This procedure can be repeated several times. Care must be taken to avoid traumatizing the rectal mucosa by stiff tubing or multiple enemas with harsh detergents. Clinical signs associated with meconium impaction in the compromised foal may be absent. In asphyxiated or premature individuals that are receiving little or no enteral feeding, meconium may remain in the large colon for days, gradually forming into hard concretions that are diagnosed by palpation or radiographs or at postmortem examination. In these cases the routine administration of an enema is often ineffective in mobilizing the impaction because it is high in the large colon. Additional therapy includes IV fluids, oral fluids, and laxatives (60 to 120 mL of mineral oil with 0.5 to 1 oz of psyllium, 60 to 120 mL of Milk of Magnesia). If the gas distention becomes severe, transcutaneous bowel trocarization can be pursued. The author avoids the use of DSS as an oral cathartic since it can cause excessive irritation resulting in diarrhea and colic. Analgesics may also be helpful in controlling the neonate's discomfort and in reducing the risk of self-trauma. Although most meconium impactions can be successfully treated with aggressive medical therapy, those few foals that are refractory to treatment or display uncontrollable pain are candidates for surgical intervention.

Uroperitoneum

Uroperitoneum is a relatively common cause of abdominal distention and depression in the neonatal foal. The condition predominates in males but may occur in females as well. Uroperitoneum may be congenital or acquired. The congenital form occurs due to failure of the dorsal wall of the bladder to close during development. The most common cause of uroperitoneum is a ruptured urinary bladder, but other sites in the urinary tract may also leak, including the ureters, urachus, and urethra. Most cases of ruptured bladders are presumed to occur during parturition because of external pressure on a distended bladder. This form occurs most commonly in colts. Uroperitoneum can also occur as a result of ischemic necrosis or infection of the urinary bladder or urachus in the compromised foal. Critically ill, recumbent foals may rupture their bladders while being lifted and turned with a full bladder or from chronic overdistention associated with their generalized disease state. Foals with botulism may also rupture their bladder as a result of bladder atony and chronic overdistention. Older foals of either sex may experience bladder rupture resulting from focal infection of the umbilical arteries and/or urachus, or ischemic necrosis of the apex of the bladder.

Clinical signs of uroperitoneum are rarely noticed before 48 to 72 hours of age, particularly if the foal is not being watched closely. The first signs may be urinary incontinence or frequent attempts to urinate, with only small amounts voided. Sometimes, particularly in those animals that rupture sometime after birth, there is a history of a period of normal urination, which at some point stopped or became abnormal. Loss of suckle, mild colic, and increasing abdominal distention are usually accompanied by worsening depression and increasing heart and respiratory rate. If the condition is allowed to persist, foals become increasingly weak and dyspneic and may present in cardiovascular collapse. Fillies with ruptured ureters have been reported to have a characteristic protruding perineum, presumably as a result of retroperitoneal accumulation of fluid.[283]

Laboratory findings commonly associated with uroperitoneum are elevated serum creatinine and BUN, hyperkalemia, hyponatremia, hypochloremia, and metabolic acidosis. These changes are probably a result of the normal diet of the foal (milk being relatively high in potassium [25 mEq/L] and low in sodium [12 mEq/L]) and the third spacing of urine in the peritoneal cavity. With urine potassium concentration relatively higher than serum and urine sodium concentration lower than serum levels, the net effect of partial equilibration of serum with peritoneal fluid across a semipermeable membrane is hyponatremia and hyperkalemia, along with an inability to excrete the waste products of metabolism. Hyperkalemia may be severe enough to induce potentially fatal bradyarrhythmias. In hospitalized foals that developed uroperitoneum as a secondary complication, these typical electrolyte abnormalities are not consistently observed. Since most of those foals were receiving replacement IV fluids (high in sodium, low in potassium) and very little milk, it was theorized that intake has a great influence on the electrolyte abnormalities associated with uroperitoneum.[284] On the other hand, the electrolyte abnormalities typically associated with uroperitoneum are not pathognomonic for that disorder. Foals with renal failure, blocked urethra, white muscle disease, and enteritis have shown the same electrolyte changes.

A diagnosis of uroperitoneum often can be made quickly using transabdominal ultrasound and a 5- or 7.5-MHz transducer to visualize large volumes of free, nonechogenic fluid within the abdomen, and a small, irregularly shaped, collapsed bladder. Abdominocentesis usually produces a free flow of peritoneal fluid that contains a low cell count, low specific gravity, and at least twice the creatinine concentration of peripheral blood. If the creatinine is the same in both serum and peritoneal fluid, other explanations for the clinical signs should be investigated. The WBC count, TP, and cytology of the fluid should also be determined. Most uncomplicated cases of ruptured bladders have fairly normal values for peritoneal fluid. In some cases, however, an increased WBC count and TP as well as the presence of bacteria may suggest peritonitis. This may be a result of the urine in the abdomen, but more commonly there is a primary ongoing infectious problem (necrotic urachus or bladder; enteritis), and the prognosis becomes worse. If laboratory facilities are not available, new methylene blue can be injected into the bladder using a urinary catheter, and a few minutes later a sample of peritoneal fluid should

VetBooks.ir

VetBooks.ir

have a blue discoloration if a ruptured bladder is present. However, this technique may not detect other causes of uroperitoneum such as a ruptured ureter or distal urachus. Positive contrast cystography using a 10% solution of water-soluble medium may be helpful in detecting the location of the urinary tract leakage. The ability to obtain urine on catheterization of the urinary bladder does not rule out uroperitoneum. Hematology and blood cultures should be performed to detect primary or secondary sepsis.

Treatment of uroperitoneum is surgical repair. However, the foal with uroperitoneum should not be rushed to surgery without first carefully stabilizing it. Serum electrolytes and blood gases should be run to determine the extent of hyperkalemia, hyponatremia, and acidosis present. Although the total amount of water in the body is usually grossly increased by the peritoneal accumulation of urine, effective circulating volume may be drastically reduced. If the eyeballs are sunken and pulse quality and capillary refill time are poor, aggressive fluid therapy is indicated to support the circulation. This is best performed by concurrently removing as much fluid as possible from the abdomen with a teat cannula, 14-gauge catheter, or peritoneal dialysis catheter to avoid worsening fluid overload and respiratory distress. The fluids of choice to treat the typical electrolyte alterations associated with uroperitoneum are saline, dextrose, and possibly sodium bicarbonate solutions, depending on the degree of acidosis present. In most instances continuous dextrose infusion is effective in decreasing the serum potassium level to an acceptable level, but values should be rechecked before anesthesia is induced. Insulin and dextrose may also be used to treat hyperkalemia, but the patient must be monitored for hypoglycemia. One suggested regimen is regular insulin at 0.1 to 0.2 U/kg SC or IV, accompanied by a continuous IV dextrose infusion (4 to 8 mg/kg/min). Some individuals also have pleural fluid accumulation and atelectasis as a result of the abdominal distention, so oxygenation and ventilation during and after surgery should be closely monitored. Broad-spectrum antibiotics should be started immediately after samples are taken for culture if infection is suspected.

The prognosis for uncomplicated ruptured urinary bladders is usually good (>80% survival), provided the animal is stabilized before anesthesia. The presence of concurrent septicemia carries with it a considerably poorer prognosis.[284] In one retrospective study among foals with uroperitoneum, 100% of those foals with a negative sepsis score lived and only 57% of foals with a positive septic score survived.[285]

Gas or Fluid Accumulation in the GI Tract: Ileus

Abdominal distention and colic resulting from excessive gas and/or fluid accumulation in all or a portion of the GI tract are common complications in the compromised neonate undergoing intensive care. The exact mechanisms responsible for the presumably altered GI motility are not well defined. Ileus is associated with the absence of intestinal sounds, abdominal distention, and intolerance of oral feeds characterized by gastric reflux. Auscultation of reduced GI borborygmi does not always correlate with the degree of intestinal compromise and decreased motility. Transabdominal ultrasonography helps identify absence of intestinal motility and the location and degree of intestinal distention. Ileus and the attending abdominal distention can cause severe colic and can induce respiratory distress in a weak or premature foal with preexisting pulmonary compromise.

Metabolic and infectious causes of ileus in the foal include hypokalemia, hypocalcemia, hypoxic-ischemic bowel injury, bowel obstruction, peritonitis, enterocolitis, and endotoxemia. Hypokalemia is associated with anorexia, diarrhea, and renal loss. Hypocalcemia is associated with prematurity, decreased dietary intake, excessive bicarbonate administration, diuretic therapy, and those conditions such as asphyxia, toxemia, and sepsis that stimulate release of cortisol and catecholamines. Peripartum hypoxia results in a preferential decrease in blood flow to the gut and kidneys. Poor perfusion of the intestines leads to varying degrees of mucosal damage and decreased motility. Severely damaged bowel requires a period of gut rest to allow healing to occur before restarting oral feeds. Premature resumption of enteral feeding is associated with colic, maldigestion, diarrhea (often bloody), and translocation of intraluminal bacteria across damaged bowel wall into the bloodstream. Some of the more common causes of bowel distention in the neonate include meconium retention, intussusception, ascarid impaction, and small intestinal volvulus. Peritonitis may be associated with intraabdominal abscessation, severe enteritis or gastroduodenal ulcer disease, and generalized septicemia. The most common causes of enteritis in foals include rotavirus, *Clostridia* spp., *Salmonella* spp., and dietary changes. Endotoxemia is usually part of generalized septicemia. Chronic bowel distention, regardless of the cause, further impedes return of normal gut motility. In the foal, aerophagia, particularly in the struggling or hypoxic neonate, often results in gas distention that is not easily removed through a nasogastric tube, since gas tends to move quickly through the GI tract. Abdominal distention is also commonly observed during mechanical ventilation in the foal and as a result of overfeeding in the calf. Foals with botulism are often intolerant of enteral feeding, probably because of altered gastrointestinal motility. Use of certain milk replacers can result in bloat, colic, and diarrhea, even in the apparently healthy orphan neonate. Discontinuation of or a decrease in the amount of enteral feeding and, if possible, increased activity of the patient usually results in resolution of the problem.

Abdominal radiographs reveal gas-distended loops of small or large intestine and may identify bowel obstruction. Sonographic examination permits evaluation of bowel wall thickness, peritoneal fluid volume and echogenicity, gut patency, intramural gas accumulation, location and degree of intestinal distention, and presence or absence of motility. An abdominal sonogram should be performed to rule out the presence of an intussusception or other obstructive lesion prior to initiating any prokinetic therapy.

Management of ileus includes nasogastric decompression, cessation or reduced volume, and frequency of enteral feeds if gastric reflux is present; parenteral alimentation if enteral feeding cannot be maintained at a rate of at least 10% of BW/day; enema administration to relieve distal meconium or fecal retention; correction of any underlying electrolyte abnormalities; exercise for ambulatory foals; and judicious use of prokinetic agents. The gut atrophies without enteral feeding. Prokinetic drugs should not be used when bowel obstruction or compromised bowel integrity is suspected. Prokinetic agents that have been used include metoclopramide, bethanechol, and erythromycin. There have been anecdotal reports of small intestinal intussusception after prokinetic use in neonatal foals.

Surgical Gastrointestinal Lesions

Most types of displacement, torsion, volvulus, and entrapments that occur in the adult horse may also occur in the neonatal foal, although probably at a lower frequency. Large colon displacement, intussusception, and small intestinal volvulus have also been observed as a result of enteritis and colitis.

Surgical correction of congenital gastrointestinal defects may be attempted. Atresia ani, atresia recti, and atresia coli have been well documented in the foal, and intestinal aganglionosis has been observed in association with recessive lethal white foals, which are usually the products of mating between two overo Paint horses.[176] Acute colic, progressive abdominal distention, and lack of meconium staining following repeated enemas have been the most common findings in newborn foals with atresia coli. Barium enemas may be of use in identifying foals with a short small colon, but may also be misleading. Surgical exploration of the abdomen offers definitive diagnosis of the severity of the malformation and the possibility of correction, but the owner should be informed before surgery of the high frequency of inoperable lesions and the high failure rate following reattachment. Before any surgery is contemplated, a thorough physical examination should be performed to identify any other congenital malformations. Surgical correction of atresia ani is often successful, particularly if the atresia is limited only to a persistent membrane blocking the anus and the anal sphincter is normal. The

VetBooks.ir

prognosis for atresia coli is guarded. Poor intestinal motility, technical difficulties of attaching bowel segments that differ so much in size, anastomosis breakdown, and peritonitis following surgery are common complications. An inguinal hernia is another congenital lesion occasionally requiring surgical intervention. These hernias occur in colts and may be caused by compression during parturition. Most congenital inguinal hernias are handled conservatively since the condition is often self-limiting by the time the foal is 3 to 6 months old. Treatment includes daily manual reduction of the hernia and frequent observation to detect possible bowel strangulation. Indications for surgical intervention in foals with congenital hernias include rupture of the common vaginal tunic, persistent colic, severe edema of the prepuce and scrotum, and trauma to the skin overlying the hernial sac. Surgical hernias are difficult to reduce manually and loops of intestines are often palpable in the subcutaneous tissues of the scrotum and medial thigh. Unilateral castration is usually performed on the affected side.

Other gastrointestinal lesions in foals that may require an exploratory laparotomy include intussusception, small or large intestinal volvulus, and mechanical obstruction (e.g., food or ascarid impaction, phytobezoar, fecalith). Intussusceptions are reported in young horses less than 3 years of age. An intussusception is formed when one segment of intestine and its mesentery invaginate into the lumen of the adjacent bowel immediately aboral to it. The invaginated segment is called the *intussusceptum* and the enveloping segment is called the *intussuscipiens*. Small intestinal intussusceptions can involve the jejunum, ileum, or ileocecal junction. Other sites of obstruction include cecocecal and cecocolic junctions. Intussusceptions are most common in foals less than 6 weeks old.[123] Causes of intussusception include segmental motility differences (e.g., a hypermotile section of bowel adjacent to an atonic segment of bowel) and local changes in the bowel wall (e.g., abscessation). Causes of altered peristalsis include enteritis, heavy ascarid infestation, mesenteric arteritis, and sudden dietary changes. Changes in the bowel wall have included granulomas, papillomas, and intramural leiomyoma. *Anoplocephala perfoliata* has been associated with ileocecal intussusceptions. Clinical signs include varying degrees of discomfort depending on the site of obstruction and its duration. Abdominal pain can be severe but is often low-grade and intermittent accompanied by decreased manure production. Ultrasonography is a useful diagnostic aid. Sonographically the cross-sectional view of the intussusception reveals a target-like pattern with a thick hypoechoic rim. The outer rim is created by severe edema of the entering and returning bowel walls of the intussusceptum.

Treatment involves a surgical exploratory. Early cases can be manually reduced followed by surgical resection. Because of the ileum's tenuous blood supply and the inaccessibility of the ileocecal junction, intussusceptions involving the ileum are usually treated with a side-to-side jejunostomy or ileocecostomy. Ileoileal intussusceptions have been reported to have a better prognosis than jejunal or ileocecal intussusception. Foals that have multiple sites of intussusception have a poor prognosis.

Volvulus may involve the small or large intestines. Small intestinal volvulus is the most common, especially among foals between 2 and 4 months of age. Signs include abdominal distention, gastric reflux, persistent tachycardia, severe pain, and sonographic evidence of uniform, severe bowel distention with bowel wall edema (>3 to 4 mm) and absence of motility. As expected, survival is poorer following correction of strangulating versus non-strangulating lesions. Strangulating lesions of the small intestines have a poor survival compared with large intestinal lesions and a higher incidence of fatal complications. Parasitic migration and abrupt dietary changes are among conditions thought to predispose to volvulus development.

Surgical colic in foals carries a poorer long-term prognosis than in adult horses. One study examined the survival rate among 67 foals less than 150 days of age undergoing colic surgery.[286] The most common lesions requiring a celiotomy were small colon impaction, large colon impaction, jejunal volvulus, and ascarid impaction. A poor prognosis was associated with strangulating lesions. Foals less than 14 days of age experienced more early postoperative complications and suffered poor long-term survival because of adhesion formation. Only 25% of foals less than 14 days of age survived in the short term compared with 71% out of a total of foals older than 15 days of age. Another study examined the outcome among 119 young horses less than 1 year of age that underwent exploratory celiotomy.[287] Among all foals the most common cause for surgery was small intestinal strangulation. Uroperitoneum and meconium impaction were the most common conditions in neonatal foals and intussusception and enteritis were more common among older foals. Significant elevations in PCV (37% to 54%), heart rate (80 to 134 bpm), nucleated cell counts and TP in peritoneal fluid (3.1 to $32.8 \times 10^3/\mu L$, 2.9 to 4.9 g/L), and rectal temperature (38.2° to 39.2° C) were observed in non-survivors compared with survivors. Non-survivors had significantly decreased serum bicarbonate, chloride, sodium, and venous pH values. Thirty-three percent of foals surviving surgery had evidence of intraabdominal adhesions.

Necrotizing Enterocolitis

NEC is a syndrome of acute intestinal necrosis that has been described in equine neonates.[288] The causes of NEC are not well defined, but predisposing factors include ischemic hypoxic gut injury, the presence of intraluminal bacteria, and enteral feeding. Following gastrointestinal ischemia, mucosal cell metabolism diminishes and the protective mucous layer is lost. This allows enzymes to break down the mucosal barrier, and intraluminal bacteria can then invade and multiply within the bowel wall. Enteral feeding provides substrate for the bacteria. Pneumatosis intestinalis develops, and the bowel frequently ruptures. Abdominal signs include abdominal distention, tenderness, ileus, and ascites. The condition may appear as a fulminant, rapidly progressive disease, or progress at a much slower pace.[154] One of the affected equine neonates was premature and was undergoing treatment for respiratory distress when the abdominal crisis occurred. The other was a term foal that had experienced a prolonged delivery and was presented at 24 hours of age for weakness and abdominal pain. Abdominal distention and abdominal pain, followed by ventral colon rupture, were noted in both foals.[288]

Clinical signs associated with varying degrees of hypoxic-ischemic gut injury include ileus, gastric reflux, colic, lethargy, abdominal distention, and diarrhea. Reflux and feces may be positive for blood. Generalized sepsis often accompanies NEC; NEC should be distinguished from intestinal ileus caused by other neonatal diseases, other surgical GI lesions, bacterial or viral enterocolitis, and intolerance to a milk diet. Although no single laboratory test is specific for NEC, the abdominal radiograph often reveals pneumatosis cystoides intestinalis, bowel wall edema, and an abnormal gas pattern consistent with ileus. Ultrasonography may reveal intramural gas accumulation (Fig. 17-15). If intestinal perforation has occurred, pneumoperitoneum and septic peritonitis may also be noted.[154,288] Intestinal perforation is associated with a poor prognosis.

Hemoperitoneum

Hemoperitoneum is a relatively uncommon cause of abdominal distention in the large animal neonate. The most common structures responsible for the hemorrhage are the umbilical vessels and rupture of the liver or spleen as a result of trauma. Occasionally other structures such as a ruptured granulosa cell tumor may bleed.[187] Depending on the cause and severity of the hemorrhage, clinical signs relating to hypovolemia and anemia may be mild or severe and appear shortly after birth or in the older foal. Diagnosis of hemoperitoneum is based on the retrieval of free-flowing blood on peritoneal tap and the detection of free fluid in the abdomen. Ultrasound examination may be of benefit in detecting the source of the bleeding. Of critical importance, regardless of the source of the hemorrhage, is prevention of hypovolemic shock, and intensive patient monitoring and intervention are often indicated. Whole blood replacement may be necessary. If an internally bleeding animal with an unstable cardiovascular system is

rushed to surgery without prior stabilization, profound shock may occur, and a poor outcome usually results.

Umbilical Problems

John E. Madigan

Patent urachus is a persistence after birth of the tubular connection between the bladder and umbilicus. The urachus drains the bladder into the allantoic sac during gestation. Urine flow should gradually change, with some urine entering the amniotic sac through the urethra in later gestation. At birth, with umbilical cord rupture, the urachus should be closed, and urine should be voided through the urethra. Foals with a patent urachus may dribble urine from the urachus during or after urination or may simply present with a constantly wet umbilical stump.

A variety of causes have been suggested for failure of the urachus to close and completely involute. Early severance or ligation of the umbilical cord, inflammation, infection, and excessive physical handling of the neonate may contribute. Rather than being the original cause for hospital admission, patent urachus develops as a complication of hospitalization in a significant percentage of foals in neonatal intensive care. Weakness of abdominal musculature may contribute to the problem in sick foals.

Ultrasound may assist the diagnosis and determine the involvement of umbilical arteries or vein. Moist hairs around the umbilicus and visualization of fluid coming from the navel are diagnostic. Ultrasound examination of the internal structures of the umbilicus is strongly recommended.

Congenital patent urachus caused by excessive torsion on the umbilical cord in utero occurs in 6% of normal foals.[289] The obstruction of the urachus caused by the torsion causes retention of urine in the bladder and overdistends the proximal urachus, which interferes with normal involution.[289] Infection of umbilical structures or the urachus itself may result in inflammation and failure to completely involute. In a review of 16 cases of umbilical cord infections in foals, 13 had patent urachus.[290] The majority of these foals had acquired patent urachus after birth, with the youngest age of onset 3 days and the mean age of onset 12 days. Excessive manipulation and improper lifting of the foal's abdomen in the presence of high urethral sphincter tone may force urine within the bladder into the involuting urachus.

Therapy consists of either conservative management through monitoring or medical treatment for infection or cauterization of the urachus using silver nitrate sticks applied into the urachus. Persistence of urine dribbling despite cauterization, the detection of involvement of other umbilical structures through ultrasound, and a rent in the urachus that produces subcutaneous swelling are indications for surgery. Use of general anesthesia and removal of the entire urachus to the tip of the bladder are performed in foals with an infected or enlarged urachus. Associated arteries and veins should be ligated and removed if they are infected or necrotic. Merely ligating the exterior stump can trap organisms and cause infection. Complications are uncommon but may include bladder necrosis and uroperitoneum caused by extension of infection and inflammation of the urachus.

Omphalitis is inflammation of umbilical structures that may include the umbilical arteries, umbilical vein, urachus, or tissues immediately surrounding the umbilicus. The umbilicus consists of three types of structures and undergoes functional and anatomic changes at birth. Two umbilical arteries connect internal iliac arteries to the placenta. These later regress and become the round ligaments of the bladder. One umbilical vein connecting the placenta to the liver and porta cava regresses to become the round ligament of the liver within the falciform ligament. The urachus connects the fetal bladder to the allantoic cavity. Umbilical abscess or infection of any of the three components of the umbilicus may produce local infection or be a source of bacteremia. The source of infection is most commonly the external environment, coupled with failure of passive transfer. Omphalophlebitis may extend the length of the umbilical vein into the liver and result in liver abscessation.

When the umbilicus is enlarged and draining purulent material, infection is easily noted. In other cases the umbilicus may be dry and larger in diameter than expected. In addition, neonates may have a completely normal-appearing, dry external navel and be severely ill from infection of the urachus, umbilical arteries, or vein. In a septic neonate without external signs of infection, involvement of the umbilicus can be difficult to determine. The presence of pain on palpation of the umbilicus indicates inflammation. Ultrasound aids in the detection of involvement of urachus or arteries and vein. The umbilical area of neonates less than 20 days of age with fever of unknown origin should be scanned.

Overt signs of infection are heat, swelling, purulent discharge, or pain. Concurrent signs of systemic infection such as joint infection, pneumonia, diarrhea, meningitis, or uveitis may be noted. Infection in more than one umbilical vessel in the neonate is common, and urachal involvement is frequent. Umbilical abscessation that is walled off and does not involve deeper structures is a less severe problem and may be treated with drainage without surgical removal of the entire umbilicus. The depth of involvement may be determined by standing behind the neonate and pressing the hands together above the umbilicus to detect internal masses and painful areas.

Early treatment with antibiotics and supportive care as described for the septic foal may allow resolution before development of abscessation and distention of the urachus or the umbilical arteries and vein. Established infection, which may occur within 24 hours, may necessitate surgical removal of involved structures in addition to medical therapy.[290] When omphalophlebitis extends into the liver, the umbilical vein may be marsupialized to facilitate drainage and flushing. The prognosis is very good when adequate passive transfer of colostral immunoglobulins has occurred and when joints or other structures are not involved. Sequelae such as renal abscessation, joint or bone infection, peritonitis, and other complications described for septicemia may develop if therapy is started too late or discontinued prematurely.

The Peripartum Ruminant

JOHN K. HOUSE, *Consulting Editor*

Recent studies in Denmark, The Netherlands, North America, and Sweden indicate that the prevalence of bovine perinatal mortality is increasing, particularly in Holstein primiparae.[1] The peripartum period is a high-risk period for the fetus and dam. Approximately 5% to 10% of the annual calf crop and 15% to 20% of the annual lamb crop in the United States dies prior to weaning.[2-4] Between 50% and 70% of neonatal mortality occurs in the first 3 days of life with dystocia, starvation, and hypothermia responsible for 50% to 60% of these losses.[3,5] The incidence of dystocia is particularly high in Holsteins with reports of 50% of heifers and 30% of cows requiring calving assistance.[6] The risk of neonatal morbidity and mortality is largely influenced by sire selection (calving ease), maternal management, and subsequently maternal health during the peripartum period.

Late-Term Complications of Gestation

Uterine torsion, vaginal prolapse, hydrops allantois, hydrops amnii, and metabolic disorders are disorders of pregnancy and the peripartum period that negatively impact on the health of the dam and the fetus during late gestation. Over the past 10 years, there has also been increasing application of advanced reproductive technologies with the production of in vitro and cloned embryos. The initial application of these methods has been associated with a higher incidence of complications during pregnancy and neonatal mortality.

Uterine Torsion

Uterine torsion is more common in cattle than other domestic species. The exact etiology is unclear, with most occurring during late first-stage or early second-stage labor.[7] Proposed risk factors include poor maternal muscle tone, strong fetal movement, and reduced rumen fill. Retrospective studies have reported no significant seasonal affect but a higher incidence in Brown Swiss cows and a lower risk in Hereford, Angus, and Jersey cows compared with Holstein-Friesians.[8] Calf birth weight is typically above average and a greater proportion of fetuses are male (63%).[8] The incidence is also significantly higher in cows compared with heifers.[7]

Clinical signs associated with uterine torsions include fever, tachycardia, tachypnea, straining, anorexia, and vaginal discharge.[8] The diagnosis of uterine torsion is based on a history of advanced pregnancy and the presenting clinical signs. On transrectal palpation, the orientation of the broad ligaments is distinctly altered; depending on whether the torsion is to the left or the right, the respective broad ligament is pulled tightly across the uterus.[9] Approximately 60% of torsions involve the vagina, and spiral folds can be palpated per vagina.[9] Most torsions are to the left (counterclockwise); in general the uterus rolls toward and over the nongravid horn (approximately 60% of all pregnancies in the cow are in the right horn).[9] Torsions between 45 and 90 degrees are uncommon; 20% are 90 to 180 degrees, 57% are 180 to 270 degrees, and 22% are 270 to 360 degrees.[8] With severe torsion, circulation is compromised. Treatment involves correction of the torsion and delivery of the calf. In a retrospective study of 164 cases, vaginal delivery was possible after manual correction (20%) or rolling of the cow (18%). Cesarean section was performed immediately in 35% of the cases, after failed detorsion attempts in 7% and because of failure of the cervix to dilate following successful correction of the torsion in 20%. When manually manipulating the fetus per vagina, it sometimes helps to have a person assist by pushing on the calf externally. Fetal survival rate is generally low, with fetal death often occurring prior to presentation if there has been delayed recognition of parturition.

Vaginal Prolapse

The primary predisposition to cervicovaginal prolapse in cattle is elevated plasma estrogen concentrations during late gestation.[9] The higher prevalence in certain beef breeds implies a genetic predisposition, with Bos indicus, Herefords, Charolais, Limousin, and Shorthorns affected more frequently than other breeds.[10-12] Other factors that contribute to the risk of vaginal prolapse include increased intraabdominal pressure in late pregnancy, obesity, and poor vaginal conformation. The pathogenesis and development of vaginal prolapses is progressive; it starts with the exposure of some of the vaginal mucous membrane. The prolapsed mass moves in and out as the cow gets up and lies down. Exposed mucosa dries out and becomes irritated, leading to straining and further prolapse. The prolapsed tissues become edematous, leading to circulatory impairment and swelling. Ultimately the cervix and occasionally the bladder may become involved.[9] The objective of treatment in the case of pregnant animals is to replace and retain the vagina within the pelvic canal and to deliver a live calf. Numerous treatment options are described for vaginal and cervical eversions.[12] These methods include suturing the vulva (caslick, Bruhners), vaginopexy (Minchef procedure), or cervicopexy (Winkler procedure). Close observation of the cow for signs of impending parturition is required following suture of the vulva. Failure to release the sutures prior to parturition can lead to severe laceration of the vulva and potentially the death of the calf. If the patient is close to parturition, induction is recommended to expedite the process and prevent recurrence prior to parturition. Since vaginal prolapse is likely to recur during the next pregnancy, it is recommended that the cow be culled when the calf is weaned.

Ringwomb

Ringwomb, or incomplete dilation of the cervix, causes sporadic dystocia, mainly in multiparous ewes bearing multiple fetuses. It is most commonly observed in sheep and may be heritable in some instances.[13] Ringwomb has no predisposition associated with breed, age, or body condition score, but it is associated with a significantly higher lambing percentage.[13] Correction with gentle manual stretching can be attempted; the use of PGE 2, administered as an intracervical gel in the treatment of ringwomb in ewes, is not effective at causing dilation of the cervix.[14] Because of the significant risk of tearing, a cesarean delivery is often required.[15] Ewes with diseases that cause abortion as a result of infectious agents may exhibit signs similar to ringwomb, as can pregnancy toxemia, consumption of

VetBooks.ir

poisonous plants, consumption of estrogenic plants, and lasalocid toxicity.[15]

Early Dilation Syndrome

Early dilation syndrome is a condition of sheep that is similar to but considered separate from ringwomb. In early dilation syndrome, incomplete dilation of the cervix occurs approximately 7 to 14 days before term. The ewe has little or no udder development or a sudden overnight blooming of the udder and placental membranes protruding when presented. The cervix usually can be dilated by hand, but the lambs, although born alive, are not viable. The syndrome occurs most frequently in ewe lambs and first-lambing 2-year-olds, but occasionally in older ewes. Affected flocks can have over 30% morbidity. The syndrome occurs in all breeds and in all flock management situations. No common link has been found from nutritional, physiologic, toxicologic, or infectious disease investigations.[15]

Hydropic Conditions

Fetal loss associated with abnormal placentation occurs sporadically and is reflected by alterations in volume and composition of allantoic and amniotic fluid. In a study of 60 cases of bovine hydrops, 88% were hydrallantois, 5% hydramnios, and 7% a combination of both.[16] Hydrallantois is often associated with disease of the uterus and hydramnios with genetic or congenital defects of the fetus (e.g., Dexter cattle with bulldog calves, Angus calves with osteopetrosis, Guernsey calves with pituitary hypoplasia or pituitary aplasia).[17]

Hydrops Allantois (Hydrallantois)

Hydrops allantois is a sporadic condition of cattle in which progressive excessive accumulation of allantoic fluid occurs. Accumulation of allantoic fluid from mid gestation is associated with placental dysfunction.[9] Placental dysfunction is characterized by a reduced number of placentomes (normal 75 to 100) and the development of more primitive villous placentation.[18] An increased incidence of hydrops allantois has been reported with pregnancies derived from in vitro fertilization (IVF)–produced embryos. In a comparative study of IVF and artificial insemination (AI)–derived pregnancies, the percentage of cows with hydroallantois was 1.8% and 0.07%, respectively.[19] A herd outbreak of hydrops allantois has also been associated with severe nutritional deficiency.[9] Allantoic fluid volume may exceed 100 L (normal 8 to 15 L near term), leading to rapid abdominal enlargement; rectal examination reveals tight distention of the uterus. The fetus and placentomes are not palpable due to the tightness of the uterine wall. Affected cows become anorectic, leading to dehydration, constipation, and eventually recumbency.

The concentration of sodium and chloride in allantoic fluid of cattle during the last 12 weeks of gestation is normally low (Na = 52 ± 20 mEq/L and Cl = 17 ± 11 mEq/L) and the concentration of creatine high (1224 ± 458 µg/mL).[20] With hydrallantois, allantoic fluid sodium and chloride concentrations rise toward extracellular fluid concentrations (Na = 116 ± 13 mEq/L and Cl = 81 ± 12 mEq/L) and allantoic creatine concentration decreases (193 ± 73 mEq/L).[20] Normal amniotic fluid has electrolyte concentrations similar to those of plasma (Na = 132 ± 7 mEq/L and Cl = 115 ± 8 mEq/L) and a lower creatine concentration than allantoic fluid (70 ± 26 µg/mL).[20] Cows with hydrallantois are also often hyponatremic and hyperglycemic.[16,21]

Because of the poor prognosis, salvage slaughter is generally recommended. Parturition can be induced if the cow is reasonably close to term and is recommended for the salvage of the calf. Attempts at medical management of affected cows include slow decompression and supportive fluid therapy. The grossly distended uterus is slow to involute and prone to severe metritis. The prognosis for future fertility is guarded.

Hydrops Amnii (Hydramnios)

Hydramnios is rare, accounting for 5% to 10% of uterine dropsy cases.[22] It has been associated with a genetic (autosomal recessive) or congenitally defective fetus in which swallowing is impaired, and the amount of amniotic fluid gradually increases over several months.[22]

TABLE 18-1

Differential Diagnosis between Hydrallantois and Hydramnios in Cattle[9]

Characteristic	Hydrallantois	Hydramnios
Prevalence	85%-95%	5%-15%
Rate of development	Rapid (within 1 month)	Slow over several months
Shape of abdomen	Round and tense	Piriform, not tense
Transrectal detection of placentomes and fetus	Nonpalpable (tight uterus)	Palpable
Gross characteristics of fluid	Watery, clear, amber-colored transudate	Viscid, may contain meconium
Fetus	Small, normal	Malformed
Placenta	Adventitious	Normal
Refilling after trocarization	Rapid	Does not occur

From Drost M. 2007. Complications during gestation in the cow. Theriogenology 68:487.

It may affect only one of twin fetuses.[9] Normal amniotic fluid volume at parturition is about 4 to 8 L; cattle with hydrops amnii may accumulate 20 to 100 L of amniotic fluid.[23] The slowly progressive accumulation of fluid during the latter half of gestation means that the abdominal muscles become stretched and the cow develops the typical "pear-shaped" abdomen. In contrast to the situation with hydrallantois, placentomes and often the fetus are palpable per rectum. The prognosis for the life and future fertility of cattle that have hydramnios is good.[23] The fetus itself is invariably defective and will not be viable. If the owner elects to keep the cow, the genetic implications should be considered. Clinical features that distinguish hydrops amnii and hydrops allantois are presented in Table 18-1.

Abnormal Offspring Syndrome

The transfer of bovine embryos produced and manipulated in vitro results in abnormalities in some conceptuses, fetuses, placentas, and offspring.[24,25] The term *abnormal offspring syndrome* is used to describe the range of abnormalities observed.[26] The exact etiology of the syndrome is uncertain, although developmental abnormalities of the fetus, placenta, and offspring have been predominantly attributed to the presence of serum in the culture medium.[27] In utero manifestations include prolonged gestation, abnormal placental development (placentomegaly, hydroallantois, and edematous placentomes in reduced numbers), and suboptimal embryonic and fetal survival.[18,28] Increased birth weight and incidence of dystocia, congenital deformities, and perinatal mortality are neonatal manifestations of this syndrome. Respiratory disease is often a limiting factor in the survival of cloned calves during the neonatal period.[29] Possible causes of compromised respiratory function include hypoventilation, ventilation perfusion mismatch, right-to-left shunt resulting from persistent fetal circulation, and respiratory distress syndrome resulting from inadequate surfactant production. Nasal insufflation at birth is recommended to support the respiratory function of cloned calves.[29]

Maternal Nutrition

Reduced fetal viability often reflects mismanagement of maternal nutrition during the last trimester of pregnancy and/or during the prepartum and peripartum period. Maintenance of adequate nutrition throughout pregnancy is essential to provide for the growing fetus and to maintain a healthy dam capable of delivering and nursing the fetus. Pregnancy toxemia, hypocalcaemia, protein energy malnutrition, micronutrient deficiencies, and obesity may all impair the health of the fetus directly, or else indirectly by affecting the health or capacity of the dam to deliver the fetus.

Underfeeding of energy (40% to 70% of requirements)[30] or protein (65% of requirements)[31] during late gestation in beef cattle produces calves that are less able to generate heat to maintain body temperature

after birth. This effect was observed despite no significant difference in birth weight.[30,31] The fetal response to growth-restrictive environmental conditions is to partition nutrients toward the development of organs essential to life, such as the brain, at the expense of less vital organs and tissues.[32,33] In humans, the repartitioning of nutrients to support fetal development has been demonstrated to have long-term effects on postnatal growth and metabolism, apparent as an increased propensity to develop insulin resistance, high blood pressure, more rapid weight gain, and increased adiposity.[34] Similarly, nutrient restriction during gestation has been demonstrated to alter postnatal glucose metabolism in calves.[35] The consequences of overnutrition during gestation on the developing fetus are less clear. A number of overfeeding trials have resulted in increased birth weight, whereas other studies have not.[36,37] Maternal consequences include deposition of fat in the pelvis that increases the risk of dystocia and subsequently fetal compromise.[38]

For high-producing dairy cows, good nutritional and cow management during the transition period is pivotal for maintaining cow health. Hypocalcemia and negative energy balance contribute to the risk of dystocia and subsequently the risk of neonatal morbidity and mortality.[39] Recently, there has been a paradigm shift in the thinking regarding the nutrition of nonlactating cows prior to calving. Previously, the focus had been on increasing the amount of energy in the ration fed to cows during the last 3 to 4 weeks prior to calving to meet the increasing energy needs associated with pregnancy in the face of the cows' declining dry matter intake.[40] Paradoxically, overfeeding energy during the dry period has been found to contribute to negative energy balance postpartum and an increased incidence of disease in the peripartum period.[41] This phenomenon appears to be associated with increased insulin resistance, similar to type 2 diabetes. The current recommendation is to feed cows throughout the nonlactating period a ration that meets but does not exceed caloric needs. Straw is added to the ration to promote rumen health and to prevent overeating.[39]

In regard to trace minerals, selenium and copper deficiency may contribute to neonatal morbidity and mortality. Copper deficiency has been associated with impaired fertility, weak calves, and high calf mortality.[42] In a larger Canadian study, myopathy and cardiomyopathy were common findings in stillborn and neonatal mortality, suggesting the possible contribution of nutritional myopathy.[43]

Investigation of perinatal morbidity and mortality should begin with assessment of maternal management. Some of the more common causes of stillbirth and perinatal mortality are listed in Box 18-1.

Environmental Management

Environmental stress prior to or around the time of parturition may also compromise the fetus or neonate. Heat stress affects fetal viability by impeding calf growth in the last trimester of pregnancy[44] and by depressing colostral quality[45] and immunoglobulin transfer.[46] Uterine blood flow and placental mass are reduced and endocrine profiles altered when cattle are heat stressed during the last trimester of pregnancy. Heat stress during the last 3 weeks of pregnancy lowers dry matter intake, contributing to a negative energy balance at this time and promoting mobilization of body fat and ketogenesis. Transfer of immunoglobulins to colostrum is impaired and the concentration of protein, casein, lactalbumin, fat, and lactose in colostrum reduced.[45] Cold, windy, and wet conditions also adversely affect calf survival. The magnitude of the effect of climate on neonatal survival

VetBooks.ir

depends on the age of the dam, the sex and size of the calf, and the incidence of dystocia in the herd.[47] Cold stress sufficient to cause hypothermia in calves leads to subcutaneous hemorrhages and delayed absorption of colostral immunoglobulins.[48]

ASSESSMENT OF FETAL VIABILITY. Fetal viability is rarely evaluated during the prepartum period in production animals but is a serious consideration when the prepartum dam is diseased or debilitated. Assessment of fetal viability is diagnostically challenging, but a number of methods are available to evaluate the fetus and fetal environment. During the physical examination of cattle, uterine blood flow, uterine tone, and presence of a vaginal discharge may be evaluated via rectal palpation and a vaginal speculum examination. Reduced fremitus in the uterine arteries and increased uterine tone may be appreciated by rectal palpation following fetal death. Abdominal ultrasound is useful for examining the uterus, placenta, and fetuses of small ruminants.[49] When the gestational age of the fetus is known, fetal growth retardation can be detected by using ultrasound by measuring abdominal circumference as well as femur and tibial length.[50] Examination of the fetus may detect gross congenital abnormalities, and ultrasound of the fetal chest allows visualization of a beating heart and determination of fetal heart rate. The normal heart rate of full-term lambs is 108 to 126 beats/min.[51] After fetal death, the following may be observed: absence of fetal heartbeat, thickening of the uterine wall, increased echogenicity of chorioallantoic and amniotic fluid, altered fetal posture and definition, altered contour of the amnion, and reduced definition and ultimately reduced size of the caruncles.

