or right paramedial approaches can also be used to gain direct access to the abomasum. In our clinic, we prefer the right paracostal approach, with the animal in left lateral recumbency, for abomasotomy and removal of abomasum contents. However, even with this approach, complete exteriorization of the abomasum and exploration of the oral portion of the abomasum and omasum is not possible, particularly in large animals. Even if the prognosis for restoring the abomasal function is poor to guarded, we have some positive results depending on the cause of impaction and the extent of abomasal lesions. External massage may help break up the contents of the abomasum. Intraluminal administration of 5% dioctyl sulfosuccinate solution or saline can also be performed.[1]

Prevention and Control

Prevention of primary abomasal impaction requires proper dietary management of cattle in cold weather. Because animals outside without shelter have substantially increased maintenance energy requirements in cold, windy weather, straw or corn stover (stalks) is not adequate as the sole feed. Concentrates and better-quality forage prevent abomasal impaction.

Monitoring body condition during winter weather alerts the good manager that supplemental feed is needed before abomasal impaction occurs.

Obstructive Intestinal Diseases

David Francoz • Charles L. Guard

Definition and Etiology Several conditions may lead to obstruction of the flow of ingesta through the intestinal tract. These conditions can be divided into functional and mechanical obstructions. Functional obstructions (pseudoobstruction or ileus) are the consequence of neuromuscular perturbations of the gastrointestinal tract. Mechanical obstructions are the consequence of physical obstruction of the intestinal tract secondary to digestive tract lesions (intussusception, volvulus, or congenital lesions) or extradigestive lesions (mesenteric fat necrosis, fibrous adhesions, or hernia). Each of the specific diseases is discussed in the following paragraphs and summarized in Table 32-19.

Clinical Signs and Differential Diagnosis Acute manifestations of obstructive diseases include a reduced amount of feces or failure to pass feces, progressive abdominal enlargement with areas of tympanic resonance on the right side of the abdomen, and sometimes colic. If pain is severe, forestomach atony may occur. Mechanical obstructions may lead to circulatory shock and collapse. Electrolyte abnormalities depend on the site of the obstruction; those in the jejunum or near the duodenum or pylorus lead to sequestration of abomasal secretions and result in hypochloremic, hypokalemic metabolic alkalosis. Obstructions of the cecum, colon, or rectum may lead to dehydration without alkalosis. If bowel necrosis or rupture occurs, acidosis may result from the circulatory collapse that accompanies peritonitis and the absorption of toxins.

Volvulus of the Duodenal Sigmoid Flexure

A new syndrome affecting the duodenal sigmoid flexure has been reported in Holstein cattle by Vogel and colleagues.[1] The etiology and pathophysiology of this condition are not known, but the authors advanced a potential role of duodenal ulcers and/or previous omentopexy (years to months before development of volvulus of the duodenal flexure). Animals have clinical presentation resembling abomasal volvulus with anorexia, decreased milk production, scant feces, tachycardia, moderate dehydration, tympanic resonance in the tenth to twelfth right intercostal spaces, and succussion of fluid in this area.[1] Clinical chemistry revealed a severe hypokalemic and hypochloremic metabolic alkalosis as well as hyperbilirubinemia. Interestingly, those modifications were more pronounced than those observed in cases of abomasal volvulus. Confirmation of the diagnosis is made by palpation of a counterclockwise duodenal sigmoid flexure volvulus during right flank exploratory laparotomy. Treatment consists in manual reduction of the volvulus, massage of the duodenum, and fluid therapy to correct electrolytic disorders. Prognosis of the condition is reported to be fair with 22 of 29 animals that were treated successfully.

Intestinal Atresia or Stenosis

Intestinal atresia or stenosis is a congenital anomaly reported in calves and lambs. Clinical signs usually become evident within a few days after birth. Animals with anal or distal rectal atresia usually have the slowest onset of signs, whereas proximal obstructions lead to more rapid onset of signs. Malformations of the anus and rectum are believed to be hereditary,[2] and breeding of surgically corrected survivors should be discouraged. Jejunal atresia in the Jersey cow has been reported to be inherited as an autosomal recessive trait. The etiopathogenesis of atresia coli in calves is not well understood, but autosomal recessive inheritance has been reported[3] and Holstein calves seem to be predisposed.[4] Rectal palpation of the amniotic vesicle for early pregnancy diagnosis (<42 days of gestation) is also suggested to be a cofactor for the development of atresia coli.[4,5] If the anus or distal rectum is atretic, animals strain or pump their tails in an attempt to defecate. A fistulous connection may exist between the rectum and the urogenital tract (e.g., either the vagina or the pelvic urethra). Visual and digital exploration of the perineum reveals the absence of feces and may permit definition of the specific defect. Stenosis or atresia of the intestinal tract may occur to any degree and can be differentiated in four types according to classification in humans: narrowing, a membranous diaphragm with a perforation, or an imperforate membrane (type 1); a cordlike remnant of the intestine (type 2); a unique blind-ended dilation with complete separation of the intestine (type 3, the most frequent); and multiple sites of atresia (type 4).[6] All have been described in cattle. Affected neonates show depression and mild colic and progress to cardiovascular collapse after the intestine proximal to the obstruction becomes distended with fluid and gas. Tympany may be easily detected by percussion. If the anus and rectum are normal, a digital examination usually reveals only mucus or blood (or both). Because the rectal and descending colon walls are thin in cases of atresia coli, retrograde

TABLE 32-19

Causes of Intestinal Obstruction in Ruminants

Disease	Animals Most Commonly Affected	Signs
Intestinal atresia or stenosis	Neonates	No feces; abdominal distention
Intestinal volvulus around mesenteric root	All ruminants; neonates more common	Colic; rapid abdominal distention; collapse; shock
Intussusception	All ruminants; LI or SI of neonates; SI of adults	Colic early, then chronic low-grade pain; dehydration; mucus plus blood in dark red feces; slow abdominal distention; decreased fecal output; mass palpated per rectum; distended loops of intestine per rectum
Cecal dilation and volvulus	Adult dairy cattle in early lactation	Mild to severe colic; distended abdomen, especially upper right; ping in right paralumbar fossa; distended cecum palpated per rectum
Intestinal tumors	Sheep, rare in cattle	Progressive weight loss; cattle—may palpate mass per rectum; sheep—identify by celiotomy or necropsy
Mesenteric fat necrosis	Cattle, especially Channel Island breeds	May discover masses on routine examination; progressive weight loss; scant or no feces; dilated loops of bowel per rectum
Intestinal incarceration	All ruminants	See Intussusception
Pseudoobstruction or ileus	All ruminants	Scant or no feces; right-sided ping; succussable fluid on right; often associated with peritonitis

LI, Large intestine; *SI,* small intestine.

VetBooks.ir

VetBooks.ir

tubes or catheters should be used with extreme caution to prevent rupture of the bowel or should be avoided completely.[6] Complete intestinal volvulus must be considered in the differential diagnosis, but histories are often different.

Surgical repair is indicated if the animal is of high value. However, the prognosis for normal and productive life is guarded. Many affected neonates develop severe complications in the immediate postoperative period. Pneumonia, sepsis, and peritonitis are among the most frequent complications, and the development of bowel stasis or ileus is common. When registered animals are involved, a letter should be sent to the appropriate breed registry stating that the defect has been corrected.

Volvulus of the Large and Small Intestine around the Mesenteric Root

Volvulus of the large and small intestine around the mesenteric root leads to severe colic and relatively rapid abdominal enlargement. Circulatory shock develops rapidly. Ruminants of any age are susceptible, but most cases are seen in preruminant neonates. Severe colic is seen, including kicking and vocalization. Affected animals rapidly become recumbent, and hypovolemic shock develops. The heart and respiratory rates increase greatly as shock develops. Variable-pitched resonant sounds may be heard bilaterally over the abdomen using simultaneous percussion and auscultation. In adult cattle, the tympany is restricted to the right side. Succussion reveals splashing sounds, particularly on the right side. Rectal examination reveals distended loops of gut. Surgical correction is the only successful treatment option.[7] The prognosis depends on the degree of devitalization of bowel. Animals surgically corrected during the early stages respond better.

Volvulus of smaller portions of the intestinal tract leads to signs similar to those of complete intestinal volvulus around the root of the mesentery, but often this is slower in onset. Colic with accompanying tachycardia, ruminal stasis, and anorexia is present to varying degrees. The abdomen is moderately distended on the right when the animal is viewed from the rear. Simultaneous auscultation and percussion on the right side reveal multiple-pitched, resonant pings from the gas accumulated proximal to the obstruction. Rectal examination may reveal scant feces, mucus, or blood. The affected bowel usually is palpable as grossly distended with gas and some fluid. Because of their relatively long mesentery, the spiral colon (or part of it), the distal jejunum, and the proximal ileum may develop an obstructive volvulus. Therapy requires correction of acid-base and electrolyte abnormalities and rapid surgical manipulation by means of celiotomy.

Intussusception

In the development of an intussusception, the oral portion of gut (intussusceptum) usually is engulfed and propelled distally by peristaltic action of the enveloping portion (intussuscipiens). Constable and colleagues reported an increased prevalence in calves less than 2 months of age compared with adults, and in Brown Swiss compared with Holstein cows.[8] The condition has also been reported in goats[9] and in sheep.[10,11] Intussusception may occur in either the large or the small intestine of calves but is much more frequent in the jejunum.[8] Clinical signs include colic caused by the tension on the mesentery on the invaginating portion of the intestine. With time, ischemia of this portion leads to pain and eventually loss of sensation. Distention of the intestine with fluid and gas proximal to the obstruction leads to abdominal pain. Therefore a cow may show violent behavior or kicking at the abdomen in the first few hours that is eventually succeeded by treading and repeated lying and standing. Over the course of several days the intussusceptum may become totally devitalized and slough. This is accompanied by severe peritonitis, and in the event of bowel rupture, toxic shock will develop. The exact cause of intussusception remains unknown. Intramural or luminal mass or lesions, viral enteritis, intestinal parasitism, abrupt dietary changes, administration of intestinal motility modifier drugs, and foreign body or prior surgery have all been reported to be potential causes, but in most cases, intussusception is idiopathic.[8]

Dehydration develops as gastrointestinal secretions accumulate in the gut lumen. In adults, hypochloremic, hypokalemic metabolic alkalosis develops gradually. The rumen becomes distended with fluid as its contents become more finely digested and abomasal reflux accumulates. The right side of the abdomen (or both sides) also enlarges as a result of the distention of the small intestine. Simultaneous auscultation and percussion of the right side of the abdomen reveals areas of variable-pitched resonance. Rectal examination reveals distended loops of small intestine. The intussusception may be palpable as a firm mass, and the cow may demonstrate pain when the mass is palpated. Feces are absent within hours of the onset of signs. The examiner may find mucus and blood in the descending colon. In long-standing cases the scant feces are very dark red and must be distinguished from the black feces (melena) associated with abomasal bleeding. Fluid obtained by abdominocentesis shows an increase in erythrocytes and leukocytes and an elevated protein level. Fever is often present because of peritonitis. If the condition is long-standing and bowel rupture has occurred, bacteria may be present. The complete blood count (CBC) may reveal neutrophilia and an elevated plasma fibrinogen level.

In neonates with enteritis, fecal output decreases as appetite is lost after intussusception. A fever may develop as peritonitis occurs. Calves and other neonates may not exhibit obvious signs of colic. Percutaneous abdominal palpation using both hands in an attempt to detect a mass is often successful in delineating an intussusception in a neonate. When neutrophilia, hyperfibrinogenemia, and loss of appetite develop after enteritis, intussusception should be suspected.

Treatment requires both surgical correction of the obstruction and parenteral restoration of fluid and electrolyte balance. Because of the losses of chloride and potassium and the development of alkalosis, 0.9% sodium chloride solution with 30 mEq/L or more of added potassium chloride is recommended. Intravenous potassium should not be given more rapidly than 1 mEq/kg/h (conservative rate is 0.5 mEq/kg/h). Once intestinal patency has been restored, oral fluid and electrolyte supplementation usually allows the patient to achieve normal status.

The prognosis is usually good if surgery is performed early in the course of disease. Complications such as peritonitis can occur and need to be controlled to maintain the chance of success. A retrospective study of 336 cases of intussusception reports a postoperative survival rate of 43% and an overall survival rate of 35%.[8]

Intestinal Incarceration

Intestinal obstruction may occur in ruminants as a result of accidental entrapment of loops, usually of jejunum, around remnants of embryonic structures or through acquired defects in mesentery or the abdominal wall. Remnants of the urachus, the omphalomesenteric duct, the left umbilical vein, and the ductus deferens have been described as responsible for incarceration of the jejunum. The authors of one report indicated that 26% of cows examined had a persistent round ligament of the liver and falciform ligament.[12] Thus tears in the falciform ligament leading to intestinal entrapment may be among the most common causes of the relatively rare problem of intestinal incarceration in cattle. Duodenal obstruction caused by malposition of the gallbladder was also reported in a heifer.[13] Intestinal adhesions caused by intraperitoneal injections of irritating substances may also lead to intestinal obstruction. Initial signs of colic followed by depression, anorexia, progressive abdominal distention, and absence of feces usually develop. Distended loops of small intestine usually are palpable per rectum. Treatment of intestinal incarceration requires surgical intervention.

Cecal Dilation and Volvulus

Cecum distention may be classified as (1) cecal dilation: The cecum is only distended by gas and the apex of the cecum is displaced

VetBooks.ir

toward the rectum and may be palpated by transrectal palpation; (2) cecal retroflexion (that can cause vascular damage and ischemia, i.e., volvulus): The cecum is distended, displaced, and folded dorsally or ventrally, the apex of the cecum is consequently oriented cranially and is usually not palpable per rectum; (3) cecal torsion: The cecum is distended and rotated along its long axis, the apex of the cecum is displaced toward the rectum and can be palpated transrectally.[14] In a large study of 461 cases of cecal dilation, preoperative clinical diagnosis based on rectal palpation was cecal dilation alone in 291 animals (63.2%), cecal dilation and retroflexion in 94 animals (20.4%), cecal dilation and torsion in 20 animals (4.3%), and in the remaining 56 animals, no diagnosis of cecal dilation could be made preoperatively.[15] In adult cattle, cecal dilation generally is believed to precede retroflexion or torsion.

The etiology and pathophysiology of cecal dilation and retroflexion or torsion remain unknown. Different feeding or management practices may predispose to cecal disease.[15] Increased luminal concentration of volatile fatty acids (VFAs) was classically believed to play a major role in the etiopathogenesis of cecal disorders. However, results of studies on the impact of VFAs on cecal motility have been contradictory. In one study, increased concentration of VFA had only minimal effect on large intestine motility and was unlikely to play an important role in the development of cecal disorders.[16] Factors that affect motility, as described for displaced abomasum, are likely similar.

Cattle with cecal dilation have a more gradual onset of illness than that noted with cecal retroflexion or torsion. The time required for dilation to develop into retroflexion or torsion is unknown. With simple dilation, feed intake and milk production decrease. Mild abdominal pain may be observed. Feces are usually still present, but the consistency may be loose and the amount reduced. Rumen motility is decreased. Distention of the right paralumbar fossa without the ribs being sprung is frequently observed in our clinic and has been mentioned in different reports. However, Braun and colleagues[15] reported that only 42 animals of the 461 cattle affected with cecal dilation, retroflexion, or torsion had distention of the right flank. The most important clinical findings for the diagnosis of cecal dilation are (1) the presence of a large area of resonance (ping), auscultable from the tuber coxae to a variable distance cranially (see Chapter 1, Fig. 1-3), associated or not with a positive succussion of the right flank[15]; and (2) the transrectal palpation in the pelvic canal or nearby of the apex of the gas-filled cecum. Cattle with cecal retroflexion or torsion have more severe clinical signs. They show an abrupt onset of anorexia, agalactia, and severe abdominal pain. Tachycardia and forestomach stasis are also present. Feces are scant or absent. The abdominal distention usually exceeds that caused by simple cecal dilation. The area of resonance in the right paralumbar fossa is larger, and fluid usually can be detected in the cecum and proximal colon by succussion. In cases of retroflexion, the apex of the cecum is not usually palpable per rectum; rather, the distended body of the cecum or proximal colon impinges on the pelvic canal because the apex is directed cranially. In cases of cecal torsion, the apex of the cecum can be palpated per rectum as well as a tense ileocecocolic ligament that spirals around the cecum.[14] Distended small intestine may be palpated with either dilation or retroflexion or torsion.

Although some cows with simple dilation have no acid-base abnormalities, most with cecal retroflexion have some degree of metabolic alkalosis with hypochloremia and hypokalemia. Hypocalcemia is reported to be observed in about 85% of cases of cecal dilation, retroflexion, or torsion.[15]

Medical management of cecal dilation is usually successful with use of fluid therapy to restore normal hydration status and correction of electrolyte abnormalities including hypocalcemia, as well as administration of nonsteroidal antiinflammatory drugs (NSAIDs) to control abdominal pain. Laxatives have also been recommended for the medical treatment of cecal dilation. However, Braun and co-workers[17] reported that the use of laxatives (liquid paraffin) for the treatment of cecal disorders delayed the time to first defecation. Moreover, magnesium hydroxide may be responsible for detrimental effects such as metabolic alkalosis,[18] increased ruminal pH,[19] and decreased ruminal microbial activity.[19] Prokinetic drugs that can be used in the management of cecal disorders are presented in the section on the acute abdomen in cattle. Finally, animals should be fed a high-fiber diet.

Braun and colleagues[15] reported that 122 of 461 animals with cecal dilation, retroflexion, or torsion were first managed medically. Forty-two of these 122 animals finally required surgery. Considerations for conservative versus surgical treatments are presented in the section on acute abdomen. Cattle with cecal retroflexion or torsion require immediate surgical intervention, fluid management to correct the hypochloremic, hypokalemic metabolic alkalosis, hypocalcemia, and administration of NSAIDs to control pain. The prognosis for surgical patients depends on the degree of ischemic injury to the cecum and other structures involved in the obstruction. The recurrence rates after surgery range from 10% to 13.8% within a year of the first incident.[15] In cattle with recurrence of cecal dilation or with devitalized portion of the cecum wall, amputation of the cecum is recommended.

Intestinal Tumors

Intestinal tumors are rare in cattle. The most commonly reported intestinal tumors in cattle are adenocarcinomas. However, lymphosarcoma, adenoma, adenomatous polyps, carcinoid, leiomyoma, leiomyosarcoma, and fibrosarcoma have also been described.[20] The incidence of adenocarcinoma in sheep is relatively high in some areas of the world, such as New Zealand.[21] The predisposing factors for adenocarcinomas are not known, but different environmental carcinogens have been suspected.[21,22] In sheep, no association with infectious agents (herpesviruses, *Helicobacter* spp., or *Mycobacterium avium* subsp. *paratuberculosis*) was found.[21] Genetic predisposition is suspected,[22] but no significant genetic defects were found in one study.[21]

Affected cattle or sheep may have a protracted course of weight loss with no other observable signs until near death. Alternatively there are reports of acute gastrointestinal disturbances manifested by colic, abdominal distention, and auscultable right-sided pings.[23] Although these cases are rare, they must be differentiated from other causes of acute obstruction in cattle such as cecal volvulus, intussusception, or abomasal volvulus. In cattle in which rectal examination is possible, the lesion may be detected on routine examination as an intramural mass or annular constriction of the jejunum or ileum. In sheep, the diagnosis is usually made at necropsy. Clinical signs in affected animals might include diarrhea, abdominal distention caused by the accumulation of gas and ingesta proximal to the obstruction, or ascites. The well-characterized lesions in sheep involve local spread of the tumor through the lymphatics and intraperitoneally. Ultimately, cellular deposits occur on all visceral and parietal peritoneal surfaces, severely impairing lymphatic drainage from the abdomen.

Mesenteric Fat Necrosis

Mesenteric fat necrosis affects cattle of all breeds, but more commonly Aberdeen Angus and Jersey cattle.[24] It has also been reported in a pigmy goat.[25] The cause remains unknown but dietary factors have been implicated, such as consumption of feed containing long-chain, saturated fatty acids; trace element deficiency; trauma; hormonal disturbance; and ingestion of endophyte-infected fescue.[24,25] The lesions develop as an inflammatory response around degenerating adipose cells. The triglycerides in these cells are thought to undergo hydrolysis to glycerol and fatty acids. The longer the carbon skeleton is and the greater the degree of saturation is, the more resistant are the fatty acids to removal by normal cellular mechanisms. Remaining clumps or crystals of fatty acids serve as inflammatory foci for the subsequent necrotic masses.[24] Affected cattle have subnormal serum free cholesterol and elevated serum free fatty acids.[26] Cattle with fat necrosis may eventually develop an intestinal obstruction. The clinical signs resemble those of progressive intestinal

VetBooks.ir

obstruction from other causes. Weight loss, anorexia, diarrhea, bloody stool, abdominal enlargement, and right-sided ping are all possible signs. Fever, tachycardia, and signs of discomfort such as tenesmus, treading, and teeth grinding may be seen as the obstruction becomes more severe. Many affected cattle have no clinical signs, and the condition is discovered during rectal examination for other reasons. Rectal examination may be impossible because of stricture of the rectum, or dystocia may occur as a result of the necrotic fat masses in the pelvic canal. Fat necrosis usually affects mature cattle,[24] but there is a report of a 6-month course of illness attributed to fat necrosis in a 13-month-old Black Angus heifer.[27] Ultrasonographic appearance of abdominal fat necrosis has been described and appears to be a useful diagnostic tool, associated or not with ultrasound-guided biopsy.[28]

Animals with fat necrosis that becomes clinical usually are not treated. Different treatments have been attempted over the years, but none was considered effective. Experimental therapy of subclinical fat necrosis using a compound that alters lipid metabolism in fungi was successful in one study.[26] The fungicide isoprothiolane was given at a dosage of 20 g/day PO for 8 weeks. Approximately half of the treated cows had a 50% reduction in necrotic masses by 12 weeks; at follow-up evaluation in 1 year, the masses were not detectable in half the surviving cows. Cows given such unapproved drugs should not be used for food.

Hemorrhagic Bowel Syndrome (Jejunal Hemorrhage Syndrome)

Hemorrhagic bowel syndrome (HBS), also called *jejunal hemorrhage syndrome* (JHS), is an acute enteric disease of cattle characterized by segmental intraluminal hemorrhage with subsequent obstruction of the small intestine (also see Diseases Caused by *Clostridium perfringens* Toxins, in this chapter). The disease seems to have been described for the first time in 1991[29] and is now reported in different countries. HBS mainly affects dairy cows, but it is also reported in beef cows and bulls.[30,31] It is principally a sporadic disease, but outbreaks in dairy herds have been reported.[32,33]

The pathogenesis of HBS is still unknown and may be multifactorial. Different pathogens have been implicated. They include *Aspergillus fumigatus,*[34] *Clostridium perfringens* type A and *Clostridium perfringens* type A with β2 toxin,[32,33,35,36] and recently mycotoxic fungi in association with Shiga toxin–producing *Escherichia coli* (STECs).[37,38] *C. perfringens* type A was the first pathogen recognized as potentially implicated in the disease and is evoked as the most likely cause by many authors.[32,33,35,36] However, it is very difficult to clearly define the precise role of *C. perfringens* in the pathogenesis of HBS because *C. perfringens* type A is present in the intestine of healthy cows and is known to proliferate rapidly after death. Ewoldt and Anderson were unable to reproduce the disease by direct inoculation in the abomasum or jejunum of *C. perfringens* type A with β2 toxin.[39] Additionally, different cases of HBS have been reported without any detection of *C. perfringens* type A.[37,38,40] *A. fumigatus* was also not found in different studies on HBS.[37,38] Inversely, recent studies in dairy and beef cattle have demonstrated that mycotoxigenic fungi in the feed (other than *A. fumigatus*) and STECs may play a role in the pathogenesis of HBS.[37,38] Authors of these studies suggested that mycotoxins could contribute to pathogen colonization, but further studies are still required to evaluate more specifically the possible interaction between mycotoxins and STECs and their involvement in HBS. Different risk factors have been described in the development of HBS. They include lactation stage (being in the first 100 days of milk and in the second or higher lactation), feeding regimen (being fed with a total mixed ration [TMR] or a high-energy diet with low fiber), and herd size (herds with more than 100 cows).[32,33,36] Berghaus and colleagues, in their study on risk factors associated with HBS, conclude that all management practices associated with high-producing cows may promote the occurrence of HBS.[41] In one study, Brown Swiss cattle were more frequently affected by HBS in comparison with other dairy cattle.[42]

Affected animals may be found dead, but they typically demonstrate an acute decrease in milk production, anorexia, mild increase in heart rate, normal temperature and respiratory rate, and slight to moderate dehydration. These clinical signs worsen rapidly as the condition evolves. Mucous membranes are frequently pale or congested, which reflects the cardiovascular and hypovolemic shock. Animals usually have slight to moderate right abdominal distention. Clinical signs of abdominal pain may be present. Ruminal contractions are decreased or absent depending on the stage of the disease. The rumen may also be distended. In most cases, transrectal examination demonstrates intestinal distention and scant to absent feces. An intestinal mass is rarely palpable per rectum. When present, feces contain digested and/or clotted blood. HBS must be differentiated from other causes of intestinal obstruction (intussusception, intestinal incarceration, volvulus of the intestine around the mesenteric root), dysentery (salmonellosis, coccidiosis, winter dysentery, coagulopathies), and melena from abomasal ulcers.

Signs of intestinal obstruction are observed during the transabdominal ultrasonography (distended intestinal loops, decreased or absent peristalsis).[43] In some cases hyperechoic structures (blood clots) are observed in the lumen of the intestine.[31,36,43] Hematologic findings are consistent with a slight to moderate inflammatory process. Hematocrit is usually normal as a result of combined hemorrhage and hypovolemic shock. A hypochloremic, hypokalemic metabolic alkalosis is frequently observed on blood gas analysis, consistent with a proximal intestinal obstruction. Postmortem lesions consist of segmental necrohemorrhagic enteritis of the small intestine. The jejunum is the portion of the intestine most frequently involved.[30,31,36] An intraluminal blood clot associated with intramural hematoma and ulceration is observed. Histologic examination of the intestinal wall frequently reveals submucosal hemorrhage, edema, and neutrophilic infiltration, as well as necrosis and ulceration of the mucosa.[30,31,36]

The medical treatment of HBS consists mainly of fluid therapy to restore electrolyte imbalance and to correct dehydration and antimicrobial drugs and NSAIDs to control pain and inflammation. In our clinics we also found a beneficial effect of transfusion of 5 to 6 L of blood.[31] Surgical treatment consists of right flank laparotomy associated with enterectomy of the affected intestines. If the intestines do not look devitalized, the clot can be dislodged by manual massage or enterotomy.

The prognosis for animals with HBS is guarded. Mortality rates of 100%[30] and 77%[36] have been described. However, prognosis of 55% (20 of 36)[31] and 58% (18 of 31)[42] have been reported from two referral centers. In the first study, two animals out of five that were treated medically and 18 animals out of 30 treated surgically survived.[31] In the other study, all dairy cows underwent surgery; among the 18 animals that survived, 6 had a recurrence within the following 12 months and 13 were still alive after 12 months. In this study, short-term prognosis was reported to be significantly improved when the blood clot could be dislodged by massage.[42]

Because the etiopathogenesis of HBS is not well understood, it is difficult to provide recommendations for the prevention of HBS. Prevention may focus on management practices, and particularly feeding practices, to provide adequate fiber length and quantity in the diet. Because the role of *C. perfringens* type A in the pathogenesis of HBS is not proven, the recommendation of a specific vaccination against this bacterium may be questionable. However, a vaccine, *C. perfringens* type A toxoid, is available in the United States. Vaccination with the commercially available seven-way clostridial vaccines does not appear to protect against development of HBS.[41] In one study, a combination of a prebiotic and a probiotic in the feed was associated with a reduction of the disease in dairy cattle.[38]

Ileus (Pseudoobstruction)

Failure to pass feces usually is a sign of intestinal obstruction. However, in adult lactating dairy cattle, a condition of ileus of the intestinal tract that mimics complete intestinal obstruction is

VetBooks.ir

commonly observed. The condition often resolves spontaneously or with medical treatment (fluids, calcium, and pain management); in rare instances surgical decompression of the affected bowel is required. Cows are most often in early lactation, and treatment is sought for partial anorexia. Colic sometimes is the presenting sign. Clinical examination reveals a normal temperature, a normal to elevated heart rate, and normal respiratory rate. Ruminal motility is decreased. Slight right-sided abdominal enlargement may be seen early and may progress to extreme distention of the abdomen on the right. No borborygmi are heard on the right side, but fluid tinkling sounds may occur. Simultaneous auscultation and percussion reveal areas of variable-pitched resonance. Succussion produces sloshing sounds. On rectal examination a distended spiral colon, cecum, or small intestine may be palpated. Early in the course of the disease the distention is not extreme, and compression easily flattens the affected bowel. If abdominal distention is severe, introducing the arm into the abdominal cavity may be difficult because of the pressure of distended bowel at the pelvic inlet. No feces are passed, but the examiner's arm may be coated with sticky mucus and feces with a stale odor. Serum electrolytes and acid-base status are usually normal. Serum calcium may be decreased. Differential diagnoses to consider include intussusception, intestinal incarceration, intestinal volvulus, and cecal dilation. There is no blood in the feces, and no masses are palpable per rectum with pseudoobstruction.

Because most obstructive lesions of the intestine in cattle are not immediately life-threatening, symptomatic therapy or simply close observation may be elected for 24 hours. If surgery is elected in the absence of an obstructive lesion, the bowel may be decompressed and drained. This is a laborious procedure that requires multiple punctures unless the distention is restricted to the cecum and spiral colon. Despite the lack of correction of a specific underlying defect, many cows begin passing feces soon after an exploratory celiotomy. Manipulation of the intestinal tract alone seems to have beneficial effects. This response is difficult to differentiate from the spontaneous recovery that may occur without surgery in cows. Relief of distention of portions of the intestinal tract may remove reflex inhibition of motility that can occur in response to extreme stretching of mural tension and pain receptors. The cause of pseudoobstruction of the intestine is unknown, and little pathophysiologic information has been elucidated. Medical management is described in detail in the acute abdomen section. It mainly includes administration of fluids, calcium, and NSAIDs. Numerous practitioners also administer oral laxatives, but as mentioned earlier, the practice of using magnesium salts may be questionable and could have deleterious effects.

Diseases Caused by *Clostridium perfringens* Toxins (Enterotoxemia, Yellow Lamb Disease, Lamb Dysentery, Necrotic Enteritis)

Paul G.E. Michelsen • Bradford P. Smith

Definition and Etiology

Clostridium perfringens is a toxin-producing, anaerobic, spore-forming rod. It is a variable species that causes a variety of diseases in human beings and animals. Some biotypes are normal inhabitants of soil, and some are commensal intestinal organisms of animals. A sometimes confusing nomenclature has evolved to organize the complexity of *C. perfringens* biology. Clinical isolates are assigned to one of the types (A through E) on the basis of possession of the major toxins (alpha, beta, epsilon, iota) (Table 32-20). In addition to these four major toxins, strains of *C. perfringens* may produce any of at least eight other recognized soluble antigens, some of which have pathogenic importance and could be called toxins. Beta 2–toxin may be an important toxin as well. Most of these antigens are named with Greek letters. The soluble *C. perfringens* toxin responsible for one type of food poisoning in humans has not received a Greek-letter name but is commonly known as enterotoxin (or CPE, which stands for *C. perfringens* enterotoxin). Enterotoxin is also the general name for toxins that affect the intestines, and many of the *C. perfringens* antigens with Greek-letter names are also enterotoxins. In this discussion the toxin that causes food poisoning in human beings is denoted CPE to distinguish it from enterotoxin as a class of toxins. CPE is not recognized as the major component of classic *C. perfringens* disease in animals, but it may be important in some cases.[1,2]

The different biotypes of *C. perfringens* cause different diseases because they have different toxins, but a clear-cut assignment to one of the groups is not always possible, and overlap is considerable in

TABLE 32-20

Types of *Clostridium perfringens* by Toxin Type and Diseases That Have Been Attributed to the Type*

Group Typing Toxins					
Type	Alpha	Beta	Epsilon	Iota	Diseases Attributed
A	XX	—	—	—	Gas gangrene (along with other organisms) Avian necrotic enteritis Hemorrhagic enteritis in cattle Yellow lamb disease Enterotoxemia of mink Type A enterotoxemia of horses Abomasal tympany and ulcers of calves Sudden infant death syndrome (crib death) Food poisoning in humans
B	X	XX	X	—	**Lamb dysentery** Enterotoxemia of sheep and goats (Iran) Enterotoxemia of foals (Britain)
C	X	XX	—	—	**Necrotic enteritis** (neonatal hemorrhagic enterotoxemia of calves, lambs, kids, foals, piglets) Necrotic enteritis of fowl, struck (enterotoxemia) of sheep (Britain) Necrotic enteritis of humans (pigbel, Darmbrand)
D	X	—	XX	—	**Enterotoxemia** ("overeating disease," "pulpy kidney disease") of sheep, goats, and cattle
E	X	—	—	X	Enteritis in rabbits Occasionally isolated from sheep and cattle Abomasal tympany and ulceration of calves

*Diseases of major veterinary importance are in boldface.

X, Toxin of minor importance; *XX,* toxin of major importance; —, not present.

VetBooks.ir

the clinical signs caused by the various toxins. Many different diseases in many different animals have been ascribed to *C. perfringens,* but the ubiquitous nature of the organism and the fact that it rapidly overgrows into tissues after death makes the significance of its isolation questionable at times unless the toxin is also demonstrated.

One additional potentially confusing bit of nomenclature concerns the term *enterotoxemia.* Although this term is widely applied to various diseases caused by *C. perfringens,* it is strictly appropriate only for diseases in which the major signs are caused by systemic spread of the toxin in the blood.

One group of diseases caused by *C. perfringens* type C is commonly called "hemorrhagic enterotoxemia," even though the disease is not always hemorrhagic and, although the toxin may incidentally reach the circulation, it is produced in the intestine and exerts its major effects locally. A better descriptive name for this disease has been proposed to be *necrotic enteritis.* It is important to realize that many of the effects of other biotypes of *C. perfringens* are systemic and that enteric clinical signs may be entirely lacking with disease caused by *C. perfringens* types A and D. Each type is discussed in the following paragraphs. Type E is only occasionally isolated from livestock and is not discussed.

Diagnosis of Disease Caused by Clostridium perfringens Meaningful diagnosis of *C. perfringens* as the cause of death or disease in an animal requires an integrative, open-minded approach. Type A is routinely isolated from soil and clinically normal animals. Types C and D are only rarely isolated from soil but can be isolated from asymptomatic individuals, especially those with neutralizing antibody to toxin. The bacterium proliferates after death, often crowding out other enteric organisms and invading tissues beyond the gut. The isolation of *C. perfringens* from a necropsied animal is not by itself sufficient basis for the diagnosis; however, if toxin is also demonstrated in gut contents and the history and lesions are compatible, a diagnosis of death from *C. perfringens* intoxication can be made.

Until recently, an isolate of *C. perfringens* was assigned to one of the five biotypes by demonstrating toxin production with mouse-protection assays or enzyme-linked immunosorbent assay (ELISA) techniques. This has been replaced by a multiplex polymerase chain reaction (PCR) technique that detects the genes for toxin production in a clinical isolate.[3] CPE, which causes food poisoning in human beings, can be detected with commercially available assays and is also detected by the multiplex PCR technique. Meaningful samples for bacterial isolation come from freshly dead animals. Samples of gut contents should be collected into sterile containers and cooled or frozen. In addition to typing bacterial isolates, demonstration of toxin or toxin genes via PCR in gut contents may aid in diagnosis. False-negative results may occur in type C disease if proteases inactivate the beta-toxin.

In the absence of definitive microbiological evidence, a presumptive diagnosis of type C or D disease must be based on the history, clinical signs, pathologic findings, and differential diagnoses. Administration of toxoid vaccines (and antitoxin to stop an outbreak) is effective and may be recommended without conclusive evidence for causation. This "whole herd" protection test may be as close as one gets to definitive diagnosis in field situations. Examination of gut-content smears from various levels of the gastrointestinal tract to demonstrate large numbers of bacteria resembling *C. perfringens* may be a helpful piece of information, but the significance of such a finding by itself is questionable. Glucosuria in urine obtained from the bladder at necropsy is often seen in sheep (but not other species) with type D disease.

Type D disease should be distinguished from other causes of acute death (see Chapter 14). A history of sudden death in a rapidly growing, apparently healthy individual is characteristic. A single lamb is much more likely to have overeating disease than is a twin. Other causes of acute disease in well-fed individuals include systemic pasteurellosis (lambs), acute bloat, grain overload, polioencephalomalacia, and thromboembolic meningoencephalitis (cattle). These generally have a longer disease course than type D enterotoxemia.

Clostridium perfringens Type A (Jejunal Hemorrhage Syndrome, Yellow Lamb Disease, and Others)

C. perfringens type A can be found in many soils and is a normal inhabitant of the gut in many species. Although all five types of *C. perfringens* produce alpha-toxin, type A strains usually produce more than other types. The toxin is a phospholipase and causes lysis of red cells, platelets, and leukocytes (equine and caprine red cells are resistant to the hemolyzing effects of toxin). The toxin also causes vascular permeability through endothelial damage and can cause necrosis at the villous tips in the intestines. There is also a report of type A having the gene to produce a beta 2–toxin.[4] The beta 2–toxin may act synergistically with alpha-toxin to cause necrotic and hemorrhagic intestinal lesions.

Hemorrhagic Bowel Syndrome

Hemorrhagic bowel syndrome (HBS; also called jejunal hemorrhage syndrome [JHS] or hemorrhagic enteritis) is an acute, often fatal condition of cattle characterized by segmental intraluminal hemorrhage in the small intestine.[5] The jejunum is the most commonly affected portion of the small intestine. The disease is considered to be an emerging disease of lactating dairy cattle in the United States, with 9.1% of herds in a 2002 National Animal Health Monitoring System (NAHMS) study reporting at least one case of HBS during the previous 5 years. It appears that high milk production is related to the condition, probably through feeding practices and management factors.[6]

Affected animals usually are anorectic, have a moderately elevated heart rate, and have a normal to subnormal temperature. Other signs consistent with small intestinal obstruction also develop, but abdominal pain is not usually observed. Feces may contain partially digested or clotted blood, and distended loops of intestine may be palpable per rectum. Transabdominal ultrasound may show an increased intestinal diameter proximal to the lesion, hyperglycemia, hyponatremia, hypochloremia, hypokalemia, and hypermagnesemia.[7]

Both medical and surgical approaches to treatment have had limited success. On postmortem examination *Clostridium* spp. may be seen in affected tissues. The odds of isolating *C. perfringens* type A from intestines of cows affected with HBS were 8.5 times greater than for cows with left-displaced abomasum (LDA).[5] Another theory is that *A. fumigatus* is the causative agent of HBS.[5]

Increasing the percentage of long-stem fiber in the diet is associated with a decrease in number of cases of HBS. [6] The value of vaccination in preventing HBS has yet to be documented.[5] An attempt to reproduce the condition by inoculating either abomasa or jejuna of cows with *C. perfringens* type A failed to produce illness or lesions.[8]

Yellow lamb disease (so named because of the icteric nature of necropsied lambs) is an uncommon disease attributed to *C. perfringens* type A. Widespread hemolysis leads to anemia, weakness, hemoglobinuria, and icterus. The animals have a high temperature and usually die within 6 to 12 hours of onset. Differential diagnoses for yellow lamb disease include other causes of hemolytic disease, such as leptospirosis and copper toxicosis. As with other type A infections, the diagnosis is always questionable because of the commensal nature of the organism and its rapid invasion after death. The finding of predominantly large gram-positive rods in impression smears from intestinal mucosa lends support to the diagnosis. One report implicates type A in neonatal calves with ruminal and abomasal tympany, abomasitis, and abomasal ulceration. The calves were 2 to 21 days old and died acutely or had signs of colic and depression of short duration. Type A is a relatively common cause of food poisoning in human beings. Speculation links this type to human sudden infant death syndrome ("crib death") as well.

VetBooks.ir

A type A vaccine is produced that claims to protect against HBS in cattle and against abomasal ulcers, abomasal hemorrhage, and abdominal tympany in calves.

Clostridium perfringens Type B (Lamb Dysentery)

Lamb dysentery is a disease of young lambs in Britain and South Africa. Type B has not been reported in North America. Its clinical course and presentation are similar to those of necrotic enteritis caused by *C. perfringens* type C. Lambs less than 1 week of age become depressed and die. A yellowish diarrhea becomes brown from blood as the disease progresses. Morbidity may be high, and mortality approaches 100%. Necropsy findings include ulcers (rarely perforating) in the small intestines and dehydration of the carcass and tissues. Sanitation and the use of type B vaccine aid in prevention and control. Types B and C toxoids cross-protect because of the overlap in toxin types (beta is the major toxin of both).

Clostridium perfringens Type C (Necrotic Enteritis, Neonatal Hemorrhagic Enterotoxemia, Pigbel, Struck)

Definition and Etiology *C. perfringens* type C elaborates the alpha (hemolytic)-toxin common to all types, in minor amounts, and the beta-toxin in major amounts. The amount of beta-toxin produced may determine the pathogenicity of a type C strain. In addition, type C strains produce the cytotoxic and hemolytic alpha-toxin, which is used to assign strains to group C if they have lost the ability to produce beta-toxin in culture. Beta-toxin appears capable of producing all the signs of necrotic enteritis; the role of alpha-toxin or CPE in disease is unclear.

Necrotic enteritis is primarily a disease of neonates and occurs in calves, lambs, foals, and piglets. A similar disease in adult sheep, known as *struck,* has a very limited geographic range in Great Britain.

Clinical Signs and Differential Diagnosis Affected animals may die acutely without diarrhea, but this is rare. The diarrhea may be yellow or, in more hemorrhagic cases, brownish. Gray-red streaks of necrotic mucosa may be present in the stools. Foals with type C disease at first show acute abdominal pain, then explosive yellow diarrhea that becomes brown and hemorrhagic. Animals become dehydrated, anemic, weak, and moribund, despite intensive therapy. Morbidity and mortality are high, but the disease is quite sporadic in occurrence. Salmonellosis and coccidiosis should be considered in the differential diagnosis, but necrotic enteritis is the more common disease in very young animals.

Pathophysiology The causative beta-toxin is readily destroyed by proteolytic enzymes such as trypsin. The neonate is especially predisposed to beta-toxin attack by the presence of trypsin inhibitors in colostrum, the function of which is to prevent proteolytic degradation of immunoglobulins. Necrotic enteritis in humans is believed to be caused by decreased proteolytic activity arising from low-protein diets or the consumption of sweet potatoes, which contain heat-stable inhibitors of trypsin. The scattered cases of necrotic enteritis in adult animals may be the result of similar dietary factors. Type C disease has been reproduced experimentally in maturing lambs by administering type C cultures and soybean flour, which contains potent protease inhibitors.

Ingestion of a protein-rich diet into a protease-deficient intestinal tract allows rapid growth of *C. perfringens* organisms. The bacteria attach to the villi, and elaboration of the cytotoxic beta-toxin results in necrosis and invasion of deeper intestinal layers. Death may result from the direct effects of the severe diarrhea or may be caused by secondary bacteremia or toxemia from the compromised gut barrier.

Epidemiology Neonates that ingest type C organisms during the first few days of colostrum feeding are at risk. They pick up the organism from an environment contaminated by an asymptomatic shedder or from contaminated feed. Type C may be isolated from asymptomatic individuals on occasion, but it is not considered a normal commensal as is type A. Once established on a premise, the disease may become endemic. In foals the disease is significantly associated with housing in a stall or drylot during the first 3 days of life, previous presence of livestock on the farm, low amounts of grass hay fed postpartum, being born on dirt, and having stock horse parentage (e.g., Quarter Horse, Paint). Feeding smaller amounts of grain prepartum is associated with decreased incidence of the disease.[9]

Necropsy Findings Necrosis of the mucosa of the small intestine, especially the jejunum, is the consistent finding in all species. The large intestine may be similarly affected in the horse, whereas in other species it may be normal except for intraluminal blood. The peritoneal cavity often contains excessive fluid, which clots when exposed to air. The mesenteric lymph nodes may be hemorrhagic. Microscopically, affected gut shows necrosis and hemorrhage throughout the mucosa and submucosa, as well as mucosal and submucosal thrombosis.[10] The tips of the necrotic villi are covered with numerous large gram-positive rods. Positive diagnosis is based on demonstrating the beta-toxin in intestinal contents.[10]

Treatment, Prevention, and Control Once a case becomes clinically apparent, treatment generally is unsuccessful because of the fulminant nature of the disease. Foals can be treated with supportive intravenous broad-spectrum antibiotics (to cover gram-negative bacteremia caused by loss of gut integrity), fluids, plasma (intravenous and oral), withdrawal of milk for 24 hours, oral metronidazole, and intravenous *C. perfringens* types C and D antitoxin. Metronidazole (10 mg/kg PO or IV given twice daily) can be given to at-risk foals in the face of an outbreak, beginning at 8 to 12 hours of age and continuing for 5 days. Toxoid has been administered to horses to control the disease on an apparently endemic property, with good results. Antitoxin consisting of *C. perfringens* types C and D antitoxin may be given to animals at risk in an outbreak, and *C. perfringens* types C and D are common components of multivalent vaccines. The primary vaccination series consists of two injections 1 month apart, with the final dose given 2 weeks before parturition, and a yearly booster thereafter. Neonates should be vaccinated at 8, 12, and 16 weeks of age on problem farms.

Clostridium perfringens Type D (Enterotoxemia, Overeating Disease, Pulpy Kidney Disease)

Definition and Etiology Enterotoxemia caused by *C. perfringens* type D is a disease of major importance in sheep and of lesser importance in cattle and goats. It is caused by strains of the bacterium that produces the epsilon-toxin. This type is not a common soil organism, as is type A, but it may be isolated from the feces of apparently normal sheep and, less often, cattle. Most clinical disease occurs in animals fed a highly nutritious diet, especially grain-fed livestock. The disease has been seen in lambs as young as 1 to 5 days of age.[11]

Clinical Signs and Epidemiology The sudden death of a well-fed, rapidly growing animal is the most common presentation of enterotoxemia. The disease may run its course in 30 to 90 minutes, with affected lambs showing ataxia, trembling, stiff limbs, opisthotonos, convulsions, coma, and death. At the onset of clinical signs, the animal is hyperglycemic. At death it is glucosuric. The differential diagnoses should include other causes of neurologic signs and acute death: anthrax, botulism, black disease, leptospirosis, listeriosis, enterotoxigenic *E. coli* infection, septicemia, polioencephalomalacia,

VetBooks.ir

toxic indigestion (grain overload), systemic pasteurellosis, and tetanus.

Sublethal doses may result in brain damage and focal symmetric encephalomalacia (see Diseases of the Nervous System, Chapter 35). Affected lambs are dull and unresponsive to normal environmental stimulation. The major differential diagnosis is polioencephalomalacia. Experimental intravenous injection of type D epsilon-toxin into calves produced neurologic signs and severe acute pulmonary interlobular edema. The histologic lesions in the brain consisted of perivascular proteinaceous edema in the interna capsule, thalamus, and cerebellar white matter, whereas in the lung intraalveolar and interstitial edema was found. These are similar to some of the lesions found in sheep and goats with type D enterotoxemia.

The disease in goats is usually confined to the intestinal tract and seldom involves system signs seen in sheep.

Pathophysiology In some feedlot situations the animal ingests *C. perfringens* type D on a regular basis, but the acid environment of the abomasum and continuous peristalsis, as well as low amounts of fermentable substrate, conspire to keep bacterial numbers low and moving out of the animal. The intestinal environment also influences the amount of toxin produced.

Some factor of overnutrition, often heavy grain feeding or very rich pasture, provides substrate for rapid proliferation of the type D organism, leading to elaboration of the prototoxin. Cleavage of the prototoxin by proteases yields the active toxin. Epsilon-toxin increases intestinal permeability, causing edema in a variety of organs, notably the lungs, kidney (hence the name "pulpy kidney disease"), and brain (focal symmetric encephalomalacia). The epsilon-toxin has been shown to attach to the distal and collecting tubules where it causes severe damage.[12] Excess pericardial, peritoneal, and pleural fluid (with or without fibrin) and subcapsular petechiation in the kidneys may be seen.[13] These lesions cause rapid deterioration and death. Hyperglycemia and glucosuria are the result of massive hepatic glycogen release caused by the epsilon-toxin.

Necropsy Findings Postmortem lesions are inconsistent. The pulpy kidney lesion may not be seen in freshly examined specimens. The epicardium, serosa, thymus, and diaphragm may have small areas of hemorrhage. The pericardial sac often contains excess fluid. The lungs may be edematous. Glucosuria is considered a hallmark of type D enterotoxemia but is sometimes not present. Ten calves with experimentally induced type D showed acute pulmonary edema, excessive protein-rich pericardial fluid, watery contents in the small intestine, and multifocal petechial hemorrhages on the jejunal mucosa.[14] The brain of one calf that survived for 8 days showed multifocal, bilateral, and symmetric encephalomalacia in the corpus striatum. The most striking histologic changes consisted of perivascular high protein edema in the brain, and alveolar and interstitial proteinaceous pulmonary edema. The animal that survived for 8 days and that had gross lesions in the corpus striatum showed histologically severe, focal necrosis of this area, as well as in the cerebellar peduncles and thalamus.[14] Histologic lesions in sheep include pleural and interlobular and perivascular edema in the lung, as well as perivascular edema in the brain of some affected animals.[13]

Treatment, Prevention, and Control If initiated at the first suspicion of overeating disease, type D antitoxin and oral antibiotics (sulfa) may have dramatic results. The diet should be adjusted downward (more grass hay, less grain and legumes) in outbreaks to try to minimize the substrate, especially starch, that reaches the bacteria. Lambs on rich pasture should be moved to poorer pasture or corralled and fed hay until they have been vaccinated twice. Lambs and calves brought into a feedlot should be vaccinated twice before arrival and should have the concentrate ration increased slowly to minimize microfloral disruptions.

Antitoxin can be given in an outbreak, but previous vaccination is more effective. Vaccination with type D bacterin-toxoid is effective in preventing disease. Two doses are given 14 to 56 days apart, before heavy grain feeding or exposure to rich pasture begins. The aluminum hydroxide adjuvanted vaccines may cause raised subcutaneous lumps (most noticeable on goats) that may go on to abscess. Dairy goats fed continuous high-grain rations may need to be vaccinated more often for continuous protection. One study of three commercial vaccines found that one of the vaccines provoked no antibody response in goats 14 days after vaccination and that at 28 days after vaccination, even the goats that had responded to the other two vaccines had titers no higher than unvaccinated controls. The vaccine is not licensed in the United States for use in goats but is routinely used. Bummer lambs may be protected by feeding bovine colostrum from cows vaccinated several times with the sheep vaccine to provide high titers in colostrum. Colostral titers from the dam are protective to 12 weeks of age, after which vaccination should be used to provide active immunity against the disease.

Beta 2-Toxigenic *Clostridium perfringens* Typhlocolitis in Horses and Ruminants

Beta 2–toxin is a newly described *C. perfringens* toxin that may play a role in intestinal diseases of ruminants and adult horses, particularly typhlocolitis. Affected animals may have a history of recent stress or antibiotic administration and show hemorrhagic, profuse, watery diarrhea; low body temperature; severe leukopenia; and hypoproteinemia.[15] The diagnosis depends on demonstration of the beta-2 gene by PCR.[16]

Oak (Acorn) Toxicosis

Bradford P. Smith

Definition and Etiology Toxic signs can appear in ruminants,[1,2] and occasionally in horses,[3] that ingest large quantities of oak buds, oak leaves (green or dried), or acorns. Most species of oak (*Quercus* spp.) cause similar signs when ingested, although there are marked differences in the amount of toxin among the 75 oak species.[4] The metabolites of oak tannins and volatile phenols present in the buds, leaves, twigs, and acorns are responsible for causing toxicosis. The mouth, esophagus, gastrointestinal tract, and kidneys (renal tubular nephrosis) are the organs most affected. Because they are less selective in what they ingest, cattle seem to be the most frequently affected species. Signs begin shortly after ingestion of 50% or more of the diet as oak, and young cattle (under 300 kg) often appear to be more severely affected than adult cattle. One paper found that adult sheep weighing about 40 kg could be fed up to 2.2 kg per day of acorn powder without detriment.[5] Acorns tend to be relatively low in crude protein (2% to 7%) but high in starch, with variable levels of tannins.

Factors leading to toxicosis include the presence of large acorn crops when forage is scarce, wind or hail that causes large numbers of acorns to drop suddenly, or the sudden presentation of oak buds and young leaves to hungry cattle, as in spring windstorms or snowstorms that cover the grass and break branches. In the southwestern United States, range cattle regularly consume some oak species, which are apparently highly palatable and nutritious.[6] The condition has been described wherever oak grows, including most of the United States, France, Great Britain, Germany, Sweden, Australia, China, and South Africa.

Acorn calf syndrome is completely different from the oak toxicosis described in this section. Acorn calves are congenitally malformed calves born to dams that ingest large numbers of acorns under poor forage conditions during the second trimester of pregnancy. The cause appears to be a combination of poor nutrition and exposure to acorns. The calves have very short leg bones and may have abnormal hoof development and a short or long narrow head. In badly affected herds, as many as 15% of calves are affected. The disease has been reproduced experimentally. Supplementation of the herd with adequate protein and energy eliminates the disease.

VetBooks.ir

FIG. 32-129 Perirectal and vulvar edema in a 3-month-old calf with acute oak bud toxicity. Acute acorn or oak poisoning causes similar lesions.

Clinical Signs and Differential Diagnosis The course of oak toxicosis usually is 1 to 12 days, but some cattle have a protracted, debilitating disease.[1,2] An outbreak in England is described in which the first death from renal failure occurred 21 days after the animals had been removed from exposure and housed.[7] In the peracute stages, cattle are recumbent, weak, anorectic, and listless.[1] The rectal temperature is normal or below normal, and the heart and respiratory rates are elevated. Marked edema is present in the perineum and vulva (Fig. 32-129), and edema is obvious in the submandibular area, brisket, and ventral abdomen. Hydration appears adequate, but anuria is present. Firm, dark, mucus-covered feces usually are present. Evidence of hydrothorax, hydropericardium, and ascites may be noted on physical examination. Some cattle may simply be found dead.

A day or two after ingestion the animals appear anorectic and listless and have decreased ruminal motility. Many calves have hemorrhagic diarrhea or dark diarrhea that tests positive for fecal occult blood. The feces may have a smell of phenol. Dehydration occurs rapidly, but vital signs may be remarkably normal until hypovolemia develops. As uremia progresses, scleral vessels become dark and engorged, and the breath may take on the smell of ammonia. The major differential diagnoses are other causes of renal failure and other toxins and clostridial diseases; viral diseases that cause ulceration of the alimentary tract should also be considered. Protracted cases most often result from renal failure and uremia, although some animals have chronic oral, esophageal, or gastrointestinal ulceration or perforation with abscessation.

In horses signs usually are peracute or acute; they include sudden death or colic, tenesmus, and hemorrhagic diarrhea.[3] Acorn husks and shells may be noted in the feces. As with most colics, tachycardia, hyperpnea, and injected oral mucous membranes are seen. Increased abdominal borborygmi often are present, and hemoglobinuria may occur. Determination of serum or urinary phenolic (hydrolyzed tannin) content, based on a gallic acid standard, may be used in acute cases.[3]

Clinical Pathology In cattle with peracute and acute signs, the serum urea nitrogen and creatinine are elevated, whereas other laboratory values may show considerable variation.[2,3] Initially hyponatremia, hyperkalemia, hypochloremia, hyperphosphatemia, and a marked hypocalcemia (5.1 to 6.8 mg/dL) accompany a mild metabolic acidosis with a very high anion gap (29 to 32).[1] Neutrophilia with mild hyperfibrinogenemia may be present. Although sorbitol dehydrogenase and γ-glutamyltransferase (GGT) may be elevated, biopsy does not indicate that significant hepatic disease occurs with oak toxicosis. Animals may be anuric. If urine is being produced, often isosthenuria, proteinuria, and glucosuria occur. The urinary fractional excretion of sodium was elevated in one steer.[6]

In protracted cases the major findings are elevated serum urea nitrogen, creatinine, and anion gap, with variable hyponatremia, hypokalemia (vs. hyperkalemia in acute stages), hypochloremia, and hyperphosphatemia. A mild metabolic alkalosis may be present. Hyperfibrinogenemia and an increase in total plasma proteins also are variable. An elevated white blood cell (WBC) count most often reflects chronic ulceration or abscessation (neutrophilia or monocytosis or both). Liver enzymes usually are normal in protracted cases. Urinalysis results are similar to those in acute cases; in addition, hematuria often is present. By 6 weeks after exposure, a normocytic, normochromic anemia may develop as a result of chronic inflammation and uremia, and hypoalbuminemia may result from chronic renal and gastrointestinal losses. By 8 weeks after exposure, surviving cattle have largely returned to normal renal function as determined by normal serum urea nitrogen and creatinine concentrations and by the ability to concentrate urine after a 24-hour water deprivation test.[1]

Laboratory findings in horses are similar to those in ruminants, except that during the acute stages rapid hemoconcentration and marked increases in packed cell volume (PCV) occur.[3] Although protein, occult blood, and hemoglobin casts have been reported to be present in the urine, the urine specific gravity was 1.052.

Pathophysiology The toxicity of oak is attributed to its high concentration of tannins, which are hydrolyzed in the rumen to gallic acid, pyrogallol, and other compounds. The tannins themselves may contribute to oral, esophageal, and gastrointestinal damage by binding to proteins, including those in epithelial cells. This results in oral, esophageal, and ruminal ulcers or perforations. Protein-bound tannins are liberated in the acidic abomasum, making them available once again to damage intestinal epithelium. Some hydrolyzed tannins are absorbed and bound to plasma proteins and endothelial proteins, resulting in hemorrhage and fluid loss from the vascular compartment into body cavities and tissues; this results in edema. The gallic acid and pyrogallols are extremely toxic to renal tubules, causing acute tubular necrosis, anuria, electrolyte abnormalities, and uremia. Ruminants are more susceptible than horses because of the hydrolysis of the gallotannins in the rumen.

Epidemiology Young cattle in the 100- to 300-kg range seem to be particularly susceptible. In the southwestern United States oak toxicosis accounts for considerable economic loss in cattle.[6] The disease is seen sporadically in other ruminants and in horses. The morbidity rate in cattle varies considerably, with several to many calves in a pasture usually affected, and case fatality rates frequently exceed 80%.[2]

The disease is most often associated with ingestion of acorns in the fall and buds or young leaves in the spring. Cattle turned onto a pasture with oak trees under which acorns have accumulated may have toxicosis even when adequate forage is available.[2] In other cases windstorms have dropped numerous acorns or branches in a pasture to which cattle were already accustomed. In the early spring a heavy, unseasonable snowstorm may occur, covering the grass and bending young trees and breaking branches so that oak buds and young leaves are accessible.[1] Young leaves and acorns are more palatable than older leaves and also contain more tannins (up to 10% dry matter in acorns). The seedlings, buds, and acorns of small scrub oak may be important forages for cattle in parts of the United States.[6]

Necropsy Findings In peracute and acute cases prominent edema is often the most striking lesion. Ascites, hydrothorax, hydropericardium, perirenal edema, and subcutaneous edema are found. The kidneys are normal in size with multiple diffuse hemorrhages on the surface and extending into the cortex. The liver is slightly swollen and pale or mottled. Digestive tract lesions vary from congestion to hemorrhage and deep ulceration or perforation with necrotizing inflammation. Mucosal ulceration is found in the pharynx,

VetBooks.ir

esophagus, rumen, abomasum, small intestine, cecum, and colon. Free blood or melena may frequently be observed.

Diffuse renal tubular damage is present. The changes include coagulation necrosis of cortical tubular epithelium and dilated tubules devoid of epithelium but with intact basement membranes. Many medullary tubules contain hyaline, granular, or cellular casts. The principal renal lesion is necrosis of the proximal convoluted tubules, but glomerular degeneration and fluid in Bowman capsules are also seen.

By 3 to 6 weeks after exposure, the lesions include gastrointestinal ulceration, often with secondary infection; some healed ulcers; secondary bacterial bronchopneumonia; and slightly swollen, pale brown kidneys. Histologically, atrophy of the cortical tubular epithelium with a marked interstitial fibrosis and mononuclear infiltrate is seen. Evidence of tubular epithelial regeneration may be present. The liver appears normal.

Treatment and Prognosis In acute stages intravenous fluid therapy aimed at promoting diuresis and correcting acid-base and electrolyte abnormalities may be lifesaving. Calcium, sodium, and chloride deficits should be replaced, and sodium bicarbonate should be given if needed to correct metabolic acidosis. In anuric animals furosemide (1 mg/kg given IV) can be administered every 12 hours, along with adequate fluid therapy. Corticosteroids and nonsteroidal antiinflammatory drugs (NSAIDs) are not likely to have a measurable effect on the course of the disease because they are unlikely to alter the direct toxic effects of the toxic metabolites. The prognosis is guarded and must be considered poor in animals that remain anuric despite therapy. The case fatality rate undoubtedly depends more on the amount of toxic material ingested than on therapy. Antibiotics, given to prevent secondary pneumonia and abscessation, ruminal transfaunation, and readily accessible grass hay and water are recommended components of nursing care.

If the animal survives the acute stage and begins to eat voluntarily, the prognosis for recovery is good unless secondary pneumonia or gastrointestinal abscessation after perforation occurs. Renal function can return to normal by 5 to 10 weeks, and weight gains as high as 1.76 kg/day may be recorded in recovered cattle.[1]

Colicky horses can be treated as one would usually treat colic (intravenous fluids, analgesics, oral laxatives). Particular attention should be paid to diuresis, acid-base balance, and maintenance of serum calcium levels.

Prevention and Control No specific antidote exists for oak toxicosis, but supplementation with calcium hydroxide (hydrated lime) immediately before anticipated exposure to oak has been effective under experimental conditions.[8] Feed containing 10% or less calcium hydroxide is palatable. Consumption of 0.9 kg/head/day of cubed or pelleted supplement containing 10% hydrated lime is effective in preventing toxic manifestations.

Supplementation of cattle suddenly exposed to oak with any feed reduces death losses, apparently by allowing hungry cattle to consume the supplemental forage preferentially.[1,8] In an outbreak in California caused by spring snows in which 2700 cattle died of oak toxicosis, ranches where hay was immediately supplemented had minimum losses compared with ranches where feed supplementation was not offered.

Winter Dysentery in Cattle (Bovine Coronavirus)

Gilles Fecteau • Charles L. Guard

Definition and Etiology Winter dysentery is an acute, contagious diarrheal disease of cattle (especially dairy) that occurs in epizootic fashion in a herd, usually during the colder months of the year (November to April). It is usually recognized by the clinical syndrome that occurs in herds and by exclusion of other causes of contagious diarrhea.[1] In the United States the disease is more common in the northern states; however, it has been reported in Australia, Sweden, the United Kingdom, Israel, France, Belgium, Japan, and Canada. The period of illness in an individual is brief (a few days to a week), and within a herd the outbreak usually lasts less than 2 weeks. Recovery is spontaneous in most individuals, but in some cases supportive therapy is necessary. The morbidity rate is usually high (from 30% after a few days to almost 100% after 1 week to 10 days). Mortality is usually rare.

The etiology of winter dysentery is a bovine coronavirus that may be related (antigenic differences are reported) to the coronavirus that causes diarrhea in neonatal calves.[2-7] By immune electron microscopy, antigenic cross-reaction has been demonstrated between the original Nebraska calf coronavirus diarrhea agent and coronavirus isolated from field outbreaks of winter dysentery.[4,6]

Clinical Signs and Differential Diagnosis Winter dysentery is an explosive diarrheal disease accompanied by some degree of anorexia and depression. In lactating cows, milk production is severely reduced. If the diarrhea is severe or persists longer than one or 2 days, dehydration may develop. Loss of body condition is apparent. Rumen motility usually is reduced, but intestinal borborygmi may be increased. Thirst often is increased, and polydipsia follows the diarrhea. Rectal examination may reveal dilated intestinal loops. The feces vary from light tan to dark brown; bubbles commonly form in the puddles that are deposited several feet behind the cow. Blood may be present in the feces of several animals in a group, typically in the first lactation heifers. The amount of blood may range from just visible to large clots, or it may be uniformly mixed into the feces. Some animals may have thick mucus in the feces. The odor in a barn during an outbreak of winter dysentery has been described as musty, fetid, and sweet and nasty.[8]

Fever usually is not present during the diarrheal phase of the disease but has been reported to precede it[1] or have no consistent relationship.[9] Mild respiratory signs consisting of serous nasolacrimal discharge and a soft cough have been inconsistently observed before diarrhea. Diarrhea caused by bovine virus diarrhea virus (BVDV), coccidiosis, and salmonellosis must be considered in the differential diagnosis of winter dysentery. With winter dysentery no mucosal lesions are visible on physical examination. The absence of coccidial oocysts or parasite ova in the feces helps exclude these agents as responsible for the diarrhea. The rapid occurrence of multiple cases within a herd, and often within herds in a locality, suggests winter dysentery. Fecal culture for *Salmonella* yields negative results in uncomplicated cases of winter dysentery.

Clinical Pathology No consistent hematologic changes that would be of diagnostic benefit have been observed. If significant dysentery persists for longer than a day, signs of anemia may develop.

Pathophysiology Epithelial cells of colonic crypts are destroyed by viral action, leading to necrosis and hemorrhage. Even though histologic changes have been observed only in the colonic mucosa, blood was observed from the distal duodenum aborally in cattle that died of winter dysentery.[7] Loss of intestinal mucosal epithelium from colonic crypts leads to transudation of extracellular fluid and blood.

Epidemiology The incubation period is thought to be 2 to 8 days. The most susceptible animals are first and most severely affected. In a small, housed herd, the typical incidence of diarrhea during an outbreak begins with the explosive appearance of signs in 10% to 15% of animals on the first day. The second day another 20% to 40% are affected. On subsequent days similar proportions become ill. By the end of a week the first affected animals are completely recovered, and only a few new cases occur. Typically within 2 weeks of the onset of diarrhea, all animals have recovered. This period is marked by significant reduction in milk production. In large herds

VetBooks.ir

the outbreak may be prolonged for 6 to 8 weeks. This scenario is typical of a herd that had not experienced an epizootic of winter dysentery during the preceding few years. In some herds milder outbreaks occur annually, with fewer animals showing diarrhea and with less severe clinical signs.

Treatment and Prognosis Most animals with winter dysentery recover spontaneously in a few days without specific treatment. Many palliative treatments have been recommended and used over the years. On the basis of 30 years of observations, Roberts[10] considered none of these treatments to alter the course of the disease. Provision of adequate fresh water, palatable feed, and free-choice salt is the most useful nonspecific therapy. The occasional animal with prolonged or severe dysentery may need a transfusion of 4 to 8 L of whole blood.

Salmonellosis in Ruminants

Bradford P. Smith

Definition and Etiology Salmonellosis is one of the few diseases that appear to be increasing in prevalence, especially in dairy cattle. Large dairy farms are more likely to be infected than small dairy farms.[1] Milk yield decreased significantly in affected herds and the reduction was detectable several months after the increase in bulk tank milk *Salmonella* antibodies. It took more than 1 year for milk yield to return to preinfection levels.[2] According to one study, 75% of dairies sampled in California had evidence of *Salmonella* infection.[3] A multistate study found that 56% of dairies sampled contained cows shedding *Salmonella* in feces.[4] *Salmonella* of concern for livestock fall mainly into one species, *Salmonella enteric* subsp. *enterica,* with numerous serovars or serotypes, such as *S. enteric* subsp. *enterica* serovar Typhimurium, with the words *serotypes* and *serovars* used interchangeably.[5] We shorten it to *Salmonella* Typhimurium by convention. More than 2500 *Salmonella* serotypes (serovars) have been identified, and many are potential animal and human pathogens. Multidrug-resistant *Salmonella* Typhimurium DT104 (serogroup B) and *Salmonella* Newport (C2) are particularly virulent to animals and human beings. The presence of identical strains of *Salmonella* Newport among bovine and human isolates indicates that zoonotic transmission is likely.[6] Fortunately 10 serotypes of *Salmonella* in serogroups B, C, D, E, and K are responsible for most disease in cattle; therefore control programs can be aimed at these. Table 32-21 lists the serotypes most commonly isolated from ill cattle in 2010 in the United States.[7] Note that group K, not long ago considered an exotic serogroup, has appeared in the number 2 position. *Salmonella* organisms are gram-negative enteric bacteria that are facultative intracellular parasites. Most serotypes are non–host-specific, but a few are host-adapted. *Salmonella* Dublin is host-adapted to cattle, *Salmonella abortus ovis* and *Salmonella* Arizonae to sheep, and *Salmonella abortus equi* to horses. Host-adapted serotypes are found most often in their host species, where true long-term carriers exist.[8] In contrast, non–host-adapted serotypes rarely achieve carrier status and usually infect an animal for a period of 3 to 16 weeks before infection is cleared,[8] although one cow with multidrug-resistant *Salmonella* Newport excreted the organisms for 190 days.[6] Infection with either host-adapted or non–host-adapted serotypes can be symptomatic or asymptomatic, depending on the dose, the virulence of the serotype, and the host's immune status. There appears to be an association between an increased incidence of *Salmonella* infections and intensive management practices such as large farms, crowded conditions, and high-protein diets. In the absence of carriers, chain infections and persistence of *Salmonella* in the environment are responsible for long-term persistence of a given strain on a given dairy.[6]

Salmonella are grouped into serogroups (A to Z and 51 to 65), depending on their cell wall antigens (somatic antigens that comprise specific oligosaccharides, often called *O antigens, LPSs,* or *endotoxin*). Thus, for example, local and regional laboratories often report that an isolate is a group D *Salmonella.* The most common group D isolate of cattle is *Salmonella* Dublin, although nonmotile isolates that do not express flagella at that time also can be found. We found that these would express motility and be typed as *Salmonella* Dublin if we inoculated the isolate into semisolid media where it had to move to get nutrition (Smith BP, personal observation). Final confirmation that the *Salmonella* isolated is indeed *Salmonella* Dublin comes from the National Veterinary Services Laboratory in Ames, Iowa, or from some other laboratory in which antisera and facilities exist for identification of all 2500 serotypes on the basis of flagellar (H) antigens and somatic (O) antigens. Some serotypes also express capsular (Vi) antigens composed of mucopolysaccharide under some conditions. Identification of the serotype is important in planning control strategies. In addition to the serotypes listed, lambs may be infected with *Salmonella* Arizonae, which comes from several different serogroups. *Salmonella* organisms are relatively easy to culture from the feces or tissues of infected animals, using common enteric agar such as XLT4 or brilliant green (BG) agar, with tetrathionate and selenite as selective enrichment media.

TABLE 32-21

Most Frequently Identified *Salmonella* Serotypes (and the Serogroup) from Ill Cattle in the United States in 2010*

Serotype (Serogroup)	Percentage of 1396 Isolates
Dublin (D)	19%
Cerro (K)	15%
Montevideo (C1)	7.5%
Typhimurium (B)	7%
Newport (C2)	6.4%
1,4,5,12:i: (B)	6.4%
Kentucky (C3)	6.1%
Typhimurium var. 5 (B)	4.2%
Anatum (E1)	3.3%
Agona (B)	2.8%
All others	24%

Data taken from 2011 USAHA Proceedings.

*Reported as percentage of 1396 isolates submitted to National Veterinary Services Laboratory (NVSL) for serotyping.

Clinical Signs and Differential Diagnosis *Salmonella* infection can cause a variety of clinical signs. The most common signs are fever and diarrhea[9] after an incubation period of 1 to 4 days after exposure or a recrudescence from the carrier state. Animals of all ages may be affected, but serious illness is observed most frequently in very young animals and parturient dairy cattle.

The character of the diarrheic feces varies from watery to mucoid with fibrin and blood. Sheets of fibrin may appear to be sloughing mucosa. The feces often have a putrid, foul odor because of the presence of plasma proteins associated with severe inflammatory bowel disease. Salmonellosis causes an acute protein-losing enteropathy. The systemic effects of endotoxins (and other toxic material) absorbed through the damaged bowel mucosa may be severe (fever, anorexia, depressed attitude, shock).

Bacteremia may occur rapidly, especially in neonates infected with *Salmonella* Dublin, *Salmonella* Typhimurium, or *Salmonella* Newport. Peracute to acute septicemia in calves may produce lesions in many organ systems. Affected calves usually are under 2 months of age (the range is 1 day to 6 months). Dyspnea, respiratory symptoms, sudden death, and occasionally diarrhea are the principal signs of *Salmonella* Dublin infection, the incidence of which usually peaks in 6-week-old calves. Blood culture results frequently are positive. Pure cultures of *Salmonella* Dublin often can be grown from specimens from the lungs of 4- to 8-week-old calves with

VetBooks.ir

pneumonic (septicemic) salmonellosis. Calves infected with *Salmonella* Typhimurium are only 14 days of age on average (the range is 1 to 35 days) and have mainly enteric lesions, including enlarged mesenteric lymph nodes, abomasitis, fibrinonecrotic plaques in the ileum, and hemorrhage of Peyer patches.[10]

Dry gangrene of the extremities may occur in calves after *Salmonella* infection, particularly with *Salmonella* Dublin. Legs, ears, and tails are most commonly affected, and cold agglutinins are suspected to be involved.[11]

In adult cattle, diarrhea or abortion may occur.[8] Abortion may occur by two mechanisms, because both culture-positive and culture-negative fetuses and placentae may be found in an outbreak. In the former, bacteremia in the dam results in infection of the placenta or fetus, with resulting fetal death and expulsion. Bacteremia and endotoxemia associated with diarrhea and damaged gut mucosa in cattle may result in release of $PGF_{2\alpha}$ and subsequent lysis of the corpus luteum. Abortion follows in 2 to 3 days, and the fetus and placenta will have culture-negative findings. When the fetus has a culture-negative finding, many other causes of abortion must be considered. Many infectious agents that infect only the dam can act similarly to cause luteolysis and abortion.

Differential diagnoses for the enteric form of salmonellosis in neonates include all the common enteropathogens of neonates: *Escherichia coli,* rotaviruses and coronaviruses, clostridia, cryptosporidia, and other forms of coccidia. Concurrent infection with these agents is common. In older animals outbreaks should be differentiated from those caused by bovine virus diarrhea (BVD), winter dysentery, and feed-induced indigestion. Pneumonic and bacteremic salmonellosis in 4- to 8-week-old calves must be differentiated by culture from pneumonic pasteurellosis; in goats, from mycoplasmal infection; and in lambs, from septicemic pasteurellosis.

Clinical Pathology

Salmonella enteritis often results in changes in the hemogram,[12] as effects of endotoxin manifest.[13] Plasma fibrinogen frequently is elevated because of the inflammatory nature of the disease, and either neutrophilia or neutropenia may be seen. In severe cases a left shift may be present. Initial dehydration may result in an elevated packed cell volume (PCV) and plasma protein level. The plasma protein level often drops over a period of days as protein is lost into the bowel lumen. Many other nonspecific abnormalities in clinical chemistry values are often seen, including elevated liver enzymes, decreased plasma calcium, and indications of prerenal azotemia if dehydration occurs.

Definitive diagnosis of salmonellosis requires culture of the organism from feces, blood, or tissues. PCR is also available. A 2007 study found that culture was most sensitive and specific when compared with enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR).[14]

Pathophysiology

Salmonellae are invasive organisms that may penetrate ocular, nasal, oral, or intestinal mucous membranes. *Salmonella* infection is most often transmitted by fecal-oral contamination from livestock or rodents, or by feeding of contaminated protein source animal by-products (e.g., fish meal, meat meal, bone meal, or feather meal, many of which are contaminated) or contaminated forages or plant proteins such as soybean or cottonseed. Of cattle feed tested for *Salmonella* in 2010, some 6.1% was positive, according to U.S. Food and Drug Administration (FDA) surveillance data. Even if small numbers of organisms are initially present, they multiply rapidly in moist warm conditions.

Once eaten, salmonellae attach to mucosal cells, probably by means of a nonfimbrial adhesion.[15] Attachment is increased if gastrointestinal stasis is present or the normal competitive flora has been disturbed or is not yet established, as in neonates. Salmonellae cause degeneration of nearby cells and penetrate both through microvilli and through tight junctions between cells.[16] The bacteria pass through the enterocytes to the lamina propria, where they stimulate an inflammatory response and are engulfed by macrophages and neutrophils.[17] Intracellular bacteria reach regional mesenteric lymph nodes or beyond. The organism has a predilection for lymphoid tissues and is found in highest numbers in Peyer patches and mesenteric lymph nodes.[18] Thrombi form in vessels, and tissue damage can be severe. Virulent salmonellae are capable of surviving in host tissues and multiplying, often as facultative intracellular parasites in macrophages and reticuloendothelial cells.[19] In the case of carrier animals, salmonellae survive in cells in the presence of high titers of specific extracellular serum immunoglobulins. Intracellular salmonellae can also avoid many antimicrobial drugs and complement. Stress may cause a latent infection to recrudesce, resulting in fecal or mammary gland shedding or clinical disease.

The cell wall of all gram-negative bacteria contains lipopolysaccharide (LPS) as a component. LPSs are also called *endotoxins,* and they are extremely biologically active, setting off an immunologic cascade of events that can lead to leukopenia, fever, anorexia, and eventually shock and death.[13]

Epidemiology and Control

Salmonella Dublin is an endemic herd problem and is shed by lower numbers of animals compared with *Salmonella* Typhimurium, which tends to be epidemic and shed in higher numbers by many more animals at a time.[20] In the northeast United States, in 11% of 831 herds with suspected clinical cases of salmonellosis, the leading isolates were *Salmonella* Newport and *Salmonella* Typhimurium.[21] A study of calves in California found that 18% of 1-day-old calves shed some serotype of *Salmonella,* but this percentage declined rapidly over the first 11 weeks of life. Farms that received calves from other sources were 35 times more likely to have calves that were shedding *Salmonella* in feces than were closed herds.[22] Infection with host-adapted *Salmonella* serotypes may occur as a cyclic endemic disease, especially in calves when *Salmonella* Dublin is involved. *Salmonella* infections on a farm are maintained by carrier animals shedding *Salmonella* Dublin in the feces[8] or milk,[23] chain infections in infected calves and cows, rodents, and environmental contamination. *Salmonella* carriers infected with a host-adapted serotype such as *Salmonella* Dublin may shed constantly or intermittently. Cattle with the highest risk of becoming *Salmonella* Dublin carriers are heifers infected between 1 year of age and first calving and cows infected in the parturient period,[24] but calves surviving *Salmonella* Dublin infection and illness may also become carriers. Infected carriers that are not shedding are called *latent carriers;* stress may cause shedding in feces or milk to recrudesce. A single infected, asymptomatic fecal shedder may produce one billion *Salmonella* Dublin organisms per day to contaminate the environment (one million organisms per gram of feces). Unlike other serotypes, *Salmonella* Dublin may be carried as a chronic gut and mesenteric lymph node infection and passed in feces or carried as an intramammary infection and passed in contaminated milk.

Calving areas must be constantly cleaned and disinfected between calvings. Raw milk feeding to calves may be a source of *Salmonella* (100 to 100,000 organisms per milliliter of milk).[23] Infected calves constantly amplify the number of organisms in the environment, causing exposure of other calves. Calves with clinical signs may shed billions of *Salmonella* into the environment daily.

Environmental contamination can be difficult to eliminate, because salmonellae survive for months in moist areas out of direct sunlight and in lagoons and drainage areas. *Salmonella* Dublin was recovered from feces dried for 41 months.[25] Freezing feces at −20° C (−4° F) kills 85% of salmonellae in 2 days and over 95% by 1 month.[26] Direct sunlight and drying in hot weather are effective at eliminating salmonellae.

Research has documented contaminated irrigation water as an important source of *Salmonella* organisms. In some cases municipal sewage treatment plant effluents had contaminated water.[27] On one dairy farm, river water used to sprinkler irrigate green chop contaminated the green chop, which was fed to cows. On another farm, *Salmonella*-contaminated river water was used to irrigate cotton. When the cottonseed from that gin was used as feed, cattle became infected. On a third dairy, contaminated irrigation water resulted in haylage containing *Salmonella* organisms.[28]

VetBooks.ir

Feedlot cattle colonized by *Salmonella* organisms could pose a public health risk when meat is contaminated at slaughter. In a study by National Animal Health Monitoring System (NAHMS), 7.5% of cattle on feed the longest shed salmonellae, whereas 3.5% of cattle that had recently entered the feedlot were shedding salmonellae in the feces.[29] Contamination of the animals before entry can cause the entering cattle to have a higher rate of shedding than was found in cattle that had been in the feedlot for several months.[30] Standing water contaminated with feces is frequently highly contaminated with *Salmonella;* culture of temporary shallow lakes (called *playas* in the southwestern United States) yielded numerous *Salmonella* serotypes.[31] An unusual outbreak of *Salmonella* Newport in cows and calves on a beef farm resulted in a cow mortality rate of 7.9% (32 of 407) and a calf mortality rate of 14.4% (52 of 361). BVD virus was also diagnosed in the group, and it was suspected of playing an immunosuppressive role.[32]

Control of *Salmonella* infection requires an integrated herd approach.[33,34] Sick pens were found to be 7.4 times more likely to yield *Salmonella* as were pens of preweaned calves.[35] Management interventions that were found effective in helping control *Salmonella* on dairy farms include separation of sick and parturient cattle into hospital and maternity pens, respectively (considered the most important and effective intervention), switching from a phenolic disinfectant to a peroxygen biocide such as Virkon S (DuPont, Sudbury, UK) for equipment disinfection, use of separate footwear or footbaths for personnel in the hospital and maternity pen sections, strict protocols for disinfection of hands and equipment between handling each sick or periparturient cow, strict separation of feeds used in the hospital and maternity pens, and use of clean bedding in the hospital and maternity pens.[6] Having one person manage the calves, good colostrum management, and not purchasing cattle from an infected premise had beneficial effects in reducing infection.[36]

To detect herds infected with *Salmonella* Typhimurium or *Salmonella* Dublin, a herd serologic profile based on ELISA can be used.[37] The commercial test available in the United States is the PrioCHECK Salmonella Ab bovine ELISA (Prionics, Switzerland). One lab that runs such tests on milk or serum is the Animal Health Diagnostic Center at the College of Veterinary Medicine, Cornell University (http://ahdc.vet.cornell.edu/). Rectal swab sampling and culture of cull dairy cows was found not to be a satisfactory method of detecting *Salmonella*-infected herds.[38] To control *Salmonella* Dublin, carrier cows and calves over 6 months of age are identified by serologic testing (ELISA) for anti-*Salmonella* antibody.[23,39-41] Suspect animals are culled or tested further by serologic means or by multiple fecal cultures and milk cultures (five samples at weekly intervals). Animals with positive test results are culled. In infected herds, *Salmonella* Dublin carriers (fecal or mammary) usually make up 0.4% to 3% of a dairy herd. Animals that remain seropositive over a 2-month period should be considered carriers, even if a culture result is negative on five samples.[23] A Danish study [42] found that only 14 of 31 persistently seropositive animals were culture positive for *Salmonella* Dublin at postmortem examination, and one seronegative animal was culture positive. One study found that ELISA serology had a good negative predictive value for cattle 100 to 300 days of age, whereas fecal culture had a poor predictive value.[43]

To control all non–host-adapted and host-adapted serotypes of *Salmonella,* calves and cows are promptly treated when signs of illness occur, and strict procedures to prevent the spread of infection are instituted. A study of 14 farms infected with *Salmonella* Typhimurium DT104 showed that clinical disease ceased by 4 months, but widespread infection and contamination continued. Over time the number of infected farms gradually declined, and vaccination correlated positively with a herd remaining free of clinical illness from DT104.[44] Control measures include the use of separate feeding utensils for each calf, washing of boots and hands by calf raisers between calves, isolation of ill calves to noncontact pens, and thorough disinfection of pens between calves. Decontamination of pens is most effectively accomplished if an all-in, all-out system is used. Pens are divided into four groups, with each group of pens used for calves born during a given week. When 3- to 4-week-old calves leave their pens as a group, these pens are cleaned and disinfected with a chlorine product such as bleach, a peroxygen product such as Virkon S, or a phenylphenolic disinfectant. This helps prevent continuous recycling of bacteria to each group of new calves. Environmental monitoring by frequent swab cultures of pens is the best way to check the effectiveness of the sanitation and disinfection program. Infection with *Salmonella* Typhimurium and other non–host-adapted serotypes most often occurs as an epidemic after the organisms enter the farm by means of purchased cattle, rodents,[45] rendering trucks, or feedstuffs. Even *Salmonella* Dublin may be maintained on a farm by mice.[45] A case control study of farms infected with *Salmonella* Typhimurium DT104 found that the most effective interventions included purchasing cattle directly rather than through a sales yard, quarantining purchased cattle for 4 weeks, housing sick cattle in dedicated isolation areas, and preventing wild bird access to feed storage areas.[46] Feeds may be contaminated by irrigation water,[28] in manufacturing when by-product ingredients contain *Salmonella* organisms, on the farm, or in shipment by birds or rodents or contaminated trucks. When an epidemic involving an exotic serotype occurs, feedstuffs should be examined as a likely source. Exotic serotypes are *Salmonella* from serogroups other than B, C, D1, E1, and K; that is, all those groups not listed in Table 32-21. Feedstuff contamination with the serotypes not considered exotic may also occur. High-protein supplements, rumen bypass protein, or calcium-phosphorus supplements of animal origin are sources of epidemics of various *Salmonella* serotypes in livestock. Many animal by-product feedstuffs in the United States are contaminated with *Salmonella* organisms. Once a *Salmonella* serotype enters a herd, the bacteria are rapidly spread among livestock and into the environment, where they may cause a prolonged course of herd illness and can be difficult to eliminate. Such appeared to be the case with *Salmonella* Newport and *Salmonella* Montevideo in dairy cattle in California in the past (Table 32-22). These and other group C *Salmonella* spp. tend to become endemic and persist for years on a dairy farm once it has become infected. Note that by 2010 Montevideo was the third and Newport the fifth most prevalent serotype from ill cattle in the United States (National Veterinary Services Laboratory [NVSL] data). Culture of feeds before use on a farm currently is the only means of preventing the introduction of exotic *Salmonella* serotypes, because national and international feed quality controls currently appear to be inadequate.

Vaccination Control by vaccination of dams using killed bacterins may be somewhat beneficial in protecting neonates under 3 weeks of age through colostral and milk immunoglobulin. Because most dairy calves are taken from their dam and fed milk replacer

TABLE 32-22

Changing Incidence of *Salmonella* Serotypes on California Dairy Farms as Illustrated by the Percentage of Farms from Which Each Serotype Was Isolated in 1985 to 1986 Compared with 1987 to 1988

Serotype	1985-1986 Percentage of Farms (No.)	1987-1988 Percentage of Farms (No.)
Dublin	78 (29)	53 (49)
Newport	19 (7)	36 (33)
Typhimurium	3 (1)	7.6 (7)
Montevideo	0	6.5 (6)
Infantis	0	2.2 (2)
Anatum	0	1.1 (1)
Arkansas	0	1.1 (1)

VetBooks.ir

after day 1 to day 3 of age, the potential benefit of intraluminal milk antibody from the dam is lost. This may account in part for the fact that vaccination of cows by itself often is insufficient to protect calves from salmonellosis. In neonates over 3 weeks of age, colostral immunity appears to play only a small role in protecting against salmonellosis. Because both humoral and cell-mediated immunity are important in protecting against salmonellosis,[47-49] active immunity is superior to passive. Modified live, genetically altered vaccines that stimulate humoral and cell-mediated immunity offer better protection for calves than do killed whole cell vaccines.[49,50]

The role of increased nonspecific immunity to gram-negative core antigens (through immunization with rough mutants of *E. coli* and salmonellae lacking complete cell walls) is being investigated. Some studies have been able to demonstrate an increased survival rate for salmonellosis after vaccination with a mutant strain of *E. coli* (J5),[51] designed to produce antibodies to the common core antigens of gram-negative bacteria. Two such products available in 2012 are Enviracor J-5 (Zoetis, Florham Park, N.J.) and J-Vac (Merial, Duluth, Ga.). Endovac Dairy (Re mutant *Salmonella* produced by Immvac Inc., Columbia, Mo.) is marketed with the same goal.

Available commercial *Salmonella* vaccines are killed whole cell bacterins for use in cattle and a genetically altered modified live *Salmonella* Dublin vaccine for calves (EnterVene-D [Fort Dodge Animal Health, Fort Dodge, Ia.], two doses 2 weeks apart). Some practitioners report that they have used the live vaccine orally and found it to be effective but with fewer adverse reactions than when used parenterally. The only products that are solely *Salmonella* vaccines contain *Salmonella* Typhimurium or *Salmonella* Typhimurium and *Salmonella* Dublin or live *Salmonella* Dublin organisms, or siderophore receptor protein (SRP) *Salmonella* Newport subunits (also see Chapter 48). Autogenous bacterins can be made for serotypes not commercially available when they are isolated from animals on a farm and believed to be the causative agent of disease. A subunit vaccine with SRP (SRP vaccine) is being marketed by Zoetis under conditional U.S. Department of Agriculture (USDA) license for vaccination against *Salmonella* and other gram-negative bacteria. Siderophores are iron chelating proteins produced by all *Salmonella,* so producing antibodies against SRPs from *Salmonella* Newport should theoretically be effective for all serotypes of *Salmonella,* and because they are a subunit, they should be less toxic. The initial vaccination requires 2 doses at 2- to 4-week intervals, followed by a yearly booster.

A major problem associated with *Salmonella* bacterins and modified live *Salmonella* vaccines is adverse reactions. Adverse reactions vary from fever, depression, and anorexia to collapse and death after vaccination. Animals may have severe reactions after the first, second, or third dose. The apparent cause of these severe reactions is a high degree of sensitivity to the presence of gram-negative endotoxin, which results in a rapid immune cascade leading to shock.[13] This sensitivity is genetically controlled, possibly accounting for the high frequency of adverse reactions in one herd and their absence in a neighboring herd. High ambient temperatures also increase sensitivity to the adverse effects of endotoxin. Adverse reactions usually can be averted or reversed by using epinephrine (1 mL of 1 : 1000 [1 mg/mL] for every 50 kg of body weight given IM or IV) as soon as evidence of polypnea, dyspnea, or weakness appears.

Lack of efficacy of killed *Salmonella* bacterins in calves is evident in experimental studies. Commercial bacterin vaccines in aluminum hydroxide administered directly to calves at 2 and 4 weeks of age failed to protect the calves when they were orally challenged at 6 weeks of age.[51] Other research has demonstrated protection in older vaccinated calves that were challenged intravenously.[52] Calves under 12 weeks of age do not serologically respond with anti-LPS antibodies after vaccination with two or three doses of killed bacterins in aluminum hydroxide.[53] On the other hand, calves over 12 weeks of age and cows do respond serologically to two doses of the same vaccine.[54] The ELISA titer in cows is short-lived (2 to 4 weeks); therefore the timing of vaccination before parturition is critical if the aim is to increase the anti-*Salmonella* colostral immunoglobulin G titer.[54] Under experimental conditions, calves fed colostrum from vaccinated dams were not protected against oral challenge at 3 weeks of age.[12] One report suggests that vaccination with killed *Salmonella* Typhimurium vaccine prevented reinfection and recrudescence of clinical signs after an outbreak of DT104 and helped in eliminating the organism from the farm.[46] As mentioned previously, these differences may in part be explained by whether or not a calf continues to receive milk from its dam and thus has or does not have intraluminal antibodies. Other live vaccines have been found effective in calves and capable of cross-protection against other serotypes, including a DNA adenine methylase–deficient *Salmonella* Typhimurium[55] and an avirulent live *Salmonella* Choleraesuis strain 54,[56] but neither was licensed for cattle in the United States as of 2012.

Necropsy Findings

ENTERIC FORM. Calves often are emaciated and have serous atrophy of fat. Especially with *Salmonella* Typhimurium, the ileal, cecal, or colonic mucosae may be thickened and hemorrhagic with adherent fibrinonecrotic plaques. Fibrin may be found in sheets, especially pronounced in the areas of Peyer patches. The abomasum, duodenum, and jejunum are often involved but less severely. The abomasum usually contains brown, fetid liquid. Bowel contents often are watery and may contain fibrin, blood, or both.[10] The mesenteric lymph nodes frequently are enlarged and dark. Chronically affected cows or calves may have discrete areas of necrosis in the cecum or colon that may involve the entire thickness of the wall.[10]

SEPTICEMIC FORM. Gross lesions of bacteremic *Salmonella* infection are acute and usually subtle. Serosal and subcutaneous petechiae are widespread. The spleen usually is enlarged. The lungs are edematous and fail to collapse and have random foci of hemorrhage or congestion.[10] The wall of the gallbladder is thickened and may contain hemorrhages. The bile frequently is inspissated into a firm coagulum.[10] Less common lesions include jaundice, cystitis, meningitis, osteomyelitis, arthritis, and dry gangrene of ears, tail, or feet. Gastrointestinal lesions may or may not be present.

Treatment

The keys to successful treatment of bacteremia caused by gram-negative bacteria are (1) antimicrobial drugs, (2) fluids and electrolytes, and (3) NSAIDs. *Salmonella* Typhimurium antiserum is available commercially. Adverse reactions by cattle to horse serum are common; care should be taken.

Early in the course of disease in calves, appropriate antimicrobial therapy often increases the survival rate markedly, because bacteremia frequently occurs. Appropriate antimicrobial therapy depends on culture and antimicrobial sensitivity patterns. Many of the most virulent *Salmonella* types are now multidrug-resistant, but isolates of relatively nonpathogenic *Salmonella* on dairies and feedlots found on surveys are usually sensitive to most antimicrobials.[22,57] In general, most *Salmonella* organisms are sensitive to florphenicol, ceftiofur (and other third-generation cephalosporins), trimethoprim-sulfonamide (TMS), gentamicin, amikacin, and fluoroquinolones such as enrofloxacin.[19,22] Higher than label doses of ceftiofur used in calves with experimentally induced *Salmonella* Typhimurium infections did not alter mortality but did reduce fecal shedding and promote more rapid clearance.[58] Sulfas and fluoroquinolones may not be used extralabel in food animals in the United States. Aminoglycosides such as neomycin, gentamicin, and amikacin produce long-term tissue residues and should be avoided in animals intended for use as food. Susceptibility to ampicillin, amoxicillin, sulfas, and tetracycline varies considerably, whereas resistance to penicillin, streptomycin, erythromycin, and tylosin is anticipated. TMS combinations are relatively inexpensive, especially when given orally, but oral TMS should be used only in calves younger than 3 weeks of age. In calves over 3 weeks of age, trimethoprim should be given intravenously because it is destroyed in the rumen and not absorbed. Antimicrobial drugs such as fluoroquinolones, florfenicol, or TMS that achieve good intracellular levels and have a large volume of distribution appear to be more effective than those that do not achieve good intracellular levels (e.g., gentamicin and amikacin). Florfenicol or

VetBooks.ir

cephalosporins such as ceftiofur are good choices for therapy against many *Salmonella* isolates depending on susceptibility testing results. Antimicrobial drugs may not be effective at altering the clinical course of strictly enteric infections without bacteremia, but because bacteremia frequently accompanies salmonellosis, systemic antimicrobial therapy often is chosen.

The effects of endotoxins can be partially dampened or controlled by the judicious use of nonsteroidal antiinflammatory drugs (NSAIDs). The cascade of events caused by bacterial endotoxin (LPS from the cell wall) must be brought under control early and rapidly, by the use of drugs such as flunixin (Banamine) at a dose of 1.1 to 2.2 mg/kg IV every 12 hours. Once the animal is stabilized, NSAIDs should be discontinued, as continued administration can lead to adverse side effects such as abomasal ulceration.

Intravenous fluid therapy to maintain blood volume and pressure and correct acid-base or electrolyte abnormalities is important in any animal that is dehydrated or in shock (see Chapter 20, Neonatal Diarrhea; Chapter 32, Equine Fluid Therapy, for adult equine; and Chapter 44, on critical care). Measurement of blood gases and electrolyte values is useful to assist in fluid therapy formulations. Fluids containing sodium, with supplementation of glucose, should be administered intravenously as needed. Metabolic acidosis with mixed water and electrolyte losses is most often seen. Oral fluids and electrolytes may also be effective supplements. The prognosis is good if animals are treated aggressively and early in the course of illness.

Control of Infectious Disease in a Veterinary Hospital Veterinarians must also be aware of preventing the spread of *Salmonella* and other nosocomial diseases within an animal hospital and should have an effective written infectious disease control program in place.[59] In one study 1.4% of cattle, mostly from dairies, shed salmonellae when in a veterinary clinic,[60] whereas the author has found an average of 7% of cattle (mainly dairy cows) in our large animal clinic are shedding *Salmonella.*

Clusters of cases occurred mainly in August and September in one northeast U.S. veterinary hospital, with 15 different serotypes involved; the most common were Typhimurium (33%), Newport (23%), and Agona (12%).[61]

See Chapter 46, Biosecurity and Infection Control for Large Animal Practices.

Paratuberculosis (Johne's Disease)

Raymond W. Sweeney

Paratuberculosis is a chronic enteric disease of ruminants caused by infection with *Mycobacterium avium* subsp. *paratuberculosis* (MAP). Cattle, goats, sheep, deer, and camelids are most commonly affected, but the disease is also reported in wild ruminants and other species. In the United States, at least 68% of dairy herds have MAP-infected animals, with a much lower prevalence among beef herds (7.9% in one study).[1,2]

The causative organism, MAP, is a hearty organism that survives for prolonged periods in the environment including soil and water. However, it has fastidious growth requirements in vitro, and culture on solid media may require 8 to 16 weeks. Recent studies indicate that MAP is also able to assume a spore-like bioform that is resistant to heat treatment in vitro, which may account for the organism's ability to survive pasteurization.[3] In vivo, the organism is an intracellular pathogen with the ability to survive within macrophages by preventing the maturation and acidification of the phagocytic vacuole. The term *Johne's disease* is often used to refer to the clinical syndrome of diarrhea and weight loss that results from MAP infection.

Transmission and Susceptibility Paratuberculosis is most commonly transmitted by the fecal-oral route. The organism is shed in the feces of infected animals (usually adults) and ingested by susceptible (usually young) animals. Critical points for potential exposure include maternity pen surfaces, cows' udders, contaminated feed or feeding implements, and calf housing areas. Small amounts of manure from heavy-shedding animals can result in vast contamination and exposure of susceptible young stock. Recent studies have also shown that MAP may be aerosolized and spread with dust barns with infected animals, raising the possibility of exposure through inhalation, or oral ingestion of organisms where contaminated dust has settled on feeding utensils, etc.[4] The organism can also be shed directly into colostrum and milk of infected cows, or these products can be contaminated by organisms on the skin, at the time of collection if insufficient sanitation is practiced. Transplacental transmission has been demonstrated and becomes more likely (40% of fetuses from cows with clinical signs) as the infection progresses to advanced stages.[5,6]

Resistance to infection with MAP in calves increases with the age of the animal, with neonates considered particularly susceptible. Most studies indicate that by the age of 1 year, susceptibility is equivalent to that of an adult animal.[7] While adult animals are more resistant to infection than juveniles, natural resistance in adult animals can be overcome by exposure to high doses of MAP organism. Furthermore, if infection with MAP occurs in an adult animal, the prolonged incubation period that ensues may result in the animal being culled for other reasons before clinical manifestations of paratuberculosis are recognized. In addition to age, the exposure dose will influence not only whether an animal becomes infected, but also the rate of progression of the disease. Exposure to higher doses of MAP is thought to lead to more rapid progression of the infection and manifestation of clinical disease at a younger age. Finally, there is growing evidence that genetic factors may play a role in susceptibility. Evidence gleaned from studies of breed differences, sire line differences, and DNA markers or candidate genes have indicated a clear genetic influence on susceptibility to MAP.[8] In the near future it may be possible to identify sires and dams with decreased susceptibility to MAP for breeding purposes.

Pathogenesis and Stages of Infection Although tonsillar invasion by MAP following oral ingestion in calves has been demonstrated experimentally, most evidence suggests that the intestinal epithelium, particularly the ileum, is the usual portal of entry. The Peyer patches are populated by specialized intestinal epithelial cells (M cells) that deliver the MAP organisms to macrophages in the submucosa of the intestine.[9] The progression of infection from this point is determined by a balance of the host's innate and adaptive immune response vs. the ability of the MAP organisms to evade destruction. In the early phases of infection, macrophages activated by T-helper type 1 (Th1) cytokines, such as interferon-gamma (IFN-γ), are able to limit proliferation of MAP and expansion of the infection.[10,11] Some animals might even eliminate the infection at this stage. In those animals that do not clear the infection, the MAP infection is kept in check by the immune system, with limited slow progression initially. However, this comes at a cost to the host, and the persistent presence of MAP antigen in the intestinal and gut-associated lymphoid tissue incites a chronic inflammatory response. Inflammatory cells are recruited to the area, resulting in granuloma formation with MAP-laden macrophages, epithelioid cells, lymphocytes, and multinucleate giant cells.[12] This period of insidious, slow proliferation is associated with a clinically silent "eclipse" phase, during which there is neither detectable fecal shedding of MAP nor detectable serum antibody production. Tests of specific cell-mediated immunity, such as detection of IFN-γ production in vitro following peripheral blood lymphocyte proliferation, might yield positive results during this eclipse phase, but are not available on a practical basis at this time.

Eventually, the host cell-mediated immune response is no longer able to contain the infection. The previously effective Th1-type response is replaced by development of a T-helper type 2 (Th2)–type response with elaboration of cytokines such as IL-4 and IL-10, which are associated with antibody production and waning of cell-mediated

VetBooks.ir

immunity.[13] Although there are no outward signs of clinical disease, and production is not yet affected, detectable fecal shedding (at a low level) begins at this stage, followed by development of detectable antibodies.[14,15] The asymptomatic fecal shedder has the potential to spread the disease within herds or between herds without arousing suspicion, as it appears clinically healthy.

As the infection progresses, MAP organisms begin to spread to extraintestinal sites, either via blood or through the lymph. This can result in transplacental infection, and direct shedding in milk and colostrum, as noted earlier. Fecal shedding of MAP also increases, so that high levels of fecal shedding may be detected before clinical signs are observed. In this subclinical phase of infection, effects on production parameters in dairy cattle are variably affected. A 16% reduction in milk production during the final lactation before culling has been reported, with little (4%) or no reduction in the penultimate lactation.[16,17] Studies on the effect of MAP infection on parameters of reproduction efficiency (days open) and udder health (somatic cell count) have had mixed results.[17,18] Thus, producers are often reluctant to cull asymptomatic infected cows, as the animals remain apparently productive members of the herd.

Ultimately, the MAP infection, and accompanying inflammatory response, progressively leads to severe granulomatous infiltration of the bowel, causing thickening of the intestinal lining, with clubbing of villi and marked lymphangiectasia. The resulting maldigestion and protein-losing enteropathy result in the clinical syndrome recognized as Johne's disease.

Clinical Johne's Disease The hallmark clinical sign of Johne's disease in cattle is watery (pipe-stream or projectile) dark green diarrhea. The diarrhea is not associated with tenesmus, there is not typically blood or mucus present, and the animal does not exhibit signs of fever, dehydration, or inappetance, but rather maintains a good appetite and possibly increased water consumption. Rapid weight loss usually accompanies the diarrhea, and edema due to hypoproteinemia develops in the submandibular and brisket areas (Figs. 32-130 and 32-131). Clinical laboratory tests will reveal hypoproteinemia, hypoalbuminemia, and possibly anemia of chronic disease. In this stage of the infection, MAP organisms are shed in the feces in massive quantities and these animals can serve as a huge source of environmental contamination. Differential diagnosis might include severe parasitism, renal amyloidosis, vena cava thrombosis, lymphosarcoma, or copper deficiency. If the animal is not culled at this point, progression to end-stage Johne's disease, with inappetance, cachexia, and death will ensue. Postmortem examination reveals grossly visible thickening and increased corrugation of the lining of the epithelium, and potentially enlargement of the mesenteric lymph nodes in the ileocecal region. Histopathologic examination reveals the aforementioned granulomatous inflammation in gut and associated lymphoid tissue, with macrophages laden with acid-fast staining bacilli.