The uterus and placenta of cattle can be examined by transrectal ultrasound, but examination of the fetal calf via transrectal or transabdominal ultrasound is often compromised by limited access. Fortnightly ultrasound of the uterus and placenta of recipient cows carrying cloned calves is conducted to detect evidence of hydroallantois and placental edema in these high-risk pregnancies.[52] The absence of fetal heartbeat is a specific sign of fetal death. The presence of large quantities of echoic particles in uterine fluids is also a sign of fetal distress or death. Fetal hyperactivity or inactivity over a 30-minute period of examination suggests fetal compromise.[53] Repeated examinations are required since hyperactivity or sleeping periods have been infrequently observed in other species and the criteria for this classification are based on limited observations in cattle.[54] Measuring the heart rate of fetal calves is more difficult than of small ruminants but can be achieved via transabdominal Doppler using a 1.5-MHz probe. The normal heart rate of full-term calves is 90 to 125 beats/min.[55] In human medicine, fetal heart rate is used as a measure of fetal viability; fetal heart rate accelerations associated with fetal movement are considered a sign of fetal well-being, and persistent bradycardia or tachycardia are considered a sign of fetal stress.[56] Normal fetal heart rate patterns of ruminants need to be characterized in more detail before fetal heart rate measurements are used for prenatal clinical assessment of ruminant fetal well-being.[54,57]

Estrone sulfate is a marker of a viable fetoplacental unit and has been used to assess fetal viability in cattle.[58] Estrogen synthesized by embryonic tissue is converted to estrone sulfate by the endometrium, which contains the enzyme sulfotransferase. Estrone sulfate assays can be used to diagnose pregnancy in small ruminants after 50 days[59] and in cattle after 100 days.[60] Estrone sulfate may be measured in plasma or milk[44,60]; baseline values are low after fetal loss, regardless of the stage of pregnancy. Compromise of the fetoplacental unit reduces estrone sulfate production. In a study of the effects of heat stress on pregnant cattle, plasma estrone sulfate concentrations were significantly lower throughout pregnancy in cows that gave birth to low-birth-weight calves.[44] Plasma concentrations of estrone sulfate rise slowly during the second trimester of pregnancy from 0.74 ng/mL to 3.66 ng/mL between day 90 and day 210 of pregnancy. The last trimester of pregnancy is associated with a rapid rise in the concentration of estrone sulfate to 13.36 ng/mL around 10 days prior to parturition.[61]

In human medicine, diagnosis of surfactant deficiency is based on the ratio of two phospholipids in amniotic fluid: lecithin (L) and sphingomyelin (S). If the L/S ratio is greater than 2.0, the surfactant system is mature and respiratory distress syndrome is rare.[62] The L/S ratio in amniotic fluid collected from cattle may also be used to assess surfactant system maturity,[63] thus providing a measure of readiness for birth, but is rarely used in clinical veterinary medicine. Crude surfactant harvested from bovine lungs at a slaughterhouse has been used intratracheally with calves that appeared to be in respiratory distress shortly after birth.[64]

Induction of Parturition

Manipulation of parturition may be considered for maternal, fetal, or management reasons. Fetal viability following induced parturition is variable among species. The viability of calves induced within 14 days of anticipated calving date is good[65]; viability of lambs and kids induced greater than 5 days prior to anticipated parturition date is poor.[17] Absorption of colostral immunoglobulins by premature calves is reduced, so colostral transfer should be monitored closely in induced neonates.[66] Induction of parturition or cesarean section is often necessary to prevent mortality of small ruminants with pregnancy toxemia.[67] Fetal viability is often improved by induction of parturition with dexamethasone; however, delivery of the fetuses via cesarean section is often necessary due to the debilitated state of the dam. Secretion of glucocorticoid hormones from the adrenal cortex increases markedly during the final days of gestation. The prenatal increase in fetal glucocorticoid secretion plays an important role in the cascade of endocrine events leading to parturition, and it stimulates maturational events in the lungs, liver, kidney, and gastrointestinal tract in preparation for postnatal life.[68]

Steroids stimulate production of surfactant phospholipids by alveolar type II cells, enhance the expression of surfactant-associated proteins, reduce microvascular permeability, and accelerate overall structural maturation of the lungs.[69] Administration of flumethasone (10 mg) or dinoprost (25 mg) to pregnant cows 30 hours prior to elective cesarean section increases the lecithin-to-sphingomyelin ratio, thus improving lung function and reducing complications associated with respiratory acidosis in the calf.[70] Induction of parturition has been used to reduce the incidence of dystocia in herds or breeds experiencing a high incidence of dystocia associated with fetomaternal disproportion.[71] Large birth weights are strongly correlated with fetomaternal disproportion.[72,73] Induction of parturition within 14 days of anticipated calving date is associated with good calf viability and a 3.2-kg reduction in birth weight of beef calves.[65]

Exogenous glucocorticoids, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), or a combination may be used to induce parturition in cattle (dexamethasone 20 to 30 mg alone or in combination with 25 mg of $PGF_{2\alpha}$) or in sheep and goats (10 to 20 mg dexamethasone and/or 15 mg $PGF_{2\alpha}$).[17] Glucocorticoids are more effective than prostaglandin for inducing parturition in sheep.[74] A lower incidence of dystocia and higher viability of calves has been reported in cattle induced with glucocorticoids compared with cows induced with prostaglandin.[75] Cows treated with dexamethasone or prostaglandin within 14 days of the anticipated calving date usually calve within 72 hours of treatment.[65] Combination of dexamethasone with prostaglandin increases the efficacy and reduces the interval to parturition (36 hours).[76,77] Retention of fetal membranes is a common complication of induced parturition in cattle.[78] Induction of parturition with dexamethasone causes a failure of immune-assisted detachment of the fetal membranes and the accompanying release of chemotactic factors.[79] Retention of fetal membranes may be associated with reduced first-service conception and subsequent pregnancy rates.[80] Treatment of cows with prostaglandin at calving was reported to reduce the incidence of retained fetal membranes,[81] but subsequent studies failed to support this.[76,82] Induction of cattle by administration of 25 mg of triamcinolone (Opticortinol) at day 270 followed by treatment with dexamethasone and prostaglandin 6 days later appears to reduce the incidence of retained fetal membranes associated with induction.[78,83]

TABLE 18-2

Arterial and Venous Blood Gas Values for Newborn Calves

	Parameters					
	Calf Age	pH	Po_2	Pco_2	HCO_3^-	Base Excess
Venous*	1 hour	7.219 (0.05)	NA	41.0 (5.9)	24.2 (2.7)	-2.9 (3.2)
Arterial†	1 hour	7.3 (0.05)	58.43 (11.61)	50.40 (5.27)	23.52 (2.78)	NA

*Blood taken from the jugular vein immediately postpartum.[97]

†Blood was taken from the brachial artery while the calf was in lateral recumbency (N = 30).[147]

NA, Not available.

Values represent mean with standard deviation in parentheses.

Where calving induction is used to align calving patterns to pasture availability, cows are induced to calve at around 7 months' gestation. Induced cows have increased rates of mastitis, metabolic disease, and retained placenta[84,85] and have reduced milk production in the lactation of treatment.[86,87] Calves born to cows induced at 7 months' gestation are often stillborn, die, or are subject to euthanasia shortly after birth because they are too weak or suffer from other neonatal diseases.[88,89]

Perinatal Adaptation

At birth, the fetus must successfully make a series of structural and physiologic changes to survive. Perinatal mortality is often attributable to cardiovascular, pulmonary, thermoregulatory, or metabolic/physiologic abnormalities. Dystocia and severe birth asphyxia compromise physiologic transitions, increasing the risk of neonatal mortality. Compromised neonates that survive the birth process are less likely to consume adequate colostrum and are subsequently more likely to die of hypothermia and infectious diseases.

The placenta functions as the respiratory organ of the developing fetus; efficiency of oxygen transfer to the fetus is increased by the high oxygen affinity of fetal versus adult hemoglobin.[90] In utero, the potential spaces of alveoli and the tracheobronchial tree are distended with fluid secreted by pulmonary tissue.[91] Oxygenated blood is delivered to the fetus via the umbilical vein, which anastomoses with the portal vein near the liver, and approximately two thirds of the blood flow is shunted via the ductus venosus directly into the caudal vena cava.[92] The caudal vena cava drains into the right atrium, where over 50% of the volume shunts directly into the left atrium via the foramen ovale.[92] The relatively hypoxic in utero environment causes constriction of pulmonary vessels and dilation of the ductus arteriosus.[92] Because pulmonary arterial resistance is higher than systemic arterial resistance, nearly 70% of pulmonary artery flow is shunted via the ductus arteriosus into the aorta, with the remainder perfusing the lung.[93] Left ventricular output is distributed to the systemic circulation via the aorta. The two umbilical arteries arise from the aorta in the region of the last lumbar vertebra to carry predominantly venous blood back to the placenta via the umbilicus.

At birth, some of the lung fluid is evacuated through the trachea during spontaneous delivery.[94] When the umbilicus ruptures, asphyxia triggers reflex gasping, respiratory movements, and increased peripheral vascular resistance.[93] The majority of lung fluid is absorbed through alveolar walls in the initial stages of ventilation.[94] This mechanism is prompted by activation of adrenaline-mediated α-adrenergic receptors in the pulmonary epithelium.[95] The rapidity of lung fluid absorption by the body is optimized at thoracic pressures between 35 and 40 cm H_2O.[94] Pulmonary ventilation reduces pulmonary vascular resistance, promoting perfusion of the ventilated alveolar tissue.[92] The increased oxygen saturation of blood stimulates closure of the ductus arteriosus within 4 to 5 minutes of birth.[93] The foramen ovale functionally closes within 5 to 20 minutes of birth when increased pulmonary venous return raises blood pressure in the left atrium, reversing the right-to-left shunt.[93] The septum secundum, a thin fold of tissue that lies in close apposition to the foramen, acts as a valve to close the opening. Healthy calves have mean pulmonary arterial pressures ranging from 40 to 82 mm Hg immediately after birth, declining to 22 to 25 mm Hg by 2 weeks of age.[96] Systemic arterial pressure is approximately 100 mm Hg and arterial saturation greater than 90%.[92] Transient mild metabolic and respiratory acidosis are observed following rupture of the umbilical cord as a result of anaerobic glycolysis in poorly perfused tissues during the transition between placental oxygen delivery and establishment of respiratory function. The mild acidosis is normally corrected within 1 to 4 hours of birth.[97] Anatomic closure of the foramen ovale and ductus arteriosus may take several weeks.[93] Normal blood gas values for the calf during the immediate postpartum period are presented in Table 18-2.

Dystocia is commonly associated with prolonged hypoxia and acidosis. Hypoxia and acidosis maintain constriction of pulmonary arterioles, and the subsequent maintenance of high pulmonary vascular resistance favors continuation of in utero right-to-left vascular shunts, which contributes to systemic hypoxia. Following dystocia, neonates are less active, slow to stand, slow to nurse, and prone to hypothermia and hypogammaglobulinemia. The normal duration of stage 2 labor (from appearance of fetal membranes at the vulva to delivery of the fetus) in ruminants is generally shorter in multiparous animals (~30 min) than primiparous animals (~60 min).[98] Fetal viability is improved with early intervention; multiparous animals should be assisted after 30 to 60 minutes of stage 2 labor and primiparous animals after 60 to 90 minutes.[73]

The range in ambient temperatures over which newborn animals are able to maintain homeothermy is much narrower than for growing or adult animals. Neonates are more susceptible to fluctuations in environmental temperature because of their large surface area to mass, evaporation of amniotic fluid, and limited caloric reserves. Starvation and hypothermia is the second leading cause of death of neonatal lambs.[3] Neonatal mortality increases with decreasing ambient temperature and with increasing precipitation on the day of birth.[47] Thermoneutrality is maintained by shivering and metabolism of brown adipose tissue. Normally at birth, blood glucose concentration in calves ranges between 50 and 60 mg/dL, rising to 100 mg/dL within the first 24 hours of life.[92] Lambs born in warm weather can survive for up to 4 days without supplemental nutrition. Severe weather stress may increase energy requirements by 500% and deplete the energy reserves of newborn lambs in 6 to 16 hours.[99] Starvation exacerbates the effects of environmental stress by reducing the available substrates for heat production, and energy depletion leads to hypoglycemia. Administration of glucose to hypothermic neonates prior to and during warming is important to avoid deaths from cerebral hypoglycemia induced by increased use of glucose by peripheral tissues.[100] Warming hypothermic lambs by immersion in 38° C (100.4° F) water is more efficient than infrared lamps or wrapping the lamb in a cotton cloth.[101]

No intrauterine transfer of immunoglobulin occurs in ruminants; hence, at birth, neonatal ruminants are agammaglobulinemic and immunologically naive. Infectious disease is the leading cause of morbidity and mortality in calves greater than 3 days of age.[102] Failure of passive transfer increases the risk of neonatal mortality.[103] Colostrum

VetBooks.ir

provides a concentrated source of energy and immunoglobulins. Immunoglobulins are concentrated in colostrum by an active, receptor-mediated transfer of IgG_1 from the blood of the dam across the mammary gland secretory epithelium beginning several weeks prior to parturition.[104] Colostral IgG_1 concentrations may be 5 to 10 times the maternal serum concentrations. IgM, IgA, and IgG_2 concentrations in colostrum are much lower.[105] The large numbers of leukocytes also contribute to providing passive immunity to the newborn.[106] Methods of assessing passive transfer and management of failure of passive transfer are discussed in detail in Chapter 19.

Dystocia

Between 40% and 60% of stillbirths are associated with dystocia. Calves that survive dystocia are more likely to have edema of the head and tongue, making suckling difficult. They are also weak and exhausted and likely to be recumbent for a longer period of time and expose themselves to more fecal pathogens.[107] Dystocia affects the uptake of immunoglobulins by the calf and calves that survive dystocia are more likely to become sick in the first 45 days of life.[108] Maternal variables correlated with dystocia and consequently calf mortality at birth include parity and conformation. Dystocia and stillbirths in heifers is most commonly caused by feto-pelvic incompatibility. Feto-pelvic incompatibility accounts for a lower proportion of dystocias in multiparous cows, but weak labor resulting from hypocalcemia, uterine torsion, and incomplete cervical dilation is more common in older cows.[38] The prevalence of stillbirths in dairy herds globally is reported to be increasing.[1] In the U.S. dairy industry, the incidence is 8% (11.3% in primiparae and 5.3% in pluriparae).[109] Dam pelvic diameter is an important determinant of dystocia for heifers.[110] Pelvic measurements can be used to identify abnormally small or abnormally shaped pelvises. Large frame size of the dam correlates with a reduced risk of dystocia; however, continued selection for large frame size tends to select for larger birth weight and dimensions of calves.[111] Age at first calving for heifers is not correlated with risk of dystocia as long as heifers are fed and managed to achieve appropriate growth and stature prior to calving.[112-114] The risk of dystocia in heifers is increased by poor nutrition in the last trimester.[115] Appropriate nutrition and management of replacement heifers to achieve appropriate size and stature at parturition reduces maternal and neonatal losses by reducing the incidence of dystocias. Maternal consequences associated with calving difficulty and delivery of a stillborn calf include decreased milk production and reduced reproductive efficiency. Reductions in milk production ranging from 100 to 400 kg have been reported to be associated with the birth of a stillborn calf. If the stillborn calf is delivered by cesarean section, the reduction in milk yield is on the order of 300 to 500 kg.[116] Delivery of a stillborn calf is also associated with depressed conception rates, increased services per conception, and delayed conception.

Use of calving ease bulls over primiparous cows helps to reduce the incidence of dystocia and subsequently mortality during parturition. The heritability of calving ease is relatively low; estimates of maternal calving ease range from 0.03 to 0.24[38,117,118] and paternal heritability around 0.147. Despite the relatively low heritability of calving ease, selection for calving ease should not adversely affect other production parameters in dairy cattle since the genetic correlation between calving ease and other dairy production traits are generally close to 0.[38] Calving ease evaluations are intended to increase the use of AI for heifers. To facilitate sire selection most breed associations provide guidelines regarding calving ease or expected progeny difference for calf birthweights. An example of such a scheme is the calving ease and reliability values assigned to AI Holstein bulls. In this system, the calving ease score is the expected percentage of difficult births predicted for calves delivered by primiparous cows.[119] The reliability score provides an indication as to the number of births that were considered in deriving the calving ease score. The higher the reliability score, the larger the number of observations the calving ease score is based on and the more likely it is that the calving ease prediction will accurately reflect the outcome.

Management variables that influence the risk of dystocia and perinatal mortality include stocking density of pre-parturient cows, timing of calving, and cow grouping. In a study of 123 beef herds, the dystocia rate was highest for cows housed in a barn and decreased progressively through barn/yard, barn/pasture, and pasture-only calving location categories.[120] The most common cause of dystocia in penned heifers was vulval constriction, whereas dystocias in paddocked heifers were most commonly associated with malpresentations.[121] Calving of beef heifers 6 weeks prior to cows has been recommended to allow the heifers longer to recover and conceive after calving than cows.[122] In a herd level comparative study, this practice was associated with a higher incidence of dystocia and stillborn calves.[120] Presumably because of better nutritional management, heifer dystocia rate is reduced the longer heifers are maintained as a separate group from cows prior to calving.[120]

Fetal variables that influence the risk of mortality include sex, size, and number. Calves born to primiparous cows, twins, and bull calves are more likely to die at birth than calves born from multiparous cows, single calves, and heifer calves.[47,123] Low- and high-birth-weight calves are at greater risk of mortality than average-birthweight calves.[47] Small calves experience greatest mortality at parities greater than one and large calves at first parity.[112] Fetal viability may be compromised in utero by a number of infectious agents. Common infectious agents associated with abortion and/or birth of weak calves are listed in Box 18-1. Manifestations of disease in the newborn are dependent on the time of exposure to the infectious agent.

Peripartum Assessment of Fetal Vitality

During parturition, fetal reflexes can be assessed to ascertain appreciable signs of life. The interdigital, bulbar, and swallowing reflexes can be assessed in calves presenting in an anterior presentation. The interdigital and anal reflex and pulse in the umbilical cord can be evaluated in calves presenting in a posterior presentation.[124] Depressed responsiveness is a feature of impaired acid-base status. An increasing proportion of calves fail to respond as the severity of the acidosis increases. Failure to elicit reflexes is not confirmatory of fetal death as an absence of reflexes has been observed in severely acidotic live calves.[125]

Criteria commonly used to assess the vitality of the newborn calf is presented in Table 18-3. Abnormal neonatal behavior in the immediate postnatal period is commonly a result of perinatal hypoxia and a combination of metabolic and respiratory acidosis. Calves and lambs normally have a head righting reflex almost immediately after birth. Sternal recumbency is usually attained within 2 to 4 minutes, followed rapidly by attempts to stand at 10 to 20 minutes for lambs and 15 to 30 minutes for calves.[126-128] Failure for calves to achieve sternal recumbency within 15 minutes of birth is highly predictive (84%) of compromised vitality and risk of mortality.[128] Hypoxic neonates may struggle and appear bright initially but have difficulty maintaining sternal recumbency, have depressed or absent suck reflex, appear slow to stand or remain recumbent, and develop a depressed mentation within hours.

The normal heart rate of calves is 100 to 150 beats/min immediately after birth. Heart rate normally stabilizes within minutes of calving, but in at-risk calves, peripartal tachycardia (>150 beats/min) is followed by a declining bradycardia.[124] Following experimentally induced hypoxia, nonviable hypoxic calves had similar heart rates (118 ± 36 beats/min) and body temperatures ($39.6° \pm 0.2°$ C) as viable calves but lower respiratory rates (14 to 18 versus normal 49 ± 12).[126] The rectal temperature of a normal newborn calf is higher than normal at calving 39° to 40° C (102° to 104° F) and gradually drops to normal within 3 to 5 hours. Calves that experience a protracted, difficult calving may experience hyperthermia (>39.5° C [>103° F]) at birth, which drops in the hours following birth and is slow to return to normal.[124]

The normal time taken to stand and nurse varies among species and breeds. The average time from birth to standing and nursing for beef calves is 35 and 81 minutes, respectively. Dairy calves are more variable and take approximately twice as long.[129] A high prevalence

TABLE 18-3

Assessing the Newborn Calf[138]

Criterion	Good Vitality	Poor Vitality
Respiration	50-75 beats/min and thoracic breathing	Gasping, primary apnea, irregular, abdominal breathing, bellowing and secondary apnea
Hair coat appearance	Placental fluid-covered	Meconium-stained
Peripheral edema	None	Capital, lingual, or limb edema
Mucous membranes	Pink and normal capillary refill time	Cyanotic, pale, and slow capillary refill time
Response to reflex stimulation	Vigorous head shake, strong corneal, suck, or pedal reflex	Weak or no response
Muscle tone	Active with head-righting within minutes	Inactivity and flaccid musculature
Heart rate	100-150 beats/min and regular	>150 beats/min followed by bradycardia (<80 beats/min) and an irregular, decreasing rate
Rectal temperature	102°-103° F (39°-39.5° C) after calving, declining to 101°-102° F (38.5°-39° C) by 1 hour and stable	103°-104° F (39.5°-40° C) after calving, declining to 101° F (<38.5° C) by 1 hour and decreasing
Sternal recumbence	Achieved within 5 minutes	Prolonged lateral recumbence
Attempts to rise	Attempting to stand within 15 minutes Standing within 1 hour	Delayed or no attempts to rise
Suckling	Commences within 2 hours	Delayed or no attempts to suckle

of delayed first sucklings has been reported among dairy calves. Failure of the newborn to nurse may result from reduced neonatal vigor, poor mothering, poor maternal conformation, or adverse conditions such as slippery flooring.[130] Calves have difficulty locating teats on low-slung udders (<45 cm from the ground)[131] and difficulty nursing teats greater than 35 mm in diameter.[132] Small ruminants are generally quicker to stand and nurse than calves, with most lambs standing within 30 minutes[127] and nursing within 90 minutes of birth.

Observation of interaction between the newborn and dam in the immediate postnatal period allows early recognition of the compromised neonate and facilitates timely intervention if maternal conformation or behavior threatens to impede the neonate's efforts to nurse. Failure of maternal bonding is more common with primiparous dams and multiple offspring, and with following delivery via caesarean section. Maternal bonding in sheep is mediated by an olfactory mechanism.[133] Parturition alters the release of monoamines, amino acids, and oxytocin within the olfactory bulb, stimulating an attraction to amniotic fluid and acceptance of the lamb.[134] Artificial vaginocervical stimulation with a gloved hand induces similar alterations in the release of monoamines, amino acids, and oxytocin within the olfactory bulb and is useful for triggering formation of maternal bonds to foster lambs for at least 27 hours postpartum.[134]

In utero infections and congenital neurologic abnormalities should also be considered as possible causes of abnormal neonatal behavior. Collection of sera prior to feeding colostrum is useful for diagnosing in utero infections. Pre-colostral serum immunoglobulin concentrations in calves are very low (IgM 0.126 ± 0.015 mg/mL, IgG 0.044 ± 0.003 mg/mL).[135] Elevated serum concentrations of immunoglobulins prior to ingestion of colostrum may be observed with in utero infections.[135] Specific serologic tests are available for Cache Valley virus, Akabane virus, bovine virus diarrhea virus, *Neospora* spp., toxoplasma, and bluetongue virus.[136] Teratogens and inherited diseases that may cause the birth of weak neonates are listed in Box 18-1.

Resuscitation of the Neonate

Assisted deliveries are usually associated with moderate to severe fetal stress. Survival of the compromised fetus is facilitated by prompt initiation of supportive care. Suction is useful for clearing the pharynx and nasal passages and has been shown to improve pulmonary function in newborn calves.[137] Squeezing the trachea gently may also illicit a cough reflex, which assists airway clearance.[138] Suspending the newborn by the hind legs for less than 90 seconds after delivery is an alternative method for clearing the airways.[139] If the newborn breathes spontaneously, it is placed in sternal recumbency to facilitate efficient pulmonary gas exchange and correction of the mixed acidosis.[139] If the calf does not breathe or move spontaneously within a few seconds after birth, tactile stimulations (e.g., inserting a finger or a length of straw in the nasal cavity, pinching the nasal septum, rubbing the calf's body with straw or towel,[140] pouring cold water in the ear or over the head or body of the calf[137]) are necessary to initiate a gasping reflex. In dyspneic neonatal calves, the respiratory center can be stimulated with respiratory stimulants such as doxapram (2 mg/kg IV). Doxapram should be used judiciously since the stimulatory action of the drug is nonselective. Convulsions may be observed with repeated dosing, increasing the demand for oxygen in an already hypoxic neonate.[141]

Weak fetuses are often born with strongly beating hearts but have difficulty initiating adequate inspiratory efforts to expand their lungs. Positive pressure ventilation is required to overcome surface tension in alveoli and the elastic recoil of lung tissue. Fluid within alveolar spaces and the lumen of the tracheobronchial tree is absorbed into the pulmonary interstitium most efficiently at thoracic pressures between 35 and 40 cm H_2O.[94] Less pressure is usually needed for succeeding breaths. Observation of chest wall movement is a reliable sign of sufficient inflation pressure. Ventilation with a pulmonary resuscitation bag (ambu bag) with a pressure relief valve set at 42 cm H_2O avoids inadvertent overinflation.[142] Direct mouth-to-mouth resuscitation is generally ineffective for delivering air into the abomasum and poses a risk for contracting zoonotic diseases such as leptospirosis, brucellosis, or Q fever.

Thermoregulation is important since recovery from acidosis is delayed by hypothermia.[143] Cold stress leads to increased metabolic needs and produces hypoxia, hypercarbia, metabolic acidosis, and potentially hypoglycemia—metabolic sequelae that resuscitation is aimed at correcting.[144]

Resuscitation procedures for more critical neonatal calves and small ruminants is similar to the approach taken with foals, as discussed in Chapter 17.

• CHAPTER 19

Initial Management and Clinical Investigation of Neonatal Disease

JOHN K. HOUSE, *Consulting Editor*
ALISON A. GUNN
GEMMA CHUCK
SHEILA M. MCGUIRK

Environmental Management

Maternal shedding of enteric pathogens increases around the time of parturition. In intensive dairy production systems, calf pathogen exposure and subsequently the risk of morbidity and mortality can be reduced by removing the calf from the dam after birth and placing the calf in a clean, dry, sheltered environment. Neonatal calves are cold tolerant when dry and sheltered from drafts. Wet drafty conditions lead to depletion of energy reserves and hypothermia. Hypothermia compromises colostral transfer and increases vulnerability of newborns to contagious and opportunistic pathogens. Under cold conditions calves generate heat by shivering and metabolism of brown adipose tissue. The calf is born with short-lived, stored energy in the form of muscular glycogen.[1] Colostrum is a critical source of concentrated energy to meet the metabolic demands of thermogenesis.

Colostrum Management

Ingestion and absorption of colostral immunoglobulins is essential for neonatal ruminants to thrive. Cows, sheep, and goats have an epitheliochorial type of placenta that does not allow passage of immunoglobulin; hence, neonates are born virtually agammaglobulinemic, rendering them susceptible to infection. Ingestion of colostrum provides maternal immunoglobulins that enterocytes selectively absorb by pinocytosis during the first 24 hours after birth. The ability of the enterocytes to absorb immunoglobulins decreases rapidly soon after birth, resulting in "closure" of the intestines by 24 to 36 hours postpartum. The immune system of the neonate starts to develop from birth, with endogenous immunoglobulin G (IgG) reaching functional levels at 3 to 6 weeks of age.[2] The uptake of maternal leucocytes by the calf also plays a significant role in the development of the neonatal immune system.

Inadequate colostrum consumption increases the risk of disease. Passive transfer achieving serum IgG concentrations 10 mg/mL or greater at 24 to 48 hours is associated with reduced risk for morbidity and mortality.[3-5] Provision of adequate good-quality colostrum also results in improved daily weight gain and feed conversion efficiency both preweaning and postweaning, although the effect of this on joining dates and age at first calving varies among studies.[5-7] Both serum IgG at 24 to 48 hours and the provision of adequate good-quality colostrum have been associated with increased milk production in the first and second lactations.[6,8]

The major factors influencing the effectiveness of passive transfer of immunoglobulins in calves are (1) the concentration of immunoglobulins in colostrum fed, (2) the volume of colostrum ingested, and (3) the age of the calf at first colostral feeding.

Colostrogenesis occurs several weeks before calving under the influence of prolactin and other lactogenic hormones. Colostrum is nutrient dense and has a higher level of energy and protein than is found in milk. Bovine colostrum contains approximately 45 mg/mL[9] of immunoglobulin and 10^6 leukocytes/mL.[10] IgG_1 is transported from blood in endosomes through the polarized mammary epithelial cell by a process known as transcytosis.[11] The IgG_1 is bound by the Fc-receptor of the neonate (FcRn) at the basal side and transferred to the apical side under the control of intracellular proteins termed *small GTPases*.[12] The FcRn receptor consists of two subunits: an integral membrane α-chain (Fc fragment of IgG, receptor, transporter, alpha [FcGRT]) and a β-light chain (β2 microglobulin [β2M]). In vitro, the expression of FcGRT and several of the small GTPases controlling the transfer of IgG are upregulated by estrogen and progesterone, and it is thought that this mechanism results in the marked increase in transport of IgG_1 observed in the 4 weeks prior to calving.[12,13] Immunoglobulins account for more than 95% of the whey protein at calving, and IgG_1 accounts for approximately 80% of this amount.[14] IgG_2, IgA, and IgM account for 10%, 7%, and 5%, respectively. The amount of IgA remains constant throughout all lactations, whereas the colostrum of cows in their first lactation contains less IgG_1, IgG_2, and IgM. Immunoglobulin levels in mature milk are much lower, comprising only 7% of the total whey protein, with an increase in the relative contribution of IgA. Older cows have a tendency to a higher ratio of IgG_1 to IgG_2.[15] This is consistent with a lower level of IgG_1 in the serum of heifers. The transport of IgG into bovine colostrum has been associated with a transient decrease in serum total protein, globulin, and IgG concentrations during the preparturient period, particularly in dairy cows. Up to 500 g of IgG_1 a week are removed from blood during the most active period of colostrum formation.[16] Passively derived immunoglobulins enhance neonatal immunity via functioning as neutralizers and opsonins. The association between failure of passive transfer (FPT) of immunoglobulins and neonatal infection has been well established in the calf.[17,18] Colostral leukocytes participate in regulation of the neonate's immune response. Comparison of the immune response of calves fed leukocyte-replete or leukocyte-depleted colostrum indicates that colostral leukocytes enhance humoral immunity and phagocyte function.[19-23] Following experimental *Escherichia coli* infection, calves fed leukocyte-replete colostrum recovered more quickly and shed fewer bacteria than calves fed leukocyte-depleted colostrum.[10] Transfer of cellular immunity via colostral leukocytes has also been demonstrated in sheep.[24] Colostral leukocytes are destroyed when

colostrum is frozen, pasteurized, or fermented. Colostrum also contains hormones (growth hormone, relaxin, prolactin, insulin, and glucagon), essential fatty and amino acids, minerals, trace elements, and (pre-)vitamins (especially beta-carotene and vitamins A, B, D, and E) (Table 19-1), as well as cytokines, growth factors (members of the IgF system, including IgF binding proteins [IgFBP]), and nonspecific antimicrobial factors such as lactoferrin. Colostrum is a significant source of copper to the newborn calf but not of selenium or zinc.[25]

Colostrum has been shown to have many roles apart from establishment of the humoral neonatal immune system. Lactose intake is insufficient to maintain plasma glucose concentrations, and colostrum feeding increases plasma glucose, most likely due to stimulation of gluconeogenesis. Newborn calves are deficient in vitamin A and have a low lactoferrin status. Both are found in elevated quantities in colostrum compared with milk. Lactoferrin is an iron-binding glycoprotein, which is a potent antimicrobial factor in the milk cistern and in the alimentary tract of newborn animals. Digestive functions develop during fetal life and undergo the largest morphologic and functional changes during the first 48 hours of extrauterine life under the influence of insulin-like growth factor-1 (IgF_1), lactoferrin, and other bioactive substances, many of which are present in significantly higher concentration in colostrum than milk. These factors are key regulators in the development of the gastrointestinal tracts of bovine neonates, including stimulation of mucosal and submucosal growth, brush-border enzymes, intestinal DNA synthesis, increased duodenal villus size, apoptosis, protein synthesis and degradation, and digestion and absorption. They also exert systemic effects outside the GIT on metabolism and endocrine systems, vascular tone and hemostasis, activity and behavior, and systemic growth.[26-28]

Provision of Adequate Colostrum

Optimal transfer of immunoglobulin will occur when calves are administered 7.5% to 10% of body weight of first milking colostrum within 2 hours of birth followed by an additional feed of 5% of body weight at 12 hours (Table 19-2). The initial feed should provide the calf with a minimum of 100 g of IgG, and at least 150 g of IgG within 2 hours of birth are required to ensure 90% of calves have optimal passive transfer.[29] Dairy calves should be administered colostrum by nipple bottle or esophageal tube, since increased FPT occurs in dairy calves that are left on their dam.[9,30,31] This is due to the reduced volume of colostrum, and therefore mass of IgG, consumed by the calf if left to suckle naturally during the first 24 hours.[5] Conversely, separation of beef calves from the dam is not practical and may result in mismothering. Generally failure of passive transfer is less of a problem in beef cattle, since the lower volume of colostrum produced results in an elevated concentration of IgG, and supplementation is only recommended following dystocia.

Failure of Passive Transfer

FPT occurs when calves do not absorb sufficient immunoglobulins. Only small amounts of IgG and IgM to unknown antigens are made by the fetus, and they offer no protection against disease. It has been estimated that approximately 31% of preweaning mortality events occurring in the first 3 weeks of life can be attributed to failure of passive transfer.[32] The problem in mixed-source calf-rearing properties is significantly worse.[3] A high percentage (19.2% to 38%) of dairy calves are still found with significant FPT.[30,31,33] Some debate exists as to the serum IgG concentration that signifies FPT. Calves are generally defined as having FPT if the calf serum IgG concentration is less than 10 mg/mL when sampled between 24 and 48 hours of age.[34] It has been suggested that serum IgG concentration below 13.4 mg/mL constitutes FPT.[29,35] Ensuring that every calf has adequate passive transfer is challenging and rates of 10% are probably indicative of good management practices.[29]

Risk Factors for Inadequate Colostrum Uptake

There is a large variation in colostrum immunoglobulin concentrations between individual cows and a variety of influences: genetic, environmental, and physical on the uptake of colostral antibodies by the calf. Although calves born to beef cows with lower colostrum immunoglobulin concentration had an increased risk of mortality,[36] numerous other studies in beef and dairy calves have failed to demonstrate an association between the colostral immunoglobulin levels and the serum immunoglobulin of the calf at 48 hours of age.[37-41] Administration of a known volume and concentration of colostrum via oroesophageal feeder at a specific time after birth to dairy calves has been shown to have more linear correlation with calf serum IgG,[29,42] but administration of sufficient colostrum to provide 150 g of IgG within 4 hours of birth can still result in FPT.

Factors Affecting Colostrum Quality

At the herd level, colostrum quality is affected by breed, parity, and climate. For individual cows the biggest determinants are colostral volume and time from calving until milking.[43,44] Colostrum concentrations of Holstein-Friesian cows varied from 20 g/L of immunoglobulin to more than 110 g/L of IgG_1 in cows from a single herd.[43] First milking colostrum samples collected within 4 hours of milking from cows at 11 dairies in Pennsylvania varied from 9 to 166 g/L of IgG_1.[45] The mean concentration of IgG_1 in first milking colostrum in three large studies of dairy cows varied between 37.5 ± 30.2 and 48.2 ± 28.9 g/L.[43,45,46] Colostrum IgG concentration declines with time after calving even if the cow is not milked.[43,44,47,48] However, several studies have demonstrated that this decline is minimal until the cow has been calved 8 to 9 hours.[43,47] There is no increase in colostral volume if postpartum milking is delayed, so it appears that the declining IgG is not due to dilution.[44,48,49] During the colostrum phase, mammary cells have leaky tight junctions,[50,51] so it is likely that

*Calves should be fed 7.5% of body weight or, at a minimum, the volume shown. IgG levels would be enhanced by 5% of body weight 6 to 12 hours later.

†Calves should be fed 7.5% of body weight and an equivalent volume 6 to 12 hours later.

‡It is unlikely that adequate passive transfer will be achieved.

Calculations of total IgG required and apparent efficiency of absorption are based on Chigerwe et al (2008)[29,160] using blood volume calculations from Quigley et al (1998).[161] The correlation between the Brix refractometer reading and serum IgG levels was calculated using Quigley et al (2013).[49] This table was compiled with the assistance of Zoe Vogels from The Vet Group, Timboon, Victoria.

It is assumed that the minimum volume fed would be 5% of body weight even where good quality colostrum is available. It should be noted that below a Brix of 22%, it is not possible to achieve adequate passive transfer with a single feed of colostrum.

once parturition occurs, the active transcytosis of IgG_1 ceases and it is passively reabsorbed.

Studies of colostrum and calf immunoglobulin levels in specific beef breeds have failed to demonstrate consistent differences between specific breeds, and many studies have shown evidence of variations within breed lines. In dairy breeds, colostrum from Holstein cows was statistically lower in total IgG than colostrum from Jersey, Ayrshire, and Guernsey cows.[52,53] Prepartum dairy cows have a significantly greater decline in serum IgG compared with beef cows[13]; however, the colostrum of dairy cows has lower concentrations of IgG because of the much larger volume. Some studies have shown very low volumes of colostrum (<2 L) in beef cows.[54,55] The volume of colostrum produced and the concentration of immunoglobulin in the colostrum is markedly affected by differences in the onset of lactogenesis, and the resulting dilution of colostral immunoglobulins—hence it is likely that much of the variation observed among breeds, lines, and cows is an effect of colostrum volume. First and second calving beef and dairy cows often have a lower immunoglobulin concentration than cows of third or greater parity.[39,43,53,56,57] Similarly, calves born to beef heifers and second parity cows have a significantly lower mean concentration of serum IgG compared with that of calves born to mature cows.[56,58,59]

Genetic variance has been found in the genes encoding the FcRn receptor involved in transcytosis of IgG_1 into the mammary gland. In Holstein-Friesian cows, haplotype 5 of the FcGRT subunit has been shown to be significantly associated with a high colostrum IgG, and FcGRT haplotype 2 shows a similar trend.[60] FPT in beef calves from 16 breeds has been associated with FcGRT haplotype 3; conversely, calves with the FcGRT haplotype 2 were less likely to have high levels of serum IgG.[61] FPT in these calves is also associated with one of eight haplotypes of the β2M subunit of the FcRn receptor.[62] It is likely that variation in this receptor is impacting the concentration of IgG_1 in colostrum, rather than the uptake of IgG_1 by the calf; neonatal uptake does not involve the FcRn receptor. An estimated 10% of Holstein cows are capable of high mass transfer of IgG_1, resulting in an IgG mass more than 1 standard deviation above the mean.[45] Variation in the FcRn receptor is probably contributing to this variation, along with other genetic or hormonal regulation of transport. Opportunity may exist to enhance the concentrations of immunoglobulins in colostrum by genetic manipulation of IgG transport in the mammary gland. However, it should be remembered that serum IgG concentrations in the periparturient cow are already decreased as a result of IgG transport into colostrum[13]; further, decrease in immunoglobulins may exacerbate the immunosuppression that occurs during the peripartum period.

Numerous studies have failed to demonstrate an effect of often severe protein and/or energy restriction for up to 3 months before calving on colostrum immunoglobulin levels.[63-66] Protein restriction may result in an increase in IgG levels and a concurrent decrease in colostral volume, making the colostrum more viscous and difficult to suckle, especially in heifers, resulting in decreased IgG levels in the calves.[58,67] This is likely to be a direct volume response as shown by other studies of colostral IgG concentration.[13,43] There was no significant effect of dietary restriction on colostral IgM in any of the studies. Selenium supplementation has been shown to increase the IgG levels in the colostrum of selenium-deficient cows,[68] but not lambs. IgG uptake by the calf may also be affected by serum copper levels.[69]

Twins have not been demonstrated to affect colostrum IgG concentration in beef cows[36,56]; however, another study of sheep, goats, and dairy cows demonstrated an increase in total protein, whey protein, and IgG concentration.[70]

Short dry periods of 28 to 35 days do not affect colostrum IgG levels, but when the dry period was eliminated completely, there was a decrease.[71-73] Elimination of the dry period did not affect

VetBooks.ir

colostrogenesis in terms of cellular and fluid composition, and it is likely that the reduced quality is due to the lack of a period of secretion and accumulation. The mean colostral IgG of these cows remained close to 50 g/L so that 3 L of colostrum would provide the calf with adequate IgG. Treatment of cows with internal teat sealant at drying off has no effect on transfer of colostral antibodies following calving, but will help prevent leaking of colostrum prior to calving and the consequential reduction of the quality of the colostrum harvested.[74]

Few studies have looked at the effects of periparturient disease on IgG levels in colostrum. A decrease in colostral IgG has been observed in cows with periparturient infections and clinical mastitis,[36] and where colostral IgG was not measured, calves of cows with periparturient mastitis had a lower serum IgG.[56] The reported effect of subclinical mastitis is also inconsistent. At the quarter level a persistent infection at the time of calving, detected by serial cultures, results in a decrease in total volume of colostrum produced but no variation in IgG_1 concentration, compared with a matched quarter on the same cow.[75] At the cow level, an increased risk of colostrum with an IgG content of less than 30 g/L is found in cows with a somatic cell count greater than 50,000 cells/mL, measured at the herd recording after calving.[57] At the herd level, cows from farms with an average count less than 200,000 in the month prior to sampling produced colostrum with higher levels of IgG_2, tocopherol, vitamin A, potassium, and total solid levels; however, no significant variation was noted in IgG_1.[46]

Environmental temperatures have an effect on colostral IgG concentrations with several large studies in dairy cattle demonstrating an increase in colostral IgG concentration in the summer[57,76,77]; however, at the extreme, heifers exposed to heat stress had decreased colostral IgG concentration.[78] Photo period has no effect on colostral IgG concentration or volume.[44]

Factors Affecting Colostrum Uptake by the Calf

TIME AND METHOD OF FIRST FEEDING. The key influences on immunoglobulin absorption by the neonatal calf are the concentration of immunoglobulins in the colostrum, volume fed, and time between birth and colostrum feeding. When small volumes are fed, the method of feeding can also affect the final serum IgG level.

Early ingestion of colostrum is crucial because IgG is absorbed by the intestinal epithelial cells of the newborn ruminant, and the ability of enterocytes to transport immunoglobulin declines linearly from 2 to 20 hours and completely ceases (intestinal closure) between 24 and 36 hours.[79] Serum IgG concentrations peak around 32 hours and then decline until the production of antibodies by the neonate exceeds the decay of passively acquired antibodies. Any delay in first feeding of colostrum results in decreased absorption of immunoglobulin and a lower serum IgG.[29,80] Absorption of immunoglobulins occurs along the whole length of the small intestine in calves, with the amount transported increasing from the duodenum to the ileum,[81] whereas in lambs and kids there is virtually no absorption from the duodenum and the majority occurs in the jejunum.[82,83] IgG and other macromolecules are mainly absorbed by micropinocytosis, although some receptor-mediated endocytosis has been demonstrated; however, this does not involve the neonatal Fc receptor FcRn.[81,82,84] Preferential absorption of homologous IgG has been observed in pigs; however, recent studies in kids and lambs have shown that similar IgG transfer can be achieved by feeding bovine colostrum, although in lambs the apparent efficiency of absorption is lower.[85-87]

The age of the calf when it receives its first feed and the amount of immunoglobulins received will influence the time of closure of the intestinal permeability to colostral immunoglobulins and the final serum immunoglobulin levels of the calf.[88-92] Cessation of absorption occurs by 24 hours in calves that receive a full feed of colostrum within the first 4 hours after birth. When the colostrum volume is less than 2 L, the gut will remain permeable for a longer time and the rate of absorption will increase in response to a subsequent feed. If the calf is older than 12 hours when it receives its first feed, there is a significant increase in the possibility of the calf being agammaglobulinemic. It is likely that the time of closure is related to the immunoglobulin concentration of the colostrum as well as the volume fed. Delay in colostrum feeding will also result in lower plasma insulin and IgF_1 for up to 48 hours after first colostrum intake and reduce plasma concentrations of β-carotene, retinol, and α-tocopherol for nearly a month after birth.[93,94]

The IgG concentration of the colostrum has the greatest effect on the mass of IgG fed and will determine the effectiveness of transfer of passive immunity when dairy calves are fed a fixed amount of colostrum. Therefore, it is important to implement routine measurement of colostrum IgG content on dairy farms. Provision of a high concentration of IgG in the initial feeding results in a much higher calf serum IgG than feeding increased volumes of lower-quality IgG.[95] When different volumes and concentrations of colostrum have been fed to calves after birth, increased volumes of high-quality colostrum resulted in a 50% increase in the calf serum IgG concentration at 24 hours, whereas the magnitude of effect of increased volume was much lower when low immunoglobulin colostrum was fed.

Calves should be fed 150 g of IgG within 4 to 6 hours of birth and earlier whenever practical. The volume at each feed should be determined after measuring colostrum IgG levels and is more important to optimize where lower-quality colostrum is the only source. There is no difference in the IgG concentration at 48 hours when 40-kg calves are administered either 3 or 4 L of colostrum with equivalent immunoglobulin levels regardless of IgG concentration.[29,42] Similarly with lower-quality colostrum, higher serum IgG levels will be achieved when two feeds of 2 L are given at 2 and 6 hours postpartum than if 4 L are given in one feed.[95] The pathophysiology underlying these observations is not fully understood, but 22% of the variation in the effective absorption of colostrum is attributed to abomasal emptying rate, and it is likely that the excessive mechanical distention of the abomasum with 4 L of colostrum delays outflow.[42,95,96]

Therefore, feeding regimens should be based around feeding 7.5% of body weight liters within 4 hours of birth, or a minimum of 150 g if availability is restricted and quality is higher than 50 g/L. Calf serum IgG levels will be significantly boosted by a further feed of 5% of body weight of colostrum within 12 hours of birth,[95] and if less than 150 g of colostrum was fed at the initial feeding because of limitations of quality or volume, then a further 7.5% should be fed.[35] Emphasis should be placed on feeding colostrum with the highest concentration of colostrum at the initial feed when the effectiveness of absorption is higher. Many farmers are currently feeding 10% to 12% of body weight as a single initial feed. Although this will provide good levels of IgG where colostrum quality is adequate, it may result in moderate depression and discomfort in the calf.[97] Good-quality colostrum is a precious resource, and more efficient use is possible by knowing colostrum quality, limiting the initial feed to 7.5% of body weight, and placing emphasis on a second feed of good-quality colostrum before the calf reaches 12 hours of age.

Method of feeding also has a significant effect on colostrum intake. A high proportion of calves left to suckle their dams shows evidence of failure of passive transfer, compared with those artificially fed by teat or esophageal feeder.[9,98,99] This is due to the reduced volume of colostrum, and therefore mass of IgG, consumed by the calf if left to suckle naturally during the first 24 hours. Therefore, it should be strongly recommended that dairy calves be administered colostrum containing 150 g IgG within 2 hours of birth.[5] Teat-feeding stimulates a reflex closure of the esophageal groove allowing colostrum to pass directly to the abomasum, where it clots before moving to the small intestine for absorption. When an esophageal feeder is used, this reflex does not occur and the colostrum passes to the reticulorumen.[100,101] Promotion of the advantages of closure of the esophageal groove has resulted in the use of a nipple bottle as the more common method of administering colostrum. However, several studies have demonstrated that there is no difference in immunoglobulin concentrations at 48 hours between calves that sucked larger volumes of colostrum from a nipple bottle and those that were administered a similar quantity via an esophageal feeder, although there may be a delay of approximately 3 hours before the serum IgG

VetBooks.ir

increases in the tube-fed calves.[97,102-104] This delay is not due to the deposition of colostrum in the reticulorumen, since all except 400 mL will immediately pass into the abomasum because of the pressure gradient resulting from the placement of the reticulorumen dorsal to the abomasum in the neonatal calf.[105] Instead, the delay is likely to be due to delayed abomasal emptying as a result of distention and changes in physiologic and neuronal control mechanisms.[96,106]

Calves fed by a nipple bottle will commonly not ingest sufficient colostrum to minimize the risk of FPT and should be encouraged to ingest the maximum volume they will voluntarily ingest within 1 to 4 hours of age.[35] Calves should be fed as soon as they are standing; delaying up to 6 hours after birth or provision of a heat lamp will not increase the amount of colostrum suckled.[35,107] Calves that have a high degree of vigor during the first hour of life and during colostrum suckling will consume more colostrum from the bottle, as will larger calves.[107] Bottle-fed calves that do not ingest their full allocation of colostrum at either their first or second colostrum feed should be targeted for immediate esophageal feeding, and the total remaining should be fed.

In order to minimize trauma when an esophageal feeder is used, the calf should be standing with its rump against a solid wall or corner. The feeder used should have a total volume of at least 3 L so that intubation only has to occur once. The calf should be encouraged to swallow prior to insertion by sucking a finger to produce saliva or by feeding a few mouthfuls of colostrum. The tube should be introduced without physical exertion, and the head should be positioned slightly downward to allow swallowing as the tube is inserted into the esophagus. Before feeding, the knob at the end of the tube should be palpated on the left-hand side dorsal to the trachea to ensure that positioning is correct. At this point the calf head may be tilted slightly upward as the bottle is elevated to administer the colostrum.

On beef properties, routine administration of colostrum to the newborn calf is disruptive and delays the time until first sucking[108] but will decrease the incidence of FPT.[37,109] Feeding colostrum to high-risk calves is likely beneficial, most commonly after dystocia. Beef cows often produce smaller colostrum volumes, and where volumes less than 1.5 L are fed, use of a nipple bottle is recommended, since serum IgG at 24 hours is higher compared with calves administered colostrum with an esophageal feeder.[110] This most likely occurs because a greater percentage of the total colostrum is deposited into reticulorumen. Where dairy colostrum was fed, this was also shown to be a biosecurity risk.

OTHER FACTORS INFLUENCING COLOSTRUM UPTAKE. Calves that have experienced dystocia are more likely to have failure of passive transfer.[5,58,59,111] Decreased vitality of the neonate and, in many cases edema of the head and tongue, result in a slower time to stand and inadequate colostrum intake as a consequence. Calves born to primiparous cows are more endangered than those born to multiparous cows. Respiratory acidosis did not result in a decreased level of IgG at 37 to 48 hours in studies where blood gases were measured promptly using arterial blood, although delayed absorption was observed in one study.[112,113] The effects of twinning are equivocal, with two large studies, both in beef herds, demonstrating opposite effects of twinning on calf serum IgG. This is likely to be related to management, since the study that showed an increase in IgG with twinning moved all cows with twins to a barn for care and observation.[56,111]

It has been shown that the conformation of the dam's udder and ventral abdomen has a significant effect on the average teat seeking time prior to first suckling. There was nearly half an hour delay in the time to suckle.[114] The overall effect on calf IgG was not measured, but a separate study demonstrated a significantly lower serum IgG in cows with pendulous udders.[115]

Protein restriction in the last third of gestation may affect uptake of IgG by the calf,[116] although IgM concentration was unaffected. This finding was attributed to the selective absorption of IgM in newborn calves, which is highly efficient when colostrum intake is low. IgM is the primary immunoglobulin that provides protection to the neonatal calf during the first few days of life, and it has been suggested that the efficient absorption of IgM is a compensatory measure that provides immunity to calves even when they are hypogammaglobulinemic.[117,118]

There is a seasonal variation in the IgG levels of calves and efficiency of absorption after colostrum feeding, being lower in the winter in cold climates and lower in the summer in hot climates.[38,119-122] Colostrum immunoglobulin concentration is reduced in hot and cold weather,[76-78] and this is exacerbated by calves also being less willing to suckle in extremes of temperature. Heat stress results in smaller calves that may be less vigorous,[121,123] and one study has shown that calves subjected to a cold and wet environment had a slower rate of colostral absorption,[124] although the serum immunoglobulin at 24 hours was not significantly different from the control calves. In that study the calves exposed to cold temperatures were fed colostrum via an esophageal feeder. The effect would be exacerbated in cold-stressed calves, since they are less likely to suckle voluntarily.

There is some evidence that IgG levels in calves at 24 and 36 hours have low to moderate heritability. The breed of the sire and dam has some effect, but there is variation within lines of the same breed.[39,41,59,125] Haplotypes of both the FcGRT and β2M genes coding for the FcRn receptor are associated with FPT in neonatal beef calves, as discussed previously.[61,62] Since this receptor is not involved in the uptake of IgG by the calf, it is likely that the risk factor for FPT is the colostrum quality of the dam.

Management to Ensure Adequate Passive Transfer (Boxes 19-1 and 19-2)

ENSURING ADEQUATE QUALITY

Colostrum Harvesting, Handling, and Storage. Colostrum collection should occur as close to parturition as possible. Fresh

BOX 19-1

Best Practice Colostrum Management for Dairy Calves

- Milk cows as soon as possible after calving. IgG concentration declines by 3.7% for each hour after calving.
- Remove calves from the calving area at least twice daily.
- Measure quality of colostrum (Brix refractometer). This will determine the quantity of colostrum to be fed. For the first feed, administer colostrum containing 150 g IgG within 4 hours of calving. Feed a maximum of 7.5% of body weight. If calf does not suckle the full amount, top with esophageal feeder.
- Feed an additional 5% to 7.5% of body weight by 12 hours of age. If the calf did not receive 150 g of colostrum in the first feed, it would be preferable to supplement 7.5% of body weight at the second feed.
- On farms with a history of Johne's, salmonella, mycoplasma, or leukosis, pasteurize colostrum.
- Avoid pooling colostrum where possible. If pooling of colostrum is unavoidable, mix colostrums of similar quality.
- Implement a monitoring program for failure of passive transfer.

BOX 19-2

Best Practice Colostrum Management for Beef Calves

- Avoid severe restriction of dietary intake prior to calving; this will reduce volume and make colostrum more difficult to suckle.
- Minimize disruption of calving cows.
- Ensure that calves receive colostrum within 6 hours of calving (active suckling): intervene when there is dystocia or dumb calf.
- Intervention may be by restraining the dam and encouraging suckling, or by administration of colostrum by a nipple bottle. An esophageal feeder should only be used when volumes greater than 1.5 L are available, or if the calf will not suck.

VetBooks.ir

cows should be removed from the calving area and milked out at least twice daily to help ensure optimal colostrum quality. Colostrum collected from cows who have leaked milk prior to calving, have signs of ill health, or have evidence of mastitis should not be fed to neonatal calves. Not only will there be a compromise in colostrum quality, but there is also increased potential for the presence of infectious pathogens, such as mycobacterium paratuberculosis, *Salmonella* spp., *Mycoplasma bovis, Staphylococcus aureus,* bovine diarrhea virus, and bovine leukemia virus.[126-128] Neonatal enteric pathogens such as cryptosporidium may also be present.[129,130] Consequently, unpasteurized colostrum is a potential risk factor for calf diarrhea and neonatal septicemia.[131,132] Unpasteurized colostrum is also a biosecurity risk, and the use of colostrum from cows from a different property should not be recommended. Risk will be increased significantly if colostrum is pooled as organisms are disseminated, subsequently infecting a larger number of calves.[132-134] This is exacerbated further if storage is poor, resulting in pathogen proliferation.[131] Colostrum with high bacterial levels not only present a significant disease risk, but also affect absorption of IgG by direct blocking of uptake and transport of immunoglobulin molecules across intestinal epithelial cells or by binding free immunoglobulin in the gut lumen.[34,135] Pooling of colostrum will also result in reduced IgG concentrations because of the overrepresentation of high-volume, low-immunoglobulin colostrum and consequently is associated with an increased level of FPT.[30,136] When pooling is necessary for pasteurization, the colostrum IgG should be estimated using a Brix refractometer and low-quality colostrum excluded.

Microbial contamination of colostrum compromises colostral quality and subsequently calf health. Bacterial contamination may occur during harvest, storage, or administration.[126,131,137] Possible sources of contamination include cow skin, milking cup liners, hoses, milking buckets, storage, and feeding utensils. Contamination of colostrum with pathogens during harvest can be avoided by careful and hygienic teat preparation in fresh cows prior to applying cups.[126] This may involve washing and drying of teats and application of a premilking teat disinfectant.[138,139] Thorough and effective cleaning and disinfection of collection, storage, and feeding equipment is essential. It is important that separate, clearly marked esophageal feeders are used for feeding colostrum and are not used for sick calves, since this may also be a significant disease risk. Milk feeding equipment should not have cracks or scratches that allow for buildup of bacteria. Equipment should be rinsed in lukewarm water, and then actively scrubbed in water hotter than 50° C (122° F) containing detergent and bleach, or dry chlorinated detergent, to remove any residue. Bottle brushes should be used to clean esophageal feeders, nipples, and feeding bottles. Finally, they should be rinsed in water containing acid or an acid rinse and then allowed to completely dry before stacking or storage. When concern exists regarding hygiene practices, plating 10 µL of colostrum onto a blood plate and incubating at 37° C (98.6° F) overnight provides a simple crude assessment of microbial contamination of colostrum being fed to calves and allows identification of the origin of any process failure. Fresh colostrum fed to calves should have a total bacteria count less than 100,000 colony-forming units/mL and less than 10,000 coliforms/mL.[126,132]

Short-term storage of colostrum is necessary in order to deliver known good-quality colostrum to neonatal calves within hours of birth to reduce the risk of failure of passive transfer. When colostrum is stored at ambient temperatures, bacterial proliferation leads to fermentation, thus reducing total solids, protein, fat, and lactose content. Refrigeration of colostrum delays bacterial growth. Producers should aim to feed refrigerated colostrum within 2 days of collection. Storage of colostrum in the refrigerator for more than 24 hours will result in a decreased amount of IgG absorbed, and this may lead to FPT if stored for more than 48 hours.[140] The addition of 10 mL of 50% potassium sorbate solution per liter of colostrum at the time of collection to colostrum (0.5% wt/vol), in combination with refrigeration, inhibits bacterial growth for 4 days.[131]

Pasteurization of colostrum is an effective way to control colostrum bacterial load, reducing the risk of infectious disease transmission from cow to calf.[141] Degradation of immunoglobulins may be a problem with large-batch colostrum pasteurizers. Calves fed large-batch pasteurized colostrum have significantly lower serum IgG levels than those fed unpasteurized colostrum.[34] However, pasteurization of small batches of colostrum (57 L) at 67° C (152.6° F) or less caused a minimal decrease in the immunoglobulin concentration of colostrum compared with pasteurization of large batches (95 L), or batches at higher temperatures (76° C [168.8° F]) and has little effect on the subsequent serum immunoglobulin in calves at 24 hours of age.[142,143] At this temperature *Mycobacterium paratuberculosis* may still survive.[144,145] Heat treatment of colostrum (at 60° C [140° F] for 60 minutes) at a commercial level has been shown to effectively reduce colostrum microbial counts while maintaining IgG concentration.[146] Calves fed such colostrum were also found to have a reduced morbidity.[147] This critical temperature appears to significantly reduce the bacterial load while not denaturing the IgG or changing the viscosity of colostrum.[148]

Longer-term preservation of colostrum can be achieved by freezing or lyophilization without change in the immunoglobulin and nutritional content.[149-151] However, the cellular content of colostrum is destroyed by freezing, which may have longer-term effects on the development of the immune system.[152] In kids, the feeding of lyophilized colostrum resulted in higher IgG levels than feeding frozen colostrums.[153] Colostrum should not be thawed in a microwave, since the defrosting of a large volume in this way results in uneven heating and clots.[102] It should be stored in 1- to 2-L aliquots in flat plastic bags and allowed to thaw at room temperature in a fridge or in a rocking heated water bath with a water temperature no more than 40° C (104° F).

Monitoring Colostrum Immunoglobulin Quality. The quality of colostrum has traditionally been measured by visual inspection or by the use of a colostrometer (a hydrometer). The level of IgG in colostrum cannot be accurately predicted based on its appearance,[154] hence the need for more objective instruments. The colostrometer measures the specific gravity of a liquid, which in the case of colostrum is associated with the protein content. Globulins contribute greatly to this protein, so the colostrometer has been used to determine the immunoglobulin content of colostrums.[155] Although they are relatively quick to use on farm, colostrometers have limited sensitivity (0.32) and specificity (0.97) for detection of low-quality colostrums.[156] Consequently, two of every three low-quality colostrum samples were incorrectly classified as acceptable. Colostrometer readings are also significantly affected by temperature,[157] and for a known quality of colostrum, the colostrometer can differ by 0.8 g/L for every 1° C (1.8° F) change in temperature. The specific gravity of colostrum can also differ among breeds and can be influenced by lactation number, month of calving, year of calving, and protein yield in the previous lactation.[77] Field experience has shown that colostrometers are most accurate for diagnosing samples of moderate or inferior quality but may indicate erroneously high readings for samples in the superior range.[40] It should be noted that the markings on a colostrometer are calibrated for Holstein cows. However, as a comparative field test, it can still be a useful tool, where calves are force-fed colostrum. In a non-interventionist situation, the dam's colostral immunoglobulin is not a good predictor of the level of immunity that the calf will attain.[37,38] From a practical perspective, colostrometers are very fragile because they are made of glass, which can render them unsuitable in a farm environment.

Cow-side immunoassay kits for measuring colostral IgG are available and have been shown to have an acceptable sensitivity and specificity for this purpose.[158] However, their lack of availability on a global scale limits their use along with financial constraints.

Optical and digital Brix refractometers can be used to measure the quality of colostrum using fresh and frozen samples.[159] The optical Brix refractometer demonstrated a specificity of 85% and sensitivity of 90.5% using a cutoff of 22% Brix. A cutoff of 22% Brix was deemed to equate to 50 g/L of immunoglobulin using radial immunodiffusion (RID); thus samples greater than 22% Brix were considered to be of adequate quality.[159] In another study, the results

VetBooks.ir

showed a cutoff point of 21% was estimated in samples greater than 50 g/L, as measured by RID.[49]

The benefits of the Brix refractometer are that they are not affected by ambient temperature and they are robust, easy, and economical to use at an on-farm level.[160] It has been found that high-quality colostrum samples can yield a "fuzziness" through the viewfinder of a Brix refractometer. Generally this happens in samples greater than 22%. A smaller sample size on the prism can help with clarity in these high-quality samples. The poorer the quality of colostrum, the clearer the value is to read.

Brix refractometers are inexpensive, easily available, and robust, and as such should be standard dairy farm equipment. Farmers should be advised to purchase a refractometer that only measures degrees Brix with a scale from 0% to 32% so that they are easy to read. To get an accurate reading, it is necessary to press the cover plate firmly over the prism while looking through the viewfinder, since some thick samples will cause the cover plate to lift off the prism. It is also important that each sample is placed on a clean, dry prism.

Enhancing IgG Uptake. Numerous attempts have been made to artificially augment passive transfer by addition of substances to colostrum that aim to increase efficiency of absorption or provide an increased concentration of immunoglobulins. Addition of dried colostrum powder,[95,162] casein, or concentrated whey protein[163,164] had no benefit or a detrimental effect on colostrum absorption. Feeding of colostrum containing 1000 IU vitamin E to calves does not influence uptake of IgG by the calves, but did result in higher levels of vitamin E in the calf plasma.[165] Similarly, the addition of 30 g of sodium bicarbonate to colostrum had no effect on uptake.[166] However, some studies have demonstrated positive benefit. The addition of spray-dried bovine serum to lower-quality colostrum to provide the equivalent level of IgG as found in a high-quality colostrum resulted in a higher level of IgG at 12 and 24 hours.[167]

The addition of 5 g/L of the mineral adsorbent zeolite (clinoptilolite), up to a total of 0.5 g/kg body weight/day, has been shown to increase the rate of absorption of colostrum in the first 16 hours and in some cases increase serum IgG at 24 and 48 hours, especially where lower colostrum volumes were fed.[168-170] The exact reason for this has not been explained, but it is thought that clinoptilolite may bind some degradation products of colostral proteins in the gut, such as ammonia, thus preventing their negative effects on mucosal epithelial cells designated for immunoglobulin absorption. It may also slow the passage rate of digesta through the intestine, allowing increased time for absorption. The addition of 1 and 2 g/kg of body weight/day has a negative effect on IgG levels at 24 and 48 hours, but when colostrum from cows vaccinated against K-99 and F-41 antigens of *E. coli* was provided, calves fed 1 and 2 g/kg body weight/day had increased blood serum levels of specific antibodies against *E. coli* at 12, 24, and 48 hours.[171,172] In all of these studies, very high-quality colostrum was fed (80 to 100 g/L) and no more than 2 L was fed at any one feeding and often 0.75 L to a 35-kg calf. The benefits of clinoptilolite when larger volumes of lower quality colostrum are fed has not been evaluated. When clinoptilolite is added to milk replacer as well as colostrum, an added benefit of increased hemopoiesis is seen, presumably because this mineral is high in iron.[172,173]

Increased uptake of IgG also occurs when a gut-active carbohydrate (mannan-oligosaccharide) is added to colostrum at a rate of 5 g/L. A 4.5-L amount of colostrum was fed at 2, 12, and 24 hours after parturition and calves receiving the gut-active carbohydrate had a higher level of IgG from 6 hours after birth right through until 21 days postpartum.[174] Again, the mechanisms responsible for this effect have yet to be elucidated. Bacteria in colostrum may directly block uptake and transport of immunoglobulin molecules across intestinal epithelial cells or bind free immunoglobulin in the gut lumen.[34,135] Gut-active carbohydrates have been shown to adsorb pathogens expressing type 1 fimbriae, reducing their ability to colonize the gastrointestinal tract; in addition, carbohydrates play a role in uptake of IgG from the gastrointestinal tract, and gut-active carbohydrates could enhance IgG uptake in a direct manner.

These studies demonstrate that it is possible to influence uptake of IgG with specific additives, and further research is required to investigate their potential while accommodating the variation in colostrum IgG concentration and standard management practices within herds.

MONITORING FOR SUCCESSFUL PASSIVE TRANSFER. Monitoring programs for FPT are an integral step in neonatal calf disease outbreaks and proactive calf health programs. A range of tests have been used to assess passive transfer.[175-177] The RID is considered the gold standard and is a direct measure of serum IgG. However, its usefulness is compromised by the processing time and expense. There is some variation in the published research as to the level of serum IgG that indicates adequate passive transfer, but most researchers use 10 mg/mL (1000 mg/dL).[113,175,178,179]

The sodium sulfite and zinc sulfate turbidity tests use salts to precipitate serum proteins, in particular the larger-molecular-weight immunoglobulins. A measured amount of calf serum is added to a standard volume of solution and incubated at room temperature for up to 30 minutes. The test results are quantified according to the degree of cloudiness of the mixture caused by protein precipitation. The sodium sulfite turbidity test has traditionally been described as a three-step semi-quantitative test using 14%, 16%, and 18% solutions. The sensitivity, specificity, and degree of association with IgG are similar to measuring serum protein with a refractometer, but the test is more complicated to perform.[175] The sensitivity has been estimated between 85% and 100% and the specificity between 53% and 87% using an 18% solution (1+ endpoint).[175,179] The zinc sulfate turbidity test can be influenced by hemolysis, making it difficult for routine use.[136] The standard test is carried out by adding 0.1 mL of calf serum to 6 mL of 208 mg/L zinc sulfate and incubating the mixture for 1 hour at 23° C (73.4° F). The test has a sensitivity of 100% and a specificity of 55%, which is lower than serum protein or sodium sulfite turbidity.[175] The specificity of the test can be improved by increasing the strength of the solution to 300 or 350 mg/L.[180] These solutions resulted in an increase of the specificity to 65% and 76%, respectively, with little decrease in sensitivity.

Measurement of serum γ-glutamyltransferase (GGT) in calves aged 24 hours can indicate positive ingestion of colostrum but has poor correlation with actual serum IgG levels.[181] A limitation of this test is that serum GGT declines rapidly during the first week of life.[182] Thus, accurate records reflecting the age of the calf are vital for this test to be interpreted accurately. Both colostrum and milk contain GGT, but activities in milk are considerably lower than in colostrum.[183] GGT rises quickly after the ingestion of colostrum and then falls rapidly over the subsequent 24 hours followed by a slow decline for the next 2 months. Calves that do not ingest colostrum have serum GGT activities similar to adult cattle. GGT is a useful test when assessing the passive transfer status of clinically ill calves less than 21 days of age where disease confounds interpretation of serum proteins. A GGT cutoff of 50 IU/L classifies 93% of calves correctly (sensitivity 93%, specificity 92%).[184]

The on-farm lateral flow immunoassay is one method for identifying calves with less than 10 mg/mL serum IgG. It takes approximately 20 minutes to perform and is relatively inexpensive but is not commercially available worldwide. The test yields only a positive or negative result as opposed to the actual level of serum IgG. This is considered a limitation of the test.[34] Published results show the sensitivity ranges from 93% to 99% and specificity from 88% to 89%.[179,185]

An optical handheld clinical refractometer may be used to measure serum protein of calves aged between 24 hours and 7 days of age. Although it is not a direct measurement of IgG concentration, it is considered an accurate indicator of the immunoglobulin status of the animal (Table 19-3).[186] Studies have compared refractometry to turbidity testing and GGT activity and have shown that it is equivalent or superior to these assays in the proportion of calves classified correctly.[3,175,181,182] This method is easier to standardize among laboratories and operators than many other indirect methods and is cheaper, quicker, and easier than most direct tests for IgG.[3] A

*It should be recognized that there is variation among refractometers.[189]

minimum of 12 calves need to be sampled and, when interpreted on a group level, provides a good correlation between serum protein and serum IgG, as measured by RID.[34] Sick (scouring) calves should not be included in the sample set because dehydration will falsely elevate the serum protein. It has been suggested that the accuracy of serum protein could be improved if a PCV was also measured as a proxy for hydration status.[184] The benefits of this method are that it is quick and inexpensive and samples do not need centrifugation.[187] This has an added advantage since it can be implemented at the farm level on large calf-rearing units to monitor for failure of passive transfer in groups of calves. A serum protein concentration less than 5.0 g/dL reflects failure of passive transfer and 5.0 to 5.5 g/dL marginal passive transfer. At a herd level the target should be for 80% of calves to have serum protein concentrations greater than 5.5 g/dL.[126] Assessment of serum protein using a refractometer is not a reliable estimate of IgG levels in calves that have received colostrum substitutes or replacers.[188]

TREATMENT OF FPT. Calves may be treated for FPT by the administration of bovine plasma at 20 to 40 mL/kg. The initial rate of administration should be 5 mL/kg with close observation for adverse effects, which most commonly include trembling, hives, edema, piloerection, stertorous breathing, and increases in heart rate and respiratory rate. If no adverse effects are noted in the first 30 minutes, the rate can be increased to 10 to 20 mL/kg/h with continued monitoring.[190] Whole blood can also be used, but the dosage should be increased to account for the presence of red blood cells.[136] Calves should be monitored as for plasma transfusions; adverse reactions are very uncommon on first-time transfusions since there are a large number of blood types in cattle. Plasma or whole blood may also be administered via the intraperitoneal route. An area in the center of the left paralumbar fossa is clipped and surgically prepared. A 14- to 16-gauge, 1.5-inch needle is used to penetrate the skin, abdominal musculature, and peritoneum, and the serum is administered through a giving set.[136] Precautions should also be taken to minimize risk factors for infection in these calves, including minimizing potential exposure to pathogens. Colostrum may be fed beyond the period of closure to provide protection at the level of the gut lumen. Where the environment is less than desirable, the prophylactic administration of broad-spectrum parenteral antimicrobials in calves with FPT should be considered.

Long-Term Benefits of Adequate Colostrum Uptake

In on-farm monitoring programs for effectiveness of passive transfer, IgG levels are often inferred by measuring serum total protein. A serum protein below 5 g/dL (approximately 9 mg/mL IgG) will result in a 2.4 to 6 times greater risk of mortality up to 6 months.[3,4,191,192] There is still an increase in relative risk of mortality when serum protein is between 5 and 5.5 g/dL compared with greater than 5.5 g/dL (IgG 13.4 mg/mL), but it is not as marked, and the cost benefit of ensuring all calves achieve a serum protein greater than 5.5 g/dL to prevent mortality is questionable.

On any farm, the baseline mortality will reflect management, nutrition, and the pathogens present. The risk of mortality associated with varying level of passive transfer is independent of baseline mortality rate. Hence, where the baseline mortality is high, adequate passive transfer will not prevent calves dying, but as serum immunoglobulin level decreases below 13.4 g/L, the risk of mortality will increase relative to that herd's specific baseline mortality. It is important to recognize that the majority of calves with total FPT will survive, especially where baseline mortality is low.[3,193] The role of the passive transfer of immunity in preventing morbidity per se is well documented, but the effect of immunoglobulin levels on prevalence of specific disease syndromes varies. Epidemiological studies reflect the variation in management, environment, and disease pathogens among properties, and a greater impact of other risk factors on disease incidence. Consequently, there are inconsistent results on the impact of adequate passive transfer on both of the main calfhood diseases: diarrhea and pneumonia, also reflecting study design and varying serum IgG levels used to define FPT.[4,5,18,194-197] Studies on the risk of pneumonia generally demonstrate FPT as a risk factor, but the impact of FPT as a risk of diarrhea is less consistent. Often where a significant effect of IgG levels on the incidence of a specific disease has not been demonstrated, increasing the sample size to look at the correlation with all calves treated with antibiotics or all morbid calves within the study has demonstrated a significant benefit of adequate passive transfer. The benefits of adequate passive transfer on disease incidence is likely to be long lasting, with evidence of ongoing prevention of postweaning disease, particularly feedlot pneumonia, although again not all studies demonstrate this effect.[4,7,198]

A better indication of the effect of passive transfer on disease appears to be consistent positive correlation demonstrated between adequate passive transfer and average daily weight gain, both preweaning and postweaning.[5-7,196,197,199] It is likely that much of the variation in weight gain is a result of changes in the incidence of disease.[4,198,199]

Navel Treatment

Omphalitis occurs in 1% to 14% of newborn calves.[200,201] It can lead to reduced growth, joint ill, and other adverse sequelae associated with bacteremia.[202] Prevention of navel ill is based on maintenance of maternity pen hygiene, reducing the residency time of calves in unhygienic maternity pens, ensuring adequate early intake of good quality colostrum, and navel antisepsis.[203] Literature on the efficacy of navel treatment at reducing calf mortality is divided. In a study of 104 dairy farms, a farm policy of navel treating newborn calves had no significant effect on calf mortality rates. A significant beneficial effect was observed when the navels of calves that had assisted deliveries were dipped with chlorhexidine; other navel treatments such as iodine tended to be associated with an increased odds of dying.[204] In a controlled clinical trial investigating the efficacy of navel dips, a reduction in the incidence of omphalophlebitis was observed in calves when navels were dipped with tincture of iodine (7% iodine), dilute iodine (0.5% or 0.2%), or a commercial product (Navel Guard [NG], Sirius Chemical Group, McDonough, GA) as compared with calves with nondipped navels.[200] Conversely, navel treatment with iodine was associated with significantly higher mortality in another study of 48 farms; however, the association of navel treatment with mortality on these farms may have reflected the response of producers to high neonatal mortality rather than indicating iodine navel treatment as a risk factor for high calf mortality.[205]

Nutrition

Although the neonatal calf stomach has four parts, the rumen is not functional at birth. At birth the abomasum is the only truly functional part and has a capacity twice that of the other compartments. Liquid is shunted past the reticulorumen into the abomasum via the esophageal groove. The groove is closed by a reflex that is stimulated by the intake of liquids; milk is the best, and electrolyte and glucose water is usually effective, but straight water becomes ineffective in

VetBooks.ir

closing the groove fairly early in life. The first enzyme to start the process of milk digestion is salivary lipase. When whole milk enters the abomasum, casein is denatured by the acidic (pH 2.0) conditions. Rennin cleaves a specific peptide bond in k-casein, which, in the presence of calcium ions, causes coagulation of the casein proteins. Fat is trapped within the coagulum, but the whey proteins, lactose, and soluble minerals and vitamins are excluded into the liquid portion (whey) as the coagulum contracts. The soluble components enter the small intestine within 2 to 3 hours after a meal, whereas the casein coagulum is digested more slowly.[206] Casein is partially digested by the abomasal protease pepsin. Polypeptides released from caseins enter the small intestine for further digestion. Milk fat trapped in the abomasum undergoes some digestion by the enzyme pregastric lipase, which is secreted in the mouth. The products of its action are diacylglycerols and free fatty acids, which enter the small intestine for further digestion and absorption. Lactose is hydrolyzed to its component sugars, glucose and galactose, by the intestinal brush-border enzyme lactase, and the monosaccharides are absorbed into the epithelial cells by specific active transport proteins.[206] The age at which ruminal digestion begins is dependent on the diet of the calf. Transition to ruminal digestion begins at 3 to 4 weeks of age; the earlier dry feed is provided, the earlier ruminal development starts.

The energy requirements of the calf may be divided into maintenance and growth requirements with the magnitude of maintenance requirements influenced by environmental conditions. The basal maintenance requirement for neonatal calves is between 44.7 and 52.4 kcal/kg of body weight/day.[207,208] Energy requirements for growth are between 268 and 307 kcal/100 g of body weight gain.[208,209] Since whole milk contains about 70 kcal/100 mL, a 40-kg neonatal calf needs about 3 L of whole milk for maintenance and an additional 4 to 5 L to gain 1 kg of body weight. Many calves are raised according to the "calf starter method," which became popular in the early twentieth century.[210] According to this method calves are fed limited amounts of milk (approximately 10% body weight). Milk intake is limited to encourage intake of calf starter, facilitating weaning at about 7 to 8 weeks of age. Forage feeding is discouraged during the milk feeding phase since it lowers starter intake. Rumen papillae growth is stimulated by volatile fatty acid production, in particular butyrate, which is highest in calves consuming larger volumes of starter.[211] During the past decade several studies have challenged the "calf starter method." Limit feeding calves has been shown to lead to poor weight gains,[212] higher risk of disease, and abnormal behaviors, indicating reduced calf welfare.[213] Providing greater quantities of milk or milk replacer improves growth and feed efficiency.[213] To achieve biologically appropriate growth, milk feeding rates are approximately twice those of the calf starter method. A rule of thumb is to provide 1.5% of body weight as milk solids during the first week of life, then 2% of body weight from the second week of life until the week before weaning, when one feeding is dropped.[214] Intake of starter lags behind calves fed on conventional systems, but increases at approximately the same rate once the amount of liquid is cut back.[214] To avoid or minimize growth slumps around weaning, calves should not be weaned until they are consistently eating 1 kg of starter daily.[206] Higher rates of growth observed early in life are associated with reduced breeding age[215] and higher milk yield when the calf matures.[216] Approximately 25% of the variation in first-lactation milk production is explained by preweaning average daily body weight gain.[216]

Cold stress significantly increases energy requirements. A 45-kg calf at −20° C requires about 725 g/d of milk replacer powder just to meet maintenance requirements and maintain body temperature, compared with about 382 g/d of powder under thermoneutral conditions.[206] Similarly, heat stress increases maintenance energy requirements by 20% to 30%.[206] Energy requirements of calves managed at different temperatures is presented in Table 19-4. The requirements for the sick, stressed calf are not well established.

Conventional milk replacers contain 20% to 22% crude protein (CP), but calves benefit most from the increased feeding when milk replacers contain higher protein and lower fat (up to 30% CP with 15% to 20% fat).[217] The digestible protein requirement for maintenance is 0.5 g/kg of body weight, and the amount required for growth is about 22 g/100 g gain in body weight. Digestibility of the protein is an important concern in the evaluation of milk replacers. Some milk replacers substitute legume proteins for milk-derived proteins. Legume-derived proteins contain antinutritional factors (ANFs) that include antigenic proteins, lectins, and trypsin inhibitors.[218] Trypsin provides a protective mechanism against clostridial disease by cleaving the clostridial beta toxin.[219] Soybean flour has been used to experimentally induce *Clostridium perfringens* type C enterotoxemia in lambs.[220]

Clinical Investigation of Neonatal Disease

The principles of clinical investigation of neonatal disease are similar to those of adults; however, the neonate signalment carries with it a higher risk for sepsis, congenital malformations, and a number of specific neonatal diseases resulting in a shift in the emphasis of history, physical examination, and diagnostic work-up. When a single individual is involved, observation from a distance, recording of vital signs, and a physical examination guide the clinician to the selection of appropriate diagnostic tests to establish a cause, make a diagnosis, and evaluate the prognosis. For conditions that affect a flock or herd of animals, the examination of affected individuals remains an essential component of the diagnostic work-up, but evaluation of records, the environment (housing and other animals), nutrition, colostrum, treatment, and vaccination protocols is also needed.

History

The investigation of neonatal disease problems is facilitated by the defined period of risk and temporal distribution of the more common disease syndromes. For health problems involving individuals or the flock/herd, it is best to start at birth and work forward. For the individual, a history of dystocia indicates the likelihood of neonatal compromise and the possibility of failure of passive transfer. The risk of specific diseases may be influenced by pathogen-specific immunity, which may be manipulated through either maternal or neonatal vaccination. Details of the farm's vaccination protocol should be collected. At a herd level, the likelihood of failure of passive transfer and the efficacy of maternal vaccination are determined by colostrum management. From a herd perspective, it is important to determine the farm's protocol for harvesting, storing, and administering colostrum since these protocols determine immunoglobulin and microbial quality and the likelihood of achieving adequate passive transfer.

Risk of neonatal infectious disease is determined by the balance between host immunity, environment, and pathogen dose and virulence. Management should strive to maximize host immunity through good colostral management, provision of adequate nutrition, and minimization of environmental stress. The risk of pathogen

Guide to Assessing the Degree of Dehydration and the Base Deficit of Calves with Neonatal Diarrhea[222]

Clinical Signs	Percentage of Dehydration (%)	Approximate Base Deficit (mmol/L)
History of diarrhea with minimal clinical signs	5	5
Eyes beginning to sink (2-4 mm), skin turgor decreased (skin tent duration of 1-2 seconds), suckling reflex present	About 7 (mild dehydration)	10
Eyes sunken (4-6 mm), skin turgor more decreased (skin tent duration of 2-5 seconds), mucous membranes tacky, suckling reflex decreased, cool extremities, calf depressed, able to stand but with difficulty	About 9 (moderate dehydration)	15
Eyes deeply sunken (6-8 mm), skin tents and does not return or very slowly (5-10 seconds), dry mucous membranes, suckling reflex very weak or absent, cold mouth, cold extremities, calf depressed, unable to stand and possibly comatose	About 11 (severe dehydration	20
Eyes very deeply sunken (8-12 mm), calf comatose or dead	<12 (fatal dehydration)	>20

exposure is influenced by environmental conditions at birth, amount of time spent with the dam, facility hygiene, colostrum and milk hygiene, personnel hygiene, and neonate age grouping. Defining the onset and progression of disease is useful because certain diseases are more likely to occur at different times. Response to treatment or lack thereof may provide clues regarding pathogen involvement, and details of treatment protocols may identity inappropriate ineffective treatment. Occasionally disease is iatrogenic, so it is important to collect details of all products administered, specifically how much, at what time, frequency, and by what route.

Examination from a Distance

The physical examination begins with examination from a distance with assessment of behavior, body condition, and stance. Drooping of the head and ears is an early sign of illness. Sick calves spend increasing amounts of time recumbent and are less inclined to drink. In beef calves, lambs, and kids, this may be reflected by udder distention in the dam. With dairy calves the calf feeder may report that the calf requires stimulation to stand and fails to drink. Abdominal contour should be noted with consideration of the neonate's reported appetite; an apparently normal abdominal contour may be abnormal if the calf has not eaten for a couple of days. Observing the neonate navigate its environment provides a simple assessment of vision. From a distance, mentation, posture, vision, abdominal contour, stance, lameness, respiratory rate, breathing effort, characters of nasal and ocular discharge, and spontaneous coughing can be evaluated. Abnormal postures exhibited by patients with respiratory conditions may be recumbency, open-mouth breathing, abnormal extension of the head and neck, head tilt, or reluctance to lie down. Abnormal breathing characteristics include prolongation of the inspiratory or expiratory phase of respiration, an expiratory abdominal press or snap, marked tachypnea, frequent spontaneous coughing, stridor, or inspiratory or expiratory noises. Abnormal mentation of neonatal ruminants may be the result of meningoencephalitis, hypoglycemia, hypoxic-ischemic encephalopathy, calving injury, or severe metabolic acidosis. Abnormal posture of the head and neck are exhibited by neonates with respiratory difficulty, but meningoencephalitis, otitis media, hypernatremia, polioencephalomalacia, congenital defects of the central nervous system, and lasalocid toxicity should be considered.

Examination from a distance on farm also provides an opportunity to assess the neonate's environment. Environmental and/or management-induced compromise in the form of inappropriate stocking density, mixed age groups, inadequate ventilation or shade, wet muddy conditions, inadequate protection from adverse weather, evidence of poor hygiene, inappropriate feed on offer, and excessive fly challenge may all contribute to the risk of disease.