In sheep, goats, and camelids, diarrhea may not be a prominent feature of clinical Johne's disease as it is in cattle. Although watery feces may sometimes be found, more often, feces may be normal or lose their pelleted form and take the form of dog stool. Weight loss is prominent, and the hypoproteinemia with submandibular edema is a frequent finding. Goats, in particular, may become quite anemic, more than might typically be expected with anemia of chronic disease. Of course anemia, hypoproteinemia, and weight loss may be exacerbated by concurrent intestinal parasitism, which may initially obscure the diagnosis of Johne's disease. Johne's disease in farmed deer may differ in that there may be a shorter incubation period with rapid progression to clinical disease with diarrhea and emaciation. Also, postmortem examination of deer with Johne's disease may reveal caseation and/or calcification of mesenteric lymph nodes.

DIAGNOSIS. The available diagnostic tests are divided into two broad categories: (1) immune-based diagnostic tests that detect the host's antibody or cell-mediated immune response to MAP infection, and (2) organism detection tests that detect MAP organisms or MAP bacterial DNA in fecal or tissue samples.

Immune-Based Tests. Tests of cell-mediated immunity include the intradermal Johnin test, which is similar to a tuberculin test, and in vitro lymphocyte stimulation with MAP antigens with detection of IFN-γ production. The intradermal Johnin test is generally regarded as unreliable because of both false-positive and false-negative reactions. Stimulation in vitro of peripheral blood lymphocytes with antigens of MAP, followed by detection of IFN-γ in cell culture supernatant, has shown the ability in a research setting to detect animals early in the course of MAP infection, in the eclipse phase before antibody production and fecal shedding are detectable. However, the tests are not available in a practical commercially available setting.

The most commonly applied immune tests are those that detect antibodies in serum or milk. These include the complement fixation (CF) test, the agar gel immunodiffusion (AGID) test, and enzyme-linked immunosorbent assay (ELISA). The ELISAs have superior performance to the CF or AGID tests when applied to serum from cattle, but some nations still list CF or AGID testing as an import requirement. The ELISA is the most specific and sensitive of the commercially available antibody tests. It may be applied to serum or milk, and studies have shown comparable results when ELISA is applied to both matrices. The ELISAs are attractive because of their

VetBooks.ir

relatively low cost and amenability to automation, which makes testing of large numbers of samples practical and cost-effective. Many Dairy Herd Improvement Association (DHIA) services now offer the option to include Johne's ELISA testing on milk samples, adding to the convenience of testing. Preservatives added to DHIA milk samples do not interfere with milk ELISA testing.

Antibody detection tests are hindered only by the natural biology of the disease, in that infected cattle do not normally produce detectable antibodies until after fecal shedding has begun. Thus, the sensitivity to detect asymptomatic cattle that are "low fecal shedders" may be as low as 15%, whereas 90% of clinically affected, "heavy shedding" cattle will be positive. The ELISAs generally enjoy a high specificity (98% to 100%).[19,20]

Organism Detection Tests. Organism detection tests on fecal samples include both culture and polymerase chain reaction (PCR) detection methods. They have the advantage over antibody-based tests in that they (1) generally allow detection earlier in the course of infection, since fecal shedding usually precedes antibody detection; (2) allow quantification of the degree of fecal shedding to assess the biosecurity impact of individual animals; and (3) definitively identify MAP in a herd at the time of first diagnosis. They have the disadvantage of being more expensive than ELISA, and in the case of culture, requiring a long incubation period to obtain results. Cultures performed on solid Herrold's Egg Yolk Medium may require up to 16 weeks for incubation. Many laboratories now employ a liquid culture system that can shorten the culture time to 1 to 2 months. Commercially available real-time PCR tests for fecal samples also permit quantification of MAP shedding and have sensitivity comparable to or better than culture. The specificity of culture and PCR methods is generally regarded as 100%, but it should be remembered that when MAP-contaminated feed is consumed by uninfected cattle, the MAP organisms may pass through the gastrointestinal tract and cause a transient positive result on fecal PCR or culture. A list of USDA-approved or accredited laboratories for Johne's disease testing is available at the U.S. Department of Agriculture, Animal and Plant Inspection Service (USDA-APHIS) website (http://www.aphis.usda.gov/animal_health/lab_info_services/approved_labs.shtml).

Testing Scenarios. Diagnostic tests should be selected on a case-by-case basis, depending on the clinical scenario, the objectives of the producer, and the inherent advantages and disadvantages of each test. For example, to confirm the diagnosis of Johne's disease in an adult cow with weight loss and diarrhea, a clinician will not have the luxury of waiting for fecal culture results before making a culling or treatment decision. Thus, a test with rapid turnaround time is indicated, and both ELISA and fecal PCR would provide rapid results with a high predictive value positive (or negative). If the case in question is the index case in a herd, then organism detection would be more appropriate than ELISA, to provide a definitive confirmation that MAP is the etiologic agent since the implications of a diagnosis for the herd may be great. Postmortem demonstration of typical lesions and identification of MAP by culture of mesenteric lymph node or ileum can also be used to confirm a diagnosis.

An alternative objective might be to identify asymptomatic cattle in a herd that is known to be infected with MAP, for purposes of culling in an eradication program, or segregation for calving pen or colostrum management. In higher prevalence herds, serum or milk ELISA can be used if the magnitude of the ELISA result is used to interpret the results (i.e., as opposed to just "positive" or "negative"). Animals with a negative ELISA result, even if infected, are unlikely shedding MAP in feces, milk, or colostrum at a significant level. Animals with "low positive results" are more likely shedding MAP in feces and might remain in the herd if production is good, but their status should be kept in mind when managing calving pens and colostrum. Cows with "high positive" ELISA results suggest heavy fecal shedding and a potential significant source of farm contamination; these cows should be culled as soon as possible. Although more expensive, fecal culture or PCR can similarly be used to identify asymptomatic infected cattle with greater sensitivity than ELISA. Where management/control is the objective, a low positive result will warrant appropriate calving pen and colostrum management but not necessarily culling, whereas a high positive result may warrant sooner culling. In an aggressive eradication program, any fecal culture positive result might result in a decision to cull, either immediately or at the end of the lactation. Testing can be performed on an annual, whole-herd basis, or in some systems, cows can be tested at the time of drying off. Using this method, if ELISA, fecal culture using liquid medium, or fecal PCR is employed, the results will be available prior to calving to guide management decisions.

A third scenario is to determine if a herd has MAP infection, or documenting test-negative or low-prevalence status for certification programs. One of the more cost-effective methods for this purpose, on dairy farms, is to perform fecal culture or PCR on environmental fecal samples collected from areas with high cow traffic and from the manure pit or storage lagoon. Culturing from 5 to 6 such sites has been shown to detect at least 70% of herds with infected animals.[21]

The USDA-APHIS Uniform Program Standards for Voluntary Johne's Disease Control Programs (VJDCP) provide testing guidelines for establishing herd infection status. Although individual states' programs may vary, the current standard establishes six classification levels. Levels 1 to 3 identify herds with low test-positive prevalence, or herds with 1 year of all-negative test results, while levels 4 to 6 identify herds with 2 or more years of test-negative results, with level 6 having the highest certainty of infection-free status. Herds establish classification status by whole herd (or statistically determined subset for large herds) ELISA or organism detection testing (individual samples or pooled). The reader is referred to the VJDCP Program Standards for more information on more detailed testing requirements (http://www.aphis.usda.gov/animal_health/animal_diseases/johnes/index.shtml).

Finally, testing may be desired to screen animals purchased as herd replacements or for use as embryo transfer recipients. Unfortunately, currently available tests are not useful for detecting infection in these animals, which are often of a young age (<3 years) and in the "eclipse" phase of infection. Greater assurance of likelihood of infection-free status in young stock can be obtained through testing of adult animals in the herd of origin. Purchasing animals from herds that have achieved VJDCP Classification level 4 or above will give the greatest assurance that the animals are not infected. If the seller does not participate in a VJDCP, results of comparable testing on adult cattle older than 3 years of age in the herd should be requested. If such results are not available, screening of potential replacements by ELISA and fecal PCR should be performed, recognizing that if the animal is in the eclipse phase, false-negative results are possible, and continued monitoring on an annual basis after addition to the herd is warranted.

Nonbovids. In goats, serum ELISA and fecal culture and PCR have similar accuracy to that found in cattle. However, serum testing for antibodies in sheep is less reliable, and organism detection tests on feces are recommended. The sheep strain of MAP is more difficult to grow in vitro than the cattle strain that affects dairy cattle, beef cattle, goats, and camelids in the United States. Development of specialized liquid media for culture of MAP from sheep feces has improved sensitivity, but best results will probably be achieved by employing fecal PCR testing. In camelids, PCR and culture in liquid media have similar sensitivity to detect MAP in feces.

TREATMENT. In most production situations, treatment for MAP infection is not attempted. However, in some cases treatment may be desirable to allow for preservation of genetics (e.g., through embryo transfer or in vitro fertilization), or for sentimental reasons, especially those animals viewed as pets. Before undertaking treatment, the owner must be made aware that treatment may result in remission of clinical signs and reduction of fecal shedding, but the infection is rarely eliminated, and daily treatment will most likely be required for the life of the animal, with relapse likely when treatment is discontinued. Treatment of a clinically affected pregnant cow to salvage her fetus is not recommended because of the high likelihood of transplacental infection of the fetus. Additionally, any chemotherapeutic

VetBooks.ir

program will involve extralabel use of antimicrobials, which in the United States must be performed in accordance with the regulations set forth in the Animal Medicinal Drug Use Clarification Act (AMDUCA). As reliable withdrawal times are not established for many of the antimicrobials employed in treatment of Johne's disease, owners should be informed that once treatment begins, the animal or its products should never enter the human food supply chain.

The therapeutic agents most often employed include those used to treat mycobacterial infections in humans (isoniazid, rifampin, clofazimine), monensin, and aminoglycosides, and combination therapy is often recommended, at least to induce remission. Clofazimine, an antileprosy drug, has been used successfully by the author at a dose of 2 mg/kg q24h, alone or in combination with other agents. Improvement in fecal consistency and plasma total protein occurred within 7 to 14 days of starting treatment. However, recently this drug has not been available in the United States, prompting use of other combinations. Thus, a typical currently employed treatment protocol, if clofazimine is not available, for cattle, goats, sheep, and camelids includes rifampin (10 mg/kg PO q24h) and isoniazid (10 to 20 mg/kg PO q24h). Gentamicin (6.6 to 8.0 mg/kg IV q24h) for the first 5 to 10 days of treatment may hasten onset of remission, provided renal function is normal and can be monitored for signs of nephrotoxicosis. For cattle, monensin should also be recommended. Approved for its effect as a coccidiostat and for its effect on rumen microflora and digestion efficiency, it has also been shown to inhibit MAP growth in vitro and ameliorate the disease in experimentally and naturally infected cattle.[22,23] Use of monensin as a feed additive also has the potential to play a chemoprophylactic role in prevention of MAP infections in susceptible cattle.

PREVENTION AND CONTROL. For herds not currently infected with MAP, prevention relies primarily on establishing a closed herd. If herd replacements must be purchased, the herd of origin should be screened as indicated earlier, and ideally have achieved level 4 or higher status in the VJDCP.

For herds that are infected, clear objectives should be established. For large production herds with high turnover, no steps may be economically warranted. For other herds, management to reduce transmission and ameliorate the economic impact of the disease may be desirable, and in other herds eradication may be the goal. Regardless of the goal, a test-and-cull strategy employed without other management changes to reduce transmission will not be successful.

Whether the goal is eradication or managing the disease to minimize losses, a risk assessment should be performed to identify potential areas of MAP transmission, especially to susceptible young stock, and a management plan developed. A plan must be individually tailored to a specific facility, but in general key control points are calving pens, calf feeding (colostrum and milk) management, and calf housing, especially as they pertain to potential exposure of calves to feces of adult infected cows, or to fecal-contaminated surfaces. Handbooks for veterinarians to assist them in performing risk assessments and management plans for both dairy and beef cattle, designed by the Johne's Disease Committee of the U.S. Animal Health Association, are available at http://www.johnesdisease.org/. On most dairy farms, control strategies will focus on calving pen hygiene, early removal of calves from the calving pen after birth, providing an uncontaminated source of colostrum and milk or colostrum replacer and milk replacer, and calf housing free of contamination by feces from adult cattle. Testing in some form to identify and remove or segregate highly infectious adult cattle is usually warranted. In beef cow-calf operations, preventing transmission to calves again must focus on manure contamination of calving areas, manure contamination of cows that are nursing calves, and other possible sources of calf exposure to feces from potentially infected adult cattle. Recommendations can be adapted as appropriate for use with small ruminants and camelids, again to focus on prevention of transmission to susceptible young stock.

Vaccination has been employed with mixed results in cattle and small ruminants. In the United States, vaccination of cattle is permitted in some states, on approval by the State Veterinarian. The only licensed vaccine (Mycopar [Boehringer Ingelheim Vetmedica, St. Joseph, Mo.]) is a killed oil suspension of *M. avium*. The vaccine is generally regarded to reduce the incidence of clinical disease, and in some instances also reduce the level of fecal shedding, yet in other studies prevalence of fecal shedding was not affected. Vaccination should be considered as a useful adjunct, particularly in herds of high prevalence and losses due to clinical Johne's disease. Vaccination alone, without implementation of management changes to reduce exposure of calves to MAP, is often unsuccessful as any resistance achieved by vaccination may be overcome by heavy MAP exposure.

ZOONOTIC POTENTIAL. Traditionally, MAP was not regarded as a pathogen of humans. However, because of some similarities between Crohn's disease in people and Johne's disease in ruminants, the possible connection between MAP and Crohn's disease has undergone further scrutiny. These studies, especially those that employ PCR methods to identify MAP in tissue samples from people with Crohn's disease, have definitively shown an association between presence of MAP in intestinal tissue and Crohn's disease.[24] However, what is more difficult to determine is whether this association is causal or secondary. Crohn's disease is thought to involve an overly florid immune response to antigens in the gastrointestinal tract. Proponents of the hypothesis that MAP causes Crohn's disease believe that MAP antigens are responsible for that response, whereas skeptics believe that MAP may be present secondarily to damaged mucosa with diminished resistance to MAP colonization. Undoubtedly, Crohn's disease is a multifactorial disease influenced by a complex interaction of genetics, environment, cigarette smoking, and potentially infectious agents. Human exposure to MAP occurs potentially via survival of MAP in pasteurized milk or drinking water contaminated by fecal runoff from infected farms. Increasingly, regulatory agencies around the world are treating paratuberculosis as a food safety issue. Although it may be difficult to scientifically establish an etiologic connection between MAP and Crohn's disease, in the author's opinion, even the potential for a role of MAP in Crohn's disease or other human conditions should motivate producers and veterinarians to control the disease in food-producing animals.

Copper Deficiency in Ruminants

John Maas • Bradford P. Smith

Definition and Etiology

Copper deficiency occurs when the diet contains an abnormally low amount of copper (primary copper deficiency) or when copper absorption or metabolism is adversely affected (secondary copper deficiency). If inadequate amounts of copper are available to tissues in the form of essential metalloenzymes, the signs of copper deficiency (hypocuprosis) may occur. Clinical signs in ruminants include diarrhea, decreased weight gain, unthrifty appearance, anemia, changes in coat color (achromotrichia) or wool quality, anemia, spontaneous fractures, lameness (epiphysitis), and demyelinization (enzootic ataxia of sheep and goats, or swayback). One of these syndromes usually predominates in a given herd.

The minimum recommended dietary copper concentration (dry matter basis) is 4 to 10 ppm (mg/kg) for cattle,[1,2] 5 ppm for sheep,[3] and 7 ppm for merino sheep.[3] Young animals and fetuses are more susceptible to copper deficiency than are mature animals, and cattle are more susceptible than are sheep. Secondary copper deficiency is associated with high dietary levels of molybdenum, sulfates, zinc, iron, or other compounds. Secondary copper deficiency often presents with clinical signs of diarrhea and weight loss or unthriftiness. It has been called *teart, peat scours, renguerra, pine,* and *salt lick disease.*[4] Salt sickness in Florida appears to be the result of combined copper and cobalt deficiencies. The cause of copper deficiency in clinical cases is often multifactorial and can be difficult to quantify. In addition, unknown factors cause clinical expression of copper deficiency in ruminants to be manifested as a variety of syndromes.

VetBooks.ir

Clinical Syndromes and Differential Diagnosis Profuse watery diarrhea with poor weight gains and/or weight loss is a common syndrome seen in ruminants with copper deficiency.[4] When it occurs on boggy pastures that contain high concentrations of molybdenum, it has been referred to as *teart*.[4] Decreased weight gains or weight loss as a herd problem can have many other causes, including parasitism, trace mineral deficiencies (selenium, cobalt), protein calorie malnutrition, and Johne's disease. A syndrome characterized by epiphyseal enlargement, stiffness, and unthriftiness is seen in young ruminants and is the result of copper deficiency[5] and is sometimes called *pine*.[4] Copper deficiency can cause spontaneous fractures in ruminants. Enzootic neonatal ataxia (swayback) of lambs and kids is characterized by progressive incoordination and recumbency that begins with the hindlimbs and progresses to the forelimbs. It has also been reported in deer and pigs. Inadequate keratinization of wool and achromotrichia is the result of imperfect oxidation of free thiol groups during hair growth and keratinization. Subsequently, the wool fibers do not crimp normally, and they appear to be "stringy" or "kinky." A copper-containing enzyme, tyrosinase (polyphenol oxidase), is needed to convert L-tyrosine to melanin. With copper deficiency, this conversion is slow and hair is lighter in color than normal (achromotrichia). Loss of wool crimp and pigmentation changes in sheep or cattle, respectively, occur late in the course of copper deficiency. In addition to the previously listed clinical syndromes that may occur alone or jointly, copper deficiency may be associated with anemia[6] (altered iron metabolism) or infertility.[7] Infertility is probably multifactorial and may not respond to an increase in copper intake alone. Copper deficiency also seems to result in decreased immune function in ruminants.[8,9]

Pathogenesis A frank dietary deficiency of copper results in hypocuprosis and eventual clinical signs. Also, a variety of conditions can decrease copper absorption from the gastrointestinal tract (large intestine in sheep and small intestine in cattle). The interactions between dietary copper, molybdenum, and sulfates (or sulfur) are important (Fig. 32-132). Excess dietary molybdenum can lead to the formation of sparingly soluble cupric molybdates in the rumen that are not absorbed from the intestine. The addition of excess sulfur or sulfates in the diet and/or water can result in the formation of insoluble copper thiomolybdates in the rumen. The interactions among these three elements are complex.[10] The infertility seen with secondary copper deficiency may be caused by excess circulating oxythiomolybdates, which interfere with the release of luteinizing hormone.[11]

It is important to note that at low sulfur concentrations in the diet, excess molybdenum has a minimum effect on decreasing copper absorption. Even when no dietary molybdenum or sulfates are present, only about 5% of ingested copper is normally absorbed. Excessive calcium in the diet, particularly in the form of limestone, decreases copper absorption. Excessive iron, 30 mg/kg of body weight or 1200 ppm in the diet of calves, reduces copper absorption.[12] Overgrazing, with the subsequent ingestion of excess soil, also decreases copper absorption. In addition, excess cadmium (3 to 7 ppm) or excess zinc (100 to 400 ppm) reduces hepatic copper concentration, probably through the combined effects of decreased absorption and competition with copper for hepatic metallothionein.[13,14] It had been suggested that excess dietary selenium might interfere with copper absorption and/or utilization, but this has been shown not to occur.[15] Copper is an essential component of a number of mammalian enzymes. Some of the medically important copper-containing enzymes are (1) the cytosol form of superoxide dismutase (copper and zinc), (2) cytochrome oxidase (c and aa_3), (3) lysyl oxidase, (4) ascorbic acid oxidase, and (5) ceruloplasmin.[16] In addition, normal copper nutrition appears essential for iron absorption and transportation of iron to the liver and reticuloendothelial system and is thus necessary for normal hemoglobin formation. The precise pathophysiology of most of the copper deficiency syndromes is not known. However, the central role of copper in preventing cellular oxidative damage and its role in iron and sulfur metabolism are probably important.

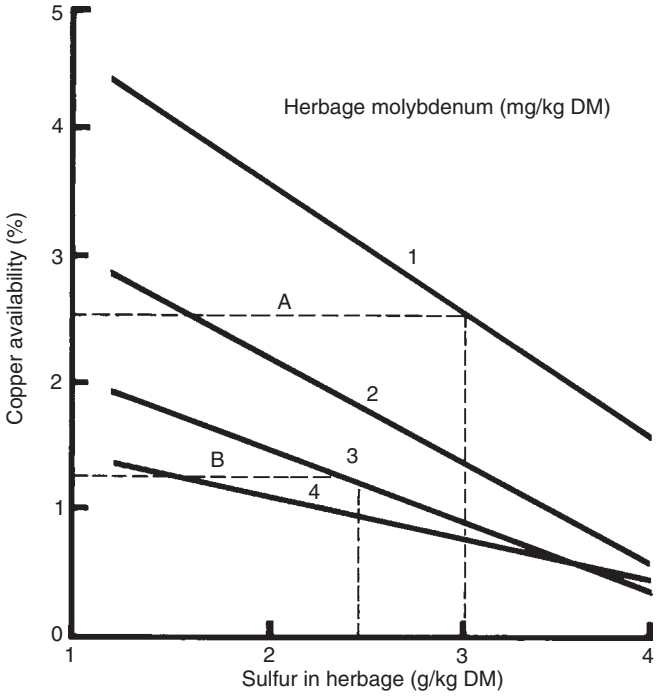

Fig. 32-132 Estimating the availability of copper in herbage from its molybdenum and sulfur concentrations: the difference of 3 mg of molybdenum and 0.5 g of sulfur per kilogram of dry matter (DM) between pastures A and B is sufficient to reduce availability from 2.6% to 1.3%, doubling the grazing animal's requirement of copper from the pasture. *(From Suttle NF. 1986. Copper deficiency in ruminants: recent developments. Vet Rec 119:519.)*

Epidemiology Copper deficiency can occur when diets are inadequate in copper or contain excess amounts of interfering substances, particularly sulfates and molybdenum. This occurs in many parts of North America. Forages and water can be sources of molybdenum, sulfur, and sulfate. To avoid primary copper deficiency, pasture (dry matter) should contain over 5 ppm of copper, with 3 to 5 ppm considered marginal and less than 3 ppm deficient. Soil copper concentrations are generally slightly lower than those of the harvested forage. Molybdenum adversely affects plant uptake of copper. Forage molybdenum concentrations greater than the copper concentrations often lead to secondary copper deficiency, even when forage copper is adequate. Because copper content in grasses and legumes can be different, forage samples must be randomly selected to reflect dietary intake. Forage copper concentrations as high as 12 to 27 ppm have been associated with copper deficiency when molybdenum levels are high.[4] The critical ratio of copper to molybdenum in feeds is 2:1, with 5:1 recommended for sheep and 5:1 to 10:1 for grazing cattle.

Clinical Pathology and Diagnosis The primary site of copper reserves is the liver and the copper concentration in the hepatic tissue is the best indicator of copper status (Fig. 32-133). The reference range for hepatic copper concentrations in cattle is approximately 90 to 200 µg/g (ppm) and in sheep 90 to 250 µg/g on a dry weight basis (dry matter basis [DMB]).[4,17,18] Hepatic copper concentrations as high as 250 µg/g DMB are not unusual in supplemented ruminants (even over 350 µg/g DMB in sheep). Blood (serum or plasma) copper concentrations can be maintained near normal until hepatic copper concentration falls to 35 ppm DMB or less, at which time the serum copper concentration invariably begins to decrease.[19] When using blood samples for copper determination, serum or plasma are normally preferred. Plasma copper concentration is usually about 5% greater than an identical serum copper concentration.[20] Normal serum copper is 0.7 to 1.2 ppm (µg/mL).[4,16] Serum or plasma copper concentrations of 0.4 ppm or less are considered as

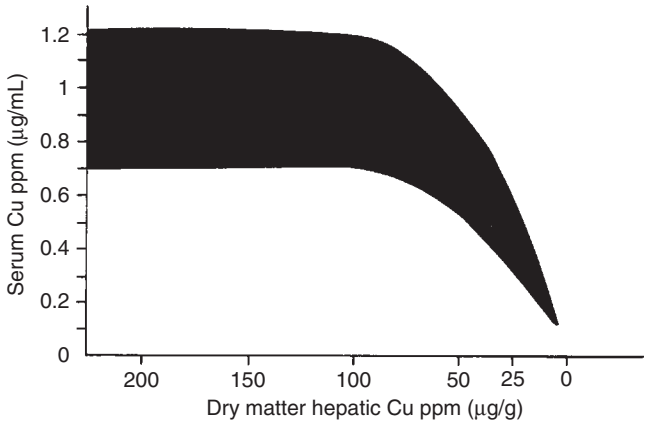

FIG. 32-133 Relationship between serum and hepatic copper concentration in ruminants.

evidence of frank deficiency. Values of 0.4 to 0.7 ppm are marginal and it is difficult to estimate the actual liver copper concentration based on these serum copper ranges. Approximately 50% to 90% of the copper in serum or plasma is present in ceruloplasmin. The remainder is bound to albumin or amino acids. The correlation between serum copper and serum ceruloplasmin was found to be weak (0.50)[20]; thus, ceruloplasmin is not commonly used to aid in diagnosing copper deficiency. Additionally, serum ceruloplasmin increases with inflammatory conditions and can result in false-normal values. Hepatic copper concentration is the preferred diagnostic sample and is easily secured at necropsy. Hepatic copper values less than 35 ppm DMB are considered deficient.[4,17-19] However, surgical biopsy is necessary for live patients, and, because laboratories generally require 100 mg or more of tissue, a biopsy instrument with an internal diameter of 3 to 5 mm is necessary.[21] The biopsy procedure in cattle is performed by locating the tenth intercostal space on the right side of the animal along a line from the tuber coxae (point of the hip) to the point of the shoulder.[21] This site is surgically prepared and blocked with lidocaine (12 mL of 2% lidocaine) and a stab incision is made. The biopsy instrument is directed slightly ventrad and craniad and advanced through the intercostal space and the diaphragm to enter the liver where the biopsy sample is obtained.[21] The liver biopsy can place the patient at increased risk for black disease or bacillary hemoglobinuria in some areas of the United States. This risk should be decreased by prior vaccination and a single dose of procaine penicillin G (4 million IU SC) administered at the time of biopsy. This technique has been shown to be safe and effective.[21] The tissues of young animals (neonates) contain variable amounts of copper compared with adults of the same species. In sheep, serum and liver copper concentrations are the same for lambs (1 week of age) and adults.[22] The plasma copper levels in lambs are low at birth but rise to adult values by 1 to 7 days of age. Plasma copper levels in the bovine neonate are lower than in mature cattle.[23] In the bovine neonate hepatic copper concentration changes little from birth to maturity; however, copper distribution in the liver is quite variable in the neonate.[18,23] Because of these differences, interpretation of neonatal serum copper concentrations is difficult. Milk is a poor source of copper, containing only 0.2 to 0.6 ppm in normal ewes and 0.01 to 0.02 ppm in severely copper-deficient ewes or cows. Milk copper in cattle is 0.05 to 0.2 ppm. To make matters worse, molybdenum is concentrated in milk.[24] Recently, research has allowed for the estimation of true wet weight (fresh) and/or dry weight of hepatic samples by concurrently measuring potassium in the specimen.[25] This allows for much more accurate estimation of hepatic copper concentration in samples that have become dehydrated prior to reaching the diagnostic laboratory. This technique allows the laboratory to accurately estimate the original wet weight or to calculate the dry weight with time-consuming drying of the specimen.[25]

Treatment and Control Treatment of copper-deficient animals is usually possible, and the prognosis is guarded to good, depending on the severity of the deficiency and the associated syndrome(s). When excess molybdenum, sulfate, and other factors leading to secondary deficiency are present, they can be overcome to some extent by increasing dietary copper or by injecting copper glycinate. Copper glycinate must be prescribed by the attending veterinarian and dispensed by a compounding pharmacy as no commercial over-the-counter products are currently available. Injectable copper glycinate (30% copper by weight) is given to adult cattle at the rate of 400 mg (120 mg copper) subcutaneously. Calves are given 100 to 200 mg of copper glycinate (30 to 60 mg of copper), depending on their age. One injection may be effective as a treatment/supplement for up to 4 to 6 months in cases of primary copper deficiency. However, in cases of excess molybdenum, sulfates, and/or sulfur, repeat injections may be necessary. Injections of copper glycinate frequently result in large swellings, granulomas, or abscesses and may be cosmetic considerations for some cattle. The reactions can be minimized by using sterile technique and using the subcutaneous tissue of the brisket as the injection site. Acute deaths can occur in calves following the use of copper glycinate injections. In some countries copper EDTA (copper disodium edetate) solutions are used as injectable copper supplements. The dosage of copper is usually the same as that recommended for copper glycinate solutions. However, acute deaths can also occur following its use in cattle.[26] Copper can be supplemented to cattle in salt-mineral mixes in situations in which adequate consumption (1 to 2 ounces [28 to 56 g]/cow/day) of the salt-mineral mix occurs. These mixes are usually 0.2 to 0.6% copper. Feed grade copper sulfate ($CuSO_4$-5 H_2O) is 25% copper on an as-fed basis (40% copper on dry matter basis). Feed-grade copper oxide is usually 50% copper as fed (80% copper on a 100% dry matter basis). To make a 0.4% copper salt mixture, add 7.2 g of $CuSO_4$ or 3.6 g of CuO to each 454 g (1 pound) of salt. For large batches add 32 pounds of $CuSO_4$ or 16 pounds of CuO per ton of salt. Salt mixtures for copper-deficient sheep should usually contain only 0.0625% to 0.13% copper (0.25% to 0.5% copper sulfate). Copper supplements can be added to a total mixed ration easily in the form of trace mineral–vitamin premixes or premix-containing pellets. Copper sulfate can be added to molasses or other sweet feed at 0.363 g/head/day for mature cattle and correspondingly less for calves. This would supply approximately 91 mg of copper to a 450-kg (1000-pound) cow per day or 10 ppm of the total diet (20 pounds [9.1 kg] of dry matter). The copper in $CuSO_4$ is more available than that in CuO. Another method of copper supplementation involves the oral administration of copper oxide needles (fine rods, 1 to 10 mm long) placed in gelatin capsules that dissolve in the reticulorumen and liberate the CuO wires. These wires reside in the reticulum and abomasum and slowly release copper for absorption. These boluses are currently available in the United States (Copasure [Animax, Bury St. Edmunds, Suffolk, UK) and contain either 25 g or 12.5 g per bolus. The usual recommended dosage is 25 g per animal 500 pounds or greater. One 12.5-g bolus is recommended for calves and the usual dose is 2 to 4 g for ewes and does,[4,27,28] which is an extralabel recommendation for sheep and goats. The copper oxide needles are thought to provide copper supplementation for 4 to 12 months. Sheep are particularly susceptible to copper toxicity, and appropriate care is necessary when supplementing them. Sheep can easily be intoxicated when consuming cattle supplements or feeds. Continued monitoring of hepatic copper concentration from slaughtered animals or via liver biopsy is an important tool in evaluating copper supplementation methods in cattle and sheep. Lambs can be given 35 mg of copper sulfate per head twice weekly to prevent swayback in endemic areas. The usual recommendation by the National Research Council (NRC) is 10 ppm (10 mg/kg) of the total diet on a dry matter basis for cattle. However, diets of 20 ppm are commonly fed to lactating dairy cattle. The most recent NRC recommendations for dairy cattle state that 40 mg/kg (ppm) of the diet on a dry matter basis is the maximum tolerable level. This is due to a number of copper toxicity episodes in the United States when the total diet contained 40 to 50 mg/kg copper

VetBooks.ir

VetBooks.ir

or more in the total ration. Copper has the smallest margin of safety of all the trace minerals in ruminants. The most important goal of copper supplementation is to provide adequate dietary amounts without oversupplementing or risking toxicity.

Cobalt Deficiency in Ruminants

Robert Sager • John Maas

Definition and Etiology A number of syndromes occur in ruminants as a result of a primary cobalt (Co) deficiency in their diet. These include ill thrift or enzootic marasmus and anemia. These conditions are characterized by decreased growth, weight loss, diarrhea, decreased feed efficiency, unthrifty appearance, anorexia, and anemia. A Co deficiency syndrome referred to as *ovine white liver disease* has been described in sheep.[1-3] This syndrome is also characterized by ill thrift, weight loss, serous ocular discharge, and occasionally photosensitization.[1-3] Histopathologic lesions of this syndrome included accumulation of lipid droplets and lipofuchsin particles, dissociation and necrosis of hepatocytes, and sparse infiltration by neutrophils, macrophages, and lymphocytes.[4] Cobalt-deficient animals are more prone to parasitic infestation, particularly *Ostertagia ostertagi* in cattle.[1] Also, Co fed at levels above National Research Council (NRC) minimal recommendations has resulted in increased antibody production to a single antigen in weaned beef calves.[5]

Clinical Signs and Differential Diagnosis Cobalt deficiency in ruminants is associated with the nonspecific signs of decreased growth, weight loss, diarrhea, ill thrift, pica, emaciation, pale mucous membranes (anemia), and lacrimation. Clinical disease is more common in young, growing animals. Sheep are apparently more susceptible to Co deficiency than cattle. Primary differential diagnoses include helminthic parasitism; protein-calorie malnutrition; coccidiosis; Johne's disease; nutritional deficiencies of selenium, copper, or vitamin D; and other chronic diseases that may be associated with weight loss. Cobalt-deficient ruminants are commonly anorexic and fail to thrive on lush pasture or high-quality feeds. Anemia with Co deficiency is characterized as normocytic normochromic and must be differentiated from other causes of anemia. Cobalt-deficient cattle are more susceptible to infestation with *Ostertagia ostertagi* and to the effects of parasitism.[4] The primary differential diagnosis when considering Co deficiency is invariably internal parasitism.

Clinical Pathology and Diagnosis Because the role of Co in ruminant nutrition is tied to the formation, absorption, and use of vitamin B_{12}, the most significant biochemical role of Co is correlated with tissue vitamin B_{12} concentrations. However, the effects of starvation tend to increase vitamin B_{12} concentrations in the liver and kidneys.[6] If Co deficiency occurs with other conditions that cause anorexia, the tissue vitamin B_{12} concentrations may appear falsely elevated (normal). The appropriate analytic methods for serum B_{12} vary from humans to ruminants, so extrapolation of ruminant serum B_{12} concentrations analyzed in a human laboratory may not be possible. Serum or plasma vitamin B_{12} levels exhibit a marked diurnal variation.[7] Additionally, serum vitamin B_{12} concentration more closely reflects short-term Co intake and can be decreased when adequate liver reserves of vitamin B_{12} remain. In normal, Co-sufficient ruminants' serum vitamin B_{12} values are usually 0.1 to 0.3 ng/mL (parts per billion [ppb]). When serum vitamin B_{12} values decrease, clinical signs of Co deficiency can become evident.[8,9] Because serum B_{12} values can give spurious results, the concentration of Co in hepatic tissue is probably the best current standard for determining Co status and making clinical decisions. The liver concentration of B_{12} for cattle and sheep considered to be adequate is 0.30 to 2.24 µg/mL (ppm) on a wet weight basis.[10,11] Table 32-23 contains reference ranges for cattle and sheep.

TABLE 32-23

Reference Values for Cobalt and Vitamin B_{12}

Analyte	Cattle	Sheep
Serum Cobalt	0.1-0.3 ng/mL (ppb)[11,12]	0.1-0.3 ng/mL (ppb)[11,12]
Serum B_{12}	1-3 ng/mL (ppb)[10,11]	1-3.5 ng/mL (ppb)[11]
Liver Cobalt	80-160 ng/g (ppb) wet weight[10-12]	80-160 ng/g (ppb) wet weight[10-12]
Liver B_{12}	0.3-2.24 µg/g (ppm) wet weight[10,11]	0.3-2.24 µg/g (ppm) wet weight[10,11]

Adult bovine liver is 27% dry weight (approximately 30% dry weight).[30] Therefore, the wet weight to dry weight conversion can be easily made. Also, the measurement of liver potassium can be used to estimate either the true wet weight or true dry weight on samples that are not fresh or have become dehydrated or for laboratories that only measure dry weight or wet weight (as received).[30]

Pathophysiology Cobalt deficiency in ruminants induces a deficiency of vitamin B_{12} (cyanocobalamin). It is the lack of vitamin B_{12} that is thought to cause the majority of clinical signs and clinicopathologic abnormalities observed. Monogastric species need to ingest vitamin B_{12} preformed, whereas ruminants can manufacture adequate vitamin B_{12} if the rumen microorganisms are supplied with adequate Co in the diet. The rumen microorganisms incorporate Co into vitamin B_{12} and a number of physiologically inactive vitamin B_{12}–like compounds. The production of vitamin B_{12} from dietary Co was estimated to be about 15% in Co-deficient sheep and only about 3% in Co-sufficient sheep.[13] About 50% of the vitamin B_{12} produced is absorbed in normal animals, but only 3% to 5% of vitamin B_{12} is estimated to be absorbed by Co-deficient sheep.[14] Although the absorption of vitamin B_{12} formed in the rumen is not particularly efficient, with normal dietary Co there are usually no clinical problems, and interference by other dietary components does not appear to be clinically important.

Ruminants use the volatile fatty acids acetate, propionate, and butyrate as their primary energy sources. Propionate produced in the rumen is the precursor of glucose for ruminant metabolism. The general metabolic steps for conversion of propionate to glucose are shown[15] in Fig. 32-134.

A primary defect in Co-deficient ruminants is the inefficient metabolism of propionate at the point in the pathway at which methylmalonyl-CoA mutase, a vitamin B_{12}–requiring enzyme, catalyzes the conversion of methylmalonyl-CoA to succinyl-CoA.[16] As Co deficiency becomes severe, the rate of propionate clearance from the blood decreases, and the intermediate metabolite methylmalonyl-CoA accumulates. [17] With severe Co deficiency, the amount of methylmalonic acid excreted in the urine increases. As the half-time for propionate clearance increases, the voluntary feed intake of Co-deficient sheep decreases.[17] These changes correlate with the degree of anorexia and weight loss observed in severely Co-deficient sheep.

The decreased growth, weight loss, unthrifty appearance, and anorexia are closely correlated to the observed abnormalities of carbohydrate metabolism. The diarrhea commonly observed with Co deficiency is not well explained; however, an increase in susceptibility to parasitism[4] might explain a portion of this clinical observation.

The anemia that is associated with Co deficiency occurs late in the development of the syndrome and is characterized as normocytic normochromic.[18] Cobalt deficiency results in the depression of the vitamin B_{12}–containing enzyme 5-methyltetrahydrofolate homocysteine methyltransferase.[19] This interference with the recycling of methionine has a marked influence on folate metabolism. In addition to potentially resulting in anemia through inefficient folate metabolism, the decreased activity of this methyltransferase could lead to a deficiency of methionine; this is a possible reason for nitrogen retention and the decreased body growth and wool growth observed.

Epidemiology and Cobalt Requirements Co deficiency in ruminants occurs in selected regions throughout the world and in

VetBooks.ir

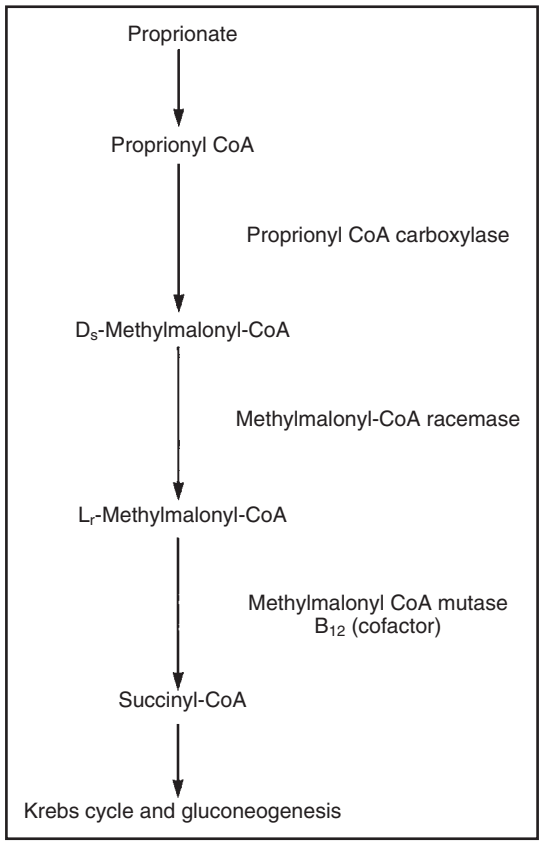

FIG. 32-134 Pathway for conversion of proprionyl CoA (from proprionate) to succinyl CoA.

association with a variety of soil types. Clinically recognizable Co deficiency is reported in New Zealand, Australia, Brazil, United Kingdom, Ireland, Scandinavia, and North America. In the United States, Co deficiency is most commonly seen in Florida, in the Northeast, along the eastern seaboard, in the upper Midwest, and around the Great Lakes.[20] Although various soil types are associated with Co deficiency, heavy fertilization with limestone reduces the Co available to plants and animals.[21] The dietary requirement of Co by ruminants is generally recommended to be 0.1 mg/kg of dry matter (DM) of the complete ration.[22-24] The Co requirement of young, rapidly growing lambs is thought to be 0.2 mg/kg (ppm) of DM of the diet.[25] When pasture Co concentrations are less than 0.07 mg/kg of DM or 0.04 mg/kg of DM for sheep and cattle, respectively, signs of deficiency can be expected to develop. On a practical basis, diets with 0.1 mg/kg of DM are considered to be adequate. Legumes have relatively high Co concentrations. Rapidly growing grasses have much lower Co concentrations, and cereal grains are poor sources of Co.[22] Oilseed meals are generally good sources of Co. Cobalt supplemented at levels above NRC recommendations (0.2 mg/kg versus 0.1 mg/kg) has been associated with increases in the immune response to one antigen in cattle.[5]

Treatment and Control Treatment is best accomplished in the short term with vitamin B_{12} injections. Ruminants poorly absorb oral vitamin B_{12}; thus injections are the most efficient. Lambs receiving 100 µg of vitamin B_{12} per week or 150 µg B_{12} every other week show remission of clinical signs.[26] Sheep receiving injections of 300 µg of vitamin B_{12} weekly or cattle receiving 2000 to 3000 µg of vitamin B_{12} weekly would also be expected to regain normal status.

Rations with 0.1 to 0.2 mg/kg (ppm) of DM Co would be expected to prevent Co deficiency in ruminants. Salt-mineral mixes containing 0.1% Co also provide adequate supplementation. 0.1% Co in salt can be made by mixing cobalt carbonate (which is 46% cobalt) at the rate of 4.35 pounds/ton of salt, or 1 g of cobalt carbonate per pound of salt. A pound equals 453.59 grams.

Cobalt sulfate as a top dressing for pastures (1.5 kg/hectare every 3 to 4 years or 0.3 kg/hectare every 1 to 2 years) has been used to increase Co concentration of pasture forage. Heavily limed pastures[21] and soils high in manganese oxide[27] decrease Co availability, and Co top dressing of the pastures or Co (B_{12}) supplementation to the animals should be considered.

A variety of rumen pellets containing Co are used to supplement grazing ruminants. These pellets have been successful in maintaining normal Co status in animals.[25-29] The pellets are not commercially available in the United States at this time.

The perennial grass, *Phalaris tuberosa,* can cause a syndrome in ruminants that is referred to as "phalaris staggers." Co supplementation can aid in prevention of this syndrome, because it inactivates or decreases absorption of the neurotoxin contained in *P. tuberosa, Phalaris minor* (canary grass), or *Phalaris* hybrids (ronpha).[29] The increased level of Co in the rumen is the important factor in preventing this condition; administration of oral or parenteral vitamin B_{12} is not effective.[26] Treatment of clinical phalaris staggers with Co is not effective, however.

Because Co is poorly absorbed, toxicity is an uncommon problem, and diets in excess of 30 mg/kg of DM are necessary for toxicosis to occur in most cases.[22-24]

Rectal Prolapse in Ruminants and Horses

Spring K. Halland

Definition and Etiology Rectal prolapse is the protrusion of the rectal mucous membranes through the anus. This evagination may be extensive and may include part of the small colon. Rectal prolapse occurs in all domestic animals, with the highest incidence in cattle, sheep, and swine. The age at which prolapse most commonly occurs is 6 to 12 months in sheep, 6 months to 2 years in cattle, and 6 to 12 weeks in swine.[1] Rectal prolapse is much less common in horses and occurs more often in mares than in males.[2]

Rectal prolapse generally is the result of an increase in the pressure gradient between the abdominal or pelvic cavity and the anus. Factors that cause the increased pressure gradient can be divided into four categories: (1) factors that result in increased abdominal fill (e.g., excess fat, bloat, and large or multiple fetuses); (2) factors that cause tenesmus (e.g., enteritis, colitis, intestinal parasitism [coccidiosis], liver disease, constipation, proctitis, urinary obstruction, dystocia, aftermath of rectal examination, and false copulation); (3) conditions that result in chronic or excessive coughing (e.g., pneumonia, parasitism, and adverse environmental conditions); and (4) miscellaneous conditions (e.g., use of growth implants, space-occupying lesions, congenital or acquired sphincter tone problems, and short tail docking [especially noted in sheep]). One study strongly revealed that sheep with short docked tails (as close to the body as possible) had a 7.8% higher incidence of rectal prolapse when finished on a high-concentrate diet.[3] Certain toxicities such as from lead, fluoride, estrogen, and zinc have been implicated as playing a role in rectal prolapse.[4] Any combination of factors may precipitate a rectal prolapse. Identification of predisposing factors becomes important in management of the case.

Clinical Signs Four categories have been used to described rectal prolapse: type I, mucosal prolapse; type II, complete prolapse; type III, complete prolapse with invagination of the colon; and type IV, intussusception of the peritoneal rectum or colon through the anus (Fig. 32-135).[2] Types I and II are much more common and more amenable to correction. On physical examination, types I, II, and III are continuous with the mucocutaneous junction of the anus, whereas with type IV a protrusion with a palpable trench inside the rectum

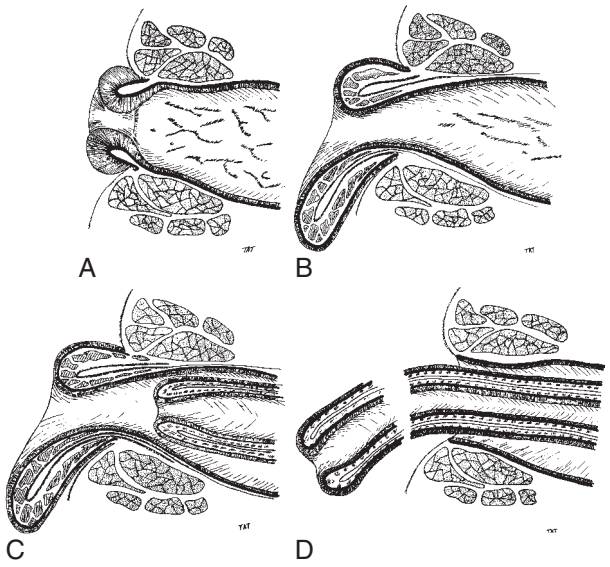

FIG. 32-135 **A,** Type I rectal prolapse. Mucosal prolapse, involving only mucosa and submucosa of the rectum. **B,** Type II rectal prolapse. Complete prolapse, involving full wall thickness of the rectum. **C,** Type III rectal prolapse. Complete prolapse plus intussusception of peritoneal rectum or small colon. **D,** Type IV rectal prolapse. Intussusception of the peritoneal rectum or small colon or both. *(From Robinson NE [ed]. 1987. Current therapy in equine medicine, ed 2. Saunders, Philadelphia, Pa.)*

is seen.[5] Chronic cases can be seen and usually are type I or II. Types III and IV often cause loss of vascular integrity to the rectum or small colon and require more immediate intervention. Types III and IV may accompany dystocias in mares.[6]

Treatment and Prognosis The first aim of therapy is identification and alleviation of the cause if possible. Early identification and correction of the prolapse is essential to saving tissues and the animal. The animal's value and intended use and the affected tissue's viability need to be considered when deciding on conservative or surgical options. The color of the membranes is a good parameter for determining if the tissue is salvageable. In general, the rectum is a forgiving structure, and attempts should be made to salvage the prolapsed tissue unless it is obviously cyanotic, necrosed, and devitalized. To prevent further damage, animals should remain standing and restrained in a small area until the prolapse can be corrected.

Types I and II usually are treated conservatively. A caudal epidural is used to reduce straining and facilitate correction of the prolapse. A range of 4 to 6 mL of 2% lidocaine is usually adequate for juvenile to adult cattle. The addition of a small amount of xylazine to the lidocaine epidural will extend the duration of the anesthetic. Sedation may also be necessary, depending on the individual animal. Effective conservative therapy includes thorough cleansing of the prolapse with warm water and mild soap to remove all debris. This allows evaluation for trauma, tears, necrosis, or sloughing. Edema can be removed by gentle kneading combined with topical application of glycerin or sugar. Generous lubrication and massage allow for reduction of the mass into the rectum. To ensure that the rectum is maintained in place, purse-string sutures using umbilical tape or other nonabsorbable suture are placed circumferentially around the anal sphincter, with care taken not to enter the rectum. The purse-string should not be so tight as to prohibit the passage of feces. If necessary, it should be loosened daily to expedite removal of accumulated fecal material. The purse-string should be removed in 3 to 4 days. Broad-spectrum antimicrobial drugs should be administered if tissue compromise is a factor. When indicated, stool softeners and enemas may be used to ease the passage of feces through the rectum.

Surgical intervention often is necessary if type I or type II prolapse cannot be reduced, if tissue necrosis is extensive, or if prolapse recurs after conservative therapy.[5] Submucosal resection, amputation, or the use of a prolapse ring are all accepted surgical options. Prolapses of types III and IV that cannot be manually reduced often require a celiotomy for surgical reduction of the intussusception or resection or both. An important fact to remember is that even with manual reduction of a type IV prolapse, significant vascular compromise may have occurred, resulting in bowel leakage and peritonitis. Vascular damage encountered by the colon may necessitate a colostomy.[6] Broad-spectrum antimicrobial drugs should be administered in these cases.

Unique problems are encountered when conservatively managing equine rectal prolapse versus ruminant prolapse. Equine patients may experience more hindlimb ataxia with caudal epidurals, which can be prevented by using different combinations of xylazine, lidocaine, detomidine, morphine, and/or mepivacaine in the epidural. Placement of an epidural catheter can facilitate long-term therapy if needed. Another problem encountered is that horse feces often are too large and dry to readily pass through the purse-string in the anus. The use of enemas and stool softeners offers some assistance. The sutures tend to cause greater anal irritation than is seen in ruminants, causing the horse to strain against them.

The common complications after rectal prolapse include prolapse recurrence, rectal strictures, obstipation, formation of a pararectal abscess, and peritonitis. The prognosis for all types of rectal prolapse depends on early identification and reduction of the prolapse. Prolapses of types I and II that can be managed conservatively have a favorable outcome. Surgical correction of types I and II also carries a good prognosis but with a higher incidence of postsurgical complications. Because of the cost of surgical repair, market animals often are slaughtered if conservative management fails. Rectal prolapses of types III and IV carry a fair to guarded prognosis, which depends on the extent of tissue involvement and viability, the surgeon's skill, and postsurgical complications.

Diseases of the Hepatobiliary System

GEOF W. SMITH and JENNIFER L. DAVIS, *Consulting Editors*

Diagnosis of Liver Disease*

Geof W. Smith

In making a diagnosis, the veterinarian should first attempt to determine that the animal *has* liver disease and then move toward trying to identify a specific cause. Therefore, this chapter first discusses the diagnosis of liver disease, then the individual conditions causing disease in horses and ruminants. The signs of liver disease are due to failure of some of the liver's many functions, but these signs are often not apparent early in the course of disease. Special tests may be necessary to detect early damage or minor impairment of function that has not yet produced clinical signs.

Liver Diseases versus Liver Failure

As with many other organs like the heart and kidney, the liver can be diseased or damaged long before it fails to function. Early liver diseases are often inapparent to the owner or veterinarian through physical findings alone. Such cases are usually detected by finding elevated levels of liver enzymes in the serum. Pathologic changes in the liver may include biliary hyperplasia, death of hepatocytes, and fibrosis—all potentially occurring long before any signs of failure develop. Some functions may fail before others, and onset of liver failure varies with the species and disease process involved.

Liver Reserve and Regeneration

The liver has a large reserve capacity, and close to 80% of it can be removed before regeneration and recovery are no longer possible. Regeneration can occur in areas receiving portal blood, but most cell division takes place in Rappaport zone 1 (the portal area), with cells being pushed to the central lobular area. The liver undergoes constant repair, and in humans it is estimated that hepatocytes are renewed every 50 to 75 days.[1]

Normal regeneration does not occur in some cases. Antimitotic agents such as pyrrolizidine alkaloid metabolites or antineoplastic drugs can prevent cell division. Regeneration may be restricted by connective tissue. Once fibrosis has bridged the various lobules, additional regeneration is impaired because the fibrosis itself perpetuates the condition. Loss of a stroma to build on or lack of portal blood supply also reduces regeneration.

Signs of Liver Disease and Pathophysiology

Many signs can be present with liver disease, but no sign is pathognomonic or present in every case. Table 33-1 lists some of the signs that may be present and other possible causes of the same signs.

The clinical history is useful in some cases but not consistently. For example, liver flukes in cattle are generally restricted to certain geographic areas and occur more commonly when animals are grazing land infested with snails. Another example would be acute serum hepatitis in horses, which is known to occur most commonly in Equidae 4 to 8 weeks after administration of horse serum. In other cases the lack of specific history information may not rule in or rule out specific causes of liver disease. For example, there may not be a history of animals consuming plants containing pyrrolizidine alkaloids because of the delay between consumption and the onset of clinical signs.

With the exception of change in liver size and pain over the liver elicited with pressure, most signs are related to failure of some function. Liver flukes may cause anemia and hypoproteinemia because of the effect of the parasite and its metabolites. Liver abscesses and other infections may produce signs like fever and anorexia owing to release of pyrogens and other inflammatory mediators (caused by the organism and not necessarily related to the liver itself).

Icterus is typically seen in acute liver disease in horses but is not seen in many cases of chronic liver disease, and it is seen less often in ruminants unless biliary blockage occurs. Icterus is due to failure of uptake, conjugation, or excretion of bilirubin. Excess production caused by hemolysis must also be considered when icterus is present. This is likely the most common cause of icterus in ruminants and occurs with several hemolytic diseases such as anaplasmosis and copper toxicity. Horses are frequently icteric (up to 6 mg/dL unconjugated bilirubin) from anorexia or fasting even when the liver is normal.

Weight loss is a common but nonspecific finding in some cases of chronic liver disease. It may be caused by anorexia or failure of metabolic functions of the liver and is probably not related to impaired fat absorption. Diarrhea is also seen, especially in cattle with chronic liver disease. It is thought to be related to portal hypertension and increased hydrostatic pressure, although the exact mechanisms are not completely understood. Diarrhea probably is not caused by fat malabsorption or steatorrhea, because the normal herbivore diet contains less than 3% fat.

Ascites can also occur in animals with liver failure. The ascites results from portal hypertension caused by venous blockage producing increased hydrostatic pressure and by protein leakage into the

VetBooks.ir

TABLE 33-1

Signs of Liver Disease or Failure

Sign	Pathogenesis	Other Causes
Icterus (E)	Failure of uptake, conjugation, or excretion of bilirubin	Massive hemolysis Bile blockage Fasting in the horse
Weight loss (E, B)	Energy demand greater than absorbed or metabolized	Poor nutrition, chronic inflammation, parasites, neoplasia, maldigestion, malabsorption
Ascites (B)	Portal hypertension and lymph leakage caused by cirrhosis or veno-occlusion	Cardiac failure Hypoproteinemia Cushing syndrome
Change in liver size	Nodular hyperplasia, tumor, cirrhosis Fatty degeneration	Right-sided heart failure Work hypertrophy Anemia
Diarrhea (B)	Bile deficit malabsorption Intestinal edema, portal hypertension	Gastrointestinal (GI) or systemic disease
Pruritus	Retention of bile salts	Dermatologic or central nervous system (CNS) disorders
Dermatitis Unpigmented areas	Hepatogenic photosensitization	Primary phototoxic photosensitization
CNS signs Behavioral change, ataxia, dysmetria, circling, stupor, coma, tremors, bellowing	Hepatic encephalopathy (see text)	Brain diseases Metabolic diseases Toxic diseases
Tenesmus (B)	Hepatic encephalopathy	Rectal or colonic disease CNS disease Urogenital disease
Rectal prolapse (B)	Tenesmus	Rectal or colonic disease
Change in feces color	Bile pigment deficit Undigested fat	Diet GI disease
Hemorrhage	Failure to synthesize clotting factors II, V, VII, IX, X	Other clotting factor or platelet deficit, trauma, disseminated intravascular coagulation
Pain over liver, inflammation, swelling	Abscesses	Traumatic reticulitis
Inspiratory stertor (E) Dyspnea	Hepatic encephalopathy	Upper airway obstruction

B, Frequent sign in cattle; *E,* frequent sign in horses.

peritoneal cavity. Production of hepatic lymph high in protein (>3 g/dL) is increased. Because the liver sinusoids are permeable to plasma proteins, the protein-containing lymph leaks into the interstitial space and then into the peritoneal cavity.[2,3] Fluid moves into the abdominal cavity secondary to both osmotic and hydrostatic forces, according to Starling law. The abdominal fluid present with liver disease is a modified transudate, but the protein content may be relatively high (3 to 3.5 g/dL) owing to leakage of protein from the liver. Hypoalbuminemia can aggravate the ascites, but if it occurs alone, it usually will result in submandibular and brisket edema.

Hepatic photosensitization may lead to dermatitis of the white areas, wherein the skin of these areas first becomes erythematous, then thickened with keratin crusts, and finally necrotic. This is caused by the photodynamic agent phylloerythrin, which is formed in the gastrointestinal (GI) tract of large animals by bacterial degradation of chlorophyll. After absorption into the portal circulation, phylloerythrin should be conjugated by the liver and excreted into the bile. With cholestasis, phylloerythrin may be carried to the skin, where it acts as a photodynamic agent.[4] After bile duct ligation, the level of phylloerythrin steadily increases.[5] Although a small amount is removed by the kidneys, the rate is not fast enough to prevent accumulation in the plasma and skin. Phylloerythrin in the skin reacts to sunlight and emits energy that causes lesions of the white areas.[4]

Pruritus is seen in a few cases of liver disease in horses. In humans, pruritus is assumed to be due to bile acid accumulation in the skin when it is not excreted by the liver. This same process may occur in horses, but pruritus is not usually seen in large animals with liver disease.

A change in fecal color is not usually noted in either adult cattle or horses with liver disease, because other pigments like chlorophyll contribute to the color. In young animals with simple digestive tracts, much of the fecal color is from stercobilin, a metabolite of bilirubin, so with cholestasis, feces may be somewhat lighter in color.

A few signs may be seen terminally in liver disease. Hemorrhage may occur when clotting factors are not synthesized in adequate amounts. Factors I, II, V, VII, IX, and X are all produced by the liver,[1,3] but the disease is usually advanced before a deficit develops.

Tenesmus, often followed by rectal prolapse, is seen in some cattle with liver disease. This may be associated with diarrhea, be part of hepatic encephalopathy, or be aggravated by edema of the bowel secondary to portal hypertension.

Pharyngeal or laryngeal collapse with loud stertorous inspiratory noises and dyspnea has developed in some cases of hepatic failure, especially in ponies. The exact mechanism for this is not known, but it may also be part of hepatic encephalopathy.[6] Horses sometimes develop a terminal hemolytic crisis caused by increased red blood cell (RBC) fragility. This has not been observed in ruminants.

Hepatic Encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by hepatic dysfunction or portosystemic shunting of the intestinal blood.[7] It is considered a potentially reversible metabolic or neurotransmitter disorder, but it is associated with characteristic (although nonspecific) lesions in the central nervous system (CNS), such as altered astrocytes.

Signs of hepatic encephalopathy are often subtle and nonspecific. Behavioral changes may be detected by the owner, who is more familiar with the patient's normal activity. Some docile animals become excitable and difficult to control, whereas other normally unruly animals may become passive. Depression and incoordination are frequent manifestations, and some animals may walk aimlessly or even head press (Fig. 33-1).[8] Apparent blindness is seen in some horses, and foot stomping was reported in 7 of 25 cases.[9] These animals eventually develop a stupor and may end up in hepatic coma. Yawning may be seen in horses, and ponies may have a stertorous

VetBooks.ir

respiratory noise. Ruminants show signs of tenesmus and sometimes vocalize excessively. In humans, hepatic encephalopathy is diagnosed by neuropsychological tests, which are not possible in animals.[10]

The pathophysiology of hepatic encephalopathy remains undefined and is controversial.[8] It occurs when portal blood bypasses the liver, as with congenital shunts in dogs, or with shunts secondary to portal hypertension induced by alcoholic cirrhosis in humans, or when the blood goes through an inadequately functioning liver. How neurologic function is altered has not been determined, but speculation abounds.

It seems possible to incriminate synergistic neurotoxins that bypass the liver. Most will agree that ammonia levels play a central role in pathogenesis. Blood ammonia is elevated in most cases of hepatic encephalopathy because the liver is not metabolizing ammonia to urea. Encephalopathy can be precipitated in cirrhotic patients by adding ammonia-generating substances, and there is an increase in cerebrospinal glutamine, the product to which ammonia is detoxified. Astrocytes contain the enzyme glutamine synthetase, which adds a molecule of glutamate to ammonia to form glutamine. The amount of glutamine formed in the brain correlates with the severity of hepatic encephalopathy.[11] However, much higher concentrations of ammonia are needed to induce coma in normal animals, and there is poor correlation between ammonia levels and degree of encephalopathy.[9] Cases of hyperammonemia and encephalopathy without liver disease have been reported in horses.[12]

Magnetic resonance imaging (MRI) of human cirrhotic patients reveals increased image intensities from the globus pallidus region, probably caused by manganese deposits.[10] Serum manganese is increased in these patients, which correlates with the increased MRI intensities and negatively with neuropsychological tests. This would indicate that manganese is another potential toxin that can enter the brain if not effectively removed from the blood by the liver.

There may be an imbalance of true inhibitory and excitatory neurotransmission. γ-Aminobutyric acid (GABA) is an inhibitory neurotransmitter. The increase in GABAergic tone was originally thought to result from an increase in GABA or its receptor sites. More recently, it has been proposed that neurosteroids with GABA-agonist properties could be involved.[13] Ammonia is believed to play a role in the metabolism of GABA in the brain and thus could act synergistically.[14] Also, receptor sites for benzodiazepine are increased in the brain of animals with hepatic encephalopathy.[15] Benzodiazepine augments the activity of GABA in stimulating the inhibitory neuron and causing sedation.

False neurotransmitters have been proposed to cause the abnormal nerve function. Increased amounts of tryptophan, phenylalanine, and tyrosine in the brain could cause more serotonin to accumulate in the brain. Plasma amino acid ratios are altered in horses with pyrrolizidine alkaloid–induced liver disease.[15] Concentrations of branched-chain amino acids (valine, isoleucine, leucine) are decreased, and concentrations of aromatic amino acids (tyrosine, phenylalanine, free tryptophan) are increased, partially because the liver is not adequately metabolizing aromatic amino acids. Amino acids are transported across the blood-brain barrier by a common transport system, so they compete for entry into the CNS. It has been suggested that higher levels of aromatic amino acids in the CNS would lead to formation of increased amounts of inhibitory neurotransmitters or to alteration of catecholamine or monoamine neurotransmitters like GABA or L-glutamate.

FIG. 33-1 Severe depression and headpressing in a horse with hepatoencephalopathy. Edema of the head developed secondary to the horse hanging its head.

Laboratory Tests and Liver-Derived Serum Enzymes

A number of enzymes are compartmentalized in the hepatocyte or in bile duct epithelium. This compartmentalization is useful in holding insoluble molecules close to the enzymes for chemical reactions. Hepatocyte damage may result in release of the enzymes into the circulation, and cholestasis may cause increased release from bile epithelium. Serum levels of these enzymes may therefore be an indication of hepatocyte integrity or bile excretion. Table 33-2 lists frequently tested enzymes and their characteristics. Serum concentrations for some of these enzymes vary with the age of the animal and sometimes even with type or use. Table 33-3 lists some approximate upper limits of normal for animals of various ages. Normal values, especially for the enzymes, should be established by each laboratory.

The cytosol of the hepatocyte contains high activities of the enzymes aspartate aminotransferase (AST, formerly serum

TABLE 33-2

Liver-Derived Enzymes

Enzyme	Specificity	Problems
GGT	Liver	High in young animals from colostrum
	Kidney*	
	Pancreas	
ALP	Liver	Not specific
	Bone	
	Intestine	
	Macrophages	
	Placenta	
IDH (SDH)	Liver	Not elevated in chronic disease; short life; not stable
GDH	Liver	Not elevated in chronic disease
AST (SGOT)	Liver	Not specific
	Muscle	
	Heart	
ALT (SGPT)	Liver	Low concentration in cattle and horses; not a good indicator in large herbivores
LDH	None unless isoenzymes	Not elevated in chronic disease; short life; not specific
OCT	Liver	Analysis not routinely available

*Elevated in urine, not blood.

ALP, Alkaline phosphatase; *ALT,* alanine aminotransferase (formerly SGPT, serum glutamic-pyruvic transaminase); *AST,* aspartate aminotransferase (formerly SGOT, serum glutamic-oxaloacetic transaminase); *GGT,* γ-glutamyltransferase; *GDH,* glutamate dehydrogenase; *IDH,* L-iditol dehydrogenase (formerly SDH, sorbitol dehydrogenase); *LDH,* lactate dehydrogenase; *OCT,* ornithine carbamoyltransferase.

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *BSP,* bromsulphalein (sodium sulfobromophthalein); *GGT,* γ-glutamyltransferase; *GDH,* glutamate dehydrogenase; *IDH,* L-iditol dehydrogenase (formerly SDH, sorbitol dehydrogenase); *LDH,* lactate dehydrogenase; *NA,* not available.

glutamic-oxaloacetic transaminase [SGOT]), L-iditol dehydrogenase (IDH, formerly sorbitol dehydrogenase [SDH]), ornithine carbamoyltransferase (OCT), glutamate dehydrogenase (GDH), and lactate dehydrogenase (LDH). These are generally referred to as *leakage enzymes,* since with acute or chronic hepatocellular injury or necrosis the activity of these enzymes increases because they essentially "leak" out of hepatocytes into the serum.[16] Cholestasis increases production of other enzymes such as γ-glutamyltransferase (GGT) and alkaline phosphatase (ALP). Activity of these enzymes generally increases secondary to biliary obstruction caused by conditions like liver fluke infection or cholelithiasis. The cholestatic enzymes are more likely to have high serum concentrations in chronic hepatic disease than the leakage enzymes because of bile duct constriction or obstruction secondary to fibrosis.[16] GGT also is present in pancreas, mammary gland, lung, kidney tubules, and other duct epithelium, but serum levels usually are not elevated with renal disease, because the enzyme is lost in the urine. Serum concentrations are normally higher in neonatal calves (sometimes >4000 IU/L after suckling)[17] because the enzyme is concentrated in colostrum.[18,19] GGT levels are also higher in foals than in adult horses, but the higher concentrations may partly be the result of increased production.[20] GGT is elevated in many horses with right dorsal displacement of the large colon, possibly caused by transient extrahepatic bile duct obstruction.[21] Elevated GGT is the most sensitive indicator of liver disease in the horse, and levels will remain elevated for several weeks.[9,22]

ALP is often elevated in chronic liver disease of the horse but is variable in ruminants. ALP can come from other sources like bone, intestines, placenta, and macrophages, so it is not specific. Both ALP and GGT are elevated with cholestasis.[23] The dehydrogenases (i.e., IDH [SDH], LDH, GDH) are found in hepatocytes and are elevated with acute hepatocyte damage, but serum concentrations may return to normal or below normal in chronic liver disease.

IDH is liver specific and extremely useful in detecting active hepatocellular necrosis, but it is not as stable as some of the enzymes (levels drop significantly after 24 hours of refrigeration). Increased IDH activity can be seen in ruminants with infectious, inflammatory, toxic, or metabolic insults to the liver. In cases of chronic disease, however, the IDH concentration may be normal because either too few hepatocytes are damaged or the hepatocellular mass is substantially reduced.[24] AST and LDH are found in many tissues other than liver (especially muscle), so they are nonspecific unless isoenzymes are determined. Muscle injury or necrosis, especially in recumbent animals, will often result in marked increases in both AST and LDH. The clinician must evaluate AST and LDH concentrations in conjunction with muscle-specific enzymes like creatine kinase (CK). Elevations in these enzymes together with increased CK activity generally suggests muscle injury. However, AST elevations occurring with CK values that fall within the reference range gives a strong suggestion of hepatic disease. AST and LDH concentrations are also found in erythrocytes, so if the serum is severely hemolyzed or allowed to remain on the clot for an extended period, falsely elevated values from leakage from red blood cells will result.

Ammonia is produced in the GI tract from the digestion of proteins and amino acids, absorbed by the intestine into blood, and carried to the liver in the portal circulation. Ammonia is converted to urea in the liver by the hepatic urea cycle. Ammonia is a useful test for assessing liver function, but it is generally not included in most serum biochemistry panels because it is highly volatile and requires special sample handling. Serum urea nitrogen (SUN) may also have some value as an indicator of hepatic disease in ruminants, since urea is produced in the liver. In severe cases of liver failure, SUN is usually low and ammonia often high. However, since rumen bacteria synthesize protein from urea, ruminants that have been off feed have low SUN concentrations because all the urea is being used by rumen bacteria for protein production. Thus low SUN levels are not always specific for hepatic disease.

No single liver enzyme value can consistently confirm or rule out the presence of liver disease. A combination of tests, including serum enzymes, total bile acids, ultrasound, and liver biopsy, may be needed. Some blood constituents may be altered because of failure of certain metabolic functions of the liver, but none of these changes is specific for liver disease. Blood glucose is sometimes slightly lower in severe liver disease, especially in young animals, possibly because of decreased gluconeogenesis, but none of 28 adult cases in one study had low blood glucose concentrations, and in fact, 14 cases had hyperglycemia.[9] In some toxic liver diseases, blood ammonia levels can increase fourfold or more because the urease necessary to convert ammonia to urea is found only in the liver. For the same reason, SUN may decrease, especially in the terminal phases. In the later stages, blood-clotting factors may be diminished, with delayed partial thromboplastin time (PTT) and other clotting times.

Terminally, serum albumin concentration may decrease. Considerable protein synthesis takes place in the liver, which produces all the plasma proteins except γ-globulins. The amount of these proteins in the blood, however, depends not only on the rate of synthesis but also on the rate of removal. The albumin half-life in cattle is about 16.5 days; in the horse, 19.4 days; and in sheep, 14 days.[25] Therefore, serum albumin is reduced mainly in chronic liver disease. With liver damage, the synthesis of α-globulins and β-globulins is increased, so total plasma protein concentration is invariably normal or elevated, but the albumin/globulin (A/G) ratio may be decreased. The healthy liver has a large reserve for protein synthesis, and lost protein can be replenished. In one study, 18% of the horses with chronic liver disease and 6% of those with acute liver disease had albumin concentrations below the reference value.[26] In a British study, only 6 of 37 liver disease cases were hypoalbuminemic, and none of these was hypoproteinemic.[9] Therefore, it is assumed that hypoalbuminemia is not a common feature in horses with liver disease, and that

VetBooks.ir

hypoproteinemia is rare. Amino acid ratios are altered in liver disease; short branched-chain amino acids are decreased, whereas aromatic amino acids are increased.[27]

Excretion Tests for Liver Function

Because the liver excretes a number of endogenous compounds and foreign substances injected into the animal, the rate of excretion or clearance of these substances can be used to test the excretory function of the liver. Bilirubin itself can be used and, if elevated above normal, would indicate liver failure, bile blockage, or excess production from hemolysis. In the horse, bilirubin is also increased during fasting in animals without liver disease.[28] With liver damage in the horse or ruminant, most of the retained bilirubin is unconjugated (indirect reacting), and the direct-to-total ratio is usually less than 0.3. With bile blockage or intrahepatic cholestasis, the direct-to-total ratio may be greater than 0.3 in the horse or 0.5 in cattle.

Bilirubin is the main bile pigment and is produced from heme, 75% of which comes from RBCs. When the erythrocytes are broken down, heme is converted first to biliverdin and then to bilirubin in the macrophage system. This unconjugated bilirubin is insoluble and must be bound to albumin for transfer; the kidneys do not remove this bound bilirubin. Unconjugated bilirubin is taken up by the hepatocytes with cytosolic binding proteins within the hepatocyte. In the hepatocyte, some bilirubin is conjugated to diglucuronide, but in the horse, more than half the bilirubin in bile is conjugated with glucose. Conjugated (direct-reacting) bilirubin is water soluble, and some will enter the general circulation; if concentration is sufficiently high, the kidneys will filter it into the urine. Conjugated bilirubin is secreted into the bile canaliculi by an energy-dependent transport process. In most species, this is the rate-limiting step, but this may not be true in large herbivores. Conjugated bilirubin passes into the intestine through the bile ducts, and if they are blocked, both conjugated and unconjugated bilirubin will increase in the plasma. In the intestinal tract, bilirubin is converted to urobilinogen by anaerobic bacteria. Some urobilinogen is absorbed and reexcreted by the liver, but a small fraction will pass the normal liver and be excreted in the urine. With complete biliary blockage, there will be no urobilinogen in the urine, and with hemolysis, there may be increased urobilinogen in the urine. Urobilinogen is not very stable in the urine, so analysis must be done within 1 or 2 hours or the amount detected will be erroneously low.

Fasting decreases the efficiency of plasma bilirubin removal in all species, but the horse shows a greater rise in plasma bilirubin, often reaching a plateau two to three times the normal state. This increase is due to a decrease in removal of bilirubin by the hepatic transport and not by an increase in its production.[28,29] In normal ruminants, total bilirubin concentrations are low compared to other species, and the magnitude of increase is generally small and inconsistent even with severe liver damage.[2] Ruminants with cholestatic disease may have moderate increases in serum bilirubin, but this is not a consistent finding. Increases in direct bilirubin are usually the result of hemolysis.

Serum total bile acid concentration is a good test of liver function in horses. The concentration of bile acids in the serum will be increased if there is hepatocyte damage, blockage of bile flow, or shunting of portal blood to the systemic circulation, bypassing the liver. The liver synthesizes bile acids from cholesterol. Cholic and chenodeoxycholic acids are the primary bile acids that are conjugated with amino acids before excretion into the bile. Only conjugated bile acids are present in the intestine; they are soluble and form micelles with fat because of their detergent properties. Most bile acids excreted in bile are resorbed by an active transport system in the ileum and carried by the portal circulation back to the liver for reexcretion. In most species, more than 95% of the bile acids are resorbed and recirculated through the enterohepatic circulation.[30]

Many simple-stomached animals have a postprandial increase in serum bile acid because bile is released from the gallbladder during eating and subsequently resorbed by the ileum. This does not seem to be important in the horse, which has no gallbladder, or in cattle, in which no relationship to feeding could be found.[31] Table 33-3 lists the upper limits of normal for liver function tests in large animals of various ages. In cattle there is an hour-to-hour fluctuation that could be as much as 60 μM/L, along with considerable variation between individual cattle.[31,32] In dairy cattle a significant decrease in serum bile acid concentrations occurs throughout the course of lactation.[33] In the horse, serum concentration above 14 μM/L would indicate liver damage, bile blockage, or shunting.[33] Serum total bile acid concentration is likely a more sensitive indicator of liver disease in the horse than serum bilirubin; only 8 of 34 horses with liver disease had elevated bilirubin, but 31 of 37 had elevated bile acids.[9] In adult cattle, because of the hour-to-hour variations, bile acid concentration on a single sample would have to be above 126 μM/L in beef cattle and 88 μM/L in dairy cattle to be an indication of liver disease.[34,35] Although ruminants have a large normal range for bile acid concentrations, significant increases have been shown to be a specific indicator of hepatic disease.[35]

A number of dyes are excreted primarily by the liver; sulfobromophthalein (bromsulphalein [BSP]) is used most often. In large animals, BSP clearance (half-time) is used much more than the retention test. In the test, 500 to 1000 mg (≈2 mg/kg) of BSP is injected intravenously. Blood samples are taken before the injection and two to four times 5 to 12 minutes after the injection (i.e., at 5, 7, 9, and 11 minutes). These samples are analyzed for color produced by BSP, and a half-life is determined by plotting the points on semilog paper. Normal horses have a BSP half-life of less than 3.5 minutes, and for ruminants it is less than 5 minutes. This may be increased in very young animals (see Table 33-3) and in pregnant females. Other dyes, such as indocyanine green, have some advantage (less renal excretion than BSP) but at present are too costly for use in large animals.

Liver Biopsy

Liver biopsy can be very useful, not only in confirming the presence of liver disease but also in determining or ruling out some etiologies. It is a relatively safe and simple procedure but should be avoided when liver abscesses are suspected. A number of biopsy instruments are available, including aspiration punches, but the Tru-Cut biopsy needle or similar notch-cutting needles seem to work quite well. In all species the skin over the biopsy site should be clipped and prepared for aseptic insertion of the needle. A local infiltration of 2% lidocaine helps reduce the animal's reaction, but it may still flinch when the pleura and peritoneum are penetrated. A small stab wound through the skin at the site of insertion is made with a scalpel blade.

The site of skin puncture for liver biopsy in the horse is the right fourteenth intercostal space at the intersection of a line drawn from the tuber coxae to the point of the shoulder.[36] Some operators recommend more cranial insertion (twelfth or thirteenth space), but more lung is penetrated at points farther cranial. If a more cranial position is selected, it should also be more ventral. If the needle is directed slightly cranial and ventral, it is more likely to remain in the liver parenchyma and not penetrate larger vessels on the visceral surface or pass on through into the right kidney, pancreas, or colon. Ultrasound guidance will increase the chances of obtaining liver specimens without penetrating other organs.

Cattle need to be suitably confined for liver biopsy. A biopsy can often be performed on quiet dairy cows in a stanchion while the tail is elevated ("tailed"). Although identification of the liver with ultrasound is preferable to a blind stick, the puncture site in cattle can be located by extending a horizontal line cranial from the middle of the paralumbar fossa. The needle is inserted where this line crosses the eleventh intercostal space on the right side. The lungs do not extend as far caudal as in the horse, so the liver is more exposed. The needle is directed slightly cranial and ventral, as in the horse.[2]

Liver biopsy in sheep and goats is slightly more difficult; additional sedation is usually required. A site at the ninth or tenth intercostal space at the level of the ventral end of the last rib has been

VetBooks.ir

recommended. The biopsy needle is advanced in a craniomedial direction until the liver is penetrated.

Diffuse or zonal lesions, as seen in most toxic, infectious, and metabolic liver diseases, can usually be diagnosed by liver biopsy. Focal lesions (e.g., abscesses, granulomas, neoplasias, as well as liver flukes) are easily missed by liver biopsy. If a liver abscess is suspected, biopsy is contraindicated because of the potential danger of rupturing an abscess. A scoring system has been developed for the prognostic evaluation of equine liver biopsies.[37] Examining liver biopsy tissue can confirm the presence of liver disease, help establish the type of disease, and aid prognosis.

Ultrasound Examination

Ultrasonographic examination of the liver is an extremely useful tool in diagnosing liver diseases (see ultrasound images in Chapter 32). Using ultrasound the clinician can determine the size of the liver, where it is located, and the diameter of the primary hepatic vessels. Hepatic abscesses, cholelithiasis, neoplasia, and fibrosis can be diagnosed by ultrasound in the horse.[38] In cattle, diseases such as fascioliasis, liver abscesses, neoplasia, thrombosis of the caudal vena cava, and even hepatic lipidosis can often be detected using ultrasound.[39-43] Ultrasound of the liver can also facilitate collection of a biopsy sample, aspiration of an abscess, or even cholecystocentesis (aspiration of a bile sample for diagnosis of liver flukes). Parenchymal pattern of the liver is changed with diffuse fibrosis. The bovine liver is situated immediately underneath the right body wall, with the cranial portion hidden by the lung. Hepatic ultrasonography is performed on the right side of the standing animal. The examination is usually done from caudal to cranial, beginning at the last rib and moving forward past the tenth intercostal space using a 3.5- to 5-MHz linear probe.[39] On sheep the examination is done on the right side in the seventh through twelfth intercostal spaces.[44] In horses the ultrasonic examination is performed below and caudal to the lung in the sixth to fourteenth intercostal spaces.[44] The liver can also be visualized on the left side of the horse in the lower intercostal spaces.

Prognosis

The severity of clinical signs may be the most useful noninvasive prognostic test in horses with liver disease.[45] Indicators of a poor prognosis in liver disease include an albumin concentration less than 2.5 g/dL in horses or an increased globulin level, a prothrombin time (PT) greater than 30% of normal, and greatly elevated GGT and ALP, especially if IDH (SDH) or LDH are normal or decreased. Marked fibrosis that bridges the liver lobules on histopathologic examination suggests a poor prognosis. Severe pyrrolizidine alkaloid toxicosis carries a particularly grave prognosis because remaining hepatocytes are inhibited from regeneration by mitotic arrest. Terminal clinical signs include development of hemolytic crisis in the horse and marked hepatoencephalopathy in the patient with a fibrotic liver.

Infectious, Toxic, and Parasitic Liver Disease

Acute Hepatitis in Horses

Jennifer L. Davis

Etiology *Theiler disease,* also known as *idiopathic acute hepatic disease* (IAHD), *serum hepatitis, postvaccinal hepatitis,* and *acute liver atrophy,* is the most common cause of acute hepatitis and hepatic failure in horses.[1-5] The disease was first recognized by Sir Arnold Theiler in large numbers of horses in South Africa. Horses developed the disease following immunization against African horse sickness with simultaneous administration of live virus and hyperimmune equine serum.[6] Since then, IAHD has been documented as a potential complication of any equine serum or plasma product used in horses. It is primarily a disease of adult horses[7] and has been most often associated with use of either tetanus antitoxin (TAT) or commercial equine plasma.[3,5,8-11] A recent outbreak was also associated with equine antiserum to botulinum toxin.[12]

Mares appear to be affected with IAHD more frequently than males, with recently parturient lactating mares at greatest risk.[7,10] The susceptibility of postparturient mares to IAHD is unexplained. One theory is that the common practice of administering TAT at the time of foaling makes postparturient mares the most likely adult horses to receive TAT, thus increasing their risk. There has been a seasonal nature reported for some epidemics of IAHD[7,13] with most cases occurring in the summer months. During some outbreaks, it has also been observed that some affected horses have not been treated with TAT or plasma[1,7,13] which has suggested an infectious agent may be involved.

Little has been known about the etiology of IAHD until recently. An investigation into an outbreak of IAHD in a group of horses receiving prophylactic botulinum antiserum has resulted in strong evidence that a viral etiology is present.[12] This virus, designated as *Theiler disease–associated virus* (TDAV), was isolated from horses that had received a similar batch of the antiserum. TDAV was also isolated from the antiserum itself, and no other detectable viruses were present in both the antiserum and clinical cases. Not all horses that tested TDAV positive developed clinical or biochemical evidence of hepatitis, however, which may suggest that other host factors, immune-mediated hypersensitivity reactions, or co-infection with other etiologic agents may be necessary for disease.[12,14] Horses may become chronically infected with virus, as evidenced by the fact that 25% of TDAV virus–positive horses were still positive 1 year after the outbreak.

Clinical Signs The clinical effects of IAHD are associated with signs of acute hepatic failure and typically occur 2 or 3 months following administration of blood products.[12] These signs include depression, jaundice, inappetence, pica, yawning, photoactive dermatitis, and hepatic encephalopathy.[†] Fever has been described as absent or rare in horses affected with IAHD.[4] Reported atypical signs include progressive weight loss, ventral subcutaneous edema, jugular pulses, ileus, and acute respiratory distress.[10,11,16] Intravascular hemolysis has been reported to lead to hemoglobinuria in some terminal cases of IAHD.[2] Evidence exists for a subclinical or chronic component in some cases.[10,17] However, some horses that received TAT have clinicopathologic evidence of liver dysfunction without developing clinical signs, indicating that disease severity may vary.[5,10,17]

Diagnosis Diagnosis of IAHD is based on the anamnesis, clinical signs, and findings from serum biochemical analysis, hepatic biopsy, and necropsy. High serum levels of unconjugated and total bilirubin and serum bile acids, coupled with high serum activity of GGT, IDH (SDH), AST, LDH, and ALP are indicative of hepatic necrosis in horses.[18] Additional findings with severe disease may include decreased BUN, hyperammonemia,[18] prolonged clotting times (PT and activated partial thromboplastin time [APTT]), and decreased albumin. IAHD may be confirmed by hepatic biopsy or postmortem examination of hepatic tissue. The liver is often small and has a characteristic "dishrag" appearance (Fig. 33-2). Typical histopathologic changes seen in biopsy specimens or obtained at postmortem examination include widespread necrosis of hepatocytes that is most severe in the centrilobular and midzonal areas, with the few living cells confined to the periportal areas.[9] The normal architecture of the centrilobular and midzonal areas is replaced by a pale, eosinophilic granular mass in which ghost outlines of necrotic hepatocytes are present.[9] A mild inflammatory cell infiltrate is seen in the portal areas, as well as a number of spindle-shaped fibroblastic cells.[9]

VetBooks.ir

FIG. 33-2 Characteristic small, "dishrag" liver from a horse with Theiler disease. *(Photo courtesy Sam Jennings, North Carolina State University.)*

The histopathologic lesion is frequently more advanced than the clinical course of the disease would suggest.[9]

Treatment There is no specific treatment for IAHD.[19] Treatment should be aimed at supporting liver function and controlling abnormal behavior. Dietary adjustments are important and should consist of reducing the quantity of protein in the diet while increasing carbohydrate intake.[2] Sorghum, milo, or beet pulp, which contains high levels of branched-chain amino acids, can be mixed with molasses to improve palatability and caloric content.[2] Diets high in branched-chain amino acids tend to lessen the degree of abnormal behavior associated with hepatic encephalopathy.[19] Oral (PO) neomycin, lactulose, and mineral oil may be administered to decrease ammonia production and absorption from the GI tract. Xylazine or detomidine may become necessary to sedate horses that display severe signs of hepatic encephalopathy.[19] Benzodiazepines (diazepam or midazolam) should be avoided. Continuous intravenous (IV) administration of dextrose and balanced electrolyte solutions to reduce hepatic workload and maintain plasma volume is recommended.[17] If spontaneous bleeding occurs at injection sites or at sites of self-inflicted injury, plasma transfusions may be necessary to replace the deficient clotting factors.[2] The use of glucocorticoids for treating IAHD is controversial but may be indicated based on some histopathologic evidence of an immune-mediated etiology.[14,18]

Currently, no preventive measures are available. However, since administration of TAT to recently parturient lactating mares is associated with substantial risk for development of fatal IAHD,[7,10,17] this practice should be strongly discouraged and its use restricted to clinical situations necessitating tetanus prophylaxis in which a history of active tetanus (toxoid) immunoprophylaxis is absent or unknown. The risk of postvaccinal IAHD should be addressed with the owner before administration of TAT. Although the prevalence of serum hepatitis associated with administration of commercial plasma appears to be low in the horse, it should be considered an uncommon risk that can have a fatal outcome.[11]

IAHD may be observed sporadically or affect a group of horses. Recognition of IAHD in one horse should necessitate careful observation of horses on the same premises for either clinical or serum biochemical signs of IAHD.[12,17] Based on recent case reports, it appears not all cases of IAHD are clinically apparent, and screening for its presence with routine serum biochemical analysis is useful in detecting subclinical cases.[10-12,17]

Black Disease

Geof W. Smith

Etiology Infectious necrotic hepatitis (black disease) is a peracute, highly fatal disease occurring worldwide. The disease most commonly affects sheep, particularly adults in good body condition, but cattle, horses, goats, and occasionally pigs may also be affected.[1,2] There has even been recent speculation that black disease is the cause of epidemic catarrh of sheep, a significant cause of mortality in Australian sheep dating back to the mid 1800s.[3] Black disease is caused by toxins produced by the bacterium *Clostridium novyi* type B; *C. novyi* is commonly found in the soil and can also be present in the digestive tracts and livers of animals grazing affected pastures. Clostridial organisms require an anaerobic environment for growth, so black disease only occurs when there has been enough damage to the liver to provide the anaerobic environment required for growth of the organism and subsequent toxin production. In practice, the liver insult is almost always caused by larval migration of the common liver fluke, *Fasciola hepatica.* Therefore, this is a seasonal disease related to the liver fluke cycle and occurring in animals typically infested by *F. hepatica.* Other liver parasites, such as *Fascioloides magna* or *Dicrocoelium dendriticum* (especially in France), are occasionally implicated, as is damage to the liver by biopsy or trauma severe enough to result in anaerobic conditions in the liver. Such a scenario should be considered when sudden deaths occur at times flukes are not usually migrating or in families like Equidae that are not normal hosts for *F. hepatica.* Black disease occurs worldwide wherever liver flukes are present.

Pathophysiology The *C. novyi* strains that cause black disease produce at least two potent exotoxins: alpha toxin and beta toxin. The alpha toxin enters cells by receptor-mediated endocytosis and inhibits ras and rho guanosine triphosphatases by glycosylation.[4] The beta toxin is a necrotizing and hemolytic phospholipase C (lecithinase). Other toxins may contribute to the pathophysiology as well.

Type B *C. novyi* is widely distributed in soils, and its spores are continuously ingested and shed in feces of grazing animals. Some of these organisms cross the intestinal mucosa and become disseminated throughout the animal's macrophage system, including the Kupffer cells of the liver. When localized anaerobic conditions occur in the liver, as with migration of liver fluke larvae, these resident spores may germinate and enter a vegetative state. As they proliferate, they release their toxins and create enlarging zones of coagulative necrosis in the liver. The exotoxins produced will enter the circulation, where they cause damage to neurons, vascular endothelium, and other tissues, eventually causing sudden death of the animal.

Clinical Signs Peracute death is the most common clinical presentation associated with black disease. When affected animals are recognized prior to death, clinical signs are relatively nonspecific. The animal will often be off by itself and will appear depressed, anorexic, and possibly in respiratory distress. Temperature is elevated initially (40° to 41°C [104° to 106°F]) but declines before death. Sheep become sternally recumbent and generally die after a clinical course of only a few hours. Venous congestion darkens the skin, giving the disease its common name, *black disease.*[2] Unlike closely related bacillary hemoglobinuria, or "redwater" (see later discussion), affected animals do not show red urine or bleeding from the nose or rectum. Clinical signs in cattle are similar, but the clinical course of disease occurs over 1 to 2 days.

Diagnosis Necropsy is often difficult because autolysis of the tissues after death is usually rapid. Fluid is often found in the pericardial sac and pleural and peritoneal cavities. Endocardial and

VetBooks.ir

epicardial hemorrhage is also a consistent finding. Urine is grossly normal. Tissues, especially solid organs like liver and kidney, appear to be in a much more advanced state of autolysis than time of death would suggest. The liver will usually be swollen and congested with small pale areas of coagulative necrosis, particularly along its diaphragmatic surface. The primary lesions of black disease are single or multiple areas (2 to 3 cm in diameter) of hepatic necrosis that appear yellow to white in color and are surrounded by a broad zone of hyperemia.[4]

Diagnosis of black disease is generally made by a combination of history, clinical presentation, necropsy findings, and isolation of *C. novyi* type B from the liver. A history of sudden death, particularly in endemic fluke areas, is highly suggestive of black disease, especially during warmer weather when fluke transmission is active. Flock or herd vaccination will be either overdue or absent. Time of death should be ascertained as closely as possible. The animal is usually presented in lateral recumbency without signs of struggle. It will be severely bloated even if death has occurred quite recently, giving the impression of a carcass in a more advanced state of decomposition than timing would suggest. Acute liver fluke infection in sheep can have a high mortality by itself, and postmortem findings may be similar to black disease. Other causes of sudden death (e.g., enterotoxemia, blackleg, anthrax) should also be ruled out.[2]

If necropsy does not confirm a diagnosis of black disease, or if additional documentation is necessary, a simple Gram stain of an impression smear taken from the margin of the liver lesion will typically reveal numerous gram-positive rods. Because clostridial organisms proliferate rapidly after death, such findings must always be interpreted carefully, with consideration of time elapsed between death and necropsy. Further diagnostic measures include anaerobic culture and isolation of *C. novyi* type B, identification of the specific toxins, and fluorescent antibody identification of the organism. Characteristic histopathologic changes may also be seen in fixed sections of liver associated with necrotic lesions. Impression smears obtained from the liver lesions are ideal for fluorescent antibody identification of *C. novyi* type B.

Treatment and Control Treatment of black disease is rarely undertaken because of its peracute presentation; animals are usually found dead. Although *C. novyi* is highly sensitive to penicillin and the tetracyclines, toxin production is usually too far advanced for antibiotics to be of value. If used, they should be administered at high doses, intravenously if possible, for most rapid onset (20,000 to 40,000 IU/kg penicillin or 10 mg/kg oxytetracycline q12h), followed by intramuscular (IM) or IV doses at appropriate intervals. Supportive fluid therapy should be initiated to correct dehydration. Even with aggressive therapy the prognosis is poor and the chances for survival slim. In the event of an outbreak, vaccination should be initiated immediately, along with possible metaphylactic administration of penicillin or oxytetracycline.

A good prevention program involves both proper fluke control and the use of clostridial bacterins. Efforts to clear soils of the offending organism are unrewarding. However, it is recommended that carcasses of animals dying from black disease be burned, buried deeply, or removed from the premises. Commercial bacterin/toxoids against *C. novyi* are available in combination with other clostridial organisms. These products are generally safe and highly effective. Duration of protection is short, however, and should not be relied on for more than 5 to 6 months. Animals vaccinated when younger than 3 to 4 months old require revaccination at weaning. Local reactions at the site of subcutaneous vaccination are common but primarily of cosmetic concern. Intramuscular vaccination should be avoided because it frequently results in permanent damage to muscle tissue, with a negative impact on meat marketing. Timing of vaccination must be determined by the local climate and liver fluke season. In more severe climates where the fluke season is relatively short, a single annual injection before fluke transmission season may be sufficient. In more moderate climates with longer periods of fluke exposure, two vaccinations per year may be required.

Control of liver fluke infestation is also closely linked to prevention of black disease. Control measures include pasture or range management, control of water sources, strategic treatment of animals with appropriate anthelmintics, and limiting access to streams, canals, ponds, and marshes. This is a complex subject, and the reader should refer to the section on liver flukes for more detail.

Bacillary Hemoglobinuria ("Redwater")

Geof W. Smith

Etiology Bacillary hemoglobinuria (redwater, icterohemoglobinuria) is a disease causing sudden death in cattle, small ruminants, and occasionally horses. The disease was first reported in California in 1916 and is caused by the toxins of *C. novyi* type D *(Clostridium haemolyticum)*. Bacillary hemoglobinuria is quite similar to black disease, where clostridial infections of the liver occur under anaerobic conditions, primarily liver fluke migration (see earlier discussion). The major toxin in *C. novyi* type D *(C. haemolyticum)* infection is the beta toxin, which is a phospholipase C that causes hepatocyte necrosis, hemolysis, and damage to capillary endothelium.[1] This results in hemoglobinuria and loss of fluids into tissues and cavities. The primary action of beta toxin is to induce localized hepatic necrosis and intravascular hemolysis. Like *C. novyi* type B, type D is also found in the soil. Spores are routinely present in the liver and can be passed in feces and urine of healthy animals grazing affected pastures. Disease occurs only when there is sufficient insult to the liver to provide the anaerobic conditions required for bacterial growth and toxin production. In almost all cases the liver insult is caused by migration of *F. hepatica* (common liver fluke) larvae.[2-4] As in black disease, *F. magna, D. dendriticum* (the lancet liver fluke), and *Cysticercus cellulosae* have also been occasionally implicated in the disease, as has liver biopsy or trauma severe enough to result in liver bruising.[5] Bacillary hemoglobinuria is, for the most part, a seasonal disease occurring at the time of larval fluke migration. In the United States, most cases are seen during summer and early fall.

Bacillary hemoglobinuria is a regionalized disease. It has been reported that *C. novyi* type D is limited to alkaline soils, but the disease is also endemic in regions with acid soils. Outbreaks often follow flooding, which can bring spores into previously uninfected areas. The factors affecting distribution of the disease are not well understood. Even in areas where it is common, distribution is erratic, with some farms severely affected while others nearby are disease free.

Pathophysiology Spores of *C. novyi* type D are ingested by susceptible animals, cross the intestinal mucosa, and are transported to the liver and other organs, probably within the phagosomes of cells of the mononuclear macrophage series. The spores can persist in the liver within Kupffer cells for long periods. Any localized anaerobic area of the liver will allow these spores to germinate. Release of toxins from the bacteria further exacerbates the anaerobic environment, favoring accelerated bacterial proliferation, toxin production, and hepatic necrosis. Absorption of toxins into the circulatory system rapidly leads to intravascular hemolysis, icterus, hemoglobinuria, and death.

Clinical Signs Bacillary hemoglobinuria is most common in animals older than 1 year of age. Like black disease, sudden death without obvious clinical signs is common in animals that have peracute disease. In those rare cases where disease is recognized antemortem, signs include depression, anorexia, and fever of 40° to 41°C (104° to 106°F), declining as death approaches. Breathing may be rapid and shallow, and blood or blood-tinged froth may be present in the nostrils. Rectal bleeding or bloody feces may also be observed. Severe hemoglobinuria or passage of dark-red, port wine–colored urine is often reported. Blood is thin and watery and coagulates slowly. Mucous membranes are pale and icteric. Severity of signs

VetBooks.ir

increases as the disease progresses. Postmortem, the animal is usually in lateral recumbency, severely bloated, and without signs of struggle. Blood is often present in the nostrils, mouth, rectum, or vagina. The carcass appears to be in an advanced state of decomposition even when it is actually quite fresh. A tentative diagnosis can be made on the basis of history and observation of the carcass.

At necropsy the mucous membranes and tissues can appear icteric. Skinning the animal reveals numerous subcutaneous petechial and ecchymotic hemorrhages, edema, and sometimes emphysema. There will be significant amounts of red-tinged abdominal and thoracic fluid. Hemorrhages are present on all serosal surfaces. Dark-red urine is present in the bladder. Lymph nodes are congested and usually hemorrhagic. There may be hemorrhage into the bowel lumen. The spleen is enlarged. The lungs are usually filled with blood-tinged froth or foam. Pericardial fluid is blood tinged, and hemorrhages are present on both the epicardium and endocardium. Organs such as liver and kidney appear to be in advanced stages of autolysis, even in fresh carcasses. The pathognomonic lesion is the so-called ischemic hepatic infarct, which has a zone of hyperemia at its interface with viable liver tissue. This area of coagulative necrosis, sometimes partially liquefied at its center, can reach up to a 30-cm diameter and have a very irregular outline.[3] Unlike a classic infarct, the lesion in bacillary hemoglobinuria results from progressive enlargement of the focus of coagulative necrosis caused by the bacterial toxins. Any thrombosis seen in the lesion is secondary, with the vasculature being included in the necrotic process, along with other hepatic tissue.[5]

Diagnosis Antemortem animals with bacillary hemoglobinuria will be anemic and have elevated hepatic enzymes such as AST and GGT.[6,7] Total bilirubin concentrations are also dramatically elevated.[6] If a urine sample can be collected, hemoglobinuria will be obvious. Postmortem, a Gram-stained impression smear from the liver will reveal numerous typical clostridial organisms. Smears may also be made from spleen, blood, or abdominal fluid, with the same outcome. Postmortem presence of clostridial organisms must be interpreted with caution because they are always present and proliferate rapidly after death. It is important to have an accurate estimate of time of death to determine the significance of these findings. Laboratory confirmation depends on identification of both the causative bacteria and the toxin. Fresh (refrigerated) and formalin-fixed liver lesions should be submitted. Fluorescent antibody tests on impression smears taken from a liver "infarct" will be positive for *C. novyi* type D antigens. Extensive biochemical and toxin identification tests are confirmatory but seldom used if lesions and fluorescent antibody tests are compatible. A polymerase chain reaction (PCR) assay that can detect *C. novyi* type D in the blood of affected cattle has also been reported.[6]

Treatment and Prevention Although successful treatment of cattle with bacillary hemoglobinuria has been described,[6,8] it is seldom undertaken because of the acute nature of the disease. If there is opportunity for treatment, penicillin at high dosages (at least 20,000 to 40,000 IU/kg IV or IM twice daily) is the antibiotic of choice, although tetracyclines (10 mg/kg IV twice daily) are acceptable. Fluids are given intravenously or intraruminally to correct dehydration. Because of severe hemolytic anemia, blood transfusion is recommended and should be repeated as necessary. In animals that recover, there will be a noticeable reduction on a daily basis in the severity of hemoglobinuria.[6]

An effective prevention program requires consideration of both the pathophysiology and immunology of the disease and the natural history of the liver fluke *(F. hepatica)* that is so intimately involved in expression of bacillary hemoglobinuria. Efforts to clear soils of the offending organism are unrewarding, but carcasses of animals dying from bacillary hemoglobinuria should be burned, buried deeply, or removed from the premises.

Commercial bacterin/toxoids against *C. novyi* type D are available in both monovalent form and in combination with other clostridial vaccines. These products are generally safe and highly efficacious. Duration of protection is short, however, and should not be relied on for more than 5 to 6 months. Animals vaccinated when less than 3 to 4 months old require revaccination at weaning. Local reactions at the site of subcutaneous vaccination are common but primarily of cosmetic concern. Intramuscular vaccination should be avoided because it frequently results in permanent damage to muscle tissue, with a negative impact on beef marketing. Timing of vaccination must be determined by the local climate and liver fluke season. In more severe climates where the fluke season is relatively short, a single annual injection before fluke transmission season may be sufficient. In more moderate climates with longer periods of fluke exposure, two vaccinations per year may be required.

Control measures include pasture or range management, control of water sources, strategic treatment of animals with products effective against flukes, and limiting access to streams, canals, ponds, and marshes. This is a complex subject, and the reader should refer to the section on liver flukes for more detail.

Liver Disease in Foals

Jennifer L. Davis

Liver disease in foals may be primary or secondary and can be due to infectious, parasitic, congenital, metabolic, or toxic causes. When diagnosing hepatic dysfunction in foals, it is important to use age-specific reference ranges to interpret biochemical indicators of hepatic disease. Several hepatic enzymes can have increased activity even in healthy neonates.[1-3] Total bilirubin may be elevated as fetal hemoglobin converts to adult hemoglobin. Elevations may also be due to a deficiency in liver binding and conjugating enzymes.[1] ALP remains elevated for an extended time in young horses as a result of increased osteoblastic activity, with normal values as high as 3752 U/L reported.[4] Increased GGT activity may be present in foals for 2 to 4 weeks after birth, whereas only slight increases of IDH (SDH) are expected during the same period.[1,3] Increased variability in ALP and GGT in healthy foals can make interpretation of hepatic function difficult. Serum bile acids (SBAs) are significantly greater in foals than adult horses for the first 6 weeks of life. According to one study, this is potentially due to upregulation of hepatic production, reduced excretion, differences in bile acid composition of the neonate, or enhanced intestinal/portal uptake.[3] An additional finding of that study was that SBAs were not significantly different between healthy and sick foals, whereas another study noted that elevated liver enzymes were common in sick foals, and those foals with high liver enzymes were more likely to have sepsis than other diseases.[3,4]

Tyzzer Disease

Tyzzer disease is an acute hepatitis affecting foals 7 to 42 days of age, with no known breed or sex predeliction.[5-12] It has also been reported in calves, lambs, and other species.[13-15] The causative organism is *Clostridium piliforme* (formerly *Bacillus piliformis*), a spore-forming intracellular obligate anaerobe.[23] Multiple strains can infect Equidae, and they are susceptible to at least two distinct strains (isolate E and R1), with no evidence of cross-reactivity of antibodies between isolates.[16,17]

Although the exact pathogenesis is unknown, bacterial spores can be shed in the manure of carrier horses, suggesting a fecal-oral route of transmission with subsequent GI and hepatic colonization.[18] Several risk factors have been associated with development of disease, including time of year, age, and resident status of the mare.[19] Foals born between March 13 and April 13 were found to be more likely to develop disease in one study, and this was thought to be due to the increased number of animals present on the farm during that time. Foals from younger mares (<6 years of age) and those not from endemic farms were more likely to develop disease, possibly owing to lack of antibiotics in the mare's colostrum or antibodies present to

VetBooks.ir

different strains of *C. piliforme*. Immunocompromised foals may be at greater risk.[11,12]

Disease may occur sporadically or as an outbreak.[12,18,19] Clinical signs are nonspecific and include severe depression, fever, icterus, and diarrhea progressing to seizures, coma, or sudden death.[5-12] Bloodwork abnormalities indicate overwhelming sepsis characterized by leukopenia, hyperfibrinogenemia, profound hypoglycemia, and severe acidosis, with concurrent elevations in IDH (SDH), GGT, AST, ALP, and LDH-5.[9,11,27] Diagnosis is usually made postmortem and is based on the presence of acute multifocal hepatitis and enteritis, with intrahepatocellular filamentous bacteria present at the periphery of the lesion.[21] Silver stains (e.g., Warthin-Starry) may help facilitate diagnosis. The fastidious nature of the organism makes culture difficult. PCR techniques have been used for detection of *C. piliforme* in multiple species, including foals.[20] This test may aid in early diagnosis and treatment.