Hands-on Examination

PHYSICAL APPEARANCE, BODY WEIGHT, AND BODY CONDITION. Congenital disorders may present with subtle changes in physical appearance and behavior. For example, Saler calves with β mannosidosis have moderately domed heads, mild superior brachygnathism, and a slight head tremor.[221] Similarly, in utero infections that lead to growth retardation may be reflected by low birth weight and poor body condition.

Head. Observation of facial expression provides an opportunity to assess cranial nerve function. Normal eyeball position and movement is consistent with normal function of cranial nerves (CNs) 3, 4, 6, and 8. Normal facial expression as well as ear and eyelid position suggest normal function of CN 7. Vision (CN 2) is assessed by watching the neonate navigate its environment. Because the menace response is learned and does not appear for several weeks after birth, it is not particularly useful in very young animals. Normal sucking behavior is consistent with normal function of CNs 5, 7, 9, and 12. Absence of atrophy of the neck is consistent with normal function of CN 11. Function of CNs 5, 6, and 7 is further assessed by the palpebral and corneal reflexes and CN 2 and 3 by the pupillary light response. Eyeball position and skin tent duration are used to assess dehydration and estimate base deficit in calves with diarrhea (Table 19-5).

Depressed mentation is a feature of a number of neonatal diseases. Sepsis and diarrhea are both commonly associated with depressed mentation as a result of toxemia and/or metabolic derangements. Bacterial meningitis is common in neonates following bacteremia; diarrhea, septic arthritis, omphalophlebitis, and uveitis are frequent concurrent clinical problems. The clinical signs of meningitis in neonates, lethargy, anorexia, and recumbency are nonspecific. Concurrent metabolic derangements may appear to provide an adequate explanation for the observed depressed mentation. In a retrospective study of 32 cases of bacterial meningitis in calves, concurrent metabolic derangements included hyperkalemia (15/25, 60%), respiratory acidosis (11/24, 46%), hypernatremia (3/20, 15%), and hypoglycemia (3/7, 43%).[223] The more classic clinical signs described for bacterial meningitis in older animals—fever, opisthotonos, extension of the head, convulsions, hyperesthesia, and signs of neck pain—may not be evident or not perceived in neonates. Seizures in calves are often subtle, manifested as facial twitches or jaw champing. Common causes of cerebral disease in lambs and kids include polioencephalomalacia and focal symmetrical encephalomalacia. Affected animals are typically depressed and blind but have normal pupillary light reflexes.

Mouth. Examination of the mouth includes assessment of the mucous membranes, moisture, color, and capillary refill time. Mucous membranes are moist and pale pink with a capillary refill time of less than 2 seconds. Gray or cyanotic mucous membranes are associated with severe hypoxia, circulatory collapse, hypovolemic shock, cardiovascular anomalies causing a right-to-left shunt, and/or severe pulmonary disease. Absence of cyanosis is not a reliable indicator of adequacy of oxygenation in the neonate, since the partial pressure of oxygen may reach very low levels (<35 to 40 mm Hg) before cyanosis is observed. Cardiac and pulmonary causes of cyanosis must be distinguished. Petechiae on the oral or nasal mucous membranes are consistent with sepsis-induced vasculitis or thrombocytopenia

VetBooks.ir

FIG. 19-1 Petechial hemorrhages on the underside of the tongue of a calf with thrombocytopenia.

induced by type II bovine virus diarrhea (BVD) (Fig. 19-1). Proliferative lesions may be observed with bovine popular stomatitis in calves or lambs. Oral erosions are often observed with BVD infections in calves. Common congenital defects include cleft palate and brachygnathism (inferior and superior). The hard and soft palate should be evaluated; animals with cleft palate may have milk run from the nose and are prone to developing aspiration pneumonia. Examination of the mouth should include assessment of breath odor. A malodorous breath may be present with necrotic pharyngeal injuries, necrotic laryngitis, cleft palate, or aspiration pneumonia. Application of slight pressure on the larynx exacerbates inspiratory stridor associated with necrotic laryngitis. Airflow from each nostril should also be assessed. Conditions causing occlusion of the upper airway, such as choanal atresia, necrotic laryngitis, pharyngeal swelling or edema, often induce pronounced inspiratory dyspnea, stridor, and/or open-mouth breathing.

Eyes. Eyes should be examined for the presence of entropion, ectropion, corneal abrasions or ulcers, uveitis and hyphema, congenital cataracts, microphthalmia, corneal dermoids, scleral injection, and scleral hemorrhage. Entropion is a relatively common cause of corneal edema and ulceration, conjunctivitis, and lacrimation in lambs. Entropion should be corrected promptly before serious corneal ulceration and keratitis develops. Mild cases may respond to subcutaneous injections of procaine penicillin G into the lower eyelid. Alternatively, entropion may be corrected by placement of vertical or horizontal mattress sutures in the affected eyelid to correct the problem. Treatment following correction of entropion includes topical administration of 1% atropine to dilate the pupil and relieve ciliary body spasm and topical antibiotics to prevent bacterial infection.

Examination of the sclera is useful to detect icterus, scleral injection, and scleral hemorrhage. Icterus may be observed as a result of liver or hemolytic diseases; both tend to be uncommon in newborn milk-fed neonatal ruminants. Conversely, scleral injection is a common finding and suggests sepsis. Observation of fibrin in the anterior chamber of the eye of a neonate is highly indicative of sepsis. Ecchymotic hemorrhages may be observed on the sclera with type II BVD infections, bovine neonatal pancytopenia, disseminated intravascular coagulopathies, or following birth trauma.

Ears. Bilateral drooped ear carriage is a common observation with sick calves and should prompt a closer examination. Unilateral ear droop may be observed with otitis and facial nerve paralysis. *Mycoplasma* spp., *Pasteurella* spp., and *Haemophilus* spp. are reported to cause otitis in calves. Clinical signs may include facial and vestibular nerve deficits and a purulent discharge from the ear. Calves infected with *Mycoplasma* spp. may also present with tenosynovitis and respiratory disease. Poor perfusion is reflected by cold extremities. A high incidence of pinna abscesses usually reflects contamination of equipment used to place ear tags. Ears should be warm and mobile.

Neck and Back. A number of congenital anomalies affect the alignment of the vertebral column, including atlantoaxial malformations, scoliosis, kyphosis, lordosis, and combined anomalies, such as kyphoscoliosis. Atlantoaxial malformations may occur with or without cervical scoliosis or signs of spinal cord compression. Holstein calves affected by the hereditary condition complex vertebral malformation may present with a range of abnormalities that include retarded growth, malformation of the head (dysplasia or palatoschisis), bilateral symmetric flexion of the carpal and metacarpophalangeal joints, posterior arthrogryposis, and interventricular septal defects. Of these, growth retardation, vertebral malformation, and symmetric arthrogryposis are the most consistent findings.[224]

The neck and brisket should be examined to evaluate jugular fill and to detect brisket edema. Distention of the jugular veins and brisket edema are consistent with right-sided heart failure but may be absent with left-sided heart failure. Examination of the skin on the side of the neck is a good place to detect lice and fleas, and a skin fold test is performed to assess hydration. Parotid and prescapular lymph nodes should also be palpated to assess size and symmetry. Enlargement of all peripheral lymph nodes may be observed with juvenile lymphoma. Enlargement of specific nodes suggests a localized inflammatory response.

Thorax. Heart and respiratory rates vary with activity, excitement, and feeding. Tachypnea can be attributed to elevated temperature humidity index, fever, thermoregulation dysfunction, excitement, pain, stress, respiratory disease, hypoxia (cardiac disease, pulmonary disease, shock), dehydration, shock, toxemia, or metabolic acidosis. Periodic apnea and abnormally slow respirations are often the result of metabolic disturbances (hypoglycemia, hypocalcemia), hypothermia, prematurity, or hypoxia-induced suppression of the respiratory center. Tachycardia may be present with excitement, pain, injury, inflammation, toxemia, dehydration, shock, infectious disease, metabolic acidosis, hypokalemia, hypocalcemia, or heart disease. Bradycardia of neonatal ruminants may be associated with hyperkalemia, central nervous system dysfunction, hypothermia, or starvation.

Cardiovascular disease in neonates may be primary or secondary to other disease processes. Congenital cardiac anomalies may be asymptomatic. Dyspnea and coughing are often the predominant clinical signs of congestive heart failure in calves. Cardiac auscultation should be carried out systematically with the aim of evaluating cardiac rhythm and detecting normal heart sounds and cardiac murmurs. In most calves the first and second heart sounds are easily audible. The third heart sound is not normally heard in calves, and fourth heart sounds are heard infrequently.[225] Cardiac murmurs are not uncommon during the newborn period. Various congenital anomalies of the heart occur in cattle as the result of defective septa and formation of the cardiac chambers.[226] The prevalence of congenital heart disease in cattle has been reported to be approximately 0.7%,[227] with ventricular septal defects representing the most common type.[228] Other frequent defects include non-cyanotic anomalies (atrial septal defect, patent ductus arteriosus without pulmonary hypertension) and cyanotic anomalies (tetralogy or pentalogy of Fallot, Eisenmenger's complex associated with a reversion of a previously left-to-right shunt resulting from pulmonary hypertension).[226] The prevalence of the different congenital heart diseases in calves is shown in Table 19-6. Serious heart anomalies may not be accompanied by any murmur, whereas a closing ductus arteriosus may cause a murmur that is very loud. This normal ductal murmur is best ausculttaed on the left side of the chest at the third intercostal space at the level of the shoulder. In some instances, however, it is described as a continuous machinery-type murmur, but far more commonly a grade II-V/VI holosystolic murmur is auscultated. Cardiac auscultation will determine heart rate, rhythm, and the presence of murmurs. Abnormal radiation of heart sounds caudal to the fifth intercostal space or dorsal to the level of the scapulohumeral joint on either side of the thorax should be noted. Thoracic percussion may be used to

TABLE 19-6

Prevalence of the Most Common Congenital Heart Diseases in Calves, According to Ohwada and Murakami (2000)*[226,229]

Congenital Heart Diseases	No. of Cases
Ventricular septal defects	198
Atrial septal defects	148
Double outlet right ventricle	66
Aortic stenosis	53
Double cranial vena cava	50
Patent ductus arteriosus	45
Anomaly of the caudal vena cava	42
Tetralogy of Fallot	32
Hypoplastic left ventricle	25
Transposition of the great arteries	24
Abnormal pulmonary vein connection	21
Total	704

*A total of 469 cases of congenital heart diseases were studied.

identify the presence of thoracic fluid, cranioventral consolidation, or atelectasis in neonatal ruminants.

Cardiac arrhythmias are observed sporadically in neonates, often associated with diarrhea. Metabolic acidosis resulting from losses of electrolytes and water causes a transcellular shift of potassium ions into the extracellular fluid in exchange for hydrogen ions.[230] Hyperkalemia decreases the membrane potential and slows down impulse conduction by inactivating Na channels.[231] As serum potassium increases (>5.5 mEq/L), aberrations in cardiac excitability occur and are manifested as progressive atrial standstill, progressing to ventricular fibrillation and asystole.[232] The response of the myocardial cells to catecholamines decreases with the reduction of blood pH.[231] Influxed H+ ions repress ventricular contraction by competing with $Ca2^{+}$ ions in binding to myocardial troponins.[231] Tachyarrhythmias may be observed in calves with cardiomyopathies, ionophore toxicosis,[233] or hypomagnesemia.

Cardiomyopathy resulting from selenium deficiency, gossypol, monensin, or lasalocid toxicity may present as a syndrome of sudden death during periods of excitement precipitated by feeding or moving calves out of hutches into group pens.[234]

Inspiratory stridor is often a feature of extra-thoracic airway obstruction, and increased abdominal effort on expiration is an indication of pulmonary disease causing reduced lung compliance. Lung disease in the newborn is usually diffuse and is the result of infection acquired in utero or postpartum and/or lung atelectasis associated with immaturity, recumbency, or surfactant dysfunction. Signs of lung disease include increased work of breathing characterized by nostril flare, rib retractions, and increased abdominal effort. A cough and nasal discharge, salient features of respiratory disease in older neonates, are infrequent findings in newborns with lung disease. Animals with few or no audible thoracic abnormalities may have severe respiratory disease.

Auscultation of the trachea, thorax, and occasionally the nasal passage is an essential element of the respiratory examination. Tracheal compression should not induce multiple coughs. Lung sounds of neonates are typically easier to hear than adults; however, lung sounds do not always correlate well with the severity of the respiratory condition that is present. Interpretation of the intensity of thoracic breath sounds can be validated by comparison to tracheal breath sounds. The intensity of tracheal breath sounds is gradually attenuated as the stethoscope is moved from trachea to the lung hilus and again to the anteroventral thorax and finally to the caudal thorax in normal animals. Loud tracheal breath sounds that are not attenuated over the thoracic area may be indicative of atelectasis, lung consolidation, or cardiac enlargement. Added breath sounds such as crackles or wheezes should be noted but may not be heard without augmenting the depth and frequency of the breathing effort with the use of a rebreathing bag.

Abdomen. Much can be learned about gastrointestinal function by observing abdominal contour, appetite, and fecal consistency and volume. A normal abdominal contour and vigorous appetite associated with the passage of an appropriate volume of pasty stool suggests normal gastrointestinal function. Examination of the neonatal ruminant should include assessment of abdominal size and contour.

Gradual abdominal distention may be observed with congenital atresia of the gastrointestinal tract. Atresia may be observed in the colon (coli), rectum (recti), or anus (ani); the spiral loop of the ascending colon (spiral colon) is the most commonly affected segment of intestine affected in calves.[235] Neonates presenting with atresia often have a distended abdomen and a history of a declining appetite. Astute owners may notice the lack of or reduced volume of feces.

External palpation of the abdomen can be rewarding, depending on the cooperation of the individual and the tenseness of the abdominal musculature. In calves it is usually possible to palpate enlargement of the umbilical vein and arteries. The inguinal rings and umbilical area should also be palpated for hernias. Abdominal auscultation, although important, is not used for forestomach and intestinal motility parameters typically evaluated in the adult ruminant, but the procedure, along with simultaneous auscultation and succession, ballottement, or percussion, may show evidence of gas, fluid, or disordered motility. Abnormal forestomach function in neonatal ruminants is often reflected by altered abdominal contour. Left and right abomasal displacement and abomasal torsion are observed sporadically in calves. Succussion (simultaneous auscultation and percussion) is useful for delimiting the boundaries of distended visci. Passage of a stomach tube helps distinguish rumen and abomasal distention and facilitates collection of a rumen fluid sample. A putrid odor to neonatal rumen fluid is common with putrefactive indigestion when milk is delivered to the rumen in greater quantities than normal by escaping the esophageal groove or via excessive backflow from the abomasum. Reflux of abomasal contents into the reticulum and rumen, independent of feeding, occurs in connection with abomasal inflammation and obstructions.[236] Evaluation of rumen fluid pH and renin activity are useful for distinguishing abomasal reflux from esophageal groove overflow. Rumen fluid pH is usually 7 or greater with rumen putrefaction, and low to normal with abomasal reflux.[236] Chymosin (renin) is normally present in abomasal juice, and renin activity in rumen fluid suggests abomasal reflux.[237] Renin activity is measured by adding 2 mL of rumen juice to 2 mL of whole milk on a California mastitis test (CMT) plate. Presence of renin in the ruminal fluid causes coagulation of the casein in the milk. Chloride ion concentration in rumen fluid from calves is higher than adults (55-102 mmol/L calves,[238] 25 mmol/L adults[236]), possibly reflecting the high chloride content of milk (45 mmol/L); as such, the chloride concentration of rumen fluid is not useful for identifying abomasal reflux in calves.

Abomasal ulceration may lead to localized or generalized peritonitis. Normal peritoneal fluid from calves has a higher nucleated cell count than that of adult cattle (3350 cells/μL vs. 1371 cells/μL). The total protein concentration in peritoneal fluid of calves is similar to that of adults (2.5 g/dL vs. 3.1 g/dL).[239]

Umbilicus. After rupture of the umbilical cord, the two umbilical arteries retract actively, and the urachus is pulled back passively by these vessels into the abdomen. Smooth-muscle contraction brings about luminal closure. The umbilical arteries ultimately become the lateral ligaments of the urinary bladder.

The umbilical vein does not retract, but collapses in association with some minor smooth muscle contraction. The umbilical sheath shrinks and dries within 3 days postpartum. The body wall closes completely around the umbilical structures within days to a few weeks.[240]

During the physical examination, the navel is assessed for diameter, discharge, and pain while the neonatal ruminant is standing and again while it is in lateral recumbency. Abdominal palpation, using both hands pressing together, is useful for evaluating the umbilicus

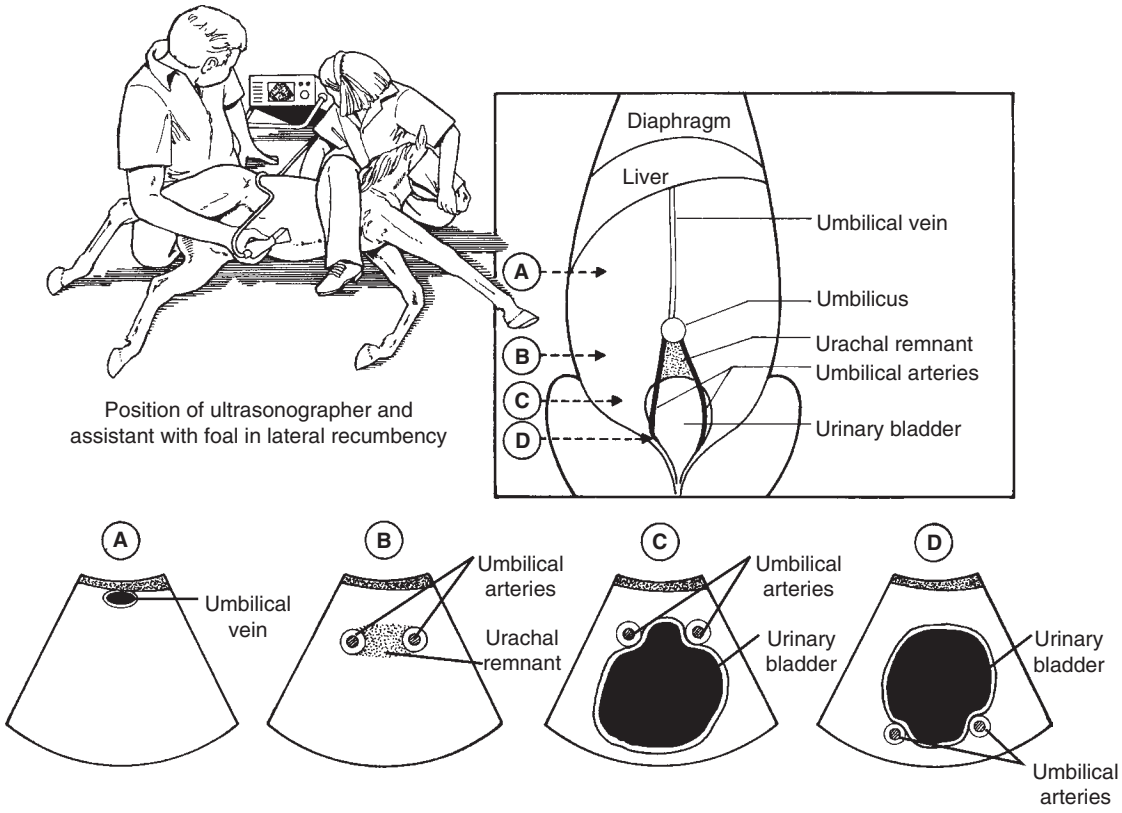

FIG. 19-2 Ultrasound evaluation of umbilical structures. Diagram depicts the positioning of the ultrasonographer and the assistant and the selected anatomic locations recommended for ultrasound examination.

of standing calves. Enlargement of the umbilical arteries can be palpated coursing caudally toward the bladder and enlargement of the umbilical vein coursing cranially to the liver. Application of pressure caudal to the xiphoid often elicits a soft grunt from calves with a septic umbilicus and associated peritonitis. Extensive adhesion of bowel to inflamed umbilical structures produces a large, easily palpable intraabdominal mass. The uterine vein and artery may also be traced within the abdomen with the calf in recumbency. Common abnormalities of the calf umbilicus include umbilical hernias, omphalophlebitis, external umbilical abscess, urachal abscess, and omphaloarteritis. Patent urachus is uncommon in calves. Disorders of the urachus or the umbilical arteries are often associated with pollakiuria and a prolonged stance of urination. Umbilical hernias in cattle do not tend to close spontaneously and are believed to be hereditary.[241]

Ultrasound examination of the calf is performed with the calf standing; occasionally the umbilical vein is easier to identify with the patient in left lateral recumbency (Fig. 19-2).[242] The umbilical vein courses from the umbilicus to the liver, which in the calf is located on the right side (see Fig. 19-2). The lumen is generally larger near the body wall with a diameter ranging from 10 to 25 mm. It appears as a round-to-oval anechoic to hypoechogenic structure (Fig. 19-3). Within 3 weeks after birth, ultrasonographic identification of the intraabdominal umbilical vein becomes impossible in up to 50% of the healthy calves. If still visible, the vein appears hypoechogenic to the surrounding tissue and indistinctly marginated.[240] In cattle, the umbilical arteries and urachus retract into the abdominal cavity when the cord ruptures and thus cannot be identified in the external umbilical stalk in normal calves.[242] The umbilical vein of calves is scanned from the umbilical stalk to the liver along the right abdominal wall. The umbilical vein enters the liver caudoventral to the gallbladder. The umbilical arteries are most easily located adjacent to the urinary bladder and cannot normally be identified much beyond the apex of the urinary bladder, unless enlarged and abnormal (Figs. 19-2 and 19-4). The identification of a urachal remnant in calves is abnormal.[242]

MUSCULOSKELETAL SYSTEM. The musculoskeletal system should be examined for evidence of birth trauma including fractured ribs, long bones, and mandibles; brachial plexus injuries; and soft tissue trauma including an edematous head and tongue from excessive traction or compression in the pelvic canal. The vertebral column, ribs, and limbs should be palpated carefully to elucidate swelling, heat, or painful areas. Strenuous manipulation during a dystocia can result in Salter Harris type 1 fractures characterized by disruption of the distal physis in one or more limbs. Femoral nerve paralysis occurs as a sporadic complication of dystocias associated with so-called hip lock in calves.[243]

Dwarfism is a relatively common inherited problem in most cattle breeds. Osteopetrosis has been reported in Angus, Hereford, and Simmental breeds of cattle. Syndactyly is considered an inherited disorder in Holstein-Friesian cattle, and affected animals are also predisposed to hyperthermia. Growth retardation, vertebral malformation, and bilateral symmetric arthrogryposis affecting the carpal and the metacarpophalangeal joints are features of complex vertebral malformation in Holsteins, a genetic condition associated with a mutation in the gene SLC35A3 coding a uridine-diphosphate-*N*-acetylglucosamine transporter.[224]

Peripheral pulses in the middle coccygeal, brachial, and auricular arteries should be strong and regular and the peripheral extremities warm. Assessment of pulse quality includes consideration of pulse strength and frequency. Concurrent cardiac auscultation is useful to verify heart rate and rhythm matches the pulse. With cardiovascular disease, the pulse may be weak and or uneven and may not correlate with the heart rate and rhythm.

The limbs should be examined for laxity, flexural, and angular limb deformities. Flexor tendon laxity occurs more commonly in calves born prematurely and in calves that are small for their gestational age. Unilateral or bilateral hyperextension of the tarsus can be encountered in newborn calves following forced extraction. A rupture of the peroneus tertius causes the hyperextension of the tarsus (Fig. 19-5). The gait is abnormal but it does not appear to be

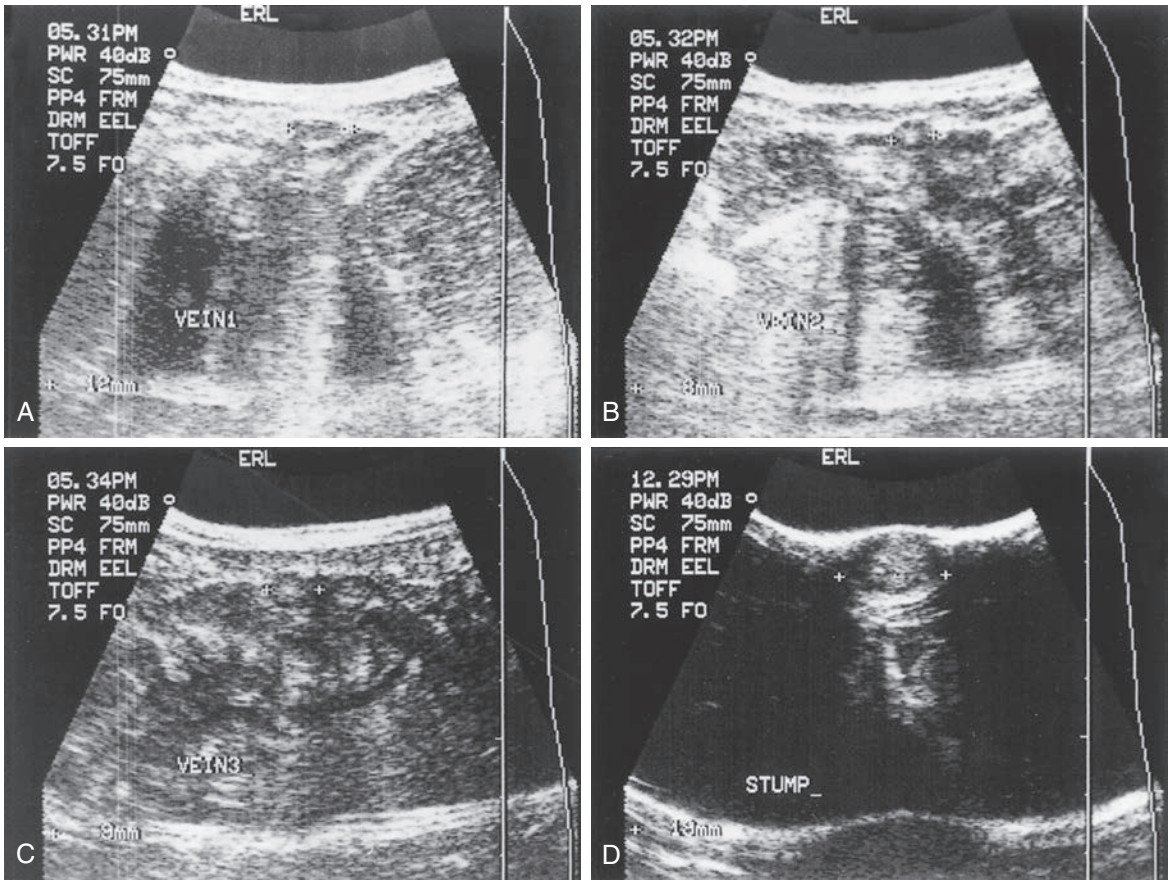

FIG. 19-3 Ultrasonogram images of four views of umbilical structures: umbilical vein views 1 **(A),** 2 **(B),** and 3 **(C),** and umbilical stump **(D).** Refer to the text for the definition of the views.

painful.[244] Congenital contracted flexor tendon is a common defect in cattle; etiologic origins include inherited factors, in utero malpositioning, and overcrowding caused by the size of the fetus relative to the dam. Contracted tendons may occur with other congenital abnormalities, such as cleft palate, dwarfism, and arthrogryposis.[244] Arthrogryposis, abnormal fixation of joints because of damage to or contracture of soft tissues, may be hereditary as a result of infection in fetal life with teratogenic viruses or result from ingestion of teratogenic plants. Following teratogenic viral infections, the clinical presentation is a result of mild–extensive loss of ventral horn motor neurons in the spinal cord gray matter and Wallerian degeneration of ventral spinal motor nerves.[245] Hereditary congenital deformity in Hereford cattle is characterized by arthrogryposis, kyphosis, torticollis, scoliosis, and cleft palate.[246] Ingestion of lupines by pregnant cows between 40 and 70 days' gestation has also caused various degrees of arthrogryposis with other associated congenital defects.[247]

Skeletal muscle myopathy is an important differential for lame neonatal ruminants. Affected neonates may present with a history of falling behind the mob when mustered and dropping into sternal recumbency. Close examination reveals firmness of the triceps and quadriceps. Deep palpation of affected muscles elicits a pain response. Lambs and kids with selenium and/or vitamin E deficiency are often mentally bright, reluctant to stand, and walk with a stiff gait and cry when forced to move. Evaluation of serum creatine phosphokinase, blood selenium, and plasma vitamin E concentrations is useful to confirm the diagnosis.

Any heat, swelling, edema, or pain around the joints or physes, or lameness, should be noted. Because of the propensity of neonates to succumb to sepsis, a swollen joint should be considered infected until proven otherwise. When sepsis is present, it is not uncommon to observe enlargement of the corresponding prescapular or prefemoral lymph node in the affected limb. When multiple animals on the same property are affected, it may reflect an infectious etiology such as salmonellosis or mycoplasma; alternatively, poor colostral management may contribute to a high incidence of opportunistic infections of immunologically compromised neonates leading to joint ill. An inflammatory leukogram provides supportive evidence of a septic process, and aseptic collection of joint fluid for cytology and culture provides confirmatory evidence. When interpreting neonatal hematology and biochemistry results, it is important to be aware of age-associated normal values (Table 19-7).

In older neonates, metabolic bone disease should be considered as a differential diagnosis for lameness associated with flaring of the physis. Diets high in energy and protein that have low calcium and high phosphorus promote rapid weight gain, thus increasing the physical load on metabolically compromised growing bones. Damage to the growing physis may result in the subsequent development of angular limb deformities. Calcium deficiency in calves leads to reduced mineralization of bone. The transverse processes of the lumbar vertebrae become soft and bend when palpated. Copper deficiency causes metabolic bone disease that is manifested by physitis and brittle bones reflected by a propensity to spontaneous fractures.

Posterior paresis is common in neonates; causes include border disease, enzootic ataxia, vertebral body abscesses, caprine arthritis encephalomyelitis virus, and vertebral body fractures associated with dietary copper deficiency or calcium phosphorous imbalance. These neurologic problems are discussed in Chapter 35.

Perineal Region

The examination from the rear includes assessment of body condition, measurement of rectal temperature, palpation of the coccygeal artery to assess pulse, examination of mucous membranes (female), and collection of urine and feces. Examination of the tail may also

reveal evidence of diarrhea. Chronic diarrhea may be reflected by poor body condition and hair loss from the caudal surface of the rear hind limbs.

BODY TEMPERATURE. Rectal temperature in calves ranges between 37.2° and 38.9° C (99° and 102° F) during the first 4 days after birth. Abnormalities of vital signs in neonatal ruminants may be difficult to interpret because a fever can be transient and patients with septicemia, infection, dehydration, or circulatory shock can be hypothermic or normothermic. Premature calves are prone to hypothermia.[248] Hyperthermia during the first week of life has been reported to be common in cloned calves.[249]

FECES. In contrast to the adult, rectal palpation of the abdominal structures of the large animal neonate is of limited value. Small amounts of blood may be observed in the feces of healthy calves. Passage of blood and fibrin is associated with inflammatory bowel disease induced by pathogens such as *Salmonella* and coronavirus that damage the gastrointestinal mucosa. Passage of melena may be associated with infectious enteritis (e.g., clostridiosis, salmonellosis)

and necrotizing enterocolitis resulting from hypoxic-ischemic bowel injury. Infectious diarrhea is the leading cause of mortality in calves between 3 and 21 days of age. Typically, more than one pathogen is involved and the physical examination provides no indication of the etiologic agent. Fecal pH may be used as an indicator to distinguish secretory diarrhea (enterotoxigenic *E. coli*) from diarrhea associated with malabsorption and maldigestion. Secretory diarrhea produces an alkaline pH, whereas malabsorption and maldigestion are associated with an acidic fecal pH.[250] Infectious agents causing diarrhea and ancillary tests available to establish an etiologic diagnosis are discussed in Chapter 20.

URINE. Normal urine osmolarity in the 2- to 3-day-old calf has been reported to be 286 to 391 mOsm/L, and urine volume voided per day of 34 mL/kg/day.[251] Congenital abnormalities of the urinary system include ruptured urinary bladder, ruptured ureter, ectopic ureter, blocked urethra, renal agenesis, fused kidney and polycystic kidneys. Rupture of the urinary bladder at parturition is uncommon in ruminants. Hemodynamically mediated renal disease is observed sporadically in calves following chronic enteritis.[252] Prolonged reduced renal perfusion resulting from hypovolemia may lead to ischemia and acute tubular necrosis. Failure to thrive following apparent recovery from diarrhea may reflect compromised renal function.

EXTERNAL GENITALIA. The external genitalia of both sexes should be examined for congenital malformations. In the calf, congenital defects described include ovarian aplasia, duplication of the cervix in Hereford cattle, persistence of the hymen (white heifer disease), and rectovaginal constriction in Jersey cattle. Congenital urolithiasis has been described in calves and lambs. Calcium oxalate is the most commonly reported congenital form of urolithiasis and may be associated with other congenital abnormalities.[253] A report of renal oxalosis in a number of beefmaster calves suggests a possible recessively inherited metabolic defect resulting in primary hyperoxaluria in this breed.[254] Freemartins (XX/XY chimeras) occur in over 90% of bovine[255] and 1% of ovine[256] female heterosexual twins. Typically, freemartins are sterile and have hypoplastic ovaries and internal tubal genitalia; the external genitalia normally are not affected. Males should be examined for cryptorchidism and male pseudohermaphroditism, and both sexes for evidence of hermaphroditism (gonads of both sexes). Mucous membrane color and capillary refill time may be assessed by examining the vulva mucosa in heifers.

Problem Solving

The process of diagnostic investigation for neonates is similar to that for adults. A problem list is developed at the conclusion of the physical examination. Differential diagnoses for each problem are considered and the likelihood of differentials ranked according to the history, signalment, and physical findings. This process progresses to a tentative diagnosis and development of diagnostic/treatment plans. Details regarding the presentation, diagnosis, and treatment of common neonatal diseases are presented in Chapter 20.

Manifestations and Management of Disease in Neonatal Ruminants

JOHN K. HOUSE, *Consulting Editor*
GEOF W. SMITH
SHEILA M. MCGUIRK
ALISON A. GUNN
MATTHEW IZZO

MAJOR CLINICAL SIGNS OR PROBLEMS ENCOUNTERED

Weakness and/or depressed mentation (somnolence), 302
Respiratory distress, 308
Abdominal distention, 312
Neonatal diarrhea, 314
Lameness and reluctance to walk, 335
Umbilical enlargement, 336
Anemia, 337
Fever, 337
Cyanosis, 337
Heart murmur, 338
Icterus, 338
Failure to thrive: cachexia and weak calf syndrome in beef calves, 338

Weakness and/or Depressed Mentation

Geof W. Smith

If weakness has been present since birth, in utero–acquired bacterial or viral infections, birth asphyxia and trauma, chronic placental problems, and congenital anomalies should be considered on the list of differential diagnoses. A number of congenital bacterial, fungal, and viral infections that cause abortions and stillbirths may result in the birth of a live but weak calf. In cattle, brucellosis, salmonellosis, leptospirosis, listeriosis, *Escherichia coli, Corynebacterium* spp., and *Aspergillus* spp. may cause placentitis and disease in the newborn. In sheep, in utero infection with chlamydia, *Campylobacter, Coxiella,* bluetongue virus, and border disease may cause disease in the newborn. Congenital viral infections of neonates are listed in Box 20-1. Clinical manifestations of fetal infections depend on the age of the fetus and the virulence and trophism of the infecting agent (see individual diseases).

Neonatal calves with storage diseases primarily affecting the nervous system may appear reasonably normal for a short period after birth and then show progressive signs of neurologic dysfunction, including tremors, spasms, depression, recumbency, and coma. Differential diagnoses for weakness and depressed mentation after a period of apparently normal strength and mentation include sepsis, electrolyte and acid-base disturbances, hypoglycemia, and hypothermia. A complete history is obtained, including a detailed description of the delivery process, and complete physical and neurologic examinations are performed. Any signs of trauma, infection, or congenital malformations should be noted. Evaluation of hematologic data and immunoglobulin G (IgG) status, combined with historical and physical examination parameters, results in a high suspicion of sepsis. Blood glucose, blood gas, serum electrolyte concentrations, and passive transfer status should be determined promptly. Blood cultures and cerebrospinal fluid (CSF) analysis are useful for verifying central nervous system (CNS) involvement and targeting antimicrobial therapy.

Septicemia

Neonatal septicemia is the third most common cause of calf mortality in the United States (behind diarrhea and respiratory disease) and occurs most commonly in calves associated with failure of passive transfer (FPT). The phagocytic and bacterial killing function of neutrophils (PMN) is a crucial component of the primary immune response against invading pathogens. Despite a larger number of neutrophils in the circulation of normal calves at birth, neutrophils from neonatal calves are functionally less effective than adult cells. Reduced Fc-receptor expression in neonatal PMNs may contribute to impaired phagocytosis and antibody-dependent cellular cytotoxicity.[1-3] Depressed PMN bacterial killing[4] may be related to reduced superoxide anion[5] and myeloperoxidase-hydrogen peroxide-halide antibacterial activity.[3] Adult-level superoxide activity in fetal PMNs suggests some of the deficits in neonatal PMN function may be a manifestation of perinatal PMN suppression.[6] Calves have elevated cortisol levels for the first 10 days of life, which may contribute to depression of neutrophil function.[7] Dexamethasone depresses neutrophil phagocytosis, antibody-dependent cellular cytotoxicity, and bacterial killing.[8,9] Undefined serum factors also appear to be important for PMN function, as phagocytosis and bacterial killing by neonatal PMNs is similar to that of adult PMNs when bacteria are opsonized with adult serum but is reduced when bacteria are opsonized with neonatal serum.[4] T-helper cells ($CD4^+$) play a central role in humoral and cell-mediated immunologic memory. Lymphokines produced by $CD4^+$ cells, interleukin-2 (IL-2), IL-4, and interferon-γ (IFN-γ) are essential components of antigen-specific immunity. Virtually all IL-4 and most IFN-γ produced by polyclonally activated adult human $CD4^+$ cells is mediated by a subset of "functional memory cells."[10] Leukocyte production of IL-4 and IFN-γ is reduced in human neonates[10] and IFN-γ in bovine neonates (Dr. David Van Metre, UC Davis, unpublished data), possibly reflecting their antigenically naive status. Depressed lymphocyte proliferation and IL-2 activity in the perinatal period correlates with elevated cortisol levels.[7]

BOX 20-1

Differential Diagnoses for the Weak or Depressed Ruminant Neonate

Bacterial Infection: In Utero or Postnatally Acquired
Septicemia
Joint and bone
Enteritis
Pneumonia
Meningitis
Peritonitis (primary or secondary)

Congenital Viral Infection
Bovine virus diarrhea virus (B)
Bluetongue virus (B, O)
Infectious bovine rhinotracheitis virus (B)
Akabane virus (B)
Parainfluenza (B)
Caprine herpes (C)
Border disease virus (O)

Prematurity/Postmaturity
Weak calf syndrome
Bacterial or fungal placentitis

Birth Asphyxia
Placentitis
Dystocia
Cesarean section
Premature placental separation
Induced parturition
Birth trauma
Brachial plexus injuries
Fractured rib, pneumothorax, hemothorax
Ruptured bladder

Congenital Malformations
Cardiac malformations
Central nervous system malformations (e.g., hydrocephalus, hydranencephaly)
Angular limb deformities
Arthrogryposis

Metabolic Derangements
Hypoglycemia
Hyponatremia
Hypokalemia or hyperkalemia
Hypocalcemia
Acidosis (respiratory or metabolic)
Uroperitoneum (with electrolyte abnormalities)
Renal failure

Severe Anemia
Blood loss
Neonatal isoerythrolysis

Brain Disease
Hemorrhage
Ischemia, edema, necrosis
Traumatic injury
Meningitis
Malformations

Spinal Cord Disease
Spinal cord hemorrhage
Vertebral malformation (e.g., atlantooccipital)
Vertebral abscessation or osteomyelitis
Vertebral fracture or other trauma to spinal cord

Peripheral Nerve and Muscle Disease
White muscle disease
Tetanus
Congenital myopathy, polymyositis
Neuropathy of spinal roots or peripheral nerves

Liver Disease
Hepatitis
Severe hypoxic insult

Storage Disorders
Maple syrup urine disease
Citrullinemia
Shaker calf syndrome (neurofilament accumulation)
GM1 gangliosidosis

Ingestion of Drugs or Toxins
Transplacental transfer of anesthetics and sedatives
Inadvertent oversedation of neonate

Gastrointestinal Disease
Gastrointestinal ulceration
Necrotizing enterocolitis

B, Bovine; *C,* caprine; *O,* ovine.

Acquisition of humoral immune competence is age and antigen dependent.[11] Neonates are capable of producing humoral immune responses to good immunogens (protein antigens) but may fail to respond to lesser immunogens (sugars and lipids). Calves less than 3 months of age vaccinated with modified live or killed salmonella vaccines produce an adult-type humoral immune response to salmonella protein antigens but do not respond to salmonella lipopolysaccharide.[12] Ingestion of colostrum suppresses the humoral response to some antigens but not others.[11]

Adverse management and environmental conditions further compromise neonatal immunity. Cold stress depresses neutrophil chemotaxis, and vasoconstriction reduces delivery of leukocytes to peripheral tissues.[13] Protein energy malnutrition in calves is associated with depressed lymphocyte IL-2 activity, lymphocyte proliferation, and humoral immune responses.[7] Micronutrient deficiencies also depress immunity. Selenium, zinc, copper, and vitamin E deficiencies depress lymphocyte and phagocyte function.[14,15]

Inherited defects in immune function are sporadically observed in neonates and should be considered when recurrent or atypical infections are observed, such as bovine leukocyte adhesion deficiency in Holsteins.

If invading bacteria are not quickly controlled by the immune system, they can establish focal infections in areas such as the joints, meninges, heart valves, or growth plates. Septicemia refers to a bacterial infection of the blood associated with adverse systemic signs. If not successfully treated, this can lead to multiple organ dysfunction, septic shock, and death. Meningitis is particularly difficult to treat successfully and therefore prevention of septicemia through good colostrum management is essential.

TABLE 20-1

Bacterial Species Found to Be Associated with Neonatal Septicemia in Calves

	Fecteau et al[19]	Hariharan et al[17]	Lofstedt et al[20]
Escherichia coli	26 (50%)	17 (65%)	29 (55%)
Klebsiella spp.	7 (14%)	0	0
Salmonella spp.	4 (8%)	0	0
Campylobacter spp.	2 (4%)	2 (8%)	8 (16%)
Staphylococcus spp.	4 (8%)	0	5 (10%)
Streptococcus spp.	2 (4%)	3 (12%)	1 (2%)
Other gram positives*	3 (6%)	2 (8%)	1 (2%)
Other gram negatives†	0	1 (4%)	4 (8%)
Anaerobic bacteria‡	4 (8%)	0	1 (2%)
Total cases reported	51	26	50

**Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *Bacillus* spp., *Listeria monocytogenes*.

†*Pseudomonas aeruginosa, Mannheimia haemolytica*.

‡*Clostridial* spp., *Bacteroides* spp., *Prevotella* spp.

Blood culture studies of debilitated calves indicate that gram-negative bacteria account for approximately 80% of bacterial isolates; *E. coli* is the most common bacteria isolated.[16-18] In a study of 190 recumbent calves on a large calf-raising facility, 31% were determined to be bacteremic; *E. coli* accounted for 51% of the isolates; other gram-negatives, 25%; gram-negative anaerobes, 5.9%; gram-positive cocci, 11.8%; and gram-positive rods, 5.9%.[16] Other common bacterial isolates include *Salmonella, Campylobacter, Klebsiella,* and different *Staphylococcus* species. A summary of bacterial pathogens found to be responsible for septicemia are listed in Table 20-1. Polymicrobial infections are common in septicemic calves (28%).[18]

Calves lack a normal adult intestinal flora, and when born in a heavily contaminated environment, colonization of the GI tract with virulent bacteria may occur prior to the establishment of normal flora. Septicemia may also result from bacterial colonization of another site such as the umbilicus. Bacterial infection and the host inflammatory response should be differentiated. The immune response, in combination with the reticuloendothelial system, prevents the development of sepsis from an opportunistic or pathogenic invasion. However, this initiates an inflammatory cascade involving highly toxic mediators, which, if uncontrolled, will eventually lead to the systemic inflammatory response syndrome (SIRS) and subsequent multiple organ dysfunction syndrome (MODS). There is a balance between an appropriate, yet effective, immune response and an overzealous response to the bacteria or their toxins.[21]

The interaction between endotoxin (lipopolysaccharide) and the immune system triggers a complex inflammatory cascade involving cytokines and other inflammatory mediators. Initiation of the cascade results in the production of arachidonic acid metabolites, release of myocardial depressant factors, activation of the complement system, as well as the production and release of many other mediators of sepsis.[21] The results include dehydration, tachycardia, pyrexia, leukopenia, hypotension, a decrease in systemic oxygen delivery and cardiac output, and generalized weakness. There is a severe and complex pulmonary vasculature response to endotoxin, leading to hypoxemia. Cattle are very sensitive to endotoxin, and even small doses can produce severe lung injury. Severe endotoxemia is frequently associated with death from respiratory failure in both calves and adult cattle. Therefore, nonsteroidal antiinflammatory drugs (NSAIDs) are critical in blocking the formation of reactive metabolites (e.g., thromboxanes) and restoring lung function.

Neonatal septicemia should be seriously considered whenever there is multiple organ dysfunction, or when severe cardiac and/or respiratory signs are encountered. Classic septicemia is described as a condition affecting newborn calves between 2 and 8 days of age. The progression is rapid and most often fatal. Very early in the disease, the clinical signs are vague, nonspecific, and likely attributed to other disease. An alteration in mental status ranging from a mild depression to coma is commonly observed. Lack of suckling ability or enthusiasm toward nursing are early nonspecific clinical signs.[21] Abnormal rectal temperature (fever or hypothermia) is not consistent; however, sustained tachycardia and eventually tachypnea develop. Hyperemia of the mucous membranes and scleral injection is frequently observed. Capillary fragility may initiate petechiation of the mucous membranes. Eventually, hypotension and clinical signs that are associated with poor cardiac output (slow capillary refill, diminished peripheral pulse, cold extremities, and decreased urine output) become prominent. Dehydration usually develops. Diarrhea is not present in all cases but is common in the terminal stages of septicemia.

Early clinical signs of septicemia can be subtle and nonspecific. Sepsis scoring models have been developed for calves but lack good sensitivity and specificity.[19,20] The most useful parameters for predicting septicemia in calves as determined by these studies include toxic changes in neutrophils, FPT, presence of a focal infection, or elevated serum creatinine concentrations. Ultimately, the presence of clinical signs including lethargy, pyrexia, diarrhea, tachypnea, polyarthritis, uveitis, omphalitis, and meningitis, along with documented presence of FPT, should make the clinician highly suspicious of septicemia. If multiple clinical signs are present, the likelihood of disease is increased. However, the definitive diagnosis of septicemia can only be based on a blood culture. The jugular vein should be clipped and scrubbed prior to sampling. An amount of 10 mL of whole blood is drawn using a sterile syringe and needle, and the blood is placed into a blood culture bottle using a new sterile needle. Taking two samples (from blood collected 1 hour apart) is sometimes recommended to increase the chances of isolating the bacteria and to facilitate the interpretation of results if opportunistic or contaminating bacteria are found in one sample.[21] The bottle is then submitted to the laboratory for culture and susceptibility testing. If the bottle is not submitted immediately, it should be stored at room temperature or at 37° C. A negative blood culture must be interpreted with caution since many factors may interfere with bacterial isolation from a blood culture. Cultures of other body fluids such as joint, cerebrospinal, peritoneal, or pleural fluids may be helpful for bacteriologic diagnosis whenever the blood culture is negative.

Some laboratory findings may increase the suspicion of septicemia. Hematologic abnormalities of septicemia vary with the severity of the disease. Abnormal neutrophil count (neutrophilia and neutropenia) and increased immature forms (bands) are frequently seen. Fibrinogen concentration is often elevated. Thrombocytopenia may be present in severe cases. One study of suspected septic shock in calves found that 8 out of 12 calves had at least three abnormal coagulation parameters, most commonly activated partial thromboplastin time (APTT) and prothrombin time (PT).[22] Hypoglycemia, or less often hyperglycemia, may be observed. A metabolic acidosis is also frequently present in septic calves. Lactic acidosis occurs as the disease progresses. Some calves will develop respiratory disease (respiratory distress syndrome) or pneumonia and will suffer from hypoxemia and/or hypoventilation.

Neonatal septicemia is a severe disease with high mortality. The primary goals of treatment are to (1) control the infection, (2) modulate the inflammatory response, and (3) support the animal during the disease. Treatment is based on selecting an appropriate antimicrobial drug and dosage, antiinflammatory therapy, and supportive therapy (including fluids). Differences between neonatal and adult animals in drug effects generally can be attributed to differences in drug distribution, metabolism, or excretion. Some general characteristics of the neonatal period include better absorption of drugs from the gastrointestinal tract, less drug binding to plasma proteins,

VetBooks.ir

increased apparent volume of distribution of drugs that are distributed in the extracellular fluid volume, increased permeability of the blood-brain barrier, and slower elimination (i.e., longer half-life) of many drugs. In general terms, antimicrobials have longer elimination times in neonates (<2 weeks of age) than adults and as such larger doses are administered with a longer dosage interval to achieve similar peak and trough antimicrobial concentrations. Antimicrobial therapy should begin as soon as possible in order to minimize the bacteremia. The choice and the dosage of antibiotic depend on several factors, and personal preference, along with past experience, is often important. It is generally accepted that the intravenous route is preferable whenever possible and that broad-spectrum drugs are preferred. Appropriate antimicrobial choices include third- or fourth-generation cephalosporins (ceftiofur 5 to 10 mg/kg/day IM or IV), sodium ampicillin (10 to 20 mg/kg tid IV), and florfenicol, although even when given intravenously at the extralabel dosage of 20 mg/kg bid, it only exceeds the MIC_{90} value in plasma for 1 hour.[23] Combinations of drugs can be used to broaden the spectrum of activity (such as ampicillin-ceftiofur or ampicillin-trimethoprim-sulfonamide). Fluoroquinolones can also be effective in countries where their use is permitted. Once the pathogen has been identified and the susceptibility pattern determined (on the individual or on the farm), the most appropriate antibiotic can be chosen.

As just described, the inflammatory response if uncontrolled often causes severe clinical signs. Therefore, NSAID therapy should be considered for ancillary treatment. Possible side effects of aggressive NSAID treatment include abomasal ulcers and renal toxicity, particularly in dehydrated animals. The duration of NSAID treatment is often limited to 2 to 3 days because of their potential toxicity. NSAIDs should not be continued for any longer than they are considered essential for survival.

Supportive treatments for septicemic calves include correction of secondary problems, administration of fluids, plasma transfusion, oral or parenteral nutrition, and oxygen administration. Problems that must be addressed include hypovolemia, hypoglobulinemia, hypoglycemia, metabolic acidosis, electrolyte abnormalities, and hypoxia. IV fluids (or oral as a compromise on the farm) should be administered. Dextrose (5%) combined with normal saline (0.9%) should be administered at a rate of at least 50 mL/kg/day. Nutrition is important and septic calves either nurse reluctantly or are inappetant; as a result, they do not ingest an adequate amount of milk. If the animal refuses to nurse, tube feeding should be used to ensure that the calf ingests at least 10% to 15% of its body weight of milk per 24 hours. The feeding schedule may involve several (three to five) feedings per day and should be gradually increased in amount to prevent abdominal distention. If the gastrointestinal system does not tolerate the tube feeding regimen, parenteral nutrition should be considered. There is usually no need for total parenteral nutrition since most animals will continue to nurse or tolerate tube feeding up to 5% of their body weight.

Multiple cases of septicemia occurring on the same farm calls for careful inspection of the environment and management practices. Clusters of septicemia could be related to specific risk factors. As an example, feeding heavily contaminated colostrum could be the origin of the septicemia on some farms.[22,24] Prevention through excellent cleanliness and management practices is the most effective means of controlling and preventing neonatal sepsis.

Meningitis

Bacterial meningitis is an important complication associated with neonatal septicemia in calves. Exactly how bacteria get into the meninges is poorly understood. Specific mechanisms may include the development of a sustained and high-grade bacteremia in the highly perfused dural venous system and choroid plexuses, adherence of fimbriae from some strains of *E. coli,* or the phagocytosis of the pathogens by circulating monocytes and endocytosis through the microvascular endothelial cells.[21] Once they gain access to the CNS, bacteria survive and proliferate well in the poorly defended CSF. Complement is essentially nonexistent in CSF, which, when combined with low numbers of specific antibodies, leads to inadequate opsonization of meningeal pathogens. The sequelae of meningitis are associated with the release of cytokines and the direct effects of bacterial invasion. Bacteria may release endotoxin, leading to inflammatory infiltrates that cause thromboses of the arachnoidal or subependymal veins. Congestion or hemorrhagic infarction may follow with subsequent necrosis of nerve cells. Inflammatory changes in the subarachnoid space may affect the choroid plexus, decreasing the absorption of fluid and potentially creating hypertensive hydrocephalus.

Although bacterial meningitis may occur as a primary entity, it more commonly is a result of generalized septicemia in neonates with FPT. Agents that cause meningitis are the same agents that cause septicemia, most commonly the gram-negative enteric bacteria such as *E. coli, Enterobacter* spp., and *Salmonella* spp. In a review of 32 cases of meningitis in calves, the clinical signs of CNS disturbance observed were lethargy, recumbency, anorexia, loss of suckle reflex, coma, opisthotonos, convulsions, tremor, and hyperesthesia.[25] Leukocytosis and a left shift were evident in 11 of 15 calves (73%). Concurrent metabolic problems were common and included hyperkalemia, respiratory acidosis, hypernatremia, hyponatremia, hypomagnesemia, and hypoglycemia. Analysis of CSF revealed pleocytosis, xanthochromia, turbidity, and high total protein concentration. Cytologically, neutrophils predominated in the CSF in calves with acute disease. Mononuclear cells dominated in calves with chronic disease. Microscopically, bacteria were evident in 10 of 22 (45%) of the antemortem CSF samples, and bacteria were isolated from slightly more than half (11 of 19). All of the calves in this review died.[25]

Calves with meningitis are often presented because they have lost their suckle reflex and appear lethargic. Previous treatment for diarrhea is common. Fever is often present unless NSAIDs have been given or if the animal is in an extremely cold environment. The calves may have an extended head and neck, and attempts to flex or reposition the neck can result in a tonic extension and thrashing of the limbs. Calves with meningitis almost always have abnormal mentation. As the disease progresses, profound depression develops and eventually the animal becomes comatose and nonresponsive or may develop seizures. Presumptive diagnosis of bacterial meningitis is based on demonstration of FPT, presence of a septic focus such as omphalophlebitis or septic arthritis, and the presence of abnormal neurologic signs. However, the definitive diagnosis is based on an abnormal CSF analysis. Collection of CSF from the lumbosacral space is easy and safe in calves. For collection of fluid from the lumbosacral space, a 20-gauge, 1- to 2-inch needle with a clear hub may be used. A change in resistance is felt when the needle penetrates the dural membranes, and CSF appears in the plastic hub as soon as the subarachnoid space is entered. Approximately 5 to 10 mL of fluid may be removed safely.

Urinary reagent strips can be used to rapidly obtain general information about the fluid. If blood is detected, the sample should be spun down after the cytologic examination. Red blood cells contaminating the sample will settle, and the supernatant should be colorless. If hemorrhage occurred before the procedure, the sample remains xanthochromic (yellow). Glucose should be present in "trace" or "positive" (+) amounts in the normal sample. Negative values in the adult suggest severe meningitis, but in the neonate they may also be caused by profound hypoglycemia. CSF analysis is most useful in determining the presence of septic meningitis. A summary of CSF findings from calves with meningitis is presented in Table 20-2. Generally an elevation in total protein and white blood cell concentration are strongly suggestive of meningitis, combined with a high percentage of the cells being neutrophils. The ratio of CSF to plasma glucose concentration is less than 1 in animals with bacterial meningitis because of bacterial metabolism of glucose in the CSF. Xanthochromia (yellow color) is inconsistent. Free or intracellular bacteria may be observed in some cases. An elevated albumin quotient suggests increased blood-brain permeability and can be seen in both

VetBooks.ir

TABLE 20-2

Cerebrospinal Fluid (CSF) Findings in Calves with Meningitis

	Normal	Green et al[25]	Scott et al[25a]
Specific gravity	<1.007	NR	1.011
Total protein	<0.4 g/L	3.07 g/L	3.2 g/L
White blood cell concentration	<10 cells/μL	4004 cells/μL	2400 cells/μL
Percent lymphocytes	>80%-90%	NR	Range of 1%-17%
Percent neutrophils	<10%-15%	73%	Range of 78%-100%
Culture positive		6 of 9 cases	11 of 19 cases

TABLE 20-3

Cerebrospinal Fluid-to-Blood Concentration Ratios (Penetration) of Antibiotics Available for Treatment of Meningitis in Calves[23,26]

	Concentration CSF/Concentration Serum (%)	
Antimicrobial*	Human	Animals
Ampicillin	13-14	8-12
Florfenicol		46 (calves)
Gentamicin	0-30	21-25
Penicillin	5-10	5-6
Trimethoprim-sulfamethoxazole	<41	35-39

*The list is not conclusive, reflecting the paucity of available data.

CSF, Cerebrospinal fluid.

hypoxic-ischemic brain injury and meningitis, but an elevated IgG index indicates increased intrathecal IgG production and is more compatible with a diagnosis of meningitis.

When treating calves with meningitis in a hospital environment, the mortality rate is high; however, aggressive early treatment can be successful. The economics and welfare implications of treating commercial calves in a field setting are questionable. Empiric antimicrobial therapy for meningitis in neonatal calves should include a gram-negative and gram-positive spectrum. Antibiotics enter the CSF predominantly via passive diffusion down a concentration gradient. The major determinant of CSF penetration is lipid solubility. Lipophilic agents diffuse via transcellular pathways; peak concentrations in CSF occur relatively rapidly, and entry into CSF is affected minimally by the presence of inflammation. In contrast, hydrophilic agents enter the CSF through paracellular pathways; their transport depends on the opening of tight junctions, and peak concentrations are relatively delayed.[26]

Table 20-3 lists CSF-to-blood concentration ratios (penetration) derived from multiple species for a handful of antimicrobial drugs available for use in cattle.

In a CSF pharmacokinetic study of florfenicol in calves, the maximum concentration of florfenicol attained in CSF was 4.67 ± 1.51 μg/mL following a single intravenous dose of 20 mg/kg.[23] The levels remained above the minimum inhibitory concentration (MIC) for *Histophilus somni* (formerly *Hemphilus somnus*) over a 20-hour period. This concentration is below the MIC_{90} for *E. coli*. Bactericidal antibiotics are proposed to be more effective for treatment of meningitis in humans, and it is recommended that the concentration of antibiotic in the CSF should be maintained at 10 times the MIC of the target pathogen.[26] Unfortunately, owing to the lack of CSF pharmacokinetic data in cattle, antimicrobial treatment of meningitis is an inexact science. Antiinflammatory therapy and nursing care should be instituted as described previously for neonatal septicemia. Convulsions in calves can be treated with diazepam (0.1 to 0.2 mg/kg IV). This can be repeated every 30 minutes until convulsions are controlled.

Metabolic Acidosis

Profound weakness associated with metabolic acidosis or "strong ion" acidosis is commonly observed in calves with diarrhea and sporadically in kids ("floppy kid syndrome") and calves without other clinical signs of disease.[27,28] This acidosis is often associated with an increased concentration of D-lactate (the anion of D-lactic acid) resulting from bacterial fermentation of carbohydrates in the gastrointestinal tract of milk-fed calves. Clinical signs of impaired CNS function including ataxia and coma in sick calves have been attributed at least partially to the increased D-lactate concentrations.[29,30] Assessment of weak neonatal ruminants for the presence of metabolic acidosis is a critical part of the physical examination. Correction of the acidosis by intravenous administration of bicarbonate produces a rapid recovery. An improvement in mentation and strength should be observed within 12 hours; persistent depression is likely to reflect incomplete correction of acidosis, sepsis, hypoglycemia, hypernatremia, or hyponatremia.

Hypoglycemia

Hypoglycemia is a common sequela to withdrawal of milk for more than 48 hours, especially in cold weather. Affected calves are weak or recumbent but appear to be normally hydrated or minimally dehydrated.[31] They are often emaciated and can occasionally have neurologic signs including facial twitches, convulsions, opisthotonos, and coma. They will respond to a bolus of 50% dextrose or infusion of 5% glucose, but often this response is temporary, especially in calves with severe malabsorptive disease. It is important to rapidly restore adequate energy intake to ensure resolution of these cases. Starvation and hypothermia resulting from mismothering are common causes of weakness in neonatal lambs. Similarly, weakness, poor body condition, and increased susceptibility to infectious diseases are observed with protein-calorie malnutrition induced by feeding poor-quality or incorrectly mixed milk replacers.[32] Hypoglycemia is also frequently seen in calves with neonatal septicemia, as discussed previously.

Hyponatremia

Hyponatremia occurs when loss of isotonic fluid through the gastrointestinal tract is replaced by free water or hypotonic solutions. The latter often occurs when too much water is added when making up an oral electrolyte solution. Hyponatremia may also occur when isotonic oral electrolyte solutions are administered to calves with compromised sodium absorption capacity. This may be a result of severe pathologic changes or an inadequate level of agents that facilitate sodium cotransport within the oral electrolyte solution. Hyponatremia results in a fluid shift from the extracellular space to the intracellular compartment along the osmotic gradient, and the resultant swelling of the cells can result in neurologic disturbances, depression, disorientation, and even convulsions.[33] Hyponatremia should be considered in calves with serum sodium less than 132 mmol/L; calves with serum sodium less than 120 mmol/L have severe hyponatremia.

The goal of therapy is to restore serum sodium levels to greater than 125 mmol/L over the first 6 hours and then to restore to normal levels over 24 hours.[33] In hypovolemic calves the initial treatment should be achieved using normal saline, and in normovolemic calves hypertonic saline should be used for the initial treatment, since the administration of large fluid volumes will exacerbate cerebral edema. If the calves are also suspected to be acidotic, this should be corrected with sodium bicarbonate solutions of appropriate tonicity.

VetBooks.ir

The amount of sodium required in the first 6 hours to raise the sodium level to 125 mmol/L can be calculated as follows[33]:

$$\text{mEq Sodium} = (125 - \text{Measured mEq serum sodium}) \times (0.6 \times \text{Body weight in Kg})$$

Calves should then be maintained on a sodium-containing isotonic fluid, such as normal saline or lactated Ringer, and treated with oral electrolyte solution as appropriate. The sodium level should be monitored frequently in the first 24 hours because of unknown losses through the gastrointestinal tract as well as unknown kidney function in a severely dehydrated patient.

Hypernatremia

Hypernatremia is defined as a serum sodium concentration greater than 152 mmol/L (although only levels greater than 170 mmol/L have been associated with nervous dysfunction).[34] Hypernatremia in food animals is generally caused by one of the following: (1) excessive loss of free water (e.g., water deprivation, heat stress), (2) iatrogenic administration of IV crystalloid solutions to animals that do not have access to water, and (3) excessive intake of sodium without an adequate volume of free water. This last cause is by far the most common syndrome in calves. Most cases result from mixing oral electrolyte solutions improperly, or in some circumstances, hypernatremia has been seen with very high osmolality milk replacers.

During hypernatremic states, water will follow concentration gradients and move into the relatively hyperosmolar CSF and plasma. This results in cellular dehydration and brain shrinkage (neurons shrink when the water moves out). Neuronal cells will increase their intracellular osmolality in an attempt to minimize the water efflux; however, this adaptation can only compensate for mild increases in sodium concentrations. Severe hypernatremia leads to neurologic disease in calves.

Early clinical signs of hypernatremia include lethargy and depression, which, without blood work, cannot be differentiated from many other possible diseases such as acidemia, dehydration, hypoglycemia, or hypothermia. More advanced clinical signs of hypernatremia include twitching of facial muscles, muscle rigidity, tremors, and myoclonus.[34,35] Calves will demonstrate seizure and/or coma activity near death. Prognosis in these calves is often guarded to poor even with aggressive treatment.

Treating hypernatremia is very difficult. If the sodium concentration is lowered too quickly, water follows a concentration gradient and moves into neurons, resulting in cerebral edema. When sodium concentrations are higher than 160 mEq/L, it is very easy to produce cerebral edema with any isotonic fluid, even those that contain sodium, because of the large difference between the calf's extracellular fluid sodium concentration and the sodium concentration in the fluids. Therefore, it becomes necessary to add supplemental sodium to standard fluid types. The fluids must be formulated so that the sodium concentration is equal to or slightly lower than the calf's sodium concentration.[34] The calf's sodium concentration should be reassessed at least one to two times per day and fluids reformulated. The goal would be to return the sodium concentration to normal over a period of several days, decreasing it by 3 to 4 mEq/L/day.[35] This approach is expensive (requiring frequent blood work) and difficult and is not always successful. Some calves will still develop cerebral edema even with careful fluid therapy.

For example, if a calf has a sodium concentration of 177 mEq/L, the goal would be to give fluids with a sodium concentration somewhere in this range (175 to 177 mEq/L). Since isotonic (0.9%) saline has a sodium concentration of 154 mEq/L, the clinician needs to add 22 to 23 mEq/L of additional sodium to the liter of fluids. Hypertonic saline (7.2%) contains sodium at a concentration of 1.2 mEq/mL. This would be equal to 19 mL of hypertonic saline per liter of isotonic saline ($1.2 \times 19 = 23$). After about 12 hours of fluid therapy, it is recommended to reassess the calf's sodium concentration and re-formulate fluids. Hypertonic saline could also be added to isotonic sodium bicarbonate (which has a sodium concentration of 156 mEq/L) if the calf had a metabolic acidosis in addition to hypernatremia. Although not always successful, a report of treating several hypernatremic calves with 5% dextrose either alone or in combination with sodium bicarbonate has been published.[36] In this study calves were given 2 to 4 L of 5% dextrose at a slow drip (about 500 mL/h) and had serum sodium concentrations decreased much faster than is usually recommended. However, the four calves in the case report were treated successfully. Although this approach may not always work and could easily result in cerebral edema, it may be practical for times when the clinician does not have the ability to formulate fluids or monitor serum sodium concentrations frequently.

If the calf's neurologic signs get significantly worse after fluid therapy has started, cerebral edema should be suspected. Treating cerebral edema is difficult but imperative to prevent further brain damage and/or death. Corticosteroids are the easiest choice normally; however, they are only marginally effective in treating moderate to severe cases of cerebral edema. Mannitol (25%) at 1 g/kg given IV over 30 minutes or an oral solution of glycerin diluted 1:1 with water has also been recommended for severe cases of cerebral edema but can be more difficult to obtain.[34]

Neuromuscular and Musculoskeletal Disease

Primary neuromuscular or musculoskeletal disease should be considered when weakness is not associated with depressed mentation. Weakness associated with micronutrient deficiencies results from myodegeneration (white muscle disease, selenium, and vitamin E) or demyelination (copper, enzootic ataxia). If weakness is detected in one or more limbs immediately after birth, peripheral nerve and muscle damage associated with birth trauma should be ruled out (see Box 20-1). Femoral nerve paralysis may be observed in calves following a "hip lock" dystocia.[37] A condition resembling congenital myasthenia gravis has also been described in Brahman calves.[38]

Nutritional myodegeneration associated with selenium and or vitamin E deficiencies may produce localized (dysphagia) or generalized paresis. Neonatal small ruminants appear to be particularly susceptible. Affected lambs may be unable to rise; others can stand but may be unable to nurse because they are unable to raise their heads. Diagnosis is based on clinical signs, increased serum creatine kinase concentration, and reduced whole blood glutathione peroxidase and/or selenium concentrations (see Chapter 42). Vitamin E deficiency is observed when pregnant ewes are fed stored forage low in vitamin E; the clinical signs in affected lambs are identical to selenium deficiency, but selenium status is adequate. Since vitamin E is labile, serum should be harvested quickly after blood collection, frozen, wrapped in aluminum foil, and sent express mail on ice.

Paraplegia and tetraplegia are commonly associated with spinal cord compression. Compression of the spinal cord in neonates most commonly results from vertebral body malformations, osteomyelitis, or fractures. Generally vertebral body malformations occur sporadically; genetic, nutritional, and environmental factors have been implicated.[39,40] In older calves, underlying metabolic bone disease (copper, vitamin D, or phosphorous deficiency) may increase the propensity for fractures to occur. Osteomyelitis and vertebral body abscess may be a sequel to bacteremia following neonatal septicemia or pneumonia.[41] The frequent isolation of *Trueperella pyogenes* from vertebral body abscesses in ruminants suggests that chronic respiratory infections is more frequently the source in these species.[42,43] Vertebral body abscesses in lambs are occasionally a sequel to infected docking wounds. Leukocytosis and hyperfibrinogenemia are commonly observed in neonates with vertebral body abscesses. In most instances vertebral abscesses do not infiltrate the pachymeninges, so the CSF either is normal or has a mild elevation of protein and/or a mild pleocytosis.[41,42]

Differential diagnoses for paresis in goat kids include caprine arthritis encephalitis virus (CAEV) and enzootic ataxia. Enzootic ataxia is also common in lambs. Progressive ataxia and paresis or

VetBooks.ir

paralysis is a feature of both diseases. There are two forms of enzootic ataxia (swayback): the neonatal and the delayed types. In the neonatal condition animals are affected at birth in the delayed type; signs of incoordination appear at 14 to 30 days of age.[44] Most affected kids are afebrile, bright, and alert, and they will continue to eat if it is physically possible. Enzootic ataxia is associated with low liver copper content, and occasionally, low serum copper concentration.[45] It has been proposed that reduction in the activity of the copper-dependent enzyme cytochrome oxidase impairs phospholipid synthesis and subsequently myelin production. Microcytic anemia and increased fragility of bones may be observed in more chronic cases.[46] The copper, molybdenum, and sulfur content of the maternal diet should be evaluated and adjustments made for copper deficiency or molybdenum or sulfur excess (see Chapter 32).

Goat kids with the neurologic form of CAEV will have mild to moderate fevers and evidence of cerebral involvement. Cerebral signs commonly identified include depression, head tilt, torticollis, and circling.[47] Evidence for CAEV would include CSF pleocytosis and increased CSF protein and a positive CAEV (AGID) or enzyme-linked immunosorbent assay (ELISA) test. Both the neurologic form of CAEV and enzootic ataxia carry a poor prognosis.

A complete neurologic examination is an important component of the work-up of the weak neonate. In particular, it should be noted if the weakness is accompanied by signs of depression and diffuse cerebral disease. Strength is preserved if ataxia is caused by cerebellar disease. Limb reflexes should be tested to establish whether components of the spinal reflex pathways are involved in the disease process (sensory nerve, lower motor neuron, neuromuscular junction, muscle). Animals with other types of spinal cord disease (e.g., trauma, vertebral malformations, enzootic ataxia) may also show weakness and ataxia yet appear clinically to have normal cerebral function. Virtually any severe systemic disease such as generalized infection can cause both profound depression and weakness in a neonate without the presence of actual brain pathology. Intermittent signs of severe weakness and depression may be caused by the narcolepsy-cataplexy syndrome.

Respiratory Distress

Sheila M. McGuirk

Respiratory conditions of the neonatal ruminant can be attributed to upper airway problems, pulmonary pathology, CNS dysfunction, cardiac disease, metabolic derangements, or other nonpulmonary disorders (Box 20-2).

Examination

A complete examination of the neonate is essential when clinical signs are indicative of a respiratory condition. When a single individual is involved, observation from a distance, recording of vital signs, and a physical examination guide the clinician to the selection of appropriate diagnostic tests to establish a cause, make a diagnosis, and evaluate the prognosis. For respiratory conditions that affect a flock or herd of animals, the examination of affected individuals remains an essential component of the diagnostic work-up, but evaluation of records, the environment (housing and other animals), nutrition, colostrum, treatment, and vaccination protocols is also needed.

From a distance, mentation, posture, respiratory rate, breathing effort, characters of nasal and ocular discharge, and spontaneous coughing can be evaluated. Abnormal postures exhibited by patients with respiratory conditions may be recumbency, open-mouth breathing, abnormal extension of the head and neck, head tilt, or reluctance to lie down. Abnormal breathing characteristics include prolongation of the inspiratory or expiratory phase of respiration, an expiratory abdominal press or snap, marked tachypnea, frequent spontaneous coughing, stridor, or inspiratory or expiratory noises.

BOX 20-2

Causes of Respiratory Distress

Upper Airway Conditions

Pharyngeal trauma
Necrotic laryngitis
Choanal atresia (nasopharyngeal atresia)
Laryngeal edema
Tracheal malformation: stenosis, collapse

Developmental Disorders

Pulmonary hypoplasia
Diaphragmatic hernia

Lung Parenchymal Diseases

Pneumonia (bacterial or viral)
Atelectasis
Hyaline membrane disease
Pulmonary edema, congestion
Aspiration syndromes
Air leaks (e.g., pneumothorax)
Pulmonary hemorrhage
Transient tachypnea syndromes

Nonpulmonary Causes

Congestive heart failure
Central nervous system lesions
Metabolic derangements (e.g., acidosis, hypoglycemia)
Severe anemia
Hypovolemia
Fractured ribs
Nutritional myodegeneration of thoracic muscles or diaphragm
Persistent pulmonary hypertension
Birth asphyxia
Pain, abdominal crisis
Fever, high environmental temperatures
Excitement
Pleural effusion (e.g., pleuritis)
Endotoxemia and gram-negative sepsis

Practitioners must assess airflow from each nostril and evaluate ocular, oral, pharyngeal, and vaginal mucous membrane characteristics, including temperature, color, moisture, and capillary refill time. The hard and soft palate should be evaluated. Animals with cleft palate may have milk run from the nose and are prone to developing aspiration pneumonia. Gray or cyanotic mucous membranes are associated with severe hypoxia (i.e., $Pa_O < 35$ to 40 mm Hg), and/or circulatory collapse as seen with hypotensive, endotoxic, or hypovolemic shock. Cardiac and pulmonary causes of cyanosis must be distinguished. Cyanosis from congenital cardiac disease of the neonatal ruminant frequently reflects right-to-left shunting of blood that may be from a tetralogy of Fallot, transposition of the aorta, great vessel anomalies, or Eisenmenger complex. Absence of cyanosis is not a reliable indicator of adequacy of oxygenation in the neonate, since the partial pressure of oxygen may reach very low levels (<35 to 40 mm Hg) before cyanosis is observed.

Auscultation of the trachea, thorax, and occasionally the nasal passage are essential elements of the respiratory examination. Tracheal compression should not induce multiple coughs. Lung sounds of neonates are typically easier to hear than those of adults; however, lung sounds do not always correlate well with the severity of respiratory condition that is present. Interpretation of the intensity of thoracic breath sounds can be validated by comparison to tracheal breath sounds. The intensity of tracheal breath sounds is gradually attenuated as the stethoscope is moved from the trachea to the lung hilus, again to the anteroventral thorax, and finally to the caudal thorax in normal animals. Loud tracheal breath sounds that are not attenuated over the thoracic area may be indicative of atelectasis, lung consolidation, or cardiac enlargement. Added breath sounds such as

VetBooks.ir

crackles or wheezes should be noted but may not be heard without augmenting the depth and frequency of the breathing effort with the use of a rebreathing bag. Cardiac auscultation will determine heart rate, rhythm, and the presence of murmurs. Abnormal radiation of heart sounds caudal to the fifth intercostal space or dorsal to the level of the scapulohumeral joint on either side of the thorax should be noted. Thoracic percussion may be used to identify the presence of thoracic fluid, cranioventral consolidation, or atelectasis in neonatal ruminants.

Heart and respiratory rates vary with activity, excitement, and feeding. Tachypnea can be attributed to elevated temperature humidity index, fever, thermoregulation dysfunction, excitement, pain, stress, respiratory disease, hypoxia (cardiac disease, pulmonary disease, shock), dehydration, shock, toxemia, or metabolic acidosis. Periodic apnea and abnormally slow respirations are often the result of metabolic disturbances (hypoglycemia, hypocalcemia), hypothermia, prematurity, or hypoxia-induced suppression of the respiratory center.

Abnormal posture of the head and neck are exhibited by neonates with respiratory difficulty, particularly upper airway obstruction, but meningoencephalitis, otitis media, hypernatremia, polioencephalomalacia, congenital defects of the CNS, and lasalocid toxicity should be considered.

Conditions causing occlusion of the upper airway, such as choanal atresia, necrotic laryngitis, pharyngeal swelling, or edema, often induce pronounced inspiratory dyspnea, stridor, and/or open-mouth breathing. Expiratory stridor and increased and prolonged expiratory effort are usually associated with lower airway disease. A malodorous breath may be present with necrotic pharyngeal injuries, necrotic laryngitis, cleft palate, or aspiration pneumonia. Inspiratory stridor is often a feature of extra-thoracic airway obstruction and increased abdominal effort on expiration an indication of pulmonary disease causing reduced lung compliance.

Lung disease in the newborn is usually diffuse and is the result of infection acquired in utero or postpartum and/or lung atelectasis associated with immaturity, recumbency, or surfactant dysfunction. Signs of lung disease include increased work of breathing characterized by nostril flare, rib retractions, and increased abdominal effort. A cough and nasal discharge—salient features of respiratory disease in older neonates—are infrequent findings in newborns with lung disease. Animals with few or no audible thoracic abnormalities may have severe respiratory disease.

Respiratory Condition Diagnostic Testing

A complete blood count, serum chemistry profile, electrolyte concentrations, arterial or venous blood gas concentrations, and a test of immune transfer status provide useful information to the clinician concerned about a respiratory condition in a neonatal ruminant. Normal values for neonatal calves are presented in Table 20-4.

Knowing whether there is anemia, evidence of infection, endotoxemia, organ dysfunction, metabolic abnormalities, hypercarbia, hypoxemia, or FPT of immunity may distinguish upper airway problems from lower airway disease or pulmonary disease from a nonpulmonary cause of respiratory difficulty.

Arterial blood gas concentrations provide a useful measure of respiratory function. Optimal sites for collection of arterial blood samples from neonatal calves are the brachial artery proximomedial to the elbow[50] or the caudal auricular artery.[51] Normal arterial blood gas values for neonates of different postnatal and gestational ages are presented in Table 20-5.

Several factors can interfere with accurate interpretation of blood gases in the neonate. First, significant inaccuracies can occur if the blood sample is collected, handled, or measured improperly. The most common artifact is the introduction of room air into the sample, with an artificially increased Pa_{O_2}, decreased Pa_{CO_2}, and more alkaline pH resulting. The position of the patient and amount of struggling during sample collection may also cause transient changes in all blood gas values. The inspired oxygen concentration should always be considered when analyzing arterial blood gas values. With supplemental oxygen, Pa_{O_2} is increased variably, depending on the inspired oxygen concentration (FI_{O_2}), the amount of pathology present (particularly the extent of right-to-left shunting), and the

TABLE 20-4

Normal Hematology and Serum Chemistry Reference Values (for Neonatal Calves)[48,49]

	Age

respiratory rate and tidal volume. Hypoxemia resulting from hypoventilation is usually addressed by increasing inspired PO_2 via a face mask or intranasal oxygen.

Common patterns of arterial blood gas derangement in the neonatal ruminant include hypoxemia (PaO_2 < 70 mm Hg) with low or normal $PaCO_2$ and hypoxemia with hypercapnia ($PaCO_2$ > 50 mm Hg). If there is hypercapnia and resulting respiratory acidosis, ventilation is inadequate or there is ventilation-perfusion inequality. Hypoventilation in neonatal ruminants may reflect depression of the respiratory center, medullary trauma, ischemia, hemorrhage or encephalitis, lack of surfactant in the premature neonate, compromised muscle function (white muscle disease), or fractured ribs.

Interpretation of venous blood gas can be deceptive and should be limited to evaluation of metabolic conditions such as metabolic acidosis but not considered adequate for assessment of pulmonary gas exchange. To avoid problems associated with regional blood sampling, peripheral venous blood should be taken from a free-flowing jugular vein, since the metabolic status of the head is usually stable.

Plasma lactate measurement may provide prognostic value for calves with acute bronchopneumonia.[52] Acute phase proteins such as haptoglobin, fibrinogen, serum amyloid A, and lipopolysaccharide-binding protein have also been evaluated for diagnostic and prognostic value in bovine respiratory disease (BRD) but they are not specific for BRD, vary with etiology and stage of infection, and do not offer a clear distinction between normal and abnormal animals.

Thoracic radiographs are helpful in diagnosing the presence, type, and extent of respiratory disease in neonatal ruminants. Shortly after birth the smaller vessels posterior to the heart and in the caudodorsal lung fields should be clear. The heart, posterior vena cava, and aorta should be clearly defined. When the radiographic appearance of the lung fields is evaluated, the type of infiltrate (interstitial, nodular, alveolar, mixed), severity, and location (diffuse, cranioventral, caudodorsal) should be noted. Other soft tissue structures (including the heart, vessels, and diaphragm) and bones (ribs, vertebrae, long bones of the forelimb) should also be evaluated. Thoracic radiographs are routinely taken in the standing or lateral recumbent position in calves. Cranioventral consolidation is a common radiographic finding of infectious bronchopneumonia in calves. Radiographic changes may either follow or precede changes in clinical condition, and sometimes major changes can occur surprisingly rapidly. Clinical signs of pneumonia frequently resolve before the thoracic radiographs return to normal.

Ultrasonographic evaluation of the neonatal ruminant thorax is useful for identification of aspiration of amniotic fluid, atelectasis, pleural effusion, nonventilated lung, pleuritis, and chest wall abscesses, and for the detection of congenital heart defects. It appears most suitable for detecting pathologic processes close to the pleura.[53]

Respiratory endoscopy can be used for evaluation of the nasal cavity and septum, oropharynx and nasopharynx, epiglottis, larynx, and trachea. It is particularly useful for diagnostic evaluation of neonatal ruminants with respiratory stridor, stertorous breathing, malodorous breath or nasal discharge, inspiratory dyspnea, or related clinical signs indicative of upper airway problems.

Airway sampling is useful to determine presence, type, and etiology of respiratory inflammation and infection of neonatal ruminants. Deep pharyngeal swabs with a guarded catheter, transtracheal fluid aspirate, tracheobronchial lavage fluid, or bronchoalveolar lavage fluid analyses and cultures have been described. Techniques, sample handling, and interpretation are described in Chapter 31. For a neonate in respiratory distress, airway sampling may not be indicated until the patient is stabilized. Selection of the appropriate airway sampling method will depend on the patient condition and demeanor, supplies and equipment, test cost, technical assistance, clinician preference, anticipated etiology, sample handling, processing, and interpretation expertise. Specific airway sample, culture, PCR, ELISA, and other available tests for respiratory bacterial, *Mycoplasma, Chlamydia,* and viral pathogens are discussed in Chapter 31. Test-positive and test-negative predictive values may be improved when used for herd level testing, rather than for individual animal test interpretation.

Postmortem examination is a useful diagnostic tool for evaluation of respiratory conditions of neonatal ruminants. In addition to the examination of the upper and lower respiratory tract, brain, heart, gastrointestinal tract, immunologic sites, navel, other mucosal surfaces, and cavity fluids can provide information pertinent to a diagnosis. Lung culture, pathology, and immunohistochemistry (IHC) results can be particularly useful.

Upper Respiratory Tract Disorders

Conditions of the upper airway of neonatal ruminants are not common, but choanal atresia, stenotic nares, congenital cysts, cleft palate, pharyngeal trauma, pharyngeal and laryngeal edema, pharyngeal dysfunction, necrotic laryngitis, and tracheal collapse have been described. With the exception of necrotic laryngitis, most upper respiratory conditions of neonatal ruminants are present within the first week of life but may become progressive with age. Upper airway conditions, particularly those affecting pharyngeal and laryngeal function, predispose to aspiration pneumonia.