Treatment of Tyzzer disease can be attempted, but the disease is highly fatal, with most foals dying within 2 to 48 hours (median survival 30 hours). There are reports of successful treatment of three suspected cases[19,22] and one confirmed[20] case in foals. When attempted, treatment should be early and aggressive and consist of antibiotics (including potassium penicillin or ampicillin), parenteral nutrition, correction of acidosis, and other supportive care.[20] Currently, there are no preventive measures available for Tyzzer disease in the foal.

Drug-Induced Hepatotoxicity

Rarely, foals treated with macrolides, trimethoprim-sulfas, or histamine-2 (H_2) blockers for pneumonia or diarrhea develop an increase in serum hepatic enzymes despite clinical improvement. With changes in drug treatment, serum enzymes return to normal, suggesting these cases may have drug-induced hepatopathy.[23] Steroid-induced hepatic lipidosis has been observed in foals receiving both prolonged and high doses of corticosteroids.

Equine Herpesvirus 1

Equine herpesvirus 1 (EHV-1) infection of a near-term fetus may result in the birth of a nonviable foal with hepatic, respiratory, and/or GI disease.[24] Affected foals may have severe neutropenia and lymphopenia, and icterus is a common clinical sign. Surprisingly, significant elevations in serum hepatic enzyme activities are not present even though a severe multifocal necrotizing hepatitis with inclusion bodies is present at necropsy.[25] Generally the clinical condition rapidly declines within 5 days after birth despite aggressive and early treatment. Treatment with oral acyclovir (8 to 16 mg/kg q8h) may improve survival rates.[26]

Other Bacterial Causes

Leptospirosis was reported to cause jaundice and death in a 10-day-old foal.[27] Although *Leptospira interrogans* serovar *Pomona* is known to cause abortion and liver disease (giant cell hepatopathy) in the equine fetus, it is also apparently a rare cause of neonatal liver disease. *Actinobacillus equuli* typically causes bacteremic embolic nephritis and acute death in very young (3-day-old) foals. It may also cause widespread multifocal hepatitis in foals. *Streptococcus zooepidemicus* bacteremia may also cause multifocal hepatic abscesses. Other bacteria and bacterial toxins may initiate an exaggerated response to sepsis (systemic inflammatory response syndrome [SIRS]), which may result in multiple organ dysfunction, including hepatic failure. Many vasoactive mediators are involved in this process; the hemodynamic system becomes ineffective, and certain organs (e.g., liver) may fail because of hypoxia. Diffuse hepatic necrosis and hepatocellular apoptosis are the characteristic lesions. The clinical signs may be identical to Tyzzer disease, except the syndrome may affect a much wider age range. Prompt and aggressive treatment is often successful. Appropriate treatments include broad-spectrum antibiotics, fluids, oxygen, and antioxidants such as dimethyl sulfoxide (DMSO) and acetylcysteine. Bacterial sepsis rarely may cause acute portal vein thrombosis. Variable degrees of hepatic hypoxemia and inflammation accompany the thrombosis. Hepatoencephalopathy does not generally occur in foals, unlike in adult horses, with portal vein thrombosis. The thrombus can be seen on ultrasound examination. Diarrhea from portal hypertension may occur in foals. Complete recovery may follow long-term antimicrobial therapy.

Neonatal Isoerythrolysis

Foals with severe and prolonged neonatal isoerythrolysis (NI) may develop liver failure,[28] which may result from a combination of chronic hypoxia and multiple blood transfusions. Foals receiving a total volume of blood products of 4 L or more were 19.5 times more likely to develop liver failure than foals receiving a lower volume.[29] Multiple blood transfusions are thought to result in iron overload and subsequent iron toxicity. One study showed that deferoxamine, an iron chelator used to prevent iron toxicity in humans receiving multiple transfusions, enhanced urinary iron elimination and decreased hepatic iron accumulation after blood transfusion in healthy foals.[30] The results of this study suggest that giving foals with NI subcutaneous (SC) injections of 1 g of deferoxamine q12h starting prior to blood administration may help prevent liver failure in those receiving multiple transfusions.

Kernicterus, or bilirubin encephalopathy, is another potential complication of NI in foals. Neurologic signs, including seizures, develop secondary to the neurotoxic effects of unconjugated bilirubin on the central nervous system.[29,31] Kernicterus is more likely to develop in foals with total bilirubin of 27 mg/dL or greater and is associated with a poor outcome.[29]

Iron Toxicity

Iron toxicity is the best documented of the toxic causes and can occur following administration of nutritional supplements or iron formulations containing ferrous fumarate.[32,33] Toxicity manifests in newborn foals given iron prior to receiving colostrum; colostral-acquired glutathione or other substances may be protective against hepatotoxicity.[33] When iron is given at birth and before colostrum, clinical signs typically develop 2 to 5 days later, although in rare cases, signs may develop in older foals. The initial clinical signs are associated with hepatoencephalopathy and include seizures, marked depression, ataxia, aimless wandering, head pressing, and abnormal behavior. Icterus is noted in most foals at the time neurologic signs are exhibited, although some foals may die so peracutely that icterus is not noticed. Abnormally high ammonia, total bilirubin, GGT and ALP activity, and packed cell volumes were present, as was an abnormally high ratio of aromatic to branched-chain amino acids. PTT and PT were prolonged, and some foals had high IDH (SDH) activity.[32] Affected foals had small livers with prominent bile duct proliferation, hepatic cell necrosis, mild periportal fibrosis, and histopathologic changes in the brain consistent with hepatoencephalopathy.[32-34]

Congenital/Inherited Diseases

Congenital portosystemic shunts (CPSS) occur infrequently in the equine and bovine patient.[35] Clinical signs may not be noted until foals are 2 to 3 months old and begin ingesting large amounts of grain or grass. Waxing and waning signs of encephalopathy are the most common signs in foals. Encephalopathic signs and tenesmus are characteristic of the disease in calves. Elevated plasma bile acids and ammonia levels in foals together with encephalopathic signs and normal concentration of hepatic-derived serum enzymes should arouse suspicion of a portosystemic shunt. Shunts may be single or multiple and may be intra- or extrahepatic. Diagnosis of CPSS can be made by computed tomography (CT) scan, positive-contrast portography, transrectal portoscintigraphy (in foals) or transabdominal ultrasound examination. Further corroborative evidence can be gained by ultrasound-guided percutaneous transsplenic injection of agitated saline with simultaneous echocardiography to look for contrast in the right atrium and ventricle.[36] Successful medical management followed by shunt ligation has been described in a foal and calf.[35-37]

VetBooks.ir

Hepatic failure has been seen in Morgan foals.[38,39] The onset of clinical signs (depression and weight loss) occurred soon after weaning. Liver enzymes and ammonia are elevated, and variable degrees of portal and bridging fibrosis with bile duct hyperplasia, karyomegaly, and cytomegaly are often seen on microscopic examination. The disease is fatal and may end with a terminal hemolytic crisis. The cause of the disease is unknown but is thought to be an inherited defect in mitochondrial transporter proteins, such as ornithine, that are required for complete urea synthesis.[39]

Glycogen branching enzyme deficiency is a fatal autosomal-recessive disease of Quarter Horses and Paint Horses caused by a mutation of the glycogen branching enzyme 1 (GBE1) gene that drastically decreases the amount of GBE protein in homozygotes.[40] Diseased foals cannot store and mobilize glycogen to maintain normal glucose homeostasis. Those that survive to parturition are often born weak and hypoglycemic/hypothermic but improve with bottle feeding. Other clinical presentations include progressive muscle weakness, inability to rise, collapse, seizures, flexural limb deformities, respiratory failure, and sudden death. Common laboratory findings include leukopenia, intermittent hypoglycemia, and moderate elevations of serum CK, AST, and GGT activities. Genetic testing is available, but diagnosis can also be made based on liver and muscle biopsies from affected foals. There is no treatment, and all cases to date have been fatal.

Chronic Active Hepatitis

Jennifer L. Davis

Chronic active hepatitis (CAH) is an idiopathic progressive hepatopathy with insidious onset. The etiology and pathogenesis are unknown but may be similar to human autoimmune or hypersensitivity conditions. Toxic and infectious etiologies have also been proposed, or it may be a manifestation of chronic cholangitis/cholangiohepatitis. In one retrospective report of 88 cases of liver disease in adult horses, CAH accounted for 9.9% of all cases reported.[1] Seven out of 9 cases in that report were in ponies, although a true breed predisposition has not been reported.

Clinical signs are those of progressive liver failure and include weight loss, depression, anorexia, colic, icterus, and fever.[2] These signs may be intermittent. Signs of concurrent intraabdominal diseases or other autoimmune diseases may also be present. In rare cases, a moist exfoliative coronary dermatitis may occur, which is thought to be an immune-mediated issue.[3] Concurrent elevations in hepatic enzymes will be present, particularly GGT and ALP, with lesser elevations in IDH (SDH) and AST, as well as bile acids and direct bilirubin. The degree of elevation in liver enzymes cannot be used as an indicator of disease severity, since the liver may have significant fibrosis at the time of diagnosis. Other supportive clinicopathologic findings include an inflammatory leukogram, bilirubinuria, prolonged BSP clearance, and a polyclonal gammopathy. Ultrasonography may reveal a small liver with increased echogenicity indicative of hepatic fibrosis. Differential diagnosis includes pyrrolizidine alkaloid toxicity, bile stones, abdominal abscesses, and other chronic wasting diseases.

The final diagnosis of chronic active hepatitis is made histologically via biopsy of the liver or at necropsy. The principal features are localized primarily along the portal/periportal areas and include infiltration of inflammatory cells, biliary hyperplasia, and fibrosis or cirrhosis.[1] A mononuclear cell infiltrate (lymphocytes/plasmacytes) often predominates, but a neutrophilic component may be present with a primary or secondary infectious process. Bacteria, particularly gram-negative enteric bacteria, may be present in some lesions, and biliary hyperplasia may be marked if there is cholangiohepatitis. Grossly, the liver appears firm and is often pale brown to green in color, and the cut surface may have prominent irregular markings. An antinuclear antibody (ANA) titer and immunofluorescent staining of skin lesions (if present) may reveal evidence of an autoimmune reaction.

Treatment of CAH involves supportive care. Specific treatments can be determined based on biopsy results. If the predominant cell types are lymphocytes or plasma cells, corticosteroids may be beneficial. Dexamethasone (0.05-0.1 mg/kg/day IV, IM, or PO decreased over 2 to 3 weeks) or prednisolone (1 mg/kg/day PO for several weeks) is recommended. Antibiotics are indicated when a bacterial cholangiohepatitis is suspected on the basis of the histologic features of the liver, culture of the liver biopsy, and presence of a persistent intermittent fever. Other recommended therapies are aimed at resolving inflammation and preventing the progression of fibrosis. Flunixin (0.5-1 mg/kg PO q24h) or low-dose phenylbutazone (0.5 g/day PO) can be used. Vitamin E (10,000 U PO q24h) is recommended to protect membrane phospholipids from oxidative damage and suppress activation of inflammatory cells. Pentoxifylline (8 mg/kg PO q8h) has been used as a weak inhibitor of the inflammatory cytokines tumor necrosis factor (TNF)α and interleukin (IL)-6, although results are variable, possibly owing to the low oral bioavailability in horses. Colchicine (0.03 mg/kg PO q24h) can be used to inhibit production of collagen and macrophage/cytokine-induced inflammation.

The prognosis for CAH is variable and depends on the underlying cause and duration of disease prior to diagnosis. A retrospective study reported that five of nine horses with chronic active hepatitis survived, but they were 7.4 times more likely to die than those where a diagnosis of unclassified hepatopathy was made.[1] Liver biopsy and response to therapy are the best guides in formulating a prognosis. The prognosis for improvement and long-term survival is extremely poor in horses that have functional hepatic failure with widespread fibrosis and disruption of normal hepatic parenchyma. The prognosis is fair to good in patients with early (less severe) lesions, particularly those with a lymphocytic/plasmacytic cellular infiltrate that responds well to corticosteroids. The presence of cirrhosis in the biopsy sample warrants a grave prognosis.

Pyrrolizidine Alkaloid Toxicity

Geof W. Smith

Etiology Pyrrolizidine alkaloid (PA) toxicity is a chronic, progressive, often-delayed intoxication that results when animals consume plants containing PAs. Plants containing these alkaloids are found all over the world, and poisoning of horses, cattle, poultry, and even humans has occurred in many different countries. PA toxicity primarily manifests as liver failure.[1] More than 350 types of PAs have been identified in over 6000 plant species.[2,3] The primary plants of importance in the United States come from the *Senecio* and *Crotalaria* genuses, but others exist. Table 33-4 lists the most common plants causing PA poisoning around the world.

PA toxicity is seen wherever plants containing the alkaloids are found. The plants are not very palatable and in most cases are not readily eaten, but animals may eat them when the growth of the toxic plant is so thick that the animal cannot separate it from normal forage, or when other forage is sparse. The plants are toxic in hay, including pelleted and cubed hay. PAs also survive ensilage; oat silage contaminated with *Amsinckia* or other PA-containing plants has been responsible for disease in dairy cattle. Seeds of *Heliotropium* plants have also poisoned feedlot cattle.[4]

The approximate toxic dose of dried *Senecio* as a percentage of body weight for each species is horses, 5%; cattle, 2% to 5%; goats, 125% to 400%; and sheep, over 150%. Most tansy ragwort contains less than 0.2% PA by weight, but there are reports of much higher levels in some of the other plants. Horses were consistently poisoned by greater than 250 mg of total PA per kg body weight.[5] The PA in hound's tongue is extremely toxic to horses.[6] This dose does not have to be eaten all at once, since the effects are cumulative. Because signs often are delayed, some animals may not become ill until a year or more after removal from feed sources containing the toxins.[7,8] Signs do not occur until hepatocyte loss and replacement by fibrous tissue have caused failure of liver function.

TABLE 33-4

Common Plants Containing Pyrrolizidine Alkaloids (PAs)

Botanical Name (Genus/Species)	Common Name
Senecio jacobaea	Tansy ragwort
Senecio vulgaris	Common groundsel
Senecio douglasii var. *longilobus*	Threadleaf groundsel
Senecio riddellii	Riddell groundsel
Senecio triangularis	Tarweed
Senecio alpinus	Alpenkreuzkraut (Europe)
Amsinckia intermedia	Fiddleneck
Crotalaria spp.	Rattlebox
Echium plantagineum, *E. lycopsis*	Patterson's curse, Salvation Jane or Viper's bugloss
Heliotropium europaeum	Common heliotrope
Symphytum officinale	Comfrey
Cynoglossum officinale	Hound's tongue (houndstongue)
Eupatorium maculatum	Bruner's trumpet
Baccharis pteronioides	Yerba de pasmo
Borago officinalis	Borage
Erechtites spp.	
Trichodesma spp.	

Pathophysiology There are a number of PAs, and many of the poisonous plants contain four to six different alkaloids. About 50% of the alkaloids are toxic, and some are more toxic than others. The alkaloid concentrations vary slightly among plants from different areas, but there is greater variation in concentrations from different parts of the same plant.[9] PAs are not directly toxic; they must be bioactivated to toxic alkaloids (pyrroles) in the liver. After absorption the portal circulation carries the alkaloids to the liver, where they are metabolized by microsomal enzymes of the hepatocyte to more toxic pyrroles.[3,10] The pyrroles may cross-link double-strand DNA in a dose-dependent manner.[11] The degree of DNA cross-linkage depends on the concentration of the pyrrole, but not on the base sequence of the oligonucleotide target.[12] The cross-linking of DNA produces an antimitotic effect.[13] The hepatocytes cannot divide and often become megalocytes as cytoplasm expands without nuclear division. As cells die, they are replaced by connective tissue rather than new hepatocytes. This antimitotic effect may explain why megalocytosis (large hepatocytes and large nuclei) is commonly seen with PA poisoning.

With progressive death of hepatocytes and subsequent fibrosis, liver function begins to fail. Blood supply through the hepatic lobule is disrupted by fibrosis, making regeneration impossible. This becomes a veno-occlusive disease, resulting in marked portal hypertension. The increased portal hydrostatic pressure leads to diarrhea and ascites in ruminants. It is unclear why diarrhea and ascites are seen infrequently in horses with PA toxicity.

Clinical Signs The clinical signs of PA poisoning are basically those of liver failure. The most common signs of PA toxicity in the horse are weight loss, slight to moderate icterus, and abnormal behavior (e.g., wandering, ataxia). Signs seen less frequently in horses include photosensitization of the white areas and, in rare cases, diarrhea. A few cases in ponies have shown loud, stertorous inspiratory noises, possibly caused by pharyngeal-laryngeal paralysis.[13,14] Abortion may occur from ingestion of sublethal doses.[15] Subtle signs such as poor performance (inability to race up to previous standards) may be seen in horses with pyrrolizidine-induced liver damage before the onset of liver failure. Secondary gastric impaction has been reported in ponies.[16] Cattle more frequently show diarrhea, weight loss, tenesmus, prolapsed rectum, and ascites. Calves are much more susceptible to PA toxicity than mature cattle. Behavioral changes or subtle neurologic signs may also be seen in cattle, but icterus is uncommon. Differential diagnosis includes other diseases causing liver failure (e.g., aflatoxicosis or liver flukes) and some chronic debilitating diseases such as GI parasites and Johne's disease.

Sheep and goats are more resistant to PA toxicosis but can be affected by certain alkaloids at doses 30 times or more than the dose that affects cattle and horses. A consortium of ruminal microbes from sheep degrades PAs found in *Senecio jacobaea* to less toxic metabolites.[17] Liver microsomal enzymes in sheep may also play a role in detoxifying PAs, but this alone does not seem to account for the differences in susceptibility.[18]

Diagnosis Hepatic enzyme activities are generally elevated during periods of active hepatocyte destruction caused by PA poisoning. Although the dehydrogenases (e.g., IDH, GDH, LDH) are elevated initially, they may have returned to normal by the time the animal first shows clinical signs of functional failure. Because lesions are largely in the portal region, GGT and ALP tend to be consistently elevated.[7,19] In a study of sublethally poisoned horses, AST and the ratio of branched-chain to aromatic amino acids were persistently elevated.[15] Bile acid concentrations are increased and levels above 50 μM/L would be a poor prognostic indicator in the horse.[5] Serum protein concentration is usually normal, and only terminally does albumin decrease or blood clotting become altered. Bilirubin, both direct and indirect, tends to be increased in the horse at the later stages of the disease process.

Although liver biopsy can be very useful in the diagnosis of PA toxicity, other causes of chronic hepatitis (e.g., aflatoxins) may produce a similar histologic appearance. The triad of fibrosis, bile duct proliferation, and megalocytosis is characteristic of PA poisoning. Modest changes in hepatocytes and biliary hyperplasia are reversible. Fibrosis bridging portal areas indicates an eventually fatal condition, as does the extensive fibrosis of an end-stage liver.

Cattle dying of PA poisoning have ascites and prolapsed rectums and are thin and emaciated. Horses are usually thin and may be icteric. In all species the liver tends to be small, pale brown to yellow, and firm and may appear to be scarred. Hepatic megalocytosis is considered the hallmark of PA poisoning, but it has also been seen in aflatoxicosis and is not always apparent in the earliest stages of PA toxicity. Biliary hyperplasia may occur early in the disease. Nonspecific nuclear changes, such as invaginations of cytoplasm into the nucleus, have been seen.[7,9] Isolated hepatocyte necrosis is seen later, and finally, portal or massive generalized fibrosis develops. Once bridging of connective tissue between the portal areas occurs, the disease is fatal.

Treatment Liver failure may occur with either acute or chronic liver disease. The two must be differentiated for prognosis because end-stage fibrosis caused by PAs has virtually no chance for regeneration and recovery. No satisfactory treatment for PA poisoning exists. Once obvious clinical signs of liver failure develop, the animal usually dies within 5 to 10 days. Horses with mild clinical signs and reversible histologic lesions survived if they retained an appetite and were not exposed to any more PA-contaminated feed.[15] An accurate prognosis concerning mildly affected cases may best be obtained from a combination of consecutive liver biopsies and liver-derived serum enzyme activity, as well as from SBA concentrations.[5,15] Preventing further exposure to the toxic plants is indicated and may delay or stop the progression of the liver lesions, particularly if an uncontaminated feed source is provided before clinical signs develop.

Therapy of liver failure is inappropriate if severe fibrosis has occurred, because regeneration is impossible. If the animal still has a reasonable appetite and only modest degrees of fibrosis histologically, treatment may be attempted by providing a low-protein, high-energy diet.

Prevention and Control PA poisoning is prevented by keeping susceptible animals from pasture, hay, cubed hay, or seeds that contain PA plants. Because most poisonings are attributed to contamination of forages or feed, careful inspection of feed is recommended. *Senecio vulgaris* tends to contaminate mainly first-cutting

TABLE 33-5

Hepatotoxic Plants

Common Name (Botanical Name)	Approximate LD50 (% BW)*	Geographic Distribution	Liver Lesion
For pyrrolizidine alkaloid–containing plants, see Table 33-4.			
Lantana *(Lantana camara)*	1	Northern North America	Necrosis, canalicular collapse
Rabbitbrush *(Tetradymia glabrata)*	0.5	Dry desert	Necrosis
Horsebrush (*Tetradymia* spp.)		Western U.S.	Necrosis
Sacahuista *(Nolina texana)*	1.1	Southwestern U.S.	Fatty and centrilobular necrosis
Lechuguilla *(Agave lecheguilla)*	4-15	Southern U.S., Mexico	Necrosis, photosensitivity
Puncture vine *(Tribulus terrestris)*	?	Warmer regions	Biliary fibrosis, necrosis (big head)
Whitebrush (*Lippia/Aloysia* spp.)	?	Southern U.S., Mexico	Fatty degeneration
Panic grasses (*Panicum* spp.)	?	Texas-California, South America	Biliary fibrosis, necrosis
Kleingrass *(Panicum coloratum)*	?	Southern U.S.	Necrosis, obstructed bile ducts
Bermudagrass *(Cynodon dactylon)*	?	North America	?
Cocklebur *(Xanthium orientale)*	0.75-3	North America	Hemorrhagic centrilobular necrosis
Lupine (*Lupinus* spp.)	Varies	Western North America	Necrosis
Mycotoxin from *Phornopsis inferior*			
Cottonseed (*Gossypium* spp.)	Varies; gossypol content	Southern U.S.	Necrosis
Gossypol pigment			Cardiac lesions
Poisonous mushrooms *(Amanita phalloides, Galerina venenata)*	Few mushrooms	North America	Necrosis, central nervous system signs
Blue-green algae *(Microcystis aeruginosa, Nodularia spumigena)*	? 0.001	Ponds, worldwide	Necrosis, dissociation
Alsike clover *(Trifolium hybridum)*	Varies	Cultivated	Portal fibrosis, biliary hyperplasia
Mexican fireweed *(Kochia scoparia)*	?	Southwest U.S.	?
Coffee senna *(Cassia occidentalis)*	0.05% BW (horse); 0.5%-2% (cattle)	North and South America, Africa, Asia, and Australia	Pericentrolobular vacuolar degeneration and necrosis
Cycad palm (*Cycas/Zamia* spp.)	?	South America, Australia	?
Yellow-wood *(Terminalia oblongata)*	?	Australia, Africa	Centrilobular necrosis
Sneezeweed (*Helenium* spp.)	0.25	Northern U.S., Canada	?
Moldy alfalfa *(Medicago sativa)*	?	Wet areas	Biliary hyperplasia, necrosis
Bitterweed (*Hymenoxys* spp.)	1	Southwestern U.S.	?

*Lethal dose (as percentage of body weight).

?, Unknown; *BW*, body weight.

alfalfa, whereas *Amsinckia intermedia* is often found in planted fields of oat hay. *Senecio* can be controlled by cultivation, because it is a biennial, or by herbicide spraying in the early rosette stage. Species-specific herbicide regimens have been developed for most plants containing alkaloids and are widely available through state weed and extension services. Sheep are sometimes used to graze *Senecio*-infested pastures to control the weed, because they are less susceptible to PA poisoning.

Other Hepatotoxins

The liver is particularly vulnerable to toxic insults because it is the first organ to receive toxins absorbed from the GI tract. Enzymes in the hepatocyte may either activate a toxin or, in some cases, metabolize it before it can cause damage. Most hepatotoxic agents are described in more detail in Chapter 54. Some of the more common liver toxins are listed in Tables 33-5, 33-6, and 33-7, but these are not complete lists because many other plants and chemicals can damage the liver under the right conditions. Once a toxic liver disease has been diagnosed, possible sources of the toxin might be identified from these tables. A more detailed description of toxins affecting the liver can be found in Chapter 54.

Liver Flukes in Ruminants

John B. Malone

Etiology The common liver fluke *Fasciola hepatica* causes a disease of production in ruminants that mimics the production effects and clinical appearance of the GI nematode-parasite complex. The disease often has its maximum economic effect in late fall and winter when animals are most likely to be under seasonal nutritional stress. *F. hepatica* is unique among the common helminths of ruminants in that it has an asexual multiplication phase of the life cycle in snail intermediate hosts that is highly sensitive to environmental conditions. *F. hepatica* is well known for its exponential propagation of infective stages under favorable conditions, sometimes leading to explosive seasonal outbreaks of severe parasitism, especially in sheep. In addition, liver parenchyma migration forms leave necrotic tracts in their wake that are a primary predisposing factor in some areas for acute fatalities caused by *C. novyi* types B (black disease) and D (bacillary hemoglobinuria), discussed earlier in the chapter.[1]

The geographic distribution of *F. hepatica* in the United States is limited mainly to areas in the south-central states and Florida and to the Pacific Northwest, where neutral well-buffered soils are found and local hydrologic conditions provide suitable habitats for lymnaeid snail intermediate hosts. The important vector species in temperate climates, recently renamed based on molecular evidence as *Galba* sp. or *Lymnaea* sp.,[2] are semiaquatic "mud" snails found in disturbed mud banks and hoofprints in shallow depressions in fields, drainage channels, and temporary water bodies in alluvial river basins, bottomlands, and coastal regions of the southeastern United States. Springs, small streams, seeps, and sloughs serve as habitats in areas of greater terrain relief in the western states. Most infections occur by grazing in and around water in fluctuating habitats that stay wet for more than half the year.

The life cycle development of both the snail host and the parasite in the snail occurs only when temperatures are above 10°C (50°F) and while snail habitats are wet. This leads to a distinct seasonal transmission in the mild, wet winter and spring of the south-central states and Florida and a late spring to fall transmission in the cooler climates of the western states (Figs. 33-3 and 33-4). It takes a

TABLE 33-6

Hepatotoxic Chemicals

Chemical	Source	Approximate Lethal Dose*	Liver Lesion
Carbon tetrachloride (CC14)	Tremacide Fumigant Solvent	10-40 mg/kg	Fatty degeneration, centrilobular necrosis, cirrhosis
C1-Hydrocarbons PCBP Solvents	Insecticides	Varies with species, chemical, and route	Necrosis
Pentachlorophenols	Wood preservative, herbicide, fungicide, molluscacide	100-200 mg/kg	Centrilobular fatty degeneration
Polybrominated biphenyl (PBB)	Fire retardant	100 mg/kg	Hemorrhagic necrosis, fatty degeneration
Carbon disulfide (CS2)	Boticide Solvent Fumigant	100 mg/kg	Necrosis
Coal tar pitch	Clay pigeons Pipe sealer Tar paper	Swine 15 g/pig	Hemorrhagic necrosis
Phenol	Wood preservative	30 mg/kg	Hemorrhagic centrilobular necrosis
Iron	Iron supplements Injectable iron	>150 mg/kg young animals	Portal necrosis
Copper	Species inappropriate supplements Fungicides, algicides Molluscacide Foot baths	Depends on species and molybdenum intake	Portal vacuolation and necrosis (hemolytic crisis)
Phosphorus	Fertilizer Matches Rodenticide	1-4 mg/kg	Portal necrosis and fatty degeneration
Tannic acid	Oak Skin astringent	20 mg/kg	Centrilobular necrosis (also renal damage)
Paraquat/diquat	Herbicide	4-10 mg/kg	Centrilobular necrosis (also lung damage)
Mycotoxins, aflatoxin B	Moldy feed	3 mg/kg	Centrilobular necrosis, biliary hyperplasia, megalocytosis
Rubratoxin B	Moldy feed	?	Necrosis
Sporidesmin	Moldy feed	?	Bile duct occlusion (big head)
Ochratoxin A	Moldy feed	?	Necrosis (also renal damage)
Phomopsin A	Lupine	?	Necrosis

*Lethal dose varies with individual, species, route of entry, rate or chronicity, enzyme induction, and many other factors.

?, Unknown.

minimum of 42 days at 25° C (77° F) or the accumulation of approximately 600 growing-degree days to complete intramolluscan development, with release of cercariae that encyst as infective metacercariae on pasture vegetation (600 growing-degree days = 25° C minus the base temperature of 10° C = 15 growing-degree days × 42 days; an equivalent value for the life cycle is 15° C or 5 growing-degree days × 120 days). Using soil water budget analysis to indicate the length of time habitats are wet and the accumulated sum of growing-degree days over 600, a climate forecast index can be calculated for use in describing the pattern of seasonal transmission at a given site and to provide an indicator of the risk of economic losses in a given climate year. Two weeks of sustained summer heat and drought ends the transmission season by killing pasture metacercariae and forcing snail populations to estivate in soil or perish. In the cooler climates of the western United States, the season ends with drying of springs, seeps, sloughs, and other habitats or with the onset of sustained cold winter weather. Variation in the annual climate alone may lead to a 100-fold variation in fluke burdens in different climate years.[3]

The amount of snail habitat present on individual farms related to pasture wetness conditions, such as premises with low-lying heavy clay soils with a high water table, is also an important consideration in evaluating the need for fluke control. This factor has also been shown to lead to a 100-fold variation in the risk of fluke losses in the same year on different premises in otherwise ecologically similar areas.[4] The snail habitat area on most enzootic livestock operations typically is only 1% to 5% of the total land area; operations with over 5% habitat may be associated with a high risk of liver fluke losses.

Clinical Signs Subclinical production effects of *F. hepatica* include reduced rate of gain and feed efficiency in growing stock. Economic effects have been experimentally demonstrated in calves on a marginal nutritional plane in the first 5 to 6 months after infection, resulting in an 8% loss in the rate of gain with a mean of 40 flukes and a 28% loss with 140 flukes. In cattle it is estimated that herd economic losses are "negligible" with a burden of less than 10 flukes per animal, "possible" at 10 to 40 flukes, and "probable" with over 40 flukes. Clinical disease is seen with a burden of more than 200 flukes. In cow-calf operations, flukes often act in concert with periods of nutritional stress and concurrent heavy GI nematode infections, causing further reduction of body condition, poor milking ability, and slower return to estrus. This translates to reduced reproductive efficiency, prolonged calving interval, and lightweight calves at weaning.[5]

In cattle, flukes may lead to chronic disease or, in rare cases, subacute disease. When clinical signs occur, the typical population "overdispersion" (individual variation in parasite burdens) is manifested first in the 10% to 20% minority of the herd that harbor most of the parasite numbers. Signs may consist of weight loss, emaciation, depression, anorexia, rough hair coat, anemia, hypoproteinemia, submandibular edema, and, in rare cases, mild icterus. The anemia

TABLE 33-7

Drugs Used in Large Animals That Could Damage the Liver

Drug	Lesion*
Carbon tetrachloride	Centrilobular necrosis or fatty degeneration
Hexachloroethane	Centrilobular or massive necrosis
Carbon disulfide	Necrosis
Alcohol	Necrosis/cirrhosis
Tetracycline	Fatty degeneration (also renal damage)
Clindamycin	Cholestasis, icterus
Erythromycin	Cholestasis, icterus
Isoniazid	Active hepatitis → cirrhosis/massive necrosis
Rifampin	Cholestasis, icterus
Nitrofurantoin	Active hepatitis → cirrhosis
Anabolic steroids	Cholestasis, icterus
Phenothiazine	Cholestasis, icterus tranquilizers
Halothane	Active hepatitis → cirrhosis/massive necrosis
Fluothane	Active hepatitis/massive necrosis
Isoflurane	Active hepatitis/massive necrosis
Some diuretics	Cholestasis, icterus
Diazepam	Cholestasis, icterus
Phenobarbital	Necrosis/cholestasis icterus
Aspirin	Active hepatitis → cirrhosis
Oil of pennyroyal	Centrilobular necrosis
Tannic acid	Centrilobular necrosis, fatty degeneration (renal damage)
Dantrolene	Active hepatitis → cirrhosis
Copper disodiumedetate	Massive centrilobular necrosis
Iron (injectable)	Necrosis, portal, cirrhosis, hemosiderosis
Glucocorticoids	Hepatocellular vacuolization
Ionophores (salinomycin)	Hepatic lipidosis, necrosis

*May vary with dose and time.

associated with *F. hepatica* infections is more than can be accounted for by fluke blood feeding. Evidence indicates that depression, anemia, and biliary hyperplasia result from high levels of proline, a product of fluke metabolism.[6] Cattle are able to mount a protective immune response, with partial acquired resistance to *F. hepatica* beginning at 5 to 6 months after initial exposure.[7] This and the short lifespan of flukes in cattle typically lead to a linear reduction of fluke numbers, with few surviving by the end of 1 year. Sheep and goats are more susceptible, and fatal acute disease with ascites, abdominal hemorrhage, pallor, and icterus can occur in association with massive entry to the bile ducts at 6 to 10 weeks after infection by 1000 to 5000 or more migrating immature forms from the liver parenchyma. Subacute disease has been associated with a burden of more than 800 flukes acquired over time. Chronic clinical disease in sheep with submandibular edema, ascites, and emaciation has been associated with fluke burdens above 200.[8]

Necropsy findings attributable to migrating young flukes are caused by tortuous tunnels of coagulative necrosis that organize and fibrose, ultimately leading to a diffusely fibrotic liver parenchyma, especially in the ventral lobe, which in severe cases undergoes marked atrophy. Fibrous tags may result from fibrinohemorrhagic deposits left by large numbers of flukes at liver penetration 3 to 4 days after infection. Inflammatory events associated with penetration of the bile ducts at 6 to 8 weeks after infection are especially pathogenic. Once in the bile ducts, flukes grow rapidly from 1 mm to 2.5 cm or more and induce a proliferative cholangiohepatitis. The spines and suckers of flukes erode and denude the bile duct epithelium, leading to a fibrosed, thickened duct wall that is irregularly dilated and stenotic and begins to calcify in cattle (but not sheep) at about 20 weeks after infection. The bile becomes darkly discolored and laden with regurgitated fluke ingesta, plasma proteins, and inflammatory cells. The extent of pathologic change is generally proportional to the fluke burdens of current or recurring previous infections.[8]

Diagnosis Fecal sedimentation methods are the standard means of diagnosing liver flukes, although classical methods are cumbersome. A reusable commercial "nematode counting chamber" (1-mL volume of sediment fluid) is available (Chalex, Wallowa, Ore.) that can be examined on a standard microscope stage. It reduces sample processing time by half and is suitable for use by practitioners for quantitative examination of individual animals or 10- to 15-animal herd composite samples. For herd or lot evaluations in cattle, egg counts of less than one egg per 2 g (EP2g) and 25% prevalence 2 to 4 months after the transmission season ends have a "low probability" of economic losses; 1 to 3 EP2g indicates "possible" economic loss; and 10 EP2g or more indicates "high probability" of heavy infections and economic loss. It is important to differentiate *F. hepatica* eggs from the eggs of *Paramphistomum* species, a nonpathogenic "rumen fluke" often found in the same herds in both the southern and the western enzootic areas. Flukecides used against *F. hepatica* are ineffective against rumen flukes, and egg counts thus persist after treatment. *Paramphistomum* eggs are gray (rather than amber), slightly smaller, and more pointed at the operculum end than *F. hepatica*. *Paramphistomum* egg counts can be used as a general indicator of the probable risk of *F. hepatica* in the absence of control in the southern states, because *Paramphistomum* flukes are known to be transmitted by the same snail vector in that region.[5]

Diagnostic enzyme-linked immunosorbent assays (ELISAs) have been developed to detect serum antibodies or coproantigen in the feces of infected animals or in bulk milk samples.[9,10] These tests have not yet found wide use outside of research laboratories in the United States but are marketed in Europe.[10] Blood and serum clinicopathologic results reflect the anemia, hypoproteinemia, and mild eosinophilia caused by *F. hepatica*. Pathologic changes in the liver bile ducts and parenchyma are reflected by an elevation in serum liver enzymes (e.g., GGT, GDH).

Treatment and Prevention Prevention is the key to control in foundation herds and flocks, because even low numbers of eggs shed can multiply asexually in snails and lead to significant infection rates during the following transmission season. A single routine fall or late fall-winter treatment after the end of the transmission season with a highly effective drug is recommended to remove adult flukes before winter stress and to prevent egg shedding and snail infection in the next season (see Figs. 33-3 and 33-4). Most of the pathogenic and economic effects of flukes in cattle are reported to occur within the first 5 to 6 months after the major exposure period and may be related to metabolic products associated with the rapid growth and heavy egg production phases of the life cycle. This, coupled with linear loss of heavy fluke burdens in cattle and the onset of effective immunity at 20 weeks after exposure, suggests the value of early flukecide treatment within 2 to 3 months after the transmission season ends. In some herds an optional curative treatment in spring may be needed in very high-risk years or on high-risk premises, or as a second treatment to remove flukes acquired during late, extended transmission on irrigation pastures or wet coastal areas in the west.

Flukecidal drugs available in the United States are effective against mature flukes in bile ducts (albendazole, 10 mg/kg; clorsulon, 2 mg/kg). Clorsulon at 7 mg/kg has added efficacy against juvenile flukes over 6 weeks old in the bile ducts. The optimum time to treat should be based on the estimated susceptibility of mature fluke populations (>12 weeks old after end of transmission season) but early enough to remove flukes while they are most pathogenic (<6 months old). Triclabendazole, which is widely used in other countries, is reported to be more than 90% effective against migrating flukes over 2 weeks old and 99% effective against mature flukes and thus can be effectively given just after transmission ends. However, significant triclabendazole drug resistance issues have emerged.[10,11] Worldwide,

VetBooks.ir

a number of other drugs are available, including oxyclozanide, niclofolan, bithionol, and hexochlorophene (80% to 99% of adult flukes), nitroxanil, closantel (>90% adult and 50% to 90% juvenile bile duct flukes), rafoxanide (>50% late migratory flukes, >90% juvenile and adult bile duct flukes), and diamphenathide (>90% migratory flukes, 50% to 80% bile duct flukes).

The economic benefit of routine flukecide treatment of feedlot calves from enzootic areas in the United States has not been consistently demonstrated industry-wide because of the high variability of fluke burdens in animals from enzootic areas, or because lots are often of mixed origin. Fluke-related losses would be expected to be mainly absorbed by stocker operations, where lightweight calves are typically placed on small grain pastures for extended periods before feedlot, a common practice in the south-central states. The economic return of treatment at feedlot should be evaluated on a case-by-case basis, because significant losses may occur if the lot originates from the same premises and the history suggests a high risk of recent heavy infection rates, such as in favorable climate years or use of irrigated pastures in fluke areas. Fecal egg counts on 10 to 15 randomly selected animals may aid in herd evaluation. An example case of the explosiveness of the life cycle is the greatly reduced feedlot performance and 100% liver condemnations of a lot from a stocker operation in the Pacific Northwest. The animals originated from irrigated pastures where some habitats stayed wet year-round, and untreated calves from fluke areas were allowed to contaminate pastures with eggs, which translated to infection later in the grazing season and to the next stocker group rotated onto the premises.

Other Flukes

Fascioloides magna, the large American liver fluke, may infect cattle and sheep that graze common areas with deer, the natural host. The life cycle is similar to that of *F. hepatica,* but with a wider variety of lymnaeid snail hosts and a broader geographic distribution in the Gulf States, the Great Lakes area, and the Northwest. Cattle are abnormal dead-end hosts that react with an intense encapsulation response, forming a closed cyst that does not allow escape of eggs and obviates diagnosis by fecal examination. The liver parenchyma and regional lymph nodes have a characteristic diffuse black pigmentation. The major economic effect of *F. magna* in cattle is condemnation of livers and other organs, such as lungs, in which aberrant migration sometimes occurs. In sheep and goats, however, *F. magna* does not encyst and migrates uninterrupted. One or two *F. magna* flukes kill sheep before the flukes have time to mature, and this parasite limits sheep production in some areas. Albendazole given at high dosage is moderately effective against *F. magna.*

In tropical regions, *F. hepatica* is replaced by *Fasciola gigantica,* a similar species that is somewhat larger, has a longer prepatent period (10 to 12 weeks), and is of somewhat greater pathogenicity. *Dicrocoelium dendriticum* occurs worldwide but in North America is an unimportant species, mainly limited to areas of central New York, with smaller foci in Pennsylvania, New England, Quebec, and British Columbia. Albendazole (20 mg/kg) and high doses of thiabendazole (150 to 300 mg/kg) are effective treatments.[1]

Hepatic Abscesses

T.G. Nagaraja

Etiology Hepatic abscesses occur sporadically in most animals but are most common in ruminants, particularly cattle fed high-grain diets. Hepatic abscesses occur at all ages and in all types of cattle, including dairy cows, but have the greatest economic impact in feedlot cattle, in which the prevalence ranges from 1% to 2% to as high as 90% to 95%, but averages 20% to 30% in most feedlots.[1] Because hepatic abscesses are generally a direct result of feeding practices, diet is an important factor influencing the prevalence. Hepatic abscesses do occur in dairy cows, and anecdotal observations have suggested as high as 40% to 60 % of prevalence in packing plants that routinely slaughter culled dairy cows.[2]

Hepatic abscesses are generally polymicrobial infections, and in most cases the organisms are anaerobes. In the bovine, *Fusobacterium necrophorum* (formerly *Sphaerophorus necrophorus*), a gram-negative, pleomorphically rod-shaped anaerobe, is the primary etiologic agent.[3] The organism also is implicated as the primary pathogen in necrotic laryngitis (calf diphtheria), foot rot, and foot abscesses in cattle.[4,5] *F. necrophorum* is a normal inhabitant of the rumen, and its role in ruminal fermentation is mainly to utilize lactic acid to produce volatile fatty acids and also digest ruminal epithelial and feed protein.[6] The organism is in higher concentration in grain-fed than forage-fed cattle, possibly because of the increased availability of lactic acid from fermentation of starch in the grain. Several virulence factors have been implicated in the pathogenesis of *F. necrophorum* infections.[5,6] These include leukotoxin, endotoxic lipopolysaccharide (LPS), hemolysin, hemagglutinin, capsule adhesins or pili, platelet aggregation factor, dermonecrotic toxin, and extracellular enzymes (e.g., proteases, deoxyribonucleases).[6] Leukotoxin is believed to be the major virulence factor. The leukotoxin is cytotoxic to polymorphonuclear neutrophil leukocytes (PMNs), macrophages, hepatocytes, and ruminal epithelial cells. Because of leukotoxin, the organism is able to survive, proliferate, and establish to set up infection of the ruminal wall and liver. There are two subspecies of *F. necrophorum,* subsp. *necrophorum* (formerly biotype A) and subsp. *funduliforme* (formerly biotype B). These two subspecies differ in cell morphology, colony characteristics, growth patterns in broth, and most importantly, in virulence factors. Subspecies *necrophorum* is more virulent (produces more leukotoxin) and thus more frequently encountered in liver abscesses than subsp. *funduliforme,* which tends to occur more often in mixed infections.[7,8]

In most situations, *Arcanobacterium pyogenes* (formerly *Actinomyces, Corynebacterium,* and now included in a new genus called *Trueperella*), a gram-positive rod-shaped organism, is the second most frequent pathogen isolated from liver abscesses. The ruminal wall appears to be the niche for *A. pyogenes,* a facultative bacterium, because the wall provides an aerobic microenvironment in an otherwise anaerobic environment of the rumen.[9] The organism may also act in synergy with *F. necrophorum* to cause liver abscesses.[10] A variety of other anaerobic and facultative bacteria, such as *Bacteroides* spp., *Clostridium* spp., coliforms, *Mobiluncus* spp., *Mitsuokella* spp., *Pasteurella* spp., *Peptostreptococcus* spp., *Porphyromonas* spp., *Prevotella* spp., *Propionibacterium* spp., *Staphylococcus* spp., *Streptococcus* spp., and many unidentified gram-positive and gram-negative bacteria, are often isolated from liver abscesses of cattle.[5,7,10]

Pathophysiology Abscesses in the liver result from entry and establishment of *F. necrophorum* either alone or with other bacteria. The routes by which the bacteria can gain access to the liver include the portal vein, hepatic artery, umbilical vein (in newborn with omphalophlebitis), bile duct system, and direct extension. Entry through the hepatic artery (after an episode of septicemia) or the bile ducts (usually from obstruction, infection ascending from duodenum, or migration of flukes) is a rare occurrence. Direct extension of infection from adjacent tissues and organs, usually of traumatic origin (e.g., direct puncture of the liver by a foreign body lodged in the reticulum), is more likely to occur in dairy cows. Traumatic reticuloperitonitis caused by metallic objects lodged in the reticulum and perforating through the reticular wall, rarely involving the ruminal wall, is often a predisposing factor for liver abscesses in dairy cows. However, in both dairy cows and feedlot cattle, the most common route of entry of bacteria into the liver is the portal vein.

Liver abscesses are secondary to the primary foci of infection in the ruminal wall. Evidence to support this is the high correlation between ruminal wall lesions (rumenitis) and liver abscesses, thus the term *rumenitis–liver abscess complex* (Fig. 33-5). More direct evidence for the pathogenesis of liver abscesses was obtained by restriction fragment length polymorphism analysis of rRNA genes (ribotyping) of *F. necrophorum* and *A. pyogenes* isolates from the rumen and liver abscesses of the same animal. The genetic similarity between the isolates from liver abscesses and ruminal walls

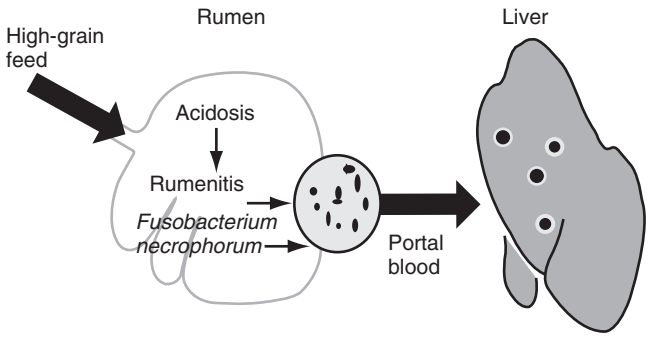

FIG. 33-5 Pathogenesis of liver abscesses in cattle fed high-grain diets. *(Modified from Nagaraja TG, Chengappa MM. 1998. Liver abscesses in feedlot cattle: a review. J Anim Sci 76:287.)*

supported the hypothesis that *F. necrophorum* and *A. pyogenes* isolates of liver abscesses originated from the rumen.[9,11] It is well accepted that ruminal lesions resulting from acidosis are the predisposing factors for hepatic abscesses. Acid-induced rumenitis and damage of the protective surface usually are associated with a sudden change to high-energy diets and other dietary indiscretions, such as a change in feeding patterns, letting cattle become overly hungry, feeding unpalatable diets, and feeding very little roughage. The ruminal damage often is aggravated by foreign objects in the feed, sharp feed particles, or hair.[10] The ruminal wall that is damaged from acidity or penetration of foreign objects becomes susceptible to invasion and colonization by *F. necrophorum.* Once colonization has occurred, *F. necrophorum* can gain entry into the blood or cause ruminal wall abscesses and subsequently shed bacterial emboli to the portal circulation. Bacteria from the portal circulation are filtered by the liver, leading to infection and abscess formation.

The virulence factors of *F. necrophorum* play a critical role in the penetration and colonization of the ruminal epithelium and entry and establishment of infection in the liver.[6] The protease activity, dermonecrotic activity, and cytotoxic effect of leukotoxin on ruminal cells may aid in penetration and colonization of the ruminal wall. *F. necrophorum*, being an anaerobe, must overcome both high oxygen concentrations and phagocytic mechanisms to survive, proliferate, and initiate abscess formation. The leukotoxin may protect it from phagocytosis. Also, the release of cytolytic products such as lysosomal enzymes and oxygen metabolites, resulting from destruction of phagocytes, has a detrimental effect on the liver parenchyma. Synergism with facultative bacteria, intravascular coagulation induced by endotoxic LPS and platelet aggregation factor, formation of fibrin-encapsulated abscesses, and impairment of oxygen transport by damaged erythrocytes (action of hemolysin) all may contribute to the establishment of an anaerobic microenvironment conducive to the growth of anaerobic bacteria within the ruminal wall and liver.

Pathology Abscesses found in the liver at slaughter or necropsy often are well encapsulated, possessing thick, fibrotic walls (Fig. 33-6). The earliest lesion is a microabscess induced by an embolus of *F. necrophorum* in the sinusoid, and the lesion then progresses to coagulative necrosis by involving adjacent hepatocytes. Subsequently, the lesion gradually changes into a pus-filled, encapsulated, true abscess. Histologically, a typical abscess is pyogranulomatous with a necrotic center, encapsulated, and often surrounded by an inflammatory zone.[8] Hepatic abscesses are pus filled, have capsules that vary in thickness, and range in size from a minute pinpoint to over 15 cm (6 inches) in diameter. The number of abscesses in the liver can vary from one to hundreds, and sizes range from less than 1 cm (0.4 inch) to greater than 15 cm in diameter, often encircled by a hyperemic zone. The larger abscesses may be the result of small abscesses coalescing early in development. The distribution of abscesses in the liver shows no consistent pattern, with superficial and deep abscesses distributed almost evenly. Often, small abscesses are scattered

FIG. 33-6 Liver from a feedlot steer demonstrating a large liver abscess

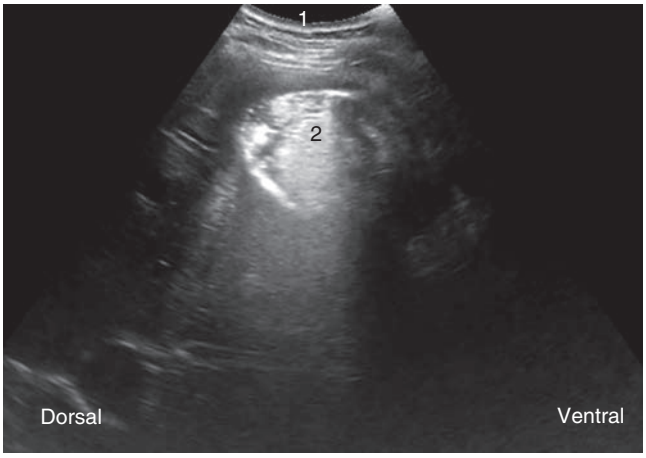

FIG. 33-7 Ultrasound image from the 11th intercostal space of a cow. Abdominal wall *(1),* liver abscess *(2).*

throughout the organ, whereas large abscesses are located close to the portal entry. Abscesses eventually become sterile and are replaced by fibrous scars, with eventual resorption.

Clinical Signs and Diagnosis Liver abscesses are detected only at the time of slaughter. Cattle, even those that carry hundreds of small abscesses or several large abscesses, seldom show any clinical signs. Occasionally the rupture of a superficial abscess or erosion and perforation of the caudal vena cava could lead to extensive spread and massive infection of other organs and eventual death. Generally, hematology and liver function tests have not proved to be good indicators of liver abscesses.[12] In animals in which abscesses were induced by experimental inoculation of *F. necrophorum,* hepatic dysfunction was documented by elevated serum protein, bilirubin, and enzymes such as GGT and IDH (SDH) concentrations.[13] In a group of Holstein dairy cattle where the presence of liver abscesses was diagnosed via ultrasound or exploratory laparotomy, the most common clinical sign was anorexia.[14]

Ultrasonography is a useful technique in the diagnosis of various hepatic diseases in cattle because of the location and tissue consistency of the liver (Fig. 33-7).[15] The technique has been shown to be useful for monitoring the onset and progression of experimentally induced abscesses where the site of injection is known.[13] The development of abscesses in feedlot calves has been recorded by ultrasonographic examination at regular intervals from weaning to slaughter.[12] However, its application to the diagnosis in feedlot cattle is limited

VetBooks.ir

because the ultrasonographic scanning cannot visualize the whole liver, particularly the left side facing the internal organs, and parts of lobes are covered by other organs (e.g., lungs, kidneys).

Treatment and Prevention Both *F. necrophorum* and *A. pyogenes* are susceptible to penicillins and macrolides.[1] Although successful treatment of cattle with liver abscesses has been described,[14] antibiotic treatment is seldom practical in cattle because complete recovery is difficult to attain. Cattle with sequelae (e.g., caudal vena cava thrombosis syndrome), for economic reasons, are generally culled for slaughter.

According to the U.S. Feed Additive Compendium, five antibiotics (bacitracin methylene disalicylate, chlortetracycline, oxytetracycline, tylosin, and virginiamycin) are approved for prevention of liver abscesses in feedlot cattle.[16] These antibiotics vary in their inhibitory effect on *F. necrophorum* and *A. pyogenes* and their effectiveness in preventing liver abscesses. Tylosin, a macrolide, is the most effective antibiotic and the most commonly used feed additive (6 to 8 g/ton, or 60 to 90 mg/head/day) in the feedlot. Studies show that tylosin feeding reduces abscess incidence about 40% to 70%. A bacterin vaccine (Fusogard, Novartis Animal Health), injected subcutaneously in 2-mL doses 21 days apart, has been shown to be effective in reducing the incidence and severity of liver abscesses in feedlot cattle. A vaccine combination of *F. necrophorum* leukotoxoid and *A. pyogenes* bacterin (Centurion) given to feedlot cattle has been shown to reduce the prevalence and severity of liver abscesses.[17] However, this vaccine is no longer available commercially. In addition to inclusion of antimicrobial compounds in the feed or vaccination, prudent bunk management to minimize ruminal acidosis is well accepted as a key factor for effective control of liver abscesses. Some of the management recommendations include gradual adaptation to high-grain diets, avoiding either under- or overfeeding, increasing feeding frequency to spread the intake, increasing roughage content of the feed, imposing quality control in mixing feeds, and providing adequate bunk space and fresh clean water.[18]

Sequelae Septic cardiac and pulmonary emboli are also associated with liver abscesses in feedlot and dairy cattle. Occasionally, sudden death has been reported in cattle secondary to rupture of liver abscesses, with septic embolization in the right side of the heart. Generally the condition starts as phlebitis caused by the extension of liver abscesses involving caudal vena cava. The phlebitis leads to thrombus formation anywhere between the liver and right atrium, but most often at the point of entry of caudal vena cava into the diaphragm. The clinical syndrome and the extent of lesions observed depend on the degree of thrombosis and type of organisms involved. The syndrome can range from death caused by rupture of caudal vena cava to various degrees of pulmonary embolism, pneumonia, infarction, endocarditis, hemoptysis, and epistaxis. Collectively, these lesions are categorized under caudal vena cava thrombosis (CVCT) syndrome.[19,20]

Economic Importance Liver abscesses are a major economic liability to the producer, the packer, and ultimately the consumer of beef. Abscesses are the leading cause of liver condemnation in the United States. National Beef Quality Audits (NBQA; 1995-2011) indicate that liver condemnation consistently ranks among the top 10 concerns of the packers.[21] The greatest economic impact of hepatic abscesses is not from the condemnation of liver but from the reduced animal performance. Cattle with abscessed livers have reduced feed intake, reduced weight gain, decreased feed efficiency, and decreased carcass dressing percentage. These effects are evident only in cattle with the most severe abscesses (one or more large abscesses or multiple small abscesses).

Hepatic Abscesses in Horses

Hepatic abscesses occur sporadically in horses and are generally part of the intraabdominal abscess complex. In studies that have evaluated horses with intraabdominal abscesses, 12% (3/25)[22] and 53% (8/15)[23] of horses had abscesses in the liver. Hepatic abscesses in horses are usually associated with septic portal vein thrombosis but may also develop as an extension of the inflammatory process involving the intestinal tract or as sequelae to abdominal surgery.[24] A variety of bacterial species, particularly anaerobes, have been cultured from the pus. The most frequently isolated bacteria include *Streptococcus equi, Escherichia coli, Bacteroides fragilis, Corynebacterium pseudotuberculosis, Fusobacterium necrophorum,* and *Peptostreptococcus* species.[23-25]

Clinically, horses with hepatic abscesses cannot be differentiated from other intraabdominal abscesses. Generally, horses have a history of fever, loss of appetite, signs of colic, depression, and weight loss. Clinicopathologic changes are typical of chronic bacterial infection and include leukocytosis, thrombocytosis, hypoalbuminemia, and decreased A/G ratio.[23-25] The prognosis is generally poor because of failure to respond to antimicrobial treatment. Percutaneous or surgical drainage has been shown to be effective, with high survival rate in humans with hepatic abscesses.

Hepatic Lipidosis‡

Geof W. Smith

Fat Cow Syndrome, Lipid Mobilization Syndrome

Hepatic lipidosis (fat cow syndrome) is a multifactorial condition occurring in dairy cows after parturition. The syndrome is characterized by progressive depression and failure to respond to treatment of other predisposing diseases. It is associated with excessive mobilization of fat to the liver in well-conditioned or overconditioned cows. This mobilization of fat is induced by the negative energy balance and hormonal changes that occur around the time of calving. This negative energy balance in most cases is aggravated by concurrent periparturient diseases that reduce feed intake and increase energy needs.[1-3]

Fat cow syndrome occurs sporadically in dairy cows but more frequently in cows that become overconditioned during late lactation and during the dry period.[2] The overconditioning may be caused by a poor breeding program associated with cows spending prolonged time in the low lactation strings and having excessive weight gain. Mortality can exceed 25%, with even higher rates occurring without intensive treatment and correction of concurrent diseases. Clinical disease in obese cows that enter the dry period can be minimized by carefully controlling their diets to meet National Research Council (NRC) requirements and preventing milk fever.

Clinical Signs The clinical condition occurs in the postparturient period. Most affected cows are either obese or very well conditioned, with a large amount of omental and subcutaneous fat. Presenting signs usually include depression, anorexia, weight loss, and weakness that can lead to recumbency. Most will have nonspecific signs like decreased rumen motility and decreased milk production. Other signs vary and are related to concurrent diseases. The concurrent diseases most frequently seen are metritis, retained fetal membranes, mastitis, parturient paresis, and displaced abomasum.[1] It is important to look for these other diseases; even if mild, they could be significant in these cases and must be treated.

Diagnosis Most laboratory tests are poor indicators of hepatic lipidosis and are of little value in determining disease severity.[4] Liver-derived enzymes are usually elevated above the level in the dry cow but are often within normal ranges. Liver enzymes most consistently

‡Contributions to previous editions by John Maas and Erwin G. Pearson are acknowledged.

VetBooks.ir

elevated in cases of hepatic lipidosis are ornithine carbamoyl transferase (OCT), total bilirubin, and AST.[5] Bile acid concentrations have not been shown to be significantly increased in most cows with fatty liver.[5] Many cows with hepatic lipidosis have a leukopenia and a degenerative left shift, but this is not specific. As expected, nonesterified fatty acid (NEFA) levels will be increased, and triglycerides and cholesterol will be decreased. Most of the total cholesterol is in lipoproteins. The sulfobromophthalein dye excretion test may be useful prognostically because those with a half-life longer than 9 minutes have a more guarded prognosis.[6]

Several recent studies have examined ultrasound as a tool to detect hepatic lipidosis in cattle. With increasing fat accumulation in the liver, an increased gray level is seen in the ultrasound image, and the liver appears brighter. However this is subjective and is also dependent on the settings of the machine. One study found that the liver increases in size and becomes rounded with increasing severity of lipidosis; however, measuring the thickness of the liver and angle of the ventral margin had limited diagnostic value.[7] Another study used digital analysis of hepatic ultrasound images via a computer-aided ultrasound system and found that imaging findings correlated well with liver triacylglycerol concentrations.[8] Digital analysis of B-mode liver images used a computer program to correct for abdominal wall effects and removal of artifacts. Although not commonly available at this point, the use of ultrasound and computer-aided correction has the potential to help determine the severity of hepatic lipidosis.

Although clinical chemistry and ultrasound may be helpful in diagnosing hepatic lipidosis, a liver biopsy is the gold standard. Liver biopsy may confirm the fatty infiltration of the hepatocytes, but a moderate to high amount of fat is present in the liver of all postparturient, high-producing dairy cows, even those that remain healthy.[9] Fat is usually quantified by histologic methods by determining percentage of hepatocytes containing lipid vacuoles, measuring total hepatic fat on a wet weight basis, or by floating in copper sulfate solutions of various specific gravity (to estimate total fat on a wet-weight basis).[10] Classification schemes characterizing severity of hepatic lipidosis based on percentage of hepatocytes containing fat vacuoles have been presented (e.g., <50%, 50% to 75%, and >75% being equal to mild, moderate, and severe lipidosis, respectively).[4] More recent studies have advocated the use of triacylglycerol analysis on a wet-weight basis to differentiate degrees of hepatic lipidosis.[3] These studies categorized hepatic lipidosis as normal, mild, moderate, and severe by triacylglycerol concentrations of less than 1% (<30 mg/g), 1% to 5% (30 to 50 mg/g), 5% to 10% (50 to 100 mg/g), and greater than 10% (>100 mg/g), respectively.[3] At present, triacylglycerol analysis of hepatic tissue is not a routine procedure in veterinary diagnostic laboratories, so total hepatic fat concentrations remain the gold standard for laboratory diagnosis. Clinically, little correlation exists between the amount of hepatic fat and signs of disease until the fat is more than 34% wet weight, at which point the liver tissue will float in distilled water with a specific gravity of 1.000.

Generalized obesity is noted at necropsy unless the animal has been sick for more than 1 to 2 weeks. Changes in the liver are most striking; it is enlarged, with swollen and rounded edges, is pale yellow in color, and may float in water. Histologically, there is fatty infiltration of the hepatocytes, especially in the centrilobular and intermediate areas. However, these liver tissues are sometimes not much different from those of healthy, high-producing dairy cows in early lactation.

Pathophysiology Storage of excess energy as fat and the periodic mobilization of fat for use as energy by the body is crucial.[2,3] The liver plays a major role in lipid metabolism and must process the absorbed chylomicrons, the volatile fatty acids, and many of the fatty acids and much of the glycerol obtained by mobilization of fat from adipose tissue (Fig. 33-8). The liver of large herbivores has unique functions because much of the dietary energy is absorbed as volatile fatty acids and not glucose. Glucose is still needed (in high amounts in lactating animals) and must be produced by gluconeogenesis, 85% of which takes place in the liver.[11]

Negative energy balance is induced by lactation, fetal growth, exercise, decreased feed consumption, environmental chilling, and diseases (Fig. 33-9). During these periods of negative energy balance and before lactation, blood glucose may drop slightly, the insulin/glucagon ratio drops, and these and other hormones (e.g., catecholamines, growth hormone) activate hormone-sensitive lipases that convert tissue fat to free fatty acids (FFAs) or nonesterified fatty acids (NEFAs) and glycerol (Fig. 33-10). Following a 4-day period of fasting in cattle, plasma insulin concentrations decreased and insulin-stimulated blood glucose reduction was decreased as compared to cows that were not fasted.[12] In this study insulin response was negatively correlated with plasma NEFA and liver triglyceride concentrations suggesting that decreased insulin response may be an important complication of negative energy balance. In the liver the glycerol may be used to produce glucose or may be recombined with FFAs to make triglycerides (TGs). In addition to being recombined with glycerol to make TGs, the fatty acids may be degraded through β-oxidation, and the two carbon fatty acids converted to acetyl coenzyme A (CoA). The acetyl CoA combines with oxaloacetate to enter the tricarboxylic acid (Krebs) cycle for the production of energy. This pathway is in competition with the use of oxaloacetate for gluconeogenesis.[2] If there is not enough oxaloacetate available, the acetyl CoA is converted to ketone bodies, which in high concentrations can reduce feed consumption and perpetuate the negative energy balance.

When the liver is overwhelmed with mobilized NEFAs, greater amounts of TGs are deposited within the hepatocytes. These TGs eventually leave the liver as very low-density lipoproteins (VLDLs), which are plasma-soluble complexes of phospholipid, cholesterol, TG, and apolipoprotein A. Hepatic lipidosis results when the rate of hepatic triglyceride formation exceeds oxidation of fatty acids and the formation and release of VLDLs into the peripheral circulation. A number of factors have been incriminated for the inability of the liver to secrete adequate VLDLs to keep up with the deposition of TGs brought about by FFA mobilization from fat. Ruminants have a poor ability to export excess lipid from the liver as VLDLs. This is particularly true in bovine hepatic lipidosis[13,14] and is theorized to result from a shortage of apolipoprotein A. Hepatic lipidosis can be induced in cows by inhibiting the production of apolipoprotein,[15] and the lowest concentrations of lipoproteins occur in the serum of cows with the most severe hepatic lipidosis.[14] Cows on low-protein diets in the dry period are more likely to develop hepatic lipidosis than those on higher protein diets, regardless of the energy content.[13] Depression in dry-matter intake in the final week before calving will increase the liver TG content after calving in dairy cows.[16] Hepatic lipidosis can be consistently reproduced experimentally in cattle by limit feeding or fasting overconditioned cows immediately after calving.[2] In the past, a lack of phospholipid or its precursor choline has been incriminated but never substantiated. However, in the face of an energy shortage, it seems redundant and a waste of energy to repackage fat and send it back to the tissues, even if the liver is being overwhelmed with fatty acids. Some of the same endocrine hormones that activate hormone-sensitive lipase and inhibit lipogenesis and glycogen synthesis may also inhibit production of VLDLs.

It has also been suggested that subclinical liver damage may inhibit the production of VLDLs, but experimental studies have indicated no significant elevation in liver-specific enzymes before lipid accumulation.[9] Function may eventually be impaired by the accumulation of fat, because fasted cows have a decrease in the surface area of rough endoplasmic reticulum and the number of mitochondria per unit volume.[17] Changes in the liver seem to be functional and not degenerative.[18] Hepatic lipidosis appears to be a reversible condition if the cause is removed and energy balance becomes positive (less negative). In cows fasted and then returned to full feed, all major liver functions returned to normal within 18 days of refeeding, and all lactating dairy cows with postparturient hepatic lipidosis had normal liver fat (<15%) content at 6 months after calving.[17]

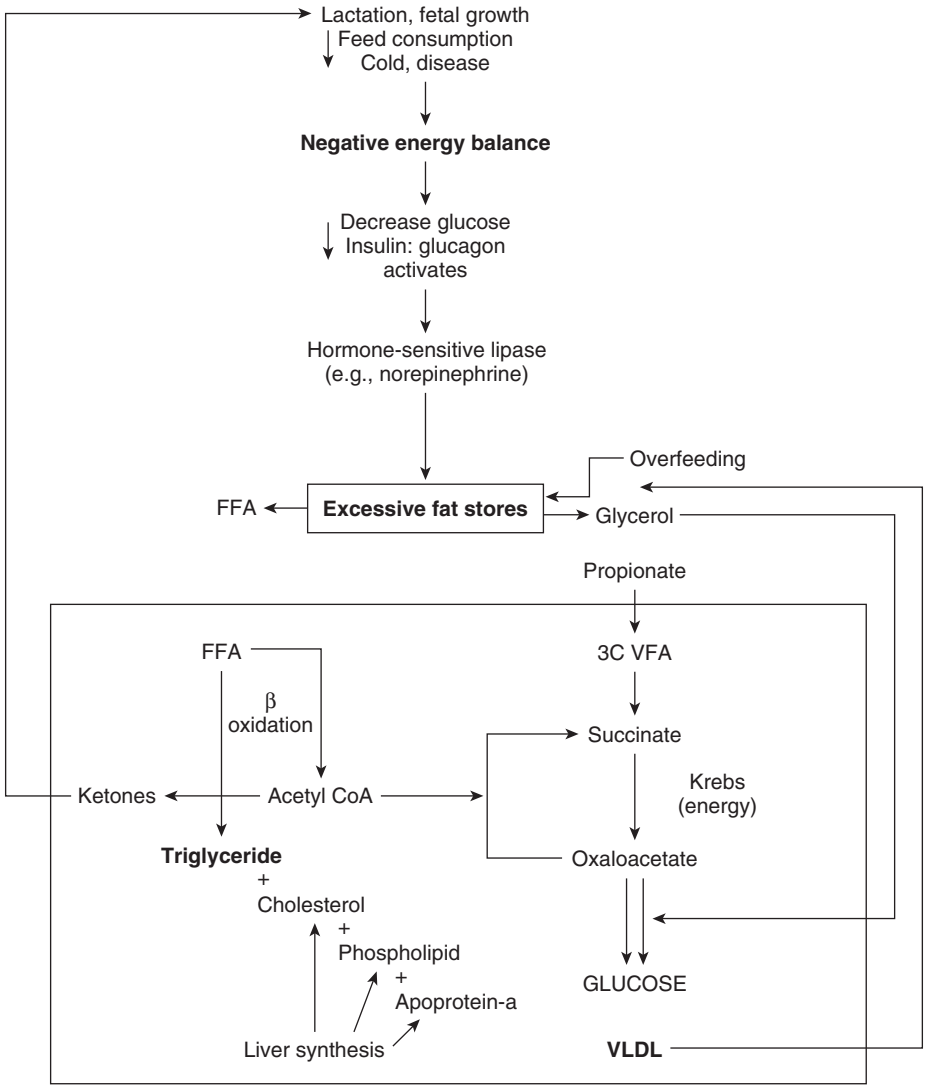

FIG. 33-8 Metabolism of fat in animals with hepatic lipidosis.

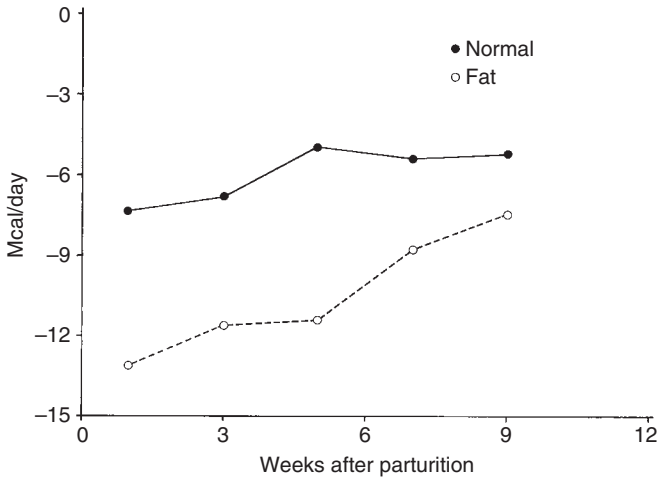

FIG. 33-9 Energy balance (megacalories per day) in normal-condition and obese dairy cows after parturition. *(From Perkins B. 1983. PhD thesis. Cornell University, Ithaca, NY.)*

All high-producing dairy cows have increased amounts of fat (15% to 32% by weight) in the liver before calving and during the first few weeks after parturition.[9,18] These fat accumulations in the liver begin before calving as the animal prepares for lactation, and the blood glucose concentration is actually lower before calving.[19] The amount of fat in the liver depends on the amount available and the extent of negative energy balance. Fatter cows tend to lose weight more rapidly and have more fat accumulation in the liver.[9]

Treatment Treatment of mild to moderate fatty liver closely parallels that of traditional ketosis. With severe hepatic lipidosis, the most important principle of therapy is elimination of negative energy balance and the factors or diseases causing it. Continual IV glucose at a rate of approximately 100 to 200 mg/kg/h may provide continuing energy and induce an insulin/glucagon ratio that will decrease hormone-sensitive lipase mobilization of fatty acids and stimulate production of VLDLs. Insulin itself may be given to alter this ratio directly. In cattle, 200 U of protamine zinc (NPH or Lente) insulin has been given every 12 hours per 1000 pounds of body weight, along with glucose. In cattle not on a continuous drip of glucose, the clinician must use insulin with caution because even low doses can result in profound hypoglycemia. Administration of glucagon at

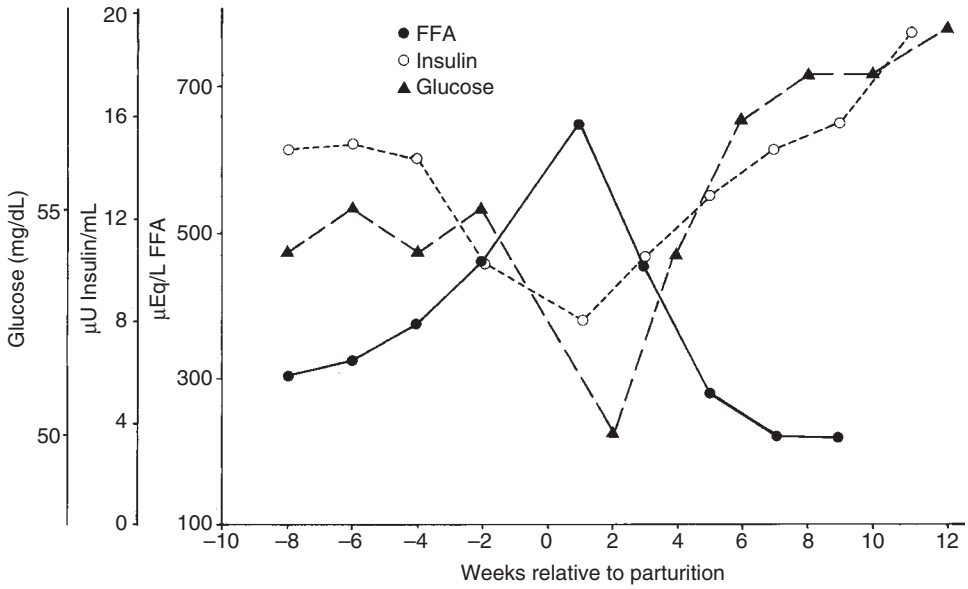

FIG. 33-10 Plasma levels of glucose, insulin, and free fatty acids *(FFA)* in dairy cows before and after parturition. *(From Perkins B. 1983. PhD thesis. Cornell University, Ithaca, NY.)*

doses of 7.5 to 15 mg/day has been shown to increase glucose and insulin concentrations and decrease plasma NEFA and liver triacylglycerol concentrations,[20] but clinical use of glucagon is prohibitively expensive. Cows with severe ketosis are generally treated with glucocorticoid injections (10 to 30 mg of dexamethasone, 2 to 5 mg of flumethasone, or 100 to 200 mg of prednisolone), with glucose precursors such as propylene glycol, glycerol, or other compounds that can be administered orally or parenterally.[3]

Precursors of lipoproteins such as choline, which is a component of phospholipid, have been advocated to increase the rate at which TGs leave the liver as phospholipids (VLDLs), but no controlled studies have proved their efficacy. Choline is degraded in the rumen,[21] but theoretically, choline chloride (25 g in 250 mL of sterile saline) given subcutaneously could have limited efficacy. Choline should *not* be given intravenously because it acts as a neuromuscular blocking agent. Addition of inositol both before and after birth did not reduce the incidence or severity of hepatic lipidosis.[22] Methionine at 40 to 50 g/day has also been used for the same purpose. Nicotinic acid (niacin) fed at 6 to 12 g/head/day may help reduce lipolysis at the tissue level and thus reduce the amount of fat presented to the liver.[23] Treatment of hepatic lipidosis with nicotinic acid is often associated with a rebound of clinical signs, and its use as a preventive measure is recommended.

Despite the treatments listed above, it is imperative to get cows suspected of having fatty liver eating again. Everything possible should be done to encourage dry-matter intake. Appetite can sometimes be enhanced by transfaunating with rumen fluid from a normal cow. This may increase the absorption of volatile fatty acids used for energy and for glucose precursors. Prognosis must be guarded unless the concurrent diseases can be treated successfully and the liver fat mobilized. It is most important to treat the primary disease. Reducing the negative energy balance and treating the hepatic lipidosis must be attacked vigorously.

Prevention Prevention is based on preventing overconditioning during the late lactation period and dry period and treating periparturient diseases in a timely manner. Hepatic lipidosis and associated conditions are most common in dairy cattle. Preventing obesity in cows during late lactation is an important factor in controlling this disease. This process involves a successful breeding program (maintaining a 12- to 13-month calving interval) and closely matching energy in the ration to the level of milk production during late lactation. Once the cow reaches 7 months of pregnancy and the dry period, any dietary restriction below requirements for maintenance and pregnancy are certain to be counterproductive.

Prevention of hepatic lipidosis involves minimizing or eliminating the primary risk factors associated with disease both pre- and postpartum. The primary prepartum risk factors for fatty liver include obesity (body condition score ≥ 4.0), severe feed restriction, feeding excess energy, and long calving interval. Postpartum risk factors include other concurrent diseases, anorexia or fasting, feed restriction, and sudden feed changes.[3] Adequate protein in the dry period is essential.[11,15] It has been shown that cows fed higher-protein diets during the dry period will perform better in the lactation that follows. Feeding good-quality to excellent-quality roughages (hay, silages) to meet most of these requirements is preferred. Additional grain 2 to 4 weeks before parturition is important to acclimate the ruminant to anticipated changes in the rations fed after calving. It must be stressed that high-quality dry cow rations be fed *but not overfed.* Dry-matter consumption should be limited to approximately 2% of body weight per day while meeting requirements. Other factors in the dry cow ration also must be considered to prevent periparturient diseases such as milk fever, displaced abomasum, mastitis, metritis, ketosis, ruminal lactic acidosis, and retained placenta. Rations should be adequately supplemented with cobalt, the precursor of vitamin B_{12} that is a cofactor in the rate-limiting step in conversion of propionate (the primary glucose precursor) to succinyl CoA. Nicotinic acid has been included in the dry cow ration at 6 g/head/day and in the early-lactating cow ration at 12 g/head/day to aid in the prevention of ketosis, which is a major risk factor for the development of hepatic lipidosis. The use of monensin in the dry cow ration and the early-lactation ration shows promise to aid in preventing ketosis and thus may be of some benefit in preventing hepatic lipidosis.[24,25] Other approaches such as sodium borate or administration of glucose precursors in the dry period have also been attempted.[3]

Immediately and aggressively treating cows (particularly obese cows) for other diseases that occur after calving is important in preventing fatty liver. This includes both infectious diseases (e.g., mastitis, metritis) and metabolic diseases like hypocalcemia. It is important to limit stress on fresh cows and provide adequate bunk space, good ventilation, and high-quality feed. Anything possible to encourage dry-matter intake is important. Several different therapies have been promoted to improve the metabolic state of cows during late gestation by supplying an extra source of glucose and decreasing the mobilization of NEFAs from fat. For example, subcutaneous injections of glucagon beginning 2 weeks prior to calving increased

VetBooks.ir

glucose and insulin concentrations and decreased plasma NEFA levels in a model of hepatic lipidosis.[26] Slow-release doses of insulin (0.14 IU/kg) have also shown some efficacy in preventing triacylglycerol accumulation in the liver, but higher doses (0.29 IU/kg) can result in profound hypoglycemia.[27] Growth hormone had no beneficial effect.[28]

Protein-Energy Malnutrition/Pregnancy Toxemia of Beef Cows

Protein-energy malnutrition (PEM) and pregnancy toxemia of beef cows are conditions of pregnant beef cattle on marginal diets, usually occurring in the winter and characterized by weight loss, weakness, depression, and sometimes inability to rise. The condition is the result of the negative energy balance caused by decreased quality and quantity of feed when caloric requirements are increased by fetal development and cold weather. Growing, pregnant heifers are especially susceptible because energy requirements for growth are superimposed on the other caloric requirements. A number of other factors, such as unpalatable feed, snow cover, and diseases, may reduce caloric intake. Fatty infiltration of hepatocytes occurs transiently in early PEM, and at necropsy the liver is smaller than normal.

Animals are usually thin and have a long hair coat. In some cases they are down and unable to rise but are still alert. The body temperature may be normal or subnormal. Occasionally the cows also develop diarrhea. Most animals die 7 to 14 days after becoming recumbent.[29] Differential diagnosis includes Johne's disease, lymphosarcoma, parasitism, chronic pulmonary disease, other deficiencies, and debilitating diseases.

Diagnosis Diagnosis is usually based on demonstrating decreased caloric intake and ruling out other chronic diseases that could cause debility. Laboratory tests support but do not rule out the disease. Total serum calcium may be decreased. Packed cell volume also may be decreased, and serum insulin levels may be reduced. Ketonuria is not typical in PEM. At necropsy, muscle mass usually is decreased. Serous (brown) atrophy of fat is often present, especially in the coronary groove, bone marrow, and perirenal areas. Lesions of concurrent disease also may be found if PEM is acute, and a fatty yellow liver may be noted.

Treatment Treatment is often unrewarding. Efforts to reverse an advanced catabolic state may fail. A 454-kg cow requires 13 Mcal of metabolizable energy daily, or approximately 6.5 L of 50% glucose solution by continuous drip. Alfalfa pellet gruels are helpful if force-fed, and approximately 11 kg/day of alfalfa is recommended. Propylene glycol (150 to 200 mL) orally twice daily can be helpful as a glucose precursor. Treatments include IV fluids, improving the energy balance, and treating any concurrent disease.

Prevention Nutrient requirements increase greatly for beef cattle during the third trimester of pregnancy. As forage quality (digestibility) decreases, the time feed material stays in the rumen increases (increased rumen turnover time). Therefore, as quality decreases, the maximum dry-matter intake (DMI) decreases, which greatly decreases the maximum nutrient (energy) intake. This compounding effect of poor-quality forage on maximum intake is particularly important for preventing hepatic lipidosis and the accompanying protein-calorie malnutrition (PCM) of pregnant beef cattle in the winter. The approximate maximum DMI of forage of poor quality (oat straw, corn stover), medium quality (meadow grass hay), and excellent quality (alfalfa hay [25% crude fiber], corn silage) is 1% to 1.5%, 2%, and 2.5%, respectively. Environmental temperature can increase energy needs for beef cattle on pasture or range; as the temperature falls from 20° C (68° F) to 10° C (50° F), roughly 10% more energy is necessary for maintenance, and at freezing temperatures, 0° C (32° F), 20% additional energy is required. The key to preventing PEM in pregnant beef cattle is adequate body condition (scores 5 to 7) entering the third trimester and availability of good-quality to excellent-quality forage in adequate amounts.

Pregnancy Toxemia in Ewes and Does

Pregnancy toxemia, also known as *ketosis* or *twin-lamb disease,* is a condition occurring in ewes and does during the last 2 to 4 weeks of gestation. It is characterized by anorexia, weakness, and depression. Nearly 80% of the fetal growth occurs in the last 6 weeks of gestation, which can result in a negative energy balance occurring from the increased energy demands of rapid fetal growth in late gestation and insufficient feed intake. The incidence of pregnancy toxemia is greater in ewes with more than one fetus, during the last 2 to 4 weeks of gestation, and in does with three or more fetuses.[30] Poor-quality feed, cold weather, lack of exercise, and stress of movement also may increase the incidence. Many ewes are overly fat initially. Does seem to be more resistant to pregnancy toxemia than ewes, in that three or more fetuses are usually required to produce the condition.

Animals with pregnancy toxemia are usually separated from the rest of the flock or herd. They have a poor appetite, and many appear blind. They eventually become more depressed and recumbent. Neurologic signs such as tremors, star-gazing, incoordination, circling, and grinding the teeth may precede terminal depression. Differential diagnosis includes other periparturient diseases, such as mastitis and hypocalcemia, as well as polioencephalomalacia, enterotoxemia type D, and toxicoses.

Diagnosis Ketonuria is usually present and detected before ketonemia. Hypoglycemia is not a consistent finding but is sometimes present. The ewes and does often are generally acidotic and may have lowered serum calcium and potassium levels.[31] Blood urea nitrogen (BUN) and creatine levels are elevated terminally in some cases. Fatty acid concentrations in the plasma are usually elevated above 500 μEq/L. Serum β-hydroxybutyrate concentrations are elevated (>1 mmol/L).[32] A nonspecific but marked neutrophilia may be found in some affected animals and is particularly dramatic in does, sometimes reaching 35,000 neutrophils/μL.

Treatment Treatment of pregnancy toxemia is based on two principles: (1) administering exogenous energy sources (i.e., glucose) and (2) removing the factors increasing the energy demand on the animal (i.e., fetuses). Mortality is high unless treatment is started early and the fetuses are removed—the most important step—either by inducing parturition or by cesarean section. Parturition can be induced in ewes with 15 to 20 mg of dexamethasone; in does the dose is either 10 mg of dexamethasone or 10 μg of prostaglandin $F_{2\alpha}$.[30,33] A cesarean section may be performed if the animal's value warrants it and there does not seem to be enough time to induce parturition. Besides removing the fetuses, the ketotic condition should be treated with IV glucose (250 to 500 mL of 10% to 20% glucose as an IV bolus followed by a slow IV drip of 5% to 10% glucose). Acidosis and hypocalcemia must be corrected if present. Administration of oral propylene glycol as a glucose precursor has also been advocated. Although recommended doses vary, an initial treatment of 2 doses (150 to 200 mL) given at a 12-hour interval followed by 60 mL per dose thereafter for 3 to 6 additional days appears to work well.[33] Giving recombinant bovine somatotropin at a dose of 0.15 mg/kg of body weight also has shown some benefit.[34] The energy intake must be increased. If the ewe is down and unable to stand, removal of the fetuses should be performed by cesarian section as soon as possible. In such cases the prognosis is often poor, so euthanasia of the ewe or doe must be considered. Immediately after parturition or cesarian section, the animal should be started on broad-spectrum antibiotics along with flunixin to prevent metritis.[33]

Prevention Preventing pregnancy toxemia and the associated severe hepatic lipidosis in ewes and does requires measures similar

VetBooks.ir

to those outlined for PCM in beef cattle. Both overconditioned and thin ewes and does in the third trimester of pregnancy are at increased risk. Because of the common occurrence of twins and triplets, nutrient requirements for pregnant ewes greatly accelerate during this period. Good-quality to excellent-quality forage for feeding sheep is very important. An additional tool for diagnosing underfeeding in ewes is measurement of plasma β-hydroxybutyrate (BHB). This test greatly facilitates assessment of nutritional inadequacy in pregnant ewes. Plasma BHB concentrations of 0.8 mmol/L or higher are diagnostic of the need for increased energy consumption by pregnant ewes. Does have been shown to have a significant decrease in blood pH, bicarbonate concentration, and base excess values well in advance of the clinical signs associated with pregnancy toxemia.[31] Therefore these parameters could also be early indicators of disease in pregnant sheep or goats.

Hyperlipemia/Hypertriglyceridemia in Ponies

Hyperlipemia is a life-threatening condition that occurs in horses, ponies, and occasionally in donkeys.[35-37] It is characterized by a fatty liver and serum that is cloudy with accumulation of lipids. TGs are usually much higher than 500 mg/dL.[35] The condition is caused by decreased caloric intake, which causes fat mobilization and fat accumulation in the liver and accumulation in the plasma. The decreased food intake may be secondary to other diseases. Suggested predisposing factors include hypophagia, pregnancy, or lactation, often in obese ponies, American Miniature horses, or donkeys.[36-38] The incidence of hyperlipemia is greater in ponies than in horses. It is seen more often in the winter, especially from February to May in animals receiving poor feed. Pregnant animals and those that are lactating are affected more frequently.

Equine hyperlipemia is characterized by production of an abnormal very low-density lipoprotein (VLDL) fraction ($VLDL_1$) that has a reduced content of apolipoprotein B-100 and an increased content of apolipoprotein B-48.[39] The substitution of B-48 for B-100 is thought to allow greater TG content because B-48 is the apolipoprotein of importance in chylomicrons. The activities of lipoprotein lipase and hepatic lipase, the enzymes responsible for VLDL catabolism, were increased in hyperlipemic ponies.[39] It was concluded that overproduction of VLDL is the cause of hyperlipemia, possibly complicated by defective catabolism.

Hyperlipidemia is a mild condition of ponies and horses characterized by mildly elevated TG concentrations (>500 mg/dL), clear plasma, and no evidence of hepatic dysfunction.[35] An increase in caloric intake is usually sufficient to reverse the condition. The more severe condition, hyperlipemia, is discussed further.

Clinical Signs The clinical signs of hyperlipemia are nonspecific. Ponies usually are anorexic, depressed, weak, and uncoordinated. Diarrhea, colitis, and abdominal pain are frequently seen in presenting cases.[40]

Diagnosis Diagnosis is based on examination of the blood and plasma to detect the white to yellow opacity caused by the presence of lipids. Bilirubin usually is elevated, as in most horses that are fasted. TGs are increased to above 500 mg/dL in hyperlipemia, and fatty acids are also increased. Bromosulfophthalein clearances are delayed, and terminally a large base deficit may be caused by metabolic acidosis.[35]

Postmortem examination reveals fatty infiltration of the liver and kidneys, which are pale and swollen and have a greasy texture. In ponies the liver is sometimes ruptured, resulting in intraabdominal hemorrhage and death. Renal lesions may be seen histologically. There may be a primary disease that produces anorexia and secondarily has resulted in hyperlipemia.

Treatment It is most important to treat any primary disease to alleviate the cause of anorexia and correct the negative energy balance. Nutritional support is critical, either in the form of dextrose-supplemented fluids or partial parenteral nutrition. Heparin is also recommended in some cases and has been shown to decrease triglyceride concentrations in affected horses.[40] Regular insulin (0.2 IU/kg) every 3 to 6 hours can be used initially for severely lipemic animals; however, this is usually discontinued within 24 hours and a longer-acting product used for maintenance. Protamine zinc insulin (PZI) has been used at an intramuscular (IM) dose of 30 IU twice daily with 100 g of PO glucose for a 200-kg pony. This is continued on odd days; on even days, IM injections of 15 IU of PZI are given twice daily.[35] Ultralente insulin can be given at a dose of 0.4 IU/kg SC q24h.[40] A slow IV drip of glucose for several days or until lipemia clears may be indicated. Heparin (100 to 250 IU/kg twice daily) has been used to alter the lipoprotein lipase activity and inhibit hormone-sensitive lipase of adipose tissue, but it may alter coagulation enough to cause hemorrhage.

The presence of hyperlipidemia is readily detected and easily solved by increasing caloric intake. Although therapy of hyperlipemic ponies and horses is often unrewarding, the diagnosis is relatively straightforward, and prevention depends on providing adequate feed of good quality.

Congenital Hyperbilirubinemia

Geof W. Smith

Gilbert Syndrome

Gilbert syndrome is an unconjugated hyperbilirubinemia in the presence of normal erythrocyte lifespan. It occurs occasionally in humans and has been described in Southdown sheep.[1] Gilbert syndrome involves a failure of unconjugated bilirubin to cross the liver cell membrane and be conjugated. This is most likely caused by a defect in carrier proteins or the conjugating enzyme.[2] Hepatic bilirubin clearance is about 30% of normal when tested with a loading dose of radiolabeled bilirubin.[3]

Affected Southdown sheep may show icterus or at least elevated plasma bilirubin levels, both conjugated and unconjugated. Affected sheep also cannot excrete bromsulphalein (BSP) into the bile. No histopathologic lesions are present, other than some pigment in the hepatocytes. The condition is inherited as an autosomal dominant trait in humans.[2] The bile acid levels are normal in humans, but one sheep exhibited defects in hepatic bile acid clearance.[4]

Dubin-Johnson Syndrome

Dubin-Johnson syndrome is a failure of conjugated bilirubin to enter the bile canaliculi. This has been diagnosed sporadically in humans and in Corriedale sheep.[5] There may be an impairment not only in bilirubin but also in excretion of other conjugated organic anions. Sheep affected by this syndrome may be jaundiced or have hyperbilirubinemia. Both conjugated and unconjugated bilirubin are increased, and BSP clearance is delayed. Bile acids are reported to be normal in humans, but delayed clearance was reported in three Corriedale sheep.[4] Histologically, the hepatocytes contain a black, melanin-like pigment.[5]

Persistent Hyperbilirubinemia in Thoroughbreds

A persistent hyperbilirubinemia has been reported in a Thoroughbred racehorse that had no evidence of liver damage, cholestasis, or hemolysis and was not fasting.[6] The horse was persistently icteric and had serum total bilirubin concentrations of 8.7 to 9.4 mg/dL; 90% or more of the plasma bilirubin was the unconjugated form. Serum bile acid concentration, along with the liver enzymes GGT, AST, and IDH (SDH), were within normal limits. The horse acted clinically normal, and the plasma fatty acid concentration was also within normal

VetBooks.ir

limits. The condition was similar to Crigler-Najjar type II syndrome in humans, which involves a deficiency in bilirubin-uridine diphosphate glucuronyltransferase needed to conjugate bilirubin, but this was not verified.

Miscellaneous Liver Diseases

Geof W. Smith

Rift Valley Fever

Rift Valley fever, also known as *enzootic hepatitis,* is an acute febrile arthropod-borne disease of sheep, goats, cattle, and humans present in most countries of sub-Saharan Africa. With the current threat of bioterrorism, it could appear in other parts of the world.[1,2] Rift Valley fever is caused by a virus of the genus *Phlebovirus.* More than 20 species of mosquitoes have been implicated as possible vectors for the virus, including some North American mosquitoes that are competent laboratory vectors.[2] The disease causes abortion in pregnant females and a febrile condition with rapid death in lambs, kids, and calves. The mortality rate in young animals approaches 100% but it is much less (20% to 30%) in older animals.[2] Clinical signs may include fever, anorexia, weakness, salivation, diarrhea, and sometimes abdominal pain, and almost all pregnant animals will abort. The primary gross lesion is hepatomegaly and hemorrhage. Histologically, a focal hepatic necrosis is identified, and eosinophilic intranuclear inclusion bodies are present. Confirmation of the diagnosis is made in the laboratory by virus isolation or immune tests. If the disease is suspected, state and federal regulatory veterinarians should be contacted.

Telangiectasia

Hepatic telangiectasia, commonly known as *sawdust livers* in packing houses, is a focal degeneration in liver lobular circulation characterized by red-brown foci 1 to 5 mm in diameter. These lesions account for more than 10% of the bovine liver condemnations but do not result in any clinical signs.[3] Microscopically, hepatocytes are distorted and sinusoids congested.[4] Hypotheses proposed to explain the pathogenesis of the lesions include necrotizing hepatitis, ischemia induced by emboli or other vascular pathologies,[5] dilation of Disse spaces, reduced density of the reticulin framework, vitamin E–selenium deficiency, alteration of the sinusoidal barrier, and immune-mediated disease.[3] Some human pathogens have been isolated from these livers as well as normal livers, but livers are condemned on the basis of aesthetics according to current U.S. Department of Agriculture (USDA) regulations.[3]

Ischemia, Hypoxia, and Congestion

Ischemia and hypoxia can lead to death of hepatocytes, but less severe insults cause fatty infiltration because lipoprotein synthesis depends on oxidative metabolism. This damage is more apparent in the centrilobular areas, which are the last to receive blood and oxygen. Chronic passive congestion causes the grossly visible "nutmeg liver," caused by distention of the sinusoids and central veins with blood. The liver may be enlarged in these cases, but other signs related to the liver are not usually present. More significant findings will be detected in the cardiovascular system.

Fetal Liver Damage

The liver of the fetus may be damaged by infectious and toxic agents, but the result is usually abortion or birth of a weak neonate with signs related to other systems. The lesions in the liver may be diagnostic of the disease. Equine herpesvirus infection of the fetus causes hepatocyte necrosis, with acidophilic intranuclear inclusion bodies in more than 50% of the hepatocytes. Aborted fetuses of cattle with infectious bovine rhinotracheitis may have some focal necrosis of the liver, but this is not enough to be diagnostic.

Failure of Drug Metabolism and Excretion

Jennifer L. Davis

Hepatic disease can affect drug metabolism in several ways. Ascites, if present, can alter drug disposition, and drug dosages should be adjusted based on lean body weight, taking into account the amount of fluid present.[1] Also, since the liver is the primary organ involved in the metabolism of exogenously administered substances and represents an important method for excretion of drugs via the bile, liver disease can affect drug metabolism and clearance.

Factors influencing hepatic drug metabolism and clearance include hepatic blood flow, hepatic metabolism, and protein binding. Drugs are often classified as having high hepatic extraction ratios (flow-limited drugs) or low hepatic extraction ratios (capacity-limited drugs). Flow-limited drugs are quickly and efficiently extracted by the liver, and their rate of elimination is limited only by hepatic blood flow. Chronic liver disease with decreased parenchymal blood flow or hepatic shunts can decrease blood flow in the liver and greatly compromise clearance of flow-limited drugs like morphine, verapamil, and lidocaine.[1] These drugs undergo a high first-pass metabolism following oral administration and, as such, are usually given at high oral doses. The dosage of these drugs may need to be decreased by up to 50% in patients with liver disease, because bioavailability will be greatly increased and elimination decreased, possibly resulting in toxic levels of the drug.[1,2] The opposite may be true for drugs that require hepatic activation, and thus subtherapeutic levels may be present.[3]

Capacity-limited drugs are slowly extracted by the liver, and their elimination is independent of blood flow but highly dependent on hepatocellular uptake and metabolism. The effect of liver disease on drug metabolism in these cases is more variable, and drug clearance can be increased, as with atenolol, or decreased, as with diazepam and chloramphenicol.[1,2] The majority of phase I (oxidation-reduction) reactions and phase II (glucuronidation) reactions take place in the hepatocytes, and diseases that result in hepatocellular destruction can reduce the ability of the liver to metabolize drugs. The purpose of these reactions is to make compounds more water-soluble and prepare them for excretion via the kidney. Clearance of drugs eliminated by phase I reactions can be significantly decreased with hepatic disease, whereas phase II reactions are often not affected unless severe disease is present or certain types of glucuronidation are needed.[4,5] For example, ester glucuronidation will be decreased in patients with cirrhosis of the liver and have a lower clearance rate compared to drugs metabolized by ether glucuronidation.[4]

Humans with intrahepatic cholestasis showed a decreased activity of phase I cytochrome P450 enzymes and impaired microsomal drug metabolism in vitro, and this was well correlated with serum concentrations of total bilirubin and bile acids.[6] Making direct correlations between human drug metabolism and veterinary species is difficult, however. Recent work shows a large interspecies variation in the types and activity of hepatic metabolizing enzyme among humans, horses, and cattle.[7,8] Further classification of the equine and bovine P450 enzymes and their roles in drug metabolism are needed.

Cholestatic diseases have been shown to decrease biliary excretion of a number of drugs in both animal models of disease and human patients with naturally occurring biliary obstruction. Increased plasma levels, prolonged mean residence times, increased area under the concentration-time curve, and decreased total body clearance have all been demonstrated.[9-11] In horses administered enrofloxacin intravenously, those animals with GGT activity greater than 200 U/L had a lower clearance and higher area under the curve than horses with GGT activity less than 200 U/L.[12] Renal clearance of some drugs may be increased as a compensatory response for the impaired biliary excretion, as is the case with cefpiramide in cholestatic human patients.[13] This decreased biliary clearance can be

VetBooks.ir

used to an advantage in certain instances when treating biliary tract infections in order to attain higher concentrations of the drug in the bile ducts, as long as the drug has a large therapeutic index.[13]

A deficiency in hepatic drug metabolism capacity may impair drug metabolism and elimination in young animals. This has been demonstrated in foals administered chloramphenicol, which is extensively metabolized in the liver via glucuronic acid conjugation and primarily excreted through the biliary system into the feces. Clearance was decreased and half-life prolonged in animals less than 1 week of age.[14] Nonsteroidal antiinflammatory drugs (NSAIDs) also show impaired metabolism in neonatal foals. Phenylbutazone, ketoprofen, and flunixin meglumine all have prolonged terminal half-lives over the first few weeks of life.[15-17] Neonatal foals also have a low capacity to metabolize enrofloxacin to ciprofloxacin, whereas in adult horses ciprofloxacin concentrations are about 17% of the enrofloxacin concentrations.[18] Drug metabolism also differs in neonatal calves and sheep, which may result in prolonged withdrawal times necessary for veal calves and lambs. Studies have shown that hepatic metabolic enzymes are similar to adult levels in sheep and calves by 7 days of age.[19,20] At this point, no quantitative research has been performed that specifically examines the development of metabolic pathways in the neonatal foal. It is likely these are decreased in the early stages but rapidly develop and are within a range similar to adult horses within the first 1 to 4 weeks of life, as is seen in other veterinary species.

Neoplasia of the Liver

Geof W. Smith

Primary neoplasia of the liver is uncommon in large domestic species. Only 0.011% of slaughterhouse animals seen in one study had liver tumors.[1] Metastatic tumors such as lymphoma are more common (Fig. 33-11), but the clinical signs of these are more likely to reflect changes at the primary site. Metastasis of lymphosarcoma in cattle is most common, but signs produced by growth in other organs (e.g., lymph nodes, abomasum, heart, uterus, spinal cord) are more predominant. In the horse, lymphosarcomas and carcinomas have metastasized from the digestive tract.[2]

Horses

Although uncommon, a number of different primary hepatic neoplasias have been reported in horses.[3,4] The nomenclature seems inconsistent throughout the years of reporting, and the signs are usually more consistent with neoplasia in general than with hepatic failure. Weight loss, weakness, anorexia, lethargy, and occasionally colic may be seen in these animals. Serum concentrations of liver-derived enzymes are elevated in many cases. The tumor can often be located by ultrasonography, but the definitive diagnosis of the type of tumor is based on histopathologic examination of biopsy tissue.

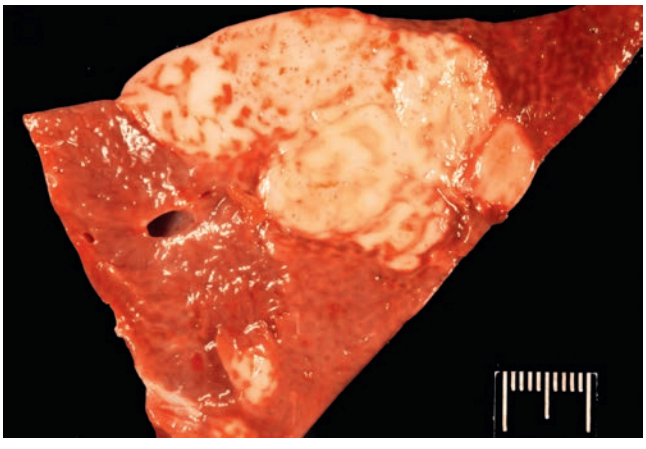

FIG. 33-11 Lymphoma in the liver of a horse. *(Photo courtesy Luke Borst, North Carolina State University.)*

Hepatoblastoma has been reported in foals, young horses, and an equine fetus.[4,5] Young horses present with weight loss or failure to grow, lethargy, anorexia, and possibly icterus. Serum concentrations of several hepatic enzymes are increased. Ultrasonography reveals hepatomegaly and a heterogeneous appearance of the hepatic parenchyma. Erythrocytosis is seen in some cases because of a paraneoplastic syndrome and increased production of erythropoietin.