Diagnosis of most upper airway disorders can usually be made with a careful physical examination in combination with arterial blood gas concentrations, radiography, and/or endoscopy. Clinical signs of upper airway conditions include inspiratory effort, dyspnea, upper respiratory noise, stridor, malodorous nasal discharge, or cough. Dysphagia, poor appetite, milk reflux from the nostril, and aspiration pneumonia may be noted. Dyspnea is likely to result in failure to thrive and malnourishment.

Impaired pharyngeal and laryngeal function may result from physical deformation or neuromuscular disorders. Sporadic outbreaks of pharyngeal and laryngeal injuries are often associated with improper application or use of damaged feeding tubes and oral medication equipment. Compression of the larynx by a retropharyngeal abscess or mass tends to cause inspiratory dyspnea. Edema and necrosis of the larynx may be observed with infectious bovine rhinotracheitis virus infections in neonatal calves.[54,55] *Fusobacterium necrophorum* typically causes necrotic laryngitis in weaned calves but sporadically infects neonates following pharyngeal trauma.[56] Partial occlusion of the upper airway induces turbulent airflow and subsequently mucosal edema. Placement of a tracheostomy tube provides an alternative, sometimes life-saving, airway and rests the inflamed mucosa.

Nutritional myodegeneration and botulism may induce laryngeal paresis. Dysphagia and subsequent aspiration pneumonia are

VetBooks.ir

common sequela. Collapsed trachea is a rare congenital or acquired condition. In this condition, there is a dynamic dorsoventral collapse of the trachea during inspiration, but no stenosis is present. The caudal cervical and cranial thoracic sections of the trachea in the area of the thoracic inlet are most frequently affected. Acquired tracheal collapse is commonly associated with fractured ribs and compression of the trachea at the thoracic inlet by the bony callus that develops with healing. Clinical signs include an intermittent honking cough, stridor, and dyspnea with mild exercise. Treatment of collapsed trachea in the calf by surgical reconstruction has been attempted, but the prognosis is poor.[57-60]

Respiratory Infection

A number of respiratory disease syndromes may be observed in neonatal calves. Pneumonia in calves less than 5 days of age is most likely hematogenous in origin, a consequence of neonatal septicemia or aspiration pneumonia from inhalation of fetal fluid, meconium, colostrum, or milk as a complication of recumbency, obtunded mentation, large-volume forced feeding, large holes in teat nipples, poor esophageal tubing technique, or pharyngeal dysfunction (white muscle disease). Fever, cough, and nasal discharge are not consistently present in the early stages of pneumonia in the neonate. With hematogenous pneumonia, evidence of infection in other organs is frequently present, including omphalophlebitis, meningitis, enteritis, and polyarthritis. Without early and aggressive treatment, sepsis can progress to shock, multiple organ dysfunction, and death relatively rapidly. *E. coli* or other gram-negative bacterial organisms are incriminated most commonly. With aspiration pneumonia, a mixture of gram-positive, gram-negative, and anaerobic bacteria can be cultured from the lungs, inciting a severe inflammatory response, toxemia, and occasionally sepsis. For hematogenous and aspiration pneumonia, broad-spectrum antimicrobial coverage must be instituted early and be accompanied by antiinflammatory drug therapy, fluid therapy, nutritional supplementation, and supportive care. Long-term treatment is frequently necessary, and prognosis for survival is guarded.

Bacterial pneumonia of dairy calves, frequently described as affecting calves 2 to 6 months of age, may occur as early as 2 weeks of age and frequently peaks in incidence at 5 to 6 weeks of age. In bacterial pneumonia of calves, inhaled pathogens first colonize the bronchoalveolar junction, overcome host defenses, incite inflammation at that site, and go on to spread through the contiguous airways or through adjacent lung tissue. Pneumonia occurs as an endemic problem on many farms but can also occur as an outbreak. Frequently the problem is multifactorial, including bacterial organisms, individual, and farm or environmental risk factors.

Clinical signs of bacterial pneumonia in young calves usually include a combination of the following: fever, nasal discharge, lacrimation or ocular discharge, cough (spontaneous or inducible by tracheal compression), depression, reduced appetite, rough hair coat, expiratory effort, or an abdominal breathing effort. Concurrent signs of otitis may be noted. Subjective parameters like attitude, appetite, appearance, activity level, or respiratory character that are used to detect pneumonia on farms can be insensitive and delay the pneumonia diagnosis and treatment. Remote recording devices that monitor objective parameters such as core body temperature, activity levels and behavior, and frequency and volume of milk consumption are becoming more common and will improve farm pneumonia detection.

Bacterial agents are frequently the primary pathogens in calf pneumonia. Alone or in combination, *Mannheimia haemolytica, Pasteurella multocida, Mycoplasma bovis,* or *Mycoplasma dispar* are the most common bacterial isolates cultured from airway samples early in the infection. *Histophilus somnus* or *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) are found in more advanced pneumonia cases. Although any *Salmonella* species can cause pneumonia, *Salmonella* Dublin can be the cause of fulminating pneumonia in 1- to 8-month-old calves. Outbreaks of respiratory disease in this age group may be associated with mixed bacterial infections, including *M. bovis,* or with primary or concurrent viral infection with bovine respiratory syncytial virus (BRSV), bovine coronavirus (BCV), or bovine virus diarrhea virus (BVDV) infection. Viral infections increase the risk of opportunistic bacterial infections by their immunosuppressive effects and damage to the respiratory epithelium and pulmonary clearance mechanisms. Pleuritis is an uncommon feature of most neonatal respiratory infections but may be a manifestation of a generalized polyserositis with specific pathogens such as *Mycoplasma* infections of ruminant neonates[61] and occasionally *Pasteurella* infections in lambs.[62]

FPT of immunity is one of the most important risk factors for the development of calf pneumonia in individual animals and in herds. Poor nutrition is another risk factor for pneumonia in dairy calves that are limit-fed milk or milk replacer. A number of pathogens capable of causing respiratory disease are shed in milk. These include *Mycoplasma* spp.,[61,63,64] caprine arthritis encephalitis virus (CAEV),[65,66] and *S.* Dublin. The practice of feeding unpasteurized mastitic milk or nonsaleable milk to neonates increases the risk of disease transmission, including *S.* Dublin, an invasive host-adapted *Salmonella* serotype to cattle, and *Mycoplasma* spp. infections of goat kids and calves and CAEV to goat kids. CAEV produces a number of disease syndromes in goats, including mastitis, arthritis, encephalitis, and pneumonia. Encephalitis and subclinical respiratory disease typically occur in kids 2 to 4 months of age and occasionally in kids as young as 1 month of age.[65,67] Goat kids infected with *Mycoplasma mycoides* subsp. *mycoides* (large colony type) are often very painful, febrile, and reluctant to stand, and have multiple hot swollen joints from acute polyserositis. Approximately 50% of kids develop pneumonia or pleuropneumonia manifest by an increase in respiratory rate and auscultable lung sounds.[61] Outbreaks of mycoplasma pneumonia in calves are usually caused by feeding waste milk contaminated with *M. bovis*.[68,69] Clinical signs include an increased rate and effort of breathing associated with pneumonia, joint and tendon sheath distention reflecting arthritis, polyserositis, tenosynovitis, auricular discharge, and a head tilt reflecting otitis media/interna[63,69] and decubital abscesses.[70] Clinical signs associated with *Mycoplasma* otitis include cranial nerve (CN) 7 and 8 deficits, unilateral or bilateral ear droop, ptosis, epiphora, head tilt, and recumbency in severely affected calves. Pasteurization of milk fed to goat kids and calves is recommended.

Additional environmental risk factors for pneumonia include extremes of temperature, poor ventilation, dust, ammonia, and overcrowding. Overcrowding, especially with commingled age groups of calves, creates a high risk for pneumonia. Housing factors associated with reduced respiratory disease prevalence in naturally ventilated dairy calf barns are solid panels between calves that prevent contact, deep bedding, and low airborne bacterial counts.[71] A minimum space requirement of 28 to 30 ft^2 per calf is associated with low airborne bacterial counts and less respiratory disease for calves in individual and group pens. Increased time between successive occupants of individual or group calf pens reduces the environmental exposure to disease organisms. An all in–all out housing system on farms reduces the chance for endemic pneumonia problems. Other risk factors for pneumonia include poor-quality feed, limited availability of water, stress, inappropriate medications, over-vaccinating, parasitism, and concurrent infection.

Herd-based pneumonia problem solving is needed where respiratory disease in calves is endemic. Routine calf care, herd vaccinations, navel care, colostrum feeding, feed types, amounts, times, and additives are important. Practitioners must learn the pneumonia definition, screening method, and treatment protocols, as well as review records to find seasonal trends, relationship to passive transfer of immunity, age at first diagnosis, and related management factors. Survival curves and incidence calculations can be useful. Practitioners should observe people and procedures and examine animals, as well as determine how many current cases have been detected and treated. Successful management of endemic pneumonia problems requires early detection, effective treatment, and resolution of the most important risk factors.

VetBooks.ir

For treatment consideration, many antibiotics are labeled for BRD. Treatment plans for individual animals or farm protocols should be based on valid diagnostic information, recent examinations, and responsible use of antibiotics. Compliance with prescribed dose, route, and frequency of administration is factored into antibiotic selection. For one-dose respiratory treatment protocols, enrofloxacin, tulathromycin, ceftiofur, florfenicol, gamithromycin, or tildipirosin may be considered. For antibiotics like spectinomycin, enrofloxacin, ceftiofur, and florfenicol, multiple-dose treatment protocols are also effective for BRD.

Mycoplasmas are susceptible to antimicrobial agents that affect DNA, RNA, protein synthesis, or the integrity of the cell membrane. Mycoplasmas are not susceptible to agents that interfere with synthesis of folic acid or that act on the cell wall. Tylosin, tetracyclines, erythromycin, tilmicosin, tulathromycin, gamithromycin, florfenicol, aminoglycosides, and fluoroquinolones have been shown to have activity against one or more *Mycoplasma* species.[72] However, the efficacy of antimicrobial therapy to eliminate the organism is limited and, although animals may recover, chronic infections may persist.[73]

Prevention of neonatal ruminant respiratory conditions includes appropriate vaccination programs, frequent observation of adults and neonates, uncomplicated births, adequate colostrum, navel care, optimal nutrition, and housing that is clean, dry, and draft free.

Neonatal Apnea and Irregular Breathing Patterns

Periods of apnea in the neonate are commonly associated with nonrespiratory factors, including infection, CNS disorders, hypothermia, and metabolic causes such as hypoglycemia. Seizure activity may be expressed by changes in breathing rate and pattern, and neonatal asphyxia may induce respiratory depression, whether or not cerebral lesions are present.[74] Neonatal respiratory distress may also cause apnea resulting from respiratory center depression or diaphragmatic fatigue. There are two mechanisms of apnea: central apnea, resulting from cessation of diaphragmatic activity, and obstructive apnea, resulting from obstruction of the airway, usually at the pharyngeal level.

Abdominal Distention

Geof W. Smith

Ruminal Bloat

Ruminal bloat is uncommon in calves less than 5 weeks of age because of the relatively undeveloped state of the neonatal rumen. Causes of ruminal bloat in calves include ruminal putrefaction, obstruction of the cardia or esophagus, and vagal indigestion (Box 20-3).

If milk arrives in the rumen in greater quantities than normal by escaping the esophageal groove, it can be subjected to putrefactive decomposition by proteolytic bacteria. Normally the rumen of neonatal calves has a stable aerobic bacterial population. Anaerobic conditions are rapidly established when appreciable amounts of fermentable substances enter the rumen.[75] Clinical signs include diarrhea, poor development, rough haircoat, and recurrent bloat. Reducing the volume of milk fed per feeding, feeding from nipples rather than buckets, and introducing calf starter to promote ruminal development help prevent the condition. A course of oral antibiotics (500 mg oxytetracycline) once daily for 3 or 4 days may help affected calves by killing the putrefactive gut flora.

Bloat is occasionally observed as a complication of severe bronchopneumonia in calves as a consequence of swollen mediastinal lymph nodes compressing the esophagus or compression or inflammation of the vagus.[76] Relief of rumen distention is important for return of rumen function. Chronic ruminal bloat may be relieved by placement of a rumen fistula (Buff's screw trocar). Correct placement of the screw, as described by Dirksen and Garry,[77] reduces the risk of inducing peritonitis. The rumen must be bloated so that it lies firmly against the body wall as the trocar is screwed into place. The site for the trocar is shaved and scrubbed, a small skin incision is made, and the trocar is quickly and forcefully screwed into the belly wall and rumen. After removal of the stylet, the outer rim of the trocar is kept under constant outward tension so that the ruminal wall is held tightly against the parietal peritoneum by the last ridge of the screw. To fix the trocar in this position, gauze soaked in antibiotic should be wrapped around the stem of the trocar between the outer rim and the body wall.[77]

BOX 20-3

Causes of Abdominal Distention

Obstruction

Foreign body (hairballs in calf)
Malformation (atresia coli, recti, ani)
Intussusception
Volvulus, torsion or strangulation

Uroperitoneum

Ruptured bladder (uncommon)
Torn or necrotic urachus, ureter

Peritonitis

Generalized infection
Devitalized bowel
Perforated gastric or intestinal ulcer
Severe umbilical infection

Gas and Fluid Accumulation in Abomasum, Intestinal Tract

Abomasal bloat
Abomasal torsion
Intolerance to diet
Ileus
Gastric, abomasal, duodenal ulceration
Necrotizing enterocolitis
Ruminal bloat

Miscellaneous

Hemoperitoneum
Ruptured umbilical vessels
Ruptured spleen or liver
Congenital tumor

Ascites

Severe liver or renal failure
Severe hypoproteinemia

Abomasal Ulcers

Abomasal ulcers are usually asymptomatic in young calves, but if perforation occurs, peritonitis and shock rapidly develop. It is often difficult to determine the underlying cause of abomasal ulcers; however, several possibilities have been identified including trauma to the mucosa from the addition of coarse roughage feeds, pica resulting from enteritis, abomasal bezoars, environmental and physical stress, hyperacidity, vitamin E deficiency, lactic acidosis, mycotic infection, and low immune status associated with copper deficiency.[78] Several bacteria including *E. coli* and *Sarcina* and *Clostridium* species have also been isolated from various calves with ulcers; however, no infectious component has been identified in cattle, unlike in humans, where *Helicobacter pylori* and gastric ulcers routinely occur together.

Four categories of ulcers are described in calves:

Type 1: Nonperforating ulcer—The ulcer does not perforate the abomasal wall, and intraluminal hemorrhage is minimal.

VetBooks.ir

Type 2: Nonperforating ulcer with severe blood loss—The ulcer does not perforate the abomasal wall, but erodes a major vessel in the submucosa, resulting in severe intraluminal hemorrhage.

Type 3: Perforating ulcer with local peritonitis—The ulcer perforates the abomasal wall, and abomasal contents leak into the peritoneal cavity or omental bursa. Peritonitis is localized by fibrin deposition, and the abomasum becomes adhered to the peritoneum, omentum, or surrounding viscera.

Type 4: Perforating ulcers with diffuse peritonitis—The ulcer perforates the abomasal wall and abomasal contents quickly leak into and spread throughout the peritoneal cavity, resulting in diffuse peritonitis.[78]

Abomasal ulcers can be very difficult to diagnose antemortem in calves. Clinical signs are vague and include sudden death, abdominal distention, pain on abdominal palpation, expiratory grunt, drooling saliva, bruxism, and melena. Less commonly a syndrome of chronic abdominal pain is observed after abomasal perforation.[79] Absence of inflammatory changes suggests the gut is unlikely to be perforated or necrotic. Severe hypoproteinemia is common with diffuse peritonitis presumably because of the combination of poor colostral uptake and loss of protein into the abdominal exudate. Obtaining peritoneal fluid from normal calves is difficult; if peritonitis is suspected, collection of abdominal fluid is facilitated by locating pockets of peritoneal fluid via abdominal ultrasound.

In general, treatment is limited to calves with bleeding or deep, nonperforated ulcers. Therapy can include blood transfusions, antibiotic administration, changes to the diet, oral administration of antacids, and administration of histamine type 2 receptor antagonists. Aluminum hydroxide/magnesium hydroxide ($Al(OH)_3$/$Mg(OH)_2$) antacids neutralize acid in the abomasum and require three doses per day. Antacids are an inexpensive option for treatment of cattle with ulcers and have a potential therapeutic advantage. $Al(OH)_3$ directly absorbs pepsin, thus decreasing the proteolytic action of pepsin in the stomach.[80] Also, $Al(OH)_3$ and $Mg(OH)_2$ bind bile acids, thus protecting against ulceration caused by bile reflux.[80] Ahmed and colleagues[81] found that healthy calves given 25 to 50 mL of oral antacid had a transient increase in abomasal luminal pH. This effect appeared to be dose related and the extent of the acid neutralization was increased when not given with milk replacer.

Histamine type 2 receptor antagonists reduce acid secretion of parietal cells by selective and competitive antagonism of histamine at H2 receptors on the parietal cells. Cimetidine and ranitidine are synthetic H2 antagonists that inhibit basal as well as pentagastrin- and cholinergic-stimulated gastric acid secretion. Daily oral administration of cimetidine at 10 mg/kg for 30 days in veal calves was found to aid healing of abomasal ulcers.[82] Oral administration of cimetidine (50 to 100 mg/kg q8h) and ranitidine (10 to 50 mg/kg, q8h) caused a dose-dependent increase in abomasal luminal pH; and ranitidine had greater potency than cimetidine.[83] Omeprazole, a proton pump inhibitor, has also been studied in calves. Once daily oral administration of omeprazole (4 mg/kg) to calves increased the mean 24-hour luminal pH by 1.3-pH units; however, this increase in pH was less pronounced with subsequent daily treatments.[84]

Surgical repair of ulcers can be performed on selected cases. Calves need to be in an operable condition and have isolated ulcers. Surgery needs to be performed early in the disease process. Typically ulcers are diagnosed during a laparotomy and can be either resected or the serosa can be inverted with a mattress suture. One study reported a survival rate of 74% following surgical repair, with survival being defined as calves living at least 3 months past surgery date or those dying because of another disease.[85]

Abomasal Displacement

Abomasal displacement is rare in neonatal ruminants. Clinical signs include reduced appetite, poor weight gain, recurrent tympany (left side), and diarrhea. An association of left-sided abomasal displacement with pneumonia in calves suggests that altered vagal function may be involved in the pathogenesis of the condition.[86,87] Typically, left-sided abomasal displacement in calves occurs between 6 and 14 weeks of age, but younger calves may be affected. Displacement of the abomasum is diagnosed by auscultation and percussion; affected animals may have a hypochloremic metabolic alkalosis. Correction can be attempted by rolling the calf on its back or via surgery.

Abomasal Bloat

Acute abdominal distention, colic, depression, and sudden death have been reported in neonatal calves with abomasal ulcers, abomasitis, and abomasal bloat. Possible sequelae to abomasal dilation include abomasal torsion, perforation, and rupture. Abomasal bloat is a syndrome in young calves characterized by anorexia, abdominal distention (either left sided or bilateral), and often death in 6 to 48 hours. At necropsy most of these calves will exhibit abomasal tympany, forestomach and abomasal edema, hemorrhage, mucosal necrosis, and occasionally mural emphysema. This condition occurs most commonly in dairy calves and seems to have a sporadic occurrence with some farms having multiple outbreaks at times. Numerous causes have been postulated, including dietary changes, in particular the addition of coarse roughage feeds; abomasal bezoars; copper deficiency; and various microorganisms. Roeder and colleagues[88] isolated *C. perfringens* type A from a group of eight calves affected by this syndrome and subsequently experimentally reproduced the disease by intraruminal inoculation of the organism.[89] *Campylobacter* and *Sarcina* species have been incriminated in other studies. Histopathologic evaluation of abomasums from 38 affected calves at necropsy revealed that 31 contained abundant gram-positive bacteria associated with the damaged abomasal mucosa.[90] *Campylobacter*-like organisms were demonstrated in 9 and *C. perfringens* in 14 of the 38 cases.[90] Studies of range cattle in west-central Nebraska and Wyoming suggest subclinical trace mineral deficiencies of copper and/or selenium may be involved in the pathogenesis of the condition in this region.[91]

Recently the abomasal bloat syndrome was experimentally reproduced by drenching young Holstein calves with a carbohydrate mixture containing milk replacer, corn starch, and glucose mixed in water.[92] The authors of this study proposed that the pathophysiology of abomasal bloat is primarily related to excess fermentation of high-energy gastrointestinal contents. Although the exact pathogenesis of abomasal bloat is not completely understood, the disease is likely to be multifactorial in origin. Having large amounts of fermentable carbohydrate present in the abomasum (from milk, milk replacer, or high-energy oral electrolyte solutions) along with the presence of fermentative enzymes (produced by bacteria) would likely lead to gas production and bloat.[93] This process would be exacerbated by anything that slows abomasal emptying or causes gastrointestinal ileus. Risk factors for abomasal bloat that potentially delay abomasal emptying include high osmolality milk replacers, feeding a large volume of milk in a single daily feeding, poor mixing of milk replacers, offering cold milk (or milk replacer), not offering water to calves, and allowing erratic feeding schedules. Thus, control of abomasal bloat should be aimed at dietary management more so than therapeutic or prophylactic medications.

Clinical signs are often mild and may inconsistently include diarrhea, mild abdominal distention with fluid and gas, splashing on abdominal succession, and mild depression. Hyperglycemia (189 to 516 mg/dL) with an accompanying glucosuria (1000 to 2000 mg/dL) consistently develop. In severe cases the calves are usually dehydrated and colicky and have prominent abdominal distention and diarrhea and become recumbent. Gross lesions include hemorrhage, edema, and necrosis of abomasal and ruminal mucosae.

Treatment generally involves placing the calf in dorsal recumbency and inserting a needle or catheter into the abomasum to relieve the gas.[94] Attempting to deflate the bloat in a standing calf is often unrewarding since it generally fails to completely drain the abomasum and carries a high risk of inducing peritonitis.[95] Kumper[96] describes good results with paracentesis using a 14-gauge, 50-mm needle when the calf is turned upside down and the abomasum is deflated by inserting a needle in the highest point of the distended

VetBooks.ir

abdominal wall between the umbilicus and xiphoid. With this technique, 20 of 21 calves with abomasal tympany were successfully managed without complications. Repeated paracentesis carries a high risk of inducing peritonitis; if after paracentesis the calf's condition deteriorates or tympany recurs, a right flank laparotomy is performed to correct a possibly torsed abomasum.[96] Intravenous fluids are administered to correct dehydration, electrolyte, and metabolic derangements. Antibiotic therapy may also be indicated in these calves (most likely parenteral procaine penicillin or oral β-lactam antibiotics to target *Clostridium* bacteria).

Abomasal bloat is a significant problem in artificially raised lambs. Feeding systems that allow lambs to drink large quantities of milk replacer at infrequent intervals and housing lambs on litter are predisposing factors.[97,98] Proliferation of *Lactobacilli, E. coli,* and *C. perfringens* has been implicated in the disease process.[98,99] Fermentation of sugars contained in milk replacer produces carbon dioxide distending the abomasum.[100] Lambs may die within hours because of acute abdominal tympany compromising vascular return and respiration. Early treatment of bloated lambs with oral doses of antibiotics is sometimes an effective treatment. Addition of 0.1% formalin (37% formaldehyde) to milk replacer reduces the incidence of the condition.[99]

Intestinal Atresia

Intestinal atresia is the most common cause of abdominal distention of calves in the first week of life.[79] Typically calves are born normally but develop progressive abdominal distention shortly after birth. Signs of mild colic are occasionally observed. The spiral loop of the ascending colon is usually the site of atresia.[101] Other congenital abnormalities may be present (18% of cases).[101] Pregnancy diagnosis by palpating the amniotic sac before 40 days of gestation may cause colonic atresia in cattle[102]; however, an autosomal recessive inheritance in Holstein cattle has recently been proposed.[103] Surgical repair by resection of the distended proximal blind end and anastomosis of the proximal segment of intestine to the descending colon have been described, but breeding affected animals is not recommended.[101] Long-term survivors are likely to have loose feces and do not tend to grow well.[101]

Intussusception

Intussusception occurs most commonly in the jejunum, but the frequency of ileocecal and colon intussusceptions appears higher in calves than adults.[104] Commonly there is a history of diarrhea. Clinical signs may include intermittent colic, absence of feces, and melena; however, these are inconsistent. The inconsistency of clinical signs and inability to perform a rectal examination makes the diagnosis more difficult in calves than adults.[104] Abdominal ultrasound may be useful. The prognosis following surgical correction is strongly influenced by the duration of the condition prior to correction.

Twisting of the intestinal mass around the cranial root of the mesentery is a rare event but occurs more frequently in calves than adults.[104] Clinically the condition is characterized by a sudden onset of severe colic (kicking at the abdomen, dropping to the ground) that rapidly progresses (abdominal enlargement, tachycardia, tachypnea, reduced or absent fecal passage) to signs of shock and recumbency. Early diagnosis and rapid surgical correction, using either a right paralumbar or ventral midline, together with a supportive fluids approach allow for a good prognosis.

Neonatal Diarrhea

Matthew Izzo • Alison A. Gunn • John K. House

Herd management variables that impact the risk of neonatal death losses in housed calves include efficiency of passive transfer, calf nutrition and environmental management (pathogen exposure), calving area sanitation, and cow vaccination status and health. Successful calf rearing is based on good management. A goal of less than 5% death loss from diarrhea is achievable. With neonatal death losses in pasture or range animals, it is important to determine the incidence of dystocia, physical management and nutritional status of the calving and nursing herds, the cleanliness of the calving and nursing areas, the provision of shelter from wind, and any biosecurity risks.

Rotavirus, cryptosporidia, coronavirus, enterotoxigenic *E. coli,* and *Salmonella* are recognized as the major pathogens associated with diarrhea in calves (Table 20-6). Rotavirus, cryptosporidia, coronavirus, and enterotoxigenic *E. coli* are common pathogens in beef calves (Fig. 20-1).[105-108] *Salmonella* is more frequently implicated in intensive calf rearing systems.[107-109] Enteropathogenic strains of *E. coli* are occasionally implicated in calf diarrhea; the true prevalence of disease associated with these strains is unknown due to the lack of routine definitive diagnostic tests. Torovirus has recently been associated with neonatal calf diarrhea (NCD) in Canada, the United States, and Europe.[110-113] Bovine virus diarrhea is infrequently associated with diarrhea in young calves.[114,115] A variety of other agents have been implicated as causes of neonatal diarrhea, but their importance in the field situation is unknown (see Table 20-6). The incidence of the various etiologic agents varies with the age of the calf, and this is useful in establishing the likelihood that a particular agent is involved (Fig. 20-2). It is usually impossible to make a definitive etiologic diagnosis on clinical grounds. It is possible to detect signs of straining or passage of frank blood and mucus that suggest the presence of colitis, implicating possible salmonella, coronavirus, BVDV, enteropathogenic *E. coli,* or coccidial infections.

Pathogenesis

Diarrhea can be the result of either increased secretion or decreased absorption. Bacteria such as enterotoxigenic *E. coli* and, to some extent, *Salmonella* cause neonatal diarrhea by secreting enterotoxins that stimulate increased intestinal secretions.[116,117] These changes are thought to be mediated by cyclic AMP or cyclic GMP, calmodulin, and changes in protein kinase activity.[118,119] The cell's structure is not affected, but the activity of the membrane pumps is altered and there is increased secretion of chloride, sodium, bicarbonate, and potassium.[120,121] Heat-stable enterotoxin induces bicarbonate secretion through the tyrosin kinase pathway.[121] Sodium absorption linked to glucose and amino acid transport across the mucosal epithelium is not affected.[122,123]

Protozoa and enteric viruses cause neonatal diarrhea as a result of the destruction of the absorptive villous epithelial cells.[124-127] Diarrhea results because intestinal digestive secretions continue while absorption is impaired.[128,129] In rotavirus and coronavirus infections, this is further exacerbated by compensatory hyperplasia of the crypt cells. The crypt cells have secretory functions and their multiplication adds to the secretory load.[128] Rotavirus can also stimulate intestinal secretion both at a cellular level and by stimulation of the enteric nervous system. This is associated with a viral nonstructural protein NSP4.[130,131]

Continued feeding may result in more nutrients presented to the small intestine than the damaged villi can absorb[132,133]; excess nutrients being fermented in the large intestine promoting bacterial overgrowth[118,134]; and generation of organic acids and other deleterious compounds. The osmotic effect of the unabsorbed nutrients drags water into the gut and contributes to the diarrhea.[128] Marked inflammation is a feature of salmonellosis and clostridiosis. This contributes to diarrhea by increasing mucosal pore size and hydraulic pressures within the intestinal wall by destroying absorptive cells and increasing prostaglandin production, which in turn stimulates secretory mechanisms within the enterocytes.[118,128]

On an individual animal basis, diarrhea is significant because of fluid and electrolyte losses. As long as the neonate can compensate for these losses, it will remain fairly bright and continue to suck. If the losses exceed intake, systemic effects of dehydration (salt and water loss) or acidosis are seen. Fluid is lost preferentially from

the vascular compartment[135,136] and cardiovascular collapse results. Acidosis has several causes including fecal loss of bicarbonate, endogenous synthesis of L-lactic acid in response to dehydration and poor tissue perfusion, and D-lactic acid production through bacterial fermentation of undigested or malabsorbed milk within the gastrointestinal tract.[137-142] Acidosis contributes to the calf's malaise by increasing vascular resistance and impairing cardiac function by direct effects and by inhibiting the action of catecholamines. Esophageal groove function may be compromised in acidotic calves, promoting ruminal drinking with the consequences of further production of D-lactic acid in the rumen and subsequent ruminal acidosis.[142,143]

The neonate becomes depressed, loses its suck reflex, and becomes weak; if the disease progresses, recumbency and coma may develop. One cause of death is believed to be heart failure as a result of

VetBooks.ir

myocardial potassium imbalance caused by the combined effects of potassium losses into the gastrointestinal tract and the redistribution of potassium from the cells to extracellular fluid as a result of acidosis.[144-146] Hypothermia will also contribute to cardiac failure. In cases of enterotoxigenic *E. coli,* cryptosporidia, rotavirus, and coronavirus infections, correcting the fluid, electrolyte, and acid-base imbalances restores the neonate's ability to walk and suck. A residual degree of malaise may persist, which can be attributed to inflammation within the gut wall and damage to the integrity of the mucosal barriers, allowing invasion of enteric microbes or their toxins. If malabsorption persists, cachexia can develop—particularly if milk continues to be withheld as part of therapy—and death from malnutrition or hypoglycemia may occur.

Salmonella are invasive and release endotoxins in the systemic circulation. Clostridia produce exotoxins. Both endotoxins and exotoxins have profound systemic effects that are often directly responsible for malaise, microcirculatory failure, and cardiovascular collapse. Correcting fluid and electrolyte disturbances in these infections will aid the neonate but will not overcome the effects of toxemia or bacteremia.

Etiology

Bacteria

ESCHERICHIA COLI. *E. coli* are part of the normal flora of the bovine gastrointestinal tract. Pathogenic strains of *E. coli* possess virulence attributes that are involved in the pathogenesis of disease. Virulence attributes include adhesins, enterotoxins, and cytotoxins. Pathogenic strains of *E. coli* may be shed by adult cattle with transmission to neonates by the fecal-oral route. Sick neonates amplify environmental contamination via prolific fecal shedding.

ENTEROTOXIGENIC *E. COLI*. Enterotoxigenic *E. coli* (ETEC) possess two virulence factors: fimbriae (pili) and enterotoxins. F5 (K99) and/or F41 fimbriae mediate adherence and thermolabile (LT) and thermostable (STa and STb) enterotoxins stimulate a secretory response by intestinal crypt cells. Although some bovine-origin ETEC produce LT, most strains that cause diarrhea in neonatal calves produce STa heat-stable enterotoxins.[147] The STa enterotoxin and F5 antigen are plasmid-mediated virulence factors. Susceptibility to ETEC is age dependent according to the binding specificity of pili antigens to immature enterocytes.[148] Disease is typically observed in calves less than 3 days of age; however, concurrent infection with rotavirus may extend this window to 7 to 14 days of age.[149,150] Intestinal cells of calves greater than 2 days of age acquire natural resistance to F5 adhesion.[148] Despite this, F5-positive *E. coli* have been isolated from healthy 4- to 12-week-old calves and F5-positive ETEC are shed in feces for several weeks following experimental infection of newborn calves.[151]

ATTACHING AND EFFACING *E. COLI* AND SHIGA TOXIN–PRODUCING *E. COLI*. Attaching and effacing *E. coli* (AEEC) and Shiga toxin–producing *E. coli* (STEC) have also been identified as causes of diarrhea and dysentery in calves.[152,153] Disease is mediated by cytotoxic damage to the intestinal mucosa. Lesions may be observed in the ileum, cecum, and descending colon.[154] AEEC (Vero or HeLa toxin producing) induce a mucohemorrhagic colitis, with petechial or ecchymotic hemorrhages in the wall of the colon and rectum.[155-157] *E. coli* that carry this toxin often belong to O serogroups 5, 26, 111, 118, and 145.[156,158] Naturally occurring outbreaks have been reported in 2-day-old to 4-week-old calves.[159] Diarrhea and enteritis have been associated with naturally occurring *E. coli* O157:H7 in 1- to 3-week-old calves in Argentina, the United Kingdom, and Korea.[160-162] The most common clinical sign is diarrhea, but dysentery, dullness, reluctance to move, weight loss, anorexia, abdominal pain manifested by bruxism, and dehydration are seen in some cases. The feces of affected calves can appear normal, but more commonly feces are watery yellow with blood.

STEC serotypes associated with dysentery in calves include O5:H-, O26:H11, O111:H-, and O113:H21[163]; these serotypes may produce Shiga toxins, those that are immunologically similar to the Shiga toxin produced by *Shigella dysenteriae* (Stx1), and those that are immunologically distinct from *S. dysenteriae* Shiga toxin (STx2).[164] Bovine STEC produce either STx1, STx2, or both.[165] AEEC, which causes disease and does not produce enterotoxins or Shiga toxin, is referred to as enteropathogenic *E. coli* (EPEC).

The prevalence of AEEC and STEC in calves and the incidence of disease caused by these strains are not clearly defined, since most diagnostic laboratories do not routinely screen for AEEC and STEC. In a study aimed at determining the clinical significance and prevalence of AEEC *E. coli* in Swiss cattle,[165a] fecal swabs of 93 cattle from two farms with calf diarrhea, and of 54 cattle from two similar farms without clinical problems, were screened for AEEC by PCR and colony-blot hybridization. On average, 21% of all cows were positive for AEEC by PCR, without differences between farms with and without diarrhea problems. By contrast, AEEC were detected by PCR in 60% of animals younger than 2 years from farms with diarrhea problems, whereas only 32% of comparable control animals from farms without clinical problems had AEEC.

The importance of AEEC and STEC has increased in recent years because of the zoonotic potential of the organisms. Cattle are a major reservoir of STEC and EHEC, including *E. coli* O157:H7, which is the EHEC serotype most often associated with hemorrhagic colitis and hemolytic uremic syndrome in humans.[162,166]

SALMONELLA. There are over 2200 reported serotypes of *Salmonella*, yet fewer than 2% of these account for approximately 80% of the disease reported in livestock[167] (see also Chapter 32). In cattle, over 95% of salmonella associated with disease is in serogroups B, C, D, and E. *Salmonella* induces a wide spectrum of disease in cattle of all ages, ranging from inapparent subclinical infections to acute fulminant bacteremia, endotoxemia, and death. The variable manifestations of disease reflect the tissue trophisms of different *Salmonella* serotypes and the influence of challenge dose and host immunity. Common clinical signs associated with "salmonellosis" include fever, diarrhea, anorexia, depressed mentation, and dehydration. Many of the clinical signs are associated with endotoxemia. Systemic signs of endotoxemia include fever, tachypnea, tachycardia, scleral injection, leukopenia/leukocytosis, and weakness. Some serotypes, particularly *Salmonella* Typhimurium, have a tendency to induce severe inflammation of the bowel mucosa resulting in dysentery, and passage of fibrin and mucosal casts. Fluid, electrolyte, and protein loss may progress rapidly and become life threatening if not corrected. With severe disease, animals rapidly become emaciated because of the catabolic state induced by release of TNF-α. Sequelae occasionally observed following invasive *Salmonella* infections in neonates include septic osteoarthritis and meningitis.

Immunity to *Salmonella* changes rapidly during the first 3 months of life. At 2 weeks of age the LD_{50} for some virulent strains is 10^5,[168] at 6 to 7 weeks 10^7, and at 12 to 14 weeks 10^{10}.[169] In contrast, administration of 10^{10} salmonella to 24- to 28-week-old calves failed to induce clinical signs of disease.[169] The numbers cited reflect the influence of age on immunity but should not be interpreted as absolute. Different age predilections, manifestations of disease, and virulence are observed between *Salmonella* serotypes and between different strains of the same serotype.[170,171] Although adults may serve as carriers and a source of infection of *S.* Dublin infection for neonates, disease in adults is less common in mature cattle compared with calves. In contrast, *S.* Typhimurium tends to manifest disease in an epidemic manner, causing illness in all age groups.

Calves on endemically infected farms are commonly exposed to *Salmonella* in the first few days of life.[172] *Salmonella* exposure may occur via contaminated colostrum or milk, or surface contamination of teats and udder, personnel, equipment, or the environment. Chronically infected carriers may shed 2.5×10^8 salmonella in milk per day (25 kg of milk containing 10^5 salmonella/mL).[173] Feeding utensils and personnel often play a significant role in transmitting

VetBooks.ir

Salmonella among calves.[174] *Salmonella* infects the salivary glands and is shed in saliva and nasal secretions.[175,176] Adequate cleaning and disinfection of feeding and medicating utensils is necessary to remove *Salmonella* contamination. *Salmonella* is sensitive to most disinfectants, but removal of contaminating organic debris is imperative since the activity of disinfectants is reduced by the presence of organic matter.[177]

CLOSTRIDIA. Although clostridia are not commonly considered a major pathogen causing NCD, there are a number of reports associating clostridial infections with enteritis and abomasitis.

Clostridium perfringens is the most important cause of clostridial enteric disease in calves. Some types of *C. perfringens* (mainly type A) are consistently recovered from the intestinal tracts of animals and from the environment, whereas others (types B, C, D, and E) are less common in the intestinal tracts of animals and can occasionally be found in the environment in areas where disease produced by these organisms is enzootic[178] (see also Chapter 32). Disease is usually precipitated by management factors that lead to the proliferation of the organism within the gastrointestinal tract or attenuated digestion of clostridial toxins within the lumen of the alimentary tract.

C. perfringens type A has been associated with acute hemorrhagic abomasitis in neonatal calves. Clinical signs include acute abdominal distention, colic, depression, and sudden death. Onset of clinical signs is rapid; affected animals become anorexic, depressed, or restless. Signs of abdominal discomfort are observed in approximately half of the cases and include treading on the spot and kicking at the abdomen. On physical examination splashing and metallic sounds are heard on succussion of the distended abdomen; passage of a stomach tube fails to relieve the distention. Fecal output is reduced and melena may be observed. Gross pathology may include abomasal ulcers, abomasitis, and abomasal tympany.[88,89] Trace mineral deficiencies of copper and/or selenium may also be involved in the pathogenesis of the condition.[91] A decreased prevalence of abomasal tympany and ulceration were reported in neonatal calves from herds having a history of these problems following implementation of a *C. perfringens* vaccination program.[91,179] Enterotoxemia caused by *C. perfringens* type A has been described in 2- to 4-month-old calves with the condition observed more often in beef calves than dairy calves.[180] The disease is characterized by a high-case fatality rate, sudden deaths, lesions of necrotic and hemorrhagic enteritis of the small intestine, and, most often, an absence of other clinical signs.[181]

C. perfringens type B is not commonly associated with neonatal diarrhea in calves. *C. perfringens* type C infections are most frequently observed in neonates less than 10 days of age.[182] Newborn animals are typically most susceptible, perhaps because of ready colonization of the gut by *C. perfringens* in the absence of well-established normal intestinal flora.[178] Alteration of the flora by sudden dietary changes may also be an inciting factor in type C infections. Vigorous, healthy calves develop hemorrhagic, necrotic enteritis and enterotoxemia, often accompanied by evidence of abdominal pain and neurologic signs that may include frenzied bellowing, aimless running, tetany, and opisthotonos. Death may be peracute, occasionally without other clinical signs, but may also follow a clinical course of several days.

Clostridium difficile has recently emerged as a pathogen in both human and veterinary medicine. Toxins released cause epithelial cell death and activation of the enteric nervous system, resulting in a malabsorptive and secretory diarrhea.[183] The role of *C. difficile* as a primary pathogen has not been established because it has been detected in both healthy and diarrheic calves[184] and experimental infection has not induced disease.[185]

***CAMPYLOBACTER* SPP.** The clinical significance of *Campylobacter* spp. in calf scours is inconclusive. *Campylobacter* spp. are part of the normal intestinal flora. Experimental challenge studies have demonstrated the capacity of *C. jejuni* to cause enteritis in calves.[144,186-188] However, there is a paucity of convincing reports that demonstrate a causal association in naturally occurring cases.

Viruses

Intestinal viruses multiply within enterocytes. As the epithelial cells are destroyed, villous atrophy develops. The various agents cannot be readily separated on clinical grounds. Diarrhea can vary in severity from soft to watery feces.