Hepatocellular carcinoma is seen in both old and young horses. These horses lose weight and are listless. Serum concentrations of LDH, GGT, and AST are often elevated. Erythrocytosis with a normal concentration of serum protein is seen in most cases as a result of paraneoplastic syndrome with elevated erythropoietin.[3,4,6]

Cholangiocarcinoma or cholangiocellular carcinoma arises from the intrahepatic bile duct epithelium and appears to be a disease of older horses.[4,7] Lethargy, fever, abdominal pain, anorexia, and ventral edema have been reported with this tumor. Some of these animals have anemia rather than the erythrocytosis reported with hepatocellular tumors. GGT and ALP concentrations may be elevated, but IDH (SDH) comes from hepatocytes and is usually within normal range.

Cattle

In addition to the lymphosarcomas, primary hepatocellular carcinomas have been described in cattle.[8] The most common presenting clinical signs are anorexia and weight loss of weeks to months in duration.[9] Liver-derived enzymes are generally elevated, and polycythemia (erythrocytosis) is a common laboratory finding in these cases.[9,10] Ultrasound of the liver may be helpful in diagnosing hepatic tumors in cattle.[9]

Hemochromatosis

Hemochromatosis is a disorder caused by deposition of hemosiderin in the parenchymal cells, resulting in tissue damage and dysfunction of the liver and other tissue. It is most frequently seen in humans and mynah birds, but hemochromatosis has been described as a new disease of Salers cattle[11] and has been reported in three horses.[12] In humans the types include idiopathic hemochromatosis, an autosomal recessive familial condition associated with increased iron stores, cirrhosis, and saturation of the iron transport capacity.[13] Both horses and cattle show increased iron deposits in the liver; histopathology of liver biopsy specimens reveals brown pigment that stains for iron in the hepatocytes as well as Kupffer cells. An increased concentration of iron can be measured in the liver, and there is fibrosis and elevated liver-derived enzymes.

In Salers cattle the condition appears to be a homozygous recessive condition more like the human familial type. There is an inappropriate absorption of iron by the GI tract, with subsequent hepatic storage (iron overload) and eventual loss of hepatic function. It has been reproduced by experimental breeding in Salers cattle.[14] The primary clinical signs in cattle are decreased weight gains, poor body condition, dull hair coat, loss of incisor teeth, and sometimes diarrhea. Serum concentrations of liver enzymes are elevated, and there is marked hepatic fibrosis, in addition to the hemosiderin deposits in the liver. Total serum iron, total iron-binding capacity (TIBC), and saturation of transferrin (>60%) are increased, similar to the familial disease in humans. Liver iron concentration will be greater than 5000 μg/g (ppm) on a wet basis (normal herdmates of affected cattle, 84 to 100 ppm).

Horses with hemochromatosis present with evidence of liver disease. Serum concentrations of the liver enzymes ALP, GGT, and AST are elevated, and serum total bile acids are greater than 40 μM/L. In the cases reported, total serum iron was not elevated, and unlike the idiopathic human condition or the cattle cases, there was no saturation of the iron-binding capacity. Total liver iron has been as high as 6700 ppm (normal, 100 to 300 ppm).[12]

Hemochromatosis should be suspected in animals with emaciation or elevated liver enzymes and in Salers cattle with greater than

VetBooks.ir

60% saturation of transferrin. It can be confirmed by histopathologic examination of the liver, with excessive iron accumulation in hepatocytes. Clinicians should differentiate hemochromatosis from hemosiderosis, in which iron accumulates in the reticuloendothelial system and not hepatocytes, and which can be caused by hemolysis and other conditions.

In humans, hemochromatosis is treated by reducing the iron stores through phlebotomies and blood removal. The one horse on which this was tried had advanced disease with severe cirrhosis, and it succumbed a few days after the blood removal. Removal of 160 L of blood over 12 months failed to reduce liver iron concentration in one heifer[11] but produced some improvement in other calves.[14] Deferoxamine is given to some human patients to induce a negative iron balance and reduce the rate at which iron accumulates.

Gallbladder and Biliary Tract Disease

Jennifer L. Davis

Biliary tract disease in large animal medicine is rare and results from both intrahepatic and extrahepatic causes. Intrahepatic causes of cholestasis include cholangitis, cholecystitis, choledocholithiasis, and presence of a foreign body. Extrahepatic causes include abscess formation, obstructive or inflammatory intestinal disease, and neoplasia.

Choledocholithiasis, Cholelithiasis, and Hepatolithiasis[§]

By definition, *cholelithiasis* describes the presence of biliary calculi in either the bile ducts or gallbladder, whereas *choledocholithiasis* describes stones found in the common bile duct. *Hepatolithiasis* indicates the presence of calculi in the intrahepatic bile ducts above the right and left hepatic ducts and is a variation of cholelithiasis. These conditions have been described in horses, cattle, sheep, and pigs, but they do not seem to be recognized as a clinical problem in sheep, and rarely in cattle.[1-15] Choledocholithiasis is the most common cause of biliary obstruction in large animals and occurs more frequently in horses.[1-9]

Biliary stone formation begins with precipitation or aggregation of normally soluble components of bile. Other mechanisms involved in the pathogenesis include ascariasis, ascending biliary infection or inflammation, biliary stasis, changes in bile composition, and presence of a foreign body.[14] Several pathogenic bacteria *(Salmonella* spp., *E. coli, Aeromonas* spp., *Citrobacter* spp., group D *Streptococcus* spp., *Clostridium perfringens)* have been cultured from the bile ducts of horses and cows with cholelithiasis.[2,6,9,16] Whether these bacteria were the cause or the result of the stone formation remains unclear. In most reports the chemical analysis has shown that choleliths have a mixed composition, containing bilirubin, bile pigments, cholesterol esters, esters of cholic and carboxylic acid, calcium phosphate, and sodium taurodeoxycholate.[6,8,9] In one study, 80% of the choleliths contained less than 10% cholesterol.[9]

Cholelithiasis should be suspected in horses when a triad of clinical signs exists: recurrent abdominal pain, intermittent pyrexia, and icterus. Hyperammonemic hepatic encephalopathy, photosensitization, and weight loss are other, less common features of cholelithiasis.[3,5,6,14,16] A subclinical presentation due to partial obstruction of the biliary tree may be recognized only on postmortem examination.[11] A large cholelith was the cause of duodenal obstruction in a horse presented for colic.[12]

Elevations in the serum activity of ALP, AST, GGT, IDH (SDH), and total bilirubin are associated with cholelithiasis.[3,6,9,14,16] The rise in total bilirubin is due to an elevation in both direct and indirect bilirubin. In the horse, cholestasis should be suspected if more than 25% to 30% of the total bilirubin is the direct type.[1] Serum bile acid concentrations also increase when bile flow is obstructed. Other laboratory abnormalities that may be seen include hyperammonemia, increased urine bilirubin, and prolonged partial thromboplastin and thrombin times.[5,6,9] The most common alterations in the leukogram include a neutrophilic leukocytosis. Elevations in globulin and fibrinogen may also occur.[5]

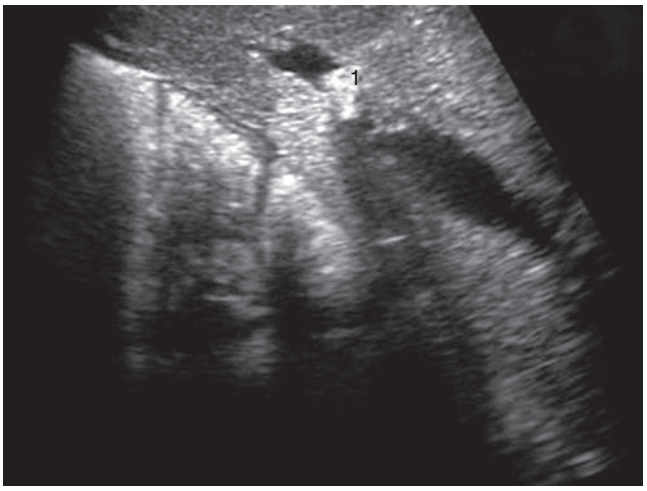

FIG. 33-12 Ultrasound image of a cholelith taken from the right side of a horse. Note the hyperechoic stone *(1)* visible inside of a distended bile duct. Hyperechoic parenchyma is also noted beneath the stone, which may represent hepatic fibrosis.

Ultrasound examination of the liver is a safe, noninvasive tool for diagnosing cholelithiasis. Hepatomegaly and bile duct dilation are seen in horses with biliary calculi. The echogenicity of the hepatic parenchyma is increased compared with that of normal horses and may approach that of the spleen. The bile ducts are thick and distended. The *parallel channel sign* (dilation of interhepatic biliary radicals adjacent to the portal vein) may also be seen. Several choleliths are generally seen, but a single stone may be present (Fig. 33-12). Choleliths may be hyperechoic, casting acoustic shadows, or they may be sonolucent. Choleliths are most likely to be visualized in the cranioventral part of the right hepatic lobe, especially in the sixth to eighth intercostal spaces. Cholelithiasis can accurately be diagnosed by ultrasound in at least 75% of horses if an adequate scanning image of the liver is obtained and bile duct dilation and choleliths are visualized.[8]

The differential diagnosis for a horse with the clinical signs associated with cholelithiasis include other causes of liver disease and mild recurrent abdominal discomfort, including verminous arteritis, mesenteric abscesses, sand enteropathy, enterolithiasis, abdominal neoplasia, and urolithiasis.[3]

Hepatomegaly is usually noted at necropsy, although a shrunken liver may be observed. The liver is firmer than normal, has a consistent texture, and varies in color from red to green-brown. The hepatic ducts and common bile duct are generally dilated and may contain the calculi (Fig. 33-13). Histologically, periportal fibrosis is a common finding. Bile duct stasis and hyperplasia are usually noted; suppurative cholangitis is less common.[9,14,16]

Treatment of cholelithiasis initially includes broad-spectrum IV antibiotics (penicillin plus gentamicin or enrofloxacin) and oral metronidazole. This is followed by long-term oral antibiotics, based on culture and sensitivity if available. If culture and sensitivity results are not available, treatment should be aimed at suspected gram-negative enteric bacteria or anaerobes. Potentiated sulfonamides or enrofloxacin plus metronidazole are good choices. Chloramphenicol has a good spectrum against most cultured bacteria, but since it is highly metabolized by the liver, it should not be used if hepatic function is severely compromised. Antibiotic treatment should continue for

[§]Contributions to previous editions by Terry C. Gerros are acknowledged.

VetBooks.ir

FIG. 33-13 Multiple choleliths present with the bile ducts of a horse.

6 weeks past the time when GGT values return to normal. DMSO (0.5 to 1 g/kg IV as <10% solution for 3 to 5 days) has also been recommended as a treatment to help dissolve intrabiliary sludge or small calcium bilirubinate stones. DMSO may cause hemolysis at higher concentrations, and horses with liver disease may already have fragile RBCs, so care should be taken with treatment. Fluid therapy may also help to thin secretions and promote bile flow. Anti-inflammatory drugs are also recommended. Choledocholithotomy and choledocholithotripsy, described in horses, have had limited success.[5-7] The prognosis is related to the degree of hepatic fibrosis, severity of clinical signs, and the number and location of the stones. Recent reports show a 75% to 80% survival rate with medical or medical plus surgical therapy.

Cholangitis and Cholangiohepatitis

Clinical disease of the bovine gallbladder is rare. Obstructive gallbladder disease has been associated with abdominal fat necrosis, choleliths, fascioliasis, foreign bodies, hepatic abscesses, neoplasia, and suppurative cholecystitis.[17,18] Adenomas and adenocarcinomas (most common tumors found in gallbladder), papillomas, and lymphosarcoma (rare) can cause obstruction.[17,19] Rupture of the gallbladder was found on necropsy of a cow in which icterus, anorexia, decreased milk production, and diarrhea had been present.[20]

Cholangitis and cholangiohepatitis may be primary or secondary and can result from cholelithiasis, duodenal inflammation, intestinal obstruction, neoplasia, parasitism, and certain toxins.[21] Sporidesmin, a fungal toxin from *Pithomyces chartarum,* causes cholangiohepatitis in cattle and sheep. Cholestasis and ascending infection resulting in cholangiohepatitis have been noted in horses with primary intestinal diseases such as proximal enteritis, right dorsal displacement of the large colon, and less frequently, left dorsal displacement of the large colon.[22-24] Duodenal strictures secondary to severe gastroduodenal ulceration have also been reported as a cause. Clinical signs associated with cholangitis and cholangiohepatitis in the horse may include anorexia, pyrexia, subtle behavioral changes, chronic weight loss, colic, and icterus. Septic peritonitis may occur as an extension of bacterial infection into the intraperitoneal space.[25] Alterations in hepatic enzyme activity may indicate hepatocellular damage, cholestasis, or both. Histopathologic examination and bacterial culture are indicated to further identify the causative agent. In cases of suspected bacterial etiology, long-term antibiotic therapy is indicated.[25] Antibiotic choice should be based on bacterial sensitivity, but in cases where no bacterial organism is identified, an antibiotic that is secreted or cleared in the bile is warranted.

Therapy of Liver Failure

Jennifer L. Davis

Antibiotic Therapy

Antibiotic therapy is indicated in cases of cholelithiasis, cholangitis, and cholangiohepatitis, as well as liver dysfunction secondary to systemic diseases causing sepsis in horses. Initial treatment should include broad-spectrum IV antibiotics, such as potassium penicillin plus either gentamicin or enrofloxacin, and oral metronidazole to cover *Bacteroides fragilis*. This is followed by long-term oral antibiotics based on culture and sensitivity (if available).[1] If no culture is available, the clinician should suspect gram-negative enteric bacteria with or without concurrent anaerobic infection. Trimethoprim sulfonamide combinations or enrofloxacin plus metronidazole are good choices. Chloramphenicol has a good spectrum against most cultured bacteria, but since it is highly metabolized by the liver, it should not be used if hepatic function is severely compromised.

Cattle with single or multiple liver abscesses often respond to penicillin therapy, but long-term therapy is required, and there is a significant rate of recurrence of clinical signs after therapy is withdrawn. Echolucent abscesses of small to medium size have the best prognosis. Abscesses with an echodense appearance are difficult to treat. Single large abscesses are best treated by surgical drainage, especially those interfering with vagal nerve function. High levels of IV penicillin and an aminoglycoside should be administered to foals with suspected Tyzzer disease.[2]

Treatment of Hepatoencephalopathy

Treatment of hepatoencephalopathy (HE) involves treatment of the underlying hepatic disease combined with supportive and palliative care. This includes IV fluids, broad-spectrum antibiotics, and gastroprotectants. Padding and wraps should be provided to help prevent self-trauma. Sedation may be necessary to control behavior or aid in treatments, but many of these drugs are metabolized in the liver, so care should be taken during dosing. Small doses of α_2-agonists like xylazine or detomidine are recommended. However, these drugs can cause respiratory depression at higher doses, and hypoventilation may aggravate signs of HE. Diazepam and other benzodiazepines should *not* be used; they may enhance the effects of GABA on inhibitory neurons, worsening HE.[3] Based on this, use of the benzodiazepine receptor antagonists has been recommended to lessen HE signs in humans.[4] The overall success of flumazenil in treating HE in humans and dogs has been low, and it has rarely been used in the horse. Sarmazenil, which has a different mechanism of action, appears to be more promising for reversing signs of HE in dogs[5] and has been used for treating moxidectin intoxication in a foal.[6]

Dietary management of HE is very important. Liver failure results in increased serum glucagon, and muscle catabolism releases amino acids. At the same time, hepatic metabolism of aromatic amino acids (AAA) is reduced and accumulation occurs, whereas muscle and adipose tissue can metabolize branched-chain amino acids (BCAA), resulting in less accumulation. AAA can act as false neurotransmitters, aggravating signs of HE, so a low-protein diet with a high BCAA/AAA ratio is recommended.[7,8] Low-protein/high-starch feeds include grass or oat hays, beet pulp, cracked corn, milo, sorghum, barley, and oats. If affected horses are anorexic, forced enteral or partial parenteral nutrition may be used. Lipids should not be added if there is any possibility that lipidosis is present, and special formulations of amino acids that consist mainly of BCAA should be used.

Other treatments for HE are designed to reduce intestinal ammonia absorption. Neomycin (10 to 30 mg/kg PO q6-12h) is an

VetBooks.ir

aminoglycoside antibiotic that suppresses enteric ammonia production. Because it is more nephrotoxic than gentamicin and can be irritating to intestinal mucosa (causing diarrhea), less than 2 days of use is recommended. Lactulose (0.2 to 0.5 mL/kg PO q6-8h) is poorly absorbed by the small intestine and acidifies the intestinal contents, causing a gradient to occur and ammonia to migrate from the blood into the colon, where it is trapped as ammonium and expelled. Acetic acid (vinegar, 0.5 mL/kg PO q12h), mineral oil, and metronidazole (10 to 15 mg/kg twice daily) have also been used to decrease ammonia absorption. Metronidazole should be used with caution because it is metabolized by the liver, and signs of toxicity may mimic HE.

Treatments aimed at reducing cerebral edema may also be necessary. Drugs frequently used include furosemide (1 mg/kg IV/IM q8-12h), mannitol (0.25 to 2 g/kg as a 20% solution IV over 20 to 30 minutes q12-24h), and hypertonic saline (4 to 6 mL/kg IV). It is also important to ensure the horse does not become too sedate with administration of α_2-agonists; it must be prevented from hanging its head and worsening edema. The prognosis for HE is poor unless the underlying disease can be quickly treated.

Fluid and Colloid Therapy

Dehydration should be corrected with a balanced electrolyte solution, preferably without lactate. Lactate is normally metabolized to bicarbonate in the liver and has an alkalizing effect. However, in horses with severe hepatic dysfunction, lactate may build up in the system and cause a worsening of acidosis. Sodium chloride (0.9%) with added calcium, dextrose (2.5% to 5%), and supplemental potassium (20 to 40 mEq/L) can be used. Additional potassium can also be given orally (5 to 20 g twice daily) to prevent or treat hypokalemia, since low potassium increases production and absorption of ammonia from the kidney.[9] Acidosis may be severe in many horses with hepatic failure, but attempts at correction must be made slowly.[10] Too rapid an increase in pH may exacerbate HE. Bicarbonate therapy should be instituted when the venous pH is less than 7.1. The prognosis is poor in horses that maintain persistent acidosis.

Glucose decreases ammonia concentration, reduces the reliance on catabolic gluconeogenesis, decreases protein catabolism, and spares hepatic energy consumed in hepatic gluconeogenesis, so it should be supplemented in cases of hepatic disease. The goal is to maintain blood glucose concentrations in the range of 90 to 120 mg/dL. In the case of hypertriglyceridemia with concurrent insulin resistance, supplemental insulin can be administered, as described in the section on hepatic lipidosis.

Polycythemia may be relatively unresponsive in some cases of hepatic failure and should not be used as the primary guide for judging adequate fluid therapy. Fresh or fresh-frozen plasma can be used to increase colloidal oncotic pressure, clotting-factor transport proteins, and antiproteases. Stored whole blood should not be used because ammonia levels may be high. Hetastarch should also not be used in hepatic failure, owing to its potential effects on coagulation.

Treatment of Inflammation and Fibrosis

Corticosteroids may be beneficial in treating lymphocytic/plasmacytic variants of chronic active hepatitis. Dexamethasone (0.05 to 0.1 mg/kg/day IV, IM, or PO decreased over 2 to 3 weeks) or prednisolone (1 mg/kg/day PO for several weeks) are recommended. Other recommended therapies for resolving inflammation and preventing progression of fibrosis can also be used. Flunixin meglumine (0.5 to 1 mg/kg PO) or low-dose phenylbutazone (0.5 g/day PO q24h) can be used for antiinflammatory effects. Vitamin E (10,000 U PO q24h) is recommended as an antioxidant and antiinflammatory agent. Pentoxifylline (8 to 10 mg/kg PO q12h) is a methylxanthine derivative and works as a nonselective phosphodiesterase inhibitor, resulting in weak inhibition of the inflammatory cytokines TNFα and IL-6. It also acts to increase RBC deformability, perhaps preventing microthrombosis. In horses, results with pentoxifylline are variable, possibly because of the variable bioavailability with extended dosing.[11] Colchicine (0.03 mg/kg PO q24h) can be used to inhibit production of collagen and macrophage/cytokine induced inflammation, potentially resulting in decreased fibrosis. Numerous side effects are reported in humans, including nervous system, renal, and dermatologic problems.

Miscellaneous Treatments

Supplemental *S*-adenosylmethionine (SAMe) (20 mg/kg PO q24h) is used for treatment of liver diseases; endogenous production is reduced secondary to reductions in methionine adenosyltransferase.[12] Presumed beneficial effects of SAMe in liver disease include augmentation of glutathione synthase levels in the hepatocyte, stabilization of membrane function, modification of cytokine expression, and inhibition of apoptosis in normal cells. *N*-acetylcysteine (NAC) (70 mg/kg IV q6h × 8 treatments) is a cysteine donor thought to be cytoprotective. It may improve hepatic microcirculation and oxygen delivery, enhance hepatic metabolic functions by restoring glutathione levels, block TNFα release, and act as a free radical scavenger.[12] DMSO (0.5 to 1 g/kg IV as <10% solution for 3 to 5 days) may act as an antioxidant as well as aid in dissolving intrabiliary sludge or small calcium bilirubinate stones. However, it may also precipitate a hemolytic crisis in animals with fragile RBCs. Ursodeoxycholic acid and silymarin are often used for hepatic disease in small animals, and there are anecdotal reports of use in horses, but safety and efficacy have not been proven. Ursodeoxycholic acid, a synthetic bile acid, is converted to toxic bile acids in the rabbit GI tract, which is similar to the horse's, so until a proven benefit is determined, this drug should not be used.[13]

Treatment of other concurrent disease should also be considered. If the hyperlipemia is thought to be associated with a pituitary adenoma, treatment with pergolide (1 to 5 mg/day PO) is warranted. Hyperlipidemia associated with diarrhea and azotemia may also occur in horses in late pregnancy, and abortion may be advisable.[14,15] Hepatic failure in cattle associated with septic metritis or mastitis, as well as biliary obstruction from hepatic abscesses, can often be successfully treated by force-feeding (e.g., alfalfa gruel, electrolytes) and systemic antibiotics.[16] Treatment of hepatic fascioliasis should be instituted as previously discussed.

Pancreatic Disease

Jennifer L. Davis

Pancreatic disease is rare in both cattle and horses. In the horse, acute and chronic disease has been reported, whereas only chronic disease has been reported in cattle.

Recognized causes of pancreatitis include migrating parasites, bacterial and viral infections, immune-mediated damage, biliary or pancreatic duct inflammatory disease, vitamin D toxicity, and deficiencies of vitamin A or E, selenium, and methionine.[1-4] Drugs known to induce pancreatitis in humans that are used frequently in horses include furosemide, tetracycline, estrogen, and certain corticosteroids and sulfonamides.[1,3] One case report in a pony suggests an association with Cushing syndrome.[5] The cause of acute pancreatitis in the horse is unknown, but it has been associated with grain overload and severe abdominal pain.[6] Three reports of acute pancreatitis in the foal suggest a possible relationship with sepsis, GI disease, vasculitis, and pancreatic lymphatic obstruction.[7,8] Pancreatitis was also diagnosed postmortem secondary to severe gastroduodenal ulceration in a foal.[9] The final common pathway may result from autodigestion by activated enzymes, but the exact mechanism remains speculative.

Clinical signs associated with acute pancreatitis are nonspecific and mimic those associated with an acute GI crisis. Characteristic clinical features are moderate to severe abdominal pain, gastric reflux, hypovolemic shock, and cardiovascular compromise.[1,4,10,11]

VetBooks.ir

Gastric distention accounts for the pain and gastric reflux associated with acute pancreatitis. Hypovolemic shock, occurring secondary to fluid losses into the peritoneal cavity and bowel lumen, results from release of vasoactive substances from the pancreas. Tachycardia, tachypnea, prolonged capillary refill, and congested mucous membranes result from hypovolemia and cardiovascular compromise. In foals, neurologic signs including dilated pupils, blindness, obtundation, and seizures have also been reported.[7] Hypoglycemia or pancreatic encephalopathy due to cerebral microthrombosis and infarction, as seen in humans, may be implicated.

Laboratory confirmation of pancreatic disease is difficult and not routinely attempted. The diagnosis is usually confirmed on histologic evaluation of the pancreas after necropsy. Laboratory tests that may be of value in the diagnosis of pancreatitis in the horse include measuring serum amylase and lipase activity, peritoneal fluid (PF) amylase concentrations, fractional excretion of amylase, and plasma trypsin levels.[4] Serum amylase values from normal horses range from 14 to 35 IU/L (mean, 21 ± 6), whereas PF values range from 0 to 14 IU/L (mean, 5 ± 4).[12] Serum lipase values from normal horses range from 23 to 87 IU/L (mean, 58 ± 19), whereas PF values range from 0 to 36 IU/L (mean, 14 ± 12).[12] Elevations of pancreatic enzyme activity are difficult to interpret because the enzymes may be elevated in horses with proximal enteritis, colic, primary renal failure, and damage to intestinal mucosal cells, as well as in pancreatitis.[4,12,13] Amylase also originates from the salivary glands, and lipase can be released from the liver. Clinical cases documented at necropsy had serum amylase activity greater than 700 IU/L; this magnitude of elevation may be helpful in differentiating acute pancreatitis from other causes. In acute pancreatitis, PF amylase levels are higher than serum levels.[13] Plasma trypsin levels increase in horses with suspected pancreatic damage and may be a better indicator of pancreatic disease.[14] Trypsin is specific to the pancreas and activates its own zymogen and those of all the other pancreatic enzymes. In one study of horses with acute abdominal disease in which pancreatic damage was suspected, trypsin activity was significantly higher than in healthy horses (196 ± 128.2 ng/mL vs. 28.5 ± 19.2 ng/mL).[14] In cattle with experimentally induced pancreatitis, serum amylase and lipase concentrations increased rapidly but returned to normal within a few days, suggesting this may not be a useful test for cases of chronic pancreatitis.[15] GGT does not appear to be a sensitive indicator of pancreatic disease in horses. In foals, an inflammatory peritoneal effusion with increased peritoneal protein and triglyceride concentrations, along with hypertriglyceridemia, has been documented.[7] Pancreatitis has not been successfully imaged with ultrasonography in the horse.[16] A technique for ultrasound examination of the right lobe of the pancreas in healthy cattle has been described.[17] Using this technique, experimentally induced acute pancreatitis was monitored ultrasonographically in cattle. Twenty-four hours after induction of pancreatitis, an increased echogenicity was noted, but within 3 days, hypoechogenicity was noted secondary to necrosis, hemorrhage, and inflammatory exudates, as confirmed at necropsy.[15]

Medical management of acute pancreatitis is symptomatic. Prevention of gastric rupture by continuous gastric decompression and control of abdominal pain are crucial in the treatment of pancreatitis.[3] Large volumes of balanced polyionic electrolyte solutions are necessary to maintain the circulating volume and prevent shock. Because hypocalcemia may be a problem, serum calcium concentration should be monitored. Broad-spectrum antibiotics are warranted because of the potential for secondary bacterial infection. NSAIDs and analgesics are used to control inflammation and pain.

Chronic interstitial pancreatitis (CIP) in horses and cattle seldom has clinical significance. In horses, *Strongylus equinus* and *Strongylus edentatus* are most often identified as the etiologic agent of CIP; however, *Parascaris equorum* has been identified in one case report.[3,18,19] In cattle, CIP has been primarily associated with the trematodes *Eurytrema pancreaticum* and *Eurytrema coelomaticum;* these parasites have not been isolated in the United States.[13]

Reports of pancreatic disease in adult cattle have been limited to endocrine dysfunction.[20-22] The most frequently reported disorder is type I diabetes mellitus, but the etiology in most cases is not determined.[20-22] Histopathologic examination generally reveals an absence of beta cells in the islet tissue. Foot-and-mouth disease virus has been associated with diabetes mellitus in cattle following convalescence.[13] Hypoplasia of the acinar pancreatic tissue has been described in calves.[13] Clinical signs include steatorrhea and diarrhea. Insulin-dependent diabetes mellitus with pancreatic beta cell dysfunction has been documented rarely in horses.[23,24] Transient type 1 diabetes has also been diagnosed in the foal,[25] and recent work shows that method of delivery (spontaneous vs. induced foaling) may have a significant effect on their pancreatic function.[26] Induced parturition was associated with two- to threefold higher cortisol levels and with differences in the absolute and age-related changes in basal concentrations of glucose, α-amino nitrogen, and insulin.[26] Adenocarcinoma of the exocrine pancreas is reported in rare equine cases and should be considered in horses exhibiting the clinical signs of pyrexia, depression, weight loss, and icterus.[2,27,28]

Pancreatic calculi found in older cattle (>5 years) during necropsy are considered incidental findings.[13] The calculi are composed primarily of calcium carbonate and calcium phosphate. Their presence may be associated with grazing on silica-rich soil, vitamin A deficiency, or chronic inflammation of the pancreatic ducts.[13]

Equine Renal System

Dominic R. Dawson Soto, *Consulting Editor*

Acute Renal Failure

Thomas J. Divers • Alexandra J. Burton

Acute renal failure (ARF) in the horse is usually due to exposure to nephrotoxins or vasomotor nephropathy (e.g., hypoperfusion or ischemia). The most common pathologic lesion with ARF is acute tubular necrosis (ATN).

Toxic Nephropathies

Aminoglycosides

Administration of aminoglycoside antibiotics is one of the most common causes of ATN in the horse. These antibiotics exert their toxic effect by accumulating within proximal tubular epithelial cells. Their entrance into the tubular epithelial cell is thought to be via urine after filtration through the glomerulus.[1] Once toxic amounts are sequestered within the cell, cellular metabolism is disrupted and tubular cell swelling, death, and sloughing into the tubular lumen occur. Release of lysosomal enzymes and intracellular accumulation of calcium are likely involved in cell death.

Most cases of aminoglycoside nephrotoxicity are not due to drug overdosing or administering the drug to an azotemic patient.[2] The healthy kidney can usually tolerate a single major overdose (i.e., 10 times the normal amount) without detrimental effects, so toxicity is almost always the cumulative effect of *repeated* administration of aminoglycosides. Because the drugs are water soluble and thus highly distributed in extracellular fluid (ECF), their clinical pharmacokinetics are strongly influenced by variations in patient ECF volume owing to disease state or age, so different doses and dose intervals may be required to attain desired peak and trough levels depending on patient specifics.[3,4] Because renal cellular uptake of gentamicin is saturable, nephrotoxicity is associated with insufficiently low trough levels rather than excessively high peaks.[5] The maximal trough concentration to minimize the risk of nephrotoxicity is unknown in horses. In humans, trough gentamicin concentrations over 2 µg/mL have been associated with nephrotoxicity.[6,7] However, optimal trough concentration for minimizing nephrotoxicity after administration of gentamicin to humans is controversial, with recommendations ranging from maintaining a trough less than 2 µg/mL to maintaining a period of less than 0.5 µg/mL for at least 4 hours.[8-10] Nephrotoxicity typically develops after several days of aminoglycoside administration to horses with diarrhea or septicemia that are not adequately hydrated,[11] or because of other factors that may exacerbate a decrease in renal perfusion (e.g., concurrent treatment with nonsteroidal antiinflammatory drugs [NSAIDs]). The shift to once-daily aminoglycoside dosing in horses, compared with previous dosing of aminoglycosides two or three times daily, has become a standard practice that likely reduces the potential for nephrotoxicity (by ensuring a longer period of the day with appropriate serum trough concentrations) but still provides a similar therapeutic response.[12-15]

Prolonged administration (>10 days) of aminoglycoside antibiotics without monitoring of aminoglycoside trough concentrations or serum creatinine concentration is a common history with aminoglycoside nephrotoxicity in the horse. Typically, gentamicin or amikacin may be safely administered for longer than 10 days if the patient is adequately hydrated and appropriate trough concentrations and creatinine concentration are maintained. With regard to the latter, experimental induction of gentamicin nephrotoxicity in ponies was reflected by a rather small increase (0.3 mg/dL) in creatinine.[16] Although it has not been proven, the neonatal equine kidney is likely more susceptible to aminoglycoside toxicity than the adult kidney. This is probably reflective of the prolonged elimination half-life seen in foals.[4,17] Sick foals appear to be at greater risk for aminoglycoside nephrotoxicity,[18] although this may simply reflect an increased incidence of septicemia in sick neonates and longer courses of treatment with aminoglycosides.

When aminoglycosides are administered to high-risk patients (concurrent dehydration or neonates), volume deficits must be replaced and serum trough concentrations or creatinine monitored frequently.[19] Aminoglycoside nephrotoxicity rarely develops in horses receiving appropriate fluid therapy. Increased urinary sodium excretion and fluid diuresis appear to have a protective effect on the kidney. In contrast, hypokalemia (or total body potassium depletion) and low calcium intake may predispose horses to aminoglycoside nephrotoxicity by decreasing urine output.[20] Supplementation with oral electrolytes (e.g., 1 to 2 oz of NaCl and KCl daily) may be of benefit to horses being treated with aminoglycoside antibiotics by increasing water intake and urine output and replacing potassium deficits in anorectic horses. In contrast, furosemide should not be administered prophylactically in an attempt to prevent aminoglycoside nephrotoxicity.[21] In patients with prerenal azotemia that receive aminoglycoside antibiotics, it is important to monitor creatinine closely and consider prolonging the interval between drug administration until volume deficits are corrected. However, because nephrotoxicity is a cumulative effect of repeated dosing, delay of administration of the initial dose of an aminoglycoside pending

VetBooks.ir

rehydration of a critical patient (e.g., septic neonate, extremely dehydrated horse) is unwarranted.

Aminoglycoside nephrotoxicity should be considered in horses that become inexplicably depressed and inappetent while being treated with aminoglycosides or within a few days after aminoglycoside therapy is discontinued. Renal failure can develop even after the drug is withdrawn, so monitoring renal function 2 to 4 days after discontinuing aminoglycoside therapy may be advised in high-risk patients. Polyuria may be observed before the onset of depression and anorexia or, if the patient becomes oliguric, mild stranguria and repeated posturing to urinate may be observed. A tentative diagnosis of nephrotoxicity is based on history of aminoglycoside use and supportive laboratory data. Abnormal laboratory findings associated with tubular damage that may be detected before onset of azotemia include enzymuria and cylindruria.[16,22] Although these parameters can be monitored for early detection of tubular injury, their finding does not necessarily indicate if or when aminoglycosides should be discontinued or to what degree the interval of administration should be prolonged.[23]

When ARF from aminoglycoside use develops, it usually manifests as nonoliguric to polyuric renal failure; outcome is generally favorable so long as the duration of ARF is not prolonged and other underlying disease processes can be corrected. Peritoneal or pleural dialysis, plasmapheresis, or hemodialysis might be considered as methods to lower serum concentrations of nephrotoxic agents and uremic toxins. However, the amounts removed by a single use of some of these therapies are small and generally not worthy of pursuit in horses with nephrotoxic renal failure.[24]

Pigment Nephropathy

Acute tubular necrosis and development of ARF subsequent to rhabdomyolysis (myoglobin pigment) can occur if the episode of tying up is severe and/or the associated dehydration is prolonged.[25,26] Pigment nephropathy can also occur secondary to any other causes of muscle necrosis. Observation of grossly discolored urine is not a prerequisite for development of renal failure. Hemolysis, which may be secondary to a variety of toxins and primary conditions, appears to be a less common cause of pigment nephropathy than myopathy, although ARF can occur sporadically. Horses with severe hemolysis or those with hemolysis accompanied by disseminated intravascular coagulation (DIC) are at greater risk of developing pigment nephropathy.[27] In one study, 40% of 32 horses with red maple toxicosis and hemolysis had evidence of renal insufficiency, but it was not found to be an important risk factor for mortality.[28] Renal failure due to pigment nephropathy should be suspected in horses that become anorectic and more depressed during the week after an episode of tying up or during a hemolytic crisis. Measuring serum activities of creatine kinase (CK) and aspartate aminotransferase (AST) may help confirm that ARF has developed in association with rhabdomyolysis. There is little preformed creatinine in muscle, so rhabdomyolysis alone does not produce an increase in it.[29]

VITAMIN K_3. Vitamin K_3 (menadione) was a common cause of ATN and ARF in certain parts of the United States before its withdrawal from the market. Nephrotoxicity can occur rapidly after a single parenteral dose of the menadione sodium bisulfite form of vitamin K_3.[30,31] Development of ARF was thought to be idiosyncratic and likely involves direct tubular damage via oxidative stress and pigment nephropathy subsequent to hemoglobinuria.[30,31] Although horses are very sensitive to its nephrotoxic effects, oral supplementation of menadione with a view to enhancing bone strength was recently investigated in horses in Japan, and no nephrotoxicity was reported.[32,33]

Nonsteroidal Antiinflammatory Drugs

Most horses do not experience appreciable adverse effects from NSAIDs as long as they are administered at the proper dose and animals are not dehydrated. However, NSAID use may produce ARF in an occasional horse when excessive doses are administered or when dehydration is not corrected promptly.[22,23] The lesion produced by NSAID toxicity in horses is medullary crest necrosis, which can be manifested by gross hematuria.[34-38] Unless severe, this lesion rarely causes overt clinical signs, and creatinine may actually decrease with fluid therapy. An occasional horse may also develop chronic interstitial nephritis and nephrolithiasis after prolonged use (months to years) of NSAIDs at recommended doses.[39] The *renal medullary rim sign,* an ultrasonographic abnormality consisting of a hyperechoic band parallel to the corticomedullary junction, has been demonstrated in NSAID toxicity in adult horses and foals.[40,41] Presence of concurrent gastrointestinal (GI) disease (ulceration) and protein-losing enteropathy would further support NSAID toxicity in both acutely and chronically affected horses. Interestingly, acute interstitial nephritis was the predominant renal histopathologic lesion recorded in clinically normal Miniature donkeys administered NSAIDs (ketoprofen (2.2 mg/kg IV), flunixin (1 mg/kg IV or PO), or phenylbutazone (2.2-4.4 mg/kg IV or PO) twice daily for 2 weeks.[42] Also, in contrast to horses who may not show increases in serum creatinine while on fluid therapy or until severe renal compromise occurs, donkeys may show more acute increases in serum creatinine with NSAID toxicity.[42]

When renal blood flow decreases because of dehydration or redistribution of cardiac output, counteracting vasodilatory mediators are produced and released within the kidney to attenuate the decrease in renal blood flow. The best studied of these vasodilatory mediators include renal prostaglandins (PGI_2 and PGE_2) and dopamine. Although the role of renal prostaglandins in controlling basal renal blood flow is likely insignificant, they are important mediators of vasodilation during periods of renal hypoperfusion.[43] Renal prostaglandin production is several-fold greater in medullary tissue, such that action of these mediators leads to a greater increase in inner cortical and medullary blood flow. It should not be surprising that the lesion associated with NSAID toxicity is renal medullary crest necrosis (due to ischemia).[44] Similarly, it is important to remember that NSAID use in dehydrated or hypovolemic patients increases the risk of acute nephrosis.[45]

Vitamin D

Vitamin D intoxication may result from ingestion of feed additives or plants (e.g., *Cestrum diurnum*) containing high amounts of vitamin D metabolites or from parenteral administration of vitamin D.[46-48] Cholecalciferol (D_3) is thought to be more toxic than ergocalciferol (D_2) in the horse.[47] In general, horses do not need dietary supplementation with vitamin D if they are exposed to adequate sunlight and have access to green forages. The effect of vitamin D supplementation is cumulative, so signs of toxicity may not develop until several weeks after supplementation was started.

Clinical signs of vitamin D intoxication may be referable to the musculoskeletal, cardiovascular, or urinary systems.[48] Calcification of tendons and ligaments results in lameness, and calcification of cardiac muscle and great vessels can lead to cardiovascular problems. Mineralization of tendons and ligaments may be detected directly by palpation or indirectly through ultrasonographic imaging. Heart murmurs may accompany calcification of the great vessels, and ultrasonographic imaging of the heart and kidney may also reveal evidence of mineralization. Further clinical signs of renal toxicity include polyuria and weight loss.

Abnormal laboratory findings with vitamin D intoxication include azotemia, isosthenuria, hypochloremia, and elevations in both serum calcium and phosphorus concentrations. The latter combination of hypercalcemia and hyperphosphatemia is unusual for any other disease in the horse, although it may be seen with neoplasia on rare occasions. A definitive diagnosis of vitamin D toxicosis can be made by measuring serum concentrations of 25-OHD_3, 25-OHD_2, and 1,25-$(OH)_2D$. Treatment of vitamin D intoxication includes removal of the inciting cause (feed or medication), fluid diuresis, and corticosteroid administration. Provision of feeds low in both calcium and phosphorus may be of benefit in less severely affected horses, but treatment is usually unrewarding once clinical signs due to tissue mineralization have developed.

VetBooks.ir

Heavy Metals

Accidental ingestion of heavy metals may result in ATN and ARF in horses. Mercury, cadmium, zinc, arsenic, and lead are all nephrotoxic but are rare causes of renal failure in the horse. Mercury has been used experimentally to study renal failure in horses,[49,50] and there are reports of ARF in horses that have had legs "blistered" or "sweated" with products containing inorganic mercury.[51,52] Because inorganic mercury also causes severe damage to intestinal mucosa, signs of GI irritation (e.g., increased salivation, oral erosions, colic, hemorrhagic diarrhea) predominate with mercury intoxication. Further evaluation may reveal oliguria. Exposure to excessive amounts of zinc and cadmium can result in nephrocalcinosis and renal failure, but gait deficits (resulting from osseous effects, particularly in foals) and ill-thrift are more likely presenting complaints than oliguria.[53]

Laboratory findings with heavy metal intoxication are characteristic for ATN: azotemia, hyposthenuria to isosthenuria or anuria (depending in part on concurrent hydration status), hyponatremia, and hypochloremia. In horses with ARF concurrent with GI disease, as with mercury toxicity, severe hypocalcemia may be present. A tentative diagnosis of mercury intoxication may be made from history of exposure, clinical signs of erosive GI disease, and oliguric renal failure. The diagnosis can be confirmed by measuring increased blood and tissue (kidney and liver) concentrations of the metal. In addition to judicious fluid therapy, treatment of ARF induced by exposure to heavy metals should include parenteral dimercaprol, 5 mg/kg intramuscularly (IM) initially, followed by 3 mg/kg IM q6h for the remainder of the first day, then 1 mg/kg IM q6h for two or more additional days, as needed, and 1 lb of charcoal orally. Visceral analgesics (flunixin meglumine) and sedatives (xylazine or detomidine) are often necessary to control abdominal pain.

Acorn Poisoning

Acorn poisoning is less common in equids than cattle but has been reported in horses.[54] Death in horses is usually due to erosive GI disease, changes in vascular permeability, and resulting shock rather than a consequence of uremia. Immature leaves and green acorns are considered more toxic than mature acorns because the former have a higher tannin content. Clinical signs may include diarrhea, edema, and body cavity effusion, and laboratory evaluation usually reveals azotemia, isosthenuria to hyposthenuria, hyponatremia, and hypochloremia. Detection of increased urinary excretion of phenols may be useful to confirm the diagnosis.

Miscellaneous Drugs and Agents

Several other drugs and agents (oxytetracycline, polymyxin B, amphotericin B, imidocarb dipropionate, ochratoxins, pyrrolizidine, cantharidin toxicosis [blister beetle poisoning], and the nematode *Halicephalobus*) have been suspected of causing nephrotoxic ARF in horses. When high doses of oxytetracycline (up to 70 mg/kg) are administered to neonatal foals for correction of limb contracture, ARF is a potential complication, especially if the foals are dehydrated or have concurrent sepsis or hypoxic-ischemic encephalopathy.[55] With renewed interest in polymyxin B as an adjunct treatment for endotoxemia, it is prudent to remember that this drug also has nephrotoxic potential. However, experimental studies have demonstrated that the risk of polymyxin B nephrotoxicity is low, especially when it is conjugated with dextran 70.[56] Amphotericin B also has considerable nephrotoxic potential, but it is rarely administered systemically to horses. Imidocarb dipropionate, used in treating *Babesia equi* infections, has been shown to cause reduced renal function after multiple dosing.[57] Ochratoxins have the potential to produce ATN, but ARF caused by ochratoxins has not been documented in horses. Similarly, pyrrolizidine alkaloid poisoning may cause renal disease in horses, but failure is unlikely. Blister beetle poisoning (cantharidin toxicosis) may cause abdominal pain, shock, hematuria, diaphragmatic flutter, dysuria, and renal dysfunction in horses fed alfalfa hay grown in regions where the beetles are prevalent.[58] One report of renal failure, as well as brain involvement, was associated with granulomas caused by the nematode *Halicephalobus*.[59] Anecdotal reports exist of horses developing renal disease after administration of bisphosphonates for treatment of orthopedic disease. Prudence should be used as renal disease is a reported complication in other species after bisphosphonate administration.[60]

Vasomotor Nephropathy

Any condition that causes sustained marked hypotension or release of endogenous pressor agents can initiate hemodynamically mediated (vasomotor) ARF. Although poorly documented, vasomotor ARF may be more common than nephrotoxic ARF in the horse. However, renal compromise due to a combination of vasomotor and nephrotoxic mechanisms probably occurs more frequently than clinically identified in sick horses receiving drugs with nephrotoxic potential. Hemorrhagic shock, severe intravascular volume deficit (e.g., as with enterocolitis), septic shock, and coagulopathy are important risk factors for vasomotor ARF in horses.[61] Another cause may be adverse drug reactions, including those accompanying intravenous (IV) administration of vitamin and mineral products or immunomodulators. The predominant lesion in vasomotor nephropathy is ATN, although diffuse renal cortical or renal medullary necrosis may also occur in some cases.

Clinical signs of vasomotor ARF are nonspecific and more often referable to the primary disease (e.g., hemorrhage or diarrhea). Additional subtle signs (e.g., more marked depression and anorexia than would be expected with the primary disease), with or without signs of mild colic, may increase suspicion of ARF. If sedation for colic signs is deemed necessary, xylazine or detomidine can be administered if intravascular volume and blood pressure are not overly compromised. Occasionally, horses with severe ARF may also be ataxic or manifest neurologic signs similar to hepatoencephalopathy.

Oliguria, often seen as a lack of expected urination in response to fluid therapy, is an important early indicator of vasomotor ARF, and production of dilute urine (specific gravity <1.020) that may be discolored (hematuria or hemoglobinuria) may be observed when urine is eventually voided. If urine produced is grossly clear, microscopic hematuria is usually present and will produce a positive result on reagent strip analysis of urine. Glucosuria due to severe proximal tubular damage may also be detected in an occasional horse with vasomotor ARF. Although the pathophysiologic relationship to ARF is not well defined, diarrhea and severe laminitis may develop in more serious cases of vasomotor ARF.

Acute Glomerulopathy

Although subclinical glomerular damage likely accompanies some diseases affecting horses, especially immune-mediated disorders (e.g., purpura hemorrhagica), acute glomerulonephritis (GN) is a rare clinical problem.[62] A syndrome of arteriolar microangiopathy and intravascular hemolysis that causes distention of glomerular capillary loops with fibrin thrombi and accumulation of large amounts of proteinaceous debris in the Bowman capsule has also been described in a few horses.[63] Affected horses presented with oliguric ARF accompanied by hematuria, proteinuria, and intravascular hemolysis; response to treatment was poor. The cause of the syndrome in horses is not definitively known. Renal lesions resemble those found with hemolytic-uremic syndrome (HUS) in humans, which is caused by toxins of *Escherichia coli*. In a recent case report of HUS with glomerular thrombotic microangiopathy in a postpartum mare, *E. coli* O103:H2 was isolated from the uterus and gastrointestinal tract.[64] Glomerulopathy with ARF caused by *Streptococcus mitis* has also been documented as a component of toxic shock in a horse.[65] Bacterial toxins, a consumptive coagulopathy, immune complex deposition, vasoactive amines, and hemodynamic alterations may all be contributors to this rare syndrome in horses. Acute glomerulopathy should also be considered in horses with severe ARF that do not have a predisposing primary disease leading to vasomotor ARF and that have not been exposed to nephrotoxins. Gross hematuria, proteinuria, and oliguria would support an acute glomerulopathy, and renal biopsy can be pursued to confirm the lesion.

Acute Interstitial Nephritis

Acute interstitial nephritis is a rare syndrome of ARF accompanied by rapid elevations in creatinine and clinical signs of uremia. Renal lesions include interstitial edema with a mild inflammatory infiltrate. Although adverse drug reactions (idiosyncratic) may be a cause, the etiopathogenesis of this disease in horses is unknown. In humans, eosinophilic infiltrates in renal biopsy tissue are supportive of adverse drug reaction. Although there are no published reports of the syndrome in horses, the author (TJD) has examined three horses with apparent acute interstitial nephritis. However, experimentally, in Miniature donkeys, interstitial nephritis (rather than medullary crest necrosis) was the predominant renal histopathologic lesion recorded following IV administration of NSAIDs twice daily for 2 weeks.[42] Because of the pronounced interstitial edema that may accompany this disease, treatment with corticosteroids may be of benefit in suspect cases.

Leptospirosis

Krista Elise Estell

ARF due to infection with *Leptospira interrogans* should be considered when an underlying renal disease is not apparent and there has been no exposure to nephrotoxins. *L. interrogans* serovar *pomona* has been documented as a cause of interstitial nephritis in horses, though the most common pathologic isolates are *L. interrogans* serovar *kennewicki* in the United States and *L. interrogans* serovar *icterohaemorrhagiae* and *Leptospira kirchneri* serovar *grippotyphosa* in the United Kingdom.[66-70] The most frequent clinical sign in both experimental and natural infection is fever, but anorexia and depression may also be present, and hematuria was observed in one foal.[71] Clinical pathologic abnormalities include azotemia and isosthenuria without bacteriuria. Leptospiruria is not a consistent finding, making diagnosis difficult. Diagnosis of *Leptospira* spp. can be achieved by urine polymerase chain reaction (PCR); administering furosemide and testing the second voided sample may increase sensitivity of this test. Serum titers performed by microscopic agglutination rise quickly after experimental infection.[72] Demonstration of a rising titer or baseline titer above 1:6400 indicates active infection.[73] Treatment includes fluid therapy and penicillin.

Diagnosis

ARF should be suspected in patients showing more marked depression and anorexia than would be expected with the primary disease process and in those that fail to produce urine within 6 to 12 hours of initiating fluid therapy. Rectal palpation in horses with ARF may reveal enlarged, painful kidneys in some cases. Enlargement can be confirmed by renal ultrasonography, which may also reveal perirenal edema, loss of detail of the corticomedullary junction, or dilation of renal pelves.[74-76] However, subtle changes in renal architecture can be difficult to detect via ultrasound, and sensitivity of this diagnostic modality largely depends upon operator experience and image quality.

The diagnosis of ARF is confirmed on the basis of history, potential exposure to nephrotoxins, clinical signs, and laboratory findings. Relative to baselines, the increase in serum or plasma creatinine concentration is often several-fold greater (e.g., up to 5 to 15 mg/dL) than that of blood urea nitrogen (BUN) concentration (e.g., up to 50 to 100 mg/dL), resulting in a BUN/creatinine ratio that is often less than 10:1. Hyponatremia, hypochloremia, and hypocalcemia are usually present, and in more severe cases, hyperkalemia, hyperphosphatemia, and metabolic acidosis may also be detected.

In addition to assessment of the magnitude of azotemia and alterations in serum or plasma electrolyte concentrations and acid-base balance, urinalysis should be performed on all horses in which ARF is suspected. As mentioned, a low urine specific gravity (<1.020) in the face of dehydration and gross or microscopic hematuria are common findings with ARF. Evidence of more substantial proximal tubular damage, including increased urinary enzyme activity and glucosuria, may be detected in some horses. Significant proteinuria (urine protein/creatinine ratio > 2:1 [see Chronic Renal Failure]) would support the presence of glomerular disease. Examination of urine sediment may reveal casts and increased numbers of erythrocytes and leukocytes, and the amount of urine crystals may be decreased. Increased fractional clearances of sodium and phosphorus are also common findings with ARF. It is important to remember that administering IV fluids to healthy horses will also result in increased fractional clearances of sodium, chloride, and phosphorus.[77] Electrolyte clearances are ideally determined using the initial urine sample voided after admission or a sample collected by catheterization (i.e., before urine is substantially altered by fluid therapy).

The most accurate assessment of renal function involves glomerular filtration rate (GFR), which can be measured by performing timed urine collections (inulin and endogenous or exogenous creatinine clearances) or assessing plasma disappearance of several compounds (sodium sulfanilate, phenolsulfonphthalein, or radiolabeled substances).[78] Recently GFR has been determined in a foal using computed tomography (CT) with single-slice dynamic acquisition and Patlak plot analysis.[79] In a clinical setting, measurement of GFR in cases of ARF is rarely pursued because multiple measurements are required to assess changes in GFR, and prognosis for recovery is more likely related to the duration of decreased GFR rather than to the magnitude of the decrease. Because of the inverse relationship between GFR and creatinine, changes in GFR can be more practically assessed by daily serum creatinine measurement.

Glomerular injury and tubular necrosis can be further confirmed by performing a renal biopsy, but biopsy is often not indicated because the diagnosis of ARF is usually evident. In a recent retrospective study of 151 renal biopsies in horses carried out at 14 different equine hospitals, biopsy specimens yielded sufficient tissue for a histopathologic diagnosis in 94% of cases, but diagnoses had only fair (72%) agreement with postmortem findings.[80] Immunofluorescent (IF) testing and electron microscopic (EM) examination are routinely performed on human renal biopsy samples to assess mechanisms of renal injury and extent of damage to glomerular and tubular basement membranes. If such detailed evaluation of renal biopsy tissue were routinely performed in horses with ARF, better information regarding etiopathogenesis and prognosis would likely be provided by the pathologist.

At present, renal biopsy is most often indicated to evaluate horses with ARF when exposure to nephrotoxins or another underlying primary disease process is unapparent. Life-threatening hemorrhage is a potential complication of renal biopsy. The above-mentioned study found a complication rate of 11.3%, generally associated with hemorrhage or signs of colic. Treatment for complications was required in only 3% of cases, and there was only one fatality.[80] Risk factors for complications included biopsy of the left kidney, a diagnosis of neoplasia, and low urine specific gravity.[80] Biopsy of the right kidney with ultrasonographic guidance, usually through the seventeenth intercostal space, is the preferred procedure.[81] Proper instrumentation (automatic or spring-loaded biopsy instruments) and adequate restraint (stocks and sedation) are important considerations. Renal tissue collected should be placed in formalin for histopathologic examination, as well as frozen (or placed into additional media specified by the testing laboratory) for IF testing and EM examination. Although biopsy of the right kidney alone usually is adequate for assessment of the disease process affecting both kidneys, samples of the left kidney can also be collected by guiding the biopsy instrument through the spleen. Again, ultrasonographic guidance is especially vital when collecting a biopsy from the left kidney or when biopsy of a specific area of either kidney is desired.

General Principles of Treatment

The general principles of ARF treatment in the horse are similar to those recommended for humans.[82,83] Initial therapy should always focus on judicious IV fluid administration to replace volume deficits

VetBooks.ir

and correct electrolyte and acid-base abnormalities. The magnitude of azotemia and serum concentrations of sodium, chloride, potassium, and bicarbonate should be monitored daily. Horses with polyuric ARF often require sodium and chloride replacement. This can be accomplished by using 0.9% NaCl as the fluid administered or through supplementation of these electrolytes in grain feedings or as oral pastes. Serum potassium concentration in horses with nonoliguric ARF is often normal, and except for postrenal problems (e.g., obstruction or rupture), therapy intended to lower serum potassium is usually unnecessary. Similarly, it is usually unnecessary to correct the mild hypocalcemia that can accompany ARF in horses.

After correcting volume deficits and electrolyte and acid-base abnormalities, an attempt should be made to determine whether the animal is oliguric or nonoliguric (polyuric); the prognosis for recovery appears to be more favorable with nonoliguric ARF. This often becomes apparent by simple observation: oliguric horses fail to produce expected amounts of urine in the initial 12 to 24 hours of IV fluid therapy and the bedding remains dry. Nonoliguric horses repeatedly void moderate volumes of dilute urine during the initial 6 to 12 hours of treatment. Edema can develop rapidly in horses with oliguric or anuric ARF and is often initially noticed in the conjunctiva (Fig. 34-1). Other manifestations include generalized subcutaneous swelling of dependent areas, progressing to tachypnea and altered mental status if pulmonary and/or cerebral edema develop. In horses with prerenal azotemia (as opposed to intrinsic ARF), serum creatinine concentration should decrease by at least 30% to 50% within the initial 24 hours of fluid therapy. In contrast, creatinine concentration may remain unchanged or even increase in ARF.

During therapy for ARF, regular assessments of attitude, vital parameters, packed cell volume, and total plasma protein concentration are important. Monitoring should also include measurement of body weight once or twice daily (patients should not gain weight with continued fluid therapy after initial rehydration) and comparison of fluid input with fluid (urine) output. Although there is no convenient method of collecting all urine voided by ambulatory foals or mares, urine output can be rather easily quantified in male horses by placing a urine collection device around the abdomen.[84] When desired, monitoring urine output in critically ill foals and mares can be accomplished by use of an indwelling Foley catheter and urine collection bag (closed system), but ascending infection is a risk.

In severely ill patients, especially those with vasomotor nephropathy, systemic blood pressure (BP) can be monitored to confirm that fluid therapy has been adequate to restore BP. Some horses may remain hypotensive (systolic BP < 80 mm Hg) despite administration of large volumes of IV fluids, owing to extravascular accumulation as edema or a third-space fluid. If systemic BP remains low, hypertonic saline, dobutamine, or other pressor agents may be required to restore BP and glomerular filtration. Fluid and sodium replacement in horses with oliguric renal failure and normal systemic BP must be monitored closely; overzealous fluid administration to horses with oliguric or anuric ARF will result in edema formation. Central venous pressure (CVP) can also be monitored as a more precise measurement of fluid balance in critical patients. CVP is measured with a manometer with the baseline at the level of the right atrium, attached to an IV catheter placed into the anterior vena cava via the jugular vein (normal CVP in horses, <8 cm H_2O).

FIG. 34-1 Severe conjunctival edema from intravenous (IV) fluid therapy in a 3-year-old Arabian with oliguric acute renal failure (ARF). The ARF and a multifocal granulomatous pneumonia occurred after IV administration of an approved immunomodulator.

In horses that remain oliguric after 12 to 24 hours of appropriate fluid and electrolyte replacement and restoration of systemic BP, furosemide at 1 mg/kg IV q2h should be administered. Unfortunately, furosemide treatment is often ineffective in increasing renal blood flow, GFR, and tubular flow in horses with ARF.[83,85] Continuous infusion of furosemide at 0.12 mg/kg/h, preceded by a loading dose of 0.12 mg/kg IV, was considered superior to intermittent use in one study.[86] If urine is not voided after the second dose, administration of mannitol (1 g/kg IV as a 10% to 20% solution) and/or a dopamine infusion (3 to 7 µg/kg/min IV) can be instituted. Dopamine administration should only be performed in a hospital setting where heart rate and BP can be monitored frequently and development of tachycardia and hypertension avoided. Dopamine use for selective renal vasodilatory and natriuretic actions has been called into question because most studies in humans have not demonstrated prevention of ARF in high-risk patients or improved outcome in those with established ARF[87]; in one study, dopamine actually worsened renal perfusion in human patients with ARF.[88] Further, the drug may precipitate serious cardiovascular and metabolic complications in critically ill patients. If these treatments are successful in converting oliguria to polyuria (may require 24 to 72 hours), they can be discontinued, but maintenance of urine production must be monitored closely over the next few days. Fortunately, the majority of horses with ARF resulting from ATN are nonoliguric rather than oliguric, and furosemide, mannitol, or dopamine are unnecessary.

When this treatment approach to oliguria remains unsuccessful for more than 72 hours, the prognosis becomes grave. One study of horses with colic or colitis found that horses with persistent azotemia after 72 hours of fluid therapy were three times as likely to die or be euthanized as the horses without persistent azotemia.[89] However, dialysis therapy may be a further treatment option in selected patients. Hemodialysis has been successfully used to treat two adult horses with myoglobinuric ARF[90,91] and a neonatal foal with oxytetracycline-induced ARF.[55] Peritoneal dialysis has been attempted in a few horses with nephrotoxic-induced ARF, but omental plugging of the catheter has limited its success, and special dialysis catheters are required for effective fluid exchange. Pleural dialysis is another option for which fluid exchange is less problematic. Hemodialysis or dialysis would likely be most effective in horses with nephrotoxic ARF, whereas vasomotor nephropathy is best treated by addressing the predisposing condition and instituting appropriate fluid therapy.

After volume deficits have been restored and polyuria achieved, patients usually need only continued fluid therapy (0.9% NaCl or another balanced electrolyte solution, 40 to 80 mL/kg/day) to promote a continued decrease in creatinine. Fluid therapy may have to be continued (20 to 40 mL/kg/day) for several days until creatinine returns to the normal range or a steady-state value and the horse is eating and drinking adequate amounts. Supplementation with oral electrolytes (1 to 2 oz NaCl twice daily) will also promote greater fluid intake and diuresis. Potassium supplementation (1 oz KCl twice daily) may also be required because diuresis results in kaliuresis. When horses remain anorectic during treatment, the addition of 50 to 100 g dextrose/L fluids can provide needed calories, and if anorexia

VetBooks.ir

persists for several days, caloric intake may have to be provided by nasogastric tube feeding or total parenteral nutrition.

Within the week after fluid therapy is discontinued, creatinine should be measured again to ensure it has not increased. Occasionally, creatinine may not decrease to below 2 to 3 mg/dL despite continued fluid therapy. As long as the horse is eating and drinking well, IV fluids can be discontinued. In some horses, further recovery will be seen as a return of creatinine to normal range within the next couple of months, whereas in other patients a persisting elevation in creatinine indicates permanent loss of renal function.

Serum Creatinine Elevations in Newborn Foals

During the first 1 to 3 days of life, the creatinine concentration in newborn foals is often 30% to 40% higher than in their dams.[92] The cause is unclear but likely related to an inability of creatinine to equilibrate rapidly across placental membranes. As supportive evidence, creatinine concentration of normal amniotic fluid (which contains fetal urine) at term is approximately 10 mg/dL (and may exceed 30 mg/dL in some mares).[93] This transient increase in creatinine, which may occasionally exceed 20 mg/dL in premature foals, has been called a "spurious" elevation—a misleading characterization because creatinine truly is increased. Further, in a recent retrospective study, 20 of 28 foals with hypercreatinemia had clinical signs of mental abnormalities and/or seizures.[94] When elevated creatinine is detected in an otherwise healthy foal (that has also been observed to urinate normally), there may be no cause for alarm, but if levels do not decline rapidly after birth (or remain >2.5 mg/dL on day 3 of life), peritoneal or retroperitoneal accumulation of urine, renal hypoplasia, or other causes of renal failure should be considered. Unlike creatinine, BUN values in foals are typically low (<10 mg/dL) after day 2 and remain low for the first several months of life. This finding can be attributed to the anabolic state of the growing foal.

Urinalysis results in normal neonatal foals are also different from those in adult horses. Specifically, for 1 to 2 days after birth, normal foals may have marked proteinuria resulting from filtration of small-molecular-weight proteins absorbed with colostrum. Fluid intake on a predominantly milk diet is high in foals (250 mL/kg/day, compared to 50 mL/kg/day of water intake by adults), so after day 2 of life, foal urine is hyposthenuric (specific gravity 1.002 to 1.006) and remains that way for several months. Finally, urinary enzyme activity and sodium and chloride clearances may be greater than adult values, and urine pH is neutral to acidic in foals.[95]

Acute Renal Failure in Foals

ATN is the most common pathologic lesion causing ARF in neonatal foals. Many cases develop during or after episodes of diarrhea, likely caused by poor perfusion (vasomotor nephropathy) subsequent to varying degrees of dehydration. Surprisingly, the diarrheal disease in some affected foals does not appear to be serious, but they may develop ARF. Similar to adult horses with ARF, the prominent clinical signs are depression and development of edema. Abnormal laboratory findings include azotemia, hyponatremia, hypochloremia, and hypocalcemia. Foals are more likely to develop significant hyperkalemia and hyperphosphatemia than adult horses with ARF. A urine specific gravity less than 1.018 and microscopic hematuria are usually also found in foals with ARF. Urine output of sick neonates should be monitored closely because they may become oliguric to anuric 12 to 24 hours before significant depression or azotemia is recognized. In addition, fluid retention during incipient ARF is another cause of inappropriate weight gain (e.g., >2 kg in 24 hours), which can often be detected before obvious edema develops.

Nephrotoxicity, most often due to aminoglycoside or tetracycline administration, is another important cause of ARF (usually nonoliguric) in neonatal foals. As in adult horses, the recent change to once-daily aminoglycoside dosing appears to have decreased the incidence of hospital-acquired ARF in foals. Seriously ill and/or premature foals appear to be at even greater risk of nephrotoxicity than term foals, owing to reduced renal clearance.[96] Although there is a general impression that amikacin may be less nephrotoxic than gentamicin in foals, no data exist to support this notion. Regardless of which aminoglycoside antibiotic is selected, monitoring trough concentrations (<2 mg/mL for gentamicin, <4 mg/mL for amikacin) is warranted to decrease the risk of aminoglycoside toxicity in high-risk neonates. It should be noted that the actual optimal trough concentrations are unknown in horses and are based on those used in human medicine. Dosage adjustment may be necessary in seriously ill neonates or premature foals, because renal clearance may be decreased, necessitating an increased dosing interval to achieve low enough trough concentrations. Judicious fluid therapy to correct dehydration and maintain BP is an important precaution. To complicate matters, foals also have a larger volume of distribution than adult horses and require an increased dose of aminoglycosides to attain therapeutic peak concentrations.[4,97] Volume of distribution may be increased even further in premature foals and with certain disease processes that increase extracellular fluid volume.

Treatment principles for ARF in neonates are essentially the same as for adult horses (see earlier discussion). However, greater attention must be paid to monitoring responses to fluid therapy, including twice-daily measurement of body weight. Although foals that have a bout of ARF in the neonatal period would seem at greater risk of developing chronic renal failure later in life, no long-term follow-up study has corroborated this speculation.

Septic Renal Disease in Foals

Multifocal renal abscesses or infarcts may be a complication of neonatal septicemia and can lead to ARF. *Actinobacillus equili* is the most common pathogen causing renal abscesses, but affected foals often die or are euthanatized because of overwhelming sepsis before clinical signs of ARF develop. Foals 2 to 4 days of age appear to be at greatest risk of developing acute *Actinobacillus* septicemia; when this problem is suspected, IV therapy with penicillin and gentamicin (at prolonged dosage) is recommended (see Chapters 18 and 20). Subsequent fibrin deposits in the kidney have also been identified in some foals with septicemia and ARF.[98]

Chronic Renal Failure

Thomas J. Divers • Theresa Lynn Ollivett

Chronic renal failure (CRF) in the horse may be divided by clinical and pathologic findings into two broad categories: primary glomerular disease and primary tubulointerstitial disease.[1,2] However, pathology in one portion of the nephron usually leads to altered function and eventual pathology in the entire nephron, so CRF is an irreversible disease process characterized by a progressive decline in GFR. The rate of decline in GFR is variable among affected horses, making the short-term (e.g., months to 2 years) prognosis guarded to favorable while the long-term prognosis remains poor.

Primary *glomerular* diseases that can lead to CRF in horses include GN, nonspecific glomerulopathy, renal glomerular hypoplasia, and amyloidosis. Primary *tubulointerstitial* diseases causing CRF include incomplete recovery from ATN, pyelonephritis, nephrolithiasis, hydronephrosis, renal dysplasia, and (rarely) papillary necrosis. Collectively, the latter disorders produce pathology categorized as *chronic interstitial nephritis.* Unfortunately, because renal disease is often advanced when horses are first presented for clinical evaluation, the inciting cause leading to CRF may be difficult to ascertain, and end-stage kidney disease (ESKD) may be the pathologic diagnosis. The inciting cause may more likely be discerned from the history (long term) rather than clinical findings at presentation, especially for primary tubulointerstitial diseases. Adjunctive diagnostic evaluation, including laboratory assessment, renal ultrasonography, and renal biopsy, may provide further evidence to document the inciting cause.

FIG. 34-3 Yearling Thoroughbred with chronic renal failure caused by renal dysplasia. Failure to grow normally and lethargy were the primary complaints.

Causes

Proliferative Glomerulonephritis

Proliferative GN, indicating increased cellularity of the glomerular tufts consequent to influx of inflammatory cells and proliferation of mesangium, is the most common glomerular disease causing CRF in horses. It is thought to result from deposition of circulating immune complexes along the glomerular capillaries or in situ formation along the glomerular basement membrane (GBM) (Fig. 34-2). Deposition of immune complexes causes activation of complement and vasculitis (type III hypersensitivity response). In one study, deposits of immunoglobulin (Ig)G and complement along the GBM were found through IF staining in a large percentage (22 of 53) of horses at necropsy.[3] However, only 1 of these 53 horses developed CRF. Thus, although immune (antigen-antibody) complex deposition and subclinical GN may be common in horses, progression to CRF appears to be an infrequent occurrence. In this necropsy survey the predominant IF staining pattern was granular (patchy deposits of immune complexes and complement along GBM), but linear deposits were found in two horses. The latter finding was supportive of true autoimmune disease with more diffuse deposition of anti-GBM antibodies (type II hypersensitivity response) along the basement membrane antibody.

Streptococcal antigens have been suggested to be an important trigger for development of proliferative GN,[4] and in one horse with CRF, streptococcal antigens were confirmed to be present in diseased glomeruli.[5] Although equine infectious anemia virus is the only other antigen that has been detected in glomeruli of horses with proliferative GN,[6] subclinical GN likely accompanies other chronic infections in horses. It has also been suggested that equine GN may also be associated with either mixed or monoclonal cryoglobulins forming antibody-antibody glomerular deposits.[7] In one horse with no evidence of viral or bacterial infection, deposits consisting solely of IgM were identified within the GBM.[8] Fortunately, GN in most patients is rarely of clinical significance.

Chronic Interstitial Nephritis

Chronic interstitial nephritis (CIN) and fibrosis may be the most common cause of CRF in horses. Interstitial nephritis (tubulointerstitial disease) usually develops as a sequela to ATN consequent to exposure to nephrotoxins or vasomotor nephropathy. Other causes include drug-induced interstitial nephritis, urinary obstruction, pyelonephritis, renal hypoplasia/dysplasia, and papillary necrosis. Although the majority of horses that develop ARF attributable to these causes recover with apparently normal renal function (they remain nonazotemic), a few may survive with significant loss of renal functional mass and subsequently (often years later) develop signs of CRF due to CIN.[9] In horses younger than 5 years of age that develop CRF unattributable to other causes, anomalies of development (e.g., renal hypoplasia, dysplasia, polycystic kidney disease) should be strongly suspected[2,10-13] (Fig. 34-3).

Pyelonephritis

Bilateral septic pyelonephritis is a rare cause of CRF in horses.[14-16] Pyelonephritis is usually due to an ascending infection and often accompanied by nephrolithiasis or ureterolithiasis. Multiparous mares (especially those with a history of dystocia) and horses with bladder paralysis are at greater risk for bacterial colonization of the lower urinary tract and subsequent development of ascending infection. Chronic distention with bladder paralysis compromises the integrity of the ureteral orifices, leading to vesicoureteral reflux and pyelonephritis. With long-standing bladder paralysis, the ureteral orifices may appear wide open during cystoscopic examination, and in an occasional affected horse, the endoscope can be advanced into the ureter with little resistance. With unilateral pyelonephritis, adequate renal function is usually maintained by the contralateral kidney, but passage of small uroliths into the bladder can lead to recurrent urethral obstruction. Gram-negative organisms appear to be the most common causative agents, although *Staphylococcus, Streptococcus,* or *Corynebacterium* spp. may be isolated in some cases, and mixed bacterial infections are not uncommon.

Miscellaneous Causes

Other reported causes of CRF in horses include amyloidosis,[17] neoplasia,[18] focal glomerulosclerosis-like disease,[19] and chronic oxalate nephrosis.[20] One study described CRF secondary to polycystic kidney disease in an aged pony with hematuria; the pony also had hepatic cysts.[21] Renal amyloidosis has been reported only in horses used for production of antiserum.[17] So-called oxalate nephropathy in horses is likely a misnomer; the presence of oxalate crystals in renal tissue of horses with CRF is typically a consequence rather than the cause of CRF.[20]

Clinical Signs and Laboratory Findings The most common clinical sign observed in horses with CRF is weight loss.[2] A small plaque of ventral edema, usually between the forelimbs, is another frequent finding.[2,22] Moderate polyuria and polydipsia (PU/PD) are usually present at some stage of the disease process, but PU/PD may not be noticed except by the astute owner or trainer.[2] Dysuria is generally not reported unless CRF is due to pyelonephritis, which may be associated with bladder paralysis, lithiasis, and lower urinary

VetBooks.ir

FIG. 34-4 Dental tartar caused by chronic azotemia in a 5-year-old Standardbred with chronic renal failure.

tract infection (UTI). Normal equine urine is rich in crystals and mucus, making a prediction of urine abnormalities on gross observation difficult. However, hematuria or pyuria (gross or microscopic) may be reported in some (but not all) horses with pyelonephritis, urinary calculi, or neoplasia. Often, urine produced by horses with CRF is light yellow and transparent because it is relatively devoid of crystals and mucus. Accumulation of dental tartar (especially on the incisors and canine teeth [Fig. 34-4]), melena, and oral ulcers are other findings that may be detected in horses with CRF. Growth may be stunted in horses with renal hypoplasia, dysplasia, or polycystic kidney disease. Although abdominal pain would be expected in horses with obstructive nephroliths or ureteroliths, colic signs are not often reported in horses with lithiasis producing obstruction of the upper urinary tract.[9,23] Rarely, signs of uremic encephalopathy such as obtundation, anxiety, head pressing, and seizure may be present.[24,25]

Clinicopathologic findings in horses with CRF vary depending on appetite, diet, and the cause and severity of renal damage. Most horses with clinical signs of CRF have moderate to severe azotemia (creatinine usually ≥5 mg/dL). The BUN/creatinine ratio may vary depending on protein intake, muscle mass, hydration, and degree of azotemia, but is usually 10:1 or greater. Mild hyperkalemia, hyponatremia, and hypochloremia are typically found in horses with CRF. Hypercalcemia, with serum concentrations sometimes exceeding 20 mg/dL, appears to be a laboratory finding with CRF that is unique to the equid. One study of horses evaluated at referral hospitals for renal failure reported 56% of 39 horses with CRF to be hypercalcemic,[26] and a larger study of 99 horses with CRF found 67% to be hypercalcemic.[2] Hypercalcemia in horses with CRF is not due to hyperparathyroidism[27]; its presence or absence appears to be more closely related to dietary intake than to the magnitude of azotemia. For example, four of four nephrectomized ponies fed alfalfa hay developed marked hypercalcemia,[28] whereas serum calcium concentration remained within the normal range in four of four nephrectomized ponies fed grass hay (although filterable calcium did increase).[29] Similarly, hypercalcemia in horses with spontaneously occurring CRF can resolve within a few days of changing diet from alfalfa to grass hay.[13] Serum phosphorus concentration in horses with CRF is usually normal to decreased, and hypophosphatemia is more often detected with concurrent hypercalcemia. Hypermagnesemia may also be detected in some horses with CRF. Acid-base balance usually remains normal until CRF becomes advanced, but metabolic acidosis is a common finding in horses with end-stage disease.

Many horses with CRF are moderately anemic (packed cell volume, 20% to 30%) secondary to decreased erythropoietin production by the diseased kidneys. Those with CRF resulting from GN frequently have hypoalbuminemia and hypoproteinemia, and horses with advanced CRF of any cause may also have mild hypoproteinemia associated with intestinal ulceration. Hyperglobulinemia may be detected in horses with immune-mediated diseases or chronic pyelonephritis. Horses with CRF can also develop hypercholesterolemia and hypertriglyceridemia (hyperlipidemia), and horses with advanced CRF may occasionally have grossly lipemic plasma.[30]

Urinalysis findings may also vary depending on the cause of CRF. As mentioned, urine collected from horses with CRF is relatively devoid of normal mucus and crystals, making samples transparent. Urine specific gravity is typically in the isosthenuric range (1.008 to 1.014), although heavy proteinuria in an occasional horse with GN may produce values up to 1.020. Quantification of urine protein concentration (as for cerebrospinal fluid) is required to accurately assess proteinuria. Urine protein concentration in normal horses is usually less than 100 mg/dL, and the urine protein/creatinine ratio should be less than 1:1.[31,32] With significant proteinuria, urine protein/creatinine ratio is usually greater than 2:1.[5] In the earlier stages of GN, excessive urine protein is primarily albumin, but with progression of glomerular pathology, an increasing amount of globulin is also lost in the urine. Horses with CIN usually do not have significant proteinuria. Hematuria (gross or microscopic) may be present with pyelonephritis, urinary calculi, or neoplasia and can produce trace proteinuria, but urine protein/creatinine ratio usually remains less than 2:1. Horses with septic pyelonephritis would be expected to have pyuria (>5 leukocytes/high-power field) and significant bacteriuria on sediment examination, but these findings are not consistently detected; a urine sample should be submitted for quantitative bacterial culture in all horses with CRF. More than 10,000 colony-forming units (CFU)/mL of urine are typically found with infection, although lower numbers do not always rule out septic pyelonephritis.

Diagnosis A diagnosis of CRF is most often made in horses with azotemia and isosthenuria that present with a complaint of weight loss or decreased performance. As discussed earlier, determining the inciting cause of CRF can be difficult because the disease has often advanced to ESKD when horses are initially presented for evaluation. Urinalysis does not often reveal the cause of CRF except in some horses with pyelonephritis. In theory, assessment of urine protein concentration and urine protein/creatinine ratio should be helpful in separating glomerular disease from tubulointerstitial disease, but in practice, these laboratory measures have not consistently been elevated in horses with histopathologic evidence of GN. However, detection of moderate to heavy proteinuria (urine protein/creatinine ratio > 2:1) without hematuria provides support for glomerular disease.

Rectal examination may be helpful in determining the cause of CRF. Horses with pyelonephritis, as well as those with ureteral calculi, often have enlarged ureters that can be palpated dorsolaterally as they course through the retroperitoneal space. Although kidneys of horses with CRF are often small with an irregular surface, these changes are not always apparent on palpation of the caudal pole of the left kidney. The right kidney cannot usually be palpated in the horse unless it is greatly enlarged or displaced caudally by the liver or a mass. Ultrasonographic imaging is useful for evaluating kidney size and echogenicity and may reveal fluid distention (hydronephrosis, pyelonephritis, polycystic disease) or presence of nephroliths.[33-35] Horses with significant renal parenchymal damage and fibrosis often have loss of detail of the corticomedullary junction, and echogenicity of renal tissue may be similar or even greater than that of the spleen. In contrast, intravenous pyelography (IVP) provides little information in adult horses, and its use is generally limited to foals less than 50 kg. When hematuria or dysuria accompanies CRF, cystoscopic examination can be helpful in determining the side (right vs. left) from which renal hematuria is originating and further allows assessment of the ureteral orifices and urine flow from each kidney.

As described under Acute Renal Failure, measurement of GFR provides the most accurate assessment of renal function, and repeated measurements at monthly or longer intervals can be useful to monitor rate of progression of CRF. It is also a useful measure to document a reduction in renal function in horses that are thought to have

VetBooks.ir

early CRF, before significant azotemia has developed. GFR can be measured by several methods, including urinary clearance of endogenous or exogenous creatinine, inulin, or technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA) (all require timed urine collections) or plasma disappearance of sodium sulfanilate, phenolsulfonphthalein, or radiolabeled compounds (e.g., ^{99m}Tc-DTPA).[13,36-39] Assessment of renal function by nuclear scintigraphic imaging of the kidneys has also been described, but in horses this technique appears to be better for documenting decreased individual kidney function (i.e., with unilateral or asymmetric disease) than for quantitative assessment of GFR.[40,41] In most clinical settings, performing a 24-hour endogenous creatinine clearance is the most practical and economical method for measuring GFR. The major challenge is application of a urine collection device for collection of all urine produced. Once urine has been collected, a well-mixed sample is submitted to the laboratory, along with a sample of serum obtained during the collection period, and GFR is estimated by the following standard clearance formula:

$$\text{GFR}\,(\text{mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}) = \{([\text{Cr}_{\text{urine}}]/[\text{Cr}_{\text{serum}}])\}\times \text{UF/bwt}$$

where *UF* is urine flow (mL min^{-1}) and *bwt* is body weight in kilograms.[37] GFR in horses with normal renal function ranges from 1.5 to 3.0 mL · kg^{-1} · min^{-1}, and values less than 1.0 mL · kg^{-1} · min^{-1} are indicative of a decrease in GFR. Although repeated measurement of endogenous creatinine clearance provides useful information about the rate of decline in GFR in horses with CRF, simply measuring creatinine and assessing body condition at monthly or longer intervals are the most common methods used to evaluate the progression of CRF in affected horses.

The inciting cause of CRF can be confirmed in some horses by renal biopsy. As discussed under Acute Renal Failure, renal biopsy should be approached cautiously and pursued only if findings are likely to change treatment or prognosis. Treatment for CRF consists of supportive care, and because the long-term prognosis is poor, renal biopsy is rarely indicated in horses with CRF. Further, most horses have rather advanced CRF at the time the disease is initially detected, and biopsy results in these patients may not provide useful information regarding the inciting cause.

Treatment Treatment of horses with CRF is most likely to produce improved renal function if there is an acute reversible component exacerbating CRF (i.e., acute-on-chronic syndrome). Similar to ARF, sudden exacerbation can be caused by exposure to nephrotoxins or vasomotor nephropathy secondary to diseases producing hypovolemia (e.g., diarrhea or sepsis causing volume depletion). Ascending UTI or obstruction can also exacerbate CRF. If an acute component is detected, it should be corrected rapidly (as described for ARF) with the goal of minimizing further loss of functional nephrons. In addition, surgical removal or fragmentation of stones may be indicated in horses with calculi thought to be disrupting urine flow.

In horses with relatively stable CRF, management changes should be kept to a minimum and, when necessary, made gradually. Treatment of horses with stable CRF consists of supportive care: providing sufficient fluids, electrolytes, and nutritional support.[42] Water should be available at all times, and salt can be provided freely so long as edema or hypertension is absent. If edema develops, salt should be restricted, even in the face of hyponatremia. In addition to creatinine, serum electrolyte concentrations and acid-base balance should be measured regularly (e.g., monthly or longer intervals). If serum sodium and chloride concentrations are decreased, 60 to 120 g (≈2 to 4 oz) of salt may be added to the feed, provided edema is not present. If metabolic acidosis is detected (e.g., blood pH < 7.35 or serum bicarbonate concentration < 20 mEq/L) and the patient is not edematous, sodium bicarbonate ($NaHCO_3$) powder (100 to 200 g/day) or a mix of $NaHCO_3$ and salt should be added to the diet. The goal of supplementation with salt and $NaHCO_3$ is to maintain serum electrolyte concentrations and acid-base balance within reference ranges. However, the effect of electrolyte supplementation on progression of CRF is unclear because high-salt diets may actually hasten the decline in GFR and exacerbate proteinuria in human patients with CRF.[43]

Although no adverse effects of hypercalcemia in horses with CRF have been documented, decreasing calcium intake (e.g., replacing alfalfa or other legume hays with grass hay) may result in a return of serum calcium concentration to the normal range. The hypophosphatemia that usually accompanies hypercalcemia in horses with CRF may prevent mineralization of soft tissues. There appears to be no need for vitamin D supplementation in horses with CRF, but regular administration of vitamin B complex and anabolic steroids may be helpful to stimulate appetite. If appetite remains good, anabolic steroids may further limit muscle wasting and may increase packed cell volume (PCV). Attenuation of anemia in human and canine patients with CRF by administration of recombinant erythropoietin has been one of the most significant advances in management of CRF, because it has eliminated the need for blood transfusions, improved exercise capacity, and decreased morbidity associated with the uremic syndrome.[44] In an occasional horse with advanced CRF, marked hyperlipemia may develop, and administration of heparin (40 to 100 units/kg subcutaneously [SC] twice daily) may stimulate lipoprotein lipase and decrease plasma triglyceride concentration.[45] This treatment is not without risk, however; it may cause a further decline in PCV and potentiate bleeding tendencies in a uremic patient. NSAIDs and corticosteroids are best avoided in horses with CRF due to primary tubulointerstitial disease. If these drugs are essential for treatment of a complicating problem, they should be used judiciously.

Treatment of CRF due to GN appears to be even less rewarding than treatment of CRF caused by tubulointerstitial disease (CIN). Immunosuppressive therapy has been of limited benefit in slowing the progression of the disease and may even hasten weight loss, although short-term improvement with dexamethasone therapy has been documented in one horse.[8] For patients with significant edema, treatment with diuretics may result in transient improvement, and plasma transfusions may be of temporary benefit to horses with edema and hypoalbuminemia.

As CRF progresses, partial anorexia and lethargy lead to more rapid loss of body condition, so nutritional management aimed at maintaining body condition is probably the most important aspect of supportive care for these horses. Increasing carbohydrate (grain) intake and adding fat to the diet are recommendations to increase caloric intake. Fat can be added by feeding corn oil (up to 16 oz/day) or a commercial fat supplement. Increased intake of omega-3 fatty acids (e.g., available in linseed oil or flaxseed oil) has been demonstrated to slow the progression of renal failure in experimental models, but potential benefits in spontaneously occurring CRF are less clear.[46,47] Restricting dietary protein intake by human and veterinary patients with CRF was once thought to have beneficial effects,[48] but the current recommendation is to provide adequate amounts of dietary protein and energy to meet or slightly exceed predicted requirements while maintaining a neutral nitrogen balance.[49] In horses with CRF, adequacy of dietary protein intake can be assessed by the BUN/creatinine ratio; values greater than 15:1 suggest excessive protein intake, and values less than 10:1 may indicate protein-calorie malnutrition. Finally, an important but often overlooked aspect of nutritional management of horses with CRF is provision of a highly palatable diet. Feeding smaller meals more frequently and varying the diet (e.g., offering various types of concentrated feeds, as appetite may vary from day to day) are helpful methods to increase food intake.

Additional treatments for CRF in human patients include antihypertensive agents, including diuretics, β-adrenergic blockers, and angiotensin-converting enzyme (ACE) inhibitors.[50] ACE inhibitors may have an additional benefit of limiting proteinuria.[51] Little is known about the roles of systemic or intrarenal hypertension in progression of renal disease in horses, and there are no reports of potential benefits of use of antihypertensive medications in horses

VetBooks.ir

with CRF. Efforts are under way to examine the roles of mediators of inflammation in development of renal fibrosis, with the hope that future specific interventions may be developed to limit the progressive interstitial fibrosis that occurs in all patients with CRF.[52]

Horses with end-stage CRF often develop oliguria and uncontrollable metabolic acidosis. At this stage, CRF can only be managed by hemodialysis or peritoneal/pleural dialysis. However, pursuit of either hemodialysis or peritoneal dialysis in horses with CRF is impractical because, even when successful, dialysis prolongs the life of the patient for only a short time.

Prognosis The progressive loss of nephron function characteristic of CRF precludes successful long-term treatment in horses, but many horses with early CRF may be able to continue in performance or live as a pet for months to a few years. In general, as long as creatinine remains less than 5.0 mg/dL and the BUN/creatinine ratio is less than 15:1, affected horses seem to maintain a reasonably good attitude, appetite, and body condition. Once creatinine exceeds 5.0 mg/dL, the rate of progression of CRF appears to accelerate, and signs of uremia (e.g., anorexia, poor hair coat, loss of body condition) become more apparent over a few weeks to months. Although this threshold value for creatinine is a useful figure for offering an initial prognosis for most horses with CRF, it is important to remember that progression of CRF is highly variable among affected animals. Thus, each case must be handled on an individual basis, with the emphasis on maintenance of body condition until humane euthanasia may become necessary.

Urinary Tract Infections

Thomas J. Divers • Dominic R. Dawson Soto

UTIs can be anatomically divided into two categories: those affecting the upper urinary tract (kidneys and ureters) and those involving the lower urinary tract (bladder and urethra). Lower UTI in horses usually results from anatomic or functional causes of abnormal urine flow, especially bladder paralysis (see Urinary Incontinence). Although recognized less frequently, upper UTI is often a more serious, potentially life-threatening problem. In horses, UTI is also frequently accompanied by urolithiasis and partial obstruction. With the exception of single large cystoliths (that predispose affected horses to lower UTI), it is often difficult to determine whether development of nephroliths, ureteroliths, multiple small cystoliths, and urethroliths was a predisposing cause or a consequence of UTI. The pathophysiology, diagnosis, and management of equine UTI has recently been extensively reviewed.[1]

Risk Factors and Causes

The most common risk factors for development of UTI in horses are bladder paralysis, concurrent urolithiasis, and urethral damage (e.g., foaling trauma in mares, neoplasia or habronemiasis in stallions and geldings). The shorter urethra and its location near the anus also increase the risk of lower UTI in healthy females. For example, in humans, silent lower UTIs and pyelonephritis resulting from infection with bacteria shed from the GI tract can develop in prepubertal girls and during pregnancy or after menopause in adult women.[2] This increased risk at certain times has been further attributed to a lack of estrogen, a hormone that appears to be important for production of glycosaminoglycans that cover uroepithelial surfaces and inhibit attachment of bacteria.[3] Whether fillies or pregnant mares are at increased risk for UTI has not been studied. However, horses with bladder paralysis (detrusor dysfunction) or decreased urethral sphincter tone (from trauma or neurologic disease) are clearly at greater risk of UTI than horses with normal detrusor and urethral sphincter function. Finally, because bladder catheterization cannot be performed in a sterile manner because of normal bacterial flora in the vestibule and distal urethra, contamination of the lower urinary tract is an accepted risk of this procedure. Nevertheless, development of lower UTI is an unlikely complication of bladder catheterization in otherwise healthy animals, because host defense mechanisms, including urine flow, are highly effective in eliminating contaminating bacteria. When urethral or bladder mucosa has been damaged or urine stasis (bladder paralysis) is present, bladder catheterization has a greater risk of producing UTI.

In a group of horses with neurologic bladder dysfunction complicated by UTI, *E. coli, Staphylococcus* spp., *Corynebacterium* spp., and *Pseudomonas aeruginosa* were the microbes isolated most frequently.[4] In the author's experience (TJD), *E. coli, Proteus mirabilis, Klebsiella* spp., and *Enterobacter* spp. are the most common pathogens isolated from individual horses with UTI. *P. aeruginosa* can cause lower UTI in some horses, but it can also be isolated from the urethra of many clinically normal horses. Gram-positive organisms are less frequent causes of UTI in horses, although *Streptococcus, Staphylococcus,* and *Corynebacterium* spp. are occasionally identified pathogens.[5,6] In horses with abnormal urine flow (e.g., with uroliths) or instrumentation of the urinary tract (e.g., indwelling bladder catheters, ureteral stents), UTI with *Enterococcus* spp. (formerly *Streptococcus faecalis*) may also develop. Similarly, lower UTI with *Candida* spp. develops in recumbent neonatal foals receiving broad-spectrum antibacterial therapy. Additional organisms such as *Actinobacillus equuli, Rhodococcus equi,* and *Salmonella* spp. have been identified in septic foals.[7] In horses without an obvious predisposing factor, primary immune dysfunction, such as pituitary pars intermedia dysfunction, should be considered.

Clinical Findings Clinical signs of UTI usually reflect the location, severity, and duration of the infection. Lower UTI is typically characterized by recognizable disturbances in urine flow but seldom causes signs characteristic of a systemic infection (e.g., fever, weight loss). Dysuria, stranguria, pollakiuria, and incontinence are consistent with lower UTI. Urine scalding of the perineum may develop with chronic UTI in mares (but should not be confused with estrus), and the sheath opening and dorsal aspects of the hindlimbs may be coated with urine crystals or blood in affected stallions and geldings. Gross hematuria may be observed if urinary calculi are present or if bladder or urethral mucosa has been eroded. Hematuria of bladder origin typically produces hematuria throughout urination, but gross discoloration of urine is most obvious at the end of urination. Hematuria caused by renal hemorrhage was a major component of pyelonephritis reported in seven horses.[8] In an occasional horse, gross pyuria may also be observed as passage of mucopurulent debris in otherwise clear urine. Horses with upper UTI are more likely to have signs characteristic of a systemic infection (e.g., fever, weight loss), but because UTI is typically accompanied by concurrent lower UTI, dysuria may also be present. As an example, recurrent urethral obstruction with small uroliths may be the presenting complaint for chronic upper UTI.

Rectal examination may help confirm a predisposing cause of lower UTI (e.g., enlarged and atonic bladder, cystic calculi, accumulation of sabulous urine sediment, bladder mass). Chronic cystitis also usually leads to bladder wall thickening, but this change is not easily detected by rectal palpation. Although ureters are not usually found during rectal examination of the normal horse, careful palpation of the dorsolateral aspects of the caudal abdomen (retroperitoneal space) usually reveals enlarged ureters in horses with upper UTI. With pyelonephritis, palpation may further reveal an enlarged, painful, or shrunken and misshapen kidney.

Diagnosis A diagnosis of UTI is based on clinical signs and laboratory analysis of blood and urine samples. With lower UTI, results of a complete blood cell count (CBC) and serum biochemical profile are usually within reference ranges, whereas CBC results with upper UTI often support a systemic inflammatory response. With chronic upper UTI, increased total protein and globulin concentrations are often detected, and azotemia may also be present. Detection of greater than 20 organisms and more than 10 white blood cells

VetBooks.ir

(WBCs) per high-power field on sediment examination of a urine sample collected during midstream voiding or via bladder catheterization is highly supportive of UTI, and growth of 10^4 or more organisms per milliliter of urine confirms the diagnosis.[9,10] When evaluating a horse for possible UTI, urine samples collected should be examined and processed for bacterial culture within 30 minutes after collection, or they should be refrigerated because bacteria can continue to proliferate when urine is stored at room temperature.[9]

Detection of azotemia, low urine specific gravity, and WBC casts in urine sediment are indicative of upper UTI, especially when accompanied by signs of systemic illness. Ultrasonographic examination of the kidneys is useful for detecting abnormal renal size, shape, or consistency in horses with upper UTI.[8,11-13] Transrectal ultrasound can further characterize the bladder, particularly thickening of the bladder wall, ureters, and left kidney. The right kidney is rarely to never visualized. Endoscopic examination of the lower urinary tract is useful for evaluating the integrity of urethral and bladder mucosa, detecting small uroliths, and assessing urine flow from each ureteral orifice.[14,15] With long-standing cystitis, especially when bladder paralysis is the underlying cause, ureteral orifices may become dilated (and appear wide open), allowing for vesiculoureteral reflux and development of ascending pyelonephritis. When unilateral pyelonephritis is suspected on the basis of ultrasonographic findings, catheterization and collection of urine samples individually from each ureter can be helpful to document unilateral disease. Ureters may be catheterized by passing sterile polyethylene tubing through the biopsy channel of the endoscope during cystoscopy or can be accomplished in mares by directing blunt-ended catheters (e.g., 8-Fr polypropylene) through the urethra into each ureteral orifice.[16]

Treatment

Treatment of UTI consists of proper antimicrobial therapy and correction, if possible, of predisposing anatomic or functional causes. Selection of the appropriate antimicrobial agent is best determined by prior knowledge of:

- Susceptibility patterns of the causative agent(s)
- Concentration of the antibiotic in renal tissue and urine
- Activity of the antibiotic at different pH values
- Ease of administration
- Toxicity
- Expense
- Compatibility with other antimicrobial drugs

Recommended antimicrobial agents for UTI treatment in horses are discussed next. It should be emphasized that in vitro resistance to a particular antibiotic may not preclude successful treatment with the drug, so long as high concentrations are achieved in urine. Similarly, in vitro susceptibility does not always guarantee a successful response to treatment. For example, *Enterococcus* spp. are routinely found to be susceptible to trimethoprim-sulfa combinations; however, this pathogen is inherently resistant to these combinations in vivo.[17]

TRIMETHOPRIM/SULFONAMIDE COMBINATIONS. Trimethoprim-sulfonamide combinations have been highly successful in treating lower UTIs in some species.[18-20] Although sulfonamides alone can be effective in treating many lower UTIs,[21] addition of trimethoprim improves the antibacterial spectrum without a prohibitive increase in expense or toxicity.[22] When selecting a trimethoprim-sulfonamide combination for treatment of horse with a UTI, metabolism of the sulfonamide should be considered; sulfamethoxazole is largely metabolized to inactive products before urinary excretion, whereas sulfadiazine is excreted largely unchanged in urine.[23] Although less of a risk with newer preparations, horses with acidic urine, dehydration, or poor renal perfusion may develop hematuria and crystalluria with sulfonamides.[24]

PENICILLIN AND AMPICILLIN. Parenterally administered penicillin is effective for treating upper or lower UTIs caused by susceptible *Corynebacterium, Streptococcus,* and some *Staphylococcus* spp.[25] Ampicillin has also been used successfully for treatment of both upper and lower UTIs in animals and human patients.[18,26] Although many isolates of the Enterobacteriaceae family demonstrate resistance to ampicillin in vitro, this drug is highly concentrated in urine, and many organisms that are resistant in vitro may be killed in the urine of treated animals.

GENTAMICIN AND AMIKACIN. Gentamicin and amikacin, which can be nephrotoxic, should be reserved for treating lower UTIs caused by highly resistant organisms or acute, life-threatening upper UTIs caused by gram-negative organisms. Pharmacokinetic studies in adults and foals are available.[27,28] Potentiated penicillins (ticarcillin or ticarcillin/clavulanic acid) may be considered as an alternative to aminoglycosides in horses with severely compromised renal function (e.g., creatinine > 3.0 mg/dL).

CEPHALOSPORINS, TETRACYCLINES, AND CHLORAMPHENICOL. Cephalosporins, tetracyclines, and chloramphenicol are frequently and effectively used to treat UTIs in other species.[26] Cephalosporins are concentrated in urine. Ceftiofur has broad-spectrum antimicrobial activity and could be selected when urinary pathogens demonstrate resistance to trimethoprim-sulfonamide combinations or penicillin. Tetracycline and chloramphenicol are predominantly metabolized in the liver, with variable excretion in bile. However, when acceptable serum concentrations are achieved, excretion of active drug into urine may be high enough that either drug may be effective for treatment of UTIs caused by susceptible organisms.[29,30]

OTHER ANTIMICROBIAL AGENTS. Nitrofurantoin has an impressive in vitro spectrum, demonstrating activity against most common gram-negative organisms including *Salmonella.*[13] The drug is inexpensive, is easily administered as an oral suspension, and achieves high concentrations in urine. Although this antimicrobial agent has not been well studied in horses, adverse effects and acquired resistance appear to be uncommon. However, nitrofurantoin does not attain high concentrations within renal parenchyma, so its efficacy in treating upper UTI would be questionable. Further limitations of nitrofurantoin usage include decreased antimicrobial activity at an alkaline pH, and increased risk of toxicity has been described in other species as GFR falls (e.g., with CRF). Because urine concentration and antimicrobial activity of nitrofurantoin after oral (PO) administration have not been well substantiated in horses, use of this antibiotic should be reserved for selected cases where specific susceptibility of a gram-negative organism has been demonstrated, or when expense precludes selection of another antibiotic for long-term therapy.

It is not unusual to find highly resistant organisms in urine of horses with chronic UTIs, especially those with bladder paralysis that have been repeatedly catheterized and have received a variety of antibiotic agents. In some cases the organisms may be highly resistant to all drugs approved for use in the equine. One of the authors (TJD) has successfully treated a few adult horses and a yearling with UTI with PO enrofloxacin (7.5 mg/kg q24h), without apparent adverse effects. Potential cartilage damage in younger horses should be considered and discussed with the owner before treatment with enrofloxacin is pursued. Ciprofloxacin has also been associated with emergence of resistant *E. coli* in humans, so care should be taken to use the drug under the guidance of appropriate culture and sensitivity profiles.[31]

When treating UTIs in horses, antimicrobial therapy should be continued for at least 1 week for lower UTIs and 2 to 6 weeks for upper UTIs. Ideally, a midstream voided urine sample should be submitted for bacterial culture 2 to 4 days after initiation of therapy and again 1 to 2 weeks after treatment has been discontinued. If the UTI recurs and the same organism is isolated, a focus of upper UTI should be suspected. Ultrasonographic or nuclear scintigraphic examination of the kidneys should be considered in such cases to rule out a nephrolith or other parenchymal disease. Cystoscopy and ureteral catheterization can also be pursued to evaluate for unilateral or bilateral infection of the upper tract. In contrast, recurrence of UTI

VetBooks.ir

with a different pathogen suggests an anatomic or functional cause of abnormal urine flow as a predisposing cause of recurrent lower or upper UTI.

Although unstudied in horses, the use of lactobacillus suppositories in human females predisposed to UTI has decreased the incidence and may be useful in mares.[32] Preliminary research on vaccines against bacterial virulence factors to reduce the incidence of UTIs in predisposed populations of humans and mice appears promising, but research on the benefits of vaccination in horses is lacking.[33,34]

Urinary Incontinence

Elizabeth Ann Carr • Dominic R. Dawson Soto

Urinary incontinence in the horse can result from urolithiasis, congenital anomalies or defects of the lower urinary tract, trauma, neoplasia, neurologic diseases accompanied by bladder dysfunction, and decreased urethral tone. Bladder and urethral calculi frequently result in transient incontinence secondary to cystitis or partial obstruction. Ectopic ureter and other congenital malformations of the urinary tract generally produce incontinence from birth, although development of incontinence in adult horses has been described.[1-4] Traumatically induced incontinence may develop after breeding injury or dystocia in mares or in both genders after sacral or spinal injury.[5] Incontinence has also been speculated to develop with long-standing lumbosacral or lower back problems that make it difficult for horses to posture to urinate. Over time, incomplete bladder emptying allows crystals normally present in equine urine to accumulate in the ventral aspect of the bladder. This crystalloid sediment becomes heavy and in some cases quite firm and further prevents complete bladder emptying. This condition, which has been termed *sabulous urolithiasis,*[6] can accompany bladder paralysis of any cause but may also be able to produce myogenic bladder dysfunction in the absence of an underlying neurologic problem. Horses with neoplasia of the lower urinary tract can also present with incontinence, but other complaints (e.g., stranguria or hematuria) are usually reported as well.

Neurologic disorders that often result in bladder paralysis and incontinence include equine herpesvirus (EHV) myelitis, equine protozoal myeloencephalitis, aberrant larval migrans, cauda equina neuritis, and sorghum toxicosis. These diseases, along with other problems affecting gray matter of the sacral segments, result in loss of lower motor neuron (LMN) function, whereas lesions of the lumbar or higher portions of the spinal cord result in loss of upper motor neuron (UMN) function. LMN damage leads to loss of detrusor muscle function and overflow incontinence. A large, easily expressed bladder is found on rectal palpation. Initially, UMN disease is characterized by increased urethral resistance, leading to increased intravesicular pressure before voiding can occur. Voiding may occur as short bursts of urine passage with incomplete bladder emptying, and rectal examination may reveal a turgid bladder that is small to increased in size. Although UMN signs are initially different from those of LMN disease, incontinence is not usually recognized until overflow incontinence develops as a result of sabulous urolithiasis and progressive loss of detrusor function. The latter progression can explain why bladder paralysis and incontinence may occasionally be found in horses with other neurologic diseases like cervical stenotic myelopathy, equine degenerative myelopathy, and even viral encephalomyelitis. Presence of other signs associated with LMN dysfunction (e.g., loss of anal or tail tone) or UMN dysfunction (e.g., ataxia) may aid in differentiating the inciting cause of bladder paralysis. Despite many possible causes, the prognosis for recovery from incontinence resulting from bladder paralysis is generally poor because sabulous concretions and UTI quickly complicate the problem.

A final syndrome of incontinence caused by decreased urethral sphincter tone has been reported in a few mares.[7,8] This condition has been attributed to hypoestrogenism, because incontinence improved after treatment with exogenous estrogen.

Diagnosis

In addition to taking a complete history and performing physical and neurologic examinations, it is helpful to observe the incontinence or any attempts to urinate. Rectal palpation, transrectal ultrasonography of the bladder and upper urinary tract, transabdominal ultrasound of the kidneys and endoscopy of the lower urinary tract are useful to rule out uroliths, neoplasia, and congenital anomalies as causes of incontinence. If trauma or sacral bony abnormalities leading to incontinence are suspected, radiographs or pelvic ultrasound should be performed. Although most affected horses remain nonazotemic (unless significant obstruction or bilateral pyelonephritis has developed), laboratory analyses of blood and urine, including a quantitative urine culture, should be performed in all horses with incontinence, because UTI is a common sequela. Urethral and bladder pressure profiles can be used to assess urinary sphincter and detrusor muscle function. Normal values for both mares and geldings have been reported.[9-10] When an underlying neurologic problem is suspected, cerebrospinal fluid (CSF) collection and analysis may also be of value.

A review of 21 horses presented to Michigan State University's Veterinary Teaching Hospital between 1995 and 2000 with a primary complaint of incontinence revealed that 15 horses had bladder paralysis, three had urolithiasis, and one foal had bilateral ureteral ectopia. Another horse had incontinence of undetermined cause that appeared to respond to treatment with phenylbutazone. The remaining horse had a urachal diverticulum, hydroureters, cystitis, pyelonephritis, an atonic bladder, and urethral sphincter dysfunction that was supported by an abnormal urethral pressure profile.[11] Of the 15 horses with bladder paralysis, four developed the problem after foaling, two of which had dystocia. Fat necrosis around the urethra and bladder neck was found postmortem in one of the latter mares. Bladder paralysis was attributed to equine protozoal myelitis (EPM) in two horses and to EHV myelitis, cauda equina neuritis, and cervical stenotic myelopathy in one horse each. One horse had segmental neuronal degeneration in the lumbosacral and caudal spinal cord, and another horse had histopathologic evidence of denervation atrophy of the detrusor that was attributed to prior spinal cord trauma. An underlying neurologic disease causing bladder paralysis could not be determined in the remaining four horses. Although originally presented for evaluation of acute-onset severe spinal ataxia and weakness, another mare developed signs of UMN bladder dysfunction (squirts of urine and a turgid bladder on rectal palpation) during hospitalization. Bladder function returned to normal as the neurologic disease improved over 2 weeks.

Treatment

Treatment for incontinence varies with the underlying cause. Removal of calculi and appropriate antimicrobial therapy are effective treatments for urolithiasis. Surgical correction is generally required for treatment of congenital anomalies, but owners should be discouraged from using affected animals for breeding. EHV myelitis and EPM carry the most favorable prognoses for recovery, although bladder paresis may persist for several weeks to months (personal observation with EHV-1, DR Dawson). To prevent continued distention and further damage to the detrusor, removal of sabulous crystalloid material (by bladder lavage through a catheter or by cystotomy) and temporary placement of an indwelling bladder catheter are indicated in cases of recent onset of bladder paresis. Debate exists in the human literature regarding the preference of intermittent versus continuous urinary catheterization. In horses, both methods carry potential risks—infection and/or trauma from repeated catheterization—and each case should be evaluated individually to choose the most appropriate method.[12,13] Antimicrobial treatment, ideally based on urine culture results, is also indicated in all horses with bacterial cystitis secondary to bladder paralysis.

Bethanechol (0.03-0.04 mg/kg SC q6-8h or 0.22-0.45 mg/kg PO q6-8h), a parasympathomimetic agent that appears to have a somewhat selective effect on smooth muscle of the GI tract and bladder, has been recommended for improving detrusor tone and strength of contraction in horses with bladder paralysis. However, response to treatment has usually been disappointing, perhaps because of

VetBooks.ir

long-standing paralysis before incontinence is recognized. Use of phenoxybenzamine (0.7 mg/kg PO q6h), an α-adrenergic blocker that decreases urethral sphincter tone, has also been recommended in combination with bethanechol in cases with UMN bladder dysfunction. In horses with evidence of urethral sphincter hypotonia, the sympathomimetic agent phenylpropanolamine (1-2.5 mg/kg PO q8-12h) has also been used, but a successful response has not been reported. Dosing regimens for these autonomic drugs have been extrapolated from other species, because no pharmacokinetic data are available for the equine species.

In general, treatment with these autonomic drugs has largely been ineffective in controlling incontinence due to bladder paralysis, and the long-term prognosis for recovery is usually poor. On a more positive note, treatment of a few mares with urethral sphincter hypotonia with estradiol cypionate or benzoate (5 to 12 µg/kg IM every day for 3 days, then every other day) has been effective at resolving incontinence as long as detrusor function was normal. Estrogen may modulate the effect of norepinephrine on α-receptor activity in the urethral sphincter, thereby improving urethral sphincter tone. Of further interest, incontinence in two mares with partial detrusor dysfunction was also reported to improve after treatment with estrogen,[8] although the mechanism by which estrogen would improve detrusor function is unclear.

Ectopic Ureter

Thomas J. Divers • Stephanie A. Brault

Although rare, ectopic ureter is the most frequently reported developmental anomaly of the equine urinary tract. This abnormality is the result of an error in embryologic development causing one or both ureters to empty into the urethra, uterus, or vagina instead of attaching normally to the dorsal wall of the urinary bladder. Of the cases reported, almost 90% have been fillies, and the primary complaint is urinary incontinence and perineal dermatitis (urine scalding).[1-4] However, this gender distribution may reflect easier recognition of urinary incontinence in females rather than a true gender predilection. In the male, intermittent urine dripping from the end of the penis is less easily recognized; further, urine entering the pelvic urethra may pass retrograde into the bladder.

Diagnosis Ectopic ureter should be suspected in young horses with incontinence observed shortly after birth. Renal function is usually normal, but the affected ureter may be extremely dilated. In young foals (e.g., <50 to 75 kg) an excretory urogram (after IV administration of contrast agent) or pyelography (after percutaneous injection of contrast agent into renal pelvis via ultrasonographic guidance) may aid in diagnosis of ectopic ureter.[4,5] Unfortunately, most patients are not presented until they are too large for this procedure to be performed (Fig. 34-5). Ultrasonographic examination may reveal mild dilation of the renal pelvis on the affected side. Vaginoscopic and cystoscopic examinations should also be pursued in older foals to determine whether the problem is unilateral or bilateral, and when unilateral, to determine which ureter is ectopic. In the latter case, cystoscopic examination should reveal urine entering the bladder from only one normal ureteral opening, located at either 2 or 10 o'clock in the bladder neck. Urine can be seen squirting from normal ureteral openings every 20 to 30 seconds. Observation of normal bouts of voiding, in addition to incontinence, further supports a unilateral problem. To determine the location of the opening of the ectopic ureter, visual examination of the vestibule and vagina (using a blade speculum) should be performed initially to look for intermittent urine flow from the area of the urethral papilla. Ectopic ureteral openings are usually not apparent unless urine flow is seen. IV administration of dyes including sodium fluorescein (11 mg/kg IV; yellow-green color), indigotindisulfonate (indigo carmine, 0.25 mg/kg IV; blue-purple color), azosulfamide (1.9 mg/kg IV; red color), or phenolsulfonphthalein (0.01 mg/kg IV; red color) to discolor the urine may help locate ectopic ureteral openings.[1,2] Nuclear scintigraphy has also been employed to assess renal function and anatomy of involved urinary tract structures prior to correction.[6]

Treatment If the ectopic ureter is unilateral, ultrasonographic examination of the opposite kidney appears normal, and azotemia is not present, the preferred treatment may be surgical removal of the kidney on the affected side and ligation of the ureter. Nephrectomy may produce an increase in creatinine (0.5 to 1 mg/dL) for a few days, but creatinine returns to the prenephrectomy value within a week. If both ureters are ectopic, which is not unusual, implantation of the distal ureters into the bladder neck should be attempted. Several surgical techniques have been described. Complications can include ascending infection, resulting from dilated ureters, and development of adhesions, but successful repairs have also been reported.[1-6]

Neoplasia

Thomas J. Divers • Stephanie A. Brault

Neoplasia of the urinary tract is rare in horses. Primary kidney neoplasms include renal cell carcinoma and nephroblastoma, with the former being the most common tumor of the kidney.[1] Renal cell carcinoma (or adenocarcinoma) occurs more frequently in older horses, but nephroblastomas may be detected in young horses. Squamous cell carcinoma is the most common bladder tumor, but horses may also develop transitional cell carcinoma.[2,3] Fibromatous polyps may also occur in younger horses, but bladder tumors usually develop in middle-aged to older horses. Adenoma, lymphosarcoma, hemangiosarcoma, and melanoma may also involve the kidneys and, on rare occasions, the bladder.[4,5]

Clinical Signs and Diagnosis Clinical signs in horses with renal neoplasia include hematuria, weight loss, and recurrent colic. Sudden death may occur if the neoplasm hemorrhages into the abdomen or thorax. Renal tumors may result in marked enlargement of the kidneys such that both left and right kidneys may be found on rectal palpation. In other cases, tumors may be small, circumscribed lesions within a kidney (Fig. 34-6) that cannot be felt during rectal palpation. Small tumors may also be difficult to visualize on

VetBooks.ir

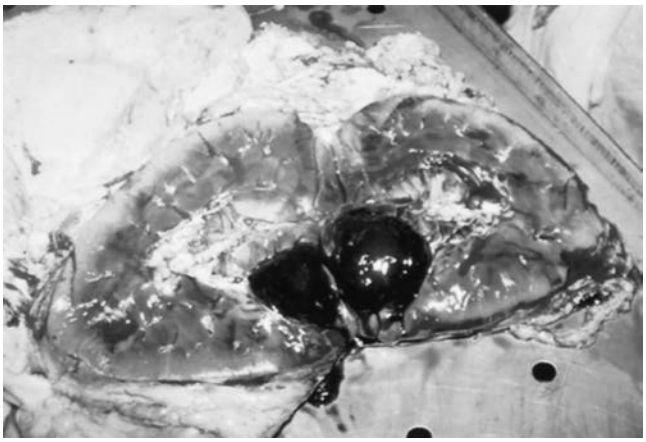

FIG. 34-6 Cut section of the left kidney from a 25-year-old horse with chronic weight loss, hematuria, and severe anemia. The kidney appeared normal except for a small 4 × 5 cm carcinoma with surrounding hemorrhage.

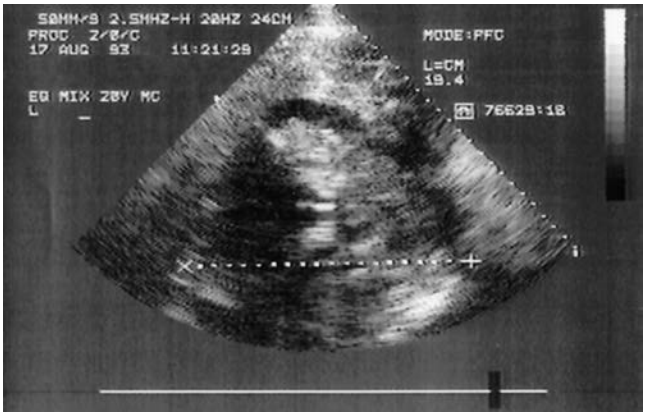

FIG. 34-7 Sonogram of the left kidney area of a 19-year-old horse with chronic hematuria. A 26 × 20 × 19 cm echocavitated mass (renal carcinoma) originates from the left kidney.

ultrasonographic examination. The diagnosis is based on history, clinical signs, and ultrasonographic findings (Fig. 34-7). Affected horses usually are not azotemic, but mild anemia may be detected when gross hematuria is observed. Although neoplastic cells are unlikely to be found in urine, cytologic examination of urine sediment is warranted. Renal biopsy has been found to be associated with a low rate of serious complications and provided a histopathologic diagnosis in most cases, although horses with neoplasia had greater odds of complications than those with any other histopathologic diagnosis.[6] Nephroblastoma usually remains limited to the kidney; renal cell carcinomas typically metastasize. The liver and lungs are the most common sites of metastasis,[7,8] but tumors can also spread to unusual sites, leading to signs as varied as lameness[9] or an ulcerated mass on the premaxilla.[10] Multiple myeloma involving the kidney resulted in hypercalcemia and a high serum parathyroid hormone–related protein concentration.[11] Hypoglycemia was the chief clinical sign in a 6-year-old horse with renal cell carcinoma producing insulin-like growth factors.[12]

In addition to hematuria and weight loss, horses with bladder tumors may also present with pollakiuria and stranguria. With bladder tumors, a mass can usually be palpated on rectal examination, but it should not be confused with a cystolith or accumulation of sabulous concretions in the ventral aspect of the bladder. Horses with gross hematuria may be mildly anemic but usually are not azotemic. Other than hematuria and associated proteinuria, urinalysis results are often unremarkable, but with bladder tumors, cytologic

The endoscope has been passed beyond the tumor and retroflexed to provide a view directed caudally; a pool of urine is in the foreground, and the tumor can be seen in the ventral aspect of the bladder neck.

examination of urine sediment is more likely to reveal neoplastic cells than with renal tumors.[2,13] A diagnosis of bladder neoplasia may be confirmed by cystoscopic examination and biopsy (Fig. 34-8).

Treatment The treatment of choice for unilateral renal neoplasia is nephrectomy. Unfortunately, most cases of renal cell carcinoma have metastasized by the time the diagnosis is made, and surgical intervention is of little benefit to horses with disseminated disease. Thus, careful evaluation for metastatic disease should be pursued before contemplating a nephrectomy.[14] Treatment of bladder tumors includes surgical excision and/or topical chemotherapy using either 5-fluorouracil or triethylenethiophosphoramide.[2]

Urolithiasis and Obstructive Disease

Thomas J. Divers • Theresa Lynn Ollivett

Renal and Ureteral Calculi

Renal and ureteral calculi can produce partial or complete obstruction of one or both sides of the upper urinary tract. Nephroliths usually develop within or adjacent to the renal pelvis, and obstruction can lead to hydronephrosis. Most ureteroliths likely originate as nephroliths that pass into the ureter, where they become lodged and enlarge over time. Ureteral stones have a propensity to lodge in the distal ureter and can sometimes be palpated rectally dorsal and lateral to the bladder neck. Occasionally, small nephroliths may pass all the way down the ureter into the bladder; unlike their human counterparts, affected equine patients are rarely recognized to manifest renal colic.[1,2] Renal and ureteral calculi are most often composed of calcium carbonate crystals; calcium phosphate stones may occasionally develop. Although usually not recognized clinically, a nidus of damaged tissue (e.g., interstitial inflammation, infection, or fibrosis; area of medullary crest necrosis adjacent to renal pelvis) is likely necessary for initiation of stone formation. Anomalies of development (e.g., renal hypoplasia, dysplasia, polycystic disease) or prior

VetBooks.ir

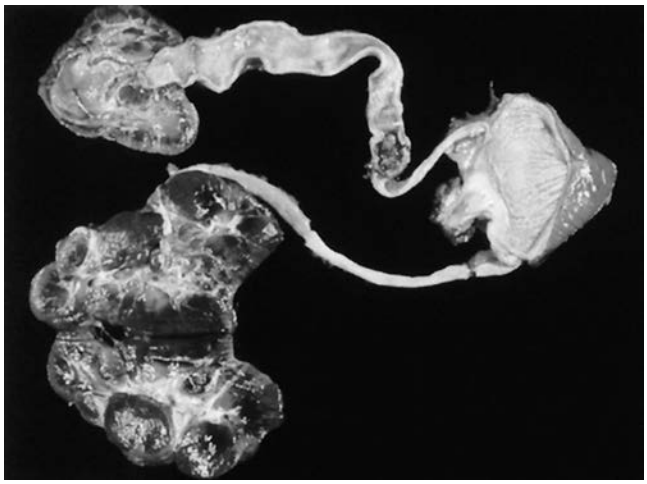

FIG. 34-9 Urinary tract removed from a 5-year-old Standardbred with chronic renal failure caused by intermittent or persistent obstruction by renal and ureteral stones. Note the location of the ureteral obstruction near the bladder. This is the most common site for the obstruction to occur.

exposure to nephrotoxins could also provide a nidus for stone formation.

Bilateral nephrolithiasis and ureterolithiasis have been best described in a series of young adult racehorses, and development of subclinical medullary crest necrosis as a result of NSAID use was a suggested risk factor[3]; this was also seen in a 2-year-old gelding.[4] When both sides of the upper tract are affected, the condition typically progresses to CRF before horses are presented for evaluation (Fig. 34-9). As described for CRF, the most common presenting complaint is weight loss, but polyuria and poor performance may be earlier complaints in competitive horses. Establishing a diagnosis of urolithiasis causing unilateral upper tract obstruction is more challenging because clinical signs are mild (recurrent colic) or nonexistent and azotemia is usually absent. In fact, unilateral upper tract stones may be detected as incidental necropsy findings in horses of all ages. In horses with clinical signs, careful rectal palpation may reveal a turgid ureter and presence of a ureterolith. When passed from the upper tract into the bladder, small uroliths may be voided without problem or may cause urethral obstruction in males. Horses with repeated bouts of urethral obstruction should be thoroughly evaluated for presence of upper tract disease.

In horses with bilateral disease leading to CRF, azotemia and isosthenuria are present. As already mentioned, azotemia is usually absent with unilateral obstruction. With either scenario, gross hematuria is uncommon unless stones have been passed into the bladder or urethra, but urinalysis usually reveals pigmenturia, and microscopic hematuria is confirmed by examination of urine sediment. Although UTI is not usually present with upper tract obstruction due to lithiasis at the initial evaluation, it may develop with catheterization or other instrumentation used for relief of the obstruction. Thus a quantitative urine culture should be considered part of the minimum database, especially if pyuria or bacteriuria is detected on sediment examination. Transabdominal ultrasonography is a valuable tool for detection of nephroliths, dilation of the renal pelvis (or complete hydronephrosis), and fibrosis (increased echogenicity) within the kidney.[5-7] However, small nephroliths (<1 cm in diameter) can occasionally be missed despite a complete ultrasonographic examination. Transrectal ultrasonography is also useful for detecting ureteral dilation and lithiasis.

If upper urinary tract obstruction is diagnosed before development of more severe azotemia (creatinine > 5.0 mg/dL), surgical removal is recommended. A nephrotomy and/or ureterotomy may be required.[1,3] When equipment is available, electrohydraulic lithotripsy is the preferred technique for removal of ureteral stones.[8] This procedure involves passing an endoscope into the ureter until the stone can be seen, then advancing a lithotriptor through the biopsy channel of the endoscope until the end touches the ureterolith (Fig. 34-10, *A*). An irrigating solution is pumped through the endoscope to distend the distal ureter, and an electrical impulse delivered by the lithotriptor causes a shock wave at the surface of the stone. Because the majority of calcium carbonate stones are inherently fragile,[9] fragmentation by lithotripsy is usually rapid (see Fig. 34-10, *B*), and remaining fragments are flushed distally by further infusion of irrigating solution (see Fig. 34-10, *C*). Before surgical intervention is pursued, both kidneys should be thoroughly evaluated for evidence of other stones, because upper tract lithiasis is often bilateral.

In addition to intermittent signs of mild colic, unilateral nephroliths may occasionally cause intermittent or persistent gross hematuria. In the absence of azotemia and evidence of disease of the contralateral kidney, unilateral nephrectomy is the treatment of choice for obstructing nephroliths and remains a reasonable alternative to lithotripsy for treatment of unilateral ureteroliths[10] (Figs. 34-11 and 34-12).

Cystic Calculi

Although occurrence is rare compared with other species, cystolithiasis is the most common form of urolithiasis in horses, and intact males appear to be at greater risk.[2,11] Calculi that develop in the bladder are usually single, large, spiculated stones composed of calcium carbonate crystals.[9,11,12] Less often, stones are a mix of calcium carbonate and calcium phosphate crystals; these stones often have a smooth surface and are more resistant to fragmentation.[13] Risk factors for development of bladder stones in horses are not well understood, but anatomic defects (e.g., diverticuli) or suture material persisting or migrating from prior urogenital surgery may predispose horses to cystic calculi.[14] Although bacteria can often be detected by culture of the center of equine calculi, their role in stone formation is unclear.[2] Considering that normal equine urine is rich in calcium carbonate crystals, it is surprising cystoliths are not more common in horses than in ruminants or small animals. Their low occurrence can likely be attributed to the large amount of mucus that is also present in horse urine. Mucus, produced by glands in the renal pelvis and proximal ureter, appears to act as a lubricant to prevent adherence of crystals to uroepithelium.

The most common clinical sign exhibited by horses with cystic calculi is hematuria after exercise. Pollakiuria, stranguria, or incontinence may also be observed. Less frequently, dysuria may be caused by accumulation of urine sediment in the ventral aspect of the bladder. This condition, sabulous urolithiasis, usually develops secondary to bladder paralysis.[15] Urinary incontinence is common in horses with sabulous urolithiasis, and prognosis is guarded to poor because of underlying detrusor dysfunction; however, return to athletic function is possible.[16]

Presence of a cystolith can be confirmed by rectal examination. It is important to remember that most bladder stones can be palpated with only the hand and wrist in the rectum. As a result of frequent urination, the bladder is usually small, and cystic calculi can be missed if the examiner passes quickly beyond the calculus during the rectal examination. Careful palpation may also allow discrimination between soft-tissue masses of the bladder (neoplasia) and sabulous urolithiasis. With the latter, firm sediment is usually palpated well over the pelvic brim in the ventral aspect of a distended bladder. Manipulation of the bladder is accompanied by incontinence, and sabulous uroliths may be indentable when palpated after the bladder has been emptied via catheterization. Although rarely needed to confirm the diagnosis, ultrasonographic examination of the entire urinary tract should be considered because calculi may be present in multiple locations. Because UTI can sometimes accompany cystolithiasis, urinalysis and a quantitative urine culture are warranted during the initial evaluation of all horses with bladder stones.

Treatment of cystic calculi usually consists of surgical removal accompanied by a 7- to 10-day course of postoperative antibiotic treatment. Cystotomy can be performed via celiotomy with or

VetBooks.ir

without laparoscopic assistance or a pararectal approach (Gäkel operation), or the stone can be removed after fragmentation with a lithotriptor passed via a perineal urethrotomy.[13,17-20] In mares, urethral sphincterotomy after epidural anesthesia with xylazine has been advocated as a practical method for stone removal. However, with sedation and epidural anesthesia, manual distention of the urethra often allows several fingers or a small hand to be passed into a mare's bladder, and depending on size, the stone can be retrieved intact or after fragmentation. Placing the cystolith into a sterile rectal sleeve or surrounding it with a similar smooth plastic material allows easier removal of spiculated stones and fragments. If available, electrohydraulic pulsed-dye or holmium:YAG laser lithotripsy may be the least traumatic method of fragmentation and removal of bladder stones in both genders, but success may be limited by the ability to lavage all stone fragments from the bladder.[21-26]

Historically, risk of recurrence after surgery has been considered low, but in a series of 68 cases of urolithiasis (at all levels of the urinary tract), 12/29 horses (41%) with follow-up had recurrence 1 to 32 months after surgery. Recurrence was more common with perineal urethrotomy than cystotomy and was attributed to the former's inability to completely remove all fragments by lavage.[2] This relatively high recurrence rate indicates that postoperative management changes are warranted to decrease risk of future stone formation. Changing from legume to grass hay is the most practical recommendation to decrease urinary calcium excretion. Urinary acidification with ammonium chloride (50 to 200 mg/kg/day PO) or ammonium sulfate (200 mg/kg/day PO) has also been recommended to decrease the amount of urine crystals in equine urine.[25,27] Unfortunately, these ammonium salts are rather unpalatable and should be administered as two or three doses daily for effective urinary acidification. Ascorbic acid administered through a nasogastric tube effectively acidified urine in one study, but when relying on voluntary consumption, results were variable.[28] IV administration of ascorbic acid was reported to effectively acidify urine, but side effects such as anxiety, sweating, tachycardia, tachypnea, mydriasis, and an intense diuresis were noted.[29] The actual benefit of urinary acidification in horses has never been established, and recurrence of urolithiasis may be more likely related to inadequate mucous secretion or persistence of damaged uroepithelium in the upper or lower tract. A more practical recommendation may be to administer 2 to 4 oz of salt in the feed daily to increase water consumption and urine flow. The increase in urine flow is accompanied by a decrease in urine pH to near-neutral values.

Urethral Obstruction

Calculi, neoplasms, congenital anomalies, and preputial edema and inflammation may all produce partial or complete obstruction of the urethra. Urethral calculi are most often calcium carbonate stones that lodge in the pelvic urethra in stallions or geldings,[30] and the most common neoplasm causing urethral obstruction is squamous cell carcinoma of the penis.[31] Preputial edema and inflammation may develop as a consequence of trauma or parasitism (habronemiasis). In addition, overweight horses may develop recurrent preputial inflammation and infection associated with fat deposition in the sheath. Horses with the latter condition may fail to drop the penis during urination, and urine scalding within the sheath is likely a contributing factor to recurrent inflammation.

Complete urethral obstruction usually causes moderate to severe signs of colic, and an enlarged, turgid bladder is detected on rectal palpation. Careful palpation of the urethra below the anus may reveal the location of an obstructing urolith or frequent contraction of the urethralis muscle. Rarely, postrenal ARF may develop, or the bladder may rupture. Partial urethral obstruction is usually accompanied by dysuria, incontinence, and urine scalding of the hindlimbs. A diagnosis of urethral obstruction is based on clinical signs, rectal examination findings, external examination of the penis and prepuce, and passage of a catheter or endoscope through the urethra to the bladder.

Treatment of urethral obstruction usually involves surgery. Urethral calculi can be removed either by a subischial urethrotomy over the site of obstruction or by hydropulsion through the urethrotomy incision. Excessive tissue trauma should be avoided because it may increase the risk of urethral stricture and recurrent urolithiasis. If available, holmium:YAG laser lithotripsy and radial extracorporeal shockwave therapy have been successful in fragmenting urethral calculi.[32,33] Laboratory assessment of fluid and electrolyte status is important for correction of dehydration, azotemia, and electrolyte alterations that may develop with sweating (caused by pain), bladder rupture, or anuria. With squamous cell carcinoma, aggressive surgical resection of involved tissues is warranted with larger lesions, whereas smaller lesions may be amenable to treatment with 5-fluorouracil ointment. However, because recurrence rate of squamous cell carcinoma of the penis and prepuce is 20% or greater,[31] surgical removal should be initially considered in all affected horses. Detrusor function may be decreased if bladder distention had been ongoing for several days, and an indwelling bladder catheter (closed system) or treatment with bethanechol (0.03-0.04 mg/kg SC q6-8h or 0.22-0.45 mg/kg PO q6-8h) may help with recovery of detrusor function.

Idiopathic Renal Hematuria

Harold C. Schott, II

Idiopathic renal hematuria (IRH) is a syndrome characterized by sudden onset of gross, often life-threatening hematuria.[1] Hemorrhage arises from one or both kidneys and is manifested by passage of large blood clots in urine. Endoscopic examination of the urethra and bladder usually reveals no abnormalities of these structures, but blood clots may be seen exiting one or both ureteral orifices. Although a definitive cause of renal hemorrhage may be established in some horses (e.g., renal adenocarcinoma, arteriovenous or arterioureteral fistula),[2,3] the disorder is termed *idiopathic* when a primary disease process cannot be found. Both genders, a wide age range, and several breeds of horses (including a mammoth donkey and a mule) have been affected. However, more than 50% of animals with IRH have been Arabians.

Use of the term *idiopathic renal hematuria* to describe this syndrome of horses was adopted from its use in human patients and dogs with severe renal hemorrhage.[4-8] *Benign essential hematuria* and *benign primary hematuria* are other terms that have been used to describe less severe hematuria that is not associated with trauma or other obvious causes of hematuria. In humans and dogs, hematuria is more often a unilateral than a bilateral problem, similar to what has been observed in the few affected horses. The pathophysiology remains poorly understood, but macroscopic hematuria has been associated with immune-mediated glomerular damage (e.g., acute postinfectious GN, membranoproliferative GN, IgA nephropathy, or Berger disease), thin basement membrane nephropathy, and the loin pain–hematuria syndrome in human patients.

Although hematuria and pigmenturia can accompany several systemic diseases in horses,[9-12] patients affected with IRH appear to have spontaneous severe hematuria in the absence of other signs of disease. Although one report suggested that severe renal hemorrhage was caused by pyelonephritis,[13] supportive data were lacking. In cases managed by one of the authors (HCS), neither UTI nor lithiasis was detected, and the magnitude of hematuria often resulted in the need for repeated blood transfusions. As with hemorrhage associated with guttural pouch mycosis, the syndrome may produce episodic hemorrhage. Initially, hemorrhage is noted by finding a large amount of clotted blood in stall bedding or in the pasture. However, other client complaints (e.g., depression, anorexia, weight loss) are typically absent. Examination may reveal dried blood at the end of the penis or in the sheath of males or on the vulvar lips and between the hindlimbs of mares. In both genders, neoplasia of the external genitalia or urinary tract is an important differential diagnosis, and in

VetBooks.ir

mares, varicosities in the area of the vestibulovaginal sphincter also must be considered, especially in multiparous mares. When blood is not detected in the sheath or vulvar areas, further evaluation may be unrewarding because the renal bleeding may cease spontaneously. In the absence of positive urine culture results, bleeding has anecdotally been attributed to cystitis and pyelonephritis, because hemorrhage stops during a course of antimicrobial therapy. More likely, spontaneous resolution has occurred. The magnitude of hematuria is considerably greater with IRH than with most UTIs, pyuria is absent, and urine culture results are negative. In our experience, one or two initial episodes of hemorrhage are followed by a more severe hemorrhagic crisis within months to 2 years after observation of the initial bleeding episode. Of interest, renal colic has been notably absent in the history of affected horses.

Diagnosis A diagnosis of IRH is made by exclusion of systemic disease, other causes of hematuria, and alterations in hemostasis. Physical examination may reveal tachycardia, tachypnea, and pale membranes, consistent with acute blood loss. Rectal palpation may reveal an enlarged, irregular bladder resulting from the presence of blood clots. Azotemia is uncommon. Endoscopic examination is important to document that hematuria is originating from the upper urinary tract and to determine whether hemorrhage is unilateral or bilateral (Fig. 34-13). Repeated examinations may be required to answer the latter question. Ultrasonographic imaging is necessary to rule out nephrolithiasis or ureterolithiasis and may occasionally reveal a distended vascular space or renal vascular anomaly as the cause of hematuria. Renal scintigraphy can be a useful technique in affected horses, providing semiquantitative information about renal function when a nephrectomy is being considered. Renal biopsy and IF staining may assist in documenting immune-mediated glomerular injury, but the significance of such results is not well understood at this time.

Treatment Treatment for IRH consists of supportive care for acute blood loss, including blood transfusions. Medications intended to promote hemostasis (e.g., α-aminocaproic acid, formalin) have also been administered, but their efficacy has not been validated. Because the condition may be self-limiting in some patients, supportive care is warranted. With severe and recurrent hematuria of unilateral renal origin, a nephrectomy may be indicated, but owners should be warned of the risk of hematuria developing in the contralateral kidney. In our experience, risk of contralateral renal bleeding appears to be greater in the Arabian breed.

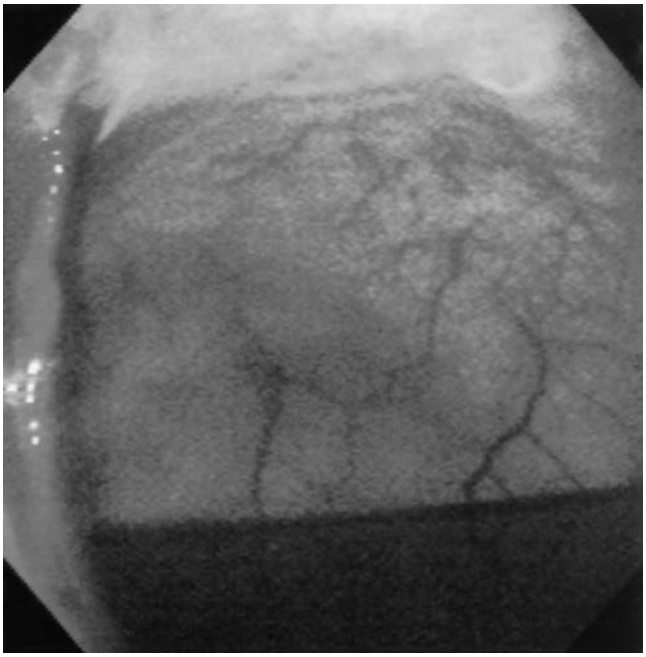

FIG. 34-13 Cystoscopic image of a 19-year-old Arabian mare with idiopathic renal hematuria. A large blood clot can be seen exiting the left ureter, whereas the right ureteral opening appears normal.

Urethral Hemorrhage

Harold C. Schott, II

Although a recognized cause of hemospermia in stallions, defects or tears of the proximal urethra at the level of the ischial arch are a more recently described cause of hematuria in geldings.[1-3] Urethral defects typically result in hematuria at the end of urination, in association with urethral contraction. Affected horses generally void a normal volume of urine that is not discolored. At the end of urination, a series of urethral contractions results in squirts of bright red blood. Occasionally, a smaller amount of darker blood may be passed at the start of urination. In most cases, the condition does not appear painful or result in pollakiuria. Interestingly, the majority of affected stallions with hemospermia and geldings with hematuria have been Quarter Horses or Quarter Horse cross-breeds that have been free of other complaints.[4,5] Treatment with antibiotics for a suspected cystitis or urethritis has routinely been unsuccessful, although hematuria appears to resolve spontaneously in about 50% of affected horses. Because the defects are difficult to detect without use of high-resolution videoendoscopic equipment, previous reports of urethral bleeding have been attributed to urethritis or hemorrhage from "varicosities" of the urethral vasculature. However, vasculature underlying the urethral mucosa becomes quite prominent when the urethra is distended with air during endoscopic examination, especially in the proximal urethra (to the point that blood can be seen flowing in the submucosal vasculature). Thus it would be logical to suspect that hemorrhage could arise from an apparent urethritis or urethral varicosity, although these problems are poorly documented in horses.

Examination of affected horses is often unremarkable, and laboratory analysis of blood reveals normal renal function, although mild anemia can be an occasional finding. Urine samples collected midstream or by bladder catheterization appear grossly normal. Urinalysis may have normal results, or an increased number of red blood cells (RBCs) may be found on sediment examination, a finding that would also result in a positive reagent strip result for blood. Bacterial culture of urine yields negative results. The diagnosis is made with endoscopic examination of the urethra, during which a lesion is typically seen along the dorsocaudal aspect of the urethra at the level of the ischial arch. External palpation of the urethra in this area is usually unremarkable but can assist in localizing the lesion, because external digital palpation can be seen through the endoscope. With hematuria of several weeks' duration, there is little evidence of inflammation; rather, the lesion appears as a fistula communicating with the vasculature of the corpus spongiosum penis (Fig. 34-14).

Although the pathophysiology of this condition remains unclear, it has been speculated that the defect is the result of a "blowout" of the corpus spongiosum penis (cavernous vascular tissue surrounding the urethra) into the urethral lumen.[3] Contraction of the bulbospongiosus muscle during ejaculation causes a dramatic increase in pressure in the corpus spongiosum penis, which is essentially a closed vascular space during ejaculation. The bulbospongiosus muscle also undergoes a series of contractions to empty the urethra of urine at the end of urination, so the defect into the urethra may develop by a similar mechanism in geldings. Once the lesion has been created, it is maintained by bleeding at the end of each urination, and the surrounding mucosa heals by formation of a fistula into the vascular tissue. An explanation for the consistent location along the dorsocaudal aspect of the urethra at the level of the ischial arch has not been documented but may be related to the anatomy of the musculature supporting the base of the penis and an enlargement of the corpus spongiosum penis in this area. Narrowing of the lumen at the distal

VetBooks.ir

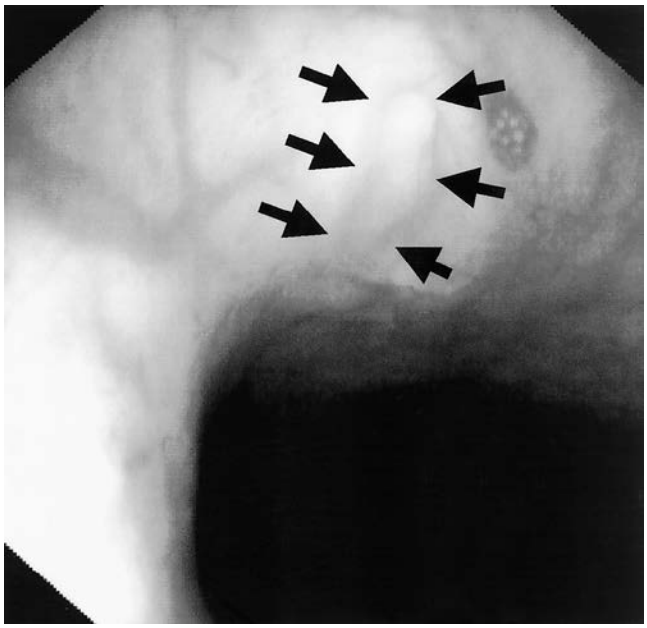

FIG. 34-14 Endoscopic image of the proximal urethra of a gelding with hematuria at the end of urination. A urethral defect can be seen between the arrows along the caudal aspect of the urethra as it passes dorsocranially over the pelvic brim.

extent of the ampullar portion of the urethra may also contribute to the location of the defects. An anatomic predisposition in Quarter Horses has not been documented but could be speculated based on an apparent increased risk in this breed.

Because hematuria may resolve spontaneously, no treatment may be initially required. If hematuria persists for more than a month or if significant anemia develops, a temporary subischial "incomplete" urethrotomy has been successful in some affected geldings. After sedation and epidural or local anesthesia, a catheter is placed in the urethra, and a vertical incision is made into the corpus spongiosum penis but not into the urethral lumen. The surgical wound requires several weeks to heal, and moderate hemorrhage from the corpus spongiosum penis is apparent for the first few days after surgery. Hematuria should resolve within a week after this procedure. Additional treatment consists of local wound care and prophylactic antibiotic treatment (typically a trimethoprim-sulfonamide combination) for 7 to 10 days.

Polyuria and Polydipsia

Harold C. Schott, II • Theresa Lynn Ollivett

Polyuria and *polydipsia* (PU/PD) are defined as urine output in excess of 50 mL/kg/day and fluid intake of more than 100 mL/kg/day.[1,2] These values equate to production of 25 L of urine and consumption of 50 L of water for a 500-kg horse. It is important to remember that urine production and water consumption vary with age, diet, workload, environmental temperature, and GI water absorption.[3,4] For example, urine production increases by 50% to 100% when the diet is changed from a grass to a legume hay.[5] Similarly, horses in heavy exercise, stabled in hot climates, or with chronic diarrhea may have a water intake in excess of 100 L/day yet produce normal volumes of urine. The major causes of PU/PD in horses include renal failure (discussed previously), pituitary adenoma (Cushing disease), and primary or "psychogenic" polydipsia. Less common causes include excessive salt consumption, central and nephrogenic diabetes insipidus (DI), diabetes mellitus, sepsis/endotoxemia, and iatrogenic causes (e.g., sedation with α_2-agonists, corticosteroid therapy, diuretic use).[2]

Polyuria/Polydipsia with Cushing Disease

Pituitary adenoma and the resulting syndrome of hyperadrenocorticism (Cushing disease) is common in older horses.[6] Although the most consistent clinical sign in horses is hirsutism, PU/PD may be reported; in one review of 17 horses with Cushing disease, PU/PD was found in 13 (76%).[7] However, in another series of 21 cases, PU/PD was not in the history of any of the affected horses.[8] This discrepancy can be explained by the fact that PU/PD associated with Cushing disease is generally of lesser volume than that observed with psychogenic PD or DI.

Cushing disease may lead to PU/PD by several mechanisms. First, polyuria may be the result of an osmotic diuresis. The renal threshold for glucose in horses (≈150 to 175 mg/dL) appears to be lower than in small animals.[9] When plasma glucose concentration exceeds the renal threshold, the resultant glucosuria can lead to an osmotic diuresis. Although often implicated as the cause of PU/PD in horses with Cushing disease, glucosuria was found in only one of five affected horses in one report.[8] Further, horses with hyperglycemia and glucosuria may still be able to concentrate their urine in response to water deprivation.[10] A second mechanism implicated in the development of PU is antagonism of the action of antidiuretic hormone (ADH) on the collecting ducts by cortisol. Although frequently cited as the mechanism of PU in canine hyperadrenocorticism, experimental evidence to support this mechanism is lacking in both dogs and horses. There is considerable species heterogeneity in the effects of corticoids on ADH activity, and in some species a primary dipsogenic effect may be more important. Growth of the adenoma may lead to impingement on the posterior pituitary and hypothalamic nuclei (located immediately dorsal to the pituitary gland), the sites of ADH storage and production, respectively. Decreased ADH production and release would result in central DI as a third mechanism for PU.[6] Therefore, PU/PD seen in some but not all horses with pituitary adenomas is likely the combined result of several mechanisms.

Psychogenic Polydipsia

Although rare, primary or "psychogenic" PD is probably the most common cause of PU/PD in adult horses for which clients will have a primary complaint of excessive urination.[4,11] Horses with this problem are generally in good body condition and not azotemic. The magnitude of their PU/PD is typically dramatic, with owners reporting that horses drink two to three times more water than their stablemates, and stalls can be flooded with urine. In some horses, primary PD appears to be a stable vice that reflects boredom, whereas in other cases it may develop after a change in environmental conditions, stabling, diet, or medication administration. Anecdotally, it has been reported to be more common in southern states during periods of high temperature and humidity.

The diagnosis of primary PD is made by exclusion of renal failure and hyperadrenocorticism. Other factors (e.g., salt supplementation, medication administration) must also be excluded. DI is excluded by demonstrating urinary concentrating ability after water deprivation.[12,13] Urine specific gravity should exceed 1.025 after water deprivation of sufficient duration (12 to 24 hours) to produce a 5% loss of body weight. In horses with long-standing PU, the osmotic gradient between the lumen of the collecting tubule and the medullary interstitium may be diminished (medullary washout). In these horses, ADH activity may not lead to an increase in urine specific gravity to values greater than 1.020. Consequently, in horses with primary PD of several weeks' duration that fail to concentrate their urine after 24 hours of water deprivation, a modified water deprivation test may be tried. This is performed by restricting water intake to about 40 mL/kg/day for 3 to 4 days. By the end of this period, urine specific gravity should exceed 1.025 in a horse that has had medullary washout. If urine specific gravity remains in the isosthenuric range (1.008 to 1.014), the polyuric horse should be further evaluated for early CRF, in which urine concentrating ability may be compromised before the

VetBooks.ir

onset of significant azotemia. In theory, this could occur when two thirds to three fourths of functional nephrons have been lost. Subtle signs of decreased performance and mild weight loss would also support early renal failure.

Management of horses with primary PD is empirical. Because this is a diagnosis of exclusion, once it has been established that the horse does not have significant renal disease, it is safe to consider restricting water intake to meet maintenance, work, and environmental requirements of the horse. In addition, steps should be taken to improve the attitude of the horse by reducing boredom. Increasing the amount of exercise and turning the horse out to pasture are possible options, along with providing a companion or diversions in the stall. Increasing the frequency of feedings or amount of roughage in the diet may increase time spent eating and thereby reduce the habitual drinking.

In an occasional case of primary PD, PU/PD may be attributed to excessive salt consumption and is manifested by an increased fractional sodium clearance.[3] Such "psychogenic salt eaters" appear to be less common than "psychogenic water drinkers" because the former would have to consume a substantial amount of salt to develop PU. In fact, salt intake may have to exceed 5% to 10% of dry matter intake before PU/PD becomes apparent.[14,15] Successful management consists of limiting water intake and preventing access to excess salt.

Diabetes Insipidus

DI may be due to inadequate secretion of ADH (neurogenic DI) or decreased sensitivity of the epithelial cells of the collecting ducts to circulating ADH (nephrogenic DI).[1,2,16] With both forms of DI, dramatic PU/PD may be reported, and affected animals fail to concentrate urine in the face of water deprivation.

In human patients, neurogenic DI is the more common form of DI, with both hereditary and acquired forms described.[16] Two well-documented equine cases of neurogenic DI have been described.[17,18] Neither animal could concentrate urine in response to water deprivation, but administration of exogenous ADH resulted in an increase in urine specific gravity and decrease in urine volume. In a Welsh pony in which the condition was considered idiopathic, the absence of an increase in plasma ADH concentration after water deprivation further supported a diagnosis of neurogenic DI.[17] Acquired neurogenic DI secondary to encephalitis was confirmed histologically in the other horse.[18]

Nephrogenic DI is most often a familial disorder in humans, with an X-linked semirecessive mode of inheritance.[16] Therefore the disorder is carried by females and expressed in male offspring. Nephrogenic DI has been described in sibling Thoroughbred colts, suggesting that an inherited form may also occur in horses.[19] These two colts could not increase urine specific gravity in response to water deprivation, although they did show appropriate increases in plasma ADH concentration. DI has also been reported in a 15-year-old gelding.[20] In all three cases, a lack of response to exogenous ADH administration confirmed resistance of the collecting ducts to ADH. Nephrogenic DI can also develop in association with drug therapy or a variety of metabolic, infectious, or mechanical (postobstruction) disorders. Anomalous or neoplastic disorders resulting in structural deformation of the kidneys are other potential causes of nephrogenic DI.[16]

After determining that an equine patient with PU/PD is not azotemic, the initial diagnostic test to differentiate DI from primary PD is a water deprivation test.[17,18] However, horses with suspected DI should be monitored closely during water deprivation, because affected horses will continue to excrete excess water in the face of water deprivation. As a result, they may become substantially dehydrated (10% to 15%) within the first 12 hours of water deprivation. When a patient fails to concentrate urine during water deprivation, neurogenic DI can be differentiated from nephrogenic DI by measuring plasma ADH concentration or by administration of synthetic ADH (as illustrated by the cases previously described). Currently, equine ADH cannot be measured at commercial laboratories, but synthetic ADH (60 IU q6h IM or SC) can be administered in combination with monitoring urine specific gravity.

Treatment of DI is directed at managing PU/PD. With neurogenic DI, hormone replacement therapy with desmopressin (dDAVP, a potent ADH analog administered as eyedrops) has been a successful treatment in small animal patients.[21] However, this treatment has not been described in horses and may be cost prohibitive. With nephrogenic DI, hormone replacement therapy is ineffective, and the only practical form of treatment for many years has been to restrict sodium and water intake and administer thiazide diuretics. The latter treatment may reduce PU by 50% in human and canine patients.[16,22] Thiazide diuretics inhibit sodium reabsorption in the distal tubule (diluting segment of nephron) and increase solute delivery to the collecting duct, but the mechanism by which such therapy benefits patients with nephrogenic DI is not well understood. Administration of prostaglandin inhibitors or amiloride may also decrease PU in patients with nephrogenic DI. The former agents probably work by decreasing renal blood flow and GFR, whereas amiloride, a sodium channel blocker, is thought to act similar to the thiazide diuretics.[5] No reports have documented the use of these treatments in horses.

Diabetes Mellitus

Diabetes mellitus (DM) is a state of chronic hyperglycemia usually accompanied by glucosuria. The resultant osmotic diuresis is an occasional cause of PU/PD in horses and was described to result in a water intake in excess of 80 L/day in one report.[23] Type 1 (insulin-dependent) DM is due to lack of insulin, which in human patients is usually attributable to viral or autoimmune disease. Individuals with type 2 (non–insulin-dependent) DM have normal to high insulin concentrations, but their tissues are insulin insensitive. The most common cause of equine type 2 DM is Cushing disease, in which elevated plasma cortisol concentration appears to antagonize the effects of insulin. Although uncommon, there are a few reports of both type 1 and type 2 DM that were not caused by a pituitary adenoma and resulted in PU/PD as one of the presenting complaints.[23-25]

Sepsis/Endotoxemia

PU/PD has been described in horses with sepsis or endotoxemia, although other clinical signs (e.g., fever, abdominal pain, weight loss) predominate.[26] The mechanism of PU/PD is unclear but may result from endotoxin-induced prostaglandin production. Prostaglandin E_2 (PGE_2) is a potent renal vasodilating agent that can antagonize the effects of ADH on the collecting ducts.[27] Some horses with chronic gram-negative bacterial infections (e.g., peritonitis, pleuritis) may have low-grade or intermittent endotoxemia as a mechanism for PU/PD, similar to the PU observed with canine pyometra.[28]

Iatrogenic Polyuria

A final cause of PU/PD may be iatrogenic secondary to several treatments. The most obvious iatrogenic cause is fluid therapy, for which PU is a desired response. PU has also been observed with exogenous corticosteroid administration, although the mechanism remains unclear. Humans and dogs appear to experience a potent thirst response to exogenous corticosteroids, so PD may be an important cause of the PU observed. In horses receiving chronic dexamethasone treatment for immune-mediated disorders, profound glucosuria (2 to 3 g/dL) may be observed and could lead to an osmotic diuresis. Finally, a transient diuresis or polyuria accompanies sedation with the α_2-agonists xylazine and detomidine.[29] Although these agents also cause transient hyperglycemia and occasional glucosuria, a more likely mechanism for PU is existence of α_2-adrenoreceptors on collecting duct epithelial cells. Activation of these receptors is another mechanism by which the action of ADH can be antagonized.[30]

VetBooks.ir

Renal Tubular Acidosis

Monica Aleman • Krista Elise Estell

Renal tubular acidosis (RTA) is a syndrome characterized by abnormal renal tubular function that results in a hyperchloremic metabolic acidosis with a normal anion gap.[1-4] Hyperchloremia develops as a result of enhanced renal conservation of chloride consequent to bicarbonate loss. RTA can be categorized as *primary* (genetic or idiopathic) or *secondary* when attributed to an underlying disease process or drug administration. Drug-induced RTA has been documented in human patients after administration of amphotericin B, trimethoprim-sulfamethoxazole, outdated tetracyclines, gentamicin, cephalosporins, carbonic anhydrase inhibitors, lithium carbonate, and other organic compounds.

Three types of RTA have been described: I (distal), II (proximal), and IV (hyperkalemic distal).[2-4] Types I and II have been reported in dogs, cats, and horses. Type I develops when distal tubular excretion of hydrogen ions (H^+) becomes compromised, and affected patients are unable to produce acidic urine. Type II results from decreased proximal tubular bicarbonate resorption and subsequent loss of bicarbonate in the urine. Because H^+ ions are normally excreted as bicarbonate is reabsorbed in proximal tubules, acidosis with both type I and type II RTA results from decreased H^+ excretion. Type I RTA results in more severe acidosis and electrolyte abnormalities, since the distal tubule is responsible for maximal acidification of the urine. In the absence of H^+ excretion, K^+ is excreted to maintain electroneutrality and can result in severe hypokalemia. Type II RTA often is a self-limiting problem but may be accompanied by more widespread proximal tubular dysfunction, leading to defective resorption of glucose, amino acids, phosphate, potassium, sodium, calcium, magnesium, uric acid, and other organic acids. The latter disorder is known as *Fanconi syndrome;* as with RTA, it may be a primary (inherited) problem or can develop secondary to kidney, metabolic, and autoimmune diseases or drug administration.[2-4] Although there are no well-documented reports, Fanconi syndrome likely develops in an occasional horse as a sequela to proximal tubule damage. Mixed type I and II RTA has been documented and is notably refractory to treatment, likely because of widespread tubule dysfunction.[5] To date, type IV RTA has only been described in human patients.[4]

RTA is a sporadically occurring metabolic disorder in horses.[6-9] There is no obvious breed or gender predilection, and to date, no evidence indicates that RTA is an inherited condition in horses. Typically, affected horses present with profound depression and anorexia and may have a history of poor performance, weight loss, and signs of abdominal pain. Vital parameters are generally within normal ranges, and horses do not appear clinically dehydrated. Hematologic and clinical chemistry findings are usually within reference ranges, with the exception of electrolyte concentrations and acid-base balance. A profound metabolic acidosis (plasma bicarbonate concentration < 13 mEq/L and venous blood pH < 7.25) and hyperchloremia (serum chloride concentration = 105 to 120 mEq/L) are characteristic for horses with RTA. A compensatory decrease in carbon dioxide partial pressure (P_{CO_2}) is also observed in most horses with RTA. Hypokalemia (and total body potassium depletion) due to the combined effects of anorexia and ongoing loss of potassium in urine may occur in horses with RTA, particularly in patients with type I.

Mild to moderate azotemia may be detected in horses with RTA, especially when they are dehydrated at presentation. Affected horses may also have evidence of renal tubular damage detected on urinalysis (e.g., pigmenturia, glucosuria), and urine specific gravity may be low. Despite profound metabolic acidosis, urine pH is generally neutral to alkaline. If pursued, renal biopsy results generally support tubulointerstitial disease (TIN).

Differentiation of type I from type II RTA in human and canine patients is most easily accomplished by assessing urine pH; it remains neutral to alkaline with type I and should be neutral to acidic with type II.[2-4,9] Most horses with RTA have had neutral to alkaline urine, but because herbivores normally have alkaline urine, this distinction may be less useful. A few reports have described horses with acidic urine, supporting type II RTA, but urine pH values near neutral are difficult to interpret.[9-11] Assessment of all laboratory abnormalities (Table 34-1), along with additional testing (e.g., ammonium chloride challenge, urinary ammonium concentration, administration of thiazide diuretics) may allow further discrimination between type I and type II RTA.[5,10,12] However, this distinction may not be entirely necessary, because the approach to treatment and the prognosis are similar for both types of RTA in horses.

TABLE 34-1

Classification of Type I and Type II Renal Tubular Acidosis

	Distal or Type I	Proximal or Type II
Acidosis	Severe	Self-limiting
Hypokalemia	Severe	Mild to moderate
Serum phosphate	Normal	Low
Urine pH	Neutral to alkaline	Neutral to acidic

Treatment of RTA consists primarily of IV and oral administration of sodium bicarbonate. For initial correction of acidosis, IV $NaHCO_3$ must be administered aggressively, and large amounts (3000 to 9000 mEq) are often required to return plasma bicarbonate concentration to values above 20 mEq/L. Half the estimated bicarbonate deficit is generally replaced with IV $NaHCO_3$ over 6 to 12 hours, and the remaining deficit is replaced with a combination of IV and oral $NaHCO_3$ (initial oral dose: 100 to 150 g twice daily; 1 g contains 12 mEq $NaHCO_3$). Close monitoring of serum electrolyte concentrations and acid-base balance is required to adjust the rate of IV $NaHCO_3$ replacement. Marked improvement in attitude and appetite usually accompanies correction of the acidosis, but unfortunately, relapse after discontinuation of IV therapy can occur. Continued oral administration of $NaHCO_3$ for months to years may be required for maintenance of a normal acid-base status.

Because potassium excretion is proportional to the bicarbonate delivery to the distal tubule, initial correction of acidosis with $NaHCO_3$ promotes kaliuresis and may exacerbate potassium depletion. Therefore, concurrent supplementation with IV or oral potassium chloride is advisable during initial correction of the acidosis. Complications associated with rapid correction of acidosis have not been described, but transient diarrhea may develop if large quantities of $NaHCO_3$ (>200 g) are given by nasogastric tube to horses that are completely anorectic.

Recurrence of metabolic acidosis also can occur when oral $NaHCO_3$ is discontinued, especially in horses that have evidence of renal damage. Relapses can be immediate or delayed for weeks to months. Reinstitution of $NaHCO_3$ supplementation usually corrects the metabolic abnormalities and accompanying depression and anorexia. The short-term prognosis for horses with RTA is good, and although the long-term prognosis has not been well documented, several horses have been reported to recover completely.[6,7,9]

Bladder Rupture in Adult Horses

Thomas J. Divers • Dominic R. Dawson Soto

On rare occasions, bladder rupture may occur in adult horses. The problem can develop in association with urolithiasis, foaling, prolonged recumbency, or trauma.[1] As azotemia develops, affected horses become depressed and inappetent. Uroabdomen may produce signs of abdominal discomfort and tachycardia.[2] Clinical signs may not be apparent for several days. Stranguria may be observed depending on the cause of the rupture. Abdominal distention may not be as apparent in adult horses as in foals.

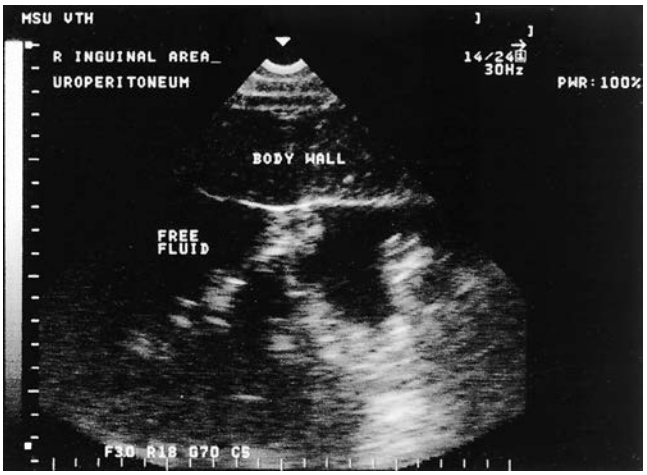

FIG. 34-15 Transabdominal ultrasonographic image of the right inguinal area of an adult horse with a ruptured bladder. A large amount of free hypoechoic fluid is apparent.

FIG. 34-16 A 2-day-old foal exhibiting stranguria caused by a ruptured bladder. Note the caudal position of the hindlegs, suggesting that the foal is straining to urinate rather than defecate. Differentiating between stranguria and tenesmus (meconium impaction) is not always easy.

The diagnosis is based on history, rectal examination findings, laboratory results, and findings on urinary ultrasonographic or cystoscopic examination. Postrenal azotemia develops within 24 hours after rupture and is accompanied by hyponatremia and hypochloremia. Unlike uroperitoneum in neonates, hyperkalemia is not a consistent finding. Transabdominal ultrasonographic examination of the abdomen reveals a large amount of peritoneal fluid (Fig. 34-15); abdominal fluid is easily recovered on abdominocentesis, and peritoneal fluid creatinine is twofold or greater than that of serum. Detection of calcium carbonate crystals on cytologic examination of peritoneal fluid is also diagnostic for uroperitoneum. Endoscopic examination of the bladder should allow determination of the location and extent of the bladder tear. Rarely, uroperitoneum may also develop in some horses without full-thickness disruption of the bladder wall, and it is difficult to establish definitively the cause of uroperitoneum in these cases.

Surgical repair is indicated in horses with large tears in the ventral half of the bladder. In mares, standing surgical repair may be feasible.[3] In patients with small dorsal tears or incomplete tears, use of an indwelling bladder catheter (closed system) to keep the bladder small may allow the tear to heal without surgery.[4] Before surgery, IV fluids should be administered to correct dehydration, along with broad-spectrum antibiotics as prophylaxis against sepsis. If the abdomen is distended, urine accumulated in the abdomen should be removed (e.g., by placement of chest tube or other large catheter through the ventral abdominal wall) before anesthesia is induced to avoid further compromising respiration.

Urinary System Disorders in the Foal

Thomas J. Divers • Dominic R. Dawson Soto

Umbilical disorders of the neonatal foal, including patent urachus, urachal infections, and omphalitis, are discussed in Chapter 17.

Uroperitoneum

Bladder Rupture

The most common bladder disorder in otherwise healthy newborn foals is bladder rupture.[1-3] In septic foals, bladder necrosis leading to leakage of urine can be experienced, possibly secondary to hematogenous spread of bacteria.[4] There may be an increased incidence in colts, but some reports fail to support this.[5] Clinical signs include stranguria and repeated posturing to urinate during the first few days of life. Urine accumulates in the abdomen, typically leading to depression and abdominal distention between days 2 and 4 of life. Repeated posturing and stranguria can easily be misinterpreted as tenesmus associated with meconium impaction (Fig. 34-16). Further, affected foals may continue to void small volumes of urine, so establishing a diagnosis of ruptured bladder can initially be challenging until more obvious signs of uroperitoneum (e.g., decreased nursing, abdominal distention) develop.

Laboratory findings in foals with uroperitoneum include hyponatremia, hypochloremia, hyperkalemia, and azotemia.[1-3,6] Foals receiving continuous fluid therapy prior to the diagnosis may not exhibit typical electrolyte changes, and instead suspicion of uroperitoneum should be raised with other signs such as decreased urinary output, abdominal distention, weakness, or other changes in clinical condition. An occasional foal may also develop intermittent fine muscle tremors or a cardiac arrhythmia resulting from these electrolyte alterations, especially hyperkalemia. Transabdominal ultrasonographic examination usually reveals a large quantity of free fluid in the abdominal cavity, but occasionally the bladder can still appear fluid filled, depending on the size of the leak. A peritoneal fluid creatinine/serum creatinine ratio greater than 2:1 or the presence of calcium carbonate crystals in the abdominal fluid confirms uroperitoneum.[1-3,6]

Treatment of bladder rupture includes surgical closure of the defect, supportive care, and broad-spectrum prophylactic antibiotics for 3 to 7 days postoperatively.[1,2,6,7] An emergency surgical procedure is usually not required, and in most cases, postponement of the surgery for several hours until electrolyte abnormalities are partially corrected (most notably correction of hyperkalemia to a serum concentration < 6.0 mEq/L) is recommended. This can usually be accomplished by IV administration of 1 to 3 L of a 0.9% NaCl/5% glucose solution. Treatment with insulin should be avoided unless hyperkalemia is causing significant electrocardiographic (ECG) abnormalities and response to initial fluid therapy is poor. With marked hyperkalemia or abdominal distention causing respiratory embarrassment, slow drainage of urine from the abdomen (e.g., by chest tube or similar catheter) may be necessary before induction of anesthesia; IV fluid support should be provided during drainage. Despite significant azotemia in some affected foals, use of aminoglycoside antibiotics is generally safe because the azotemia is postrenal rather than reflecting intrinsic renal disease. In most cases, placement of a urinary catheter to maintain an empty bladder for the initial 2 postoperative days is unnecessary, but careful monitoring of urine output along with serial abdominal ultrasound is recommended if a catheter is not placed. Postoperative bladder atony requiring bethanechol and an indwelling urinary catheter has been reported.[8] Uroperitoneum may recur after surgery in an occasional foal as a result of ongoing leakage from the bladder tear. When this complication occurs, it can

VetBooks.ir

VetBooks.ir

usually be managed conservatively by placement of an indwelling bladder catheter (closed system) for 3 to 5 days. Rarely, a second celiotomy may be required.

Urachal Urine Leakage

Uroperitoneum may also develop in foals with urachal infection or ischemia. Affected foals are often septicemic or hospitalized for treatment of prematurity, hypoxic-ischemic encephalopathy, or botulism, and uroperitoneum is recognized later (e.g., after 5 to 10 days of treatment).[7,9] Prolonged recumbency and bladder distention are likely risk factors. The urachus of many affected neonates appears normal during the first 2 days of life, but in some cases, particularly with septicemia, may subsequently become patent. Urine leakage through the umbilicus may or may not be accompanied by leakage into the abdominal cavity or subcutaneous tissues of the abdominal wall. In other affected foals the umbilicus remains normal, and all urine leakage accumulates into the abdominal cavity. When monitored, inappropriate weight gain (e.g., >2 kg in 24 hours) is another common finding in hospitalized neonates that develop uroperitoneum, along with decreased urinary output.

Laboratory abnormalities typical for uroperitoneum may be found in affected foals but are not consistently abnormal, because these patients are often being treated with IV fluids. Correction of the problem includes surgical removal of the diseased urachus, closure of the bladder apex, and continued supportive care for the primary disease. The prognosis for a successful outcome for these foals is not as favorable as for simple bladder rupture, because they often have a degree of peritonitis (increasing risk for adhesions), and uroperitoneum is often only one of several complications of the underlying disease.[7,9]

In an occasional foal, the urachus may also rupture more distally than usual and lead to subcutaneous accumulation of urine, ventral abdominal swelling, stranguria, signs of colic, and distress.[10] The swelling may be differentiated clinically from a hematoma or septic omphalitis because it may enlarge quickly and often becomes cold. Ultrasonographic examination and/or local aspiration of fluid and measurement of creatinine (twofold or greater than in serum) confirm the diagnosis. Prompt surgical removal of the leaking urachus is indicated.

Ureteral Defects

Ureteral defect(s) or disruption may also lead to development of uroperitoneum in both male and female foals.[11-14] Stranguria is usually absent, and urine initially accumulates in the retroperitoneal space, but with time the retroperitoneal tissue ruptures, causing uroperitoneum. Affected foals may not be presented until 5 to 10 days of age because urine accumulation is slower than with a ruptured bladder. Clinical signs include decreased nursing, depression, and mild colic, and in fillies an external bulging of the vagina may be observed. Laboratory findings are typical for uroperitoneum, and with significant hyperkalemia, intermittent muscle fasciculations may be also noted.

If urine accumulation remains localized to the retroperitoneal space, ultrasonographic examination of the lower abdomen may be normal, but a large amount of retroperitoneal fluid will be detected around the kidney and upper flank (within retroperitoneal space) on the affected side(s). In addition, the renal pelvis may be mildly dilated.[15] If the peritoneal membrane is ruptured, physical and ultrasonographic examination findings are similar to those seen with a ruptured bladder, but careful ultrasonographic examination may also reveal a full bladder or concurrent retroperitoneal fluid accumulation. As with a ruptured bladder, the ratio of retroperitoneal or peritoneal fluid creatinine/serum creatinine is greater than 2:1. In small foals (e.g., <50 to 75 kg), excretory urography (after IV administration of contrast agent) or pyelography (after percutaneous injection of contrast agent into renal pelvis with ultrasonographic guidance) may be useful for localizing the ureteral defect(s).

One or both ureters may be involved, and during surgical exploration, one or more defects can usually be found in the proximal half of the ureter, often near the renal pelvis. During surgery the defects can be localized by placing a catheter into the ureter through a cystotomy and injecting dye (e.g., Evans blue, methylene blue). Successful correction of unilateral and bilateral defects can be accomplished by placing a stent in the affected ureter(s) for 7 to 10 days.[11,12]

A report describing bilateral ureteral defects adjacent to the renal pelves provided histopathologic evidence that the lesions were traumatic in origin rather than developmental anomalies.[14] The foal in that report had previously been kicked by its dam. One of the authors (TJD) has seen three foals with similar ureteral defects, all of which also had multiple rib fractures. Ureteropelvic junction injuries and proximal ureteral tears are a recognized complication after blunt abdominal trauma in human patients.[16] Taken together, these observations suggest that many ureteral defects in foals may more likely be traumatically induced at foaling rather than being developmental anomalies.

Cystitis

Cystitis in foals can develop in septic, recumbent, premature, or neonatal foals being treated with broad-spectrum antibiotics. Evidence indicates that bacterial infection of the urinary tract, whether primary or due to hematogenous spread, may contribute to the development of uroperitoneum.[4,5] When cystitis is suspected, the bladder should be catheterized and a urine sample submitted for urinalysis and quantitative culture. UTIs with *Candida* spp. are fairly common in recumbent neonates. Specific antimicrobial therapy is not usually necessary for *Candida* cystitis as long as systemic antibiotics can be discontinued. If antibiotic therapy continues, dissemination of the yeast infection can spread to other sites (e.g., joints).

Ruminant Renal System

David C. Van Metre, *Consulting Editor*

Ulcerative Posthitis and Vulvitis

Stacey R. Byers

Ulcerative posthitis and vulvitis (enzootic balanoposthitis, pizzle rot, sheath rot) is an ulcerative bacterial infection of the mucous membrane and surrounding skin of the prepuce and vulva of small ruminants.

Clinical Signs and Differential Diagnoses In male small ruminants, the infection begins as a moist ulcer, usually at or near the mucocutaneous junction of the prepuce. A thin, loose, brown to red, malodorous scab (Fig. 34-17) covers the ulcer. If the scabs are removed, little or no hemorrhage occurs. Focal swelling is often noticeable at the cranial aspect of the prepuce, and the area is painful on palpation.

VetBooks.ir

FIG. 34-17 Ulcerative posthitis in a Suffolk ram.

If untreated, the infection spreads along the mucosal surface inside the prepuce, creating the more serious internal form of ulcerative posthitis. In such cases the entire prepuce may be swollen and elongated. Affected animals often show dysuria, and goats may vocalize during voiding. As the local inflammation progresses, ulceration may result in fibrous adhesions between the penis and prepuce. Severe inflammation of the glans penis can cause stricture of the urethral process (pizzle) and restrict urine egress, resulting in signs similar to those of obstructive urolithiasis. Impairment of breeding soundness may result from admixing of blood or exudate into the ejaculate, penile adhesions, scarring of the preputial orifice, or suppurative urethritis. Pain may limit libido as well. Weight loss may occur in chronic cases.

Ulcerative lesions of similar appearance can develop on the vulva and perineum of affected ewes and does. Gross vulvar enlargement may be noticed from a distance. Dysuria may result from involvement of the urethral orifice. The fibrosis and contracture that develop in chronic severe cases may distort normal vulvar conformation to the point of impairing copulation or parturition.

Ulcerative dermatosis (lip and leg ulcer) in sheep is dermatitis caused by poxvirus-related contagious ecthyma. Infection with this agent may manifest as balanoposthitis and vulvitis, and the crusted ulcers that develop closely resemble those induced by infection with *Corynebacterium renale*. Ulcerative dermatosis can be differentiated from ulcerative posthitis, since lesions are also present on the face and legs. The lesions readily bleed and often contain a nonodorous purulent discharge.

Contagious ecthyma (orf) occasionally affects the genitalia and perineum, although lesions are much more frequently found on the lips, face, and udder. These lesions are raised, appear proliferative, and are covered with a thick, durable scab.

Urolithiasis must be strongly considered in the differential diagnosis of any dysuric male small ruminant. Although rare in small ruminants, preputial trauma, particularly if resulting from entrapped grass awns, can cause preputial swelling, pain, and exudation within the preputial cavity. External ulcerative lesions would not be expected in such cases.

Caprine herpesvirus 1 (CHV-1) infection has been documented to cause posthitis in a buck goat on a California farm wherein this agent had caused abortions.[1] The affected buck had shallow, red, irregularly shaped ulcers in its prepuce that tested positive for CHV-1 by PCR. Biopsy of the ulcers revealed intranuclear inclusion bodies within the stratum spinosum of the preputial epithelium. Acute pustular vulvovaginitis, characterized by marked vulvar swelling, erythema, and focal pustules of the vaginal mucosa, has been described in does infected with CHV-1; notably, there were no abortions in the affected herd nor lesions detected in comingled bucks.[2] The bucks of that herd were seropositive to CHV-1 and were considered a potential source of the virus.

Corynebacterium pilosum, Corynebacterium cystitidis, Mycoplasma mycoides subsp. *mycoides* Large Colony, *Actinobacillus seminis, Ureaplasma* spp., *Mycoplasma ovine-caprine* serogroup 11, and *Mycoplasma capricolum* subsp. *capricolum* have also been implicated in posthitis in sheep.[3,4]

Pathophysiology

C. renale is the bacterium most commonly implicated in ulcerative posthitis. These are aerobic, gram-positive, pleomorphic, club-shaped bacteria that are normal inhabitants of the skin and external genitalia of small ruminants. The bacteria contain the enzyme urease. A high-protein diet results in increased ammonia production in the rumen, which is converted to urea in the liver. The urea is eliminated through the renal system. *C. renale* proliferates, and the urease hydrolyzes the urea back to ammonia, causing chemical irritation and ulceration of the prepuce and surrounding skin.

Epidemiology

The condition appears to be more common in males than in females. Risk factors are associated with increased or excessive dietary protein concentration (usually >16%) such as alfalfa hay or lush legume or legume-grass pastures. However, diets with protein levels as low as 12% have been implicated.[4] Rams, pet wethers, club or show lambs or kids, wool and fiber production animals, and feedlot lambs are most predisposed to the disease. Increasing the plane of nutrition in intact males prior to breeding predisposes to development of this disease, and multiple animals can be affected simultaneously.[5] Breeds with dense wool or hair, such as Merino sheep and Angora goats, are also at risk owing to urine soaking the coat near the preputial orifice.

Disease can occur in individual or multiple animals, since the organism can persist in wool, hair, and scabs for as long as 6 months. The organism can also survive freezing in scabs and exudative material. Venereal transmission of the disease has been documented; several months may pass between exposure of ewes to infected rams and development of vulvitis in the ewes. Production losses result from debilitation caused by pain, incapacitation of breeding animals, loss of breeding soundness, and deformation of external genitalia.

Treatment and Prognosis

Reduction of protein and nonprotein nitrogen intake is crucial for successful treatment of affected animals and for prevention of additional cases. Dietary changes alone may result in satisfactory cure if the lesions are early in development. Incorporation of grass hay feeding into a program of legume pasture grazing may help limit protein intake.

Affected animals should be isolated to limit venereal or contact transmission. Wool or hair should be removed from the skin surrounding the prepuce or vulva, and a topical antibiotic may be applied. Caustic antiseptic solutions should not be used. Treatment with systemic antibiotics is indicated for advanced cases or for outbreaks, in which handling of several animals for topical therapy is not feasible. *C. renale* is sensitive to penicillin, ampicillin, cephalosporins, and oxytetracyline. Treatment should continue until the lesions have dried and acute inflammation has subsided. Topical therapy of the preputial mucosa includes application of mastitis treatment tubes, triple antibiotic ointment, or "petercillin." Petercillin is prepared by mixing 240 g anhydrous lanolin, 20 mL of procaine penicillin G (300,000 U/mL), and 200 mg aqueous prednisolone. A small amount can be warmed up and injected into the prepuce using an AI infusion pipet or small feeding catheter. Oral or injectable NSAIDs can be used to decrease the inflammation and pain associated with the infection.

Surgical treatment of advanced cases is recommended for severe strictures. The ventral preputial tissue can be resected to allow for normal urine flow or be incised along part of its length.

Response to treatment is optimal early in the infection, before deformation of the prepuce or vulva as a result of fibrosis. The chances for full recovery without recrudescence are poor if dietary protein intake is not reduced. Complete recovery of breeding soundness is unlikely in animals with internal ulcerative posthitis. In breeding males, the presence of ulcerative posthitis does not directly

VetBooks.ir

influence semen motility or morphology, but since the pain involved is likely to suppress libido, proper treatment and documentation of lesion resolution is recommended in affected males prior to the breeding season.[6]

Prevention Prevention primarily involves limiting both protein and nonprotein nitrogen intake. Breeding males should be body-condition scored early enough before the breeding season so that any necessary weight gains can be made slowly rather than a sudden onset immediately prior to breeding season. Separation of affected males will help decrease spread through contact with exudative materials. Shearing, especially at the time of highest protein intake, may be efficacious in reducing disease incidence.

Urolithiasis

Stacey R. Byers

Definition and Etiology Urolithiasis is a common metabolic disease in all livestock species, but castrated small ruminants appear to be particularly at risk. Uroliths cause disease through trauma to the urinary tract and obstruction of urinary outflow. Urolithiasis can occur in outbreaks or as an endemic problem in group-housed animals or as an individual disorder in animals kept as pets. A definitive diagnosis of urolithiasis in a single animal suggests that all males in the population are at risk for the disease because of the importance of dietary and environmental factors in its pathogenesis.[1]

The clinical signs of urolithiasis vary and are based on duration, extent (complete vs. partial), and location of the obstruction. The early clinical signs can be remarkably subtle and may include anorexia, depression, and mild bloat. A history of colic and straining to urinate or defecate may be provided, and novice owners often mistake stranguria for constipation or tenesmus. If investigating a sick, castrated small ruminant, urolithiasis should be high on the differential list regardless of the clinical signs.

Four common disorders can result from urolithiasis: acute urethral obstruction, chronic urethral obstruction, urethral rupture, and urinary bladder rupture. Less commonly seen are ureterolithiasis and hydronephritis.

Clinical Signs and Differential Diagnoses

Acute Urethral Obstruction

Impacted calculi lead to urethral trauma and progressive bladder distention, resulting in stranguria and abdominal pain. Affected animals may be restless, tread, swish their tails, and grind their teeth. Goats and camelids may vocalize. Tachycardia, tachypnea, and mild bloat secondary to ruminal stasis are common findings. Stranguria is manifested as repetitive bouts of stretching and contraction of the abdominal muscles. Straining may induce secondary rectal prolapse, so urethral obstruction should be investigated as the primary disease in cases of rectal prolapse. Rarely, affected calves develop a visible dilation of the urethra at the midline of the perineum proximal to the obstruction.[2] Anuria occurs if urethral obstruction is complete, whereas urine may dribble in cases of partial obstruction. Crystals or blood may be found on the hairs of the preputial tuft; in cases of anuria the hairs are dry. If a urine sample can be collected for dipstick analysis, proteinuria and occult hematuria are frequently detected.

Rectal examination (digital rectal examination in small ruminants) often reveals pulsation of the pelvic urethra. In cattle, bladder distention is palpable per rectum, although if bladder or urethral rupture has occurred, the bladder is typically not palpably enlarged.

Abdominal palpation may be useful in affected small ruminants, small camelids, and pot-bellied pigs. The examiner should place the fingertips of each hand into the ventral flank on each side of the abdomen. While slowly pressing the fingertips toward midline in the caudal abdomen, the examiner may encounter an orange- to grapefruit-sized, firm, spherical structure, which is the distended bladder (Fig. 34-18). Severe bladder distention will not be palpated in cases of incomplete urethral obstruction or bladder rupture.

FIG. 34-18 Palpation of the bladder of a Barbados wether.

The lumen of the bovine urethra narrows at the distal aspect of the sigmoid flexure, near the insertion of the retractor penis muscles.[3] Calculi most frequently become lodged at this site in cattle, and pain or focal swelling over this area may be appreciated.[3] The urethral process is the most common site of calculous obstruction in sheep and goats and should always be examined in suspected cases of urolithiasis.[4]

Owing to the frequent lack of specific clinical signs, acute urethral obstruction can resemble a variety of diseases. Tachycardia, colic, bloat, and anorexia are characteristic of GI obstruction, but auscultation and percussion of the abdomen, abdominal succussion, rectal examination, and transabdominal or transrectal ultrasonographic examination should differentiate this condition from acute urethral obstruction. Encephalopathies, salmonellosis, coccidiosis, and proctitis from rectal prolapse or trauma frequently cause tenesmus. Additional signs of primary neurologic or GI dysfunction should be evident with these diseases.

Although rare in male ruminants, primary UTI may result in dysuria and pollakiuria. Bladder distention is uncommon with UTI, and large numbers of WBCs and bacteria are present in the urine sediment.

Occasionally an animal with urolithiasis successfully voids the obstructing urolith(s). The resultant traumatic urethritis might cause dysuria, but the rate and ease of urination typically improve over time and with antiinflammatory treatment.

Juvenile male camelids have been observed straining or posturing to urinate. On cystotomy, no uroliths have been discovered. Etiology has not been conclusively determined, but transrectal ultrasound has identified prostatitis in some individuals. It is suspected that hormonal influences or ascending UTIs may be contributing to prostatic or urethral inflammation.

In younger animals, it is important to consider congenital abnormalities (e.g., ectopic ureter(s), pelvic displacement of the urinary bladder, urethral duplication). Congenital abnormalities may be manifest at birth or not until later, depending on the level of observation and whether the defect results in obstruction, partial obstruction, or constant urine dribbling.

Chronic Urethral Obstruction

Uncommonly, partial urethral obstruction causes chronic dysuria and stranguria if calculi impair but do not completely obstruct urine outflow.[5] If a chronic partial obstruction is present, the affected animal has a characteristic slow or intermittent urine flow during voiding. Lethargy, reduced appetite, and thin body condition are

VetBooks.ir

evident if renal failure has developed. On rectal examination the bladder may be small, and thickening of the bladder wall may be palpable.[5]

Urine dribbling may also occur in animals with neurologic disease, previous urethral trauma (stricture formation), congenital anomalies of the urogenital tract, infection, or neoplasia. Contrast urethrography may be used to identify the presence of strictures or anomalous structures. Small ruminants with the internal form of ulcerative posthitis may dribble urine. In such cases, characteristic preputial lesions are present. Tumors of the urinary tract, although rare compared to urolithiasis, may cause gradual obstruction in cattle, small ruminants, and camelids.

If there is a complete urethral obstruction for approximately 36 hours or more, the animal is at risk of developing bilateral hydroureter and hydronephrosis, and imaging studies of the kidneys and ureters are warranted.

Urethral Rupture

Urethral rupture is a common complication of urethral obstruction in ruminants and camelids. The wall of the obstructed urethra undergoes pressure necrosis, causing leakage of urine into the subcutaneous tissue of the perineum and ventral abdomen. Sequelae include cellulitis, penile adhesions (possibly creating phimosis), urethral fistula formation, and urethral stricture. Erection failure secondary to vascular obstruction of the corpus cavernosum of the penis has been reported as a sequela to urethral obstruction and rupture in a goat.[6]

Affected animals are frequently depressed and inappetent and have bilaterally symmetric, pitting edema in the ventral perineum, inguinal region, prepuce, and ventral abdomen (Fig. 34-19). Swelling of the abdominal wall may extend as far forward as the axillae. The affected areas are initially warm and painful on palpation. As necrosis progresses, the tissues become cool, dark, nonpainful, and potentially gangrenous. A fistula may develop to allow urine to escape. Fever may occur if tissue necrosis and sloughing are extensive. Transrectal palpation or ultrasound reveals a small bladder.

Ventral abdominal swelling is also found with umbilical or scrotal hernias and omphalophlebitis. These conditions can be differentiated from urethral rupture by careful palpation of affected tissues, aspiration of any fluid pockets for cytologic examination, and ultrasonography. In bulls, penile hematomas may cause localized swelling of the prepuce in the prescrotal region and caudal sheath, but the swelling does not involve the ventral abdominal wall. Aspiration of a suspected penile hematoma is not recommended because of the risk of iatrogenic infection.

Urinary Bladder Rupture

In all ruminants and camelids, prolonged bladder distention secondary to urethral obstruction may result in pinpoint perforations, tears, or necrosis of large areas of the bladder wall. In cows, bladder rupture may also occur as a rare complication of dystocia.[7] Rupture of an urachal remnant may also result in uroperitoneum.[8] The dorsum of the bladder fundus is the most common site for rupture, but rupture in other bladder regions occurs.

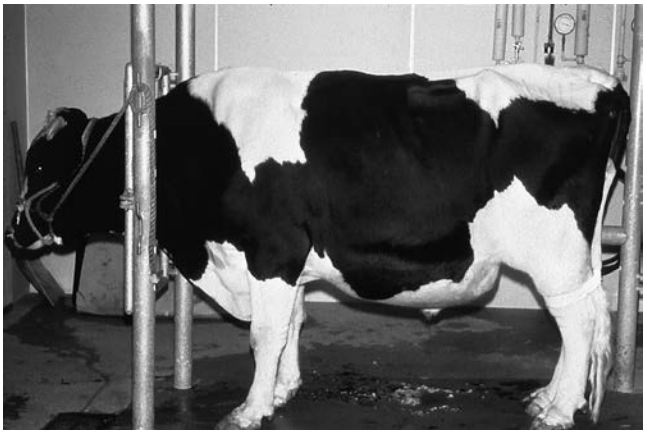

FIG. 34-19 Urethral rupture in a Holstein steer. Tissue swelling from urine accumulation may extend to the sternum and axillae.

Relief of bladder distention causes cessation of stranguria. Bilateral distention of the ventral abdomen develops within 1 to 2 days after rupture and is accompanied by worsening clinical signs of depression, anorexia, weakness, dehydration, and shock. Ballottement of the abdomen may elicit a fluid wave. Rectal temperature may be normal, but shock may result in hypothermia. The animal's breath may smell like ammonia. On transrectal or transabdominal palpation, the bladder is small or not palpable. Transabdominal ultrasonography reveals a large volume of free fluid and a collapsed or partially filled bladder. Abdominocentesis yields a large volume of blood-tinged fluid; the fluid may smell like urine when heated, although this is quite subjective. On occasion, urine will translocate into the thoracic cavity or into the scrotum through the inguinal canals. Uremia and dehydration result in debilitation and eventual death if medical and surgical treatments are not provided.

Seepage of urine across the bladder wall and into the abdominal cavity may occur in cases of severe bladder distention; in such cases, rupture is often imminent. Differential diagnoses for bladder rupture include diffuse peritonitis, ileus, enteritis, vagal indigestion, ascites secondary to liver fibrosis, caudal vena caval thrombosis, and hypoproteinemia. Marked peritoneal cavity effusion may be found in cases of mesothelioma or lymphoma. These conditions are differentiated from bladder rupture through transrectal examination, ultrasonography, cytologic and chemical analysis of peritoneal fluid, evaluation of serum chemistry, and abdominal exploratory surgery.

Ureterolithiasis and Nephrolithiasis

Animals with acute ureteral obstruction may show severe colic with stretching, kyphosis, treading, collapse, and vocalization. Signs of distress may be less severe or even absent if obstruction is intermittent or incomplete.[9] Enlargement of the blocked ureter may be palpated transrectally, and if the left ureter is obstructed, enlargement of the left kidney may be appreciated. Transabdominal or transrectal ultrasound may aid in the diagnosis. Rarely, pyelonephritis is the inciting cause of ureteral obstruction, because necrotic debris and calculi may be released into the ureter from the infected renal pelvis. Pyelonephritis can also be a consequence of ureteral or renal calculosis.[9,10] With ureteral or renal rupture, uroperitoneum or retroperitoneal accumulation of urine may occur.

Similar signs of abdominal pain or colic can result from GI or urinary tract obstruction in ruminants and camelids. Auscultation and percussion of the abdomen, rectal examination findings, ultrasonography, or radiography may allow for differentiation of GI obstruction from ureteral or renal obstruction. Cases of ureteral or renal calculosis without colic may show nonspecific signs of illness, and serum chemistry, urinalysis, and ultrasound examination are needed for definitive diagnosis.

Ancillary Diagnostic Tests

EXAMINATION OF URETHRAL PROCESS IN SMALL RUMINANTS. Sedation or general anesthesia facilitates extrusion of the penis for examination. Because of its diuretic effect, xylazine may exacerbate bladder distention and is not recommended. Diazepam (0.1 mg/kg IV slowly) and acepromazine (0.05 to 0.1 mg/kg IV or IM) have been used successfully, either as sole agents or in combination with butorphanol (0.05 to 0.1 mg/kg IV). Alternatively, the use of isoflurane by mask can be used.

An adjunct or alternative to sedation is administration of epidural anesthesia, which provides greater patient comfort and eliminates muscular resistance to penile extrusion. One milliliter of 2% lidocaine per 15 kg (33 lb) of body weight is injected into the epidural space at the lumbosacral junction. Lower dosages may provide sufficient anesthesia. The total dose should not exceed 15 mL of 2% lidocaine in any small ruminant, regardless of size. If CSF is obtained,

VetBooks.ir

half of the epidural lidocaine dosage can be administered as a true spinal block. Hindlimb motor blockade is expected with either epidural or true spinal anesthesia at this site; the effects typically last 1 to 2 hours.

To exteriorize the penis, the sheep or goat is propped up on its rump, and the hind legs are pulled up alongside the trunk. For larger sheep or goats, this can be aided by a person sitting in a chair, with the animal propped up between his or her legs. It is critical that the animal be positioned such that its spine is perpendicular to the floor. Addition of lidocaine jelly or several milliliters of 2% lidocaine added to a water-based lubricant and squirted into the prepuce may decrease discomfort for exteriorizing the penis. The examiner can then exteriorize the penis by pushing the sigmoid flexure cranially from the base of the scrotum while pulling the sheath caudally. In some cases, preputial mucosa must be carefully grasped with small forceps or Allis tissue forceps to aid in extruding. The penis can then be grasped with a piece of gauze to keep it exteriorized. The urethral process can then be inspected and palpated for the presence of discrete uroliths or sand-like grit within the lumen. If the urethral process is obstructed, it can be amputated with a scalpel blade (see Surgical Treatment).

ULTRASONOGRAPHY AND RADIOGRAPHY. A presumptive diagnosis of urolithiasis can usually be made through historical and physical examination findings. Ultrasonographic and radiographic evaluation of the urinary tract may allow for confirmation of a diagnosis and prognosis.[11-15] In cases of prolonged urethral obstruction (≥48 hours) or urethral obstruction with severe azotemia, it is prudent to perform ultrasonographic examination of the kidneys before considering surgical treatment (see ultrasound images of the bladder in the ruminant section of Chapter 32). Detection of severe hydronephrosis warrants a poor prognosis for recovery.

Ultrasonographic evaluation of the bladder of pot-bellied pigs, small ruminants, and camelids is most easily accomplished through transabdominal scanning directed caudodorsally from the inguinal area. Both kidneys of small ruminants and camelids and the bovine right kidney can be examined from the right paralumbar fossa. In cattle, transrectal examination of the pelvic urethra, bladder, ureters, and left kidney can be performed. Marked distention of the bladder, thickening of the bladder wall, and echogenic material within the bladder lumen may be seen with acute urethral obstruction. A large volume of free fluid in the abdomen is characteristic of uroperitoneum and is suggestive of existing or impending rupture.

Radiographic examination of the urinary tract is limited to pot-bellied pigs, camelids, small ruminants, and young cattle. Lateral views of the abdomen can be used to detect radiodense calculi in the bladder and urethra. This is accomplished most easily with the animal in lateral recumbency with the hindlimbs pulled caudally. It is also recommended to image the entire urethra to determine the presence and location of stones. Positive-contrast urethrography allows for detection of radiolucent urethral calculi, urethral stricture, or urethral rupture. After catheter placement about 5 cm into the penile urethra, injection of a volume of 10 to 30 mL of water-soluble contrast media has been used with success in adult bucks and rams. To avoid accidental introduction of bubbles into the catheter, it should be completely filled with contrast material before insertion. Injection should be performed slowly with minimal pressure to avoid iatrogenic urethral rupture. Following tube cystostomy, contrast urethrethrography can be performed by injecting the contrast material into the bladder through the catheter. The catheter can then be clamped shut temporarily to evaluate for the continued presence of stones, strictures, or urethral rupture.

CLINICAL PATHOLOGY

Acute and Chronic Urethral Obstruction. Hematologic and serum chemistry findings may be unremarkable in ruminants with acute urethral obstruction uncomplicated by urethral or bladder rupture. Hyperglycemia and a stress leukogram may be present. With time, hemoconcentration and azotemia develop secondary to reduced water intake. Hematuria and proteinuria are consistent abnormalities, whereas crystalluria is a variable finding. With chronic urethral obstruction, hyponatremia, hypochloremia, hypocalcemia, hyperphosphatemia, and severe azotemia with isosthenuria suggest extensive nephron damage caused by hydronephrosis. Pyuria is present with traumatic urethritis, cystitis, or secondary bacterial infection.

Bladder Rupture. Bladder rupture and accumulation of urine in the abdomen result in hematologic and serum biochemical parameter alterations that worsen as time progresses. Urine osmolality is normally two to three times that of extracellular fluid (ECF), and urine contains higher concentrations of urea, creatinine, and potassium but lower concentrations of sodium and chloride than ECF. Therefore, movement of water, urea, and electrolytes occurs along diffusion gradients, resulting in hyponatremia, hypochloremia, hyperphosphatemia, uremia, and hemoconcentration.

Serum potassium concentration in ruminants with bladder rupture is more variable, depending on appetite and time before diagnosis. Although animals with uroperitoneum are at risk of hyperkalemia, serum potassium concentration tends to be normal or low in ruminants with bladder rupture, even if uroperitoneum exists for several days. Anorexia may contribute to hypokalemia or normokalemia in these cases, and aldosterone release secondary to volume depletion results in dramatic increases in salivary potassium excretion, providing an alternative route of potassium excretion in affected animals. Once in the GI tract, potassium absorption may be diminished by ileus and preferential absorption of sodium over potassium. Alkalosis, which occurs secondary to hypochloremia, may also serve to reduce ECF potassium concentration by encouraging movement of potassium intracellularly.

Although only a small fraction (<10%) of phosphorus excretion in the ruminant is via urine, hyperphosphatemia may occur secondary to uroabdomen. Potential mechanisms for hyperphosphatemia include phosphorus diffusion from the urine into the ECF, reduced glomerular filtration, and tissue hypoxia causing breakdown of organic phosphate compounds in cells. In addition, reduced salivary flow from anorexia may limit phosphorus excretion in the saliva, contributing to phosphorus retention. Anorexia, ileus, and a competitive effect of hyperphosphatemia may contribute to reduction in serum calcium concentration in cases of uroabdomen.

Measurement of creatinine in the peritoneal fluid can be used to confirm a diagnosis of uroperitoneum. Creatinine is a relatively large polar molecule that does not readily diffuse from the abdominal cavity into the ECF space. Therefore, peritoneal fluid creatinine can be compared to serum creatinine concentration, with a peritoneal fluid/serum creatinine ratio of 2:1 or higher indicating uroperitoneum.

Uroperitoneum may induce a mild chemical peritonitis. However, experimentally induced bladder rupture did not cause peritonitis in steers, even after several days of uroperitoneum.[16] Nonetheless, WBC count and blood fibrinogen levels may increase in cases of ruptured bladder, possibly reflecting more extensive tissue necrosis and inflammation in natural cases. With uremia, impairment of blood coagulation may become an important clinical consideration. Reduced platelet aggregation and alteration of coagulation factor function occur in uremic patients of other species.[17] Bleeding diathesis and elevation of partial thromboplastin time (PTT) have been reported in azotemic cattle.[18] Bleeding complications should be considered prior to surgical treatment.

Urethral Rupture. Leakage of urine into the subcutaneous space following urethral ruptures produces hematologic and serum biochemical alterations that are similar but less severe than those seen with bladder rupture. The muscles and subcutis holding the urine do not possess as large a surface area as the peritoneal cavity. Therefore, less rapid and less extensive movement of water, ions, and waste products occurs, and the resulting changes in serum electrolytes and creatinine are less marked than in bladder rupture. Tissue necrosis and secondary infection may result in neutrophilia, leukocytosis, and hyperfibrinogenemia.

VetBooks.ir

Ureterolithiasis and Nephrolithiasis

Azotemia and secondary hydronephrosis are most severe if the obstruction is bilateral. With chronic ureteral obstruction, hyponatremia, hypochloremia, hypocalcemia, hyperphosphatemia, and severe azotemia with isosthenuria suggest extensive nephron damage caused by hydronephrosis. Pyuria is present with traumatic urethritis, cystitis, or secondary bacterial infection.

Pathophysiology Multiple factors influence the development of urinary calculi, but of primary importance is the development of high urinary concentrations of soluble ionized minerals (crystalloids) that aggregate to form insoluble crystals. Supersaturation of urine with a calculus-forming crystalloid is a prerequisite for urolith development,[19] but supersaturation alone is not solely responsible for urolith initiation, because normal urine is typically supersaturated with a variety of calculogenic ions. Urine contains variable concentrations of mucopolysaccharides, ions, and organic acids that act as intrinsic inhibitors of crystallization. Through physical and electrochemical interactions, these compounds maintain calculogenic minerals in a colloidal suspension. Calculus formation is initiated if supersaturation of urine with appropriate crystalloids exceeds the protective capabilities of the crystallization inhibitors. The crystalloids are rendered insoluble and precipitate out of the aqueous phase of urine. Calculi enlarge as further mineral precipitation takes place on the crystal surfaces. Dietary, environmental, and management influences interact to determine the degree of supersaturation of urine with calculogenic minerals. Dehydration, with resultant concentration of urinary minerals, would appear to be a potential contributing factor in the development of all types of uroliths.

The solubility of some calculogenic crystalloids is influenced by urinary pH. Struvite (magnesium ammonium phosphate), calcium phosphate, and calcium carbonate uroliths are less soluble in alkaline urine, whereas calcium oxalate solubility is not affected by changes in urine pH within the physiologic range. The effect of urinary pH on silica calculi is debatable, but recent findings show a trend toward reduction in formation under conditions of mild aciduria.[20]

Primary UTIs are considered an uncommon cause of ruminant urolithiasis. Purulent debris within the urinary tract may serve as a nidus for crystal development, and bacterial ureases may increase urinary pH, thereby reducing the solubility of certain crystalloids. Pyelonephritis, with presumed secondary urolithiasis, has been reported in cattle.[10] Urolithiasis may be considered as both a rare cause and a rare consequence of a UTI.[9,10]

Vitamin A deficiency has been incriminated as a contributory factor for urolith development by leading to metaplasia of urinary tract epithelium.[19] This may create nidi for calculogenesis through desquamation of cells or altered cell surface characteristics.

Feeding patterns may influence the formation of urinary calculi. In ruminants, providing a ration in one or two feedings per day induces ADH release soon after feeding which resulted in a marked but transient decline in urine output and an increase in urine concentration.[21] These changes in urine composition can be limited through ad libitum feeding. The influence of water hardness (dissolved mineral content), in particular in magnesium concentrations, has been implicated in the pathogenesis of this disease in ruminants.[22]

PHOSPHATIC CALCULI. Ruminants consuming rations high in phosphorus (grain-based rations) typically develop struvite (magnesium ammonium phosphate hexahydrate) calculi or apatite (calcium phosphate) calculi.[1,19,23-25] Rations where the calcium/phosphorus ratio is less than 2:1 are particularly prone to cause outbreaks of urolithiasis.[19] However, the role of phosphorus in urolith formation is not clearly defined, and struvite urolith formation appears to be primarily affected by the magnesium and to a lesser extent, other minerals in the diet.[19,26-28] Magnesium absorbed from the gut is excreted through the kidneys. Experimental increases in dietary magnesium levels to 0.6% of dietary dry matter induced calcium phosphate and struvite urolithiasis in calves.[28] High potassium in the diet alters the dietary cation-anion difference (DCAD) and increases the risk of urolith formation (see more about DCAD in Prevention).[29]

Pelleting of rations has been associated with an increased incidence of phosphatic urolithiasis.[1] Ruminant saliva is rich in phosphorus, and the GI tract is the primary route of phosphorus excretion in ruminants. In theory, ruminants consuming pelleted rations produce less saliva, which would reduce GI phosphate losses and increase urinary phosphate excretion.[1]

Struvite uroliths are typically white or gray, usually smooth, radiopaque, and easily broken.[19] They can be found as a single stone or sand-like debris, which is more commonly seen in ruminants.

SILICA CALCULI. Silica urolithiasis is primarily a problem of ruminants grazing native rangeland grasses of western North America. For example, in western North America, silica calculi can be found in the urinary tracts of 50% to 80% of range cattle, with urinary tract obstruction occurring in a variable percentage of these animals.[21] The silica fraction of these grasses tends to increase with maturity and may continue to increase even after growth ends. In some areas, 4% to 8% of total grass dry matter may be silicon compounds.[20] A fraction of dietary silica, as unpolymerized silicic acid, is dissolved in the ruminal fluid of the grazing animal, absorbed, and excreted in the urine.[19] In sheep and cattle on range, water intake is usually intermittent. During periods of water deprivation, avid water and sodium resorption by the kidneys results in the formation of highly concentrated urine. Silicic acid may be concentrated to such an extent that it polymerizes to the less soluble form, polysilicic acid. Polysilicic acid in turn forms large micelles in solution that quickly become insoluble when bound to urinary mucoproteins.[30]

Dietary deficiencies of copper and zinc have been identified as contributory factors in silica urolith formation in rats.[31] The incidence of silica urolithiasis can be increased by feeding sheep rations that have a high calcium/phosphorus ratio (≥2.8:1) and induce more alkaline urine.[20,32] It is important to note that a high calcium/phosphorus ratio in the diet can help to prevent one type of urolith (struvite) but may be a contributory factor for another (silica). This underscores the importance of both ration and urolith mineral analyses in the formulation of preventive measures for this disease.

Silica uroliths in ruminants are hard, smooth, white to brown, radiopaque, and often layered.[19] The uroliths are usually composed of about 20% mucoprotein, 75% silicon dioxide, and variable amounts of calcium oxalate and calcium carbonate.[19,21]

CALCIUM-BASED CALCULI. The two main types of calcium-based uroliths are calcium carbonate and calcium oxalate. Calcium carbonate uroliths (Fig. 34-20) are common in small ruminants grazing lush, rapidly growing clover pastures or being fed alfalfa hay.[33,34] Forages like these are rich in calcium and low in phosphorus and magnesium and have high oxalate content. In the gut, oxalate avidly binds calcium and makes it unavailable for absorption. With gradual introduction of oxalate-rich diets, ruminal bacteria efficiently metabolize oxalate to bicarbonate, so metabolism of oxalate

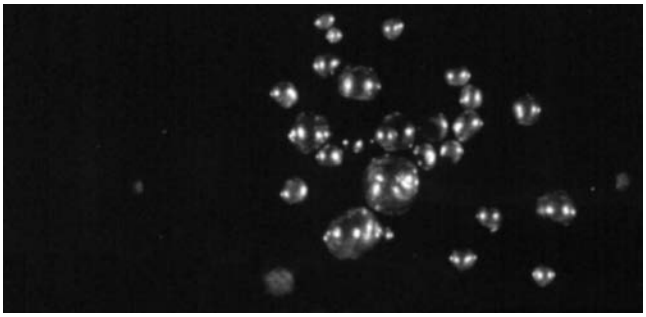

FIG. 34-20 Calcium carbonate calculi.

VetBooks.ir

in the rumen may increase the availability of dietary calcium.[35,36] These factors may combine to increase urinary calcium excretion and alkalinize urine, thereby promoting calcium carbonate calculogenesis.

Although humans at risk for calcium oxalate stones should limit foods high in oxalates, similar dietary and metabolic factors that influence formation of calcium oxalate uroliths have not been elucidated in ruminants.[19,37] Reports indicate that oxalates in the diet, as well as low calcium and decreased water intake, may increase the risk of forming calcium oxalate stones.[38,39] Given its very low solubility, calcium oxalate crystals are often present in normal urine and may be incorporated into other uroliths as a trace component.

Calcium carbonate uroliths have a characteristic round, smooth shape and golden color and are often present as multiple uroliths scattered throughout the lower urinary tract. Calcium oxalate uroliths are typically dense, hard, white to yellow, and either smooth or jagged.[19]

Epidemiology

GENDER. Obstructive urolithiasis in ruminants and camelids is almost exclusively a disease of males and castrated males. Urinary calculi appear to develop to a similar degree in female ruminants, but most calculi can pass through the relatively short, distensible urethra of the female, making urethral obstruction uncommon. The urethra of the male is long and surrounded by the less distensible corpus spongiosum and tunica albuginea.

Research indicates calculi form to a similar extent in the urinary tracts of bulls and steers. Because of the trophic effect of testosterone, the urethral diameter of yearling bulls is roughly 25% greater than that of yearling steers. Urethral obstruction therefore is more common in steers.[21] A similar predisposition for urethral obstruction may exist for wethers relative to buck goats.[40] However, because many wethers are kept as pets, factors such as diet, environment, and age are likely to differ compared with bucks. Specific gender risks in camelids and pot-bellied pigs is not well described; in commercial pigs, urolithiasis is generally associated with husbandry problems such as improper calcium/phosphorus ratio in the ration and inadequate water availability.[23]

SEASON. The incidence of urolithiasis increases in the late fall and winter in North America.[21] Limited water availability, increases in the silica content of range grasses, and a larger population of susceptible animals (young, growing males) during this time of year may be responsible for this trend. In warmer climates, urolithiasis is more frequently a problem in the arid months of the year, underscoring the role of water intake in the pathogenesis of the disease.[21]

AGE. Cattle of various ages may develop obstructive urolithiasis. The tendency for this disease to be seen in younger ruminants may be the result of dietary influences, because younger animals are more often fed concentrates for weight gain and eventual slaughter than are mature males kept for breeding. Because relatively fewer mature males are kept for breeding, the apparently increased prevalence of urolithiasis in younger animals may simply reflect the greater numbers of younger males and castrated males at risk.

OTHER. Inherent differences in an individual animal's mineral metabolism or urinary tract health may also play a role; some animals can ingest a calculogenic diet and remain unaffected, others develop uroliths rapidly. Animals prone to develop uroliths may have ineffective protective capabilities within the urinary tract, such as a lack of crystallization inhibitors. UTI is not a major risk factor for urolithiasis in ruminants, swine, and camelids.

Certain breeds of ruminants appear to be predisposed to urolithiasis; for example, African pygmy goats appear to be prone to developing this disease. Again, because these goats are often kept as pets, it is possible these animals may be fed or managed in ways that increase their disease risk.

Necropsy Findings

When the urethra is opened along the sagittal plane, hemorrhage and necrosis of the urethral mucosa are evident at the site of obstruction. Particular attention should be paid to examination of the distal urethra in camelids, the urethral process in sheep and goats, and the sigmoid flexure in cattle. Calculi may be relatively large, discrete mineral aggregates or very fine and sand-like. Calculus material should be collected for analysis of mineral composition (Box 34-1). Occasionally, no calculi can be found in the urinary tract, but mucosal trauma and necrosis of the bladder or urethra persist.