ROTAVIRUS. Rotaviruses are the most common cause of neonatal diarrhea in calves.[189,190] Affected calves are generally 5 days to 2 weeks of age, although disease can occur at 24 hours, particularly in colostrum-deprived calves (see Fig. 20-2).[191,192] This age predilection is thought to be because many cows secrete anti-rotavirus antibody in their colostrum, which confers local protection against rotavirus attack until antibody levels in milk decline 48 to 72 hours postpartum.[193,194] Resistance to infection is not age dependent, but age-dependent resistance to clinical disease has been demonstrated.[195] Age restriction may be related to acquired immunity, since neutralizing antibodies increase with age and virus exposure. In addition, the expression of intestinal mucins and the rate of epithelial cell replacement and fluid absorption are also age dependent and have been shown to affect rotavirus infection and disease expression.[196]

Mature villous enterocytes of the small intestine are the main target for rotavirus.[127] Infected enterocytes are rapidly shed and replaced with immature squamous and cuboidal cells from the crypts, resulting in villous blunting.[127,197] Intestinal secretions are increased due to the compensatory hyperplasia of crypt cells and enterotoxigenic activity of the viral nonstructural protein NSP4.[130,131] Both increased secretory load and impaired absorption caused by villus hypoplasia contribute to the diarrhea. It is thought that virulent strains replicate more quickly and infect a larger area of epithelium. Difference in rotavirus replication rates in the gut and age-dependent differences in the rate of enterocyte loss and natural replacement rate may explain the differences in clinical outcome. Concurrent infection with ETEC has also been shown to cause clinical signs at a later age than with a single infection of either agent alone.[198]

Rotavirus of calves, lambs, kids, pigs, foals, mice, and children are morphologically identical. They are classified by the antigenic properties and/or sequence of the genes encoding the viral capsid proteins. Viral protein (VP) 6 is used to separate them into seven antigenically distinct serogroups A-F. Rotaviruses from serogroups A, B, and C have been isolated from cattle, and serogroup A is the most common cause of diarrhea in calves. Group B rotaviruses have been isolated from calves and adult cattle; however, there is less information regarding their significance and prevalence in cattle.[199-203] Group B rotavirus are more common in lambs than calves.[204] Group C rotavirus have only been isolated from adult cattle.[202] Each serogroup may be classified further by G-types (glycoprotein) and P-types (protease-sensitive protein) that correlate to the serotype and/or genotype of capsid proteins VP7 and VP4, respectively.[205] A range of both serotypic and genotypic diversity and virulence has been reported within serogroup A.[195,206-208] Rotavirus is shed in the feces of infected animals, and transmission is primarily fecal-oral. Clinical signs occur 1 to 3 days after infection and last for 5 to 9 days. Virus excretion commences with the onset of clinical signs and continues for 3-7 days.[195,209] Adult cows can be subclinically infected and intermittently shed the virus during pregnancy and especially at parturition.[210-212] This is likely the most common source of infection, with carrier cows infecting their calves and then these calves infecting other calves.[213] Calves from carrier cows have a significantly higher risk of clinical disease, and the birth of calves from known carrier cows has been associated with the beginning of an outbreak. Recovered calves can become reinfected and shed virus.[214]

The environment may be an important source of infection. Rotaviruses can survive in fresh water for more than 2 weeks at 23°C and for months in water or soil less than 5°C.[215] They are also stable in feces and effluent for up to 9 months and therefore are likely to remain in calving areas from year to year.[216]

VetBooks.ir

CORONAVIRUS. BCV commonly causes diarrhea in calves 5 days to 1 month of age.[107,112,217,218] Disease can occur within 24 hours in colostrum-deprived calves and has also been recorded in calves up to 5 months of age.[219] Respiratory infections are common in older calves and may be important in the epizootiology of enteritis.[219]

Calves may be infected with coronavirus by the oral or respiratory route.[209] Fecal shedding commences 3 days after infection and persists for up to a week; nasal shedding can be detected 2 days after infection and persists for 2 weeks. Once infected, calves initially excrete high levels of virus and are potent sources of contamination. Infection persists for weeks in apparently recovered calves, and these excrete low levels of virus for weeks.[220] Subclinical infection is common. Disease is more common in the winter months, and coronavirus survives in the environment from year to year.

Calves may be infected by virus shed by persistently infected cows.[221] Coronavirus has been detected in the feces of more than 70% of clinically normal cows.[212] The rate of virus excretion increases at parturition and in the winter months.[210,222] Calves born to carrier animals are at a significantly increased risk of developing diarrhea.[210]

The pathology of coronavirus is often more severe than rotavirus, resulting in a muco-hemorrhagic enterocolitis. The virus infects both the small and large intestine. In the spiral colon there is widespread destruction of the cells of the colonic ridges.[124,126] Virus replication occurs in the surface epithelium, especially in the distal half of the villi, resulting in stunting and fusion of the villi. Immature cells replace epithelial cells, and in severe infection there can be areas of complete desquamation. Intestinal secretions continue and absorption is impaired by reduced surface area. Undigested lactose accumulates in the intestinal lumen, often resulting in a secondary bacterial overgrowth, fermentation, lactate production, and an osmotic imbalance that draws fluid into the intestinal lumen. Most infections are self-limiting because the virus rarely attacks crypt epithelial cells.[221] In response to infection the mitotic rate of crypt cells increases, producing immature cells that are more resistant to virus infection and that migrate up the villi to replace the damaged cells.

In experimental challenge studies, diarrhea develops 48 hours after infection. Calves are initially depressed and anorexic for the acute phase and may become dehydrated and pyrexic in a severe infection.[221] Severe infections can result in death as a result of dehydration, acidosis, shock, and cardiac failure. Respiratory signs are generally mild. Rhinitis, sneezing, and coughing may occur. Lesions may be found in the lungs, but clinical signs of pneumonia are rare, except when secondary infection occurs.

BOVINE VIRAL DIARRHEA VIRUS. BVDV occasionally causes diarrhea and thrombocytopenia in young calves outside the confines of the persistently infected disease model.[114,115] Colostral antibodies generally protect young calves from BVDV infection, but disease may occur as a result of FPT or the introduction of novel BVDV strains with new cattle or viral mutation in persistently infected homegrown cattle. BVDV is also thought to exacerbate infections because of other pathogens.[223] It has also been implicated in necrotic enteritis, an acute enteritis of 7- to 12-week-old beef calves reported in the United Kingdom.[224] Affected calves usually show oral ulcerations, particularly on the hard and soft palate. The buccal papillae are often blunted and the tips may be ulcerated.[225] Some variants of the virus produce intestinal bleeding, petechiation, ecchymosis, or prolonged bleeding from venipuncture sites as a result of thrombocytopenia.[114,226-228] Hematologic findings often include leukopenia and thrombocytopenia. The disease must be differentiated from other causes of enteritis that are complicated by bovine papular stomatitis infection. Bovine papular stomatitis (see Chapter 32) is common in neonatal calves. It produces oral lesions that are hyperemic and red, with a central white area of necrosis and often a raised rim of proliferating epithelial cells. These lesions often involve the mucosa around the molars. They are usually of little consequence, and their importance lies in the fact that they may be confused with BVDV. One feature that helps identify BVDV ulcers is that they lack the zones of epithelial proliferation seen in bovine papular stomatitis.

BOVINE TOROVIRUS (BREDA VIRUS). Bovine torovirus has been detected worldwide[229-232] and has recently been implicated as an important cause of calf diarrhea.[110,111] Initially known as Breda virus, it is part of the Coronaviridae family. It has been relatively infrequently reported because it is difficult to recognize by EM and it cannot as yet be grown in cell culture, which has precluded the development of routine immunospecific diagnostic tests.[110] Laboratory studies using PCR have implicated it as the sole pathogen isolated in between 25% to 30% of fecal samples from calves with diarrhea under 6 weeks of age.[110,111] It is also found in the feces and nasal secretions of asymptomatic animals,[110,112] implying that the epizootiology is likely to be similar to that of rotavirus and coronavirus, with asymptomatic carriers acting as a reservoir of infection within a herd.[210] It is mainly a disease of calves less than 3 weeks of age with diarrhea commencing as early as 1 to 3 days after birth,[231,232] but clinical signs have been observed up to 10 months of age.[111,233] Clinically it produces mild to moderate diarrhea in calves under both experimental and field conditions.[181,232,234] The virus infects the distal half of the ileum, jejunum, and colon, resulting in necrosis of the crypts and villous enterocytes.[235,236] Clinical signs develop 24 to 72 hours after experimental infection.[232] It has also been isolated from the respiratory tract of cattle and associated with respiratory signs in calves at 1 month and 4 to 6 months of age.[237]

OTHER VIRUSES. Calicivirus, astrovirus, adenovirus, parvovirus, and picobirnavirus have all been associated with neonatal calf diarrhea.[238-242] The pathogenicity and contribution of these viruses to field outbreaks are uncertain.

Protozoa

CRYPTOSPORIDIUM. Four species of *Cryptosporidium* have been identified in cattle: *Cryptosporidium parvum, C. andersoni, C. bovis,* and *C. ryanae.*[243] *C. parvum* has been implicated as the main cause of diarrhea in dairy calves worldwide.[244,245] *C. andersoni* has been found in the abomasum of adults and young calves, but its significance is still dubious.[246] *C. parvum* and *C. andersoni* have morphologically distinct oocysts and differ genetically.[247] *C. bovis* and *C. ryanae,* which are morphologically identical to *C. parvum,* were detected using PCR and are mainly responsible for diarrhea in postweaned calves,[248-251] but they have also been found in all age groups of cattle.[252]

C. parvum was initially thought to be a single species that affected both humans and a broad range of animals. Later, it was recognized that two distinct genotypes were present: type 1, which was found in human sources, and type 2, which was considered to be zoonotic and could be isolated from bovines and other farm animals such as sheep and goats.[253,254] The most recent molecular work recognizes that *C. parvum* genotype 1 isolates are *Cryptosporidium hominis*, a human-specific pathogen that is responsible for the majority of cases of cryptosporidiosis in humans in the United States.[255] Calves generally become infected between 1 and 4 weeks of age and display clinical signs for 4 to 14 days. Animals of all ages can be infected, but diarrhea is mainly associated with calves preweaning.[256] Cryptosporidial infections are asymptomatic in cattle older than 4 months of age. *C. parvum* mainly infects the distal small intestine, but lesions are also found in the cecum and colon and occasionally the duodenum.[257] The parasite invades the superficial cells of the mucosa in the intestine but is surrounded by an invagination of the host cell membrane and remains extracytoplasmic. Parasitic invasion of the mucosa leads to epithelial destruction and mild to moderate villous atrophy, with microvillous shortening and destruction. This leads to impaired nutrient digestion and transport and a resulting malabsorption diarrhea. Recent studies have also documented increased mucosal prostaglandin secretion, resulting in crypt secretion of chloride and bicarbonate combined with inhibition of villous sodium chloride absorption.[258]

VetBooks.ir

Affected calves often show no sign other than diarrhea but can show depression, dehydration, and anorexia.[259] Pyrexia and tenesmus have been noted.[260,261] Variable levels of morbidity have been reported and mortality is generally low.[259,260,262] Other pathogens can be involved and are likely to contribute to the severity of the disease. Affected calves can take 4 to 6 weeks to recover. Cryptosporidiosis occurs less frequently in suckler calves at pasture, but when these calves are affected, outbreaks were reported to be more severe than those in dairy calves, with mortality rates up to 30%.[246] High mortality rates have been attributed to lack of herd immunity in seasonal calving herds where the transmission cycle is broken. Neutralizing antibodies in colostrum and milk reduce infectivity by immobilizing the parasite, blocking invasion, and inhibiting adhesion to host cells or direct cytotoxicity to *Cryptosporidium* sporozoites.[263] High mortality rates have also been associated with concurrent low levels of selenium, inadequate nutrition, presence of concurrent enteric infections, and specific management practices.[246]

Transmission is fecal-oral by ingestion of an encysted, sporulated oocyst. Transmission can be direct from host to host, by ingestion of contaminated food or water, and probably mechanically via flies.[264] A study of oocyst shedding in experimentally infected neonatal calves demonstrated a prepatent and a patent period ranging from 3 ± 6 and 4 ± 13 days, respectively.[265] The parasite is capable of autoinfection, sporulating within the intestine and immediately infecting adjacent cells, which can result in protracted clinical illness and relapses. The ability to autoinfect results in huge parasite burdens following very small infective doses. Calves aged 1 week to 4 months of age are most likely to be actively shedding significant numbers of oocysts with peak shedding occurring between 1 and 3 weeks of age.[256,265-267] Infected calves can shed in excess of 10^6 oocysts/g of feces.[265,268] *C. parvum* oocysts have also been isolated from adult cows with herd prevalence ranging from 7% to 100%.[256,269-271] Mean shedding intensity reported for adult cows has ranged from 3 to 900 oocysts/g of feces.[271-273] It is likely that carrier cows are a source of infection for young calves.

The most critical factor affecting environmental oocyst survival is the temperature. Drying of oocysts has been shown to dramatically reduce their viability and infectivity in mice.[274,275] Oocysts can enter watercourses and ground water by direct contact with cows or from run-off of rain or irrigation water from pastures and manure storage areas.[246,276] *Cryptosporidium* oocysts have been shown to survive in water for at least 12 weeks at 4° C.[277] Oocysts are resistant to chlorination of water and most disinfectants[246] and have also been shown to survive in silage.[278] Wildlife may be a significant reservoir for *C. parvum* and act as a method of amplification and infection in the environment.[269,279,280]

Cryptosporidia cause diarrhea and sometimes death in 3- to 30-day-old lambs. Protracted infections and mortality are most common in lambs infected in the first few days of life, since age resistance is seen after about 3 weeks of age.[137,281-283] Cryptosporidiosis has also been described in goats where it affected 5- to 20-day-old kids, signs lasted from 3 to 7 days, relapses were not uncommon, and there was a moderate mortality rate.[284]

People working with diarrheic neonates should be warned of the risk of zoonotic disease. An outbreak of cryptosporidiosis has been described in caregivers in a veterinary hospital treating diarrheic calves. Affected people suffered from watery diarrhea, cramping, flatulence, and headache.[285] One person became infected as a result of handling soiled clothing.

GIARDIA. Giardia is often found in diarrheic calves in association with other pathogens, but its relevance as a pathogen in its own right is unclear. Several authors have documented cases of diarrhea where giardia infection has been implicated as the causative agent either by itself or in conjunction with *C. parvum* and rotavirus.[286-288] Affected calves are at least 2 weeks old, and often older than 1 month of age, with infection often becoming chronic and lasting for several months.[266,286,289-291] Giardia has a prepatent period of 7 to 8 days, and the delayed interval between birth and infection is likely to relate to high levels of colostral protection against *Giardia* but low protective levels in milk.[292] Many calves were shown to have a poor specific immune response to the infection, accounting for the chronicity of the infection.

The significance of *Giardia* as a primary pathogen has been questioned by the observation of similar or lower rates of infection in calves with diarrhea compared with asymptomatic calves.[266,293] Treatment of affected calves with fenbendazole reduces the duration but not the number of diarrhea episodes.[288]

COCCIDIOSIS. Thirteen species of *Eimeria* have been reported in cattle.[294] *Eimeria bovis* and *E. zuernii* have historically been the most common pathogenic species; however, there are increasing reports of *E. alabamensis* causing disease.[295-297] Transmission is fecal-oral. Infected animals pass unsporulated oocysts in their feces that then sporulate and become infective. The sporulated oocysts are protected from the environment by a double cyst wall.[298] Moist, temperate, cool conditions favor sporulation, and oocysts can survive for several years. Sporulated oocysts can resist freezing to −8° C for several months but are destroyed by high temperatures and dry conditions within a few weeks.[299] Under optimal conditions sporulation can occur within a few days. The prepatent period of the two main pathogenic species is 15 to 20 days, and the patent period around 11 days. *Eimeria alabamensis* has a prepatent period of only 8 days and a patent period of 5 days.

Calves start shedding at about 1 month of age and shed for 3 to 4 months. *E. bovis* and *E. zuernii* schizonts first reproduce in the lower small intestine and then produce second-generation schizonts and gamonts in the cecum and colon, where they attack crypt cells.[294] These latter stages induce both local and more extensive lesions.

Outbreaks of disease in calves and lambs are often related to overcrowded and confined conditions. Up to 95% of infections are subclinical, causing decreased growth rates that are often unnoticed.[300] Clinical disease can be chronic or acute and is generally found in calves aged 3 weeks to 6 months, although animals of 2 years of age or older may be affected. In beef cattle the most common reports of clinical disease are associated with weaning stress.[301] Clinical signs may include diarrhea, ill thrift, increased susceptibility to pneumonia, tenesmus, increased mucus in feces, and hematochezia. Pyrexia, dehydration, and anemia may also be observed. The disease is usually self-limiting without reinfection. Chronic disease is often underdiagnosed.[300] Calves appear weak and listless with pasty feces, drooping eyes, and a staring coat. Fecal oocyst count is low or negligible. Disease results from continual reinfection resulting from a heavily contaminated environment.

Nutritional Diarrhea

Producers often express the opinion that scours is caused by calves consuming too much milk. However, there is no documented research in healthy calves to support this. Calves fed 16% to 20% of body weight per day or allowed ad libitum access to milk have not developed problems with diarrhea.[302,303] However, in studies in which calves are also infected with enteric pathogens, the diarrhea and depression were exacerbated by feeding normal amounts of whole cows' milk in the early stages. Villous atrophy as a result of attack by an enteropathogen reduces the ability of the calf to digest nutrients,[129,133] and this predisposes to gastrointestinal overload with fermentation of milk in the large intestine. Deliberate underfeeding of healthy calves also predisposes to diarrhea.

Studies in Scotland have shown that poor clotting ability of milk is associated with diarrhea and abdominal distention in calves aged 1 to 3 weeks of age in beef suckler herds.[304-306] Milk should clot within 7 minutes when incubated with rennet; the milk from the affected cows took at least 1 hour to clot and in some cases more than 24 hours. Diarrhea may be due to the rapid passage of undigested milk through the bowel, or a result of infection by enteric pathogens facilitated by the conditions created in the bowel. Milks with poor clotting ability were shown to have low ultrafilterable calcium levels and low total magnesium levels.[306] Calves responded to treatment with 30 mL

VetBooks.ir

of 1 molar solution of CaCl administered three times daily PO and relapsed when this treatment was stopped. The majority of the milk samples clotted when 100 µL of 1 mol/L calcium chloride solution was added prior to the addition of rennet. The exact cause of the impaired clotting ability was not determined. The diet of one group of affected cows was shown to be low in calcium.[304,305] After a mineral mixture containing additional calcium was added to the diet of these cows, the clotting time was reduced to less than 12 minutes; treatment of the calves was stopped and there was no recurrence of clinical symptoms.[304]

Calves seem to experience more problems with diarrhea on certain milk replacers. One study showed that calves performed well on milk replacers containing soy protein when healthy, but that during an outbreak of salmonellosis, there was better weight gain and less mortality in calves fed whole milk.[307]

Establishing an Etiologic Diagnosis

An etiologic diagnosis is useful in selecting specific diagnostic and preventive regimens for bacterial infections. Establishing an etiologic diagnosis for viral infections will allow establishment of specific control methods and development of an appropriate vaccination strategy. Diagnosis of salmonellosis, cryptosporidiosis, and giardiasis can have public health implications. Once an agent has been identified, one of the major problems is in interpretation of whether or not that agent is responsible for diarrhea in the individual or herd, since most agents can also be found in a percentage of normal calves (see Fig. 20-1).

Sample Collection

Appropriate selection of diagnostic specimens is required to achieve a meaningful diagnosis. Best results are obtained when fresh samples and specimens are collected from calves early in the course of disease. In order to establish causality, a fresh necropsy is informative because it provides an opportunity to relate the presence of pathogens to a disease process. The quality of the information gathered is to a large extent determined by the quality of the samples submitted to the diagnostic laboratory. Autolysis and bacterial invasion of gut mucosa begin within 5 minutes of death. Autolysis is a common cause of poor tissue sections for histopathology; this may reflect prolonged postmortem interval or poor tissue preparation, handling, or transport. To avoid autolysis, formalin needs to distribute into the lumen of intestinal sections; hence, intestinal specimens should be no longer than an inch long and the tissue to formalin ratio should be no greater than 1:10.

Diagnostic Tests

Bacterial Pathogens

ESCHERICHIA COLI. *E. coli* is a normal inhabitant of the gastrointestinal tract. Isolation of *E. coli* from fecal samples or gut contents is therefore of no significance unless the isolates are demonstrated to possess virulent attributes that are consistent with the clinical and or pathologic presentation. Virulence attributes include adhesins, enterotoxins, and cytotoxins. Enterotoxigenic *E. coli* adhere to enterocytes in the jejunum and ileum.[308] On gross pathology, enterotoxigenic *E. coli* is associated with fluid-distended loops of bowel without enteritis.[309] Calves infected with enterotoxigenic *E. coli* have a mild inflammatory reaction in the small intestinal wall and some villous atrophy. In fresh specimens, sheets of gram-negative bacilli can be seen adhering to the small intestinal wall.[308] Definitive diagnosis of enterotoxigenicity rests on demonstration of the ability of the *E. coli* to dilate intestinal loops.[310] Enterotoxigenic *E. coli* can also be identified by the presence of the F5 (K99) using antigen-specific immunoassays, including latex agglutination,[311] ELISA,[312] fluorescent antibody,[313] slide agglutination,[313] multiplex PCR,[165] real-time RT-PCR,[314] and rapid dipstick tests. A potential limitation of immunoassays is the specificity of the antibodies used; strains of enterotoxigenic *E. coli* using non-F5 fimbriae will not be detected by these tests.[153,315]

Attaching and effacing *E. coli* (AEEC) and Shiga toxin–producing *E. coli* (STEC) mediate disease by cytotoxic damage to the intestinal mucosa. The confirmatory diagnosis of AEEC is made by microscopic examination of the small intestine and colon. A distinct histologic appearance occurs at the attachment sites where clusters of gram-negative rods attach and form a scalloped appearance to the epithelial cells.[159,316] Diagnosis of *E. coli* infection may be achieved using phenotypic differentiation of pathogenic strains from nonpathogenic normal flora *E. coli* via bioassays or immunoassays for toxins and fimbriae. Immunoassays have been developed to identify the presence of Stx1 and Stx2 in feces as a presumptive test for the detection of STEC in cattle feces.[317-319] An alternative approach to identify and differentiate ETEC, AEEC, and STEC is to use PCR to identify virulence-associated genes commonly found in these *E. coli* strains (F5, F41, enterotoxin, intimin, Stx1, and Stx2).[165] The significance of STEC, EPEC, and AEEC in bovine enteritis is unknown due to a lack of appropriate assays for routine detection and because of the widespread presence of verotoxin-producing *E. coli* strains in healthy cattle that complicate the interpretation of detecting fecal shedding in sick animals.[320-322] Demonstration of verotoxin in cultures from bovine enteritis is not sufficient to imply a causative association.

***CLOSTRIDIUM* SPP.** *C. perfringens* has been associated with enterotoxemia and hemorrhagic abomasitis in calves.[178,181] *C. perfringens* are normal flora of the gastrointestinal tract; hence, isolation of *C. perfringens* from feces is not in itself diagnostic. Pathogenic strains of *C. perfringens* produce exotoxins, and five of these (α, β, ε, ι, and enterotoxin) are involved in the pathogenesis of disease.[178] The complete pathogenesis of enterotoxemia and abomasitis has yet to be completely elucidated. Production of specific toxins can only be demonstrated in a proportion of cases.[323] Isolation of toxin-positive *C. perfringens* from intestinal contents does not confirm a clinical diagnosis of bovine enterotoxemia as almost as many *C. perfringens* isolates from normal calves produce toxin and toxin production cannot be demonstrated in as many as 40% of affected calves.[324]

A fresh necropsy is required to definitively diagnose clostridial enteritis. Observing many gram-positive bacilli in the mucosa associated with hemorrhagic enteritis is suggestive of clostridial enterotoxemia. Quantitative bacterial counts of intestinal contents at the site of the lesion have proved to be one of the most reliable methods for diagnosing enterotoxemia.[181] A *C. perfringens* count greater than 10^6/mL of intestinal contents is consistent with a diagnosis of enterotoxemia.[181] Demonstrating the presence of *C. perfringens* toxins or the capacity to produce toxins provides support for the diagnosis. Tests for detecting toxins or the bacteria's capacity to produce toxins include bioassays, immunoassays, Western blot, and PCR.[325] The basis of the bioassay is to demonstrate protection of mice using antitoxin. *C. perfringens* enterotoxin is produced during sporulation. In vitro detection of enterotoxin production capacity by a *C. perfringens* isolate using Western blot or immunoassays requires sporulation to occur. In vitro techniques to induce sporulation are not 100% efficient, so detection of enterotoxin using these methods is less sensitive than PCR at detecting the genes required to produce enterotoxin.[326]

***SALMONELLA* SPP.** Salmonellae are capable of causing disease in cattle of all ages. Neonatal infections are common. The classic pathologic lesion is fibrinous or fibrinonecrotic to ulcerative enteritis.[327] The severity of lesions is usually greatest in the distal small intestine and proximal large bowel. Hypertrophy of the mesenteric lymph nodes is a common finding.[328] Serosal hemorrhages may be observed in the small and large intestine. Septic infarcts in the kidneys and inflammation of the gallbladder are less common findings. Pneumonia is a common finding with *S.* Dublin infections, and gangrenous necrosis of distal extremities may also be observed.[329] Bacteremia is a feature of neonatal salmonellosis and may manifest as osteomyelitis and/or meningitis.

VetBooks.ir

Isolation of salmonella from the feces of calves with diarrhea is consistent with a diagnosis of salmonellosis but in itself does not necessarily establish causality because salmonella may be isolated from the feces of apparently healthy calves.[330] Isolation of salmonella from tissues at necropsy is indicative of invasive salmonellosis. A definitive diagnosis of salmonellosis is based on the clinical presentation, pathologic lesions, and isolation of salmonella from tissues at necropsy.

Numerous methods exist for isolating and detecting the presence of salmonella. These include direct culture, enrichment cultures, PCR (both conventional and real time), immunoseparation, and immunoassays.

The process of directly inoculating tissues or other samples onto plating media, except in the case of acute infections, is usually nonproductive. Typically, with subclinical infection the number of salmonellae shed in feces is low relative to the high number of other bacteria. Fecal samples should be inoculated into selective enrichment media for optimal recovery of Salmonella. Selective-enrichment broths are formulated to selectively inhibit other bacteria while allowing Salmonella to multiply to levels that may be detected after plating. Internal organs that are normally sterile do not need to be inoculated on selective media; rather, they should be inoculated onto nonselective (blood agar) or weakly selective (MacConkey agar) media.

A number of rapid detection methods have been developed to expedite the detection of salmonella. These methods include electrical conductance and impedance, immunologic techniques, nucleic acid–based assays, and PCR. These methods generally take 24 to 52 hours to screen for or detect and identify salmonella. The majority of these tests, particularly the enzyme-linked immunologic techniques, require 10^5 cells/mL for reliable results. Accordingly all these tests involve a pre-enrichment stage, and some also involve a selective enrichment culture.[331] When salmonella is causing disease, clinically affected calves may shed 10^9 salmonella per gram of feces.[332] Detection of salmonella in clinical samples when it is the inciting cause of the disease process is not normally difficult when multiple samples are collected from a representative sample of the affected population.

Viral Enteropathogens

Viruses are usually identified by direct examination of the feces, immunoassays, or fluorescent antibody examination of intestinal mucosa. Molecular techniques involving conventional PCR and real-time RT-PCR have been described for most pathogens but are not routinely available in all diagnostic laboratories. Electron microscopic examination of feces is not a sensitive means of detecting virus particles, but it has the advantage in that many different types of viruses can be detected, including those such as parvovirus that are not recognized as common causes of diarrhea. The recent development of relatively inexpensive immunoassay diagnostic test kits makes these an attractive option; limited test-specific data regarding test sensitivity and specificity limit the application of some of these tests.

CORONAVIRUS. Coronavirus replication occurs in the epithelial cells of the distal half of the villi of the lower small intestine and colon. Infected cells die, slough, and are replaced by immature cells. In the small intestine these changes result in stunting and fusion of adjacent villi, and in the large intestine they lead to atrophy of the colonic ridges. On histopathology the tall columnar epithelial cells are replaced by cuboidal and squamous epithelial cells; in severe infections there may be areas of complete desquamation.[333] Virus is shed in respiratory secretions and feces. There are several methods for detecting BCV in feces. These include isolation of the virus in cell culture,[334] electron microscopy,[335] immunoelectron microscopy,[219] immunoassays,[212,312,336-339] and molecular techniques including dot-blot hybridization assays[340] and conventional and real-time RT-PCR.[341-344] Isolation of BCV using cell culture techniques is not often performed in diagnostic laboratories because the technique is difficult and requires viable virus (fresh samples or shipped on dry ice).[345] Electron microscopy has been used as a standard diagnostic method for BCV. Although the intact virion of BCV is fairly characteristic in appearance, it is not uncommon for the identifying surface projections of the virus to be lost during sample preparation or storage, making it difficult to properly identify virus particles by EM.

Numerous ELISA assays have been described for the detection of BCV antigen in feces. A number of companies have developed commercial kits using this technology. The use of monoclonal antibodies rather than polyclonal antibodies is reported to increase the sensitivity and specificity of BCV ELISAs.[339] The limit of detection for ELISA assays ranges from 10^4 to 10^5 virions per milliliter of feces.

A one-step RT-PCR assay, targeting a 730-bp fragment of the nucleocapsid gene of BCV, as well as a nested PCR assay, targeting a 407-bp fragment of the nucleocapsid gene, has been developed to detect BCV. Compared with an antigen-capture ELISA, the limit of detection for the RT-PCR and nested PCR was 10^3 and 10 virions/mL, respectively, compared with 10^5 virions/mL for the ELISA.[346,347]

Two qRT-PCR methods have been used for detection of coronavirus in feces: the TaqMan and the SYBR Green assays.[343,344] Detection levels achieved using the TaqMan assay for coronavirus have been on the order of 10^1 to 10^9 RNA copies and were shown to be 1 log more sensitive than gel-based RT-PCR. The SYBR Green chemistry assay had similar detection levels but was unable to differentiate among different coronaviruses like the TaqMan assay.

ROTAVIRUS. Bovine rotavirus infects enterocytes, which are predominantly in the distal one third to one half of the villi. The age at the time of infection influences the distribution of the virus in the gastrointestinal tract and the number of virions shed in feces. In experimental challenge studies, infection of day-old calves resulted in a uniform distribution of virus throughout the small intestine.[348] Challenge of 10-day-old calves led to a patchy distribution of the virus with maximal viral load observed in the mid small intestine.[348] Villous stunting is more pronounced in young calves.

Methods for detection of rotavirus include cell culture, fluorescent antibody staining, electron microscopy, immunoelectron microscopy, immunoassays, electrophoretic procedures, and conventional and real-time RT-PCR.[199-203,311,312,337,349-352] Bovine rotavirus is difficult to isolate in cell cultures because of the cytotoxic nature of feces and fecal filtrates and because the virus is inconsistent in production of cytopathic effects.[350] The fluorescent antibody technique is simple, rapid, and specific; however, rotaviral antigen is usually difficult to detect within 24 to 72 hours after the onset of diarrhea because rotavirus-infected epithelial cells are rapidly shed from the tips of the villi.[353] Comparative studies evaluating methods of detecting rotavirus in feces give good agreement between antigen capture assays (ELISA, latex agglutination) and electron microscopy.[311,337,350,354] Direct immunofluorescence testing of fecal samples gives good agreement (90%) with electron microscopic examination for rotaviruses when samples are collected during the 24 hours following the onset of diarrhea,[355] but poor agreement (33%) for field specimens submitted to a diagnostic laboratory.[350]

Real time RT-PCR detection for rotavirus has been shown to be both highly sensitive and specific when the correct primers and probes are identified.[352] Real-time RT-PCR assays have the ability to increase the sensitivity of detection by up to 100-fold compared with one-step RT-PCR.[356]

BOVINE VIRUS DIARRHEA. BVDV rarely causes diarrhea in neonatal calves.[115] Sporadic disease may be observed in persistently infected calves. Pathologic lesions include ulceration of the oral cavity, particularly on the hard and soft palate, and blunting of the buccal papillae.[225] Erosions may be observed in the esophagus, and necrosis of Peyer patches may be observed in the ileum. Thrombocytopenia has been observed with BVD type II infections. Outbreaks of neonatal disease have been observed with this strain. Petechial and ecchymotic hemorrhages are a feature of this

VetBooks.ir

condition.[114,227,228] Hematologic findings often include leukopenia and thrombocytopenia.

Several options are available for the detection of BVD; these include virus isolation,[357,358] RT-PCR,[359] immunohistochemistry,[360] and antigen-capture ELISA.[361] Immunohistochemistry and antigen-capture ELISA assays are used in most commercial laboratories. Maternal antibodies reduce the sensitivity of the ELISA assay in young calves.[359]

BOVINE TOROVIRUS (BREDA VIRUS). Bovine torovirus produces cytolytic infections of villi and crypt enterocytes in the small and large intestine.[362] Bovine torovirus does not grow in tissue culture, cell culture, or embryonated eggs.[363] Therefore, the large-scale preparation of reference antisera and antigens for the development of diagnostic tests has been precluded. Torovirus is capable of causing diarrhea in cattle with disease observed most frequently in calves less than 3 weeks of age.[112,232,234,236,364,365] Like other enteric viruses, bovine torovirus has been detected in feces of normal calves; therefore, detection of the virus in feces from diarrheic cattle cannot be interpreted as causal. The lack of diagnostic reagents has limited the study of bovine torovirus, leaving questions about its epidemiology and relative importance in calf diarrhea.[111] Diagnostic methods that have been used to detect bovine torovirus include electron microscopy, immunofluorescence, antigen-capture ELISA, and RT-PCR.[111,232]

Protozoa

***EIMERIA* SPP.** *Eimeria* spp. are host specific. *E. bovis* affects primarily the mucosa of the cecum and the proximal part of the large intestine, whereas *E. zuernii* affects the mucosa of the cecum as well as the entire large intestine, including sometimes the rectum.[366] The clinical signs of bovine coccidiosis are associated with the final stages of the eimerian life cycle and commence shortly prior to oocyst shedding. Gross lesions in the cecum and large intestine range from semi-liquid contents with little or no blood and few areas of epithelial sloughing to extensive hemorrhage and large areas of epithelial sloughing and necrosis of the mucosa.[366] The serosal surface is often reddened opposite the affected mucosal area and the submucosa and external muscular layers thickened by edema.

Oocysts usually can be recovered 2 to 4 days after the onset of diarrhea.[367] Oocysts can be identified microscopically by direct smear, flotation, or centrifugation methods. Oocyst counts of 5000 or greater per gram of feces are considered significant in cattle.[298] Identification of oocysts in feces is not diagnostic for clinical coccidiosis because the parasite is frequently detected in small numbers in the feces of healthy cattle.[368] When investigating scour problems, multiple samples should be collected for oocyst counts to provide an indication as to the level of infection within the group. The potential for discord between clinical signs and fecal shedding limits the diagnostic utility of a single sample from an individual animal.

GIARDIA. Giardia infection is not associated with changes in intestinal villous height or crypt depth. However, transmission electron microscopy has been used to demonstrate a reduction in microvillous surface area.[369] Diagnostic methods for detection of *Giardia* include direct microscopy, immunomagnetic separation, fluorescent antibody staining,[287,370] ELISA,[371] and PCR.[372] When using direct microscopy, fecal samples should be examined within 24 hours of collection. Concentration of trophozoites and cysts via density gradient centrifugation or filtration followed by fluorescent antibody staining is the diagnostic method used in most veterinary epidemiologic studies of Giardia in calves.[266,373,374] The use of other immunoassays and PCR techniques are emerging in human diagnostic laboratories.[371,372]

CRYPTOSPORIDIA. *C. parvum* infections are mainly concentrated in the distal small intestine, but lesions may also be found in the cecum and colon, and occasionally in the duodenum.[375] The pathologic findings associated with *Cryptosporidium* are a mild to moderate villous atrophy, villous fusion, and changes in the surface epithelium with infiltration of mononuclear cells and neutrophils in the lamina propria.[375]

Calves infected with *C. parvum* usually develop diarrhea in 72 to 96 hours; diarrhea is observed for 4 to 23 days,[376] during which time oocysts are excreted in feces. Oocysts are stable in feces for many days at room temperature.[377] Laboratory methods for the diagnosis of cryptosporidial infections include microscopic examination of fecal smears or fecal preparations, immunoassays, and PCR. Cryptosporidia oocysts are small (4 to 6 µm in diameter) and are easily missed on a fecal smear. Because fecal smears do not concentrate the oocysts, this technique is less sensitive than fecal flotation. Concentration of the protozoa is achieved by salt[378] or sugar flotation. Special stains may be used to facilitate detection of cryptosporidia during microscopic examination. Differential staining techniques are useful to distinguish *Cryptosporidium* oocysts from other fecal components (especially some yeasts) of similar size and shape.[379-382]

A number of immunoassays have been developed for the detection of cryptosporidia. The detection threshold of the different methods have been reported to be 3×10^5 oocysts/g for a monoclonal antibody-based antigen-capture ELISA, compared with 1×10^6 oocysts/g^{-1} detected by examination of acid-fast stained fecal smears and 1×10^3 oocysts/g^{-1} detected by indirect immunofluorescence.[383] The detection threshold may be further enhanced by using a combination of immunomagnetic separation coupled with immunofluorescent microscopy. With this combination it is possible to detect as few as 10 oocysts/g^{-1}.[384] A number of dipstick immunoassays have also been developed; the detection threshold for this technology is reported to be 1×10^3 oocysts/g^{-1}.[385] This technology offers the potential for rapid, cost-effective detection of cryptosporidia in fecal specimens.

Molecular techniques have been described for detection and typing of cryptosporidia.[249,253] The capacity to differentiate the different genotypes makes this approach useful for epidemiologic studies of cryptosporidia.[249]

Multiplex Real-Time PCR

Several multiplex real-time RT-PCR assays have been developed for the simultaneous detection of the major enteric pathogens.[386] The multiplex qRT-PCR offers significant advantages over individual pathogen testing in that 96 fecal samples can be tested at the same time within 4 hours. This offers increased efficiency through decreased cost, labor, and turnaround time. Another major advantage of RT-PCR is the ability to detect and measure the accumulation of amplicon during the reaction, thus allowing precise quantification, which can be important in determining causation. The major disadvantage of RT-PCR is that the equipment required is expensive and significant expertise is needed in order to run the assays.

Risk Factors for Neonatal Calf Diarrhea

It is important to identify risk factors, both to set up effective preventive programs and to initiate control in the face of a disease outbreak. The etiology of calf diarrhea is multifactorial; consequently, it is common for several factors to contribute to the outbreak and perpetuation of disease in a herd.

Dystocia

Dystocia is associated with neonatal calf diarrhea in more intensive beef and dairy systems,[106,387] and it is a risk for preweaning mortality with over 40% of preweaning deaths occurring in calves born to cows suffering dystocia.[388-390] Dystocia affects the ability of the calf to suckle colostrum, resulting in decreased serum IgG levels; consequently, calves that survive dystocia are two to four times more likely to become sick in the first 45 days of life.[391-393] Calves that experience dystocia are likely to have edema of the head and tongue, making suckling difficult. They are weak, exhausted, and likely to be recumbent for longer, increasing exposure to fecal pathogens.[217]

VetBooks.ir

Stocking density and cow grouping of preparturient cows, timing of calving, breed, cow pelvic area, multiple calvings, calf sex, gestation length, and dam nutrition all influence the risk of dystocia.[394,395] Low- and high-birth-weight calves are at greater risk of mortality.[389] Small calves experience greatest mortality at parities greater than one and large calves at first parity.[396] Increased feed intake before calving will increase calf birth weight but does not increase the risk of dystocia unless cattle become obese.[397-399] Weight loss is associated with prolonged labor, increased dystocia, and increased perinatal mortality.[399,400]

Dam Parity

Calves born to first and second parity cows have an increased mortality compared with those born to older cows, and the risk of diarrhea in calves born to heifers is 3.9 times greater than that in those born to cows.[389,401,402] Heifers have an increased risk of dystocia, lower colostrum quality, and inferior mothering ability.[391,392,402-404] The difference in the rate of dystocia between the first and second parity is usually much greater than between second and subsequent parities.[405] The stocking density of heifers is often increased prior to calving to facilitate observation, with the consequence of exposing their calves to a greater environmental pathogen load. These factors are all likely to contribute to increased morbidity, and consequently the percentage of heifers in the herd will affect the risk of diarrhea. Calves from carrier heifers shedding rotavirus and BCV are more likely to develop clinical disease than calves born to carrier cows.[210] Studies in dairy herds have shown that there is a positive correlation between the number of young stock in the herd, the overall herd size, and herd production with the risk of neonatal calf diarrhea.[406-408]

Colostrum Management

Many studies have shown that FPT results in increased risk of neonatal calf diarrhea in beef and dairy herds.[409-415] Calves are only able to absorb immunoglobulins for a limited time after birth, and the subsequent serum immunoglobulin concentration is determined by the perinatal state of the calf, timing of colostrum ingestion, and the mass of immunoglobulin consumed.[416] Colostrum also provides local (enteric) immunity with the major benefits lasting for about 3 to 4 days after birth.[417-419] After this period, milk contains little immunoglobulin and most colostral antibody has been cleared from the intestine. Colostral antibodies protect against rotaviral infections in the first 4 days of life[193,194]; in contrast, anti-F5 (K99) *E. coli* antibody is present in low amounts in unvaccinated cows,[420] and enteric *E. coli* infections are usually seen in very young calves. After 4 days, the protective effects of colostrum are primarily due to systemic antibodies, and there is evidence that these can leak back into the gut and probably give limited long-term protection against diarrhea.[421] Colostral quality is affected by colostral volume, genetics, nutrition, parity, timing of collection, climate, and periparturient vaccination.

Beef Cow Herd Management

In beef herds, high stocking rates in the calving area and the use of one calving area are major risks for neonatal calf diarrhea.[422,423] The practice of leaving nursing dams and calves with calving cows further increases stocking rates and promotes disease transmission.[411] The weather at calving affects both pathogen survival and calf comfort; shelter in the nursing area is associated with decreased mortality resulting from neonatal calf diarrhea.[401] Major calf scour pathogens can survive in the environment for months or years in cool wet conditions, and consequently both the incidence and mortality from diarrhea increase with prolonged use of the same paddock or a longer calving season, and the incidence of diarrhea increases as the calving season progresses.[390,401,402] Adverse weather conditions cause cows to move to shelter and shade, concentrating cows and calves in small contaminated areas. Calves born into a contaminated environment potentially become infected during or shortly after birth and shed enteropathogens even when they remain clinically normal. This further increases the environmental load of infectious agents, infecting adult cattle as well as calves. The outcome of host pathogen interactions is largely influenced by the pathogen challenge dose and the age of the animal, with clinical disease becoming more frequent both in younger animals and as pathogen exposure increases (Fig. 20-3).