Urethral rupture is characterized by the subcutaneous accumulation of urine in the inguinal area, prepuce, and ventral abdomen and hemorrhage at the site of the urethral defect.

In cases of bladder rupture, the abdominal cavity is filled with a large volume of blood-tinged fluid. Defects in the bladder wall vary in size and location, and necrosis of large areas of bladder wall may be present. In rare cases the bladder wall is intact but obvious uroabdomen exists, suggesting transmural seepage of urine.

Hydronephrosis, hydroureter, and bladder wall hypertrophy may be present in animals with chronic urethral obstruction.[5]

Treatment and Prognosis

SALVAGE. Steers and feeder lambs may be sent for immediate slaughter if urethral obstruction is diagnosed before development of azotemia or urinary tract rupture.

MEDICAL TREATMENT. Medical treatment of urolithiasis is aimed at relief of the obstruction and correction of any fluid and electrolyte abnormalities. The antispasmodic effect of certain tranquilizers may facilitate passage of a urethral obstruction.[1] These drugs may also aid in relaxation of the retractor penis muscle, which results in straightening of the sigmoid flexure to facilitate passage of calculi. In small ruminants, however, medical treatment with IV fluids, NSAIDs, or tranquilizers alone has not met with much success, and surgical intervention is usually necessary.[4,41]

While stabilizing a patient before surgery or as an adjunct to medical treatment, the bladder can be drained with a percutaneous catheter inserted in the lower flank or ventral abdomen.[42] Long IV catheters or a suprapubic catheter can be inserted, using ultrasonography as a guide, and temporarily left in place. Percutaneous infusion using Walpole solution has been used following cystocentesis in goats.[42] Urine was removed and the solution infused into the bladder 1 to 3 times to decrease the urine pH to 4 to 5. This process was thought to promote chemical dissolution of uroliths in the bladder and urethra.

VetBooks.ir

Ruminants and camelids with urinary tract obstruction, particularly those with uroperitoneum, often require preoperative stabilization of hypovolemia and correction of electrolyte abnormalities, especially if surgery is to be performed under general anesthesia or with the animal restrained in recumbency. Fluid therapy should be guided by analysis of serum electrolyte concentrations. An initial bolus of hypertonic (7%) saline followed by physiologic (0.9%) saline solution can be used to correct intravascular volume deficits, hyponatremia, and hypochloremia. Calcium salts can be added to the fluids if indicated.

Empirical supplementation of IV fluids with potassium should be avoided because the potential for hyperkalemia always exists. Hyperkalemia can induce bradycardia and fatal cardiac dysrhythmias, and this effect is augmented by concurrent hyponatremia. Administration of dextrose, sodium bicarbonate, and/or insulin (regular insulin at 0.25 to 0.4 U/kg SC or IM) reduces serum potassium concentration by promoting movement of potassium from the extracellular to the intracellular space. Blood glucose should be closely monitored when insulin is administered. Uremic animals undergoing IV fluid therapy may develop pulmonary edema, so attention must be paid to respiratory rate, auscultatory findings, and respiratory effort during fluid therapy.

Slow drainage of urine from the abdominal cavity reduces pressure on the diaphragm and slows progression of metabolic derangements caused by uroperitoneum. In long-standing cases of uroabdomen, urine may also be present in the thorax, further warranting close observation of respiratory function during anesthesia. Thoracocentesis to remove thoracic urine is indicated if respiratory function is compromised; otherwise, abdominal drainage usually induces resolution of thoracic urine accumulation.

Although bacterial infection is not considered to be a common primary cause of urolithiasis, secondary UTIs may develop after surgical intervention. Loss of the flushing effect of urination, urinary mucosal damage, impaired host cellular defenses secondary to uremia, and indwelling urinary catheter placement may contribute to the development of ascending UTI. Perioperative antibiotic therapy is therefore prudent, with due consideration of withholding times in animals intended for slaughter.

SURGICAL TREATMENT. Surgical treatment of urolithiasis is dictated by economic considerations, intended use of the animal, available facilities and equipment, and status of the patient. Removal or bypass of the obstruction and restoration of urine output are the goals of surgical treatment. The prognosis for both short- and long-term survival will vary according to the patient's status and the surgical procedure chosen. ARF is an occasional sequela to urinary tract obstruction and should be considered in the prognosis.

Urethral catheterization and retrograde flushing have been used to dislodge urethral calculi and restore urine flow, but successful clearance of the urethra is rarely achieved, and retrograde flushing under pressure may result in urethral rupture.[4] Retrograde passage of a catheter may also allow for localization of the urethral obstruction, potentially guiding further surgical treatment. Passage of a catheter into the bladder of ruminants and camelids is difficult because of the presence of a urethral recess located near the ischial arch. Catheters passed retrograde almost invariably become lodged in this recess.

Surgical options include amputation of the obstructed urethral process, penectomy, perineal urethrostomy, prepubic urethrostomy, urethrotomy, cystotomy, tube cystostomy, and bladder marsupialization. In sheep and goats, *amputation of an obstructed urethral process* is a simple procedure that may at least temporarily restore urethral patency. The urethral process can be removed without detrimental effects on breeding soundness. Success rates for initial restoration of urine flow after urethral process amputation range from 37.5% to 66%.[4,43] However, recurrence of urethral obstruction is extremely common, and urethral patency is often maintained for only hours to days before reobstruction occurs.[4,43] Therefore, urethral process amputation is palliative and may provide enough time to allow feeder lambs to survive until slaughter. For pet wethers, rams, and bucks, recurrence of urinary tract obstruction is common if this is the only procedure performed.

Penectomy is an option for animals intended for slaughter. *Perineal urethrostomy* is a surgical option for ruminants not intended to be used for breeding. In small ruminants, postoperative stricture of the stoma or recurrent obstruction with additional calculi is a long-term risk.[4] *Ischial urethrostomy* with placement of a Foley catheter into the bladder has been used as a treatment for urolithiasis in heavy feedlot steers and bulls.[3,44] If urethral damage is not severe, this procedure allows the breeding ability of bulls to be maintained.[3]

Prepubic urethrostomy has been reported in a sheep and a goat.[45] In this procedure a midperineal penectomy is performed. The perineal segment of the penis and pelvic portion of the urethra are dissected free from the surrounding soft tissue using perineal and ventral celiotomy incisions, respectively. Bilateral ileal and ischiadic osteotomies may be required to free the pelvic urethra. The urethral mucosa is then sutured to the skin of the caudoventral abdomen to create a long-lasting stoma.

Urethrotomy (removal of obstructing calculi and primary closure of urethra) is another option.[3] Urethral stricture, adhesions resulting in phimosis in breeding males, and reobstruction with additional calculi are long-term complications.

Cystotomy allows for maintenance of breeding soundness and removal of additional calculi from the bladder. In small ruminants and camelids, bidirectional (normograde and retrograde) flushing is used to restore urethral patency.[4,43] Even if the urethra is successfully cleared of calculi, traumatic urethritis may cause significant postoperative dysuria in these animals. Therefore, some surgeons prefer also to perform a tube cystostomy to allow for rest and healing of the irritated urethra.

Tube cystostomy (surgical or percutaneous placement) allows urine to exit the bladder through a temporary Foley or other type of suprapubic catheter, which is anchored in the bladder lumen and exits the ventral abdomen.[41,46,47] Urethral patency is apparently restored when calculi are spontaneously expelled from the urethra, dissolved, or refluxed into the bladder, at which time the catheter can be removed. Spontaneous resolution of urethral obstruction with tube cystostomy may take several weeks or longer; a mean time of about 11 days in small ruminants has been reported.[41,46,47] To judge when removal of the catheter is appropriate, the catheter can be clamped shut and the animal observed for urination through the urethra. Fewer complications of tube cystostomy have been reported with surgically placed tube cystostomies versus percutaneously placed cystic catheters.[40,41,46] The primary complication is a dislodged catheter followed by tears of the bladder, leakage of urine into the abdomen, adhesions of the bladder to intestine or body wall, and obstruction of the catheter.

In cases of urethral rupture where patency of the entire urethra is the preferred outcome, tube cystostomy is often the sole feasible option. Primary repair of the urethral defect is rarely successful because of swelling and maceration of the damaged mucosa and risk of stricture formation. Contrast medium can be introduced into the bladder through the catheter to monitor urethral patency, locate urethral obstruction, or identify urethral rupture.[12] The catheter can also be used to lavage the bladder to facilitate dissolution of calculi using Walpole solution or a commercially available urinary lavage product (Renacidin, Guardian Laboratories, Hauppauge, N.Y.).[42,47]

In cases of bladder rupture, the urine should be drained from the abdominal cavity, and a surgical procedure should be performed to divert urine to the exterior. If primary repair of the bladder defect is desired, a laparotomy and cystotomy or tube cystostomy can be performed with the animal under local or general anesthesia. Primary repair of the bladder defect is not always necessary, however, because spontaneous sealing of the bladder with fibrin or omentum can occur. Depending on the size and location of the bladder defect, daily or continuous abdominal drainage may have to be performed until spontaneous sealing occurs. Tears are more likely to seal spontaneously if they are located on the dorsal aspect of the bladder.

VetBooks.ir

In *bladder marsupialization* the apex of the bladder is exteriorized using a small paramedian incision, and the seromuscular layer of the bladder is circumferentially secured to the abdominal wall. A cystotomy is performed, and the bladder mucosa is secured to the skin, creating a permanent opening for urine drainage from the bladder to the exterior.[48] Advantages of bladder marsupialization include decreased hospitalization time and expense for the owner. However, complications include chronic urine scalding, stricture formation, reobstruction, and bladder prolapse. Failure of bladder marsupialization was reported to be 33% in one study.[40]

Ureteral calculi may be removed by *ureterotomy.*[49] *Nephrectomy* may be performed in unilateral cases of obstructive nephrolithiasis.[50] If unilateral nephrectomy is under consideration, measurement of BUN, serum creatinine, and urine specific gravity should be performed. Renal biopsy and ultrasonography may be useful to evaluate the remaining kidney.

POSTOPERATIVE CONSIDERATIONS. Continued assessment of hydration, urine output, and serum urea nitrogen, creatinine, and electrolyte concentrations is indicated after surgery. Postobstruction diuresis may result from tubular damage, accumulation of urea or natriuretic factors, or preoperative fluid therapy. Induction of modest diuresis through fluid therapy after surgery may help to reduce azotemia and accumulation of blood clots and bacteria in the urethra.

Antimicrobial therapy with an antibiotic that achieves high urine concentrations (e.g., penicillin, ampicillin, sulfonamides) is warranted. Duration of therapy depends on the surgical procedure chosen, residue withholding considerations, and whether UTI exists at surgery. For tube cystostomy, antimicrobial therapy is recommended by some while the tube is in place and for at least 1 week after the tube is removed. Antimicrobial therapy should be maintained for at least 3 weeks after surgery in animals with active UTI.

Prevention

A preventive approach to a urolithiasis problem begins with a search for risk factors associated with the diet, management, and the environment. Whenever possible, ration analysis and mineral analysis of the urolith(s) should be performed to accurately identify causative dietary factors. Consult Box 34-1 for analysis laboratories. If uroliths are not obtained, ration analysis and a thorough dietary history may provide a strong suggestion of the urolith type. In light of the central role of urinary supersaturation in calculogenesis, the ultimate aim of preventive measures should be reduction of urinary concentration of calculogenic mineral ions. In addition, the urine should be diluted to such an extent that the calculogenic ions are less prone to precipitate. Dilution of urine is achieved through increased salt and water intake.

DIETARY MANAGEMENT. Prevention of urinary calculi can be difficult because of the conflicting dietary effects of minerals, pH, individual animal susceptibility, feed availability, and so forth. General guidelines for prevention of phosphatic calculi require adjustment of the dietary calcium/phosphorus ratio to a level of 2:1 or greater, which can be performed by reducing the amount of grain or other high-phosphorus dietary components and/or increasing calcium in the diet with forages like alfalfa or other legumes. Use of a 0-mEq/kg DCAD diet using ammonium chloride has been shown to help reduce urinary pH to between 6.0 and 6.5 without significantly decreasing blood pH.[29] Increasing the quantity of long-stem forage in the ration may increase salivary flow and fecal phosphate excretion.

Because restriction of dietary silica intake in ruminants grazing native grasses is not feasible, dietary management is limited to salt (sodium chloride or ammonium chloride) supplementation to increase water consumption and thereby produce a diuretic effect to reduce urinary calculogenic compounds. Loose salt or lick salt is unlikely to be ingested in sufficient quantities to affect water intake. Gradually increasing quantities of sodium chloride supplementation of palatable creep feeds up to a level of 15% of dry matter has been effective for range calves.[51] The feeders should be located near a reliable source of palatable water. Ammonium chloride supplementation (1% of dry matter) has also significantly reduced silica urolith development in lambs.[20,32] In the same study, reduction of the dietary calcium/phosphorus ratio from 2:1 to almost 1:1 resulted in a trend toward reduced silica calculi formation. The role of copper and zinc deficiencies in ruminant silica urolithiasis remains to be determined.

Prevention of calcium carbonate uroliths in pet small ruminants can be reduced by feeding or supplementing with grass hay rather than feeding alfalfa alone. Salting the grass hay with increasing concentrations of salt may increase water consumption to help maintain a dilute urine. Use of ammonium chloride can aid in urine acidification and increase water consumption.

Ammonium chloride supplementation fed at a level of 0.5% to 1.5% of ration dry matter was found to reduce urine pH to 6 to 6.5 in a group of goats.[29] A urine pH in this range should increase the solubility of struvite and apatite crystals. However, the pH of the urine is also influenced by the relative concentrations of strong cations (sodium and potassium) and strong anions (chloride and sulfate) of the entire ration, so the efficacy of ammonium chloride in reducing urinary pH may vary among different livestock operations, because the concentration of these cations and anions will vary among rations.[29,52] Long-term supplementation with ammonium chloride has been reported to result in chronic metabolic acidosis with a corresponding decrease in bone density.[53] Feeding a too-high concentration, resulting in a DCAD diet of −150 to −75 mEq/kg, caused excessively low urine and blood pH.[29] Ammonium chloride is not palatable, so mixing the salt with a more palatable low-potassium product (e.g., sucrose) is typically necessary. Reports indicate that some species appear to have a renal physiologic adaptation resulting in gradually increasing urine pH with long-term feeding of ammonium chloride, but this effect has been variable in ruminants.[29,54,55] Owners can monitor for changing urine pH with urine pH strips used on a weekly basis.[29] Pulsed feeding of ammonium chloride (e.g., 2 weeks on, 2 weeks off) can be attempted if the urine pH begins to increase.

WATER MANAGEMENT. Maximizing water intake is an important aspect of urolithiasis prevention, regardless of the urolith type involved. Cleaning water containers should be a regular practice. Water palatability may also be improved by providing shade for water containers during the summer. White water containers allow owners to see contamination of the water with dirt and feed; this may prompt more frequent cleaning. Heaters should be used to warm water during the winter. Automatic waterers should be checked regularly for proper function. Shallow containers capable of rapid refilling provide higher rates of water turnover, resulting in less stagnation.

In operations involving multiple animals or large pastures, placement of multiple watering sites might allow for more frequent intake. This is especially true for sheep, whose banding instinct usually prevents individuals from traveling alone to distant watering sites.

Urachal Disorders

Stacey R. Byers

Definition and Etiology

Abnormalities of the umbilicus and umbilical remnants, including the urachus, are frequently encountered disease conditions of neonatal calves. Infections of the urachus are often associated with omphalophlebitis, which commonly arises from environmental contamination of the umbilicus at birth. Cloned calves appear to be predisposed to having a patent urachus.[1] The association of umbilical abnormalities with calfhood morbidity and mortality has been established.[2] Occasionally, more insidious and chronic conditions of the urachal remnant are observed in older calves and mature cattle, with internal abscessation, adhesions, sepsis, peritonitis, uroperitoneum, cystitis, and intestinal strangulation

VetBooks.ir

reported.[3-8] Urachal fistulas or acquired patent urachus is infrequently observed in ruminants.

Chapter 20, Manifestations and Management of Disease in Neonatal Ruminants, provides more information on these disorders.

Clinical Signs and Differential Diagnoses Calves with internal urachal abscesses, adhesions, and other sequelae are usually older than 4 weeks of age. A history of umbilical infection during the neonatal period may or may not exist, and external umbilical abnormalities may not be present. Clinical signs may be nonspecific and include fever, lethargy, poor body condition, rough hair coat, and poor growth or productivity. Dysuria, pollakiuria, stranguria, and colic may be evident on examination or may be included in the medical history. When an infection extends into the bladder lumen, hematuria and pyuria are present.[4,8] Transabdominal palpation of the umbilicus and abdomen in smaller calves may reveal painful and enlarged umbilical remnants. Transabdominal ultrasound of the umbilicus and ventral abdomen is useful to identify abnormal structures, but adhesions may not be visualized.[9] Complications from associated septicemia (e.g., lameness and joint distention, pneumonia, hypopyon, meningitis) can occur.

If the urachus fails to regress completely, a persistent communication between the bladder apex and the pouch-like urachal remnant occurs. The volume of urine retained in the urachal remnant is variable. Animals with this problem may dribble urine from the urachus during micturition or remain asymptomatic. Urine retention can predispose the animal to UTIs.

Spontaneous rupture of the infected urachal stalk may result in the acute onset of peritonitis. If the urachal remnant communicates with the bladder lumen, rupture of the urachus results in uroabdomen. Rupture may occur spontaneously or after abdominal trauma or parturition in older animals.

A detailed ultrasonographic examination of the interior of the umbilical remnant and caudoventral abdomen is warranted in suspected urachal or umbilical abnormalities.[9] The bladder and other viscera may assume abnormal shape or position as a result of urachal adhesions. The luminal contents of the urachal remnant and bladder may appear flocculent in cases complicated by concurrent cystitis. Uroabdomen is characterized by accumulation of echolucent fluid in the abdominal cavity, with variable amounts of fibrin deposition evident.

Because of the variable nature of urachal problems, the differential diagnosis will vary according to the organ(s) involved. Urachal adhesions to the intestine or uterus may result in colic, signs of intestinal obstruction, and postpartum peritonitis or uroabdomen. Concurrent signs involving the lower urinary system might indicate the potential for primary ascending infections, such as cystitis or pyelonephritis. In cases of uroabdomen in males, obstructive urolithiasis is an important differential. Urolithiasis, urethritis, or neurologic disease may be included in differential diagnoses of dysuric animals. Nephritis of hematogenous origin is worthy of consideration in animals showing ill-thrift, colic, kyphosis, or abnormal urine.

Clinical Pathology Laboratory findings may be variable, but an inflammatory leukogram, hyperfibrinogenemia, and hyperglobulinemia are expected. Urinalysis may be normal or indicative of cystitis if the urinary bladder is involved. Abdominocentesis findings are variable and depend on the presence and extent of peritonitis associated with the urachal lesion. Voluminous blood-tinged abdominal fluid suggests uroperitoneum, and analysis of the fluid and serum creatinine concentration is indicated (see Urolithiasis section).

Pathogenesis Following bacterial infection of the urachus, the inflammatory response within the abdomen precipitates development of fibrinous adhesions between the urachus and surrounding viscera, including the rumen, intestine, uterus, bladder, or ovaries. Abscesses may form in single or multiple locations in the urachal stalk; although uncommon, abscesses involving the apex of the urinary bladder result in concurrent cystitis.[4,8] Urachal fibrosis and adhesions may serve as a means of mechanical interference of bladder emptying, resulting in secondary cystitis from chronic urine retention.[8] Infrequently, the urachal abscess perforates, with subsequent peritonitis, sepsis, or uroperitoneum.[3,4] Most urachal infections involve *Trueperella pyogenes* or *E. coli,* but other organisms may be present as well.[5,9,10]

Treatment and Prognosis Ventral midline celiotomy, paramedian celiotomy, or laparoscopy under general anesthesia is recommended to enable complete evaluation of the abdominal cavity.[11,12] Resection of the urachal remnants, with careful dissection of adhesions, is often required for complete resolution. Resection of the apex of the urinary bladder is necessary if the urachus incorporates or communicates with the bladder. Perioperative and postoperative antibiotic therapy is essential, and appropriate antibiotic selection should be based on culture and sensitivity of the abscess(es) or urine.

Outcomes of the surgical management are often satisfactory, but recurrence of adhesions should always be considered as a potential outcome. A guarded to poor prognosis is warranted for severe peritonitis or extensive adhesions. Without surgery, medical management with long-term antibacterial therapy would be expected to provide limited success, because the structural problems created by adhesions and abscesses are not directly addressed.

Urinary Bladder Eversion and Prolapse

Stacey R. Byers

Definition and Etiology Urinary bladder eversion or prolapse are uncommon events that occur during or shortly after parturition in cows.[1-5] With eversion, forceful straining moves the bladder fundus caudally, eventually turning the bladder inside out. The bladder is then forced out of the urethral orifice. Prolapse of the bladder is more frequently associated with dystocia.[1,2] In this condition a full-thickness tear of the vaginal wall occurs during delivery, allowing the bladder (and possibly other viscera) to be displaced from the abdominal cavity into the vagina.

Clinical Signs and Differential Diagnosis Cows with either eversion or prolapse of the bladder have a smooth, spherical mass within the vagina, usually protruding from the vulva. An affected cow may be alert and ambulatory, but if concurrent hypocalcemia, exhaustion, or peritonitis exists, the cow may be recumbent and depressed. Careful vaginal examination is required to differentiate these two conditions from each other and from vaginal prolapse, vaginal polyps, fat protrusion from a vaginal tear, vaginal neoplasia, fetal membranes, and uterine prolapse. Prevention of straining through epidural anesthesia is essential because expulsive efforts can cause herniation of viscera through the urethra (bladder eversion) or through the vaginal tear (bladder prolapse).[1] Epidural anesthesia also facilitates cleaning of the area, because straining may result in continual fecal contamination of the perineum and vestibule.

With a urinary bladder eversion, the mucosal surface of the bladder is exposed. The ureteral openings may be visible on its dorsal aspect, although these may be occluded and difficult to see if the wall of the bladder is edematous.[4] Vaginal palpation reveals that the protruding tissue originates from the urethral orifice. With time, constriction of the everted bladder by the narrow urethra may cause venous congestion, edema, thrombosis, and eventual necrosis.[1] Palpation and ultrasonographic examination are required for detection of herniation of other viscera through the urethral orifice and into the interior of the everted bladder. Strangulation of incarcerated bowel may occur.[2,3] Careful fine-needle aspiration of the interior of the eversion has been used to differentiate eversion from prolapse of the bladder. With bladder eversion, aspiration may yield peritoneal fluid, but laceration of herniated bowel is a concern.[1]

The serosal surface of the bladder is exposed with a urinary bladder prolapse. Careful palpation of the vagina reveals that the

VetBooks.ir

bladder protrudes from a full-thickness tear in the floor or lateral wall of the vagina. Other viscera may be present in the vagina as well. Fine-needle aspiration yields urine from the bladder lumen.

Treatment and Prognosis Manual reduction of an everted bladder may not be possible if it is edematous or if other viscera have herniated into its interior. The dorsal aspect of the urethra may be incised to widen the route through which the bladder is to be replaced.[1,2] Laparotomy is required for assessment of the viability of herniated bowel, and subtotal cystectomy may be performed if extensive bladder trauma or necrosis has occurred.[2] The viability of the involved structures is of primary concern for prognosis. Bladder paralysis and rupture are potential sequelae to ischemic damage that develops during eversion.[1] Cystitis and pyelonephritis may develop as well, and antibiotic therapy is warranted if repair is attempted. Animals with chronic conditions may develop hydroureter, hydronephrosis, and renal failure.[5]

A bladder prolapse can be resolved by first passing a flexible catheter into the urethra to remove urine from the bladder. This also confirms the diagnosis and facilitates bladder replacement. After catheterization and removal of urine, the bladder can be replaced into the abdominal cavity, and the vaginal tear can be sutured. Severe contamination of the peritoneal cavity may render attempts at treatment unjustified. Antibiotic therapy is indicated for surgical candidates.

Pelvic Entrapment of the Bladder

Stacey R. Byers

Definition and Etiology In pelvic entrapment of the bladder, the apex and fundus of the bladder are displaced caudodorsally into the pelvic cavity, resulting in impaired urine outflow. Occurrence has been associated with postpartum straining, perineal hernia, and vaginal prolapse.[1-3]

Clinical Signs and Differential Diagnoses Bladder emptying is impaired, and the presence of the bladder in the pelvic inlet induces straining. An affected cow or sheep may show tenesmus, pollakiuria, and stranguria. On rectal examination a soft, fluctuant mass may be detected beside the vagina.[1] In calves, radiography has been used to demonstrate the pelvic position of the bladder.[3] Ultrasonographic examination can also be a useful diagnostic tool.[2]

Differential diagnoses include proctitis, vaginitis, retained placenta, bladder paralysis, cystitis, and perivaginal abscess. Needle aspiration of the bladder per vaginum has been used to make a definitive diagnosis, although the danger of uterine puncture should be considered.

Treatment and Prognosis Draining the bladder through catheterization or needle aspiration facilitates replacement of the bladder by manipulation per vaginum. However, fibrinous adhesions between the bladder and vagina may make laparotomy necessary to replace the bladder.

Enzootic Hematuria

Stacey R. Byers

Definition and Etiology Enzootic hematuria is a disease of chronic or intermittent hematuria in cattle and small ruminants and is associated with chronic ingestion of bracken fern (*Pteridium aquilinum;* Fig. 34-21).[1] A different fern species, *Cheilanthes sieberi,* may induce this disease in Australian cattle.[2] Hemorrhagic cystitis is the initial consequence of exposure to the toxic compound(s) in the plant. With continued ingestion of bracken fern, cattle develop bladder neoplasms of epithelial, mesenchymal, or mixed origin. Bladder infection with bovine papillomavirus type 2 is involved in carcinogenesis.[1]

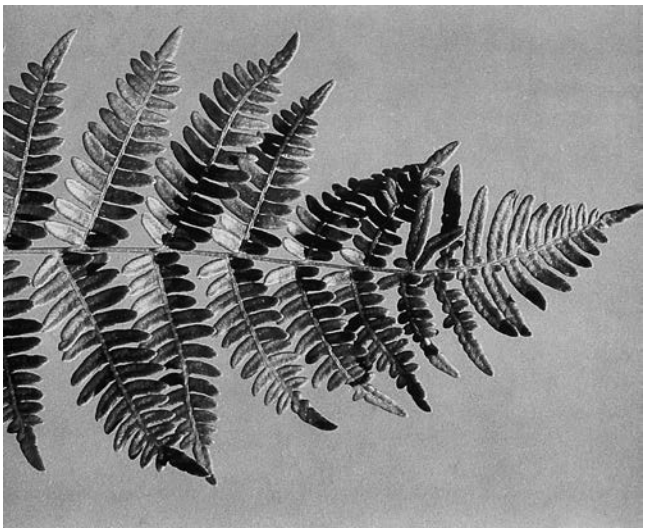

FIG. 34-21 Bracken fern *(Pteridium aquilinum).*

The syndrome of enzootic hematuria is quite different from acute bracken poisoning. Enzootic hematuria occurs after ingestion of large quantities of bracken fern (approximating the animal's body weight), usually over 1 to 3 months. Acute bracken poisoning manifests as an acute coagulopathy or fulminant septicemic crisis associated with severe bone marrow suppression. Acute bracken poisoning is further described in Chapter 54.

Clinical Signs and Differential Diagnoses Affected animals are typically in a group that is grazing a particular pasture or being fed a particular type or cutting of hay. Protracted, possibly intermittent, hematuria is the first clinical sign detected in most animals. Blood clots may be voided on occasion. Chronic blood loss eventually results in tachycardia, tachypnea, exercise intolerance, pale mucous membranes, and a decline in productivity and body condition. Bladder wall thickening and bladder tumors may be palpated per rectum. Proliferative changes or overt neoplasia of the bladder may cause dysuria, pollakiuria, and rarely, obstruction of the bladder trigone. Occasionally, blood clots may cause urethral obstruction. Depending on the magnitude and duration of bracken fern ingestion, hematuria may last for months to years before severe debilitation or death occurs. Ultrasonographic examination of the urinary bladder of affected animals may reveal bladder thickening and an irregularly shaped bladder wall. In an Indian study, affected cattle showed a bladder wall thickness of 4 to 5 mm (normal, 1 to 2 mm).[3]

Examination of serum for evidence of hemolysis and analysis of sediment from a freshly voided urine sample for intact RBCs allow for differentiation of hematuria from the hemoglobinuria found in hemolytic diseases. Icterus, also characteristic of ruminant hemolytic disorders, is not found in cases of enzootic hematuria. Hematuria may be evident in a UTI, but pyuria and bacteriuria are marked, and anemia, if present, is usually mild. Simultaneous involvement of several animals is uncommon with UTI but common in enzootic hematuria. Hematuria may also be evident in cattle affected by malignant catarrhal fever. Protracted, severe hematuria is rare in cases of urolithiasis, and anemia is also not expected. Without necropsy, a diagnosis of enzootic hematuria requires documentation of access to bracken fern in animals with characteristic clinical signs and laboratory data.

Clinical Pathology Severe anemia is often seen on hematologic examination of cattle and sheep with enzootic hematuria. Evidence of a regenerative response may not be present if bone marrow suppression is severe. The platelet, segmented neutrophil,

VetBooks.ir

and lymphocyte counts may be reduced. Urinalysis reveals hematuria, proteinuria, and variable pyuria.

Pathophysiology All parts of the plant are toxic to sheep and cattle. Several compounds in bracken fern possess irritant, mutagenic, immunosuppressive, or carcinogenic activities. These include ptaquiloside (aquilide A), quercetin, and α-ecdysone.[4-7] The carcinogenic principles are present in the milk of cows grazing bracken fern.[8] Bracken fern compounds may cause recrudescence of latent bovine papillomavirus 2 (BPV-2) infections through immunosuppression. Mutagenic compounds in bracken fern interact with BPV-2 in bladder infections to induce local neoplasia.[1,2] Growth of the resultant neoplastic tissue may be enhanced by further exposure to mutagenic bracken fern compounds.

In multiple species, cyclooxygenase-2 (COX-2) is overexpressed in epithelial neoplasms, including those of the urinary bladder origin. Certain types of tumors of urinary epithelium may co-express COX-1 and COX-2. Bladder carcinomas from cows with enzootic hematuria have been shown to express both COX-1 and COX-2 at a high level relative to normal controls when evaluated by immunohistochemical methods.[9] The efficacy of COX-2 inhibitor drugs on cancer prevention or treatment in cattle at risk for bladder tumors remains to be investigated.

Epidemiology Enzootic hematuria has a wide geographic distribution, with cases reported in North and South America, the United Kingdom, Australia, and several European countries. Bracken fern is found in all areas of the United States except the Great Plains, with most livestock poisonings occurring in the Pacific Northwest and upper Midwest. The plant grows best in well-drained, fertile soils and is often localized in open areas of forests. Sheep and cattle are poisoned by grazing the plant or consuming contaminated hay.

Enzootic hematuria is primarily seen in adult sheep and cattle. Cattle grazing infested pastures may develop hematuria by 2 to 3 years of age. Papillomas of the bladder have occurred as early as 1 year after bracken feeding begins, with invasive carcinomas arising 2 to 6 years later. Within endemic areas, up to 90% of adult cattle may be affected.[10]

Necropsy Findings Tissue pallor from anemia is often appreciated. The bladder wall is thickened and the mucosa hemorrhagic and ulcerated. Microscopic examination of the bladder wall reveals capillary engorgement, intramural hemorrhage, and metaplasia of the bladder epithelium. Several types of bladder tumors and mixed-origin neoplasms may be present. Metastasis of epithelial neoplasms to the regional lymph nodes or other organs can occur.[10]

Treatment and Prevention Treatment of enzootic hematuria is limited to reduction or elimination of bracken fern in the diet. Wooded areas that support growth of bracken fern can be fenced off, and forage improvement may help limit incorporation of the plant into hay. If such measures are not feasible, a program of early culling may help prevent low productivity from anemia and neoplasia. Hematuria will cease if bracken feeding is discontinued before the onset of tumor formation.

Urinary Tract Infection

Brandon J. Dominguez

UTIs in ruminants typically present as cystitis, ureteritis, and pyelonephritis from ascending infection with *C. renale* or *E. coli*.[1] Other coliform species[2] and other close relatives of *C. renale* may be involved with lesser frequency.[3] Less commonly, *Salmonella* spp., *T. pyogenes, P. aeruginosa, Streptococcus* spp., and *Staphylococcus* spp., among others, have been implicated in renal infections of hematogenous origin (suppurative embolic nephritis).[4,5] In small ruminants, *Corynebacterium pseudotuberculosis* has been cultured from renal infections.[6]

Clinical Signs Cystitis is suggested clinically by dysuria and pollakiuria; hematuria and pyuria may not be grossly apparent. Affected cattle may dribble urine, tread their feet, swish their tail, or retain an arched stance after voiding. Occasionally, blood, purulent debris, or urinary crystals may be found on the ventral commissure of the vulva.[1] The bladder may be thickened and painful on rectal palpation, and on cystoscopy, catarrhal, hemorrhagic, fibrinous-purulent, and fibrinous-hemorrhagic lesions may be observed.[7] Generalized signs of malaise are not seen if infection is limited to the bladder.[1]

Acute cases of pyelonephritis are often presented with a history of sudden reductions in feed intake and milk production. Fever, increased heart rate, increased respiratory rate, decreased skin turgor, enophthalmos, ruminal stasis, scleral injection, and occasional episodes of mild colic may be noticed in addition to signs of cystitis.[1] When the left kidney is involved, renal enlargement, pain, and loss of the normal lobulation may be noted on rectal palpation. Affected calves may dribble urine, resulting in phosphate calculi present on the vulvar hairs. This may be accompanied by wet hair on the perineum and hind legs, progressing to excoriations due to urine scald.

Evaluation of the right kidney can be accomplished via ultrasound (see ultrasound images of urinary tract in ruminant section of Chapter 32) with a 5.0-MHz or lower frequency transducer in the 12th intercostal space and right paralumbar fossa.[8,9,10] In small or thin cattle, the left kidney may be visible in the left paralumbar fossa on transcutaneous ultrasound. Alternatively, the left kidney can be assessed with a 5.0-MHz or higher transducer via the rectum. Renal enlargement, abnormal kidney shape, dilated renal calyces, and flocculent echogenic material in the renal pelvis and ureter are suggestive of pyelonephritis.[8,9,10] The ureters may be palpated per vaginum, with the examiner using his or her fingers to detect one or both enlarged painful ureters adjacent to the ventral vaginal wall.[1]

Chronic pyelonephritis presents with vague signs.[1] Weight loss, muscle wasting, poor growth, anorexia, diarrhea, and reduced milk production may be evident from history. No abnormal behavior or posturing during urination may be noted. Pale mucous membranes (due to anemia) may be noted during physical exam. A loss of lobulation on the left kidney may be evident on rectal palpation; pain and enlargement may not be noted.[1] Cystic lesions may be noted ultrasonographically in chronic renal disease.[10]

Differential Diagnosis Mild colic may be a symptom of numerous GI or intraabdominal disorders, and urinalysis findings will be normal. Dysuria may be the result of vaginitis, perivaginal abscess, pelvic entrapment of the bladder, vulvar trauma, or postparturient swelling of the vagina and vulva. Urolithiasis can cause dysuria and hematuria, but males are typically affected, whereas females are predisposed to UTI. On palpation, bladder distention will be evident in cases of urolithiasis, a finding not expected with UTI. A careful neurologic exam will help determine whether there is underlying bladder paresis or incomplete voiding from neurologic diseases. Hematuria may be due to bleeding from parturition, papillomas in the urinary tract, postparturient hemoglobinuria, or enzootic hematuria. In cases of enzootic hematuria, multiple animals are typically affected, and presence of bracken fern can be demonstrated. Additionally, a profound anemia is expected with enzootic hematuria, and if pyuria or bacteriuria is present, it will be mild. Papilloma of the bladder may be ruled out with cystoscopy.

Clinical Pathology A neutrophilic leukocytosis with hyperfibrinemia is expected in cases of pyelonephritis. If the duration of the infection has been several days, a hyperglobinemia will develop. Continued severe proteinuria, resulting in hypoalbuminemia, can lead to diarrhea because of decreased plasma oncotic pressure. As the chronicity of the disease lengthens, anemia may develop. This may be due in part to the decreased production of erythropoietin in the affected renal tissue and from blood loss through urination.[1] Measurement of serum BUN and creatinine is critical for prognosis in cases of

VetBooks.ir

pyelonephritis.[7,11] When azotemia and isosthenuria are combined in cases of pyelonephritis, bilateral kidney involvement is indicated, and the prognosis for successful treatment is poor.[1] Prerenal causes should be considered when evaluating the severity of azotemia.

Urinalysis is necessary for definitive diagnosis of UTI. A midstream or endstream caught sample should provide the most accurate results as contaminants in the distal urogenital tract are purged. Concomitant metritis, vaginitis, or prostatitis may contaminate urine with blood, bacteria, and inflammatory cells. Hematuria, proteinuria, and bacteria should be present in the urine of a UTI-afflicted cow. Specific gravity may be in the range of 1.005 to 1.020.[10] A Gram stain of the urine may yield preliminary identification of the causative organism.

Pathophysiology Initiation of an ascending infection is dependent on the amount and virulence of bacteria introduced into the urinary tract. Urogenital trauma during calving or obstetric manipulation, abnormal vulvar confirmation, conditions leading to urine retention, and bladder catheterization may provide routes of introduction for pathogens. Impaired bladder emptying due to bladder adhesions, urachal remnant infection, or diseases of the spinal cord may create an environment for the establishment of cystitis and ascending infection. Urethral trauma from catheterization, urolithiasis, breeding, or urogenital papilloma may be adequate to initiate infection.[12] Vesiculoureteral reflux due to decreased bladder contractility or ectopic ureters may occur, aiding in the expansion of infection up the urinary tract. Ureteral and renal obstruction due to inflammatory debris, hemorrhage, and fibrin deposition may lead to episodic signs of colic. After pyelonephritis is established, necrosis of papillary and tubular epithelium leads to an accumulation of necrotic debris in the renal pelvis, loss of functional nephrons, abscessation, fibrosis, and distortion of the renal shape. Struvite uroliths and other renal calculi may develop when necrotic debris serve as foci of crystal deposition in the alkaline microenvironment created by bacterial urease activity.[4]

C. renale is a large, pleomorphic, non-motile, gram-positive bacillus.[3] It is grouped with and closely related to two other *Corynebacterium* that may cause pyelonephritis, *C. cystitidis* and *C. pilosum*.[5] *C. renale* pyelonephritis has been documented in a sheep[12] and induced experimentally in goats.[13] Evidence suggests that *C. renale* may be maintained in the environment for several weeks.[3] The bacterium may be transmitted by direct vulvar contact between cows or by splashing of urine from infected cows. Iatrogenic transmission may occur via contaminated obstetrical instruments or urinary catheters. Bulls may spread *C. cystitidis* and *C. renale* through sexual contact.[14] *C. renale* adhere to the urinary tract epithelium via pH-mediated pili.[15] Adherence is enhanced in alkaline conditions and reduced in acidic conditions.[16] This pH influence may explain the improvement in clinical signs realized after the feeding of urine-acidifying salts. The organism uses ureolysis and ammonium production to maintain urine alkalinity and promote colonization of the epithelium. A serum antibody response will develop after renal infection. This humoral response is rarely curative, nor does it provide resistance to reinfection.[1]

E. coli, among other coliforms, is frequently implicated in ruminant UTI.[1] The serotype(s) and virulence factors of *E. coli* specifically involved in bovine pyelonephritis are unknown at this time. Because of the ubiquitous nature of this gram-negative coliform, it is thought that infection originates from fecal contamination or a loss of natural defenses in the urogenital tract.

Epidemiology On-farm prevalence of pyelonephritis varied from 0.3% to 2.7% in an Israeli study.[11] Female animals have a greater potential for infection owing to a shorter urethra in addition to potential contamination and trauma during parturition and breeding. A majority of pyelonephritis cases develop within 90 days post calving, which suggests that the postpartum period is a significant risk period in the development of infection.[4] Reproductive tract abnormalities such as pneumovagina, metritis, and poor perineal conformation were identified in 7 out of 15 cows diagnosed with pyelonephritis.[1]

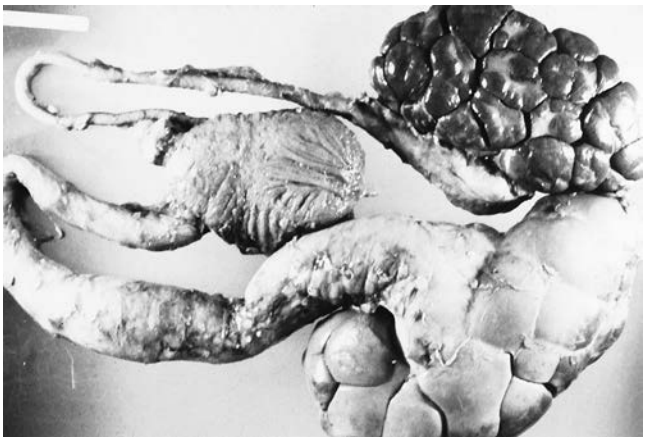

FIG. 34-22 Postmortem specimen of unilateral pyelonephritis and ureteritis in a cow. The affected kidney and ureter are greatly enlarged.

C. renale has typically been regarded as the most common pathogen in bovine pyelonephritis.[2,10] In some studies, *E. coli* has been found as the more prevalent bacteria in pyelonephritis cases.[4,5,17] *C. renale* and *C. pilosum* have been found in healthy cows, whereas *C. cystitidis* is considered the most virulent pathogen in the *C. renale* group.[5] Once established, *C. renale* can be difficult to eradicate on a herd level.

Necropsy Findings The bladder will have evidence of hemorrhage, ulceration, and fibrin deposition on the epithelial surface, which may extend through the urethra. Polypoid growths may develop with chronic infection. As these resemble tumors, histopathologic examination is necessary for definitive diagnosis.[2] Ureters may be noticeably enlarged on one or both sides and full of purulent debris. Acute to subacute pyelonephritis cases may show gross enlargement of the affected kidney(s). A viscous gray, odorless exudate may be found in the renal pelvis and extend into the medulla and cortex, especially on sagittal section. A Gram stain of the exudate is helpful for differentiation of the cause. Chronic cases of pyelonephritis may have gross distortion of renal size and shape due to abscesses (Fig. 34-22).

Treatment and Prognosis Aggressive and long-term antibiotics are required for successful treatment of UTI. Prolonged antibiotic therapy is often required. Diuresis with oral or parenteral fluid therapy is beneficial in facilitating the removal of necrotic debris and bacteria from the urinary tract.[1] Nephrectomy in cases of unilateral pyelonephritis that are unresponsive to medical therapy is an option.[10] Studies have indicated that there is no apparent limitation on growth and production following unilateral nephrectomy if the remaining kidney is normal and healthy.[18]

Penicillin is typically the first choice treatment of *C. renale* and *E. coli* infection. Twice daily IM administration of procaine penicillin G (22,000 to 44,000 IU/kg) or ampicillin trihydrate (11 mg/kg) is effective.[1] Higher serum and urinary concentrations may be attained with IV administration of sodium or potassium penicillin (22,000 to 44,000 IU/kg q6h) or sodium ampicillin (10 to 50 mg/kg q8h). Cows with coliform UTI should be continually monitored for appetite, attitude, pyrexia, and reagent-strip urinalysis. If there is no improvement within 96 hours of treatment, therapy should be modified.[1] Gentamicin (2.2 mg/kg IM bid),[1] trimethoprim-sulfadiazine (15 mg/kg IV once daily),[2] or ceftiofur (3 mg/kg IV bid)[19] have been used to treat refractory coliform UTI. The nephrotoxicity of gentamicin is an important consideration.[1] Current U.S. regulations limit the use of ceftiofur in food-producing animals to label dosage, routes, and frequencies.[20] Meat and milk withdrawal times must be extended appropriately after prolonged and extralabel dosages of any antibiotic.

VetBooks.ir

Urinalysis and urine culture should be assessed 1 week after therapy is discontinued to confirm resolution.

Treatment is more likely to be successful the earlier it is initiated in the course of disease. Case fatality and nonvoluntary cull rates due to pyelonephritis in dairy cattle have been reported between 18%[1] and 47%[4] for treated cases. Recrudescence rates have been reported at 9.4%.[11] Cystitis alone yields a better prognosis than concurrent ureteritis or pyelonephritis, especially if bilateral disease is evident. Cows with marked azotemia noted by a BUN above 100 mg/dL and/or a creatinine above 1.5 mg/dL and pyelonephritis were at much greater risk of culling than nonazotemic cows with pyelonephritis.[11]

Prevention and Control Isolation of diseased animals, particularly with *C. renale,* is recommended to limit the spread of the organism. Cleaning and disinfection of contaminated areas is advisable. Aseptic technique during urogenital and obstetric procedures can limit iatrogenic transmission. Venereal transmission is difficult to control in herds with natural service and subclinically infected bulls. Artificial insemination or mass treatment programs could be introduced in herds with increased problems due to UTI.

Amyloidosis

David C. Van Metre

Amyloidosis is caused by deposition of insoluble fibrillar protein in various organs.[1] Amyloid may generate from a variety of normal or abnormal precursor proteins. Amyloid develops when these precursor proteins become abnormally folded. Misfolded proteins are normally degraded intracellularly by proteasomes or by macrophages in the extracellular space; this regulatory mechanism fails to occur in amyloidosis. Amyloid molecules tend to aggregate together into β-pleated sheets that are highly resistant to degradation. As a result, amyloid gradually collects in tissues, eventually resulting in dysfunction of the parent organ. In animals, the kidney, spleen, and liver are most commonly affected.[1]

Renal amyloidosis in cattle is an uncommon chronic wasting disease marked by chronic diarrhea and sustained heavy proteinuria.[2-6] It occurs secondary to long-standing inflammatory diseases such as traumatic reticuloperitonitis and metritis. Amyloid deposition in the kidney disrupts the normal glomerular structure, resulting in a protein-losing nephropathy. In a study sample population of 82 cattle with chronic bacterial infections, renal amyloidosis was identified in 5 animals (6%).[4]

Clinical Signs The most common clinical signs of bovine renal amyloidosis include chronic diarrhea, weight loss, generalized edema, and poor productivity in mature animals.[2-6] Reduction in appetite, lethargy, and other signs may reflect the underlying inflammatory disease. Enlargement of the left kidney may be palpated during rectal examination. The enlarged kidney is not painful and maintains its normal lobulation. Because of its abnormally high protein content, urine may form a stable foam after hitting the ground or being shaken in a container.

Clinical Pathology Cattle with renal amyloidosis consistently develop marked proteinuria and hypoalbuminemia.[2-6] Hyperfibrinogenemia and/or hyperglobulinemia may be present, and other inflammatory changes may be apparent on the hemogram. Serum creatinine and BUN levels may be elevated if renal damage is advanced. Amyloidosis would be supported by finding persistent heavy proteinuria in the absence of RBCs, WBCs, or bacteria in the urine sediment. Importantly, one would expect a positive reaction for protein on urine dipstick when the urine is alkaline (as it often is in ruminants), so more specific tests for protein (e.g., sulfosalicylic acid precipitation test) should be used to confirm the presence of true proteinuria. Polarized light microscopy and electron microscopy have been used to examine urine sediment for the presence of amyloid protein in urine.[5]

Differential Diagnosis Amyloidosis must be differentiated from other diseases causing chronic diarrhea, hypoproteinemia, weight loss, and poor productivity. Diseases to consider include Johne's disease, copper deficiency, salmonellosis, bovine viral diarrhea, GI parasitism, liver fluke infestation, bovine leukosis virus infection, and GN. GN is the only other differential diagnosis wherein persistent proteinuria is an expected feature. Renal biopsy can be performed to differentiate GN from amyloidosis in the live animal.

Pathophysiology Light-chain (AL) amyloidosis is associated with immune cell dyscrasias (e.g., plasmacytoma, multiple myeloma) and is quite rare in domestic animals.[1] Amyloidosis of cattle is classified as the reactive (AA) type,[2-6] which is frequently associated with chronic inflammatory disease in domestic animals and humans.[1,7,8] Concurrent inflammatory disease—traumatic reticuloperitonitis, pneumonia, mastitis, and metritis—have been found in some but not all cattle with amyloidosis.[2-6] Serum amyloid A protein (SAA) is an acute-phase protein that is synthesized in the liver and is a precursor of amyloid A (AA) fibril in tissues[1,7,8]; SAA concentrations increase in cattle with inflammatory disease.[4] Amyloid deposition in this population may be due to abnormal catabolism of SAA or an inherent structural abnormality in SAA that renders it prone to misfolding and deposition as amyloid in organs.[1,7,8] AA fibrils are resistant to proteolysis, allowing for their accumulation in tissues over time. Accumulation of amyloid in the glomerulus alters glomerular filtration and enables sustained albuminuria and a gradual loss of plasma oncotic pressure. Diarrhea develops as a result of gut wall edema or amyloid deposition in the GI tract.[3] The resulting clinical picture resembles the nephrotic syndrome of humans: massive proteinuria, hypoalbuminemia, and generalized edema.[7] Renal or pulmonary thrombosis may develop secondary to loss of low-molecular-weight anticoagulant proteins through the compromised kidney.[9]

Necropsy Findings Renal enlargement with yellow-tan to white discoloration is frequently present. A waxy quality of the renal parenchyma may be appreciated on the cut surface of the kidney.[2] Generalized edema resulting from hypoalbuminemia may be present. Some animals will have renal or pulmonary thrombosis.[3] Primary inflammatory disease is expected to be found in other sites.

Histologic examination of the kidney may reveal amyloid deposition in the glomerulus, interstitium, and tubule lumen. Congo red staining is typically used to demonstrate amyloid; under normal light, stained amyloid appears pink, whereas under polarized light, stained amyloid displays a bright green birefringence.[1,7,8]

Prognosis The prognosis for affected cattle is poor. The resilient nature of the amyloid protein generally results in its persistence in tissues, even if the underlying cause of inflammatory disease is successfully treated.[7] Specific treatment for amyloidosis has not been reported in cattle.

Glomerulonephritis

David C. Van Metre

GN is a rare clinical disorder of ruminants that may result from deposition of antigen-antibody complexes in the glomerulus or binding of antibody to intrinsic or foreign antigens localized to the glomerulus. Immune system targeting of glomerular tissues leads to glomerular injury. Nonimmune mechanisms may be involved in certain forms of the disease.

Clinical Signs Cattle with GN may have a history of weight loss, poor productivity, and chronic diarrhea.[1,2] Lethargy and generalized edema may be detected on physical examination. Rectal palpation may reveal a mildly enlarged but nonpainful left kidney.[2] GN

VetBooks.ir

may be clinically occult in cattle acutely[3] or persistently infected with bovine viral diarrhea (BVD) virus[4] and in cattle with fascioliasis.[5] GN has been associated with pregnancy toxemia in ewes[6]; affected animals tend to show clinical signs typical of pregnancy toxemia (see Chapter 33).

Mesangiocapillary GN has been described in Finnish Landrace lambs of specific lineage in Scotland and Canada.[7] The disease is heritable, but the exact mode of inheritance remains unknown. Clinical signs of this disease begin within hours after birth to 3 months of age. Affected lambs may be dull, ataxic, and appear blind. Fine muscle tremors, colic, and convulsions may also be seen.

Differential Diagnosis The differential diagnosis for cattle with GN is similar to that for amyloidosis (see preceding section).

Clinical Pathology Heavy proteinuria, mild anemia, and hypoalbuminemia have been reported in cattle with GN.[1,2] Granular casts, RBCs, and leukocytes were found in the urine sediment of one affected cow.[1] Azotemia, proteinuria, and ketonuria are found in ewes with GN associated with pregnancy toxemia.[6] Mesangiocapillary GN in Finnish Landrace lambs is characterized by uremia, hypoalbuminemia, proteinuria, hypocalcemia, and hyperphosphatemia.[7]

Pathophysiology In humans, GN may result from a variety of infectious, toxic, or autoimmune disorders, all of which induce eventual immunologic injury to the glomerulus.[8] Antibodies may be directed against host or foreign antigens located in the vascular endothelium, mesangial cells, or basement membrane. In addition, circulating immune complexes may deposit in the glomerulus. The ultimate consequences are activation of complement and chemotaxis of leukocytes, both of which result in glomerular injury and increased glomerular permeability.[8]

Passage of plasma albumin through the damaged glomerulus results in chronic albuminuria, eventually leading to reduced plasma oncotic pressure and generalized edema. Urine losses of the anticoagulant protein antithrombin III may result in a hypercoagulable state.[9]

Immunohistochemical data suggest involvement of immune-mediated mechanisms for spontaneous GN in cattle[1,2] and sheep,[7] GN associated with persistent BVD infection[4] and fascioliasis in cattle,[5] and mesangiocapillary GN of Finnish Landrace lambs.[7] Galav and colleagues demonstrated glomerulonephritis in calves experimentally infected with an Indian BVD 1b isolate; viral antigen was detected in affected glomeruli, but immune complexes were not, indicating that certain strains of this virus may incite direct glomerular injury.[3] Notably, glomerulonephritis may also be an incidental histologic finding in animals with acute septic disease.[7]

The clinical and histopathologic characteristics of GN of pregnancy toxemia in ewes resemble those of the preeclampsia syndrome of women.[6] Enlarged glomeruli with reduced blood content in glomerular capillaries are found throughout the renal cortex of affected ewes. The renal lesion in preeclamptic women may result from endothelial injury during DIC or an excessive glomerular vasomotor response to angiotensin.[10] The lesion can be reversible in women, but the consequences of this condition in ewes have not been described.

Treatment and Prognosis Treatment of GN in ruminants has not been described. Because most cases of GN are advanced at diagnosis, the prognosis is poor. Mesangiocapillary GN in Finnish Landrace sheep is not invariably lethal, and some affected lambs may survive into adulthood.[6]

Congenital Defects

David C. Van Metre

Most severe urinary tract congenital defects of ruminants manifest at an early age, but they occasionally remain clinically occult until adulthood[1] and should be considered in the differential diagnosis for a young animal with renal disease or abnormal urination. However, tubular necrosis caused by severe volume depletion, nephrotoxins, and infectious diseases is much more common. If a congenital defect of the urinary tract is identified, careful examination of other body systems should be performed; 73% of lambs with urogenital defects were found to have one or more defects in other organ systems.[2]

Renal Defects

Renal cysts are considered a common bovine renal defect[3] and have been described in sheep[2] and a goat.[4] These fluid-filled cavities in the renal parenchyma are usually of no clinical significance unless they are large or numerous (polycystic kidneys).[1,3] *Renal agenesis* was found to be the most common renal defect in lambs, with hydronephrosis and renal dysgenesis occurring less frequently.[2] A retroperitoneal perirenal *pseudocyst* (a fluid sac lacking an epithelial layer) has been reported in a ram with acute abdominal pain.[5] Pseudocysts typically develop as outpocketings of the renal capsule and can develop as a result of renal trauma, urinary tract obstruction, or vascular or lymphatic anomalies.

Renal oxalosis is a metabolic disease that is suspected to have an inherited basis; it has been reported in Beefmaster calves.[6] The calves show weakness, lethargy, and anorexia within days to several weeks of age. Dehydration, diarrhea, and alopecia over the head, neck, and extremities may also be seen. Evidence of renal failure is found on serum chemistry analysis. An inherited abnormality of glycine or glyoxylate metabolism may generate high levels of endogenous oxalate, which readily complexes with calcium. As a result, calcium oxalate crystals accumulate in the renal tubules, obstructing outflow of the tubular filtrate. Exposure to oxalate-containing plants and ethylene glycol must be ruled out in all cases of renal oxalosis.

Ectopic Ureter

Ectopic ureter is a rare congenital defect in which one or both ureters terminate in an abnormal location. An ectopic ureter may terminate in the urethra, vagina, or cervix or caudal to the bladder trigone in females. In males the ectopic ureter usually terminates in the urethra, vas deferens, or seminal vesicles. Urinary incontinence is the most common presenting complaint for affected animals.[7] Urine dribbling results in scalding of the perineum and medial surfaces of the hindlimb in heifers, and scalding in males is usually located on the prepuce and ventral abdomen. Occasional episodes of normal micturition may be seen. UTI, polycystic kidney(s), and hydronephrosis may exist concurrent to ectopic ureter(s).

Definitive diagnosis requires IV contrast urography or endoscopic examination of the urinary tract. Options for surgical correction include transposition of the ectopic ureter(s) or, in the case of unilateral involvement, ipsilateral nephrectomy. The latter option is valid only if the contralateral kidney is functional, as determined by blood chemistry, and structurally normal or near normal, as determined by ultrasonography or IV pyelography. Breeding affected animals should be discouraged.

Neoplasia

David C. Van Metre

Other than those associated with ingestion of bracken fern, primary neoplasms of the urinary tract of ruminants are rare. In a North American abattoir survey, primary tumors of the bladder were detected in 0.05% of more than 21,000 cattle examined, with cases of papillomas, adenomas, and transitional cell carcinomas identified in the sample population.[1] Tumors of the genitalia, typically fibropapillomas and squamous cell carcinomas,[2] may impinge upon urine egress from the urethra. In does, ectopic mammary tissue located in the subcutaneous tissue of the vulva can cause vulvar swelling during lactation; this may be misinterpreted as neoplasia.[2]

Renal carcinoma has been described in cattle,[3-5] and nephroblastoma has been documented in a ewe and an aborted lamb.[5] Urinary

tract involvement may be seen in occasional cases of lymphosarcoma in ruminants.[2,6]

Hemolytic Uremic Syndrome

David G. Renter

Hemolytic uremic syndrome (HUS) is a thrombotic microangiopathy (TM) disorder characterized clinically by microangiopathic hemolytic anemia, thrombocytopenia, and in many cases renal failure. HUS is characterized morphologically by thrombotic lesions in capillaries and arterioles in tissues, including those of the kidney.[1] The presence of schistocytes (fragmented red cells) in peripheral blood is considered an important diagnostic indicator of TM,[1] but an apparent lack of schistocytes in peripheral blood has been reported in both human[2] and equine[3] cases of HUS. Unlike DIC, TM disorders are generally associated with normal coagulation times and normal to slightly elevated fibrin split products.[1] TM disorders can be classified as typical HUS, atypical HUS, and thrombotic thrombocytopenic purpura.[1] Reports of HUS are rare in the large animal veterinary literature and more common in human medicine.

The typical form of HUS in humans is associated with consumption of food or water contaminated with Shiga toxin–producing bacteria, whereas atypical HUS is associated with inherited mutations of complement-regulatory proteins and diverse causes of endothelial injury, including antiphospholipid antibodies, complications of pregnancy and contraceptives, vascular renal diseases like systemic sclerosis and malignant hypertension, use of chemotherapeutic and immunosuppressive drugs, and radiation.[1] Typical HUS is a major cause of ARF in young children and infants, and the majority of the cases occur after intestinal infection with Shiga toxin–producing enterohemorrhagic *E. coli* (EHEC).[1,4] *E. coli* O157:H7 is the predominant causative serotype of EHEC in human cases of HUS, but many other EHEC serotypes have also caused the syndrome.[4] Although literature on HUS in large animals is limited, case reports on four horses[3,5,6] and two cows[7,8] have demonstrated clinical syndromes and pathologic lesions consistent with HUS in humans.

Clinical Findings Horses with clinical signs indicative of HUS have exhibited fever, lethargy, diarrhea, hematuria, hemoglobinuria, azotemia, oliguria, and ventral edema.[3,5,6] Hematologic findings in three cases included leukocytosis, anemia, and evidence of hemolysis.[5,6] The blood smear of one of the four equine cases of apparent HUS revealed the presence of poikilocytes and schistocytes.[3,5,6] All four horses with evidence suggestive of HUS were euthanized following unsuccessful treatment with fluid therapy and diuretics.[3,5,6]

In a postparturient mare ultimately diagnosed with HUS, there was initial clinical and laboratory evidence of endotoxemia and endometritis.[3] However, after clinical signs of endotoxemia subsided, stanguria, hematuria, hemoglobinuria, tubular casts, thrombocytopenia, hyperfibrinogenemia, azotemia, and a left shift in the leukogram were noted.[3] Her foal was apparently healthy at birth but subsequently developed progressive CNS signs culminating in refractory seizures.[3] Although a direct causal relationship was not established, *E. coli* O103:H2 was recovered from the GI contents of both the mare and foal, as well as from the mare's uterus. In humans, serotype O103:H2 is one of the more common non-O157 EHECs.[4]

A reported fatal postparturient HUS case in a heifer was demonstrated by severe progressive anuric renal failure, acute hemolytic anemia, and consumptive thrombocytopenia.[8] A 6-year-old cow that had evidence of metritis 1 month after parturition was a suspected HUS case, based on clinical and laboratory findings including anemia, hemolysis, thrombocytopenia, azotemia, and a tendency to bleed.[7]

In humans, HUS can present suddenly as generalized hemorrhagic diathesis (especially hematemesis and melena), pallor, severe oligoanuria, hematuria, edema, microangiopathic hemolytic anemia, and on occasion seizures or other prominent neurologic changes.[1,9] In prodromal human cases, HUS develops an average of 1 week after the onset of diarrhea.[9] The classic clinical presentation of typical HUS in people includes the triad of ARF, thrombocytopenia, and hemolytic anemia.[1] Treatment in this acute phase of HUS primarily involves supportive care; there is limited evidence for more specific therapies, and some treatments may be detrimental.[9,10,11] At this writing, conflicting data exist in the published literature regarding the efficacy or potential for harm imparted by certain antimicrobials used to treat HUS. For example, in vitro research indicates that fluoroquinolone administration may result in increased Shiga toxin production by certain strains of causative bacteria,[11] so avoiding use of this drug in cases of suspected HUS is likely prudent. New therapeutic strategies, including those aimed at binding or neutralizing Shiga toxins, have shown promising results in animal models for human disease.[11] Supportive therapy that includes fluid and electrolyte replacement, plasma therapy, and dialysis can be critically important at the acute stage of HUS. Approximately one third of those surviving the acute phase are at risk for chronic sequelae.[10] Although diabetes, intestinal strictures, myocardial infarction, and motor, sensory, or intellectual deficits and other sequelae can occur, chronic renal lesions leading to end-stage renal disease is more common.[10]

Pathophysiology and Necropsy Findings Two processes appear to dominate the pathogenesis of TM and ultimately cause vascular obstruction and vasoconstriction resulting in organ ischemia: (1) endothelial injury and activation, leading to intravascular thrombosis, and (2) platelet aggregation.[1] In humans, endothelial injury appears to be the primary cause of HUS, and HUS is the most common life-threatening complication of hemorrhagic colitis from EHEC infection.[1,4] EHEC produces exotoxins Shiga toxin 1 and Shiga toxin 2, also referred to as *verotoxin 1* and *verotoxin 2*. Shiga toxins are considered a necessary but insufficient cause of typical HUS, because other bacterial and host factors are important for disease progression.[4,12] Many serotypes of *E. coli* (as well as *Shigella* and other Enterobacteriaceae) can carry Shiga toxin genes and are capable of causing disease, yet certain EHEC serotypes (e.g., O157:H7) are more common human pathogens.[4] EHECs are considered noninvasive but attach to the intestinal mucosa and produce characteristic attaching and effacing lesions seen histologically.[1,4,12] Microvascular endothelium is the major target of Shiga toxins, which are released from the bacteria in the intestine and absorbed across the gut epithelium, where they access the systemic circulation and are transported to small vessel endothelial cells.[4,12] The toxins bind to specific glycolipid receptors on the surface of vascular endothelial cells, are internalized by endocytosis, and may injure the cell through inhibition of protein synthesis, stimulation of prothrombotic messages, or induction of apoptosis.[4,12] Exposure of subendothelial collagen followed by activation of the coagulation cascade may result in thrombosis of small vessels in the kidney and other organs. Acute oliguric or anuric renal failure can result from fibrin/platelet thrombi in renal vessels and glomeruli, fibrinoid necrosis of vessel walls, congestion of glomeruli, and tubular ischemia.[1,12]

Cattle feces are considered to be a major source of EHEC, but these bacteria have been isolated from the feces of many other asymptomatic species, including other livestock and humans.[12,13] Although EHECs do not generally cause illness in cattle, they do colonize their large intestine.[13] It is generally believed that the lack of specific glycolipid receptors for Shiga toxins is the reason cattle typically do not develop severe colitis or HUS, despite the common presence of EHEC in their gastrointestinal tracts.[13] Humans are generally infected with EHEC via consumption of food and water contaminated by feces. However, the small infectious dose makes direct contact with EHEC-positive animals (e.g., at petting zoos) and person-to-person transmission also a concern.[12,13]

In four of the large animal cases reported with HUS, the inciting cause was uncertain and isolation of EHEC or other Shiga toxin–producing organisms was not attempted.[5,6,8] One heifer had a necrotizing endometritis, but during postmortem examination of three horses, no focus of infection was identified.[5,6,8] Renomegaly, renal

VetBooks.ir

VetBooks.ir

infarcts, and scattered petechial and ecchymotic hemorrhages within the renal parenchyma were apparent on gross necropsy. Acute tubular necrosis and fibrin thrombi within the glomerular capillaries were evident on histologic examination.[5,6,8]

In another equine case report, an EHEC serotype O103:H2 carrying a Shiga toxin gene was recovered from both the mare and foal, but direct Shiga toxin assays were not performed.[4] While the causal significance of this finding is unclear, the unusual and concurrent disease progression in both animals may suggest a common etiology. Except for lack of evidence of microangiopathic hemolysis on a blood smear, the mare had clinical and postmortem signs consistent with HUS.[4] Significant renal pathology included evidence for plasma protein and hemoglobin in both cortical and medullary tubules, with occasional epithelial necrosis. In addition, renal capillary lumina were apparently obscured by fibrin, and only remnants of glomerular capillary endothelial cell cytoplasm were evident. Evidence of numerous platelets within the glomerular capillaries and their adherence to exposed basement membranes were apparent, as were other pathologic changes.[4] The foal's brain had evidence of widened perivascular spaces, with apparent perivascular plasma protein accumulations in the corpus striatum and thalamus.[4]

Although the etiology is often undetermined in large animal cases of apparent HUS, the clinical signs and pathologic lesions reported are compatible with a diagnosis of HUS. It may be notable that three of six reported cases occurred postpartum. Based on the HUS reports in large animals, it appears there may be features comparable to the disease syndrome in humans.

Tubular Necrosis

Meredyth L. Jones

Tubular necrosis is a term referring to intrinsic ARF caused by hemodynamic, nephrotoxic, glomerular, or interstitial disorders. Tubular damage may be a primary clinical entity or a secondary effect of another systemic illness. The kidneys receive a large proportion of circulating blood volume, resulting in high rates of toxin exposure, as well as increased vulnerability to ischemia and reperfusion injury in disease states that reduce the delivery or oxygen content of blood. ARF—characterized by a sudden decrease in GFR, nitrogenous waste accumulation, and loss of the ability to manage sodium, electrolytes, protein, acid-base, and water balance—develops over hours or days. Depending on the nature and duration of the primary insult, widespread dysfunction or necrosis of tubular epithelial cells may produce reversible renal injury, ARF, or CRF. Classification and causes of TN are included in Table 34-2.

Clinical Signs

The clinical signs of ARF in ruminants are nonspecific and usually not indicative of overt urinary tract dysfunction. Depending on the inciting cause, anuria, oliguria, or polyuria may exist. Cattle with ARF are frequently presented for evaluation of poor appetite, diarrhea, or epistaxis.[1] Depression, nasal discharge, ileus, melena, and mild free-gas bloat may also be present. If a concurrent septic condition exists, fever, tachycardia, and scleral injection may be present. The saliva may have a strong ammonia smell. Muscular weakness, even recumbency, may result from the acid-base and electrolyte imbalances and intravascular volume depletion that occur with severe acute TN. Rectal palpation findings are usually unremarkable, although renal enlargement and perirenal edema may be found in occasional cases. If untreated, CRF may ensue, usually producing weight loss in addition to the signs listed. In such cases a reduction in size of the left kidney may be appreciated on rectal palpation. Table 34-2 lists additional clinical criteria that may facilitate diagnosis of TN caused by nephrotoxins.

Renal (uremic) encephalopathy is a syndrome of brain dysfunction associated with renal disease. It is characterized by signs of intracranial disease (altered behavior or sensorium, weakness, motor dysfunction, convulsions) that may resolve on restoration of normal renal function or improvement of clinical parameters of renal disease. The pathogenesis of renal encephalopathy is complex and incompletely understood, but neurologic function appears to be impaired by alterations in the extracellular fluid content of acids, phosphorus, amino acids, or certain hormones. Alteration in neurotransmitter balance or release within the CNS may also be involved. Renal encephalopathy appears to be a rare complication of renal failure in ruminants, as reported in two cows and a goat, where the lesions included myelin vacuolation.[2-4]

Differential Diagnosis

Formulation of a differential diagnosis list for a ruminant with TN may be difficult because of the nonspecific nature of the clinical signs and the variety of primary disease conditions that may predispose cattle to TN. Generic systemic illness differentials are similar to those of renal origin. Diseases causing signs of acute severe illness in ruminants include pneumonia, pleuritis, mastitis, metritis, peritonitis, endocarditis, and metabolic derangements.

Pathologic Studies

The CBC and serum biochemistry can provide important evidence for the presence of renal disease and clues to its etiology. Inflammatory diseases are common in ruminants, and the leukogram may reflect those primarily affecting the upper urinary tract. Acute inflammation affecting renal tubules may result in neutropenia or a left shift to immature (band) neutrophils.

TABLE 34-2

Clinical Characteristics of Acute Toxic Nephrosis Caused by Common Nephrotoxins

Nephrotoxin	Clinical Findings*
Aminoglycosides	Usually nonoliguric, ototoxicosis possible; hematuria, glucosuria, proteinuria, increased serum trough concentration of drug
Tetracycline	Hematuria, glucosuria, proteinuria; possible hepatocellular enzyme elevation
Ionophores	Diarrhea, dark urine, dyspnea, cardiac dysrhythmias; elevated CK, AST, and indirect bilirubin
Ethylene glycol	Anuria or oliguria, tachypnea, ataxia, weakness; hemolysis, increased anion gap, increased serum osmolality, increased osmolar gap, acidosis, calcium oxalate crystalluria
Oxalate-containing plants, vitamin C	Hindlimb ataxia or paresis, apprehension, salivation; hypocalcemia, calcium oxalate crystalluria, aciduria, increased renal cortical echogenicity on ultrasonogram
Oak, acorns	Hemorrhagic diarrhea, ascites, hydrothorax, subcutaneous and perirenal edema; hyperfibrinogenemia, increased hepatic enzymes
Myoglobin	Muscle stiffness and weakness, dark urine; elevated serum CK and AST, positive reactions for blood and protein on urine chemistry strip, hemolyzed serum not present
Hemoglobin/ methemoglobin	Icteric to pale mucous membranes, tachycardia, tachypnea, red or brown urine; positive blood and protein reactions on urine chemistry strip, anemia, elevated serum total protein, hemolyzed serum (hemoglobin only)
Arsenic	Colic, hemorrhagic diarrhea, ataxia; elevated blood and liver arsenic levels

*Many general clinical characteristics of acute tubular necrosis are also present. See Clinical Signs and Clinical Pathology.

AST, Aspartate aminotransferase; *CK,* creatine kinase.

Renal waste products and electrolytes evaluated in the serum biochemistry are useful indicators of renal function. Blood or serum urea nitrogen (BUN) is interpreted as a measure of GFR, reflecting function and perfusion of the kidneys. BUN is influenced by the protein level in the diet and the ability of the rumen to recycle urea. Creatinine is produced and eliminated in constant amounts in the body and is not influenced by rumen physiology, making it superior for evaluation of renal perfusion and function in ruminants, although it may be present in the serum in concentrations above reference ranges in healthy, heavily muscled bulls with adequate renal function. Azotemia may result from prerenal, renal, or postrenal causes, with renal causes indicated by the persistent isosthenuria or hyposthenuria in the absence of iatrogenic causes.

Fractional excretion (FE) of electrolytes can further delineate the nature of renal azotemia. Fractional clearance of sodium has been used to help document renal failure in cattle, with values of 0% to 4% described in normal cattle.[5] Age, ration, and metabolic status may affect FE values.[5] When applying this test, it is prudent to compare the patient's FE value for sodium to that of an age-matched herdmate in a similar physiologic state and on a similar ration. The normal values for several urinary diagnostic indices in healthy calves have been reported.[6]

Hyponatremia, hypochloremia, and metabolic alkalosis may also be present with ARF, with variable potassium levels.[1,7] Because the kidney is the primary organ controlling magnesium excretion in ruminants, hypermagnesemia may occur in TN, particularly under conditions of high magnesium intake.[1,8] Hyperphosphatemia results from reduced phosphorus excretion in saliva during anorexia, reduced urinary phosphorus excretion, and tissue hypoxia.[9,10] Hypocalcemia is also common in TN in ruminants because of reduced calcium intake, GI stasis, urinary losses, and the competitive effect of hyperphosphatemia.[1] Metabolic acidosis may develop in juvenile ruminants with TN and concurrent diarrhea.[5,10]

A urinalysis should be performed on all animals with suspected renal disease. Proteinuria, hematuria, and granular casts may be found in cases of TN.

Pathophysiology The mechanisms of TN include hemodynamic changes within the kidney as well as ischemic and toxic damage to tubular cells. Reduced blood flow to the kidneys most often occurs during generalized loss of vascular volume, as seen with marked blood loss, septicemia, endotoxemia, or severe dehydration. In ruminants, the most common primary conditions resulting in these changes include mastitis, metritis, enteritis, rumen acidosis, and intestinal accidents. These conditions may also cause infarction of the renal cortex and renal vein thrombosis.[1] Acute severe renal TN has recently been reported in lambs as heat stress–related injury, similar to ischemic heat-induced injury in humans.[11] Prolonged severe ischemia may destroy the tubular basement membrane, thereby preventing tubular epithelial cell regeneration.[12] Rumen acidosis or other conditions resulting in severe rumen distention may additionally result in mechanical obstruction of renal vasculature, impairing renal perfusion.[1]

Bilateral bacterial infection of the kidneys may result in ARF or CRF as a result of destruction of nephrons by bacterial toxins and host inflammatory response. Renal infection may be established by ascending UTI or via hematogenous infection of the kidneys.

Pigment nephrosis is an endogenous toxicity that is due to presentation of large amounts of hemoglobin or myoglobin to the kidneys as a result of hemolytic disease or myopathies. These pigments result in renal vasoconstriction and tubular obstruction from protein coagulation.

A variety of toxins (Box 34-2) may result in significant damage to the kidneys by a variety of mechanisms that result in ARF. The high metabolic demands of renal tubular epithelial cells render them susceptible to toxins that disrupt cellular enzymes. The injury caused by most nephrotoxins is compounded by dehydration, which concentrates the toxin in the tubular filtrate, slows toxin clearance, and if severe, reduces renal perfusion. Because some nephrotoxins are therapeutic agents, it is vital that the veterinarian monitor appetite, body weight, water intake, urine output, routine urine chemistry, serum drug concentration, and serum creatinine concentration during administration of these agents. Young or elderly patients, patients with preexisting renal insufficiency or sepsis, those receiving other potentially nephrotoxic drugs, and patients on prolonged or high-dose therapy with these agents warrant the closest attention.[13] NSAIDs block the effects of prostaglandins, which are important for maintaining renal blood flow. NSAIDs can cause medullary crest necrosis when used in pediatric, geriatric, and inadequately hydrated patients or for a prolonged dosing regimen.[14] Some sulfonamide antimicrobials have been associated with deposition of insoluble precipitates in the renal tubules and blocking excretion of creatinine.[15] Aminoglycoside antimicrobials, particularly gentamicin, have cumulative effects on the renal tubules and may cause cell death through mitochondrial injury and other mechanisms.[13,16]

Ethylene glycol, the primary ingredient in many antifreeze products, is converted by the liver into nephrotoxic metabolites, mainly

glycolic acid. Calcium oxalate crystals form and are deposited into the renal tubules, causing further compromise.[17] Lethal doses for ethylene glycol are 5 to 10 mL/kg in mature cattle and 2 mL/kg in preruminating calves.[18,19] Insoluble oxalate crystal deposition in the renal tubules is also a common pathologic mechanism for some nephrotoxic plant poisonings (e.g., halogeton, greaseweed, pigweed, sorrel, dock, Russian thistle). Several nephrotoxic plants also exhibit effects on other body systems, including the respiratory, GI, cardiac and hepatic systems, with additional symptoms observed. Many of the nephrotoxic plants, particularly those causing oxalate toxicity, are also nitrate accumulators.

Treatment and Prognosis Treatment of ARF should include binding and removing any offending toxin or source, promoting diuresis through IV fluid administration and diuretic medications, correcting acid-base and electrolyte derangements, and close monitoring of positive or adverse responses to treatment. Rumenotomy, with removal of toxic material, is most beneficial if performed soon (within 24 hours) after the animal has ingested a nephrotoxin. Activated charcoal (2 to 4 g/kg PO) may bind the agent in the gut lumen. Magnesium sulfate or other magnesium-containing laxatives should be avoided in such cases because severe hypermagnesemia may result in animals with concurrent compromise of renal function.[8] Drugs that directly target known nephrotoxins, such as heavy metal chelators, may be initiated. Prophylactic diuresis should be instituted as soon as an animal has suspected exposure to a potentially harmful quantity of a nephrotoxin. Delay until the appearance of azotemia results in a significant (>75%) loss of nephron function prior to medical intervention.

The cornerstone of treatment of TN is restoration of adequate renal perfusion and urine production. This is most effectively achieved through IV administration of isotonic sodium-containing fluids, with calcium and potassium supplementation as indicated. Normal (0.9%) saline or 0.45% saline + 2.5% dextrose serve as reasonable base fluids. Additional IV potassium can be substituted if indicated after initial therapy, being cautious to remain below the generally recommended toxicity rate of 0.5 mEq/kg/h. Diuresis should continue until the patient is producing sufficient volumes of urine. If cost or facilities make IV fluid therapy impractical, repeated administration of water and electrolytes by stomach tube is an option. A small-bore stomach tube can be passed through the nasal cavity into the rumen and secured to the animal's halter to allow one person to administer fluids repeatedly without the need for repeated tube passage. Placing a small rumenostomy or securing a nasogastric tube in place allows one person to administer fluids repeatedly with relative ease. Administration of IV or oral fluids at 1.5 to 2 times the adult maintenance level of 60 mL/kg/day may be adequate to induce diuresis. The patient should be monitored for chemosis or labored or rapid respiration, which may be indicative of overhydration. Fluid therapy should be continued until azotemia resolves, at which time the patient's voluntary fluid intake can be assessed. Oral supplementation of potassium and calcium salts may be necessary in some cases because it is often not possible to add adequate yet safe levels of these salts to IV fluids in cases of refractory hypokalemia and hypocalcemia, respectively.

Restoration of urine production is necessary in anuric or oliguric animals. If fluid therapy does not promote diuresis, furosemide (1 mg/kg IV or IM) may be administered. Repeated administration (q1-2h) may be necessary to induce urine production. With repeated use of furosemide, the patient's serum sodium and potassium concentrations must be monitored. Mannitol (0.25 to 1 g/kg IV bolus) can be used to provide osmotic diuresis.

Vasopressors and inotropes may assist, but must be administered using fluid pumps as constant rate infusions (CRI). These have wide and controversial ranges of therapeutic efficacy. Drugs and dosages used anecdotally in ruminants include IV dopamine (2 to 5 µg/kg/min), dobutamine (5 to 10 µg/kg/min), and combination norepinephrine (0.4 µg/kg/min) + dobutamine (5 µg/kg/min), based on available information.[20] It should be noted that use of dopamine alone in cases of ARF may not be as beneficial as once thought, and potential adverse effects have been discovered.[21,22]

Additional supportive therapy may include secure broad-spectrum antimicrobials against susceptible infectious agents, plasma transfusion to treat hypoproteinemia, and nutritional support through parenteral nutrition or rumen transfaunation. Antiinflammatory agents may prove useful but should be used cautiously where renal damage exists and should only be used where the kidneys are being therapeutically well perfused. Urinalysis and fractional excretion of electrolytes can be measured in conjunction with serum monitoring parameters during intensively managed cases.

Lesions that occlude tubular blood flow (renal vein thrombosis, DIC) warrant a poor prognosis, whereas renal failure resulting from toxic causes carries a more favorable prognosis with early diagnosis and aggressive therapy. Return of appetite and progressive reduction in BUN and serum creatinine levels are positive prognostic indicators.[23] Prolonged supportive treatment (2 to 3 weeks) may be necessary to allow for regeneration of tubular epithelium in cases of acute TN.

Leptospirosis

Robert J. Callan

Leptospirosis is a complex disease of both animals and humans caused by pathogenic species of *Leptospira*.[1-8] Pathogenic *Leptospira* species persist as chronic infections of the renal tubules of the maintenance host species, often causing little or no disease. Transmission to incidental hosts results from direct contact with urine from an infected maintenance host or through environmental and feed contamination with infected urine. Infection in the incidental host can cause acute disease in multiple organ systems (e.g., kidney, liver, CNS) and result in abortion or reproductive failure. This discussion focuses on *Leptospira* infection and disease of the urogenital system of ruminants.

Leptospira is a diverse genus of motile, gram-negative, obligate aerobic, tightly coiled spirochetes approximately 0.1 to 0.3 µm in diameter and 6 to 20 µm in length.[1,2,5,8] The bacteria can survive in the environment for up to 6 months.[2,5,9] *Leptospira* spp. prefer a warm, moist environment with a pH of 7.2 to 8.0. Survival is short under dry conditions or at temperatures below 10° C.[2] *Leptospira* does not survive freezing in the environment.[10]

Before 1989, *Leptospira* was divided into the pathogenic species *L. interrogans* and the nonpathogenic saprophytic species *Leptospira biflexa*. The current taxonomy and classification of *Leptospira* use a complex system of both genetic and serologic characteristics.[1,5,11] The *Leptospira* species is determined by DNA sequence similarity.[1,5] Twenty genomospecies are identified based on DNA sequence heterogeneity (e.g., *Leptospira borgpetersenii*).[11] Further classification by serovar is based on antigenic grouping of the lipopolysaccharide (LPS) and other outer surface antigens using the cross-agglutinin adsorption test (CAAT).[11] More than 250 serovars are characterized for pathogenic strains of *Leptospira* (e.g., *L. borgpetersenii* serovar *hardjo*). Serovars may be further divided into serotypes (e.g., *L. borgpetersenii* serovar *hardjo* type hardjobovis). Serogroups represent antigenically related serovars and are determined by the microagglutination test (MAT). There are currently 24 serogroups described for pathogenic strains of *Leptospira*.[11] Since serovars of a given serogroup can be distributed across multiple *Leptospira* species, the serogroup classification does not represent taxonomic relatedness.

Epidemiology Leptospirosis is predominantly observed under conditions where livestock come in direct or indirect contact with urine from an infected maintenance host (Table 34-3).[1,2,5,9] The prevalence of infection within a maintenance host population tends to be high (30% to 50%); in such populations, infection is often spread between animals by direct contact.[2] Transmission to incidental hosts is generally by contact with the environment, feed, or water that is contaminated with urine from an infected maintenance host.

L. borgpetersenii	*ballum*	Mice	—
Leptospira kirschneri	*grippotyphosa*	Raccoons, muskrats, squirrels	Cattle, sheep, horses, dogs

Transmission can also occur from contact with an infected fetus or uterine discharge. Survival of the bacteria in the environment and the incidence of infection in animals are increased in regions with warm, humid climatic conditions. The seasonal incidence is higher during the summer or fall in temperate regions and during the rainy season in warm-climate regions.[5] Environmental conditions that contribute to moist surroundings and foot abrasions may contribute to *Leptospira* transmission, particularly in housed dairy cattle.

Cattle are the primary maintenance host reservoir of *L. interrogans* serovar *hardjo* type hardjopragitno and *L. borgpetersenii* serovar *hardjo* type hardjobovis. *L. interrogans* serovar *hardjo* type hardjopragitno is isolated primarily from cattle in the United Kingdom, and *L. borgpetersenii* serovar *hardjo* type hardjobovis is observed worldwide. Cattle can also serve as maintenance or incidental hosts for *L. interrogans* serovar *pomona* and *L. interrogans* serovar *grippotyphosa*.

Serovars *hardjo, pomona,* and *grippotyphosa* are most often implicated in renal infection of cattle.[12] Although data are scarce, renal disease caused by leptospirosis in small ruminants appears to be uncommon.[10,13] Detection of *Leptospira* spp. from vaginal fluid and semen of sheep and goats has been reported and suggests the possibility of venereal transmission in those species.[14] Sheep may serve as subclinical carriers of serovars *hardjo, hardjobovis,* and *pomona.*[3,15,16] Some serovars of *Leptospira* have zoonotic potential, and humans are always considered an incidental host.[1,2,4,5]

An abattoir study of more than 5000 cattle in the United States identified approximately 2% renal carriers of *L. interrogans*.[12] Serovar *hardjo* was the most common renal isolate, followed by serovar *pomona* and serovar *grippotyphosa*. A study of Texas slaughterhouse cattle detected *Leptospira* spp. in 36% of urine samples by PCR. The seroprevalence for serovars *pomona* and *hardjo* was 22% and 15%, respectively.[17] A national survey showed 49% seroprevalence for *L. interrogans* serovars in cattle, with the highest seroprevalence found in cattle from southeastern, south-central, and Pacific Coast states.[18] Because contact with urine from infected animals is a means of transmission within cattle populations, high stocking density or confinement may increase the rate of infection in a herd.

In general, infection of cattle with the host-adapted serovar *hardjo* rarely results in acute severe disease. If present, signs of disease are usually mild in acutely infected cattle and may simply present as cases of undifferentiated fever. Persistent latent urogenital infection usually follows acute infection of host-adapted serovars in cattle, with most overt losses attributable to adverse effects on reproduction.[4,19-21]

Acute severe renal disease is more characteristic of incidental (also termed *accidental*) infection of cattle, particularly calves, with a non–host-adapted serovar of *Leptospira*. However, exceptions to this generalization do occur because host immunity and virulence of the organism are variable.[3,4]

Clinical Findings

Serovar *hardjo* is host-adapted to cattle, and many infections are asymptomatic or result in nonspecific reproductive failure or abortion. *Leptospira* serovar *hardjo* infection of cattle may produce chronic interstitial nephritis of variable severity, but overt renal dysfunction is rarely observed.[22] Chronic infection of the genital tract of cows and bulls is common.[7,23] Protracted shedding of the organism in the urine often occurs, possibly lasting for the life of the animal.[22,23] Infertility, stillbirth, abortion, and birth of weak calves are typical clinical manifestations of infection with serovar *hardjo* in cows.[7,20,24,25] The fetus can be infected in utero, and if it survives the acute infection, it may be born persistently infected.[2] Fever, agalactia, and mastitis may occasionally occur, and the resulting syndrome has been termed the *milk-drop syndrome*[3] or *flabby udder*[4] in lactating cows. The udder is uniformly soft, and the milk may be yellow- or red-tinged and thick.

In contrast, infection with the non–host-adapted serovars can result in severe systemic disease, hemolytic anemia, hepatitis, interstitial nephritis, and tubular nephrosis in calves and less often in adult cattle.[7,22] Meningitis is a rare manifestation.[13] Agalactia and mastitis often occur in lactating cows, and pregnant cows may abort. Urine shedding of non–host-adapted serovars by infected cattle can persist for weeks to months.[4,7,25] Renal lesions result from direct damage to the vascular endothelium during leptospiremia, hypoxia from endothelial damage and hemolysis, tubular epithelial damage from hemoglobin, and interstitial nephritis.[2,5,22] Some *Leptospira* serovars, particularly *pomona,* produce hemolysins that can cause acute intravascular hemolysis and anemia in cattle.

Clinical signs associated with acute infection may include fever, anorexia, lethargy, decreased milk production, petechiation, hemolytic anemia, and hemoglobinuria. Oliguria may be seen with interstitial nephritis or hemoglobinuric nephrosis. Elevated creatinine concentration caused by prerenal or renal causes may be observed on serum chemistry analysis. Examination of the urine may show proteinuria, pyuria, and cellular or granular casts in cases of nephritis. Hemoglobinemia and hemoglobinuria may be observed in patients with leptospire-induced hemolysis and can occasionally result in hemoglobinuric nephrosis (pigment nephropathy).

Pathophysiology

Contaminated feed and surface water, wildlife, rodents, and domestic animals are potential sources of pathogenic serovars for cattle.[2-5] Leptospires penetrate external mucosal surfaces and scarified or macerated skin. The bacteria multiply locally during an incubation period that can last 2 to 20 days.[2,5] After the incubation phase, the organism enters the bloodstream through the lymphatics or by direct penetration into the blood vessel. Leptospiremia results in dissemination throughout the body and infection of multiple organs. This bacteremic phase lasts 4 to 7 days. Fever and other systemic signs are often present in clinically affected animals. Humoral antibodies can be detected at the end of the bacteremic phase. Opsonizing antibodies are generated and aid in clearing infection from most tissues in the host.

During the convalescent phase, leptospires may become localized in the mammary gland, kidney, or genital tract, where they appear to be protected from the immune response.[2,26] Depending on the virulence of the serovar involved, chronic renal infection may create few histologic changes, mild interstitial nephritis, or diffuse, severe, lymphocytic interstitial nephritis with fibrosis.[13] Nephritis may persist long after the host immune response has cleared the organism. Chronic infection of the kidney or reproductive tract allows for

VetBooks.ir

transmission of the organism in urine, uterine and vaginal secretions, placenta, fetal tissues, and semen.[3,7,23,27] Shedding in the urine may last for weeks to months with non–host-adapted infections. Renal shedding of host-adapted serovars can persist for months to years. The bacteria reside in the lumen of the renal proximal tubules, where they are protected from phagocytes and humoral antibodies. The bacteria do not stimulate a systemic immune response while localized in the proximal tubule lumen, so serum antibody titers can decline and become negative even though the kidney is infected and urinary shedding of bacteria continues.

Multiple potential virulence factors may contribute to leptospirosis.[1,5,8,28] Virulence mechanisms include the toxin effect of lipopolysaccharide, adhesion to cells and extracellular matrix, bacterial motility, hemolysins, and iron sequestration. Leptospiral LPS and outer membrane proteins are believed to contribute to the development of interstitial nephritis. Motility is an important pathogenic mechanism and contributes to invasion and dissemination of the bacteria. As many as 50 genes are related to leptospiral motility.[1] Adherence to cells is in part conferred by fibronectin-binding protein present on the surface of pathogenic strains but not on nonpathogenic strains. Leptospiral immunoglobulin-like protein A, B, and C (LigA, LigB, LigC) may also be involved in attachment and invasion. Additional proteins that may contribute to virulence include hemolysins, sphingomyelinase C, sphingomyelinase H, and hemolysis-associated protein 1 (HAP-1).[1,5,8,28] There appears to be significant redundancy in proteins associated with virulence mechanisms, making it difficult to isolate individual virulence factors using single gene knockout mutations.

Diagnosis

The microscopic agglutination test (MAT) is the most widely used serologic test for the diagnosis of leptospirosis in cattle. The MAT detects antibodies to specific serovars, but cross-reactivity occurs between related serovars, particularly within the same serogroup. Thus, an infection with one strain may result in increased MAT titer to multiple serovars. Serum antibody enzyme-linked immunosorbent assay (ELISA) tests have been developed for research but have not yet been adopted in the routine clinical diagnostic setting for animals.[29-32]

An elevated serum antibody titer is observed after the bacteremic phase and is suggestive of *Leptospira* infection when associated with concurrent clinical signs, but interpretation of a single titer is problematic in vaccinated animals or when endemic exposure is suspected.[7,8,26] A fourfold increase in MAT titer between acute and convalescent serum samples, or conversion from a negative titer to a titer of 100 or greater, supports a diagnosis for both host-adapted and non–host-adapted serovars. However, vaccinated animals may have a diminished serologic response after challenge and renal colonization with *L. borgpetersenii* serovar *hardjo*.[33] Serologic detection of persistent infection with serovar *hardjo* can be difficult because paired serum titers may be increasing, static, decreasing, or undetectable at the time of clinical examination (e.g., at abortion).[7,26] Serology is unsuitable for screening individual animals for carrier status, because many animals that are chronically infected and shedding may have negative serologic status.[34] Considering the serovar with the highest titer as being the infecting strain is generally recommended. However, recent studies demonstrate that serologic antibody titers may not accurately predict the infecting strain in humans because of cross-reaction between different serovars within the same serogroup.[35] Consultation with a clinical immunologist affiliated with the laboratory performing the MAT is recommended for accurate interpretation of results.

Leptospira shedding in urine and semen can be detected by multiple tests, including urine culture, phase-contrast microscopy, darkfield microscopy, fluorescent antibody (FA), PCR, nucleic acid hybridization, and immunoblot.[8,12,26,27,36-38] Urine cultures are often unrewarding because of the fastidious nature of the organism, and conclusive results may not be obtained for up to 6 months.[8,27] Darkfield microscopy, FA, and PCR assays are typically used by veterinary diagnostic laboratories to identify *Leptospira* species from urine samples. None of these tests will determine the infecting serovar. The sensitivity of detecting *Leptospira* shedding can be improved by performing two tests on a single sample.[27,38] Evaluation of serovar-specific antibody titers from positive animals may aid in identification of the infecting serovar.

Second-voiding urine samples collected after administration of IV furosemide are recommended for urine testing.[10,39] Furosemide is administered at 0.5 to 1.0 mg/kg IV or IM, and the first-voided urine is discarded. A second urine sample is then collected after cleaning the vulva of gross debris. Approximately 10 mL of urine should be collected and stored on ice (not frozen) for transport to the diagnostic laboratory. Urine from 10 to 15 adult animals should be tested when evaluating a herd for endemic *Leptospira* serovar *hardjo* infection.

Biopsy or necropsy samples of renal tissue may be treated with Warthin-Starry or Levaditi silver stains for microscopic examination.[13] Immunoperoxidase staining was shown to be more sensitive for identifying *Leptospira* species in kidney and liver of naturally infected cattle than Levaditi silver stain.[40]

Treatment and Prognosis

Treatment of acute leptospirosis caused by non–host-adapted serovars should focus on eliminating the bacteria, systemic support, and diuresis if renal involvement is observed. In vitro susceptibility has been demonstrated for several antibiotics that could be used in food-producing ruminants, including ampicillin, amoxicillin, penicillin G, erythromycin, tetracycline, tylosin, and tilmicosin.[25,41-43] Daily oxytetracycline (100 mg/mL, 10 mg/kg IV or IM once daily for 5-7 days) or long-acting oxytetracycline (20 mg/kg IM or SC every other day for 2 to 4 treatments) are considered clinically effective, but controlled clinical studies reporting efficacy in acute leptospirosis have not been reported. Penicillin G procaine (25,000 IU/kg IM twice daily) and sodium ampicillin (20 mg/kg IM twice daily) have been suggested for treatment, but the efficacy of these regimens in cattle remains unproven.[10] In humans, doxycycline (100 mg q12h for 7 days) has been shown to reduce the duration and severity of illness.[5] Consideration of other antibiotics for treating acute leptospirosis should be based on their efficacy in clearing renal infections with host-adapted *L. borgpetersenii* serovar *hardjo* (see below).

IV or oral fluids may be indicated for systemic support. In animals with severe hemolysis, blood transfusion may be considered. Diuresis should be established in animals with hemoglobinuria or evidence of ARF from hemoglobinuric nephrosis or interstitial nephritis. The prognosis for renal disease caused by leptospirosis is influenced by the virulence of the serovar involved, host immunity, and extent of renal lesions. Cases with renal azotemia warrant a guarded prognosis because more than 75% of nephrons are affected in such cases, and chronic interstitial nephritis and fibrosis may occur after treatment of the acute disease.

Several antibiotics have been shown effective in clearing *Leptospira* spp. renal colonization and shedding in cattle. Long-acting oxytetracycline (20 mg/kg IM or SC, two doses 10 days apart) has been recommended to treat chronic leptospiral infections or reduce the risk of introduction of infected animals into a herd.[3] Oxytetracycline (20 mg/kg IM once), ceftiofur sodium (2.2 mg/kg IM q24h for five treatments), ceftiofur crystalline free acid (6.6 mg/kg SC at the base of the ear once), tilmicosin (10 mg/kg SC once), and tulathromycin (2.5 mg/kg SC once) have been shown effective in clearing renal shedding of *L. borgpetersenii* serovar *hardjo* type hardjobovis from experimentally infected cattle.[44,45] The efficacy of these antibiotic treatments has not been demonstrated in acute infections with other species and serovars of *Leptospira,* but their use could be considered relative to the lack of clinical data showing specific antimicrobial efficacy for treating acute leptospirosis in ruminants and swine.

Prevention

Draining or fencing off standing water may reduce transmission. Maintaining a dry, clean environment may also help reduce exposure and infection. Limiting rodent and wildlife contact

VetBooks.ir

with cattle and their feed and water is often difficult to accomplish, but it reduces the potential for transmission of non–host-adapted leptospires.[7] For host-adapted *Leptospira* serovar *hardjo,* preventing or eliminating the renal carrier state in infected cattle is necessary to reduce transmission.

Vaccination is regarded as an effective means of preventing losses from leptospirosis. Conventional pentavalent *(L. canicola, grippotyphosa, hardjo, icterohaemorrhagiae,* and *pomona),* whole-cell, inactivated leptospiral vaccines are recommended in calves and adult cattle as an aid to prevent clinical disease caused by *Leptospira* spp. However, these conventional pentavalent vaccines may not consistently prevent renal colonization and shedding after challenge with host-adapted *L. borgpetersenii* serovar *hardjo* type hardjobovis.[46,47]

A monovalent *L. borgpetersenii* serovar *hardjo* type hardjobovis vaccine (Spirovac, Pfizer Animal Health, New York) is licensed for preventing *Leptospira* serovar *hardjo* infection, including reproductive and renal tract colonization and urinary shedding for up to 12 months. This vaccine stimulates an immune response characterized by IgG1 and IgG2 agglutinating antibodies, as well as antigen-specific T-cell production of interferon (IFN)-γ.[33,48-50] The strong IFN-γ response is consistent with induction of a type 1 immune response and may be responsible for antibody class switching to IgG2, which is a more potent opsonin than IgG1.[48] Combination pentavalent *Leptospira* vaccines have been developed that promote high *Leptospira* serovar *hardjo* antibody titers in addition to the other serovars contained in the vaccine. Because *Leptospira* species are largely extracellular pathogens, the relevant protective immune response appears to be antibody-mediated neutralization and opsonization during leptospiremia.[1,5] There is no indication that cytotoxic immunity is a relevant immune response for protection or resolution of *Leptospira* infection. However, the exact immunologic mechanism responsible for protection from colonization and shedding of *L. borgpetersenii* serovar *hardjo* type hardjobovis in cattle is not fully understood. Vaccine efficacy and the methods used to evaluate vaccine efficacy for *L. borgpetersenii* serovar *hardjo* type hardjobovis infections in cattle remain controversial.

Although vaccines help prevent colonization and shedding of *Leptospira* serovar *hardjo* from the kidney, they are not effective in resolving current renal infection and elimination of the carrier state. Thus, vaccination at an early age followed by annual boosters is recommended to prevent initial renal colonization. Renal shedding in previously infected animals can be resolved by antibiotic treatment, and vaccination can be used to prevent future colonization.

Diseases of the Nervous System

ROBERT J. MACKAY and DAVID C. VAN METRE, *Consulting Editors*

Cerebrospinal Fluid

Mary O. Smith • Lisle W. George • David C. Van Metre

Cerebrospinal fluid (CSF) is partly derived from and in equilibrium with the extracellular fluid that bathes the brain and spinal cord parenchyma.[1-3] The composition is an indicator of the state of the intrathecal contents. CSF is produced by a combination of ultrafiltration of plasma and active secretion.[5] The sites of CSF production are the choroid plexuses of the lateral, third, and fourth ventricles; the ependymal lining of the ventricular system; the pia arachnoid; and the meningeal blood vessels. The CSF in the ventricular system flows caudally and diffuses out of the lateral apertures in the fourth ventricle. It then circulates around the brain and spinal cord. Circulation of CSF is achieved through regional pressure changes caused by spinal motion and pulsations of blood vessels. Resorption of CSF occurs from both the cranial cavity (75%) and the spinal canal (25%).[6] Some resorption of brain CSF occurs at the arachnoid villi associated with large veins and sinuses, but most resorption occurs at the cribriform plate, into nasal lymphatics.[7,8] Resorption of spinal CSF occurs into the lymphatics associated with spinal nerves.

The predominant direction of CSF flow in the spinal canal is cranial to caudal. CSF can be collected from the cisterna magna when the site of interest is the brain, whereas it should be collected from the lumbar subarachnoid space when the lesion is in the spinal cord. In large animals, however, the risks associated with the general anesthesia required for cisterna magna tap are considerable, so lumbar puncture is usually the most suitable technique for CSF collection in these species, regardless of the site of the lesion.[9,10]

Collection of Cerebrospinal Fluid

Lumbosacral Spinal Tap

For collection of CSF by lumbosacral puncture, the animal is lightly sedated and the skin of the dorsal midline over the junction of the sixth lumbar (L6) and first sacral (S1) vertebrae is surgically prepared (Fig. 35-1). A variety of standard sedative protocols are suitable, although xylazine has been shown to reduce CSF pressure.[11] Correct placement of the spinal needle is more easily achieved with the animal standing. The proper anatomic site for insertion of the spinal needle is between the dorsal spinous process of L6 cranially and S1 caudally and the two tuber sacrales laterally. The overlying skin forms a depression that can be recognized by palpation, although this may be difficult in well-muscled horses. The correct site for needle placement can also be located by determining (1) the dorsal midline at the highest point of the quarters or (2) the point where a line drawn between the caudal aspects of the two tuber coxae intersects the midline.

The skin is anesthetized with 2% lidocaine, and a 1-cm incision is made with a No. 15 scalpel blade. A 6- to 9-inch, 18- to 20-gauge spinal needle is inserted perpendicularly through the incision and advanced until the tip punctures the lumbosacral cistern (a 3½-inch needle can be used in small ruminants, foals, and small cattle). A "snapping" sensation is sometimes felt as the needle passes through the interarcuate ligament. The patient may reflexly contract the tail, anus, and gluteal muscles. Some patients, particularly horses, may respond with violent motor activity. Therefore a lumbosacral spinal tap performed on a conscious horse should be done only when the animal is restrained in stocks. The average depth of insertion is 17.64 cm (7 inches) in horses, 8.26 cm (3⅓ inches) in ponies,[10] and about 7.5-10 cm (3-4 inches) in adult cattle.

The spinal needle is advanced gently to the floor of the spinal canal. Passage of the needle through the terminal spinal cord or the cauda equina does not cause subsequent neurologic abnormalities. When the needle is seated in the spinal canal, gentle negative pressure can be applied by withdrawing spinal fluid into a series of 3-mL syringes. If frank blood is obtained, the tip of the needle is probably in one of the ventral vertebral sinuses. The needle should be withdrawn a few millimeters, and a clean syringe should be attached to the hub. Compression of the jugular vein causes engorgement of the ventral vertebral plexus, which increases CSF pressure in the lumbosacral cistern.

Cisterna Magna Tap

General anesthesia is required for a cisterna magna tap. After the patient has been anesthetized, the dorsal area of the neck overlying the atlantooccipital joint is surgically prepared. The patient's head is held flexed at a right angle to the neck, with the sagittal plane of the head parallel to the floor or table on which the patient is lying. The head must not be allowed to move while the needle is inserted. The needle is inserted at 1 to 2 cm caudal to a point corresponding to the intersection of the dorsal midline, and a line is drawn between the cranial aspects of the wings of the atlas. This point is usually 6 to 9 cm (2½ to 3½ inches) from the poll (Fig. 35-2). A 3½-inch, 18-gauge spinal needle is inserted perpendicular to the skin and aimed toward the nose. The needle is advanced slowly with the stylet seated. After the needle has been advanced a few millimeters, the stylet is removed and the hub of the needle is examined for CSF flow. The stylet is replaced if it is dry and CSF is not spontaneously dripping from the hub, and the needle is advanced another few millimeters and checked again for CSF flow. Entry of the tip of the needle into the cisterna magna may be accompanied by the sensation of "popping" through a tissue plane or by a sudden decrease in resistance to the advancement of the needle. In other cases, however, no such sensation is perceived—thus the precaution of checking for CSF flow every time the needle is advanced a few millimeters.

In most large animals the needle is seated at approximately 5 to 8.75 cm (2 to 3½ inches). While advancing the needle, the heel of the hand should be held firmly against the animal's neck to minimize the possibility of spinal cord injury. The mean depth of insertion is 6.16 cm (2½ inches) in horses[10] and 5.08 cm (2¼ inches) in cattle. In a cisterna magna tap, the needle entry site is close to the cervical spinal cord and the brainstem. To minimize the danger of central

VetBooks.ir

nervous system (CNS) damage during a cisterna magna tap, the animal should be adequately anesthetized and ventilated, because an increased partial pressure of carbon dioxide (P_{CO_2}) results in elevated intracranial pressure.[12] Removal of fluid from the cisterna magna is contraindicated in a patient with increased intracranial pressure because a possibly fatal herniation of the brain through the foramen magnum may occur. Signs of increased CNS pressure include a moderate to marked decrease in mentation, mydriatic pupils, opisthotonos, extensor rigidity, ventrolateral strabismus, and papilledema.

Ultrasonography can be used as an aid to needle placement for collection of CSF from both the atlantooccipital cistern and the lumbosacral subarachnoid space.[13,14]

Myelography

Contrast material for myelography is injected into the cisterna magna in large animal patients. Withdrawal of CSF before injecting the contrast medium is unnecessary, as is reinjection of CSF after it has been withdrawn. The turnover of CSF is rapid and under strict homeostatic control; therefore withdrawal of CSF through a spinal tap does not have deleterious effects that require its replacement.[15-17]

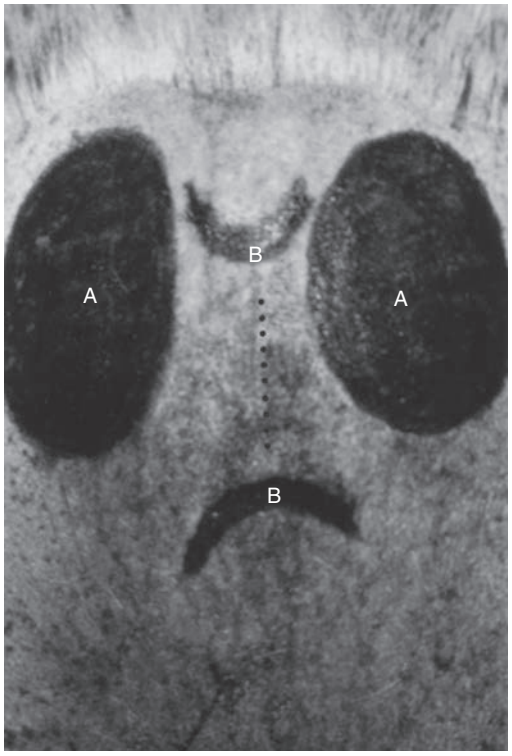

FIG. 35-1 Close-up view of landmarks for a lumbar cistern puncture in a horse. The large dark ovals *(A)* represent the position of the two tubers sacrale. The smaller curved lines *(B)* represent the respective caudal and cranial aspects of the L6 and S1 dorsal spinal processes. The dotted line represents the optimum area for placement of a skin stab.

Analysis of Cerebrospinal Fluid

The color of the CSF should be noted as it flows from the hub of the spinal needle. Blood can originate from the tapping procedure (iatrogenic hemorrhage) or from a traumatic CNS lesion. Iatrogenic hemorrhage is unevenly mixed in the CSF and disappears as the fluid drips from the needle. Fluid collected immediately after placement of the spinal needle tends to be mildly contaminated with blood even when this is not apparent grossly. Successive aliquots are usually less contaminated, so the later aliquots are most suitable for cellular and protein analysis.[18] Blood resulting from CNS hemorrhage is evenly mixed with CSF even after a large amount has been removed. Hemorrhage that has occurred days earlier may have a brownish rather than red discoloration. Prior hemorrhage also results in *xanthochromia,* a yellow discoloration of the CSF. Xanthochromia can be observed in the CSF for at least 10 days after the introduction of blood. Xanthochromic samples do not contain bilirubin.

The normal values for CSF are presented in Table 35-1. Cell counts should be determined in a noncentrifuged specimen as soon as the sample is collected, using a hemacytometer. Automated methods for counting cells are not suitable for CSF because the low numbers of cells in CSF compared with blood result in erroneous counts. Morphologic examination of cells from CSF is most suitably done on cytospin preparations in an appropriately equipped

FIG. 35-2 View of the ideal area for a cisterna magna cerebrospinal fluid tap in a cow. The two lines *(a)* represent the wings of the atlas. The large spot in the center *(b)* is the optimum area for needle insertion. It is essential to prevent head movement by use of anesthesia and restraint.

TABLE 35-1

Normal Range of Values in Cerebrospinal Fluid for Large Animals[1,4,5]

Component	Unit	Equine	Bovine	Ovine	Caprine
Specific gravity	1.004-1.008	1.004-1.008	NA	NA	NA
Refractive index	1.3343-1.3349	1.3343-1.3349	NA	NA	NA
Protein	mg/dL	5-100	20-40	8-70	24-40
White blood cells (WBCs)	WBCs/dL	0-6	0-3	0-5	0-7
Glucose	mg/dL	30-70	35-70	48-109	45-87
Sodium	mEq/L	140-150*	132-144*	145-157*	NA
Potassium	mEq/L	2.5-3.5	2.7-3.2	3-3.3	3
Creatine kinase	IU/L	0-8	2-48	NA	NA
Magnesium	mEq/L	NA	1.7-2.7	NA	NA

*Cerebrospinal fluid (CSF) sodium is the same as serum or plasma sodium when measured with ion-specific electrodes. When other measurements are used, the CSF sodium is usually higher than plasma sodium.

laboratory. Normal CSF from large animals contains fewer than six white blood cells (WBCs) per deciliter. Some reports have documented occasional WBC counts greater than 40 cells/dL in the CSF of normal horses.[19] Although suggested to correct for the effects of iatrogenic blood contamination, various "correction factors" are inaccurate and should not be used.[18,20]

The refractive index of normal CSF is less than 1.335. The protein concentration of CSF in normal adult ruminants is less than 50 mg/dL, and in normal horses it is less than 100 mg/dL, although reference values vary with the techniques used for protein measurement. Reference values should be established for each laboratory.[21]

Studies of the specific and relative quantities of albumin and immunoglobulins, particularly IgG and IgM, have been stimulated by the increasing importance of immunologic testing of CSF for diseases such as equine protozoal encephalomyelitis. Reference values for a number of parameters have been established.[22] The most important of these parameters are *albumin quotient,* a measure of blood-brain barrier (BBB) permeability,[23] and *IgG index,* a measure of intrathecal production of IgG.[24] The formulae for these parameters are as follows:

$$\text{Albumin quotient} = (\text{CSF albumin}/\text{Serum albumin}) \times 100$$

$$\text{IgG index} = (\text{CSF IgG}/\text{Serum IgG}) \times (\text{Serum albumin}/\text{CSF albumin})$$

Reference values must be established for each species. An elevated albumin quotient indicates BBB leakage or contamination of CSF with blood, with possible introduction of immunoglobulins from serum. An elevated IgG index indicates intrathecal production of IgG and may support a diagnosis of infectious disease of the CNS. The usefulness of these parameters is influenced by a number of other variables, including the immunoreactivity of blood.[24] Therefore clinical interpretations must be made with great caution. The composition of protein from the CSF of horses and cattle has been established.[3-5,10]

The concentrations of glucose and protein in the CSF of newborn foals are almost twice those found in the CSF of adults, but they approximate adult normal values by 2 weeks of age.[25] In contrast, calves between 1 and 2 months have lower protein concentration and higher leukocyte numbers in CSF than adult cattle.[26]

Neural tissue contains the BB isoenzyme of creatine kinase (CK), which increases after damage to the nerve cells.[27,28,30] The molecule does not cross the BBB, so CK in the CSF originates from neural tissue. Contamination of CSF with dura or fat, however, falsely elevates the CK concentration. Some have suggested that CK is an accurate marker and a prognostic indicator for CNS disease, but other studies have not supported this conclusion, and measurement of CK, although interesting, has limited clinical utility.[27,29,30]

The normal CSF concentration of glucose is approximately 80% of that in blood. A decline in the ratio of CSF to serum glucose occurs in animals with bacterial meningitis because of increased use of glucose by inflammatory cells.

Measurement of the sodium concentration of the CSF may be helpful for diagnosing salt poisoning in cattle. In animals that do not have salt poisoning, this value is less than 160 mmol/L; in animals with salt poisoning, the concentration is usually greater than 160 mmol/L.

Diseases Presenting Principally with Forebrain Dysfunction or Multiple-Level Brain Dysfunction

Alphaviruses

Robert J. MacKay

The causative agents of eastern, western, and Venezuelan equine encephalomyelitis (EEE, WEE, and VEE) are New World arboviruses belonging to the genus *Alphavirus* of the family Togaviridae.[1] Ross River virus is an Old World alphavirus in Australia that has been shown to cause fever in some experimentally infected horses and is suspected of causing a syndrome of lethargy, muscle soreness, and ataxia in horses in Victoria and South Australia.[2]

EEE, WEE, and VEE affect all common domestic equid species including horses, mules, and donkeys. Each of the viruses was first isolated during epizootics in the 1930s.[3-5] Alphaviruses are unsegmented, single-stranded, positive-sense ribonucleic acid (RNA) viruses; viral genomes are 11 to 12 kB, and infectious virions are spherical enveloped particles 60 to 70 nm in diameter.[6] Each of the 3 equine alphaviral encephalitides is among the 13 equine infectious diseases that are notifiable to the World Organization for Animal Health (Office International des Epizooties [OIE]). Data on the occurrence of these diseases in the United States are collected by veterinarians, diagnostic laboratories, and state animal health officials and reported to the National Animal Health Reporting System.

At least three subtypes of WEE have been identified. Two of these are found in both North and South America, suggesting that circulation of viruses between the New World continents is common.[6,7] There is a distinct North American variety and three South American antigenic varieties of EEE.[6] In contrast to the situation with WEE, there is no evidence for movement of EEE viruses between North and South America.

The VEE antigenic complex contains 8 viral species, 7 subtypes, and at least 14 varieties,[6,8] most of which are maintained continuously in enzootic life cycles in northern South America. Until the 1990s, when an IE variant caused two outbreaks in Mexico, all equine epizootics had been caused by subtypes IAB and IC.[9]

History and Distribution

WESTERN EQUINE ENCEPHALOMYELITIS. What was almost certainly the first recorded outbreak of WEE in horses occurred in Kansas, Nebraska, Colorado, and Oklahoma during the late summer and early fall of 1912 when at least 35,000 horses died of the disease.[4,10] Epizootics in California and other western states in 1930 to 1932 resulted in the deaths of an estimated 9200 horses and mules (≈50% of those affected).[4,11] In 1938 WEE was recognized in every state west of the Mississippi River and affected more than 184,000 horses in that year alone.[12] By the 1970s, WEE had been recorded as far east as Tennessee. WEE virus was also implicated in outbreaks of fatal equine disease in the early 20th century in Canada and Argentina, and epizootics have since been reported in Saskatchewan, Alberta, and Manitoba in western Canada; Mexico; Central America; and South America.[13] Between 1972 and 1981 there was an annual average of 267 cases of WEE in horses reported by the National Veterinary Services Laboratory in Ames, Iowa[12]; in 1993 there were 15 cases in 10 states, and since 2005 no case has been reported in the United States. There have been isolated cases of encephalomyelitis in Florida horses associated with the Highlands J virus, an eastern member of the WEE virus complex with epidemiologic characteristics similar to those of EEE virus.[14]

EASTERN EQUINE ENCEPHALOMYELITIS. An outbreak of what was probably EEE was recorded in 1831 in Massachusetts.[15] Approximately 100 horses were affected and 75 died. Over the subsequent century, there were at least five other outbreaks consistent with EEE—in Long Island, New York (1845); North Carolina (1902); New Jersey (1905); Florida (1908); and Maryland, New Jersey, and Virginia (1912).[16] In 1933 there was an epizootic involving a least a thousand horses in the coastal regions of Delaware, Virginia, and Maryland.[3] Epizootics of EEE in North America have since occurred periodically in the coastal areas of the Atlantic, the southeastern United States, and Texas. The largest recorded outbreak was in 1947 in southern Louisiana and Texas when 14,344 cases of EEE were recorded, resulting in 11,722 deaths (mortality rate of 81%).[17] Focal outbreaks and sporadic cases have also occurred more or less regularly in Michigan and are occasionally reported from other locations in the eastern half of the United States and Canada. A single case of

VetBooks.ir

EEE in a stallion in California was reported in 2002.[18] Although the origin of the infection in this horse was not determined with certainty, incompletely activated EEE vaccine was suspected. Despite the availability of effective vaccines since the late 1930s, cases of EEE still occur every year in Florida and other southeastern states. The annual incidence of EEE in horses in the United States over the past 10 years has ranged from 71 (2011) to 732 (2003).

Epizootics of what was probably EEE have been reported in Argentina since 1908. Since then, reports of EEE in Central and South America have been widespread, extending from Panama south to Argentina.[16] The disease has also caused serious losses in the Caribbean with epizootics documented in the Dominican Republic, Haiti, Jamaica, and Trinidad.[15]

VENEZUELAN EQUINE ENCEPHALITIS. The disease in equids was first recognized and described in Venezuela and Colombia in 1938.[5] At intervals of approximately 10 years, there were large subtype IAB or IC epizootics in northern South America that usually involved tens of thousands of horses. Some of these outbreaks may have been caused by incompletely inactivated vaccine. One epizootic in central Colombia during 1962-1964 was estimated to have killed 100,000 horses.[19] An outbreak of VEE caused by subtype IAB began in Peru in the winter of 1969, jumped to Central America in June 1969, and then entered Mexico in 1970. The outbreak spread north to the U.S. border in the spring of 1971, and the first case of VEE in a U.S. horse was confirmed on June 30.[20] By the time of the last case on November 7, 1971, more than 1500 horses had died in the southern counties of Texas. There was no further epizootic activity reported until 1992, when a series of epizootics of subtype IC VEE began. Subtype IE was associated for the first time with fatal VEE in small epizootics in Mexico in 1993 and 1996.[21]

Natural History

EASTERN EQUINE ENCEPHALOMYELITIS AND WESTERN EQUINE ENCEPHALOMYELITIS. In North America, the WEE and EEE viruses are maintained between epizootics by low-level cycling between New World passerine birds (i.e., songbirds) and ornithophilic mosquitoes in freshwater, forested swamp habitats.[1] Snakes may also be an overwintering host for North American EEE virus.[22] Infected mosquitoes can be found throughout the year in Florida and other southeastern states. Under favorable environmental conditions, the viruses periodically spread outward from focal reservoirs to infect the general wild bird population, where they are spread and amplified by rapid bird-mosquito-bird transmission. The mosquito vectors involved in maintenance and amplification of WEE and EEE viruses are usually *Culex tarsalis* and *Culiseta melanura,* respectively. Many avian species including migratory passerine birds (e.g., starlings and northern cardinals) and wading birds become infected and develop high-order viremia and high serum titers to EEE or WEE but usually do not become ill. Some introduced species, including pigeons, house sparrows, Chukar partridges, and Chinese pheasants, may suffer high morbidity and mortality when infected with EEE virus.

Cases of encephalitis usually begin in susceptible horses 2 to 3 weeks after the virus spreads into birds. Human cases may occur several weeks later. *Culex tarsalis* transfers WEE virus from bird to horse (and human). Although *C. melanura* may also function in some locations as a bridge vector for EEE, mosquitoes of a variety of other species usually transfer the virus from bird to horse.[6,16] Although mosquito-mediated transmission of EEE virus between horses has been confirmed in an experimental setting,[23] viremia is low titer, so further infection of feeding mosquitoes with either EEE or WEE virus is unlikely and horses are considered "dead-end" hosts. Both EEE and WEE viruses have been associated with naturally occurring and experimentally induced neurologic disease in calves, and EEE has been associated with fatal infections in New World camelids, deer, ratite birds, cats, dogs, mice, foxes, sheep, and pigs.[6,24-26]

Epizootics of EEE and WEE usually last 1 to 3 months and occur in summer and early fall when warmth and humidity favor breeding, longevity, and mobility of mosquito populations.[27] Outbreaks in Massachusetts and Michigan were most likely during the second consecutive year in which rainfall exceeded the annual mean by more than 20 cm; however, unusually high temperatures did not appear to be a risk factor.[27,28] The month of peak incidence of disease onset varies from June in Florida to August or September in northern and western states.[4,24,29,30] In Florida and some other southeastern states, isolated cases of EEE can be seen at any time of year.[29] Standing surface water for mosquito larval development, bush cover for wild hosts, and the immune status of the various hosts also affect the timing and magnitude of equine epizootics. Many of these physical factors are significantly affected by the cultivation, clearing and irrigation of land, and by drainage of swamps. The proximity and size of plantations of trees were risk factors for EEE for horses in Florida.[31] The equine epizootic usually declines with the onset of cool or dry weather unsuitable for mosquito and/or bird activity, as well as the depletion of susceptible equine hosts by death or development of immunity among survivors.

The epidemiology of EEE and WEE viruses in South America is poorly understood. Small mammals play a greater role in sylvatic cycles of viral transmission than is the case in North America. *Culex (Melanoconion)* subspecies and *Ochlerotatus albifasciatus* appear to be involved in transmission of EEE and WEE, respectively.[7,32]

VENEZUELAN EQUINE ENCEPHALOMYELITIS. Enzootic VEE viruses are maintained by cycling between mosquitoes and small rodents. The Everglades virus, a subtype II found in the Everglades region of Florida, is of this type, cycling between *Culex (Melanoconion)* subspecies mosquitoes and wild rodents.[8] The epizootic varieties IAB and IC have probably arisen on at least four separate occasions by mutation of a single enzootic subtype 1D strain and changes in host range.[9] Because of the high-order viremia that develops in infected animals, the defining characteristic of epizootic VEE varieties is the use of equids as amplification hosts. Domestic rabbits, goats, dogs, and sheep also suffer fatal disease during VEE outbreaks.[8] There does not appear to be any single "epizootic" vector mosquito species; during outbreaks, virus may be isolated from mosquitoes of many different species.[8] Epizootics terminate when susceptible horses are no longer available. The leapfrog spread characteristic of VEE is usually attributed to transport of horses incubating the virus. Movement of infected bats may also contribute to discontinuous spread of virus. By contrast to the situation with the WEE and EEE viruses, birds do not have an important role in amplification and spread of epizootic VEE virus. It is not yet clear whether neurovirulent subtype IE virus is amplified in horses. Evidence from experimental infections suggests that viral titers in blood of infected horses may be insufficient to infect feeding mosquitoes.[33] The interepizootic reservoir of epizootic varieties, if any, is not known.

Clinical Findings

Clinical signs following infection with each of the viruses are similar, although signs of EEE are typically more severe and rapidly progressive than those of VEE and WEE.* Infected horses respond in any to all of the following ways after experimental infections[36]: (1) Inapparent infection with a very-low-grade viremia and fever about 2 days after inoculation. This presentation corresponds to the initial viremia following viral proliferation in regional lymph nodes and probably occurs commonly during outbreaks without progression to subsequent stages. (2) Generalized febrile illness (up to 41.7° C), with anorexia, depression, tachycardia, and diarrhea. This stage is associated with viral proliferation in various body organs after spread from regional lymph nodes. (3) Clinical encephalomyelitis, which is the classic form of the disease. Young horses (especially yearlings) are most susceptible: Approximately 90% of 95 horses with EEE admitted to the University of Florida (UF) were younger than 5 years of age. The onset of neurologic signs, associated with the second febrile crisis, typically occurs about 5 days after infection (range 2 days to 2 weeks), and most deaths occur 2 to

*References 3, 4, 17, 18, 27, 34, 35.

VetBooks.ir

FIG. 35-3 Eastern equine encephalomyelitis in an 18-month-old Paint filly. At presentation, the filly was febrile (103.8° F), stuporous, cortically blind, and had a marked head tilt and body lean to the left, indicative of asymmetric central vestibular dysfunction. Vaccination history was unknown. With nursing care, this filly completely recovered over several weeks.

3 days later.[35,36] Almost all horses with EEE are febrile at the onset of neurologic signs (mean of 40.3° F in horses admitted to UF), although the temperature declines thereafter. The onset of severe neurologic signs is peracute to acute, and progression is rapid. Horses may be found recumbent and comatose or dead. If observed, initial CNS signs are quite variable and referable to diffuse or multifocal cerebral disease; evidence of brainstem and spinal cord involvement quickly becomes obvious as the illness progresses (Fig. 35-3). Obtundation is the most common initial clinical sign, although owners also report suspected colic as part of the initial presentation. Affected horses often stand apart from pasturemates, have no interest in food, or fail to respond to an owner's call. Further signs of dementia may follow including head pressing, teeth-grinding, hyperesthesia, irritability, aggression (rarely), leaning against a wall or fence, or compulsive walking, often in a circle (especially around the inside of a stall or small paddock). Several observers have noted a "peculiar looseness of the lips" as a characteristic early sign.[4,37] Blindness and lack of a menace response may be noted at this stage. Signs of cranial nerve disease including abnormal pupillary light reflexes, head tilt, nystagmus, tight circling, facial and tongue paralysis, and inability to swallow often occur as the disease advances. Abnormal signs usually present asymmetrically, at least initially. Ataxia and paresis of the trunk and limbs result in a progressively more unsteady gait. Tremors are seen in the antigravity muscles of the limbs. Once recumbent, affected horses seldom regain their footing and are often noted to make galloping or swimming movements in lateral recumbency.[4] Seizures occur in about a third of horses with EEE and may happen at any stage. Mucopurulent nasal and ocular discharges and abrasions/lacerations of the face and limbs are the most common non-neurologic findings; the latter occurs secondary to trauma from falling, seizures, or running into objects.

Mortality rates are 75% to 95% for EEE, 19% to 50% for WEE, and 19% to 83% for VEE.[4,6,17,32,38] Vaccination within the preceding year was associated with lower risk of death in horses with EEE.[27,29] Death is usually preceded by a period of recumbency during which the horse may be semicomatose and convulsing. Surviving horses gradually recover over a period of weeks. Many horses with WEE apparently recover completely, but it is estimated that two thirds of horses that survive EEE have residual signs of CNS damage such as central blindness, dullness, and diminished learning capacity or signs of cranial nerve dysfunction such as facial paralysis and head tilt.[16] Such horses are often referred to as "dummies."

Laboratory Findings Abnormalities seen in hemograms and plasma chemistry panels of horses with alphaviral encephalomyelitis are minor and nonspecific. Horses with EEE may have abnormal WBC counts and high fibrinogen concentration. In 73 horses with EEE admitted to the University of Florida, the following hematologic abnormalities were noted: leukocytosis (56%), neutrophilia (60%), hyperfibrinogenemia (57%), monocytosis (36%), lymphopenia (13%), leukopenia (7%), neutropenia (4%), and lymphocytosis (3%). Slight leukopenia was noted during experimental infections of horses with WEE and VEE viruses. Mild elevations in plasma enzyme activities of affected horses reflect organ damage secondary to anorexia, fever, stress, recumbency, and seizures. Hyponatremia is found in some horses with EEE; in humans with EEE, hyponatremia predicts mortality but its significance is unknown in horses.

The results of CSF analysis for horses with EEE are quite distinctive. More than 95% of horses with EEE admitted to the University of Florida had abnormal CSF cytology. Among UF patients, 88% of samples had high protein concentrations (mean of all samples: 139 mg/dL, range 38 to 526 mg/dL). Nucleated cell counts were high in 87% of samples (mean 248 μL, range 0 to 3100/μL; normal range 0 to 6/μL); pleocytosis is characterized by high neutrophil concentrations (mean 46%, range 0 to 97%). Neutrophils are typically nondegenerate. Protein concentration and nucleated cell counts are typically higher in samples obtained from the atlantooccipital (AO) site than they are in samples from lumbosacral taps. In the WEE outbreaks of 1930 to 1932, CSF nucleated cell counts were typically 12 to 30/μL and most cells were lymphocytes.[11]

Diagnosis A presumptive diagnosis is usually made clinically, especially in areas where these diseases are prevalent during the mosquito season. The finding in a CSF sample of moderate neutrophilic or lymphocytic pleocytosis further supports a diagnosis of alphaviral encephalomyelitis. Hemagglutination-inhibition (HI), complement fixation, fluorescent antibody, and virus neutralization tests have traditionally been used for serologic diagnosis.[16] The immunoglobulin M antibody capture (MAC) enzyme-linked immunosorbent assay (ELISA) is the method of choice for use in horses with viral encephalomyelitis because at titers of greater than 1 : 400 it can distinguish between vaccinal (IgG only) and viral infection–induced (IgM and IgG) titers.[33,39] These assays are available at many state diagnostic laboratories and also at the National Veterinary Services Laboratories (NVSL) in Ames, Iowa. In surviving horses, demonstration of a fourfold or greater rise in HI or plaque-reduction neutralizing titer between acute and convalescent samples provides additional diagnostic support. It should be noted that positive results in these tests could simply reflect *subclinical* infection with either virus. Virus can be isolated from fresh or frozen brain in tissue culture or mice and can be detected in histologic sections by immunohistochemistry or polymerase chain reaction (PCR) techniques.[40]

Differential diagnoses include hepatoencephalopathy; gastrointestinal hyperammonemia; heavy metal or other toxicosis; rabies; other viral encephalomyelitis (West Nile, Borna disease, equine herpesvirus myeloencephalopathy [EHM], Aujeszky disease, louping ill); equine protozoal myeloencephalitis (EPM); trypanosomal (South America), verminous, or bacterial meningoencephalomyelitis; space-occupying lesion within the calvarium (e.g., cholesterol granuloma, neoplasia, brain abscess); brain infarct; brain trauma; and leukoencephalomalacia.

Treatment Treatment is largely supportive and, in the case of EEE, usually ineffective. Any adult horse with EEE that is unable to stand should be euthanized. Such horses should not be subjected to slinging. Hyperthermia is known to exacerbate brain injury and must be treated vigorously with cold water or alcohol baths until rectal temperature is less than 102° F. Convulsions can be

VetBooks.ir

controlled with diazepam, xylazine, or barbiturates (pentobarbital or phenobarbital).

In addition to excellent general nursing care, all horses should be treated for brain edema and inflammation, although only horses whose signs are mainly cerebral are likely to respond. Drugs used for this purpose include dimethyl sulfoxide (DMSO), 1 g/kg as a 10% solution intravenously (IV) or intragastric, flunixin meglumine (or equivalent nonsteroidal antiinflammatory drug [NSAID]) intramuscularly (IM), IV, or orally (PO) at 1.1 mg/kg q12h for 3 days, dexamethasone (or equivalent corticosteroid) IM or IV at 0.05 to 0.1 mg/kg daily for several days for 3 days then tapered, and mannitol (IV at 0.25 to 1 g/kg as a 20% solution) or hypertonic saline (e.g., 7.2% saline IV at 2 mL/kg 4 to 6 times during the first day). A lengthy course of dexamethasone is believed anecdotally to be an important determinant of neurologic recovery in surviving cases. Treatment should be titrated to minimize neurologic signs but generally must be tapered over several weeks. Complete recovery, if it occurs, may take several months.

Treatment with serum from horses hyperimmunized against WEE virus was thought to reduce mortality modestly during the 1930 to 1932 outbreak; however, these claims were not tested scientifically.[4] Furthermore, administration of large quantities of hyperimmune serum to experimentally infected horses by investigators at Lederle Laboratories was reported to have no beneficial effect.[41]

Adjuvant antiviral therapy with interferon (IFN) α or β has salutary effects in some experimental models of alphaviral encephalitis[42] and could be tried in valuable horses. A reasonable protocol is described in the West Nile encephalitis section. The nucleoside analogue ribavirin boosts the antiviral activity of IFN in vitro against encephalitic alphaviruses[43] and holds some potential as future therapy for EEE in humans and perhaps horses.

Public Health Significance All three viruses infect humans causing subclinical, febrile, or neurologic disease.[6] Since 1964, there have been 640 cases of human WEE reported in the United States, with an average of 27 cases/year in the period up to 1987. Since 1988, there have only been five cases of WEE reported. By contrast, the 268 cases of EEE in humans reported in the United States since 1964 have occurred at a fairly steady rate of 6 cases/year. Epidemics of VEE are closely associated with equine epizootics; thus during the 1962 to 1964 epizootic in central Colombia, which killed about 100,000 horses, 200,000 humans were infected, of whom 0.5% died. Although nonpathogenic for horses, the enzootic Everglades subtype II strain has caused human encephalitis in Florida. No cases of human disease were recorded during the VEE subtype IE equine epizootics in Mexico in 1993 and 1996, and South American strains of EEE are not known to cause encephalitis in humans. Short-term mortality rates of EEE, WEE, and VEE in humans are 74%, 4%, and less than 1%, respectively. Most survivors of EEE suffer long-term neurologic impairment.

Postmortem Findings There is congestion of most organs and a slate-gray discoloration, often with petechial hemorrhage, of the brain and spinal cord, especially obvious on section of formalin-fixed tissue.[40,44,45] Often there is brain swelling and evidence of occipital subtentorial herniation, with brainstem compression. Histologically, there is evidence of acute to subacute and multifocal to diffuse meningoencephalomyelitis. There is predominant involvement of gray matter, with diffuse neuronal degeneration, gliosis, perivascular and neuroparenchymal infiltrates, and meningitis. Neutrophils are prominent in acute EEE, whereas lymphocytes predominate in older lesions. On occasion, eosinophils may predominate in EEE. Lymphocytes are usually the primary inflammatory cell in WEE lesions.[44] Previous therapy with potent antiinflammatory agents, particularly corticosteroids, may suppress the inflammatory-cell infiltrates, which then appear mild.

Bronchopneumonia is found in about 20% of fatal cases of EEE, probably secondary to pharyngeal paresis and aspiration of particulate material. Up to 10% of horses with EEE have histologic evidence of myocardial necrosis, likely a sign of brain-heart syndrome.[45]

Because high infection rates in humans have been documented following exposure to aerosols from infected laboratory animals or from laboratory accidents (or, potentially, equine carcasses), necropsies of horses with suspected VEE should only be performed by personnel who possess demonstrable immunity in the form of neutralizing antibody.[46] All laboratory manipulations must be carried out within certified biological safety cabinets following containment level 3 procedures.

Control Active immunization through use of formalinized vaccines began in 1934 and is still the only commercial method of immunization of horses against EEE and WEE. These inactivated vaccines are also used routinely to protect ratites from EEE and WEE and South American camelids from EEE.[47] The attenuated, tissue-culture-origin vaccine, TC-83, derived from a Trinidad VEE virus isolate, which was originally developed to protect military personnel, provides durable immunity against VEE and was effective in minimizing the incursion of VEE into the United States in 1971[20] and in limiting the 1993 and 1996 outbreaks in Mexico. Although TC-83 is no longer licensed for use in horses in the United States, a formalin-inactivated vaccine containing the TC-83 vaccine strain is available and is often included with EEE and WEE in trivalent products.[48] For any of the formalin-inactivated alphavirus vaccines, adult horses should be given an initial two inoculations 4 to 6 weeks apart at least a month before the anticipated risk period or before the onset of vector mosquito activity and then revaccinated at intervals reflecting the likely risk. Vaccination should begin in January or February in Florida to May or June in parts of Canada and the northern United States. Clinical evidence suggests less than 6 months of protection following vaccination against EEE or WEE, so revaccination at least once during the mosquito season is necessary in areas with warm climates and long mosquito seasons. Vaccinated mares should receive a booster dose 4 to 6 weeks before foaling to provide colostral antibody for newborn foals.

Foals should be given an initial inoculation at 4 to 6 months (vaccinated mare) or 3 to 4 months (unvaccinated mare), then a second inoculation 4 to 6 weeks later and a booster at 10 to 12 months of age. AAEP guidelines for 2012 recommend that foals of vaccinated dams in high-risk areas should be given a primary series of four doses beginning at 2 to 3 months of age. Two additional inoculations are then given at approximately 4-week intervals and a booster at 10 to 12 months of age, before the onset of mosquito season. It will be important to validate this method of vaccination because of concerns that early frequent vaccinations may suppress immune responses to EEE.[49] Until this issue has been resolved, the author will continue to recommend that the initial inoculation be given to foals in high-risk areas no earlier than 4 months of age (as for foals in moderate-risk areas).

Routine surveillance of the virus pool by serum antibody testing of sentinel chickens and virus detection in trapped mosquitoes by health authorities often provides early warning of an impending outbreak and allows time for vaccination of susceptible horses. General mosquito control (removal of standing water, spraying by local authorities) will reduce risk of EEE and VEE in horses.[27] Because of the role of horses in amplification and transmission of VEE virus, quarantine of infected and exposed horses with area-wide and international restrictions on horse movement is an integral part of the management of VEE epizootics.[50]

Miscellaneous and Foreign Emerging Viruses Causing Neurologic Signs

Robert J. MacKay

Since the encroachment of West Nile virus (WNV) in 1999 into North America, the potential for emerging foreign disease with widespread impact has been realized. Given the opportunity, many other

VetBooks.ir

viral infections could become established in new countries as a result of the globalization of the horse industries and effects of global warming.

Getah/Ross River Viruses

The Semliki Forest complex of the Togaviridae are widespread throughout their geographic range, either in the Orient (Getah) or South Pacific (Ross River).[1,2] Although closely related, there is little geographic overlap among these viruses. As with the North American alphaviruses, these viruses are transmitted by mosquitoes (*Aedes, Anopheles,* and *Culex* spp.).[3-6] The reservoir for Getah virus (GV) is not known, although swine appear important in its transmission to mosquitoes.[6,7] Other feral species are not firmly established. For Ross River virus (RRV), marsupials are important reservoirs.[8] With GV, horses might develop sufficiently high viremia to transmit virus, but this is unlikely with RRV. Many animals have been found to be seropositive to GV, including ruminants, and seroprevalence in horses varies from less than 10% to more than 90%.[6,9-11] RRV is endemic in horses and widespread, with seroprevalence ranging from 50% to 80% in Australian horses.[1,12-14] With the recent increase in Kunjin/West Nile encephalitis in Australia, RRV has become an important differential diagnosis for horses with neurologic disease and is usually included in serologic and PCR testing of diagnostic samples.

Getah virus is likely more pathogenic in horses than RRV.[9,11,15] Clinical signs include pyrexia, edema of the limbs, and stiff gait. Horses may also develop urticaria and submandibular lymphadenopathy. The course of GV disease is 7 to 10 days. With RRV, horses also develop fever, lameness, swollen joints, inappetence, generalized stiffness, and even colic.[1,12,14] High rates of mortality are not a feature of either virus.

Serologic detection of IgM is the mainstay of diagnosis of these viruses, although a vaccine against GV complicates diagnosis.[16,17] RRV can be detected by PCR and isolated from the blood of horses during the disease course.[18] Pathologic changes associated with these viruses are seldom described because of the low mortality of associated diseases. Horses primarily develop perivascular inflammation in the brain.

Treatment is supportive; no antiviral is specific for alphaviruses. A vaccine for GV is available in Japan. An inactivated vaccine against RRV for humans is being tested in Australia, but no equine vaccine is available.[19]

Borna Disease

Classical Borna disease (cBD) is a viral encephalitis principally of horses and sheep that was first recognized in southwestern Germany in the 18th century but is associated with the village of Borna in the Kingdom of Saxony, where the disease emerged in the late 19th century. It is estimated that approximately 16,000 horses died annually in Saxony from 1896 to 1940.[20] These numbers declined rapidly in the 1960s in parallel with declining horse numbers, and only 1216 horses died of cBD in Saxony from 1958 to 1991.[20] Outbreaks of cBD have been restricted to central Europe in the upper Rhine valley around Switzerland, Austria, and Liechtenstein. Borna disease virus (BDV)-associated encephalitis has also been reported in cattle, an alpaca, deer, zoo herbivores, cats, rabbits, and dogs.[21] During recent decades, evidence of BDV infection including antibodies, antigen, RNA, or the virus itself has been reported in many countries and in numerous mammalian species including humans. There is serologic evidence of BDV infection in horses in the United States.[22,23] Some of these reports are questionable because of problems with contamination of samples by laboratory BDV strains and poorly validated immunoassays; however, there are enough well documented infections to confirm widespread distribution of BDV or BDV-like virus.[21] The possibility of involvement of BDV in several human neuropsychiatric diseases has raised interest in BDV but remains controversial.

The etiologic agent of Borna disease is a nonsegmented, negative-sense, single-stranded RNA virus of the order Mononegavirales, family Bornaviridae. Although regional genetic variation occurs, the BDV genome is considered remarkably stable for an RNA virus. Related viruses, termed *avian Borna viruses* (ABVs), have been discovered in birds, and endogenized BDV sequences are common in the genomes of mammals. The significance of this last intriguing finding is unknown.

Most outbreaks in horses and sheep occur during the spring and early summer. Although horse-to-horse transmission is theoretically possible, it is unimportant in the evolution of an outbreak.[21] The virus is likely maintained in small mammals with geographic ranges approximating the endemic Borna disease area. Bank voles, bicolored white-toothed shrews, and bats have been suggested as possible reservoir hosts.[24] BDV is shed through nasal and lacrimal secretions and in the urine of infected animals.[21,25] BDV is resistant to drying and other adverse environmental conditions. It is assumed that BDV enters the horse though intranasal infection and migrates to the brain transaxonally.[26] Direct replication occurs in neurons and glial cells, with centrifugal spread to peripheral nerves and retina. BDV infection of the retina may contribute to the blindness that characterizes acute Borna disease in horses.[27] Subclinical BDV infection is common with seroprevalence of horses in endemic areas of 10% and 20%, and as high as 50% among stablemates of horses with Borna disease. The neurologic signs of Borna disease are associated with the florid cell-mediated initial immune response to the virus. In subclinically infected horses and horses that recover from Borna disease, the virus becomes quiescent and largely undetected by the immune system.

The clinical signs of Borna disease in large animals are similar to those of the other equine encephalitides. The incubation period is thought to be about 2 months in naturally occurring cases. There is a predominance of forebrain signs initially, followed by signs of brainstem and spinal cord involvement. In moderate to severe cases, horse die 1 to 4 weeks after onset of disease. In mild cases, recovery can occur, but persistent abnormalities and exacerbations are common. There is a prodrome characterized by fever, inappetence, colic, and vague behavioral changes. The onset of neurologic signs is marked by changes in mentation with alternating hyperresponsiveness and stupor; compulsive walking, often in circles; teeth-grinding; and aggression. Other signs of brain disease include trismus, pupil constriction, nystagmus, head tilt, and blindness. With progression, there is ataxia and weakness of the limbs and trunk and areas of cutaneous desensitization or hyperesthesia. Collapse into recumbency and seizures are the final stages. The mortality rate is about 80% in horses and 50% in sheep.

For antemortem diagnosis, antibodies to the agent may be found in the serum and CSF of most infected animals by ELISA, indirect fluorescent antibody (IFA), and Western blot.[24] CSF analysis often reveals mononuclear pleocytosis and high protein concentration. Reverse transcriptase nested PCR techniques have demonstrated virus in the CSF and peripheral mononuclear cells.[28] The criteria for diagnosis include a horse with neurologic abnormalities testing antibody positive for BDV in serum or CSF or a horse with neurologic signs and appropriate histopathologic changes.

Pathologic abnormalities resemble those of a viral encephalomyelitis, and confirmatory diagnosis is by immunohistochemistry, virus isolation, and detection of viral nucleic acids.[21,24,29-33] The characteristic microscopic lesion of Borna disease is the Joest-Degen inclusion body in the neuronal nucleus, but this is not always observed. Virus is detectable easily with monoclonal or polyclonal antibodies. Histopathologic changes are those of a typical polioencephalomyelitis, with a particular loss of neurons in the hippocampus. There is involvement of the gray matter of the olfactory bulb, basal cortex, caudate nucleus, thalamus, hippocampus, and medulla oblongata.

No antiviral agents are available for BDV, and use of the amantadine sulfate (developed for treatment of influenza infection) is controversial but commonly used.[34,35] Likewise, vaccination as a protective strategy is controversial. It is widely assumed that a modified live vaccine would offer more protection; however, the live vaccine available until the early 1990s in East Germany was removed from the market because of questionable efficacy.

VetBooks.ir

Henipavirus

Hendra virus (HeV) infection of horses was first recognized in 1994 during simultaneous outbreaks of severe respiratory disease in Queensland, Australia: one in the Hendra suburb of Brisbane and the other near the town of Mackay. Mortality was high among the 22 affected horses and each outbreak was associated with transmission to humans, 2 out of 3 of whom died.[36-38] Since 1994, there have been at least 33 outbreaks of HeV infection in horses, all in Queensland or northern New South Wales. Cases have occurred every year since 2006, and there were 11 outbreaks involving 23 horses in 2011. Five outbreaks also involved seven human cases, of which four were fatal. Signs of neurologic disease were seen in some horses during the initial outbreaks, and neurologic signs dominated the clinical presentation in five horses in an unusual outbreak at an equine referral practice in the Redlands suburb of Brisbane in 2008. The signs were those of fulminant febrile encephalitis with severe obtundation, dementia, vestibular signs, and progressive ataxia. Nipah virus (NiV) emerged as the cause of porcine respiratory and encephalitis syndrome in Malaya in 1998.[38-40] Signs were predominantly respiratory, and most affected pigs recovered. NiV also caused severe febrile encephalitic illness among workers in contact with infected pigs; 105/265 affected people died. NiV has also been recovered from the brain of a horse with encephalitis.

HeV replicates initially in the respiratory epithelium before spreading hematogenously to multiple organs, including the CNS, to cause widespread vasculitis, endothelia syncytia, vascular thrombosis and hemorrhage, and cellular necrosis.

HeV and NiV are closely related viruses that occupy a new genus, *Henipavirus,* of the family Paramyxoviridae. They are enveloped, single-stranded, negative-sense RNA viruses. The henipaviruses are highly pathogenic for a wide range of mammals including horses, pigs, and humans. The natural reservoirs throughout the geographic range in Northern Australia, Malaysia, and Bangladesh are fruit bats from the genus *Pteropus* (also known as flying foxes).[41] Transmission from bats in each spillover event is likely via contact of the horse with urine or reproductive fluids from infected bats. Horses incubating HeV are infectious to other horses for at least 48 hours before the onset of clinical signs, and at least two outbreaks in stables were caused by introduction of preclinical horses incubating the virus.

Diagnosis is made both by detection of serum neutralizing antibodies by immunoassay and detection of RNA by quantitative reverse transcriptase PCR in blood, other body fluids, or from tissues taken at necropsy.[40,42,43] Virus is secreted in all body fluids and feces of infected horses, and appropriate precautions must be taken to prevent transfer to other horses and humans. Guidelines for biosecurity have been developed by the Australian Veterinary Association (available at http://www.ava.com.au) and by Biosecurity Queensland (http://www.biosecurity.qld.gov.au).

Infected horses are euthanized as a matter of public health. Ribavirin is used with partial success to treat NiV and HeV infections of humans, and a monoclonal antibody (mAb m102.4) has been shown to be protective in experimental animals if given before clinical signs and has been used in several exposed humans.[44] An HeV subunit vaccine (HeV-sG) has been tested successfully in multiple species including horses against both HeV and NiV challenge and was launched commercially in Australia in 2013 for vaccination of horses in endemic areas (EquiVac HeV, Pfizer Animal Health).[44]

California Serogroup Viruses

The Bunyaviridae are mostly arboviruses and are found worldwide. These viruses are usually maintained in mosquito-vertebrate host-mosquito cycles with midges acting as the arthropod hosts for a few viruses.[45] Twelve serotypes, known collectively as the *California serogroup,* have been isolated in North America, South America, Africa, Europe, and Asia. In rare cases, these viruses can cause acute encephalitis in horses. Snowshoe hare virus and Main Drain virus have been associated with encephalitis in horses,[46,47] and serologic evidence of subclinical infections of horses with Jamestown Canyon virus and Cache Valley virus was found in horses in southern California and Michigan, respectively.[48,49] Clinical signs in a horse from which Main Drain virus was isolated included ataxia, weakness, stiff neck, head pressing, dysphagia, tachycardia, and fever.[47]

Equine Encephalosis

Equine encephalosis is an arthropod-borne viral infection, affecting all species of equids, usually characterized by mild or subclinical infection but occasionally causing severe clinical disease.[50] The causal agent, equine encephalosis virus (EEV), is transmitted through the bites of certain *Culicoides* spp. biting midges. EEV is an orbivirus, as are African Horse Sickness virus (AHSV) and bluetongue virus (BTV). All equids (horses, donkeys, zebras) are susceptible to EEV, although donkeys and zebras are thought to be resistant to the clinical disease. The infection is endemic in southern Africa where seven EEV serotypes have been identified.[51] An outbreak of febrile disease due to EEV in Israel in 2008-2009 involved 60 horses, and serologic evidence of the infection has since been found in several other areas outside southern Africa.[52,53]

The virus was originally named for isolation from a horse with typical signs of encephalitis including mild to severe ataxia, reluctance to walk and stiffness, dementia, and seizures.[50] In its current forms, infections are either subclinical or associated with an influenza-like syndrome of fever, edema, tachycardia, tachypnea, and congested mucosae. An AHSV-like syndrome of respiratory distress and cardiac failure has been described, and pregnant horses may abort. A competitive ELISA for detection of group-specific antibody to EEV has been described for use in diagnosis.[54] There is no recognized treatment or method of prevention for EE.

West Nile and Other Flavivirus Encephalitis

Robert J. MacKay

The causative agent of West Nile encephalitis (WNE) is a small, positive-sense, single-stranded, enveloped RNA virus.[1] West Nile virus (WNV) is a member of the Japanese B encephalitis (JE) antigenic complex of neuroinvasive arboviruses within the genus *Flavivirus,* family Togaviridae.[1] In addition to WNE virus, Kunjin, JE, and Murray Valley encephalitis (MVE) viruses are members of the JE antigenic complex that have caused encephalomyelitis in horses outside the United States. There are two main genetic lineages of West Nile encephalitis virus: Outbreaks of neuroinvasive disease in horses and humans have traditionally been associated with lineage-1 isolates that circulate among Mediterranean basin, West African, and northern European countries. A virus of this lineage is responsible for the North American epizootic. Lineage-2 isolates are widespread in sub-Saharan Africa and commonly have infected horses without apparent clinical effect. In the past few years there have been several cases and even outbreaks of neurovirulent equine and human disease caused by Lineage-2 WNV in Africa and Europe.[2,3] The Kunjin virus is a lineage-1 WNE virus that traditionally has caused mostly subclinical or febrile non-neurologic disease in horses and humans in northwestern Australia and Papua New Guinea. A neurovirulent strain of Kunjin virus emerged in 2011 in New South Wales in Australia in the late summer and fall and caused encephalitis in at least 1000 horses in southeastern states with a mortality rate of 10% to 15%.[4-6] This unprecedented epizootic of Kunjin encephalitis (and also of encephalitis due to the arboviruses Ross River virus and Murray Valley encephalitis virus) followed unusually high spring rainfalls in southeastern Australia.[6] Compared with prototypic Kunjin virus (WNV_{KUN}), the neurovirulent strain ($WNV_{NSW2011}$) has acquired at least two of the known virulence markers of the North American strain. There was also a sharp increase in Murray Valley encephalitis cases in horses as part of the 2011 arboviral encephalitis epizootic.[6] Since the last MVE epizootic in 1974, cases had been reported only sporadically.[7] Japanese B encephalitis virus is endemic in east Asia and southeast Asia and has made incursions into the northern tip of

VetBooks.ir

Australia.[8] It is maintained in cycles among porcine and avian reservoirs using mosquito vector hosts. Humans and horses are dead-end hosts. Cases of encephalitis in horses are seen sporadically throughout the virus's range, and effective vaccines are available.[1] Although there is minimal overlap between the ranges of WNV and JEV, diagnostic serology may yield confusing results in areas where both diseases (and vaccinations) do occur. Louping ill virus and Powassan virus are tick-borne flaviviruses that have the potential to cause encephalitis in horses.[4]

History and Distribution WNV was originally isolated from the blood of a febrile adult woman in the West Nile region of Uganda in 1937. Cases of encephalitis in humans were first recorded in Israel in the 1950s and in horses between 1960 and 1965 in Egypt and France.[9,10] Since 1996 there have been small localized outbreaks of equine WNE in numerous countries in the Mediterranean basin and northern Europe with repeated seasonal epizootics in the Camargue marshlands of France and in the Tuscany region of Italy.[11,12] Although the virus usually did not persist in these locations after equine or human disease waned, there is recent evidence for overwintering of WNV in the Tuscany region of Italy.[12]

In August 1999, the first case of WNE in humans was reported in Queens, New York.[13] Characterization of the virus from this outbreak showed it was highly homologous with Israel 1998 (Is98), a strain of WNV that had originally been isolated from a goose.[14] Eventually, 62 cases occurred in humans in1999 and 7 died. From August to October 1999, 25 horses on Long Island were diagnosed with WNE.[15] Nine of these horses died. Deaths occurred in numerous native bird species, particularly in corvids (crows, ravens, jays) and in exotic species housed at the Bronx zoo. In 2001 the disease became a national epizootic with cases seen for the first time in Florida, Kentucky, Louisiana, Georgia, Alabama, Illinois, Indiana, Mississippi, New Hampshire, North Carolina, Tennessee, and Virginia.[16] There were 738 cases reported nationally, of which 33.2% died or were euthanized. Despite the availability of an effective vaccine from August 2001 onward, there was a dramatic westward spread of WNE in 2002, with 15,257 horses affected in 40 states.[16] The national incidence of the disease in horses declined in 2003 to 5181 cases in 44 states. By 2006 equine cases had been reported from all 48 contiguous states. Total annual cases dropped below 1000 in 2007, and only 79 were reported in 2011. In 2012 there was an upswing in WNE in all parts of the country with 618 total cases, of which 116 were in Texas.[16] The human epidemic dramatically expanded in 2012 with a provisional total of 2734 cases of neuroinvasive disease, second only to the 2866 cases recorded in 2003. This alarming upswing in cases may be explained, at least partially, by the unusually mild winter, early spring, severe drought, and high mean temperatures of 2012.

Natural History

WNV cycles between mosquito vectors and avian reservoir hosts. In temperate climates, the virus overwinters by vertical (transovarial) transmission in vector mosquitoes and possibly by latent infection of avian hosts.[1] *Culex*-species mosquitoes are the most important vectors for the North American epizootic in birds. Different species transmit the virus in different parts of the country. Major vector species include *Culex pipiens* in the northeast and central United States, *Culex tarsalis* from the far west to the panhandle of Texas, and *Culex quinquefasciatus* in the southeastern United States from Texas to Florida. Although birds of more than 300 species have been reported WNV positive, passeriform (true perching bird) and charadriiform (shorebird) species are considered the most competent reservoir hosts for WNV in the United States. Corvid species such as crows and blue jays are efficient hosts but have suffered high mortality during the North American epizootic. The house sparrow (an Old World passerine species) also develops high-titer viremia after WNV infection but is relatively resistant to the adverse effects of the virus. A variety of domestic mammals including sheep, alpacas, and dogs have suffered fatal WNE during the North American epizootic. Horses, humans, and other mammals are "dead-end" hosts and do not amplify the virus in quantities sufficient to infect mosquitoes. In contrast, alligators experience high-titer viremia and may be important reservoirs for infection in the southeastern states.

"Bridge vector" species of mosquito transmit the virus from birds to mammals, including horses. The mosquito species important for bird-horse transmission are not known with certainty but may include members of *C. pipiens* complex, *C. tarsalis,* and *Culex salinarus*.

The occurrence of WNE reflects vector mosquito activity, which is seasonal in temperate zones and year-round in tropical and subtropical regions. Significant viral activity begins in July, with peak incidence in September and October. The epizootic usually declines rapidly after the first frost.

Clinical Signs Experimental infections of horses result in viremia 3 to 5 days after viral inoculation into the CSF and clinical signs beginning at 7 to 10 days.[1] Experience during clinical outbreaks indicates a similar 1- to 2-week incubation period before signs of WNE are seen.

Clinical signs have been extremely varied; however, surveys of cases published across the United States and from Europe have revealed some consistent combinations of signs.[9,12,15,17-20] Roughly a quarter of affected horses have had mild to moderate fever at the time of initial examination, although it is likely that most were febrile before examination. Consensus neurologic signs seen have included limb ataxia (71% of 726 cases from the northeastern United States, Florida, Indiana, Nebraska, and Colorado[9,12,15,17-20]), limb weakness (58%), muzzle twitching (45%), obtundation (43%), recumbency (31%), lip droop (22%), hyperresponsiveness/hyperesthesia (18%), teeth-grinding (12%), dog-sitting (10%), thoracic limb collapse (7%), compulsive walking (7%), muscle atrophy (6%), seizure (4%), blindness (4%), circling (4%), and head pressing (3%). Clinical signs reflect the reported predominance of lesions in the gray matter of the hindbrain and spinal cord of horses with WNE with lesser involvement of the rostral brainstem and forebrain.[21]

The observation of coarse twitching of the muzzle (and to a lesser extent the eyelids) is a particularly distinctive finding in acute cases of WNE. Less frequently, there are fine fasciculations of the cutaneous muscles of the torso and neck. Horses acutely affected may be frantic, fearful, and hyperresponsive to stimuli. This stage is transient (usually <1 day in duration) and typically is the only behavioral change seen. Mild obtundation is common at initial presentation and progresses to stupor with narcoleptic episodes in horses with severe midbrain or hindbrain involvement. In addition, such cases often have facial and/or tongue paralysis or vestibular signs of head tilt and body lean. Ataxia and weakness of the trunk and limbs occur with or without signs of brain disease and may present asymmetrically. Such presentations are clinically indistinguishable from those of horses with equine protozoal myeloencephalitis. Because of the predilection of WNV for involvement of gray matter in thoracic spinal cord segments, horses may present with the unusual combination of acute-onset bilateral thoracic limb weakness/collapse and normal pelvic limb strength (Fig. 35-4). Severely affected horses are often unable to roll from lateral to sternal recumbency and tend to lie quietly without much voluntary activity. Comparable presentations in human patients with paralytic forms of WNE are described as "polio-like."[22] With time, muscles of the thoracic girdle can become severely atrophied and such horses are rendered permanently unable to move from lateral to sternal recumbency even though they may be able to walk once assisted to stand. The convalescent stage of WNE is described later in the Treatment section.

Published mortality rates during the U.S. epizootic have ranged from 22% to 44%. For 2326 reported cases from across the United States, including national statistics for the years 1999 to 2001, the overall mortality rate was 31%. Surprisingly, death rates have been relatively high (43%) for the 1050 cases reported from California during 2004 to 2006. A history of no or incomplete vaccination, persistent recumbency or difficulty standing, paresis of pelvic limbs, and facial or tongue paralysis was associated with poor outcome, and

VetBooks.ir

FIG. 35-4 West Nile encephalomyelitis in a 3-year-old Thoroughbred gelding with involvement of the gray matter of the spinal cord supplying the thoracic limbs. During the first 5 days after onset, the gelding frequently buckled in its thoracic limbs and collapsed into this position for several minutes before regaining his feet. Pelvic limb strength was normal.

mortality rose with increasing age greater than 5 years.[17,18,20] In one study, females were 2.9 times more likely to die than were males.[18]

Laboratory Findings Abnormalities found in hemograms and serum/plasma chemistry results are usually mild and nonspecific. Of 46 horses admitted to the University of Florida (UF) with acute WNE, the most common abnormalities were lymphopenia (23%), hyperbilirubinemia (72%), and high plasma creatinine concentration (8%).[17] Hypokalemia, hyponatremia, and hypochloremia were also commonly seen, as were high muscle enzyme activities secondary to trauma and prolonged recumbency.

Most affected horses have CSF pleocytosis. Of 30 samples collected in the University of Florida series, 22 (73%) were abnormal on the basis of high nucleated cell count and/or protein concentration.[23] Mild xanthochromia was also commonly seen. Mononuclear pleocytosis was found in 16 (53%), and high protein concentrations with normal nucleated cell counts were found in the other 6. Nucleated cell counts in abnormal samples ranged from 0 to 882 cells/μL (median 14 cells/μL), and protein concentrations ranged from 64 to 316 mg/dL (median 100 mg/dL). Cells were predominantly lymphocytes or macrophages with occasional neutrophils. Of 14 samples with pleocytosis (nucleated cell count >6 cells/μL) without significant red blood cell (RBC) contamination, neutrophil percentage ranged from 0 to 8% (median 2.5%) (Wamsley HL, personal communication, 2007). Interestingly, nucleated cell counts and protein concentrations were significantly higher in lumbosacral samples than in atlantooccipital samples.[23] The CSF analysis has not correlated well with the severity of the clinical presentation.

Diagnosis A presumptive diagnosis is often made clinically, especially in areas where the disease or virus is currently active. Diagnostic confidence is increased by the observation of muzzle twitching. The finding in a CSF sample of mild to moderate mononuclear pleocytosis with low numbers of neutrophils further supports a diagnosis of WNE. In a horse with signs of encephalomyelitis, presumptive diagnosis requires a positive serum MAC (IgM antibody capture)-ELISA test. Single-point assays of anti-WNV IgG such as the plaque-reduction neutralization test are not particularly useful because titers can be affected by prior vaccination; however, demonstration of a fourfold or greater rise in titer between acute and convalescent samples is supportive of the diagnosis in unvaccinated horses. It must be emphasized that serum antibody tests are diagnostic only of WNV infection, not WNE. For every case of WNE, approximately nine horses undergo non-neurologic or subclinical WNV infections.[1] The finding of WNV-specific IgM in CSF increases the specificity for WNE of a positive result.

At necropsy, polymerase chain reaction, immunohistochemical, and viral isolation methods are used to demonstrate presence of viral components in the CNS,[1] although immunohistochemistry for WNV is much less sensitive than it is for EEE.

Differential diagnoses for WNE in horses include alphaviral encephalomyelitis (eastern equine encephalitis, western equine encephalitis), rabies, verminous or bacterial meningoencephalomyelitis, equine protozoal myeloencephalitis, brain or spinal cord trauma, cervical stenotic vertebral myelopathy, hepatic encephalopathy, or compressive mass in the calvarium or vertebral canal.

Treatment There is no readily available antiviral treatment for horses with WNE. Ribavirin, a drug used to treat hepatitis C in humans, is effective against WNV in tissue culture, but its use has not yet been extensively evaluated in human patients with WNE. Type I interferons (i.e., interferon α or β) or interferon inducers stimulate nonselective cellular resistance to viral infection and are used for prevention or treatment of viral diseases. The limited data so far reported for the use of interferon in humans with WNE do not suggest any positive effect on outcome, although there is some anecdotal evidence to support this approach in horses. A reasonable dosage is 3 to 15×10^6 international units (IU) interferon β_{1a} IM or IV (Avonex 30 μg; Biogen IDEC, Cambridge, Mass.) given three times weekly. The concept of therapy with WNV-specific globulin is supported by findings in a guinea pig model of WNE, although no controlled studies of its use have been reported for horses. In a limited series of cases, there was a trend for less recumbency in horses given a hyperimmune globulin product but there was no significant effect on severity of clinical signs or mortality.[1] Several commercial products of this type are available for horses in the United States. These products are given slowly intravenously according to label instructions.

Supportive care is of paramount importance. Secure footing, deep dry bedding, protective covering of distal limbs and bony prominences, climate control, and provision of ample food and water are important in all cases. In recumbent horses, regular repositioning of the horse from one side to the other and attention to decubital injuries are essential. Early and systematic use of slinging is helpful in some otherwise recumbent horses. The Davis-Anderson sling, which transfers some of the horse's weight onto the upper limbs, is likely more effective in WNE horses than slings that rely entirely on torso support. In one series of 12 horses with prolonged recumbency that were treated by slinging, 2 were able to stand unassisted after slinging and 2 were able to stand after slinging was discontinued.[18] In horses that have long-term difficulty in rising to the standing position, semipermanent mobile slinging systems have been devised and marketed. These slings are stocklike frames that have wheels on each corner and webbing that rides under and supports the horse's torso.

Nonsteroidal and other antiinflammatory drugs are typically used empirically in horses with WNE to control local pain, inflammation, and fever. Flunixin, 1.1 mg/kg IV or PO (bid in U.S., sid in Europe); DMSO, 0.25 to 1 g/kg in a 10% solution IV or intragastrically bid; vitamin E, 20 IU/kg PO q24h; and pentoxifylline, 10 mg/kg PO bid are drugs commonly used for this purpose. The use of corticosteroids is controversial. Because there is at least a theoretical concern about recrudescence of WNV infection and clinical relapse in recovering immunosuppressed horses, corticosteroids should only be used in horses that are recumbent or in imminent danger of becoming so. A typical dosage regimen is dexamethasone 0.05 to 0.1 mg/kg IV or 0.1 to 0.2 mg/kg PO once or twice daily for 1 to 3 days. Affected horses are often treated for presumptive EPM with antiprotozoal drugs (e.g., ponazuril, 5 mg/kg PO q24h) until MAC-ELISA results become available.

Recovery, when it occurs, takes from 1 day to several months (mean of 22.3 days for 271 horses recovered from WNE in Nebraska and Colorado[18] and 10.7 days for 569 horses in North Dakota[20]) and is not always complete. Of 125 predominantly pleasure horses in Minnesota that survived WNE, 22 (17.6%) were classified by their owners as incompletely recovered 6 months after diagnosis.[24] Gait abnormalities, behavioral changes, muscle atrophy, and lethargy were among the residual abnormalities reported by the horses' owners. An

VetBooks.ir

additional 29 horses (23.2%) were considered fully recovered with residual deficits. A surprisingly high 9% of horses suffered some form of relapse of clinical signs 2 weeks to 5 months after diagnosis.

Necropsy Findings Gross abnormalities of the CNS in horses with WNE are limited to meningeal congestion and hemorrhagic foci in the brain and spinal cord. Histologically, there is mild to severe multifocal lymphocytic polioencephalomyelitis with predilection for the ventral and lateral horns of the thoracolumbar spinal cord.[25] In the brain there is lymphocytic perivascular cuffing and microgliosis in the medulla oblongata and pons and, to a lesser extent, in the basal nuclei, thalamus, and mesencephalon. In severe cases, there is evidence of neuronal degeneration characterized by central chromatolysis, cytoplasmic swelling, or cell shrinkage. The cerebral and cerebellar cortices usually are relatively free of lesions.

Control General mosquito control is important at the individual operation level. Local authorities may undertake area-wide mosquito abatement when sentinel chicken serology or viral isolations from wild birds suggest high local WNV activity.

A killed virus vaccine has been available since August 1, 2001, and has had full U.S. Food and Drug Administration approval since 2003. This vaccine is effective beginning about 2 weeks after the second dose of the initial series, but antibody levels drop substantially by 4 months after vaccination. Since then, two additional vaccine types have become available: a recombinant modified-live vaccine in a pigeon pox virus vector and a live chimera virus vaccine based on an attenuated yellow fever virus backbone. Two inactivated vaccines are now available in combinations with alphaviral encephalitis and tetanus vaccines. The live chimera vaccine was withdrawn in 2010 for safety reasons and an inactivated version is now offered. For all products the primary series or booster vaccination is completed at least 1 month before anticipated WNV activity, and boosters are given once or more annually, depending on the length of the vector season. Various challenge models have been used for each of these vaccines (except the killed version of the chimera vaccine) to demonstrate early protection against encephalitis and continuing protection against infection 12 months after a primary vaccination series. Foals of vaccinated mares should begin vaccination at 4 to 6 months of age and should have been given three inoculations by 12 months of age. Boosters should be given at least annually and more often in high-risk areas. Vaccine failures are more common in old horses. A deoxyribonucleic acid (DNA) vaccine against WNV was approved by the U.S. Department of Agriculture in July 2005, but thus far no product has been marketed.

Trauma to the Brain and Cranial Nerves

Robert J. MacKay

Because of their flighty temperaments, fast gaits, and relatively thin calvaria, horses suffer head trauma more often than do other livestock and have a higher rate of neurologic sequelae to such trauma. Head injuries to horses occur from blows to the frontal-parietal area from running into stationary objects or being kicked by other horses, as well as from impact to the occipital protuberance (poll) or temporal areas after flipping over backward during handling or restraint accidents.[1] Specific cranial nerves may also be injured on the outside of the skull by focal trauma. In the special case of temporohyoid osteoarthropathy, fractures of the petrosal bone can occur suddenly without any external trauma. Temporohyoid osteoarthropathy is covered in a separate section.

Frontal/Parietal Trauma

Blows to the front of the head over the dome of the calvarium directly injure the cerebral cortex adjacent to the point of impact.[2] Brain injuries are most severe when the overlying bone is fractured and pushed inward or if there is hemorrhage around or within the brain. Because of the violent distortions and movements of the cerebral hemispheres related to the impact, additional cortical injuries may occur diametrically opposite the point of collision (contrecoup) and caudally adjacent to the tentorium cerebelli. With the development of the secondary phase of cerebral injury and edema, the enlarging cerebral hemispheres herniate under the falx cerebri (asymmetric injury) and/or tentorium cerebelli to compress other parts of the brain. Horses may recover from the acute effects of calvarial fracture only to suffer recurrent seizures later. Horses that collide at speed with fixed objects are at risk for both head trauma and spinal cord injury.[3]

Impact to the Poll and Temporal Areas

When a horse flips over backward the point of contact is either the poll or the side of the skull.[4-13] Fifteen of thirty-four horses with neurologic signs due to head trauma were injured by flipping over backward.[14] Nine of these horses were younger than a year old. The force of impact is absorbed by the occipital protuberance and/or zygomatic arch and transmitted around the skull to the petrosal bones. Presumably because of the asymmetry of impact, only one side is usually injured. This may be either the upper or lower (i.e., impacted) side. There is hemorrhage into the middle and inner ear with or without fracture through the petrosal bone. The vestibulocochlear end organs in the inner ear are vulnerable to injury by both hemorrhage and the lacerating effects of fracture. In the latter case, the facial nerve may be damaged as it courses through the facial canal within the petrosal bone. When the point of impact is centered on the occipital protuberance, the basilar bones under the brainstem are subject to fracture and separation (Fig. 35-5). The basioccipital and basisphenoidal bones are pulled apart at their synchondrosis connection, at least in part by the strong distracting force of the rectus capitis ventralis muscles. Fragments of bone from the basisphenoid may be displaced ventrally and caudally by muscular attachments.[13] Because the synchondrosis is beneath the midbrain and flanked on each side by the foramina lacera and guttural pouches, basilar fractures are clinically serious. There may be life-threatening arterial hemorrhage between or into the guttural pouches; injury to cranial nerves IX (glossopharyngeal), X (vagus), XI (accessory), and the mandibular branch of V (trigeminal) as they pass through the foramen lacerum; and/or direct laceration and contusion of the midbrain and adjacent parts of the brainstem. Because the connection between the basilar bones ossifies and fuses by 2 to 5 years of age, this type of injury is probably more likely in young horses. In the most serious cases, fracture lines extend laterally and dorsally through the squamous temporal and occipital bones or rostrally through the sphenoidal bones (see next section).

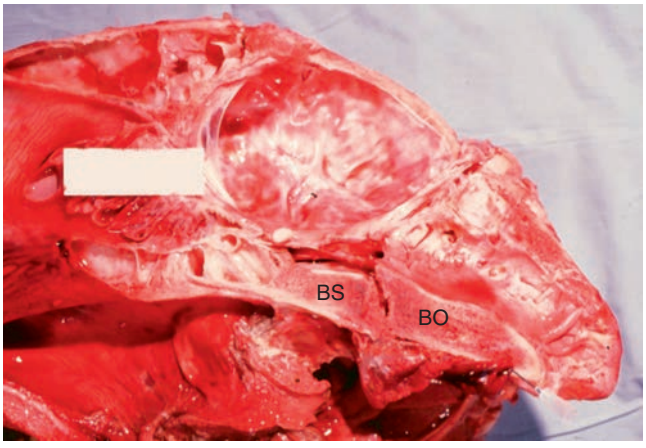

FIG. 35-5 Sagittal section of the skull of a 2-year-old colt that flipped backward during handling and suffered multiple skull fractures. Note separation/fracture in the region of the synchondrosis between the basioccipital *(BO)* and basisphenoid *(BS)* bones and hemorrhage in the region of the attachment of rectus capitis ventralis major.

VetBooks.ir

Other Cranial Nerve Injuries

The optic nerve(s) of one or both eyes can be stretched and damaged within the optic canals by the violent to-fro gyrations of the brain after impact to the head[11,15] and/or by fractures through the optic canals. Sphenoidal bone fractures also may involve cranial nerves III (oculomotor), IV (trochlear), and VI (abducens) or the ophthalmic and maxillary branches of V as they pass to the orbital foramen and foramen rotundum. Injury to the facial nerve proximal to the vertical ramus of the mandible causes full facial paresis. Proximal facial nerve trauma is usually caused by fractures of the petrosal bone, vertical ramus of the mandible, or stylohyoid bone or by fracture of the paracondylar process related to pulling back in a tied horse.[16] Distal facial nerve damage is usually due to direct injury from a blow or lateral recumbency or strangulation by a tight-fitting halter. Cattle whose heads are clamped in the head-catch on stanchions may present with "stanchion head" or ptosis and drooping ears caused by bilateral neurapraxia of the auriculopalpebral branches of the facial nerves. The nerve or its branches are often damaged as they cross the mandible and/or zygomatic arch. Facial paresis following recumbency during general anesthesia is common and usually involves only the nose and/or lips. When a horse pitches headfirst into the ground while traveling at speed, it is possible for components of a fractured atlas to be driven rostrally around the occipital condyles, where they may traumatize cranial nerve XII (hypoglossal) as it exits the hypoglossal foramen.

Skull fractures occur in cattle from blows to the top of the calvarium.[17] Most skull fractures are located in the center of the frontal bones, where the internal and external plates of the frontal sinus are fused into a single-layer dorsal wall of the cranial vault. This position can be located on the skull as the imaginary cross found by intersecting lines drawn between the medial canthus of the eye and the horn of the opposite side. Injuries in this area compress the frontal and parietal lobes of the cerebral cortex. The pressure changes result in loss of sensorium, sensory deficits, blindness contralaterally, or convulsions.

In young goats and horned sheep younger than 4 to 6 months of age, the calvarium can be inadvertently opened by removal of excessive bone during disbudding or dehorning. In goats, cerebrocortical burns can occur from overapplication of a hot iron or caustic dehorning paste. Cortical necrosis caused by bacterial infections after dehorning of calves has also been described.

Clinical Signs

Epistaxis is common after a blow to the head of sufficient severity to cause neurologic signs.[4,8] After frontal/parietal or poll trauma, blood may flow from either or both nostrils and is typically dark (venous) and of low to moderate volume. With poll trauma, epistaxis may be bilateral, copious, occasionally bright red, and may also issue from the mouth.[13] In such cases, the hemorrhage is from one (usually) or both guttural pouches and originates from adjacent veins and/or arteries.[18] If the tympanum is perforated, blood additionally may flow from the external ear. Profuse hemorrhage into the retropharyngeal area may cause obvious swelling behind the vertical ramus of the mandible and *inspiratory dyspnea,* which can be life threatening. Respiratory distress may also be associated with a poorly understood syndrome of noncardiogenic *pulmonary edema* that is reported to occur after serious head injury. Head trauma in humans is often complicated by *systemic arterial hypotension*. The cause is not completely understood but may be explained in part by *brain-heart syndrome* wherein myocardial damage is inflicted by the reflex actions of sympathetic nerves.

Immediately after impact to the frontal/parietal area, there is often a period of apparent concussion that may last minutes to hours. The most severely affected animals transiently lose all reflexes and are sometimes thought to be dead. Even after recovery of consciousness, such horses are typically obtunded for up to several hours. Altered behavior (i.e., dementia) is another characteristic of forebrain injury—there can be loss of affinity of a suckling foal for its dam; failure to respond to training cues; yawning; head pressing; compulsive walking, often in circles around the inside of an enclosure (usually toward the side of the injury); or, rarely, hyperexcitability or aggression. Because of damage to the visual centers in the occipital cortex, vision and *menace response(s)* may be impaired in the eye contralateral to the lesion; however, pupillary light reflexes should be intact. Injury to the somesthetic centers of the parietal cortex interferes with awareness of (and thus response to) touch on the opposite side of the head in a manner analogous to the way in which trauma can cause cortical blindness and abnormal menace response. This *perception of touch* is best evaluated by comparing the horse's reactions to tapping the nasal septal mucosa on either side. *Seizures* occurred in 7/34 cases of head trauma in one equine series.[14] These seizures are likely to be generalized, with loss of consciousness and uncontrolled autonomic activity (e.g., salivation, urination, defecation, pupillary dilatation, chewing movements) and abnormal motor function (e.g., muscular rigidity, followed by running and paddling movements of the limbs). In comatose horses with cerebral injury, the breathing pattern may be irregular with periods of either Cheyne-Stokes breathing or hyperventilation.

Fortunately, midbrain injury is a relatively uncommon but serious complication of head trauma of any type. It may occur immediately after the injury or be secondary to subtentorial herniation of forebrain components, rostral herniation of the cerebellum, or intraparenchymal bleeding. Because of involvement of the ascending reticular activating system (ARAS), affected horses are usually obtunded and may be comatose. Weakness of limbs is seen bilaterally or on the side opposite to an asymmetric midbrain lesion. In recumbent horses with severe midbrain injury, the neck, back, and limbs may be rigidly extended in a decorticate posture. If the nucleus of cranial nerve III (oculomotor) is involved, there is strabismus and a dilated, unresponsive pupil. With severe diffuse injury, bilateral pupillary miosis may be seen initially, followed by gradual progression to fixed, dilated pupils. Vision is normal unless there is involvement of other parts of the brain.

Vestibular dysfunction is seen commonly in horses after poll trauma or temporohyoid osteoarthropathy (THO). Clinical signs may arise because of injury centrally or, more commonly, because of involvement of the vestibular apparatus or vestibulocochlear nerve (VIII). With peripheral vestibular disease, there is head tilt, neck turn, body lean, and staggering in tight circles, all toward the side of the lesion. These signs can be revealed or exacerbated by blindfolding. With acute severe vestibular dysfunction secondary to THO, there may be sudden recumbency with flailing and thrashing movements. These signs of vestibular disease can easily be mistaken for seizures. The ipsilateral eye is usually rotated ventrally and laterally, especially when the horse's nose is elevated, and there may be horizontal or rotatory nystagmus, with the fast phase away from the side of the lesion. There may also be facial paralysis attributable to damage to cranial nerve VII as it passes close to the middle/inner ear. With central vestibular disease, signs are similar to those seen when the injury is peripheral; however, there will likely be additional signs suggestive of brainstem damage, including spontaneous vertical nystagmus, signs of other cranial nerve dysfunctions, obtundation, and limb ataxia and weakness. In horses, central lesions quite commonly result in a *paradoxical vestibular syndrome* in which the lesion (usually in the caudal cerebellar peduncle or the flocculonodular lobe of the cerebellum) is located on the side opposite to that which is expected from the clinical signs. An important clue to the presence of this syndrome is the finding of other signs of cranial nerve dysfunction (e.g., facial paralysis) on the side opposite to the direction of circling.

In horses with traumatic damage to the pons and medulla of the hindbrain, there is evidence of dysfunction of multiple cranial nerves in association with obtundation and limb ataxia/weakness. There may be reduced jaw tone or deviation of the jaw (Vm), reduced facial sensation (Vs), facial paralysis (VII), vestibular signs (VIII), dysphagia and respiratory stridor (IX and X), or tongue paralysis (XII). The gait may appear hypometric (spastic) like that seen in horses with compression of the cervical spinal cord. With severe hindbrain

VetBooks.ir

lesions, rapid deep breathing or other abnormal respiratory patterns are sometimes seen.

Signs of cerebellar injury occur rarely and are usually a result of poll trauma. Coarse head tremors are the most consistent sign; these are especially obvious during attempts to eat or suckle (intention tremor). The horse with cerebellar injury typically has a broad-based swaying stance, and limb movements may be spastic, clumsy, faltering, and jerky. Infrequent signs of cerebellar trauma include absent menace response(s) with normal vision and paradoxical vestibular syndrome (see earlier).

With traumatic optic neuropathy (usually after poll trauma), vision and pupillary light reflexes are impaired or absent and pupils are dilated immediately after the injury. Because the secondary phase of nerve injury continues for many hours after the initial trauma, visual function may progressively deteriorate during at least the first 24 hours post trauma. The signs of facial nerve injury depend on the site of damage. Complete unilateral facial paralysis is evident as deviation of the nose toward the normal side, reduced flaring of the ipsilateral nostril during inspiration, and ipsilateral drooping of the lip, eyelid, and ear. Reflexes involving cranial nerve VII such as the lip, eyelid, ear reflexes, and menace response are reduced or absent. Inability to close the eyelid causes minimal corneal problems unless there is also damage to the secretomotor fibers of the facial nerve at or proximal to the geniculate ganglion (keratitis sicca), in which case a deep horizontal corneal ulcer develops within hours of the injury. The tongue protrudes out of the paralyzed side of the mouth, often erroneously suggesting a problem with lingual function. Buccinator (cheek) paralysis causes a form of dysphagia, evident as dropping of and accumulation of feed between the teeth and cheeks (quidding). The peripheral parts of other cranial nerves are infrequently damaged with head trauma. The key to distinguishing central versus peripheral causes of neurologic deficits is that the former usually involve multiple cranial nerves and have additional features of obtundation, ataxia, and weakness that are not found with peripheral lesions.

Pathophysiology

Impact to the brain causes immediate damage to intracranial vasculature, neuronal cell bodies, axons, and glia.[19,20] Neuronal depolarization initiated at the site of impact may spread centrifugally throughout the cortex and cause the transient coma characteristic of severe concussion. In axons, a dramatic rise in intracellular calcium concentration activates processes that cause interruption of axoplasmic flow and result over hours to days in death of the distal axon. Diffuse axonal injury is thought to account for many of the permanent neurologic sequelae of head trauma. These early events constitute *primary* brain injury. Subsequent damage occurring during the response phase is termed *secondary* injury.

The surface and parenchyma of the brain may be lacerated by fracture fragments pushed inward from the calvarium. Significant bleeding at any site compresses the brain against the skull, thereby raising intracerebral pressure (ICP). Extravasated blood also elicits inflammatory responses in glial and other cells, initiating many of the autodestructive cascades that characterize the secondary phase of traumatic brain injury. Bleeding, ischemia, and mechanical damage to tissues evokes liberation and production of vasoactive and other mediators.[19,21] The production and action of damaging mediators is much affected by brain temperature—adverse effects are muted when there is hypothermia and are exacerbated by increased temperature.

Hemorrhage, increased permeability of damaged vasculature, and inflammatory edema all increase extravascular volume at the expense of brain volume. Exuberant swelling of the relatively mobile cerebral hemispheres may force portions under the falx cerebri (if asymmetric) or tentorium cerebelli.[19,20] In extreme cases, the pressure of subtentorial herniation in turn pushes the caudal cerebellum through the foramen magnum. The effects of reduced systemic blood pressure and increased ICP combine to choke off oxygen and glucose supply to cells and prevent removal of cellular metabolites such as lactic acid.[21] The consequent tissue hypoxia is more severe if there is also reduced blood oxygen content, as may occur after traumatic blood loss anemia or hypoxemia.

In the hypoxic environment of the traumatized brain, there is rapid depletion of neuronal adenosine triphosphate (ATP) and collapse of energy-dependent membrane homeostatic systems.[21] Calcium and sodium ions flux into cells in response to changes in membrane ion channel function associated with energy depletion, damage by ROS, and the actions of glutamate/aspartate. Brain damage that occurs during the primary traumatic event is irreversible; however, there is a window of minutes to days in which equally important secondary injuries theoretically can be prevented or treated.

Diagnosis

Changes in routine hemograms and chemistries are nonspecific. Collection of CSF from the atlantooccipital cistern is generally contraindicated in head trauma because of concern about inducing cerebellar herniation, but CSF can be collected via the lumbosacral space. Characteristic changes include yellow discoloration (xanthochromia), high RBC count, and protein with normal nucleated cell count.

Conventional diagnostic radiography is the best and most practical method for initial evaluation of skull trauma; however, radiographs significantly underestimate the extent of bony and soft tissue abnormality. Because the brain is not visible in plain radiographs, degrees of brain injury must be inferred from secondary changes in the skull. Fractures are visible as radiolucent lines within the calvarium, which may or may not be associated with normal suture lines. A step defect is visible when there is misalignment of the fracture fragments. Lateral views are most useful for detecting parietal/frontal and basilar fractures and for finding bone fragments originating from the basisphenoid or nuchal crest. On dorsoventral projections, a thickened stylohyoid or radiodense osseous bulla is most easily appreciated. Increased opacity of the affected bulla may reflect hemorrhage into the middle ear associated with petrosal bone injury or reactive thickening of the ventral bulla wall in cases of temporohyoid osteoarthropathy. Intracranial or spinal intrathecal gas shadows may be seen if there is a communication between the subarachnoid space and the skin surface, nasal cavity, paranasal sinuses, or middle ear. There may be radiographic evidence of bleeding into the paranasal sinuses, guttural pouches, or retropharyngeal area. In cases of frontal/parietal impact, it is also prudent to radiograph the cervical spine so as to detect fractures/dislocations caused by the axial compressive force of the original impact.

Computed tomography (CT) characteristics of brain trauma include change in ventricular size, shape, or position; deviation of the falx cerebri (falx shift); and focal change in brain opacity. Administration of iodinated contrast medium intravenously causes focal enhancement of areas of brain injury or hemorrhage. CT is particularly useful for identifying fractures of the bones that surround the caudal fossa—such fractures are often not well resolved by conventional radiography.[22] These include fractures of the petrosal bone, basilar and sphenoid bones, occipital condyles, and squamous temporal bone.[15] Blood in the middle ears, paranasal sinuses, guttural pouches, or retropharyngeal tissues and changes associated with temporohyoid osteoarthropathy are also easily seen. The principal disadvantage of CT in North America, apart from high cost and limited availability of necessary equipment, is the need for general anesthesia.

The main advantages of magnetic resonance imaging (MRI) over CT include lack of beam-hardening artifacts, ability to acquire images in any plane, and higher sensitivity for detection of early infarcts and edema. CT is more sensitive than MRI for detection of bony abnormalities, acute brain hemorrhage, and intracranial gas. The brain is not accessible to ultrasound imaging; however, the technique is sometimes useful for assessing fractures of the skull.

Clinical findings and historical information may form the sole bases for diagnosis in many cases.

Treatment

Relevant treatments for brain injury can be classified in two levels according to evidence-based support for their use. All applicable level 1 treatments should be used in every case of

VetBooks.ir

clinically apparent brain injury, whereas level 2 treatments are less clearly indicated and can be considered optional.

Level 1

TREAT OTHER INJURIES OR DISEASES. The normal principles of critical care medicine apply to the brain-injured patient—establish an airway, obtain vascular access, clean and dress wounds, stanch the bleeding, and sedate the horse if necessary and move to a cool, well-padded area. If necessary, a padded helmet can be used to minimize additional head trauma. A regimen of broad-spectrum antibiotics should be begun if there is an open wound or fracture.

TREAT HYPERTHERMIA. Hyperthermia after head trauma results from either a resetting of the hypothalamic temperature set point (fever) or excessive heat production in horses with normal set points. High brain temperature accelerates all of the destructive forces unleashed during the secondary phase of brain injury, so it must be detected and treated vigorously. Rectal temperature should be checked frequently, and efforts at cooling should begin when the temperature exceeds 101°F. In brief, ambient temperature can be reduced, the body can be clipped, ice water or isopropyl alcohol can be repeatedly applied to and removed from the skin (including the head), and overhead or box fans can be placed close by. Antipyretic medication (e.g., flunixin meglumine 1.1 mg/kg IV) is particularly useful when the horse has a fever but should be tried in all cases of hyperthermia. Nonsteroidal antiinflammatory drugs have the additional advantages of analgesic and antiinflammatory action.

PREVENT OR TREAT HYPOTENSION. Blood pressure must be at or close to normal to sustain adequate cerebral perfusion. The old notion that head trauma patients should be "kept a little dry" is no longer viable. Blood pressure should be monitored frequently, and heart base–adjusted systolic blood pressure should be maintained above 110 mm Hg.[23] Blood volume should be maintained or expanded by IV infusion of isotonic (Normosol-R; Plasmalyte-A; lactated Ringer solution) or hypertonic (hypersaline) crystalloid or colloid (plasma, hetastarch) solutions. Plasma possibly has additional useful effects including antioxidant and protease-inhibiting activities. In the case of significant blood loss, cross-matched whole blood is the fluid of choice. If volume resuscitation alone is inadequate to restore normal pressure, pressor/inotropic drugs may be used (e.g., dopamine, dobutamine, norepinephrine).[23] Remember that the effects of these drugs on cerebral vascular tone are difficult to predict.

OPTIMIZE OXYGEN CONTENT OF BLOOD. Oxygen is carried in blood either bound to hemoglobin (predominantly) or as free gas. Thus it is important that both hemoglobin concentration and Pa_{O_2} are at least in the normal range. Hypoxemia (arterial oxygen saturation <94% in this setting)[23] should be treated by establishing airway patency, treating underlying pulmonary disease (e.g., head trauma–associated noncardiogenic pulmonary edema), and beginning nasal or tracheal insufflation with oxygen. Foals may be intubated and manually or mechanically ventilated. At several equine hospitals, there are hyperbaric oxygen chambers that theoretically could be used to dramatically increase blood oxygen content in horses with brain injury. The efficacy and safety of this approach has not been established. Hemoglobin concentration must be kept above 7 g/dL (packed cell volume of 21%) and should probably be kept above 11 g/dL. Anemia can be treated with whole blood (preferable in the case of blood loss anemia) or packed RBCs.

ENSURE ADEQUATE PULMONARY VENTILATION. High P_{CO_2} has the potential to exacerbate CNS acidosis and cerebral edema. In foals, hypercapnia can be addressed by mechanical ventilation of the lungs. In all horses with head trauma, pulmonary ventilation must be optimized by ensuring a patent airway and treating lung disease. For example, acute pulmonary edema may be treated with furosemide (0.5 to 1 mg/kg IV q8h). Ventilation-induced hypocapnia has been advocated as a way to lower ICP[24]; however, low P_{CO_2} may cause reflex cerebral vasoconstriction and probably should not be used in foals with brain injury.

CONTROL PAIN. Alleviating pain in brain-injured horses is not only humane but also may reduce ICP.[25] A nonsteroidal antiinflammatory drug (e.g., flunixin meglumine, 1.1 mg/kg IV or PO bid) or opioid (e.g., morphine, 0.1 to 0.3 mg/kg IV or IM qid) can be used for this purpose. Useful analgesic effects have also been seen with constant-rate infusion of butorphanol or lidocaine.

REGULATE BLOOD GLUCOSE AND MAINTAIN NUTRITION. Experimental studies have shown that at least 140% of maintenance energy is expended by animals with severe brain injury.[26] Even during the first 24 hours after injury, nutrition (enteral or parenteral) probably should be provided to anorexic horses with head trauma. Blood glucose concentration ought to be kept greater than 80 mg/dL in order to provide adequate substrate for brain cells and less than 150 mg/dL so as to prevent hyperglycemia-induced exacerbation of CNS acidosis and apoptosis of brain cells. IV infusions of dextrose and regular insulin can be used as needed to maintain normal blood glucose concentration.

PREVENT OR TREAT BRAIN SWELLING. If possible, the neck should be free of constrictive wraps and only one jugular vein should be punctured or catheterized in order to prevent obstruction of venous flow from the head. Likewise, any recumbent horse should have its head elevated at least 10 degrees in order to facilitate blood flow. If the horse is significantly depressed (i.e., at least stuporous) or has signs of worsening brain function, a hyperosmolar infusion should be given to try to reduce the extravascular volume of the brain. The solution of choice is hypertonic saline (e.g., 1232 mmol Na/L), which is given as a continuous IV infusion of 1 mL (1.2 mmol)/kg/h for 6 hours and then 0.2 mL/kg for another 12 hours. Alternatively, boluses of 2 mL/kg can be given q4h for 5 infusions. Further treatment with hypertonic saline should be based on reassessment of clinical signs and plasma Na concentration (keep <150 mmol/L). Hypertonic saline has additional salutary actions including plasma volume expansion, antiinflammatory effect, and reduction of microvascular permeability. Mannitol (20% solution) can also be used for this purpose as a series of bolus infusions of 0.25 to 1 g/kg q4-6h. Craniectomy is not used yet for this purpose in horses, although the necessary surgical approaches have been described.[27]

TREAT SEIZURES. There is no justification for prophylactic antiseizure medication. Seizures should, however, be treated vigorously when they occur. They may be treated with diazepam phenobarbital or pentobarbital. Once a horse seizes for the first time, antiseizure medication (usually phenobarbital) should be continued for at least a week. If delirious thrashing or recurrent seizures remain a problem, the horse can be immobilized by continuous infusion of propofol or pentobarbital for up to 24 hours.

PERFORM EMERGENCY SKULL SURGERY. After initial stabilization of the patient, depressed fractures of the frontal/parietal area that impinge on the cerebral cortex may be carefully elevated and reduced under general anesthesia using techniques described in standard texts.[28-30] No surgical approach to basilar fractures has been described for the horse—such an approach would be extremely difficult and risky.

Level 2

Such treatments are supported by either strong anecdotal data from equine practice or convincing experimental data in other species. The downside of these treatments is that they do not meet the standard of evidence-based medicine.

TREAT WITH ANTIOXIDANTS. Oxidant damage is known to be an important part of the secondary phase of brain injury, yet clinical evidence supporting the therapeutic use of antioxidants is scant.

VetBooks.ir

Dimethyl sulfoxide (DMSO) is widely used by equine practitioners for treatment of CNS trauma (and almost everything else). The potential advantages of this drug's antioxidant and diuretic actions are obvious; however, there is virtually no evidence for effectiveness in the setting of brain injury. Common use suggests a protocol of 1 g/kg as a 10% solution in isotonic solution given IV or by NG tube q12h. Vitamin E (α-tocopherol, 50 IU/kg PO daily), vitamin C (ascorbic acid, 20 mg/kg PO daily), mannitol (see earlier), and allopurinol (5 mg/kg PO q12h) are all antioxidant therapies that can be used in the horse and can be rationalized as part of the overall approach to brain trauma.

GIVE CONVENTIONAL DOSES OF CORTICOSTEROIDS. High-dose steroids are harmful to humans with brain trauma[31] and should not be used in horses. Traditional antiinflammatory doses of dexamethasone (0.05 to 0.1 mg/kg IV or 0.1 to 0.2 mg/kg PO q12-24h) or prednisolone (1 to 4 mg/kg PO bid) likely inhibit production and action of injurious mediators in the brain and may be of some value.

GIVE MAGNESIUM SULFATE. Magnesium sulfate has the potential to inhibit several aspects of the secondary injury cascade including glutamate release, activity of the *N*-methyl-D-aspartate and calcium channels, and lipid peroxidation.[32] In light of these findings and its demonstrated safety in horses, it seems reasonable to give a single IV infusion of $MgSO_4$ at 50 mg/kg. This dose (25 g in a 500-kg horse) can be conveniently administered with the first 5 to 10 L of IV fluids.

Prognosis In one series, horses that had basilar fractures were 7.5 times more likely to die than those that did not.[14] Nevertheless, one horse with a basilar fracture returned to racing. Twenty-one of thirty-four horses survived to discharge. Most horses should recover completely, although residual vestibular and facial nerve signs are sometimes seen.

Facial nerve dysfunction due to neurapraxia should resolve over days to weeks. If there is morbid axonal injury (axonotmesis), the facial nerve may regrow via axonal sprouting along existing nerve sheaths. Regrowth of nerves occurs at a rate of about 1 cm per week, and reinnervation may continue for at least a year.

Traumatic Optic Nerve Blindness of Horses

Robert J. MacKay

Severe blunt trauma to the skull in horses may result in a rapid caudal displacement of the brain and avulsion or stretching of the peripheral optic nerves within the bony optic canals. Typical settings for such injuries are blows to the poll from flipping over backward and trauma to the frontal-parietal area from running into stationary objects such as posts or trees. The clinical signs include sudden blindness, loss of pupillary reflexes, and pupillary dilation. Ophthalmoscopic changes in the retina occur after 2 to 4 weeks and include pallor of the optic discs, reduction in the number and caliber of the retinal vessels, and linear peripapillary pigment disruptions (Fig. 35-6). The condition can be partial or complete, asymmetric or symmetric, and generally does not respond to treatment.[1,2] Because traumatic optic nerve injury likely progresses for many hours after the initial injury, there is a rationale for robust antiinflammatory treatment during the first 3 days after injury. This should include an NSAID such as flunixin meglumine at a dosage of 1.1 mg/kg q12-24h IV or PO and a corticosteroid such as dexamethasone, 0.05 to 1 mg/kg IV or IM sid or bid.

Thiamine Deficiency of Horses

Mary O. Smith

Horses may develop thiamine deficiency when fed diets that contain thiaminases. Common sources of thiaminases are bracken fern *(Pteridium aquilinum),* horsetails *(Equisetum arvense),* and amprolium (400 to 800 mg/kg). The clinical signs of thiamine deficiency are ataxia, conscious proprioceptive deficits, heart block, bradycardia, blindness, weight loss, dysuria, hypothermia of the extremities, and periodic muscular fasciculations. Terminally, affected horses develop convulsions. Electrolyte changes include hyperkalemia, hyperphosphatemia, hyperglycemia, and decreased glucose tolerance. Parenteral thiamine is effective treatment.[1,2]

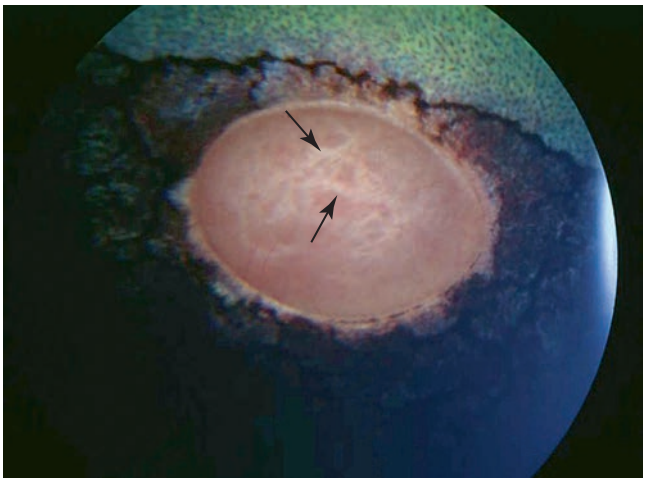

FIG. 35-6 Fundus of 4-month-old Thoroughbred colt that was blind as a result of severe bilateral nerve injury that occurred as a result of poll trauma 2 months earlier. Note absence of fundic blood vessels and exposure of the lattice-like lamina cribrosa *(arrows)* indicating demyelination.

Equine Leukoencephalomalacia

Robert J. MacKay

Equine leukoencephalomalacia (ELEM) is a fatal CNS intoxication of horses caused by ingestion of fumonisin toxins on corn or corn by-products.[1-3] Fumonisin toxins (B_1, B_2, and B_3), produced by the fungi *Fusarium verticillioides* and *F. proliferatum* (previously combined as *F. moniliforme*), interfere with sphingolipid metabolism, disrupting endothelial cell walls and basement membranes.[4] Although all three are toxic, B_1 is the most common and most thoroughly studied. See Chapter 54 for more details.

Clinical Signs The onset of ELEM is usually sudden. Previously healthy animals may be found dead, but most horses show abnormal neurologic signs for hours to days before death.[5,6] These include obtundation to the point of stupor and dementia manifested as compulsive walking in large circles, head pressing, and hyperesthesia. There is blindness and menace deficit, as well as reduced reaction to touch around the face. Movements of the muzzle, lips, and tongue may be weak and ineffectual. Signs are typically asymmetric. Muscle fasciculations occur over the neck and withers and in antigravity muscles, and limb ataxia and weakness are prominent terminally. Seizures are common after affected horses become recumbent, and animals often die while convulsing. The few horses that survive usually have permanent neurologic dysfunction. Hepatic involvement occurs in many cases, as evidenced by high serum liver enzymes, although hepatic failure is uncommon.[4,7] Signs of liver disease include icterus, petechiation on mucous membranes, and swelling of the muzzle or lips. Fatal outbreaks of liver disease without brain involvement have been reported.[4] Cardiovascular abnormalities are also described in horses with experimental ELEM and include decreased cardiac contractility, heart rate, arterial pulse pressure, and increased systemic vascular resistance.[8]

Fumonisin toxins cause a variety of clinical syndromes in other species including pulmonary edema in swine, but horses appear to

VetBooks.ir

be the most susceptible domestic animal species and can show signs when exposed to toxin concentrations as low as 5 to 10 ppm.[4] Regulatory guidance issued by the U.S. Food and Drug Administration calls for fumonisin (B_1+B_2+B_3) concentrations of no more than 5 ppm in horse feeds.

Clinical Pathology and Diagnosis ELEM has no unique findings on routine bloodwork. Serum liver enzymes (i.e., aspartate transaminase, γ-glutamyltransferase, and sorbitol dehydrogenase) and bilirubin are often high. Anemia, leukocytosis, and leukopenia all have been reported, but none is a consistent finding. Markedly high protein concentration (i.e., >100 mg/dL) with normal nucleated cell count typifies CSF analysis of affected horses.[9] High serum sphinganine, sphingosine, and sphinganine-to-sphingosine ratio suggest acute fumonisin toxicosis,[8] but these assays are only available at research laboratories. In practice, antemortem diagnosis relies on recognition and demonstration of fumonisin (B_1+B_2+B_3) concentrations greater than 10 ppm in feed. Fumonisin assays are widely available through diagnostic laboratories, and turnaround should be rapid.

Differential diagnoses include traumatic brain injury, the arboviral encephalitides, hepatic encephalopathy, equine protozoal myeloencephalitis, and botulism.

Epidemiology Leukoencephalomalacia occurs worldwide. Corn becomes contaminated during growth rather than in storage, and climatic factors that stress the plants, such as drought followed by high rainfall, contribute to the likelihood of mold development. The fungus is introduced into the growing corn by insects such as the western flower thrip, which enters the ear and damages the kernel as it feeds.[10] Most cases of equine disease occur during the winter and early spring.[1] Repeated exposure to the toxin, rather than a single large dose, seems to be associated with the development of clinical signs.[11] Experimental studies with infected corn demonstrated an onset of clinical signs on the ninth day after the beginning of the feeding period, but the reported delay between exposure and signs in outbreaks has ranged between 4 and 180 days. Older animals develop clinical signs of ELEM more rapidly than younger animals and thus appear to be more susceptible to the effects of the mycotoxin.

The rates of disease in exposed horses vary widely, from 14% to 100% in some reports; lethality is close to 100%.

Pathology The major pathologic features in the CNS result from the vascular damage caused by fumonisin toxins, including liquefactive necrosis and degeneration or malacia of the white matter of one or both cerebral hemispheres.[5,12] The size of the lesions may vary from grossly inapparent to complete subcortical cerebral necrosis. Flattening of the cortical gyri, enlargement of the cerebral cortex, vascular congestion, cortical softening, yellowish discoloration of the white matter, hemorrhage, and cavitation of the cerebral cortex may be present.[1] A gelatinous fluid can be seen in many of the cavitary lesions. Hemorrhage in the CNS has also been reported. Lesions in the visceral organs including hepatic congestion, centrilobular hepatic necrosis, hemorrhagic enteritis, and cystitis are found in some horses. The relationship between these lesions in the CNS and those in the liver, urinary bladder, and gastrointestinal (GI) tract is unknown.

Treatment Specific treatment is not available, and early euthanasia is usually the best option. Because there is cerebral edema, IV antiedema drugs including corticosteroids (e.g., dexamethasone 0.1 mg/kg daily), DMSO (1 g/kg as a 10% solution), hypertonic saline (4 mL/kg of 7.2% NaCl every 4 hours), or mannitol (1 g/kg as a 20% solution) can be rationalized. Nonsteroidal antiinflammatory drugs (e.g., flunixin meglumine 1.1 mg/kg PO or IV bid); antioxidants (DMSO, tocopherol, 20 IU/kg PO); ascorbic acid (25 mg/kg in IV fluids); and thiamine (5 mg/kg, slowly IV) can all be tried to limit secondary brain injury, but none of these treatments is likely to be effective.

Intracarotid Drug Injection

Robert J. MacKay • Mary O. Smith

Intracarotid drug injection is common in horses because the jugular vein and the common carotid artery are closely apposed in the caudal third of the neck. The condition is rarely seen in cattle because the omohyoideus muscle lies between the carotid artery and the jugular vein in the posterior part of the neck.[1] Hypertonic or caustic drugs including phenothiazine tranquilizers, chloramphenicol, chloral hydrate, barbiturate anesthetics, phenylbutazone, calcium gluconate, and sodium iodide cause cortical necrosis when injected into the carotid artery.[2-5]

The carotid artery provides blood supply to the circle of Willis via the internal carotid artery and thence to the thalamus and rostral and middle cerebrum. The internal carotid also provides arterial supply to the eyeball via the ophthalmic artery. By contrast, the blood supply to the caudal cerebrum, midbrain, pons, medulla, cerebellum, and inner ear is via the vertebrobasilar arteries and originates in the vertebral branches of the subclavian arteries. Thus the carotid artery injectate travels principally to the ipsilateral thalamus, cerebrum, and eye while relatively sparing the rest of the brain. The effect of the arrival in the forebrain of a bolus of irritant material is akin to a cerebral stroke of variable severity. There is intense vasospasm and physical endothelial damage with endothelial swelling, increased vascular permeability, mural necrosis, hemorrhage, intercellular edema, and thrombosis. As a result of ischemia there is glucose, oxygen, and energy starvation, progressing to Ca influx and anaerobic metabolism, and finally loss of function and accumulation of excitotoxic amino acids, free radicals, and eicosanoids. At necropsy, there is grossly evident ipsilateral brain swelling and hemorrhage.

When the drug is injected into the carotid artery, the animal recoils backward and falls over. Some horses strike or rear violently or run wildly, often in circles toward the injected side, without regard to obstacles. After falling, many horses convulse violently, whereas others become comatose without showing excessive motor activity. Severely affected animals may die after a variable period, but others regain their footing and recover completely. Milder and residual neurologic signs include contralateral (thalamic) or ipsilateral (retinal) blindness, contralateral facial hypalgesia, circling (toward the side of the injection), and contralateral conscious proprioceptive deficit.

If it can be done safely, seizing horses should be given IV antiseizure medications (diazepam, 0.2 to 1.0 mg/kg; pentobarbital, 2 to 10 mg/kg; xylazine, 0.2 to 1.1 mg/kg), which can be repeated as needed to control seizures. If possible, horses should be placed in a padded stall and treated with anti-inflammatories including dexamethasone (0.05 to 1 mg/kg IV or IM), flunixin (1.1 mg/kg PO or IV) or equivalent, and DMSO (1 g/kg IV as a 10% solution). The use of hypertonic antiedema drugs in this setting is controversial because of the possibility of active bleeding in the CNS and loss of the blood-brain barrier.

Intracarotid injection of drugs is best prevented by the use of large-bore needles or catheters for intravenous injections. In the horse, venipunctures should be performed in the anterior one third of the jugular furrow because the artery and vein are separated by the omohyoideus muscle in this area. The inexperienced phlebotomist may prefer to place the needle into the vessel without a syringe attached to confirm that the blood is dark and drips from the hub, indicating proper placement into the jugular vein. Conversely, intracarotid placement of the needle results in forceful, often pulsatile ejection of bright red arterial blood from the hub.

Brain Tumors

Mary O. Smith • Lisle W. George

Nervous system tumors of ruminants include medulloblastoma, ependymoblastoma, neurofibrosarcoma, angioblastoma, meningioma, meningeal hemangioma, neurofibroma, schwannoma, choroid

VetBooks.ir

plexus papilloma, pituitary adenocarcinoma, primitive neurectodermal tumor, and reticulosis.[1-5] CNS tumors of horses include pituitary adenomas, microgliomas, medulloepithelioma, choroid plexus papilloma, ependymoma, neurofibroma, meningioma, meningeal carcinoma, and reticulosis.[1,6-10] Secondary tumors that invade the CNS include melanoma, lymphosarcoma, adenocarcinoma, squamous cell carcinoma, hemangiosarcoma, and osteoma.[1,10-15] Of these, lymphosarcoma is most often encountered.[16,17] Metastatic invasion to the CNS occurs either by vascular routes or by extension along the peripheral nerve rootlets.[18] Local extension from adjacent tissue, such as the paranasal sinuses, can also occur.[11]

Clinical signs of brain tumors vary with the location and include abnormalities of gait (ataxia, paresis, hypometria/hypermetria); seizures; altered mentation (especially dullness); facial paresis or paralysis; facial anesthesia or analgesia; dysphagia; head tilt; strabismus; nystagmus; and loss of the menace reflex.[11,18-20] Migration of facial tumors (squamous cell carcinomas) into the cranial vault through the cranial nerve foramina may also result in facial swelling, exophthalmos, Horner syndrome, or asymmetric airflow through the nares.[17] Pituitary adenomas of aged horses (see Chapter 41) rarely cause neurologic disease, but they secrete melanocyte-stimulating hormone, which stimulates the adrenal cortex and causes Cushing disease. Some tumors are discovered as incidental findings at necropsy.

Antemortem diagnostic tests include radiographs of the skull (for tumors that spread locally and some metastatic tumors), and electroencephalography (EEG) to elucidate brain dysfunction.[11] Where available, CT or MRI can greatly facilitate diagnosis, but limited availability and considerations of cost restrict their use in most cases.[18,20-22]

Treatment of brain tumors in horses and livestock is generally not feasible because of limitations of cost, nursing care challenges after craniotomy, lack of access for large animals to radiation therapy, and considerations of safety for personnel handling animals with significant neurologic deficits. Palliative treatment such as corticosteroids may reduce clinical signs temporarily in some animals. Euthanasia is the choice for most large animals with brain tumors.

Cholinesteric Granuloma Encephalopathy

Robert J. MacKay • Mary O. Smith

Cholinesteric granulomas (CG) are found associated with the choroid plexuses of the fourth ventricles and lateral ventricles. Up to 20% of older horses have CGs in one or both lateral ventricles, usually without adverse effect.[1] CGs are thought to develop as a chronic inflammatory reaction to cholesterol released from extravasated degenerating RBCs within the choroid plexus. Syndromes of neurologic dysfunction in association with CGs have been described in horses from 7 to 23 years old.[2-5] The onset of signs is ascribed to combinations of attenuation and edema of cerebral tissue overlying a large CG, hydrocephalus secondary to obstruction by a CG of CSF efflux from the lateral ventricle through the foramen of Monro, and ependymitis/meningitis in response to proinflammatory substances released from CG.[2-5] In some cases there is a history of months to years of intermittent neurologic episodes presumably related to waxing and waning hydrocephalus and/or intermittent inflammation.

Signs can develop insidiously or present suddenly and are usually referable to forebrain dysfunction.[2,4] There may be dementia, manifested as irritability, aggression, yawning, head pressing, compulsive walking, drifting to one side when walking, circling, abnormal body posture, loss of learned skills, syncope-like attacks, seizures, blindness and menace deficit with normal pupillary light reflexes, and reduced response to tactile stimulation of the face.[2-5] With presumed CG-associated cerebral edema, signs suggestive of brainstem compression also have been described including stupor, limb weakness and ataxia, anisocoria, head tilt, stiffness at the walk, and facial paresis. Signs are typically asymmetric or unilateral, reflecting asymmetric involvement of the lateral ventricles.

CG should be suspected in any mature horse showing signs referable to waxing and waning forebrain dysfunction. Results of cerebrospinal fluid analysis may be normal, show high protein concentration with normal cell count, or show mild pleocytosis notable for the presence of nondegenerate neutrophils. The diagnosis is strongly supported by advanced imaging. CT in the standing[5] or anesthetized horse[2,3] is the diagnostic of choice, although MRI has also been used.[4] The finding by CT of heterodense, hyperattenuating, poorly contrast-enhancing masses in the lateral ventricles is tantamount to the diagnosis of CG. A technique for CG biopsy has been described and can be used to exclude the possibility of other choroid plexus tumors including papillomas and ependymomas.[3] At necropsy of clinically affected horses, CGs are found as brownish ellipsoid masses at least 3 cm in the smallest diameter attached to the choroid plexuses of one or both lateral ventricles. Histologically, these masses contain abundant cholesterol crystals interspersed with empty clefts, hemosiderin, and heavy infiltrations of macrophages and giant cells.

Traditionally, horses with CGs have been considered terminal and untreatable. It is clear, however, that all of the components of the pathophysiology of CG encephalopathy—namely, enlarging granulomas, hydrocephalus, and ependymal inflammation—are potentially treatable with antiinflammatory drugs. Horses with CG encephalopathy that were given antiinflammatory drugs, including dexamethasone, prednisolone, and phenylbutazone, have gained clinical remissions lasting from months to indefinitely. A reasonable treatment protocol includes seizure control as needed, induction of remission from clinical signs with dexamethasone (0.05 mg/kg IV or 0.1 mg/kg PO, once daily for 7 to 14 days), followed, if successful, by prednisolone, 1 mg/kg PO bid, to be given indefinitely except for intermittent trials designed to test the effect of tapering the dose. Hyperosmolar IV solutions (mannitol, 0.5 to 2.0 g/kg as a 22% solution; 7.2% saline, 1 to 2 mL/kg) can be given acutely to address cerebral edema and repeated as needed every 4 to 6 hours for the first 24 hours. More aggressive interventions including direct drainage of CSF from enlarged lateral ventricles and surgical removal of CG using techniques adapted from human brain surgery are also possible but not described. The prognosis for short- to medium-term (i.e., up to a year) maintenance of remission of clinical signs of CG encephalopathy should be regarded as fair.

Epilepsy

Robert J. MacKay

Epilepsy is defined as a persistent predisposition of an animal to repetitive seizures that has resulted in seizures on at least two different occasions.[1,2] For this purpose, a cluster of seizures occurring over hours to days is classified as a single seizure. Epilepsy may be primary or secondary. *Primary* epilepsy (also known as *idiopathic* or *true epilepsy*) occurs because of known or suspected genetic predisposition. This diagnosis is rare in large animals, but a few heritable epilepsy syndromes have been described including juvenile idiopathic epilepsy of Arabian foals of Egyptian lineage,[3] Arabian lavender foal syndrome,[4] and suspected familial epilepsy in cattle of various breeds.[5,6] *Secondary* epilepsy occurs as a result of known or suspected underlying brain dysfunction, termed *symptomatic* and *cryptogenic,* respectively. A systemic condition or chemical/drug may cause a normal brain to generate *reactive* seizures; however, these are not classified as epilepsy. Nevertheless, anything that lowers seizure thresholds including the use of epileptogenic drugs such as macrocyclic lactone anthelmintics (e.g., ivermectin) or the occurrence of estrus in females may compromise management of epilepsy.[2]

Seizure activity results from abnormal, synchronous, electrical discharges in the neurons of the forebrain that spread to the somatic and visceral motor areas to initiate spontaneous, paroxysmal, involuntary movements that may begin and end spontaneously. Each seizure (ictus) may be *generalized,* involving the entire cortex and resulting in generalized bilateral motor activity over the whole body, or *partial,* involving a focal cortical region with localized motor signs

VetBooks.ir

or sensations. Partial seizures may become generalized. Generalized seizures usually begin with tonic muscle contractions of the muscles of the neck and limbs but progress to rhythmic clonic limb thrashing, often accompanied by abnormal eye positions and movements. Affected animals usually fall and display various autonomic signs, such as salivation, urination, and defecation. Partial seizures begin as involuntary tonic or clonic contractions of groups of facial, jaw, or body muscles. These signs may stop spontaneously without progression but more typically spread from their initial focus to involve the whole body. Seizures may be preceded by an aura of up to several hours' duration, usually characterized by signs of restlessness or disorientation, and be followed by a period of stupor, restlessness, and central blindness that is usually short-lived but can last several days in foals.

Recurrent seizures in large animals are usually classified as secondary epilepsy with the majority of these of the cryptogenic type.[1] As diagnostic techniques improve, a higher proportion of such cases will be classified as symptomatic. In the horses of a recently published case series, epilepsy manifested in approximately equal numbers as either partial or generalized seizures.[1] Diagnoses in cases of symptomatic epilepsy in this series included intracranial neoplasia, cholesterol granuloma, congenital structural abnormalities of the brain, degenerative processes (white matter cavitation and focal neuronal dysplasia), and equine protozoal myeloencephalitis.

In large animals, the best characterized primary epilepsy syndrome is *juvenile idiopathic epilepsy* of Arabians of Egyptian lineage.[3] Seizures usually begin in foals by 2 months of age (range 2 days to 6 months), although onset as late as 18 months has been described. Seizures are usually symmetric and generalized, often with no preictus. After a brief period of whole-body myotonus and collapse into lateral recumbency, there are clonic ("galloping") limb movements, opisthotonos, sweating, retracted lips, and staring, unblinking eyes. Each seizure can last up to 5 minutes but typically is less than a minute. Postictal signs are usually profound and persistent and are often the first abnormality detected by the owner. There is obtundation, cortical blindness, loss of maternal bond and interest in suckling, and other variable behavioral signs. Blindness, the last sign to resolve, typically lasts several days (range: hours to 2 weeks). Injuries, especially to the skull, may occur during seizures or as a result of collisions during the period of blindness. Juvenile epilepsy responds well to anticonvulsant therapy and does not usually recur (see treatment section later). Untreated foals also may grow out of the condition by a year of age but are subject to cumulative seizure-associated injury and there are anecdotal reports of permanent behavioral abnormalities in untreated horses.

A diagnosis of epilepsy is supported by the finding of epileptiform discharges in interictal electroencephalograms (EEG), although this procedure does not appear to be highly sensitive.[7] Epileptiform discharges were identified in EEGs of only 9/13 foals with juvenile idiopathic epilepsy.[3] Artifacts induced by patient movement or sedative drugs limit the usefulness of traditional EEG in large animals. It has been suggested that ambulatory EEG recording, as is routinely used in human neurology, may be a more sensitive and reliable method for investigating suspected seizures in large animal patients.[7] In food animals, evaluation of seizure disorders may be performed using evocative drug challenges with pentylenetetrazol, ketamine, or other seizure-inducing agents and established techniques, but care must be taken to prevent injury to the animal.[8,9]

Specific drug therapies have not been established for most large animal species. However, most seizures are controlled acutely with diazepam (0.05 to 0.2 mg/kg IV) and long term with oral or IV phenobarbital (see following section). A simple approach to treatment of epileptic horses has been described and can be followed in other species.[2] This protocol is based on the use of oral phenobarbital at 5 mg/kg once daily, begun without a loading dose. Treatment at this dose is continued for at least 2 weeks. If signs are insufficiently controlled, the dose rate is increased by 1 mg/kg and continued for another 2 weeks. This cycle of incremental dosage increase is continued until adequate control is achieved or side-effects prevent further increase. Potassium bromide (90 mg/kg once daily PO, optionally after a loading course of 120 mg/kg/day for 1 week) can be added to phenobarbital in these cases to provide additional anticonvulsant effect. Therapeutic trough concentration of phenobarbital is 15 to 40 µg/mL. After 6 months of seizure-free therapy, the dose of phenobarbital can be tapered in increments of 1 mg/kg every 2 weeks. If the animal remains seizure-free for 6 months after anticonvulsants have been discontinued, the horse is considered by some to be no longer epileptic; however, it is prudent to continue to advise owners that such horses should never be ridden or used for sporting purposes. Foals with juvenile idiopathic epilepsy are usually given phenobarbital twice daily at 5 mg/kg, and tapering can be begun after 3 months of seizure-free treatment. All ruminants experiencing seizures should also immediately be treated with thiamine (10 to 20 mg/kg IV, IM, or subcutaneously [SC]).

Narcolepsy-Cataplexy

Robert J. MacKay

Definition and Etiology Narcolepsy is a CNS disorder characterized by excessive sleepiness, episodes of muscular weakness (cataplexy), and rapid eye movement (REM)-onset sleep.[1,2] The disorder is defined as an abnormal tendency to transition from wakefulness into REM sleep. Attacks of narcolepsy and cataplexy are considered a paradoxic form of sleep because the EEG is characteristic of an alert, awake animal, but the REM is characteristic of deep sleep.

Sleep-wake regulation is normally achieved through reciprocal interplay of consciousness-arousing and consciousness-depressing regions of the brain.[3] Included in the arousal system are cholinergic and monoaminergic (histaminergic, serotonergic, dopaminergic, and noradrenergic) neurons located in the caudal hypothalamus/brainstem regions that diffusely project to the forebrain to upregulate cortical function. Conversely, gamma-aminobutyric acid (GABA)-ergic neurons of the rostral hypothalamus play a critical role in sleep by inhibiting neurons of the arousal system. Recently, it has been shown that the novel neuropeptides, hypocretins 1 and 2 (also known as *orexins A* and *B*), produced exclusively by neurons in the lateral hypothalamus, are critically involved in the neuronal circuitry regulating sleep/wake states. Via numerous afferent connections, hypocretin neurons sense the body's external and internal environments and regulate wakefulness accordingly, mostly via stimulation of consciousness-arousing monoaminergic neurons. Multiple lines of evidence suggest that sporadic narcolepsy in humans is caused by a dysfunctional hypocretin system, usually as a result of degeneration of hypocretin neurons. Some familial cases are associated with nonfunctional hypocretin receptors. With removal of hypocretin neuronal function, monoaminergic and GABAergic neurons set up a poorly regulated mutually inhibitory circuit, resulting in unwanted and abrupt transitions between wakefulness and sleep recognizable clinically as narcolepsy and cataplexy.[3]

Narcolepsy has been reported in numerous horse and pony breeds, a Suffolk lamb, Spanish fighting bulls, a Guernsey bull, and a Brahman bull.[4-13] Most cases appear to be sporadic, but early-onset, probably familial occurrence has been reported in American Miniature Horse, Lipizzaner, Suffolk, Shetland pony, and Fell pony foals[2,4] and has been seen by the author in a family of Morgan horses. The collapse syndrome associated with squeezing neonatal foals traditionally has been viewed as a transient form of narcolepsy; however, a recent study found that the associated EEG patterns were slow waves consistent with non-REM sleep and thus were not narcolepsy.[14]

Clinical Signs The clinical signs of narcolepsy include staggering, lowered head and neck, buckling of the thoracic limbs, kneeling posture, flaccidity of the lips, closure of the eyes, loss of the menace reflex, stertorous breathing, and ataxia. During severe narcoleptic attacks the animal collapses into lateral recumbency and appears

VetBooks.ir

comatose. Only rarely is REM sleep observed after collapse. The sensorium returns to normal after seconds to minutes. In the periods between attacks, the animal appears normal, although repeated attacks result in trauma to the dorsal aspects of the fetlocks and the knees and to the face.[1,2] Cataplexy, a sudden episode of paralysis of the voluntary muscles, may be induced by strong emotions (usually positive) in the patient and can range from atonic, areflexic paralysis of all skeletal muscles, except those of the diaphragm and eyes, to slight transient buckling of the limbs without collapse into recumbency. Episodes of cataplexy last seconds to minutes. Environmental factors that can stimulate cataplectic attacks include active restraint, suckling, feeding, changing the stall environment, grooming, or cross-tie–related activities of horses like saddling, removal of tack, and washing. Despite this association, narcolepsy in adult horses usually occurs while horses are in stalls or at pasture without any obvious prior stimulation.[1] Most cases of narcolepsy in humans are associated with cataplexy, but sleep attacks without cataplexy also occur. Mild cataplexy and attacks of excessive sleepiness can be difficult to distinguish in adult large animals in that both may cause blank facial expression, hanging of the head and neck, and buckling of the limbs with or without collapse into recumbency.[1] Sudden arousal associated with the stimulation of collapse and ground impact also could terminate either type of episode. In light of diagnostic ambiguities based on observations of mild sleep attacks, cataplexy that persists after collapse is the most frequently recognized manifestation of sleep disorders in large animals.

Signs are generally stable and lifelong. The cataplexy component of juvenile cases usually improves as the animal gets older but rarely completely resolves.

Diagnosis Strict EEG criteria, including the early onset of waveforms typical of REM at the beginning instead of the middle of a sleep cycle, are in place for confirming the diagnosis and for distinguishing narcolepsy from narcolepsy without cataplexy. The EEG changes of narcolepsy and cataplexy have been reported in a Brahman bull.[5] The waveforms vary between low-voltage high-frequency (LVHF) and high-voltage low-frequency (HVLF) patterns, with LVHF corresponding to the actual period of narcoleptic attack. In horses, EEG waveforms may be normal or may reveal fast waves typical of REM activity.[1] Hypocretin concentrations in CSF are typically low in humans and dogs with sporadic narcolepsy but normal in familial forms associated with mutations in the genes for hypocretin receptors.[15,16] In CSF from a narcoleptic Icelandic foal, immunoreactive hypocretin concentration was comparable with those from two control horses.[17] It will be important to evaluate this diagnostic in both juvenile and adult-onset forms of the disease in large animals.

It is reported that cataplexy can be induced by IV administration of the centrally acting cholinesterase inhibitor physostigmine salicylate (0.05 to 0.1 mg/kg),[6] but attacks cannot be evoked in all animals. In one series of narcoleptic horses challenged, only 1/10 horses had a positive response.[11] Signs of narcolepsy can be reversed for at least 24 hours by atropine sulfate (0.02 to 0.1 mg/kg IV once).[11,17] Diagnostic drugs must be used with caution because of the possibility of inducing colic, especially in horses.

Syncope and seizures are important differentials for narcolepsy. In general, syncope is characterized by acute collapse without warning and, unlike narcolepsy, is not preceded by a gradual lowering of the head and drowsiness. Increased focal or generalized tonic-clonic muscle activity and postictal depression are typically seen with seizures, but not in animals with narcolepsy. In addition, excessive sleepiness can be seen in horses that have an underlying painful physical condition, environment, or social position that prevents them from lying down to sleep. Therefore a complete history and thorough physical examination are essential.

Treatment and Prevention The tricyclic antidepressant imipramine (0.5 to 1 mg/kg PO bid to qid) can be used to treat cataplexy but is ineffective in treatment of the sleepiness component of narcolepsy. This drug must be used with caution, and oral dosages in horses should not exceed 2 mg/kg.[8] Results of oral imipramine therapy are inconsistent; duration of effect is about 5 hours. Anecdotally, tyrosine has been of benefit in some, but not all, narcoleptic horses. Its presumed mode of action is by increasing dopamine neurotransmitter concentrations.[1]

Selective serotonin reuptake inhibitors are also used in humans for treatment of cataplexy but have not been evaluated in large animals for this purpose.[18] Sodium oxybate (the sodium salt of gammahydroxybutyrate) is widely used as a wakefulness-promoting drug in narcoleptic humans and may apply to the treatment of veterinary patients.[18]

Headshaking in Horses

Robert J. MacKay

Headshaking in the horse is an important cause of wastage among otherwise normal riding or driving horses. There is no obvious predilection for age, breed, or gender. Surveys have usually found more than 50% of headshakers are geldings, and mean ages for published series are from 7.3 to 12.8 years (range 1 to 28 years).[1,2] Most headshakers are either used for pleasure riding, dressage, or show jumping, but horses of any breed or discipline can be affected.[3,4] Signs of headshaking usually first occur while the horse is being ridden or driven (i.e., with the horse in a bit and bridle) and become more pronounced over time, both in severity and duration of headshaking episodes.[1] The condition usually renders a horse unsafe or at least unsatisfactory for riding and in severe cases may cause inhumane suffering to the affected horse. Once established, the condition occurs during any form of exercise and about 60% of affected horses eventually also headshake at rest.[1,3] Additional trigger factors that exacerbate or provoke headshaking have been identified. These include bright light, sun, heat, cold, stress, extreme neck flexion, riding on narrow roads, hearing people's voices, or riding near trees or water.[5] On average, approximately one half of cases from multiple series[5] are either partially or completely seasonal with signs beginning suddenly or getting worse in spring and ending in the late summer or fall.[1,6] Signs may stop for weeks only to recur for no apparent reason.

Headshaking is classified as either *symptomatic* or *idiopathic*. The former have an identifiable physical cause that, if removed, permanently resolves the problem. The remaining cases either have no discernable basis or continue after removal of a putative cause. Reported or postulated symptomatic causes have included skull lesions,[7] allergic rhinitis, vasomotor rhinitis, otitis externa or media/interna, *Trombicula autumnalis* (harvest mite) infection, fungal sinusitis,[8] temporohyoid osteoarthropathy, mites or ticks in the external ear canals, guttural pouch mycosis, *Onchocerca* dermatitis, dental problems, cervical arthritis, and ocular lesions including cystic corpora nigricans, "floaters" in the anterior chamber, and blocked lacrimal ducts.[9] Because horses are normally programmed for headshaking as, for example, for fly avoidance,[10] almost any unpleasant condition around the head (or possibly elsewhere on the body) seems to have the potential to amplify the behavior to abnormal levels. Despite the seemingly impressive (and incomplete) list of potential causes given earlier, no physical basis for headshaking was found in 89 of a series of 100 reported cases.[1] Headshaking does not appear to be associated with latent equine herpesvirus 1 infection.[11]

Headshaking may be defined as involuntary sudden violent repetitive movements of the head, either dorsally and ventrally in the median plane (most common), horizontally, and/or in a rotatory manner. Other signs, particularly in horses with idiopathic headshaking, have included snorting, sneezing, snoring breath sounds, rubbing the face on stationary objects, keeping the head low while trotting or even rubbing the nose along the ground, acting as if a bee has flown up the nose, excessive nasal and lacrimal discharge, hyperesthesia/hyperresponsiveness around the face, anxiety and agitation, hopping off the ground in one or both thoracic limbs, head pressing, shade-seeking, muscle fasciculations, sweating, and striking

VetBooks.ir

at the nose. Many of these signs seem directed by the horse toward noxious sensations coming from the nose or face. Anesthesia of the infraorbital nerves at the infraorbital foramina prevented headshaking in 3 of 19 horses,[12] whereas 24 of 27 horses stopped headshaking when the posterior ethmoidal nerves (branches of the ophthalmic nerves) were blocked.[13] The latter technique may also block the proximal aspect of the infraorbital nerve and even the maxillary nerve.[14] These results indicate that idiopathic headshaking is set off in the caudal parts of the nasal passages in most horses. Some cases of headshaking are almost entirely induced by bright light and appear to represent optic-trigeminal summation of stimuli arriving via both nerves.[2] It is not yet known how these clear-cut cases of *photic* headshaking relate to the much larger number of cases wherein light is not directly involved or is only a weak trigger factor. It may be that photoperiod (i.e., the proportion of the day that is light) is more important than light intensity in such horses and may explain the role of season in many cases.[2] Whatever the inciting cause, idiopathic headshaking appears to be a nasal/facial pain syndrome associated with hyperactivity of trigeminal pain pathways.[13] In humans trigeminal neuralgia is often caused by vascular impingement on the trigeminal ganglion or nerve adjacent to the brainstem. Such a possibility has not yet been investigated in equine headshakers.

Examination of horses with headshaking includes a complete physical examination; ophthalmic, otoscopic, neurologic, and dental examinations; endoscopic examination of nasal passages, pharynx, and guttural pouches; radiography of the skull, and a complete blood count and chemistry panel. When available, CT is the preferred imaging technique. No abnormalities are usually noted in these examinations.[15]

Treatment

PHYSICAL. Mild cases of headshaking can often be partially suppressed by the use of a muzzle net. About 30% of horses treated this way improved at least 70%, although the durability of any salutary effect has not been established.[16] There was no difference in the effectiveness of full face versus nasal nets. A number of organizations and jurisdictions now allow horses to be shown wearing a muzzle net. A few horses respond to a heavy hair net or a dangling device that makes contact with the nose area or upper forehead. This type of contact may prevent the nerve from firing, similar to blocking a sneeze by placing a finger under the nose and applying pressure.[15] Facemasks and contact lenses that substantially reduce ambient light are available and are very effective in preventing photic headshaking.[2] An argument has been made that bitless bridles may be helpful if there are headshaking trigger points related to the action of the bit.[17] These devices have not found wide application.[5]

SURGICAL. Surgical approaches to headshaking are controversial because considerable morbidity and even severe suffering are frequent side effects of the procedures.[5] Notwithstanding these problems, surgery does appear to achieve a permanent cure in some horses.[12-14,18] The objective of surgery is interruption of pain pathways in the trigeminal nerve or its branches. Two approaches have been used—infraorbital neurectomy and caudal infraorbital nerve compression. In the first procedure, a 2-cm section of nerve is removed just rostral to the infraorbital foramen.[12,18] To effect nerve compression, up to eight platinum embolization coils are introduced via the infraorbital foramen and packed around the infraorbital nerve within the caudal aspect of the infraorbital canal.[13,14] Five of twenty-six (19%)[12,18] and 26 of 57 (46%)[13] horses had long-term elimination of headshaking after infraorbital neurectomy and caudal compression, respectively. Additional horses had temporary remission of headshaking only to relapse weeks to months after surgery. Further long-term remissions were achieved when the procedure was repeated in some of the relapsed horses.[13,18] Exacerbation of headshaking and self-inflicted trauma around the muzzle and lips were problems in most horses after these procedures. These complications typically resolved within weeks but were persistent in some; four of these horses were euthanized because of the severity of signs. The results of nerve blocks did not completely predict response to surgeries; however, two of three horses that responded to infraorbital blocks achieved complete remission with infraorbital neurectomy.[12] Tracheostomy has been shown to be effective as a salvage procedure, presumably by bypassing the passage of air through the nasal passages.[5]

MEDICAL. It is unlikely that complete and permanent remission can be achieved medically. Cyproheptadine, 0.3 mg/kg PO twice daily, has been used with some success for photic headshaking[2] and with limited success in other cases of idiopathic headshaking.[3,12,19] Mild lethargy and colic are occasional side effects. Headshaking can be suppressed for variable periods by the potent analgesic antiseizure drugs carbamazepine and gabapentin, but effects are often not complete and signs return within several weeks of beginning treatment.[5,20] Cyproheptadine may potentiate the analgesic actions of carbamazepine. In one horse persistent 95% remission was obtained by the CT-guided injection of glycerol into the trigeminal ganglia.[21] Individual horses are reported to have responded to corticosteroids or antihistamines, perhaps indicating a role for allergic rhinitis in those few cases.[1,12] Nonsteroidal antiinflammatory drugs have not been effective. Melatonin is advocated as a way to suppress the neurologic responses to increasing photoperiod (i.e., seasonal effect), so it should be started before the anticipated seasonal onset of headshaking.[2] This has reportedly been effective in a few cases. A variety of other supplements and traditional or alternative products have anecdotal or conceptual support with (as yet) no evidence. At least most of them are inexpensive and nontoxic at recommended doses. There are protocols for chiropractic therapy and acupuncture for headshaking. These have not been successful in the author's experience.

Maedi-Visna Virus Infection (Ovine Progressive Pneumonia Virus Infection; Zwoegerziekte)

Mary O. Smith • David C. Van Metre • Lisle W. George

Definition and Etiology Maedi-visna virus, or ovine progressive pneumonia virus (OPPV), infection is a chronic disease of sheep caused by a retrovirus (subfamily Lentivirinae).[1-4] Visna virus is closely related to the many lentiviruses that cause immunodeficiency and neurologic disease in other species; these viruses include equine arteritis virus, caprine arthritis-encephalitis virus, and simian, feline, and human immunodeficiency viruses.[5] Caprine and ovine lentiviruses constitute a single virus group, termed the *small ruminant lentiviruses* (SRLVs), which can readily cross between species.[6-8] These agents are enveloped RNA viruses.[9] The respiratory aspects of the viral infection are discussed in Chapter 31.

Clinical Signs Neurologic disease caused by maedi-visna virus is relatively rare. Adult sheep and lambs as young as 4 months of age can be affected.[10] Nervous system signs may be characteristic of a diffuse encephalitis and include ataxia, twitching of the facial muscles, conscious proprioceptive deficits, normal gait along a straight path, staggering or stumbling when turned or forced to perform a complex maneuver, circling, and blindness. Coma, convulsions, and hyperexcitability may be seen in terminal stages. Other sheep have gradually progressive limb weakness and ataxia, often worse in the rear limbs; neurologic dysfunction localized to the spinal cord may be the sole clinical manifestation of maedi-visna.[11] Some sheep merely show emaciation without neurologic signs. Others may show nonsuppurative, progressive arthritis of one or more joints or symmetric enlargement of the mammary gland. The time between the onset of clinical signs and death is highly variable but can be as long as 1 to 2 years. The presence of antibody in the serum is usually considered evidence of active infection.[12,13]

Clinical Pathology The CSF of affected animals is characterized by pleocytosis, with the cell counts per deciliter ranging from 1012 to 1478 for animals infected for 1 month and 4 years,

VetBooks.ir

respectively.[14] The protein concentrations of CSF range from 50 to 100 mg/dL for 30 days after infection. Antiviral antibody and virus can be detected in CSF specimens.

Pathophysiology The lesions of maedi-visna virus infection are partly induced by the host's inflammatory response. Experimental immunosuppression of infected sheep ameliorates the severity of the clinical signs and reduces the CNS lesions without altering the amount of viral shedding.[15,16] The maedi-visna virus is immunosuppressive, and infections may lead to a variety of secondary bacterial infections.[17] Chronic viremia is typical.

Pathology Gross lesions of visna infection are seen only rarely, when inflammation and malacia are extensive. In such cases, areas of yellowish tan discoloration are present in white matter.[18] The microscopic lesions of visna are predominantly those of a diffuse, nonsuppurative, perivascular inflammation throughout the neuraxis, with white matter affected more severely than gray matter. The lesions include demyelination, gliosis, lymphocytic choriomeningitis, and focal necrotic areas that are infiltrated by macrophages.[19,20]

After exposure to the virus, sheep develop an asymptomatic infection for as long as 6 weeks. Replication of the virus occurs in circulating cells during this stage of the infection.[21] Once the disease has been recognized, the affected sheep should be culled or slaughtered. Control measures are discussed in Chapter 31.

Diagnosis and Epidemiology Spread of maedi-visna virus occurs through ingestion of infected milk by neonates, through in utero transmission, and horizontally within a herd.

The diagnosis of visna infection is made initially by recognition of the clinical neurologic disease in groups of animals in which the pulmonary, joint, or mammary form of the disease is also present. Agar gel immunodiffusion (AGID) testing has been superseded by more accurate ELISA and PCR tests.[22] The diagnosis and epidemiology of maedi-visna virus infection are discussed in detail in Chapter 31.

Treatment and Prevention No effective treatment for maedi-visna virus infection is available for field use. Prevention is based on herd hygiene and culling of affected animals, as described in Chapter 31.

Caprine Arthritis-Encephalitis Virus Infection (Infectious Leukoencephalomyelitis)

Definition and Clinical Signs The caprine arthritis-encephalitis (CAE) virus is a small ruminant lentivirus that belongs to the retrovirus group and is closely related to the virus that causes maedi-visna and ovine progressive pneumonia in sheep.[1] The systemic manifestations of the disease are thoroughly discussed in Chapter 38. The distribution is worldwide, but disease tends to be more common in regions with intensive goat-rearing operations. The leukoencephalomyelitis form of CAE is predominantly seen in young goats younger than 1 year of age; only occasional cases occur in older goats.[2] The clinical signs of leukoencephalomyelitis are highly variable but typically involve the spinal cord. Signs include progressive ataxia, paraparesis, paraplegia, tetraparesis, tetraplegia, hemiparesis, and hemiplegia. Goats with high cervical spinal cord lesions (L1 to L4) are recumbent and unable to raise their heads from the floor. They may show resistance to passive neck flexion. Spinal reflexes range from hypertonia and hyperreflexia to hypotonia and hyporeflexia. Intracranial signs may also develop; these include head tilt, nystagmus, tremors, torticollis, salivation, depression, coma, and opisthotonos.[3-9] Vision and pupillary light reflexes may be diminished. The neurologic deficits may be either symmetric or asymmetric. This diversity of signs is related to the variable location of lesions in the CNS.

Other signs that may be associated with CAE infection include fever (although this is highly variable), enlarged joints, mammary gland enlargement, vague and shifting leg lameness, weight loss, and tachypnea without significant auscultatory abnormalities.

The major differential diagnostic considerations for the neurologic form of CAE include head or spinal trauma, listeriosis, cerebrospinal nematodiasis (verminous meningoencephalomyelitis caused by the meningeal worm of the white-tailed deer, *Parelaphostrongylus tenuis*), and multisystemic infections with *Mycoplasma* spp. The CAE virus causes neurologic lesions in numerous regions of the CNS, whereas the lesions of listeriosis are generally restricted to the brainstem. Mycoplasmal infections typically affect kids ranging from 1 to 6 months of age, and affected animals are systemically ill and often display septic polyarthritis and polyserositis. *Mycoplasma* infections of goats are described further in Chapter 38. Verminous meningoencephalomyelitis can be differentiated from CAE by serologic or PCR testing for the virus, CSF analysis, season, and geographic distribution of the white-tailed deer host.

Diagnosis Previously, an AGID test was used for the diagnosis of CAE, but this has been superseded by ELISA and PCR tests.[10,11] The virus may also be cultured from infected tissue.[12] One study has reported an increase in total plasma protein and hypergammaglobulinemia in affected goats.[4] The results of other hematologic and blood chemistry analyses are normal. The changes in the CSF are characteristic only of a chronic granulomatous inflammation. Specific changes include an increased protein concentration and pleocytosis.[13] Cell counts in the CSF of affected goats range from 5 to 1800/dL, and the protein concentration ranges from 0 to 700 mg/dL.[2]

Pathogenesis When inoculated into goats, the virus causes a chronic infection characterized by demyelinating encephalomyelitis, arthritis, and interstitial pneumonia. The pathologic changes resemble those of an autoimmune process and are probably caused by interactions among the host's immunologic responses, denatured myelin, and the virus.[14] Macroscopic pathologic changes in the CNS of naturally infected goats include cloudiness of the meninges and tan discoloration of the white matter.[3] Microscopic changes include disseminated perivascular accumulations of mononuclear cells, demyelination originating in the subependymal region, astrocytosis, and mononuclear leptomeningitis.[3,7,10,14,15] Spinal cord lesions are most frequently observed in the thoracolumbar segments.[2]

Treatment No treatment is available for goats with leukoencephalomyelitis. Control measures are discussed in Chapter 38.

Border Disease (Hairy Shaker Lambs; Hypomyelogenesis Congenita)

Definition and Etiology Border disease is a congenital infection of sheep and goats caused by a noncytopathic togavirus (genus *Pestivirus*).[1] The border disease agent is antigenically similar to the bovine viral diarrhea (BVD) and hog cholera (classical swine fever) viruses. Once introduced into a flock, the border disease virus causes abortion, infertility, and deformed lambs. During pregnancy in a naive ewe, viral infection results in a variety of fetal malformations, including early embryonic death, abortion and stillbirth, and small, malformed lambs. A seroprevalence rate as high as 29% has been seen in a newly infected flock. It is important to note that lambs infected in utero become immunotolerant and remain viremic for life, similar to calves persistently infected with BVD virus.[2] Adult sheep that become infected with the border disease virus develop an inapparent, short-lived viremia and become immune to reinfection.

Clinical Signs The severity of clinical signs in affected lambs varies. Changes are most marked in newborn lambs infected in early gestation (before 50 days). The CNS, skin, and skeleton are the most seriously affected. The hairs of congenitally affected lambs are coarse, straight, and elongated and stand out from the body like a halo.[3] The

VetBooks.ir

coat is abnormally pigmented and may have a dark-gray appearance or hyperpigmented spots that are especially prominent over the top of the neck.[4] Animals that survive shed the abnormal hairs at 9 to 12 weeks of age and replace them with normal hair fibers. Affected lambs also have a short, thickened body; shortened legs; smaller orbital size; and doming of the frontal bone.[5,6]

Arthrogryposis occasionally occurs. Some infected lambs show neurologic symptoms such as ataxia and uncontrollable tremors; the latter sign, combined with the characteristic hair coat, gives affected lambs the common term of "hairy shakers." The tremors are coarse, involve the trunk and head, and disappear when the animal is asleep.[7,8] The lambs are often alert and appetent but initially need assistance to stand and nurse. Some animals walk normally but hop on the rear limbs when forced to run. The CNS signs usually disappear by 20 weeks of age, but the animals appear stunted. Affected animals have greatly decreased viability compared with uninfected herdmates and may die unexpectedly. Aside from neonatal death losses, economic burdens imposed by the viral infection include low birth weights, diminished weaning weights, lowered carcass quality, and infertility.[6,9]

Abortions that occur 9 to 106 days after inoculation were seen in 30% of experimentally infected sheep.[4,5,10] In field outbreaks the average gestational age of the aborted fetus is 63 days. Teratogenic effects are most often observed when lambs are infected at 50 to 90 days of gestation.[11] Fetal mummification may occasionally be seen.

The border disease virus is also pathogenic in goats.[12] As in sheep, inoculation of pregnant does results in fetal mummification and abortion. The spinal cords of infected kids are hypomyelinated, but the haircoat is normal.

The border disease virus has low pathogenicity for cattle. Abortions can be induced in cows inoculated with the virus at approximately 50 days of gestation, and affected calves have cerebral cavitations.[13] When comingled with infected sheep, natural infection of cattle can occur.[13a]

Diagnosis Identification of the viral antigens in tissues using fluorescent antibody tests is the most accurate method of diagnosing border disease. Tissues that most consistently contain viral antigens are those of the abomasum, pancreas, kidneys, thyroid, and testicles.[14,15] Serodiagnostic methods including serum neutralization (SN), AGID, and complement fixation tests have been developed.[16] In most cases the BVD virus has been used as the indicator antigen. Serodiagnosis of infected lambs is difficult because the lambs tend to be immunotolerant and therefore do not develop strong serologic responses. The presence of viral antibodies in the CSF suggests border disease virus infection.

Pathophysiology Hypomyelination is probably caused by a combination of virus-induced degeneration of the oligodendroglial cells (dysmyelinogenesis), persistent viral infection, and diminished secretion of the thyroid hormones L-3,3′,5′-triiodothyronine and thyroxine.[17] The diminished production of thyroid hormones is thought to be related to direct inhibition of the thyroid gland because the pituitary activity of these lambs appears to be normal. Lambs infected in utero have decreased white and gray matter in their spinal cords as a result of the decreased myelin content.[18] Depressed blastogenic activity of lymphocytes, a decrease in T-helper cell function, and an increase in T-suppressor cell function have been demonstrated in affected lambs between 4 and 7 months of age, indicating a viral immunosuppression.[19-21] Such lambs may succumb to parasitism, diarrhea, and bronchopneumonia.

Epidemiology Border disease is transmitted both vertically and horizontally.[19,22] As for BVD in cattle, the major reservoir in infected herds is the asymptomatic, congenitally infected, seronegative animal.[2,23] Sheep exposed to the virus as adults develop antibody responses and clear the infection. Asymptomatically infected animals may shed the virus through the placenta, infected offspring, saliva, respiratory secretions, urine, or feces.[10,19] In one seroepidemiologic study of infected ewes in the western United States, lambs were more often seropositive than ewes.[2] A large percentage of the seropositive lambs were born to seronegative ewes, indicating the presence of a large amount of virus cycling from asymptomatic carriers. Strain-related differences appear to exist in viral pathogenicity.[24]

Necropsy Findings The macroscopic changes associated with border disease virus infection are hydranencephaly, porencephaly, microcephaly, cerebellar hypoplasia, abnormal curvature of the ribs, brachygnathia, doming of the frontal bones of the skull, narrowing of the distance between the orbits, a decrease in orbital size, shortening of the crown-to-rump and diaphyseal lengths, retention of secondary hair fibers, and abnormal skin pigmentation.

Microscopic changes in lambs with congenital infection include hypomyelinogenesis and hypercellularity of the white matter with abnormal-appearing glial cells.[7,8,11] The CNS shows dysmyelinogenesis, secondary demyelination, and periarteritis. Viral antigen can be demonstrated in CNS arterioles.[25]

Differential diagnoses for border disease virus infections in sheep and goats include other causes of infectious abortion, copper deficiency (swayback), and other viral diseases that may result in hydranencephaly, such as those caused by the Cache Valley, bluetongue, and Schmallenberg viruses.

Treatment and Control In herd situations, virus isolation from whole blood or examination of skin biopsies by fluorescent antibody tests can be performed to identify carriers.[14] Serologic testing is not a reliable indicator of infection because congenitally, persistently infected animals may be immunotolerant of the virus. Noninfected pregnant sheep should be kept separated from others in the flock for the first 60 days of gestation to ensure that in utero infections do not occur.

Encephalitic Bovine Herpesvirus Infection

Clinical Signs Two herpesviruses, bovine herpesvirus type 1 (BoHV-1) and type 5 (BoHV-5), have been rarely associated with encephalitis in cattle.[1-4] BoHV-1 infection typically results in infectious bovine rhinotracheitis (IBR), an acute upper respiratory tract disease characterized by fibrinonecrotic white plaques of the nasal, pharyngeal, and tracheal mucosa and abortions (see Chapter 31). Other clinical conditions associated with bovine herpesvirus infections include epizootic conjunctivitis (Chapter 39) and infectious balanoposthitis or vulvovaginitis (Chapter 43). The clinical signs of encephalitis include depression, mild nasal and ocular discharge, conscious proprioceptive deficits, head pressing, aimless circling, bellowing, salivation, bruxism, paralysis of the tongue, head tilt, nystagmus, convulsions, blindness, coma, and death.[2,3] The seizure activity is characterized by a tonic-clonic convulsion with violent spasms or tremors of the head, with all four legs flexed and the head in opisthotonos. Rectal temperatures of 41°C to 42°C (106°F and 107°F) have been reported.[5] Encephalitic herpesvirus infection is frequently fatal, although asymptomatic cases have been induced experimentally.[5a] In experimental infection, signs develop 1 to 2 weeks after infection. A mononuclear pleocytosis is found on analysis of CSF.[5a] Encephalitis may be evident on histopathologic examination of fetuses from cows that abort from BoHV-1.[5b]

Differential diagnoses for encephalitic herpesvirus infections in cattle include almost all encephalitic, encephalopathic, and neurotoxic diseases of cattle, including rabies, polioencephalomalacia, salt poisoning, and lead toxicity. Accompanying respiratory disease raises the index of suspicion for herpesvirus. A rising serum neutralizing antibody titer in surviving animals can be used to confirm infection, although this does not distinguish between BoHV-1 and BoHV-5. Specific diagnosis is usually made at necropsy using a number of modalities including virus isolation, immunohistochemistry, and PCR.[6-8] Many of these tests do not distinguish between BoHV-1 and BoHV-5; more specific PCR tests can differentiate between these two virus types.[9]

VetBooks.ir

Epidemiology Bovine herpesviruses cause disease in cattle worldwide. Epidemiologic factors that appear to favor dissemination of herpesviruses among cattle include a high stocking rate, repeated introduction of animals from diverse backgrounds, and mass weaning of calves at a time when the passively acquired anti-IBR antibodies are waning.[2] BoHV-1 may survive in the environment for up to a month; cooler ambient temperatures and higher humidity promote virus survival.[10] Calves younger than 6 weeks old are most susceptible, but infection and resultant neurologic disease also have been described in adult cattle.[1,3-5,11-13] Animals that survive the disease become persistently infected; virus survives in the nasal and tracheal mucosa and the trigeminal ganglion.[13] Reactivation and virus shedding may occur during periods of stress.[4,10,13] Although clinical disease caused by reactivation of latent virus is usually mild and may go unnoticed, shedding of virus during such episodes provides a source for infection of in-contact animals. The viruses grow in the nasal and pharyngeal mucosa. Brain involvement results from centripetal spread along the sensory neurons of the trigeminal and olfactory nerves.[13]

Pathophysiology Encephalitic IBR infections cause a nonsuppurative meningoencephalitis that is widely distributed in the gray matter of the brain, primarily in the cerebrum and thalamus. Extensive lymphocytic meningoencephalitis is evident on histologic examination. Intranuclear inclusion bodies are rarely seen in bovine herpesvirus encephalitis. The virus can usually be isolated from affected calves.[5a] Signs of respiratory disease may precede or occur coincidentally with neurologic disease.[5a]

Treatment and Control No adequate therapy exists for the encephalitic form of BHV-1 infection. Treatment is symptomatic and supportive and should include oral or intravenous fluid support, NSAIDs, antibiotics in animals with respiratory signs, and nursing care. Diazepam or phenobarbital may be used for seizure control when necessary (Table 35-2). Animals with severe clinical signs may be euthanized for humane reasons.

Vaccines that protect against BoHV-1 have been considered potentially useful in the prevention of BoHV-5 infection because of the close antigenic relationship between the two viruses.[11,11a] However, more recent trials have shown that certain BoHV-1 vaccines may not confer protection to cattle challenged with BoHV-5.[11b,11c]

In some European countries, eradication programs that employ testing and culling of infected animals have been successful in eliminating BoHV-1. Bovine herpesviruses can be spread through fomites and by aerosol transmission for up to 4 miles (6.4 km).[10] Strict biosecurity procedures are therefore essential to developing and maintaining virus-free herds.

Bovine Spongiform Encephalopathy ("Mad Cow" Disease)

Christine F. Berthelin-Baker • David C. Van Metre

Definition and Etiology Bovine spongiform encephalopathy (BSE) is a transmissible spongiform encephalopathy (TSE) of cattle that was first described in 1987 in Great Britain (GB).[1] The TSEs are a group of slowly progressing, invariably fatal neurodegenerative diseases that can affect humans and animals. They are also called *prion diseases* because of the accumulation of prion in the CNS. Since the prion hypothesis was first formulated in 1982, prions have been widely accepted as the etiologic infectious agents of the TSEs.[2] The prion is an altered conformation (PrP-BSE) of the normal prion protein (PrP), a host-encoded membrane protein that does not carry any nucleic acid. PrP-BSE replicates by inducing a posttranslational conformational change in the normal protein PrP to form the abnormal prion PrP-BSE.[2-4] After a characteristically prolonged incubation period, the abnormal isoform of the protein aggregates and accumulates in the CNS of affected animals, creating progressive neurologic dysfunction.

Clinical Signs As with all TSEs, BSE has a long incubation phase. It occurs mostly in 4- to 6-year-old cattle (age range, 20 months to 18 years). The clinical signs of BSE are usually insidious in onset.[5,6]

The detection of clinical signs of BSE and the array of clinical signs reported are influenced by how closely the cattle are being observed and the handlers' awareness of the insidious and nonspecific nature of the clinical signs. Subtle early behavioral changes are unlikely to be observed in large herds. Cattle may become apprehensive, stay apart from their herdmates, and become fearful of their handlers. As the disease progresses, cattle often become extremely excitable,

TABLE 35-2

Recommended Drug Dosages for Treatment of Cerebrocortical Disease

	Dose	Route	Frequency
Anticonvulsant Drugs			
Diazepam	0.01-0.4 mg/kg	IV or IM	Twice daily or as needed
Pentobarbital sodium	2-10 mg/kg	IV	Three times daily
Phenobarbital	Loading dose 20 mg/kg	IV	One time
	Maintenance dosage 1-4 mg/kg	IV, PO, or IM	Divided twice daily
Antiinflammatory or Antiedema Drugs			
Methylprednisolone	1-30 mg/kg	IV	One time
Dexamethasone	1-4 mg/kg	IV or IM	Twice daily
Mannitol	0.25-0.5 g/kg 20% solution	IV	Twice daily
Furosemide	1 mg/kg	IV, IM, or SC	Twice daily
Flunixin meglumine*	1 mg/kg	IV or IM	Twice daily
Phenylbutazone†	2-4 mg/kg	IV or PO	Twice daily
Dimethyl sulfoxide (DMSO)	1-2 g/kg	IV	Twice daily
Acetylsalicylic acid (aspirin)	7-10 g/500 kg	PO	Twice daily

*Monitor for signs of gastric or abomasal bleeding (fecal occult blood).

†An initial loading dose of 10 to 20 mg/kg, followed by 2.5 to 5 mg/kg daily to every other day thereafter has been recommended for cattle. Because of the prolonged plasma half-life in ruminants, serial administration of the drug should be accompanied by careful monitoring of renal function and gastrointestinal bleeding.

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

VetBooks.ir

especially when restrained or placed in confined quarters or an unfamiliar environment. BSE cattle may refuse to move through previously familiar doorways and become impossible to restrain. Unprovoked aggression is less frequently seen. Hyperesthesia is most marked around the head and neck. A light touch on the hindlimbs may induce violent and often repetitive kicking, which may also be observed during milking. Animals may overreact in response to sudden visual, tactile, or auditory stimuli. The startle reaction may be gauged by a hand test (punching fist abruptly toward the animal's head without touching it), flashlight test, a hand clap, or a loud metallic "bang." Normal animals rarely startle in response to such stimuli, or they may startle once or twice when the stimulus is repeated. BSE cases will frequently startle in a violent and repeatable fashion, with no habituation to a repeated stimulus. In some cases the response may escalate to an extreme aberrant startle, with headshaking and seizure-like head bobbing, which may be followed by violent turning, running around, and falling.

Other possible clinical signs of BSE include ptyalism, increased head rubbing, muscle fasciculations, and excessive vocalization. Other behaviors seen in BSE may include frequent and repetitive head tossing, licking of the nostrils, yawning, flehmen, head butting, and restlessness.[7] A relative bradycardia (60 beats/min) may be observed in animals when a tachycardia is expected because of their hyperexcited state. Affected animals often lose weight and have reduced milk output. Ataxia and tremors are seen in more advanced cases. Tremors most often involve the head and neck and may become generalized, especially with exercise. Ataxia is most marked on turns, when going over steps, or on uneven terrain; it may also be accentuated with exercise. BSE animals may become recumbent and unable to feed if the disease is left to run its course. Recumbency may also be triggered by an intercurrent illness or an injury during a fall. The clinical signs of BSE may be more difficult to recognize in animals that have become recumbent than in less advanced cases,[8] and systematic targeted surveillance of downer cattle (fallen stock) have allowed for the detection of previously unsuspected cases of BSE in various countries.[9]

Pathophysiology The exact function of the prion protein is unknown, as are the mechanisms of neurodegeneration and CNS dysfunction in TSEs. On the basis of recent research in transgenic mice expressing bovine PrP, the prion is thought to undergo limited propagation in the distal ileum before spreading to the CNS, most likely by moving through the gut-associated lymphoid tissue (GALT) into the peripheral nerves.[10,11] Studies of naturally infected cattle, combined with experimental oral challenge studies in cattle, have revealed that BSE infectivity may exist in the brain; spinal cord; retinal tissue; optic nerve; cervical, thoracic, and trigeminal ganglia; facial and sciatic nerves; and the distal ileum. The skeletal muscles, spleen, and lymphatic tissues did not demonstrate infectivity.[12,13] Intracerebral inoculation of cattle has also been demonstrated to result in infectivity of the tonsillar tissue.[14] Following a prolonged incubation period, accumulation of PrP-BSE in the CNS creates progressive and irreversible neurologic dysfunction.

Epidemiology and Zoonotic Potential Current evidence indicates that BSE has resulted from a single agent.[15-20] BSE may have derived from feedstuffs containing rendered carcasses of scrapie-infected sheep, or it might have been a preexisting sporadic and rare disease unrecognized in the bovine population. The BSE epidemic was traced to the recycling of BSE-infected carcasses into cattle feed, which occurred mostly in the 1980s in the United Kingdom (UK).[16] Cattle in other countries were affected as a result of the importation of infected feedstuffs or cattle, followed by later recycling the agent in their own rendered ruminant feedstuffs. At present (early 2013), according to the World Organization of Animal Health (Office International des Epizooties [OIE]), BSE has been detected in 26 countries including the United States.[21,21a] From 1986 to December 2012, a total of 181,128 cases of BSE were confirmed in GB, according to the Department for Environment, Food, and Rural Affairs.[22] These cases have been distributed among 36,194 farms.[22] The cattle cohorts born in 1986 to 1989 had the highest incidence of BSE cases, and the peak of the outbreak occurred in 1992, when 36,680 cases were detected through scanning of suspect clinical cases (passive surveillance) in GB. Active surveillance has revealed a sustained and sharp decrease in the number of cases since 2001.[22] The decline in the GB epidemic is directly related to the successive bans on the feeding of ruminant-derived meat and bone meal to cattle. The initial 1988 ban took effect in 1989 in the UK and has been tightened and refined since then. Similar feed bans have been adopted by many countries around the world. A list of countries that have reported home-born or imported cases of BSE and the number of cases reported each year is available and regularly updated on the website of the OIE.[21]

Bovine spongiform encephalopathy has predominantly affected dairy cattle because of their longer lifespan and more intensive feeding and wider use of concentrate than beef cattle. No clear genetic predisposition to BSE has been demonstrated in cattle, unlike for scrapie in sheep. The disease is considered to be a food-borne disease of cattle, associated with the ingestion of meat and bone meal contaminated with the BSE prion. This is substantiated by the steady decline in the incidence rate of BSE in endemic countries following enactment of bans on feeding ruminant protein to ruminants.[21a]

Since the onset of BSE epidemic, new TSEs have been identified in animals other than cattle. Strain typing in mice showed that these new TSEs were caused by the BSE agent,[23,24] which has proven to be a relatively promiscuous TSE agent, capable of experimentally infecting mice, sheep, goats, pigs, cats, mink, and primates.[15] The disease in humans, termed *new-variant Creutzfeldt-Jakob disease* (vCJD), was first identified in 1996 in the UK, where it has affected 176 people as of January 2013.[25] Other countries have detected vCJD cases in people who had lived in the UK between 1980 and 1996, as well as in citizens who never traveled to the UK. The emergence of vCJD has put worldwide emphasis on the prevention and detection of TSEs in animals. The route of infection of people by BSE has not been clearly traced, but on the basis of a case-control study, the consumption of food that included infected cattle nervous tissue was demonstrated to be associated with increased risk of vCJD.[26] This and other evidence has led to successive "Specified Risk Materials" bans in many countries, aimed at preventing contamination of human food with nervous system or other specified high-risk tissues from ruminant animals.

Rigorous, active surveillance programs have been initiated in many countries to screen cattle and beef products for the BSE agent. This large-scale testing recently led to the detection of two extremely rare, novel prions based on protease resistance patterns and glycopatterns.[27-30] These novel agents have been termed *H-BSE* and *L-BSE,* and animals from which these agents have been identified have been termed *atypical BSE* cases.[15] These novel BSE cases have been detected in multiple countries by rapid prion detection tests conducted on aged (>8 years) cattle that were tested either during slaughter surveillance or through targeted surveillance of downer cattle. Investigations regarding the origin and pathogenesis of atypical BSE are ongoing. Owing to the advanced age of affected cattle and the low known prevalence of atypical BSE, it has been speculated that atypical BSE may arise spontaneously.[15]

Diagnosis No in vivo test is available for the diagnosis of BSE. Clinical suspicion can be confirmed only by postmortem examination. The diagnosis of BSE is based on microscopic brain examination or tests that identify the abnormal prion in brain or spinal cord tissue.[1,31] Rapid prion tests include Western blot, paraffin-embedded tissue (PET) blot, and ELISAs.[32-35] Rapid tests have enabled the detection of BSE through surveillance in targeted at-risk populations such as fallen (downer) cattle.

Histopathologically, BSE is characterized by neuronal degeneration and intraneuronal vacuolation in specific brain areas. The vacuolation is accompanied by or preceded by the accumulation of

VetBooks.ir

PrP-BSE.[16,17,36] The obex of the medulla is currently considered to be the tissue of choice for detection of the BSE agent.[37]

Differential Diagnosis Nervous system diseases that could be confused with BSE include viral encephalopathies (pseudorabies, rabies, Borna encephalitis, bovine immunodeficiency virus encephalitis), listeriosis, polioencephalomalacia, lead poisoning, CNS parasitic migration, brain tumors and abscesses, and vitamin A deficiency. Hepatic encephalopathy and other metabolic imbalances may also be confused with BSE. Because of the insidious nature of BSE, affected cattle may appear to recover coincidentally with blanket therapy for suspected metabolic imbalances and later relapse. This must be kept in mind whenever therapy for metabolic imbalances initially appears to be successful but is followed by one or more relapses.

Treatment and Prognosis BSE is always fatal, and no treatment is available.

Control Various measures have been taken to protect public health by removing potentially infected animals and tissues from the food chain. The disposal of BSE-infected tissues and the sourcing of bovine tissues and body fluids for the preparation of medicinal products must take into account the extreme resistance of TSE agents. All TSE agents remain infectious after exposure to a wide range of inactivating treatments and environmental changes such as autoclaving, rendering, storage for months to years, exposure to ultraviolet light, freezing, thawing, prolonged boiling, and incubation with formalin.[38-40] Because of the public health risk, the carcasses of animals suspected of having BSE should be disposed of in an alkaline-hydrolysis tissue digester designed to inactivate TSE agents.[41]

In countries that have had an outbreak of BSE, the complete exclusion of ruminant tissues from ruminant feed has aided progress toward eradication of BSE, as previously noted. In the UK the initial feed ban of 1988 was found to be insufficient and was reinforced by successive measures. The 1996 ban on feeding mammalian meat and bone meal to all farmed animals was introduced to prevent contamination of ruminant feed at feed mills and down the supply chain to the farm. Because of the long incubation period of BSE, a time lag has occurred between the implementation of feed control measures and reduction in the incidence of this disease.

Scrapie

Definition and Etiology Scrapie is a TSE that naturally affects sheep, goats, and mouflons. It is the oldest known TSE, described over 2 centuries ago. The causative agent is considered to be a prion (PrP-Sc) distinct from that of BSE.[1] At least three distinct types of the scrapie agent have been identified in the natural hosts.[1] Although sheep are susceptible experimental challenge with the BSE agent, natural BSE has not been reported in sheep.[1]

Clinical Signs Most animals with scrapie are 1 to 5 years old. The clinical course varies but is typically slow and may last several months. Early behavioral changes are often accompanied by weight loss. Scrapie cases may stay apart from the flock and become nervous and restless.[2] Pruritus of increasing intensity is a common feature; sheep may rub on fixed objects, scratch with their horns or hooves, and bite or lick at themselves excessively. The head, withers, flanks, back, rump, base of the tail, and lower limbs are typically affected, showing secondary wool loss, dermatitis, and skin infections or excoriations.[2,3] Head and face rubbing and shaking may also cause ocular lesions or aural hematomas. When scratching the pruritic areas (mostly the back and rump), the animal may display a "scratch reflex" (or "nibble reflex"), which may include reflex nibbling, lip licking, and rhythmic head movements. This reflex is often but not always present in scrapie cases. Importantly, this response may also be observed in other CNS diseases and in pruritic skin diseases, particularly ectoparasitism, so it should not be considered specific for scrapie.

Other clinical signs of scrapie include bruxism, ptyalism, and regurgitation. Tremors may start with the head and generalize to the whole body. Apathy, exercise intolerance, hypermetria, and ataxia may develop. The most severe and advanced cases show stupor, episodic collapse, and convulsions. Death may occur during a convulsion or as a result of starvation. The clinical signs of scrapie in goats are broadly similar to those in sheep.[3-7] Scrapie has been identified in fallen (down) sheep as well.

Pathophysiology In contrast to BSE, which is restricted to the gut-associated lymphoid tissue and nervous tissue, the scrapie agent can be identified in infected sheep in a variety of non-neural tissues such as the lymphoreticular system, kidney, and placenta.[8,9] This difference has facilitated the development of lymphoid tissue biopsy techniques to detect scrapie (described later). Most transmission of scrapie appears to take place during the birthing season.[1] The scrapie agent is most likely spread by the placentas and birthing fluids of infected animals,[10,11] and oral uptake is considered the most likely route of entry.[10-12] Transport of PrP-Sc to the CNS likely occurs along the vagus nerve from the GI tract,[13] and the agent can be demonstrated in most cases in the vagal nucleus of the brainstem early in the stage of neuroinvasion.[14] Spread into higher brain centers follows. Dysfunction of the CNS appears to correlate roughly with accumulation of PrP-Sc in the brain; however, subtle dysfunction can occur with little or no characteristic histologic changes. The exact mechanism(s) that cause neurologic dysfunction remain to be fully defined.[8]

Epidemiology Scrapie occurs endemically in sheep flocks worldwide, with the exception of Australia and New Zealand.[1] Sheep are the natural host of scrapie, but the infection can be maintained in goats that have no direct contact with sheep, indicating both lateral and vertical transmission of the agent in that species.[3,4,15] Scrapie cases occur sporadically in infected flocks. Only one or a few animals are affected at any given time. Outbreaks may occur if scrapie is introduced into a genetically sensitive flock.

Although there is no known breed predisposition to scrapie, the genetic makeup of the host controls differences in susceptibility and resistance to scrapie in various breeds.[1,16,17] The molecular basis of this resistance is largely controlled by the PrP gene.[18] Polymorphisms at three codons of this gene (171, 136, and 154) appear to be the main determinants of the susceptibility of sheep to scrapie.[1] According to current evidence, the genotype $VV_{136}RR_{154}QQ_{171}$ (or $AA_{136}RR_{154}QQ_{171}$ in some breeds) is most susceptible, and the genotype $AA_{136}RR_{154}RR_{171}$ is highly, but not completely, resistant.[1] Susceptibility is most clearly linked with variation at codons 136 and 171 in breeds studied to date; the genotype of a particular animal is often referred to as RR, QR, or QQ to designate the alleles at site 171. Selection of scrapie-resistant sheep flocks may be based on pedigree, phenotypic expression of the disease, or genetic testing to select sheep of "resistant" PrP genotypes. Genetic polymorphisms or the PrP gene may also influence susceptibility to and/or the incubation period for scrapie in goats.[19]

Treatment and Prognosis Scrapie is a fatal and irreversible disease for which there is no known treatment.

Diagnosis Because the scrapie agent can disseminate in lymphoid tissue before the development of clinical disease, immunohistochemistry may show PrP-Sc in biopsies, lymphoid tissue in the tonsils,[20] nictitating membranes,[21] retropharyngeal lymph nodes,[22] or rectoanal junction.[23,24] However, these tests have limited sensitivity, primarily because of variable lymphoid involvement among infected sheep, a phenomenon that may be associated with the host's genetic makeup.[25] Microscopic examination of the brain and spinal cord is the classic diagnostic method for scrapie. It is possible only when tissues are collected soon after death, before autolytic changes take place. Neuronal vacuolation and PrP-Sc deposits are found in specific

VetBooks.ir

brain nuclei.[26-31] At present, collection of brainstem (particularly the obex), tonsillar tissue, and medial retropharyngeal lymph nodes is currently recommended for testing suspect sheep in the United States.[32] In autolyzed tissues, PrP-Sc can be identified by immunohistochemistry testing, Western blot tests, or ELISA.[33-36] As for BSE, heightened active surveillance for scrapie has revealed at least one atypical strain of scrapie (termed *atypical scrapie*), and investigations into the host range and detection methodologies for this novel agent are ongoing.[37]

DIFFERENTIAL DIAGNOSIS. Nervous system diseases that could be confused with scrapie include pseudorabies, rabies, Borna encephalitis, listeriosis, polioencephalomalacia, lead poisoning, cerebrospinal nematodiasis, gid (coenurosis), brain tumors, brain abscess, maedi-visna virus infection, vitamin A deficiency, pregnancy toxemia, and other metabolic imbalances. When pruritus is the only clinical sign, skin diseases such as psoroptic and sarcoptic mange, ringworm, myiasis, pediculosis, and atopy may be considered as differential diagnoses. Because of the insidious nature of the illness, animals with early scrapie may initially appear to respond to a variety of treatments. This must be kept in mind whenever specific therapy for another suspected illness appears initially to be successful but is followed by relapse. When therapy of an alternate condition fails, the final diagnosis must rely on detailed examination of appropriate postmortem samples.

Control

Because there is no effective treatment for scrapie, control measures designed to prevent the spread of the disease are especially important. Scrapie is a reportable disease. Eradication measures vary from country to country. Animals suspected of having scrapie are slaughtered and destroyed. Contaminated pastures or paddocks may be left empty of livestock, but the scrapie agent is unlikely to be inactivated in the environment. Contaminated stalls, corrals, and sheds should be disinfected with sodium hypochlorite diluted at 4% available chlorine. In the United States and Canada, scrapie-affected and related animals are destroyed and their flocks are quarantined. Lines of sheep genetically resistant to the development of clinical scrapie have been selected,[38,39] and genotype testing is currently used to select for resistance to the disease.[1]

Public Health Considerations

Although scrapie has been endemic in various areas of the world for more than 2 centuries, epidemiologic studies have not shown any correlation between the incidence of Creutzfeldt-Jakob disease in humans and that of classical scrapie in sheep; the zoonotic potential of atypical scrapie remains under investigation.[1] It is nevertheless prudent to take precautions to minimize the potential for human exposure to scrapie, owing to the high fatality rate characteristic of TSEs and the potential for emergence of novel strains of prions with unknown host ranges.[1]

Pseudorabies (Aujeszky Disease, Mad Itch, Bulbar Paralysis)

Christine F. Berthelin-Baker • Lisle W. George

Definition and Etiology

Pseudorabies is an acute, severe, and usually fatal encephalitis caused by an encapsulated DNA virus, suid herpesvirus type 1 (Su-HV1), a member of the genus *Varicellovirus,* subfamily Alphaherpesvirinae, family Herpesviridae.[1,2] This virus can infect the CNS and other organs (e.g., respiratory tract) of virtually all mammals except humans and most primates. Domestic and feral swine are the natural hosts and may become latent carriers. The virus can also infect cattle, sheep, cats, dogs, goats, wildlife (e.g., raccoons, opossums, skunks, rodents), and, rarely, horses.[3-6]

Clinical Signs

The incubation period ranges from 90 to 156 hours, and the illness may last 8 to 72 hours, although some affected animals have been found dead without any observed clinical signs.[7,8] The initial clinical sign in ruminants is usually a manifestation of paresthesia, with acute and severe pruritus inducing self-trauma, dermal abrasions, swelling, and alopecia.[7] Other signs may include fever, bellowing, bloat, feet stamping, excessive salivation, twitching, chewing of the tongue, ataxia, circling, nystagmus, and strabismus.[9-11] Aggression may be seen, but most affected animals become depressed. As the disease progresses, there may be hyperesthesia, tenesmus, excessive licking of the nostrils, continuous mastication, vocalization, coma, convulsions, and opisthotonos.[12] Most cases are fatal. The clinical signs of pseudorabies in cattle closely resemble those of rabies, polioencephalomalacia, salt poisoning, meningitis, lead poisoning, hypomagnesemia, and enterotoxemia.

Clinical Pathology

The Aujeszky disease virus (ADV) can be isolated from the pharyngeal or nasal secretions of affected animals and can be easily cultured from infected nervous tissues. Strains of ADV are antigenically distinct from other herpesviruses but share common antigens with the infectious bovine rhinotracheitis (IBR) virus. Heterospecific antibodies to the IBR virus may cross-neutralize the pseudorabies virus and confound serologic tests. For virus culture, tissues should be collected from sensory ganglia or the dorsal horn of the spinal cord. Segments serving the pruritic sites should be collected preferentially because these areas contain the highest concentration of virus.

Pathophysiology

Ruminants are susceptible to pseudorabies infection after intradermal, subcutaneous, intranasal, or oral exposure to the virus. After subcutaneous, oral, or nasal infection, the virus spreads centripetally to the CNS by axonoplasmic transport. During the acute infection the virus may be present in the nasal mucosa, secretions, and saliva.

Epidemiology

Aujeszky disease has a worldwide distribution and, although cases occur only sporadically, is an economically important disease because of the regulatory quarantine and other restrictions imposed on animals from affected herds. Until recently, Aujeszky disease was endemic in the United States, but it has been successfully eradicated from domesticated swine. As of December 2006, all states are classified as free of pseudorabies in domesticated swine (OIE status V), although ADV remains present in feral pigs in parts of the United States.

The viral infection in cattle is perpetuated partly by the occurrence of latent infections in pigs, which can be recrudesced by stressful conditions.[13] Occasional spillover of the virus from swine into ruminants occurs because of the proximity of the two species in many livestock operations.[8,14] The natural routes of transmission include nose to nose, fecal oral, and venereal.[3,15] Indirect transmission usually occurs by inhalation of aerosolized virus. The virus may travel via aerosols up to 2 km (1.2 miles) in certain weather conditions and may survive up to 4 days in straw bedding. It is inactivated by drying, sunlight, and high temperatures (37° C). Dead-end hosts such as dogs, cats, and wildlife can transmit the virus between farms, but aside from feral swine, these animals survive only 2 to 3 days after becoming infected.

Latency of the viral infection in ruminants is not an important mechanism for perpetuation of an outbreak because most animals die within 48 hours of disease onset. In the few that survive longer, shedding in saliva occurs for up to 6 days after infection. Direct spread of the virus between infected and uninfected cattle is unlikely.[14] Wild mammals such as raccoons may play a role in pseudorabies survival and transmission; rats, however, develop transient infections and do not appear to transmit or perpetuate the virus.[16-18] The pseudorabies virus may survive in contaminated meat products for up to 7 weeks. The role of this prolonged survival in perpetuating outbreaks in ruminants is unknown.

Necropsy Findings

Gross findings include excoriation, alopecia, edema, and hemorrhage at the pruritic site. The neuropathologic changes include nonsuppurative encephalitis, neuronal

VetBooks.ir

degeneration, and eosinophilic intranuclear (Cowdry type A) inclusion bodies. The lesions are most pronounced in the dorsal nerve rootlets and the dorsal horn.

Treatment There is no treatment for pseudorabies, which is usually fatal in livestock, although rare recoveries have been reported.[10]

Prevention The most effective method of preventing pseudorabies virus infection in ruminants is eliminating their exposure to swine. Contaminated pens can be disinfected with 10% sodium hypochlorite solution, quaternary ammonium compounds, tamed iodine, or phenolic compounds.[19] At least 5 minutes of contact time should be allowed before the disinfectant is rinsed from the contaminated surfaces. Fumigation with formaldehyde for 6 hours effectively kills the virus, as does 360 minutes of contact with ultraviolet light.

Ovine Encephalomyelitis (Louping Ill)

Definition and Etiology Louping ill is an acute, fatal encephalomyelitis of sheep that occasionally infects humans, wild ruminants, horses, and cattle.[1-3] The disease has been reported in England, Scotland, Ireland, Norway, Turkey, and Bulgaria.[4-6] The etiologic agent of louping ill is a neurotropic, single-stranded RNA virus (flavivirus) that is transmitted by primarily the tick *Ixodes ricinus,* as well as by *Rhipicephalus appendiculatus, Ixodes persulcatus,* and *Hemaphysalis anatolicum.* Most outbreaks occur in swampy areas with dense populations of infected ticks and wild animals. Infection through blood contamination of hypodermic needles, other fomites, and blood products has been reported.[7] Minor genetic variations occur among viruses from different geographic areas, forming four subtypes.[8]

Clinical Signs In sheep, the initial clinical signs of louping ill include fever, anorexia, depression, constipation, and generalized muscular tremors. The ensuing signs are characteristic of CNS disease and include ataxia, conscious proprioceptive deficits, head tremors, hypermetria, and hyperexcitability. The hypermetria results in a characteristic "bunny-hopping gait," which gives the disease its name (to "loup" is to leap in vernacular Scottish). Further progression of clinical signs is associated with cerebrocortical dysfunction; these signs include head pressing, hyperesthesia, recumbency, convulsions, coma, and death. Survivors have residual neurologic deficits. The duration of the illness is approximately 12 days.

Clinical Pathology Both hemagglutination inhibition and complement fixation tests can be used to detect virus in infected animals.[7] High levels of virus-specific IgG and IgM can be detected in the CSF of affected animals.[9] Viremia peaks at approximately 3 days after inoculation and disappears by 7 days. Because animals are usually not viremic at the time the nervous system lesions develop, virus recovery is best done from the brain or spinal cord.

Pathophysiology Ticks become infected when feeding on a viremic host. The virus survives in the salivary glands of the tick and can overwinter there, being transmitted to a new host when the tick becomes active the following year.[7] After inoculation into susceptible sheep, the louping ill virus migrates into the regional lymph nodes and spleen and then replicates. Viremia occurs 6 to 20 days after the invasion of the lymphatic tissues.[2] Viral replication in the brain causes nonsupportive inflammation and neuronal degeneration. Rapid antibody production is associated with recovery.[10] Concomitant infection of sheep with the agent of tick-borne fever *(Ehrlichia phagocytophila)* results in a greater level of viremia and increased mortality from the louping ill virus.[11] The virus is transmissible in unpasteurized sheep and goat milk.[11a]

Epidemiology Louping ill principally affects yearling sheep in the spring, although lambs and adults can be affected. Maternal immunity wanes when lambs are about 3 months old. Infection develops weeks to months after sheep have been placed on pastures infected by *Ixodes ricinus.* In any outbreak the prevalence of clinical louping ill is low, but the seroprevalence of antibodies in adult sheep in endemic areas is high, indicating a continuous, low-level exposure to the virus, and many animals are asymptomatically affected. Factors such as climate, tick population, and immune status of the flock all play a role in the severity of an outbreak.[7] The attack rate may reach 60% of the population, whereas the mortality rate rarely exceeds 15%. Adults tend to be more heavily parasitized by the host ticks and thus play a major role in virus survival and transmission.[12] Pigs, goats, cattle, horses, and red deer also become infected with the virus and can develop similar clinical disease.

Sylvatic cycles of virus transmission occur in which viral amplification takes place through certain wild mammals and red grouse.[1,13,14] The hare serves as an important source of virus for the red grouse.[15,16] It has been demonstrated that the red grouse can be infected by ingesting the infected tick, rather than by being bitten by the tick.[17] The louping ill virus probably is maintained on pastures through infected sheep because grouse populations become unstable and die out whenever the virus is introduced.[18]

Mild occupational infections can occur in shepherds, veterinarians, and laboratory workers who cultivate the virus. The high incidence of louping ill in the spring and summer months probably corresponds to the peak activity of ticks. The virus may persist for long periods in the arthropod vector, but it is unclear if transovarial transmission of the agent occurs. *Ixodes ricinus* is a three-host tick with a life cycle of 3 years. The ticks do not walk, and dissemination requires animal transport. After a blood meal, the tick molts and then rests on vegetation until the next meal, approximately 12 months later. The activity of the ticks tends to increase greatly in the spring whenever the ambient temperatures are above 7° C (43° F).

Necropsy Findings Gross lesions are absent at necropsy. The histologic lesions of louping ill reflect meningeal inflammation with mononuclear cells.[19,20] Microscopic lesions are most severe in the Purkinje cells, motor nuclei, and ventral horn cells. The forebrain is spared.[21] Virus in tissue can be detected by virus isolation, immunohistochemistry, and RT-PCR.[7,22,23]

Prevention There is no treatment for louping ill encephalitis, but supportive care should be provided.

A formalin-inactivated vaccine given in the last trimester of pregnancy has been recommended for preventing louping ill encephalitis.[24] A single dose of the vaccine provides responses that are protective for at least 2 years. Other methods of preventing the disease include frequent acaricidal dipping of sheep and clearing of pastures to reduce the population of infected intermediate hosts.

Louping ill has not been detected in the United States, but it is a reportable disease. Any suspicion of this disease should be reported to state and federal authorities. The disease also has a zoonotic potential; infection of humans is rare but can occur through tick bites; unpasteurized, infected sheep or goat milk; or fomites.

Rabies

Christine F. Berthelin-Baker • Lisle W. George

Definition and Etiology Infection with rabies virus results in severe and usually fatal neurologic disease. Most mammals are susceptible and are infected through bites from other animals during or near the clinical phase of illness. The rabies virus and other highly neurotropic rabies-related viruses belong to the genus *Lyssavirus,* family Rhabdoviridae (bullet-shaped RNA viruses). Wildlife provides a natural reservoir for rabies, and each rabies strain is maintained in particular reservoir host(s). Although they can readily cause rabies in other species, wildlife-adapted strains of rabies usually die out when passed into species to which they are not adapted. Other "rabies-related" lyssaviruses can cause a neurologic disease identical

VetBooks.ir

to rabies. They include the Lagos and Duvenhage viruses of bats in parts of Africa, the Mokola virus of rodents and shrews in Africa, and the European and Australian bat lyssaviruses.[1-3]

Clinical Signs Livestock cases of rabies have been reported mostly in cattle and occasionally in horses, sheep, and goats.[3,4] Rabies should be included in the differential diagnosis of any unexplained acute, rapidly progressive intracranial disease, especially in the presence of autonomic instability, dysphagia, hydrophobia, paresis, or paresthesia.[3,5,6] The incubation period ranges from a few days to 6 months, depending on the pathogenicity of the inoculum and the distance from the site of inoculation to the brain. The shortest incubation periods are seen in animals bitten on the head, whereas the longest incubations have been reported after bites on the extremities of the pelvic limbs.

The disease is usually fatal after a clinical course of 1 to 8 days. Occasionally, an animal may be found dead without any previously observed clinical sign. Early clinical signs of rabies in livestock may be nonspecific sensory and behavioral changes including anorexia, restlessness, depression, separation from the herd, and mild ataxia. Rumination may stop. Horses often appear colicky. Affected animals may show regional paresthesia with pruritus, creating excoriation and hair loss. As the disease progresses, animals may become hyperexcitable, fearful, or enraged *(furious rabies)* or mentally depressed *(dumb rabies)*. Cattle rabies frequently manifests as dumb rabies with flaccid paraparesis, tetraparesis, and tetraplegia *(paralytic rabies)* as the disease progresses. Therefore, the examiner should consider appropriate personal protective equipment (coveralls, boots, gloves, mask, and eye protection) when examining downer cattle in rabies-endemic areas.

In an experimental study, all cattle and sheep infected with the rabies virus exhibited excessive salivation and behavioral changes, and the majority also displayed tremors, bellowing, aggression, hyperesthesia, and pharyngeal paresis/paralysis.[3] Tetraplegic animals may show frantic motor activity of the legs and bellow when stimulated. Animals with dumb rabies are depressed, inappetent, and often febrile (>39.4°C [103°F]), and they may have a drooped head and neck, ptosis, flaccid facial musculature, profuse salivation, and yawning. They may demonstrate repeated nibbling motions with the lips. Other signs include tenesmus, paraphimosis, priapism, odontoprisis, head pressing, circling, basewide stance, difficulty rising, and falling episodes. Flaccidity of the tongue, tail, anus, and urinary bladder may also be evident, as may blindness, strabismus, and nystagmus.

The first clinical sign of paralytic rabies in horses may be an unexplained ataxia or shifting leg lameness, soon followed by paraparesis or paraplegia.[7] Spinal reflexes and tone in the affected limbs may be decreased or absent. Most affected animals become recumbent in 3 to 5 days. Initially the recumbent animal may be able to eat and drink with help, but it soon becomes anorectic and develops encephalopathic signs, followed by generalized seizures and coma[8,9] (Fig. 35-7).

Regardless of the clinical manifestations, rabies is a rapidly progressive and fatal disease leading to cardiorespiratory failure, and death usually occurs within 10 days. In all disease forms of livestock, the clinical signs rapidly worsen over 1 to 3 days, until the patient becomes recumbent and comatose. Animals may develop a pharyngeal-laryngeal paralysis resulting in stertorous breath sounds, inability to drink (thus the common name of *hydrophobia*), and accumulation of frothy saliva at the commissures of the lips.[10]

One summary of 21 cases of rabies in horses enumerated the frequency of particular clinical signs seen as the presenting complaint (Table 35-3). Rabies can only be differentiated from other encephalitic disorders by specific postmortem tests or virus isolation, which is usually not possible before death occurs. In horses the clinical signs of rabies are often indistinguishable from other encephalopathies such as hepatoencephalopathy, leukoencephalomalacia, togaviral encephalitis, equine herpesvirus 1 (EHV-1), protozoal and other meningoencephalomyelitides, and space-occupying masses. In ruminants, rabies may resemble pseudorabies, herpesvirus encephalitis, infectious thromboembolic meningoencephalitis, nervous ketosis, grass tetany, hypocalcemia, polioencephalomalacia, nervous coccidiosis, or even focal spinal cord or peripheral nerve diseases. Most horses die of fatal encephalopathy within 5 days of the onset of signs, but cases lasting as long as 14 days have occasionally been observed.[11]

FIG. 35-7 Ten-month-old mixed-breed calf with terminal rabies virus encephalitis. The calf is comatose and showing opisthotonos.

TABLE 35-3

Occurrence of Particular Clinical Signs of Rabies in Horses

Clinical Signs	Frequency of Occurrence
Ataxia, paraplegia	11/21
Lameness	5/21
Pharyngeal paralysis	2/21
Recumbency	21/21
Colic	2/21
Hyperesthesia	17/21
Tail and anal paralysis	12/21
Fever	11/21

From Green S, Smith LL, Vernau W, et al. 1992. Rabies in horses: 21 cases. J Am Vet Med Assoc 200:1133.

Clinical Pathology There is no valid antemortem test to diagnose rabies in livestock. Rabies usually remains immunologically and serologically silent throughout the incubation and clinical phase of the illness. Clinicopathologic tests are not specific for rabies but may help rule out other, more common diseases. The CSF may be normal or may show moderate mononuclear pleocytosis (5 to 30 cells/μL) and increased protein (60 to 200 mg/dL), occasionally with neutrophils, eosinophils, or xanthochromia reported. Laboratory personnel should be warned that rabies is on the differential diagnosis list when CSF is submitted for analysis.

Pathology and Postmortem Diagnosis Rabies causes a nonsuppurative meningoencephalomyelitis. Microscopic changes include edema, meningeal congestion, focal areas of hemorrhage, perivascular cuffing, gliosis, neuronophagia, and neuronal degeneration. These changes are most severe in the dorsal root ganglia and can be seen in most CNS regions.

A definitive diagnosis of rabies may be based on the finding of Negri bodies on histologic examination of brain tissue (notably, these are not always present, especially in cases euthanized early in the disease course) or through a positive direct or indirect fluorescent antibody (DFA, IFA) test conducted on fresh smears of CNS tissues (thalamus, hippocampus, brainstem, pons, medulla, cerebellum).[12-14] If these tests are negative or inconclusive and there has been human exposure, additional testing can be done using intracerebral

VetBooks.ir

inoculation of mice with CNS tissue from the suspect case. The DFA test on brain tissue has become the standard by which the value of other rabies tests is evaluated.[12] In cases of human exposure, public health authorities should always be contacted before sample collection and submission. The diagnostic pathologist will usually accept the refrigerated head (or even whole body for small animals and bats) or refrigerated brainstem and cerebellum collected through the foramen magnum in mature cattle and horses. Care should be taken to prevent any human exposure to body fluids and CNS tissue of any animal with rabies on the list of differential diagnoses, especially in areas where rabies is known to be present in any domestic or wildlife species; open wounds or small healing sores may provide portal of entry for the rabies virus.

Pathophysiology After subcutaneous or intradermal inoculation, the rabies virus replicates locally. Subsequently, it binds to the acetylcholine (and other) receptors of the peripheral nerves and then migrates retrogradely to the CNS through peripheral nerves, spinal rootlets, and the spinal cord. After entry into the nerve cell rootlets, the virus travels to the brain along nerve tracts and into CSF. From there it spreads centrifugally along the rootlets of the cranial nerves to the salivary glands and the nasal epithelium. While inside cells, rabies evades the immune system by blocking certain signaling proteins necessary for those cells to respond to interferons.[15] The virus must replicate in the brain before it can reach the salivary and nasal secretions. Therefore whenever an animal bites a person, the attacking animal can always be sacrificed and tested for the potential of rabies virus transmission, and it not necessary to wait for disease progression before testing an animal for rabies, as recommended earlier when histologic examination for Negri bodies was the main diagnostic test for rabies. Negri bodies are aggregates of viral proteins and nucleic acids, most commonly seen on histologic examination of the hippocampus of rabies-infected animals. In humans, most cases become apparent within 1 to 3 months of infection, but a small proportion of cases have had incubation periods in excess of 6 months, extending to several years in rare cases.[1] The rabies virus replicates in the cell bodies (gray matter) of the CNS. Dysfunction of these neurons results in behavioral changes and variable abnormalities of the cranial and the peripheral nerves, with multifocal loss of lower motor neuron and autonomic function. Death results from cardiorespiratory paralysis as the virus infects the brainstem medullary centers.

Epidemiology Rabies is a reportable zoonosis that has been detected worldwide, with some exceptions (primarily islands). It does not presently occur in Sweden, Norway, the United Kingdom, Ireland, Australia, New Zealand, or Iceland.[1] The disease is endemic in other parts of the world including the United States, Canada, and Europe but remains epizootic in Central and South America, Africa, and parts of Asia, especially where a tropical climate and a high population of infected feral mammals favor viral propagation and transmission.[2,4] The rabies virus is shed in the saliva and does not survive when dried or exposed to ultraviolet (UV) light. The most common method of viral transmission to domestic animals is through the bite of an infected feral or wild mammal. Humans and laboratory animals have also developed fatal infections after respiratory exposure to viral aerosols. Low levels of rabies virus are also shed in the milk of infected animals and may occasionally infect offspring nursing infected dams.[16,17] Laboratory animals, foxes, and skunks can also be infected experimentally by ingestion of infected tissues from rabies cases.[16,17] In the United States, survival of the virus in the wild may depend on cycling of infections in skunks, bats, or raccoons, which are also common sources of livestock infections.[18,19]

Certain strains of rabies virus have low virulence in skunks and bats, resulting in asymptomatic carriers serving as reservoirs. The rabies virus is also transmitted directly among bats through aerosols in caves. The bats may die off from rabies during periods of high viral contamination. In the United States the most common wild reservoirs are foxes in Alaska and along the border of Mexico, raccoons in the East, and skunks in the central and western regions.[4] Mandatory vaccination of dogs has virtually eradicated canine rabies from developed countries, where rabies transmission from domestic dogs to livestock is rare.[1,20] Island nations have been able to remain free of rabies by imposing a 6-month quarantine on imported dogs and cats. In South America, rabies outbreaks in cattle often result from vampire bat bites, causing up to 50,000 cattle deaths annually. Human rabies cases may result from bites inflicted by infected pets, feral dogs and cats, bats, or wildlife. Cases resulting from contact with infected cattle or horses are rare.[4,20,21]

Prevention Although widespread rabies vaccination of livestock is neither economically feasible nor justifiable on public health grounds, vaccination of valuable livestock or animals that travel or are in regular contact with humans (e.g., petting zoos, animal shows) should be considered, particularly in or near rabies epizootic areas. A list of licensed rabies vaccines for the protection of animals against rabies is regularly updated by state veterinary authorities.[22] Strict adherence to label directions for use of these vaccines is mandatory. In some jurisdictions, immunization of large animals is considered by regulatory authorities to be valid only if the vaccine is administered by a licensed veterinarian.

The disposition of livestock that have been bitten by rabid animals depends on the animal's vaccination history, local and national regulations, and the value of the bitten victim. In the United States and Canada, the disease must be reported to the state public health department. Management of exposed livestock must be coordinated with public health officials. Any livestock bitten by a wild animal should be considered to have been exposed to rabies, regardless of the availability of the biting animal for testing. If a bitten horse had been vaccinated before the bite, it should be revaccinated immediately and kept under observation for 90 days. Other exposed, unvaccinated animals with a low economic value should be euthanized, or if the animal is valuable, the bite wound may be washed with copious amounts of water and iodine or quaternary ammonium disinfectants, after which the animal should be quarantined for at least 6 months and the brain should be examined if it dies.[22] The prolonged quarantine period is based on case reports of prolonged incubation periods in certain species.[1]

Vaccination of animals shortly after rabies virus exposure is not recommended because it is less effective than prophylactic vaccination, and idiopathic responses to the vaccine may complicate interpretation of the animal's disease status after exposure.[1] Whenever human exposure to rabies virus is suspected, the suspected animal must be euthanized and its brain must be examined for evidence of infection. A vaccinated or valuable animal may be quarantined for 6 weeks under veterinary supervision, and the brain must be examined if it develops clinical signs suggesting rabies during that period. The World Health Organization (WHO) publishes and regularly reviews its recommendations for vaccination and prophylaxis in humans after exposure or suspected exposure to the rabies virus.[2]

Control of rabies by immunization of susceptible wildlife using baits containing modified live vaccines has been successful in certain cases.[1,4,23,24] Such approaches may provide a means for large-scale immunization of wildlife or feral animal populations for eventual eradication of the disease.

Sporadic Bovine Encephalomyelitis (Buss Disease; Polyserositis; *Chlamydophila pecorum* Infection)

Sporadic bovine encephalomyelitis (SBE) is caused by *Chlamydophila pecorum* biotype 2, an organism previously named *Chlamydia psittaci* and *Chlamydia pecorum*.[1] The disease was first reported in the United States in 1940.[2] A similar but not identical viral disease occurs in cattle in Australia and has been named *bovine ephemeral fever*.[3-5] Outbreaks of SBE are rare, but the attack rate in an epizootic ranges from 5% in adults to 25% in calves. The mortality is highest in calves and approximates 30% for all age groups.[6]

VetBooks.ir

Infected cattle shed the organism in urine, feces, nasal secretions, and milk. It can also be found in the feces of asymptomatic calves exposed to clinically affected herdmates. The agent tends to remain endemic on a single farm, and sporadic outbreaks of disease may occur only on those premises. The pattern of these outbreaks varies, from a few cases annually to acute, recurrent epizootics with high case-attack rates that subside after 3 to 4 weeks.

Clinical Signs Affected animals show signs of a multisystemic disease. The initial clinical signs in cattle are fever (39° C to 41.5° C [102.1° F to 106.7° F]), diarrhea, anorexia, depression, and stiffness. Early cases may show signs of a respiratory disease characterized by nasal discharge, dyspnea, and cough. These animals occasionally have a painful response to percussion of the hoof, as well as swelling of the coronary band or polyarthritis and tenosynovitis.[2] Auscultatory abnormalities may include high-pitched wheezes and crackles over the lung fields or pleural and pericardial friction rubs. Because of the fibrinous peritonitis and pleuritis, the clinical signs in some affected animals may resemble those of hardware disease. These animals may grunt or groan when sudden pressure is applied to the xiphoid region. Progression of the disease is related to development of the meningoencephalitis and is characterized by ataxia and conscious proprioceptive deficits, circling, head tilt, opisthotonos, hyperesthesia, stiff neck, convulsions, and coma. Animals may die after 4 to 10 days.

Diagnosis The detection of reticulate bodies in the exudate cells of pleural and peritoneal effusions is highly suggestive of SBE. The agent can be most readily detected in clinical samples by PCR, although inoculation of laboratory animals may also be used.[1] Serologic testing is difficult to interpret, as antibodies to *C. pecorum* may cross-react with other species of *Chlamydophila* on certain serologic tests.[1]

Pathogenesis and Pathologic Lesions The mode of transmission and the genesis of pathologic lesions are unknown in natural cases, but postmortem lesions support the role of hematogenous dissemination of the organism to the CNS and other tissues. The extracellular form, termed an *elementary body,* is metabolically inert and can be shed in the feces and urogenital secretions of multiple animal species.[1] The pathogenesis of infection and invasion into the host's bloodstream is not well understood. Growth of the organism in the arteriolar endothelium causes vasculitis, hemorrhage, edema, and accumulation of fluid in the body cavities. Diffuse fibrinous pleuritis, peritonitis, and meningitis are also seen. Microscopic changes include perivascular mononuclear cell infiltration and neuronal degeneration.

Treatment Early cases of SBE can be treated with oxytetracycline (20 mg/kg/day for a minimum of 7 days). Efficacy is indicated by a reduction of fever within the first 24 hours of treatment.

Control There are no known effective control measures for the prevention of SBE. The chlamydial agent is susceptible to a number of disinfectants including 2% sodium hydroxide (NaOH), 5% cresol, and 0.3% quaternary ammonium compounds.

Meningitis (Suppurative Meningitis; Bacterial Meningitis)

Definition and Etiology Bacterial meningitis is defined as inflammation of the meninges surrounding the brain and/or spinal cord that results from bacterial invasion of these tissues.[1] If the infectious process extends into brain tissue, the condition is termed *meningoencephalitis;* if it extends into the ventricles of the brain, it is meningoventriculitis. Differentiation of meningitis from the other two conditions almost always requires advanced imaging techniques or histologic examination, but the conditions result in similar clinical signs.[2] It is a relatively rare condition in large animals. It is most often the result of hematogenous infection in neonates, as a consequence of septicemia with partial or complete failure of passive transfer of colostral antibodies, or with septicemia resulting from translocation of invasive bacteria from the gastrointestinal tract, respiratory tract, or umbilicus.[2,3] Hematogenous infection of the meninges and/or brain can also occur sporadically in adults; such events may be associated with septicemia from a primary focus of infection such as the udder, uterus, gastrointestinal tract, or other sites. As for neonates, underlying immunodeficiency may predispose adult animals to this disease.[4,4a]

Bacterial meningitis can also result from direct extension of infectious agents into the calvarium such as extension of pyogenic infections into the calvarium from infected skull fractures,[5,6] osteomyelitis from sinusitis or otitis media/interna,[7] or osteonecrosis caused by thermal cauterization during dehorning (particularly in goat kids).[8] Improper placement of trephination holes, cribriform plate fractures, and extension from infected coccygeal vertebrae are additional routes of meningeal infection. In horses, septic meningitis is a potential sequela to surgical removal of progressive ethmoidal hematomas and has also been reported as a consequence of local spread of infections of the paranasal sinuses, nasal cavity, periocular tissues, and submandibular lymph nodes.[9]

A multitude of bacteria have been isolated from the blood, meninges, brain, and/or spinal cord of affected large animals. In neonatal calves and foals, gram-negative enteric bacteria such as *Escherichia coli, Salmonella* spp., and *Klebsiella* spp. are considered common isolates.[1,2] *Mycoplasma* spp. may be isolated in goat kids. *Histophilus somni* is a potential cause of meningitis in juvenile cattle in feedlots and is reviewed later in this chapter, as are CNS infections caused by *Listeria monocytogenes*. A variety of gram-positive and gram-negative bacteria may be involved in adults, a fact that underscores the importance of cytologic examination, Gram staining, and aerobic and anaerobic culture of CSF samples obtained early in the clinical course of disease.[1,2,10] PCR assays of CSF may be used to identify specific organisms of high clinical suspicion, as was recently done for diagnosis of meningitis caused by *Borrelia burgdorferi* in a horse.[4a]

Clinical Signs The earliest clinical signs of meningitis are often nonspecific and may reflect the signs induced by a primary infection site (e.g., diarrhea in neonates with invasive bacterial enterocolitis). Fever is common, as is anorexia and/or loss of a coordinated suckle in a neonate.[3] Reluctance to lift or bend the neck may be evident, and manipulations by the examiner may induce responses suggestive of hyperesthesia.[2,3,11] Slight tactile stimulation of the skin may result in strong spasmodic extension of the limbs, fasciculations of the underlying musculature, or even generalized frantic motor activity. The patient's behavior may vary from extreme depression to hyperexcitability. A subtle intentional head tremor is often observed in foals. Dysfunction of one or more cranial nerves may result in facial muscular tremors, nystagmus, facial palsy, blindness, anisocoria, or strabismus. Progression of the clinical signs is associated with a decreased sensorium, propulsive walking, coma, seizures, and status epilepticus. Sequelae to septicemia such as septic arthritis or polyarthritis, uveitis, panophthalmitis, hypopyon, cardiac murmurs secondary to valvular endocarditis, and pyuria/proteinuria may be detected as well.

Differential Diagnosis The clinical signs of bacterial meningitis closely resemble those of viral encephalomyelitis caused by such agents as rabies, West Nile, and togavirus encephalomyelopathies (eastern equine encephalomyelitis, Venezuelan equine encephalomyelitis, and western equine encephalomyelitis, described elsewhere in this chapter). Metabolic encephalopathies may also mimic bacterial meningitis including hypomagnesemia, hypocalcemia, hypoglycemia (which may occur simultaneously with septic meningitis in neonates), hepatic encephalopathy, renal encephalopathy, and encephalomalacias (e.g., salt poisoning, polioencephalomalacia). Congenital neurologic disorders of neonates may be

considered; however, these disorders do not typically induce fever, inflammatory leukogram, or inflammatory changes in the CSF.

These numerous differentials are distinguished from bacterial meningitis by compilation of data obtained by physical examination, serum immunoglobulin measurement, serum biochemistry analysis, complete blood count, and most importantly, cytologic examination, Gram stain, and culture of CSF. Early clinical suspicion of bacterial meningitis and rapid administration of appropriate antimicrobials are necessary to improve survival and minimize long-term neurologic impairment,[1,2,10] In a human study of pneumococcal meningitis, a delay of antimicrobial treatment of more than 3 hours after arrival was associated with higher morbidity at 3 months after admission.[12] Therefore it may be prudent to initiate appropriate antimicrobial therapy if the animal shows signs compatible with bacterial meningitis, then withdraw or modify antimicrobial therapy if that diagnosis is subsequently refuted by ancillary diagnostic data.

Clinical Pathology Diagnosis of meningitis is based on examination of the CSF (for normal values, see Table 35-1). The CSF of animals with meningitis may be turbid and white to amber in color, may foam when shaken, and may clot. Xanthochromia may be observed in some specimens. The WBC counts in CSF of calves with purulent meningitis are typically greater than 100 neutrophils/μL, and protein concentrations range from 20 to 270 mg/dL.[12] The differential cell counts in the CSF are either predominantly neutrophilic or mononuclear. Owing to bacterial consumption of glucose in the CSF, the concentration of glucose in the CSF is often less than 50% of the corresponding concentration in the serum. Gram staining of CSF should be conducted in all cases. Abnormalities in the blood are inconsistent and reflect secondary conditions such as septicemia, diarrhea, or concurrent fluid therapy. These changes could include leukocytosis, left shift, toxic changes in the neutrophils, hyperkalemia, respiratory acidosis, hypoglycemia, and hyponatremia or hypernatremia.

Pathophysiology Bacterial proliferation in the CNS results in production of bacterial endotoxins, cytokines, and other products of inflammation that damage the neural parenchyma. Vascular sequelae of infection may include thrombotic or hemorrhagic infarcts. After several days, inflammation of the arachnoid trabeculae and choroid plexus can result in decreased CSF absorption and hypertensive hydrocephalus.[1,3]

Necropsy Findings Gross lesions of primary infection in other organs and/or lesions suggestive of generalized sepsis may be apparent. When meningitis occurs secondary to trauma, the site of organism entry may be detectable. The meningeal vessels appear to be congested, and the meninges are swollen, opalescent, and petechiated. The CSF is cloudy or amber and may contain fibrin clots. Microscopic changes of CNS tissues include infiltration by neutrophils and lymphocytes, inflammation of the meningeal vessels, scattered hemorrhages, and bacterial colonies around the blood vessels of the meninges and the brain parenchyma.

Treatment Treatment of bacterial meningitis is difficult, and the mortality rate is high, so treatment should be initiated only after owners are appropriately counseled. Early recognition and treatment are essential for adequate recovery. Antimicrobial sensitivity tests performed on isolates from CSF may provide valuable information on ideal drugs. Because prompt treatment of meningitis is critical, antibiotic therapy must be based on the Gram-staining characteristics of bacteria in CSF and the initial 24-hour cultures. When expert laboratory cytologists are not immediately available, CSF can be placed into microhematocrit tubes and centrifuged for 10 to 15 minutes. The tube can then be scored with a file and broken at the interface of the fluid with the clay sealant, and the cell-rich fluid from the two ends of the broken tube can be smeared for cytologic examination and Gram stain. In rabies-endemic areas, appropriate precautions should be taken when handling CSF.

Domestic animals have a well-defined blood-CSF barrier, and antibiotics that reach high plasma concentrations may not necessarily reach bactericidal concentrations in the brain. However, under conditions of local inflammation, this barrier becomes considerably more permeable to certain antimicrobials.[1,10] As a general rule, in order to maximize distribution of antimicrobials across this barrier into infected meningeal or neural tissue, the highest dosage of antimicrobial established for the species in question should be used.[1,10] Toxicity potential and/or excretory organ dysfunction may limit dose escalation of certain classes of drugs such as aminoglycosides. Intravenous administration is preferred in order to obtain peak blood concentrations and spur greater diffusion of drugs across this barrier. Owing to the lack of endogenous immune capacity in normal neural tissue, bactericidal antimicrobials have been considered superior to bacteriostatic drugs, although this is controversial because successful use of bacteriostatic drugs has been reported.[1,10] The primary factors influencing CSF penetration of drugs in the healthy state are the lipid solubility (increased penetration with more lipid solubility) and molecular size (increased penetration with smaller size). However, the penetration capacity of a given antibiotic is not the sole determinant of appropriate antimicrobial selection because the blood-CSF barrier is made more permeable in bacterial meningitis. In fact, high-dose therapy with certain β-lactams—some with limited lipid solubility—either as monotherapy or in combination with antimicrobials of other classes, is currently recommended for many bacterial agents that cause meningitis.[10]

At present, use of all antimicrobial agents in treatment of bacterial meningitis in food animals and horses represents off-label use, and due consideration of legal restrictions on use should be considered in all cases. Further, the paucity of clinical reports and the variety of treatments used in those reports complicates the goal of making evidence-based decisions for treatment of this disease in horses and food animals. Therefore guidelines from published reviews of treatment in horses,[1] cattle,[3] and human medicine[10] are presented here.

When possible, meningitis caused by the gram-negative enteric bacteria should be treated with specific third- (ceftazidime, ceftizoxime, ceftriaxone, cefoperazone, cefotaxime) or fourth-generation (cefepime) cephalosporins. For horses, ceftriaxone (50 mg/kg IV q6h) or cefotaxime (40 mg/kg IV q6h)[1] have been used. Owing to a high degree of protein binding in serum, ceftiofur (at 2 mg/kg IM) does not appear to distribute into the CSF of normal horses.[1] Its performance in penetration of the inflamed blood-CSF barrier remains to be determined. Alternatively, penicillin G sodium or potassium (20,000 to 40,000 IU/kg IV q6h) or sodium ampicillin (20 mg/kg IV q8h) may be used, with success considered to be highly dependent on the susceptibility of the causative organism, a parameter that is often unknown in the initial treatment decision process. If enteric organisms are suspected in a neonate and third- or fourth-generation cephalosporins are not available or are cost prohibitive for use, ampicillin is considered to have superior gram-negative spectrum over penicillin G. Coadministration of an aminoglycoside can be considered for such neonates, with due consideration of nephrotoxicosis potential and, in animals intended for food, withdrawal time.[1,10] Although aminoglycoside antimicrobials are highly effective against gram-negative bacteria and are bactericidal, their efficacy for the treatment of purulent meningitis is diminished by their polar characteristics and low attainable CSF concentrations. Nonetheless, combination therapy consisting of a β-lactam and aminoglycoside may be effective for achievement of broad-spectrum coverage[10]; it can be speculated that the latter drug may at the very least reduce the circulating burden of gram-negative bacteria in the bloodstream and elsewhere. Although still used on occasion, intrathecal administration of preservative-free aminoglycosides has not been shown to produce tangible clinical benefit when compared with intravenous use.[10]

Alternative treatments for meningitis caused by gram-negative enteric bacteria, based on anecdotal data, include enrofloxacin (5 mg/kg IV q12h, with due consideration to potential cartilage damage and reduction of seizure threshold[1]), or trimethoprim-sulfonamide

VetBooks.ir

VetBooks.ir

(5 mg/kg based on trimethoprim component, q12h IV).[3] In horses, chloramphenicol (25 to 50 mg/kg PO q6h) may be considered for use.[1] If β-lactam–resistant organisms are suspected, imipenem (10 to 20 mg/kg IV q6h) may be used, but its efficacy for meningitis in foals remains undetermined[1] and it carries the potential to lower the patient's seizure threshold.[10]

Meningitis caused by gram-positive bacteria may be treated with high doses of intravenous penicillin, ampicillin, or trimethoprim-sulfonamide combinations as described earlier. Third- and fourth-generation cephalosporins can be considered because these retain activity against certain gram-positive organisms.[1] For humans, moxifloxacin penetrates the blood-CSF barrier and have greater gram-positive activity than earlier fluoroquinolones.[10] Other antimicrobials showing promise against specific gram-positive agents in human medicine include daptomycin and linezolid.[10]