FIG. 20-3 Cow on a farm with a high incidence of neonatal diarrhea. Note that the mud is so deep around the feeders that it covers the cow's hocks. As a result the teats will be contaminated by manure and enteric pathogens.

Farms that purchase replacement calves aged less than 4 weeks have an increased mortality resulting from neonatal calf diarrhea.[401] Purchased calves may introduce new pathogens that challenge a susceptible population. Stress from transport and arrival at a new location may increase shedding and predispose to clinical disease, increasing the environmental pathogen load. The risk of pathogen introduction increases when introduced calves are commingled from multiple properties prior to introduction.

Intensive Calf-Rearing Systems

Intensively reared calves have an increased risk of diarrhea associated with housing, nutrition, and weaning. Variables that have been observed to increase the risk of scours include feeding milk once versus twice a day within 14 days of birth,[424] placing preweaned heifers in groups of seven or more, damp versus dry bedding,[424] a male having primary responsibility for the care and feeding of preweaned heifers, calves not receiving hay or other roughages until greater than 20 days old, and feeding mastitic or antibiotic milk versus whole milk.[425] Use of individual calf hutches has been reported to increase the risk of scours but to reduce mortality.[424]

In regard to the risk of cryptosporidia, infection factors significantly associated with a decreased risk of infection included ventilation in calf-rearing areas, daily addition of bedding, feeding of milk replacer, daily disposal and cleaning of bedding, and use of antibiotics. Postweaning practices that reduced risk of infection included moving animals after weaning, cleaning of soiled bedding, and use of antibiotics and ionophores as preventive measures. Maternity management factors that reduced risk of infection included use of fresh colostrum to feed calves and having a concrete floor in the calving area. General management factors that influenced risk included the total number of dairy cattle, total number of other species of agricultural animals on the farm, and the distance of the barn water source from the septic system.[426]

Herd Strategies to Prevent Neonatal Diarrhea

Management practices that reduce the risk of calf scours also promote good health, improve growth rates, and reduce the risk of transmitting other enteric pathogens such as *Mycobacterium paratuberculosis*. The principles of prevention are to minimize pathogen exposure, ensure adequate colostral intake, boost specific and nonspecific immunity, and promote farm biosecurity.

VetBooks.ir

Minimizing Pathogen Exposure

Enteric pathogens may be shed in large numbers by calving cows, scouring calves, and asymptomatic cohorts, especially those aged up to 4 months of age. All enteric pathogens can survive in the environment for months or years in moist, damp conditions. Other sources of infection include people who have treated or handled infected calves, contaminated water, contaminated colostrum, milk, or solid feed and equipment that has been used to feed or medicate infected calves.[175,210,212,246,272,427-429]

MINIMIZING PATHOGEN EXPOSURE IN DAIRY HERDS. Strategies to prevent disease in dairy calves focus on calving cows in a clean environment, removing calves from cows at birth, feeding adequate good-quality colostrum, placing calves in a clean dry environment separate from other stock, feeding good-quality milk or milk replacer, providing adequate shelter, and providing access to water and high-quality calf pellets. Microbial contamination is an important determinant in the quality of colostrum and milk. Good sanitary practices are required for the harvest, storage, and feeding of both products. Microbial contamination of colostrum compromises passive transfer and, in the case of pathogens like salmonella, may lead to a direct pathogen challenge. Similarly, feeding milk with a high bacteria count increases the risk of diarrhea. On-farm heat treatment of colostrum (60° C for 1 hour) significantly decreases bacterial numbers without affecting IgG levels.[430] Calves that are fed heat-treated colostrum have significantly higher IgG levels and lower incidence of neonatal calf diarrhea when compared with calves fed untreated colostrum.[431]

In dairy systems, where calves are reared by hand, the number of young stock on the farm and the incidence of respiratory disease are positive predictors for calf diarrhea.[406] Cleanliness of the calving area is important, bedding should be changed between each calving, and large numbers of cows should not be cycled through a few stalls.[406] Prior to calving, the udder and the perineum of the cow should be cleaned. The calf should receive adequate colostrum.[423] In recent years the use of calf hutches has gained widespread acceptance for managing calves after they have been separated from their dam. This system provides individual isolated housing for each calf. Cleaning is facilitated because the hutches can be moved to new sites between calves. Keeping preweaned calves in groups larger than six puts them at increased risk of diarrhea.[408]

Cleaning and disinfection after each calf batch plays an important role in reducing contamination in housed calves. The key to decontamination is the physical cleaning. Physical removal of organic contamination through scrubbing is preferred to application of high-pressure sprays, which can aerosolize organisms, allowing dissemination. On smooth, ideal surfaces, physical removal of visible contamination by thorough washing with soap and water removes 99% of the microbial load (2 logs). However, on typical housing surfaces, washing only removes 90% (1 log). Application of disinfectant following washing is important to eliminate remaining pathogens and to prevent bacterial pathogens from proliferating. Physical cleaning cannot be replaced by applying disinfectants in larger quantities because organic material neutralizes most disinfectants. In regard to disinfectants, pathogen elimination is time dependent.[432] Other important variables that influence the effectiveness of disinfectants and rate of pathogen reduction include concentration, temperature, pH, and water hardness.

In addition to cleaning between batches, it is important to clean nipple buckets and other feeding utensils between each feed. Separate equipment should be used to administer oral electrolytes and colostrum. Salmonella and coronavirus are shed in saliva and can contaminate equipment used for oral medication. Washing with warm soapy water is required to remove the fat residue left by milk and colostrum-handling equipment.

Several microbial characteristics should be considered when disinfecting equipment that contacts calves. Rotavirus is susceptible to sodium hypochlorite but is relatively resistant to many common disinfectants, such as chlorhexidine. As a nonenveloped virus, rotavirus is not affected by soaps; washing with soap alone may actually spread the virus around on the washed surface.[433] Coronavirus is an enveloped single-stranded RNA virus and is not as stable in the environment as rotavirus. Because of their envelope, these viruses retain infectiousness better at lower rather than higher relative humidity[434] and are considerably more sensitive to soaps and common disinfectants than are nonenveloped viruses. Because *Cryptosporidium* can autoinfect the original host, the infectious dose can be small. In the environment, cryptosporidia are extremely resistant to most veterinary disinfectants except 5% ammonia, 6% hydrogen peroxide, 10% formalin, or 2% cresolic disinfectants.[274,435-437] They survive very well in water, requiring 4 to 11 weeks to decline by 1 log.[438] On the other hand, cryptosporidia are susceptible to drying with oocyst infectivity, declining in 1 to 4 days.[275]

The most readily cleaned surfaces are made of smooth impervious materials such as plastic and varnished wood (Table 20-7). Usually buildings are cleaned and then either disinfected or fumigated.[439] Many disinfectants are inactivated by organic matter; viruses, coccidia, and particularly cryptosporidia may be resistant to their action (Table 20-8). Disinfectants may also be toxic and are best applied by personnel wearing rubber gloves and respirators (if indoors). In general, potent phenolics such as cresol (cresylic acid) are very useful for disinfecting dirty surfaces because they are not inactivated by organic matter and are effective against gram-negative bacteria and viruses. The phenolics are highly toxic and leave lingering odors. Hypochlorite solutions (5 g available chlorine/L) have a broad spectrum of action but are rapidly inactivated by organic matter. They would be useful as a final disinfectant on previously cleaned surfaces. Because hypochlorite is unstable, it is unlikely to leave toxic residues. Iodophors are not very effective against rotavirus, particularly if organic matter is present. Virkon, a newer disinfectant/cleaner containing potassium monopersulfate as the active ingredient, is effective for all pathogens except cryptosporidia. Normally, a 1% solution is used and is prepared by mixing 10 g of powder to 1 L of water. Contact time should be a minimum of 10 minutes. Virkon has the advantage of having a detergent action that facilitates cleaning.

Formaldehyde is one of the few agents that are effective against cryptosporidia. It requires a long contact time and is highly toxic. It is usually used for terminal fumigation in buildings that can be tightly sealed. Formaldehyde gas is best generated by heating paraformaldehyde (5 g/m^3 of building) in an electrically heated pan at 204° C. Some manufacturers of paraformaldehyde provide pans especially designed for this purpose. The pans should be placed no more than 30 m apart and arranged so that electricity to the pan can be

controlled from outside the building. There must be a safety mechanism to ensure that the pan does not overheat and cause a fire. The building must be sealed for at least 24 hours and cannot be entered until it has been thoroughly ventilated. Formaldehyde gas can also be generated by boiling formalin or by adding potassium permanganate to formalin. The latter method generates a violent chemical reaction and carries risks of explosion. Formalin aerosol generators are ineffective.[440] Following cleaning and disinfection, one should allow a rest period for the building to ventilate before reintroducing calves. It is very important that cleaning and disinfection be thorough. Attention should also be given to rodent control since these can be a reservoir for *Salmonella*.[441]

MINIMIZING PATHOGEN EXPOSURE IN BEEF HERDS. In beef herds, calving areas should be located to take advantage of natural shelter and drainage and rotated from year to year to avoid pathogen buildup.[402,422,442,443] Pregnant cattle are moved into a clean paddock no more than 2 weeks prior to the start of calving. It is best that cows and heifers are managed separately until after calving. This gives the opportunity to provide better feed to the heifers and to minimize infection between the groups. Confined, wet, or muddy areas should be avoided for calving cows; where they need to be used, the stocking rate should be decreased. Feed-out areas should be rotated to encourage cow disposal and separated from watering points. When pasture for calved cows is limited, supplementary feed should be fed to dry cows to ensure enough fresh pasture for calving and nursing cows. Clean water should be available in a trough that is accessible to cows and calves. Chronically sick animals, weak calves, and cows with no milk should be removed from the calving paddock and kept isolated from the herd.

Grazing and reproductive management have a significant impact on pathogen load. Where appropriate to grazing management, calving paddocks should be left vacant during the summer. For producers that manage periparturient cows in smaller calving paddocks to facilitate supervision, the emphasis should be on minimizing the stocking density in the calving paddock by removing cows and calves shortly after parturition.[422,442] Alternatively, cows can be moved away from cows with calves every 1 to 2 weeks or more frequently in large herds. Young calves in the calving paddock will markedly increase the rate of pathogen buildup and the subsequent challenge to newborn calves. Moreover, the increased stocking rate will amplify stress, affecting both transfer of passive immunity and the ability of young calves to rest. Often calving areas are small due to the perceived need to assist cows for dystocia.[443] Well-grown and appropriately fed heifers mated to suitable sires can minimize this need. Beef cows with calves at foot moved from the calving paddock should be moved into nursing groups that have a maximum age range of 4 weeks and a low stocking rate. Groups should not be mixed until all calves are at least 4 weeks old.[422,442,443] Reproductive management influences pathogen load by determining the age spread of the calves. Sick calves amplify environmental contamination. A prolonged calving period leads to a buildup of contamination so that calves born later in the calving period experience an increased pathogen challenge. It is desirable to maintain a calving period that is less than 60 days.

Boosting Specific and Nonspecific Immunity

Ensuring adequate passive transfer is necessary to achieve enhanced pathogen-specific immunity through maternal vaccination. Colostrum management is discussed in detail in Chapter 19.

ENTEROTOXIGENIC *E. COLI*. The protective efficacy of enterotoxigenic *E. coli* bacterins is well documented.[444-447] Because ETEC scours occurs during the first 3 days of life, the neonate does not have time to mount a protective immune response to vaccination. Protection is afforded by vaccinating cows in late gestation in order to ensure high concentrations of anti-F5 (K99) colostral antibodies. Good maternal management is required to ensure that the calf receives the maternal antibodies. Anti-pilus antibodies block the adhesion of the pathogen to enterocytes and subsequently prevent disease.[447a] In general, it is recommended that the vacci nes are given 6 and 3 weeks prior to calving. Studies with some vaccines have shown that the vaccine is still effective if the priming dose is given 18 months before calving and boosting is carried out in the second half of gestation.[448] Clinical experience in beef farms suffering severe outbreaks of *E. coli* F5 (K99) diarrhea indicates that vaccinating cows that are more than 10 days from parturition can give considerable protection against death from enterotoxigenic *E. coli* infection.

Products containing monoclonal antibodies against F5 (K99) antigen have been shown to reduce the severity of diarrhea when calves are experimentally challenged a few hours after receiving the product.[449] In field situations, however, monoclonal products can have a low efficacy, presumably because a single dose only provides a short period of enteric protection. Antibody supplements are expensive and vaccination of the dam to boost colostral immunity will usually be more cost effective. On farms experiencing an outbreak of neonatal diarrhea caused by F5 (K99) *E. coli,* there may be a place for the use of these products until vaccinated cows begin to calve. However, short-term administration (once a day for the first 3 days of life) of an antibiotic to which the *E. coli* is susceptible is also highly effective in preventing diarrhea in herds experiencing outbreaks of enterotoxigenic *E. coli*.

VetBooks.ir

SALMONELLA. The successful reduction of *Salmonella* prevalence in livestock on a national level via implementation of a *Salmonella* control program emphasizing immunoprophylaxis with modified live and killed *Salmonella* vaccines indicates the potential benefits that can be derived from the application of effective *Salmonella* vaccines.[450] *Salmonella* vaccine studies in cattle have focused on killed whole cell (bacterins), bacterial fractions (subunit), and attenuated modified live *Salmonella*.

There are conflicting reports regarding the efficacy of *Salmonell* a bacterins. The reported efficacy of *Salmonella* bacterins ranges from good to ineffective.[451-459] The overall consensus of these reports is that vaccination of cattle with *Salmonella* bacterins provides partial protection against *Salmonella* challenge. In the only reported controlled field trial, an autogenous *Salmonella* bacterin was not found to have any effect.[459] Adverse reactions in the form of anaphylactic reactions are occasionally reported in cattle vaccinated with *Salmonella* bacterins. The cause of these reactions is unknown but has been suggested to be associated with the LPS content of these products. Similar allergic-type reactions in humans caused by *Salmonella* bacterin vaccination during typhoid outbreaks are well documented.[460]

A commercial subunit vaccine has become available in the United States that is based on purified extracts of siderophore receptors and porins (SRP) of *Salmonella* Newport.[461] The SRP proteins are critical for iron acquisition and are highly conserved between most gram-negative organisms.[462] There have been no peer-reviewed studies examining the efficacy of the vaccine for the prevention of diarrhea.

Several naturally occurring and genetically manipulated attenuated *Salmonella* strains have been used to immunize cattle against salmonellosis. The most widely tested genetically altered *Salmonella* mutant vaccines in cattle are the auxotrophic strains. Aromatic amino acid (aro) and purine (pur) auxotrophs of *Salmonella* are attenuated and have decreased virulence.[463-469] Comparative vaccine trials indicate that modified live attenuated *Salmonella* vaccines provide greater protection against virulent *Salmonella* challenge than *Salmonella* bacterins.[457,469,470] Vaccination with modified live *Salmonella* vaccines attenuates the severity of clinical signs and pathologic lesions and reduces *Salmonella* shedding and mortality.[450,465,471]

Calves immunized with modified live *Salmonella* vaccines are protected from homologous and heterologous *Salmonella* serotypes when challenged within 3 weeks of vaccination.[472-474] Live *Salmonella* vaccines induce transitory T-cell–independent nonspecific protection, which disappears about 1 month after immunization following clearance of the organisms from the reticuloendothelial system. Thereafter, protection to oral challenge is species and serotype specific with recall of immunity presumably involving specific antigen recognition.[475,476]

The level of passive protection of calves achieved via feeding colostrum from vaccinated cows is questionable. A number of reports suggest immune colostrum provides passive protection and others report no protective effect. In trials in which protection was achieved, calves were challenged at 1 week of age; trials in which no protection was observed involved challenging calves at 3 weeks of age, suggesting that the duration of passive immunity associated with colostral transfer is relatively short. Considering that many calves are exposed to *Salmonella* in the first week of life, colostral protection may be useful.

ROTAVIRUS AND CORONAVIRUS. BCV is associated with a number of diseases in cattle; all BCV isolates are believed to belong to a single serotype.[477] Differences in hemagglutination-inhibition characteristics have been used to classify strains as type 1 through 3.[478] Seven serogroups of rotavirus with group A exist, accounting for the majority of pathogenic isolates. Members of the group A rotaviruses are further classified according to antigenic and genetic differences in their outer capsid proteins, G and P. Both of these proteins are involved in neutralization of infectivity in vitro and in vivo.[479] In the United States, 8 G serotypes/genotypes and four P serotypes/genotypes have been identified in cattle isolates.[206] The genome of rotavirus is composed of 11 gene segments that can be exchanged among isolates when animals are infected by more than one virus at the same time.[480] Genetic reassortment can generate new progeny viruses that can evade what was once a protective immune response, thus allowing persistence of rotavirus in susceptible populations.[479]

Two approaches have been taken with immunoprophylaxis against rotavirus and coronavirus infections in calves. The first approach involves oral vaccination of neonatal calves with a modified live vaccine. Calves begin producing detectable levels of local secretory IgM within 4 to 6 days of vaccination.[481] Calves are resistant to challenge from the initial appearance of local IgM antibodies.[481] In order to consistently elicit an effective immune response, the vaccine must be administered orally, immediately after birth, and before the calf has nursed because the colostrum of most cows contains virus-neutralizing antibodies that interfere with the vaccine.[482] There are conflicting reports of efficacy with these types of vaccines. In double-blind field studies that include vaccinated and nonvaccinated calves, the vaccine was not shown to be effective.[483] Conversely, when all calves were either vaccinated or not vaccinated in sequential comparisons, morbidity and mortality were significantly reduced.[483]

The second approach involves intramuscular vaccination of pregnant cows with either modified live vaccine or inactivated viral vaccines to stimulate high levels of specific viral-neutralizing antibodies in colostrum and milk during the first several days of the calf's life. Infectious viral particles are neutralized within the gut lumen, preventing infection of intestinal villous enterocytes. One advantage of passive immunization is the fact that cross-protection between serotypes is less of a problem. This is due to the fact that vaccination of a mature cow that has had natural rotavirus exposure leads to cross-serotype stimulation of heterotypic antibodies.[484] Single serotype vaccination therefore stimulates antibody production to a wide range of rotavirus serotypes, negating the need for multivalent rotavirus vaccines. Passively absorbed anti-bovine rotavirus IgG1 antibodies are transferred to the small intestinal lumen, where they protect against experimental challenge.[485] Antigen-sensitized maternal lymphocytes also confer partial protection against challenge with virulent bovine rotavirus.[486] Colostrum and milk with a high virus-neutralizing antibody titer are highly protective while it is being consumed by the calf. For example, administering 400 mL of immune colostrum daily to calves from day 2 to 12 reduced the incidence of diarrhea from 41% to 3% in one study.[487] The concentration of rotavirus- and coronavirus-neutralizing antibodies in milk of vaccinated cows falls below protective levels by 3 to 7 days following parturition.[488-490] In lieu of complete protection, the manifestations of passive immunity to bovine rotavirus that are often noted are (1) a delay of a few days in the onset of clinical signs, and/or (2) a reduced severity of clinical signs, and/or (3) a reduction in the length of the period of viral shedding associated with infection.[491] Although there are reports of successful field trials involving bovine rotavirus/bovine rotavirus-coronavirus–vaccinated cows,[446,492,493] negative results have also been reported.[494] A common problem with commercial vaccines on the market in the United States and Europe is a lack of vaccine-specific data supporting efficacy claims. Protection correlates with serum titers; independent studies have sometimes failed to demonstrate effective seroconversion with some products.[495]

Nonspecific Immunity

DIET. The microbial quality of the diet is an important factor in preventing diarrhea. Calves that are fed milk from mastitic quarters or antibiotic-containing milk are at increased risk of diarrhea.[408] Following fresh colostrum feeding, young calves have less diarrhea if placed on whole cows' milk rather than other diets. Pasteurizing surplus colostrum and waste milk reduces the incidence of diarrhea on these diets.[496] It is also important to offer good-quality calf starter from about 2 to 3 days of age; at first, little will be ingested, so producers should offer small amounts and keep it fresh.

Some producers routinely administer vitamin A to neonatal calves. Many, but not all, studies in human children indicate that supplementation can reduce the incidence of diarrhea in areas where

VetBooks.ir

clinical and subclinical vitamin A deficiency is endemic.[497] In cattle, vitamin A deficiency is most likely when a diet of unsupplemented straw and grain is fed. Calves born to cows fed good-quality green forage or to cattle receiving a vitamin A supplement should not require supplementation, particularly if they received adequate colostrum. Enteric absorption of vitamin A is diminished in calves with cryptosporidiosis so the systemic route should be used in calves with this type of infection.[498]

BIOSECURITY. Infectious diseases are often purchased with brought-in stock. Operations that buy in calves for rearing purposes should be encouraged to buy from as few sources as possible. Direct purchase from one farm is best; assembling collections of calves through auction markets should be avoided if possible.

Treatment of Individual Calves

Examination

Physical examination of the diarrheic calf is the first step in establishing therapeutic needs. It is important to determine the presence of any intercurrent disease. Treatment of uncomplicated cases of diarrhea depends on the estimation of dehydration, severity of acidosis, likelihood of intercurrent infection, presence or absence of hypothermia, and hypoglycemia. The severity of dehydration is gauged from the eyeball position and skin tent (Table 20-9). In acute diarrhea the degree of enopthalmos is the most reliable indicator of dehydration, but because the position of the eye within the orbit is also dependent on body fat stores, the skin tent in the cervical region may be the most reliable in calves with chronic diarrhea or cachexia.[499] Skin tent can be measured over the eyelids and neck. Best results are obtained when the neck is held straight and the skin of the mid-neck is tented in the direction of the long axis of the neck to avoid the natural skin folds that run across the neck. Some have claimed that a relationship exists between severity of dehydration and acidosis. However, this has not been borne out in studies of diarrheic calves.[500] Instead, acidosis can be gauged from the calf's suckling/drinking drive and the degree of weakness and the age of the calf (Fig. 20-4).[500,501] Estimation of severity of acidosis from either laboratory or physical findings is very important to the successful therapy of severely depressed calves. A recent study has questioned the relationship between metabolic acidosis and clinical signs since administration of hypochloric acid failed to induce abnormal clinical signs in calves.[502] The clinical signs associated with metabolic acidosis are mainly attributable to elevations in D-lactate.[140,143] Rectal temperature measurement will determine whether or not the calf is hypothermic.

Heart rate is variable in diarrheic calves. Bradycardia (<90 beats/min) is clinically important and may indicate the presence of hypothermia, hypoglycemia, or hyperkalemia. Cardiac arrhythmias occur[501] and are usually due to severe hyperkalemia (K^+ above 8 meq/L) (Fig. 20-5). Hyperkalemic arrhythmia can usually be differentiated from arrhythmia resulting from cardiomyopathy (selenium deficiency) because the heart rate is not elevated. The presence of bradycardia or arrhythmia indicates the need for immediate fluid therapy with bicarbonate-containing solutions to prevent death.

Body condition is usually good at the start of an attack of diarrhea. Poor condition often indicates chronic infection, mismothering, or poor feeding programs, which may be exacerbated by milk withdrawal for therapeutic purposes.

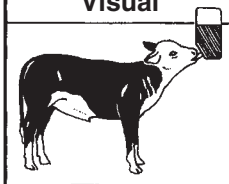
It is important to check for intercurrent infections; these are easily missed even with careful examination. The lungs should be examined for signs of pneumonia; the navel palpated for pain, swelling, and wetness; and the joints checked for signs of distention and lameness. The boundary between calves in which the primary insult is septicemia with a secondary diarrhea and those in which primary diarrhea is complicated by septicemia is blurred. Calves that are recumbent, are under 1 week of age, have lost their suck reflex, or have evidence of intercurrent infection are more likely to be septicemic and require concurrent antibiotic therapy.[503] Calves in which septicemia has progressed to produce signs of meningitis (e.g., extended neck with reluctance to flex neck), joint involvement, or ophthalmic signs (congested scleral vessels with hypopyon or iridospasm) carry a poor to very poor prognosis. It is best to identify these cases prior to instigating therapy so that the owner can decide whether treatment is economically feasible.

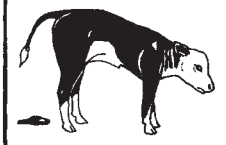
The laboratory is useful in quantifying metabolic disturbances in diarrheic calves. Blood gas analysis will accurately determine the degree of metabolic acidosis. The development of point of care devices (such as i-STAT, Abbott Laboratories, Abbott Park, Ill.), which are relatively affordable, has enabled practitioners to evaluate acid-base abnormalities in the field. The portable analyzers are capable of quantifying concentrations of Na^+, K^+, iCa^{2+}, and tCO_2 as well as determining pH, PCO_2, PO_2, base excess, and hematocrit. Correlations between the i-STAT and a reference analyzer in cattle and sheep were good or excellent for most variables.[504] Alternatively, blood can be collected into a heparinized syringe, capped, placed in a styrofoam cup surrounded by ice, and transported 4 hours or more to a laboratory. The practice laboratory may also have a total CO_2 (Harleco) analyzer or access to serum bicarbonate estimation as part of a serum chemistry profile. Total CO_2 or bicarbonate is a useful index of the severity of metabolic acidosis. Blood glucose can be readily determined using a handheld glucometer.

Fluid Therapy

The most common causes of death in diarrheic calves are dehydration and acidosis.[505] The immediate objective in treating depressed diarrheic calves is to restore them to a normal systemic state. In some calves it may also be necessary to correct hypoglycemia or hypothermia, to restrict milk intake, or to give antibiotics.

The estimated severity of dehydration can be combined with estimates of losses through diarrhea and for the maintenance of essential functions to give the total daily fluid requirement (see Table 20-9). The hydration status of the calf can be estimated from the degree of enopthalmos, the degree of skin tent on the neck, and evaluation of the mucous membranes (see Table 20-9). The volume (L) required to replace the deficit is % dehydration × calf body weight (kg). The ongoing losses through diarrhea should be estimated from the nature and volume of the diarrhea. Fecal losses can range from 1 to 6 L in diarrheic calves.[506] Maintenance requirements have been estimated at 50 to 100 mL/kg/day.[31,506] The degree of hydration and the volume of feces passed should be reassessed daily and the treatment adjusted accordingly. Only 60% to 80% of oral fluids are absorbed, and this needs to be accounted for in the calculation.[507]





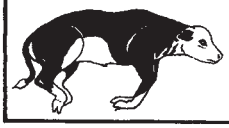


TABLE 20-9

Guidelines for Assessing Dehydration in Neonatal Calves

Dehydration (%)	Eyeball Sunkenness	Neck Skin Tent (Seconds)	Mucous Membranes
0	None	<1	Moist
1-5	None to slight	1-4	Moist
6-8	Slight separation of eyeball and globe	5-10	Tacky
9-10	Gap, <0.5 cm, between eyeball and orbit	11-15	Tacky to dry
11-12	Gap, 0.5-1 cm, between eyeball and orbit	16-45	Dry

VetBooks.ir

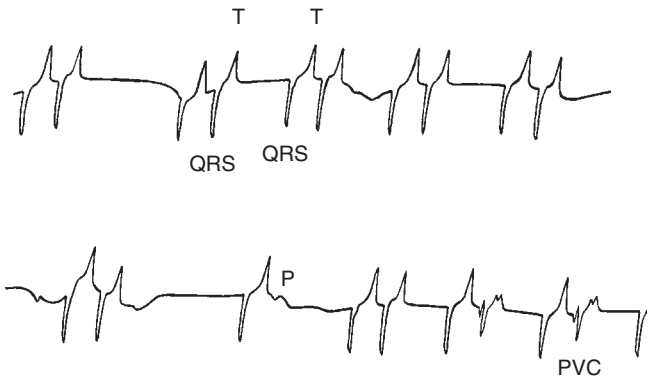

FIG. 20-5 Bradycardia and atrial standstill in a severely hyperkalemic diarrheic calf. Heart rate is 84 beats/min. There is bigeminy, and the T waves are abnormally large. There is only one P wave, and it is not conducted. Serum potassium was 8.9 mmol/L, and sodium 116 mmol/L.

Bicarbonate requirements can be calculated from base deficit values (based on blood gas measurements or estimated from physical findings) as follows:

$$\text{mmol bicarbonate} = \text{Body weight (kg)} \times \text{Base deficit (mmol/L)} \times \text{Volume of distribution (0.6 in calves)}$$

A chart of bicarbonate requirements for various body weights and base deficit values is available in Table 20-10.

Measurements of serum total carbon dioxide content or bicarbonate are also reliable estimates of bicarbonate requirements.[508] Bicarbonate requirements are as follows:

$$\text{mmol bicarbonate} = \text{Body weight (kg)} \times (30 - TCO_2) \times 0.6$$

For example, a 40-kg calf has a serum bicarbonate or TCO_2 of 10 mmol/L. The calf has a bicarbonate deficit of 30 mmol/L − 10 mmol/L = 20 mmol/L, so 40 kg × 20 mmol/L × 0.6 = 480 mmol bicarbonate is required to replace existing deficits. Ongoing diarrhea may require additional bicarbonate.

Calves that are unwilling to suck and are severely depressed are best treated with IV fluids. Calves that are only moderately depressed may also be treated with intravenous fluids if the condition is worsening rapidly. Catheterization is easier if a no. 15 scalpel blade is used to nick the skin. If it proves very difficult to catheterize the calf it can be suspended upside down so that blood will pool and distend the jugular veins. The calf's neck should be clipped and prepared prior to inversion and the calf lay flat as soon as the catheter is placed. It should be possible to place a catheter in less than a minute even in severely dehydrated calves using this technique. Alternatively, the auricular vein can be easily catheterized using a 20-gauge catheter, or fluids may be administered by intraosseous infusion in the critically ill neonate when IV access is not possible. In calves, intraosseous fluids may be administered via placement of a 16- or 14-gauge needle in the head of the femur or humerus. A 16- or 14-gauge needle is inserted in a longitudinal plane. Neonatal bones are soft, so the needle can be drilled into the bone using finger pressure. Commonly a core of bone will plug the needle, requiring the drilling needle to be discarded and replaced with a new needle placed in the same hole. After placement of the needle, attach a 60-mL syringe and inject sterile saline under slight pressure to start the flow. As the fluid is administered, check for subcutaneous leakage to ensure the needle is correctly placed within the bone marrow. Between 1 and 2 L of saline or isotonic bicarbonate administered to the severely dehydrated calf is often sufficient to restore blood pressure for placement of an IV catheter.

Once the catheter is placed, fluids can be administered. If the calf is hypothermic, these should be warmed prior to administration because cold fluids can decrease cardiac output and may kill a critically ill calf. Fluids can be warmed by a number of methods; one convenient technique is to run the fluids through a coil of tubing immersed in a bucket of hot water (check the temperature regularly) on the way to the calf.

Saline-based fluids are suitable for rehydration (Table 20-11); most severely depressed calves are acidotic and more consistent recovery is obtained if an alkalizing agent is also used. A wide variety of alkalizing agents are available (lactate, acetate, gluconate), but clinical trials show that only bicarbonate is consistently effective in severely acidotic calves (Fig. 20-6).[138,509] Many diarrheic calves require large amounts of bicarbonate to correct their acidosis.[136] An isotonic solution (156 mmol/L) of bicarbonate can be readily made by dissolving 13 g of sodium bicarbonate (baking soda) in 1 L of water.[510] Sodium bicarbonate solutions can be mixed with saline; there is a possibility that precipitates may form if bicarbonate is mixed with calcium-containing solutions such as Ringer solution.

Some clinicians may prefer to rehydrate the neonate first and then reconsider the need for bicarbonate if it is not up and sucking within 12 hours of therapy. However, this is time consuming. It is not always necessary to completely correct acidosis; blood pH from 7.25 to 7.45 has little adverse effect (normal calves have a venous blood pH of 7.34, bicarbonate of 30 mmol/L, and a base excess of 5 mmol/L).

Ideally, dehydration and acidosis should be corrected over a 24-hour period. However, it is unusual to see problems when the fluid and acid-base deficits are corrected over 4 hours, although the calf may continue to improve after this period. Rapid resuscitation techniques include the administration of either hypertonic saline (with or without dextran) or hypertonic sodium bicarbonate. Hypertonic saline (7.2% NaCl) or hypertonic saline dextran (7.2% NaCl containing 6% dextran 70) administered at 4 mL/kg body weight during a 4-minute period concurrently with an isotonic alkalizing oral electrolyte solution is effective in resuscitating dehydrated calves with

TABLE 20-11

Fluids Commonly Used in Intravenous Therapy

Item	Concentration (mmol/L)									
	Na^+	K^+	Ca^{++}	Mg^{++}	Cl^-	HCO_3^-	$Lactate^-$	$Acetate^-$	$Gluconate^-$	Glucose
0.9% saline	155				155					
1.3% sodium bicarbonate*	156					156				
Ringer solution	147	4	5		156					
Lactated Ringer solution†	130	4	3		107		30			
Ionalyte (diluted)†	139	10		3	101			55		167
Normosol R†	140	5		3	98			25	25	
Plasmalyte 148†	140	5		3	98			27	23	
5% dextrose (D_5W)‡										278

*Do not mix sodium bicarbonate with calcium-containing solutions; precipitates may form. Mixtures of 1.3% sodium bicarbonate and saline are usually used for treating recumbent diarrheic calves.

†Multiple electrolyte solutions are equivalent, with the exception that one should be careful of using Ionalyte in severely hyperkalemic neonates. All are suitable for rehydrating neonates that can stand.

‡Intravenous fluids are often spiked with 50% dextrose to give a final concentration of 5% dextrose in the drip when hypoglycemia is suspected.

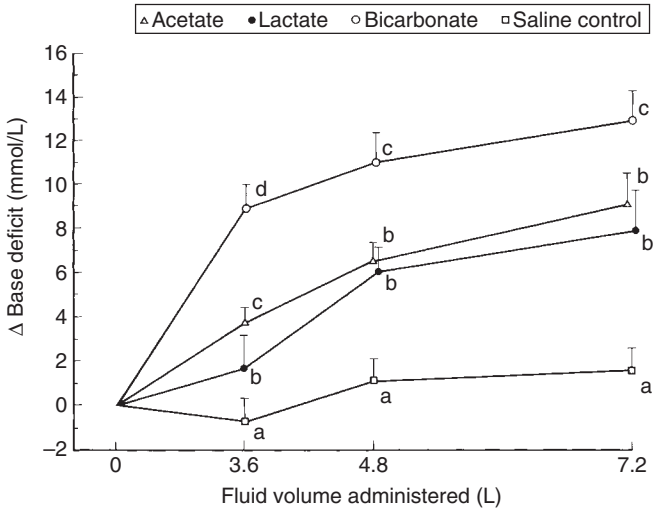

FIG. 20-6 Comparison of the alkalizing effect of various bases in diarrheic calves with severe dehydration and acidosis. At the start of the trial, all calves were at least 8% dehydrated and had a mean blood pH of 7.032 and a base deficit of 18 mmol/L. All calves received a total of 7.2 L of fluid containing 102 mmol/L of saline plus 50 mmol/L of the sodium salt of the respective alkalizing agent. Letters *(a, b, c, d)* are statistically different ($p < 0.5$) from one another at that point. *(From Kasari TR, Naylor JM. 1985. Clinical evaluation of sodium bicarbonate, sodium L-lactate, and sodium acetate for the treatment of acidosis in diarrheic calves. J Am Vet Med Assoc 187:392.)*

diarrhea.[511,512] Hyperosmotic sodium bicarbonate solutions may also be used to rapidly resuscitate acidotic dehydrated calves.[513-515] The base deficit can be corrected by administering 8.4% sodium bicarbonate 10 mL/kg body weight over 8 minutes.[515a] Hypertonic fluids should always be given concurrently with an isotonic oral electrolyte solution. After 24 hours of appropriate therapy, one would expect the calf to be standing and show a good suck reflex. Persistent depression is usually a sign of uncorrected acidosis or toxemia.

Most diarrheic calves are not markedly hypoglycemic, but glucose supplementation is needed to treat severe hypoglycemia (glucose concentrations <2 mmol/L or <36 mg/dL). Severe hypoglycemia is treated by adding glucose to the IV fluids to a final concentration of 2.5% to 5%. Severe hyperkalemia is seen in some dehydrated diarrheic calves, but this responds to rehydration (restores renal perfusion and dilutes out potassium) and correction of acidosis (redistributes potassium into the cells). Nutritional support is not needed if the calf is in good body condition but should be given if the calf is emaciated or if the calf has been deprived of milk for more than 3 days.

There are increased losses of potassium in diarrhea; potassium depletion can result in weakness. When necessary, potassium supplementation can be estimated using the following equation:

$$\text{Replacement K (mEq)} = 0.4 \times \text{Body weight (kg)} \times \text{K deficit (mEq)}$$

Potassium can safely be added to fluids at a rate of 20 to 30 mEq/L. The rate of potassium administration should not exceed 1 mEq/kg/h. If acidosis is present, hydrogen ions are exchanged for intracellular potassium ions, resulting in a relative increase in serum [K]. As the acidosis is corrected, there will be an influx of K ions back into cells, resulting in potential hypokalemia, which must be anticipated during fluid therapy.

Once the calf is able to nurse or drink, therapy is usually switched to oral electrolytes. This is also the route of choice for treatment of mildly affected calves on the farm. Calves with weak suck reflexes and calves that are unused to hand feeding can be tubed. Oral electrolyte solutions need to supply sufficient sodium to facilitate normalization of extracellular fluid deficits, nutrients to facilitate absorption of sodium from the intestine, alkalizing agent to treat metabolic acidosis, and supplemental energy.[516] The first two requirements depend on the coupled active transport of glucose and sodium ions across the brush border membranes of enterocytes, which results in passive absorption of water and other electrolytes.[517] This function remains largely intact in calves with enterotoxigenic *E. coli* diarrhea, but where there is endothelial damage, it may be impaired. Certain amino acids (glycine, L-alanine, L-glutamine) enhance the absorption of sodium and water,[517] as do acetate and propionate.[518] In order to effectively combat acidosis, oral electrolyte solutions need to contain 50 to 80 mmol/L of alkalizing agent. Acetate, lactate, citrate, gluconate, or bicarbonate are all used as alkalizing agents. Bicarbonate combines with hydrogen ions directly whereas the other agents remove hydrogen ions during their metabolism within cells.[506] Electrolyte solutions that contain more than 40 mmol/L of bicarbonate or citrate have marked adverse effects on milk clotting.[519] Bicarbonate raises abomasal pH, whereas citrate binds calcium, so the presence of either interferes with the normal clotting of milk in the abomasum. Breakdown of abomasal milk clots results in the gradual release of some nutrients into the small intestine. Bicarbonate also reduces milk digestibility. A reduced growth rate was recorded when electrolyte solutions with bicarbonate were given to milk-fed calves.[520] Solutions containing bicarbonate may also alkalize the gastrointestinal tract of milk-fed calves and promote bacterial overgrowth in the small

VetBooks.ir

intestine as well as ETEC attachment and toxin production.[521] Acetate is the best alkalizing agent to include in electrolytes that are to be fed to calves that are still receiving milk; it has excellent alkalizing ability and does not interfere with milk clotting in the abomasum. Any of the commonly used alkalizing agents are likely acceptable for calves held off milk.[519]

There are a wide variety of oral electrolyte preparations on the market, and different products are suited to different situations. Almost all of the products contain water and electrolytes and are suitable for rehydration (Table 20-12). Beware of products that are designed for medicating hundreds of liters of water—the final solution is often very dilute (<10 g electrolytes/L) and will not rehydrate sick calves. These products are often marketed as "boosters" and "stress relievers." Glucose and glycine are usually added to oral electrolyte solutions to facilitate sodium absorption. Research in people has shown that adding glycine to solutions containing 110 mmol/L of glucose aids rehydration. It is probable, however, that there is little additional benefit to supplementing solutions that contain more than 200 mmol/L of glucose with glycine. Solutions that contain large amounts of glucose are hyperosmolar and are absorbed more slowly than isotonic solutions, but the differences are too small to be clinically important.[522] The ionic composition also affects absorption; mixtures of sodium chloride and citrate, bicarbonate, or acetate have improved absorption over chloride salts alone. Oral electrolyte solutions are almost completely absorbed in healthy calves, but absorption can be as low as 60% in severe *E. coli* diarrhea.[523]

The ability to counteract acidosis varies greatly between oral electrolytes. Some have a net acidifying effect whereas others alkalize blood (Fig. 20-7). These differences are therapeutically important and are responsible for differences in survival rates among products. Highly alkalizing solutions give the best results; one study showed that it was more important that an electrolyte solution contain bicarbonate than chloride.[524] This is particularly important in older calves. Recently there has been interest in adding glutamine to oral electrolyte solutions because it is an important fuel for the gastrointestinal tract and can promote mucosal repair.[525-527] However, studies show that oral electrolytes containing glutamine as the sole amino acid are no more effective in diarrheic calves than other well-designed solutions that use glycine as the amino acid.[528] Psyllium has been added to some oral electrolyte solutions for a number of perceived benefits, but controlled studies show no clinical advantages, although there may be some moderation of bacterial fermentation within the gastrointestinal tract.[529,530]

The other problem to be considered in the chronically scouring calf is the need for nutritional support. Maintenance metabolizable energy requirements for a 50-kg calf are about 2000 kcal, and 3500 kcal are required to support a weight gain of 0.5 kg/day. These requirements can be met by 3.3 and 5.7 L of whole cows' milk, respectively. Comparative studies indicate that weight loss in calves fed oral electrolytes are inversely proportional to the energy content of the solutions.[531] Assuming a 4-L daily intake and 100% digestibility of oral electrolyte nutrients, regular electrolyte solutions supply between approximately 15% and 25% of energy needs. As a result diarrheic calves that are held off milk for prolonged periods lose weight[532] and can become emaciated. When maintaining body condition is a concern, and little milk or solid food is being ingested, then a high-energy oral electrolyte should be fed. Products such as Biolyte, Lifeguard/Enterolyte HE, and RESTART HE provide about 50% of energy requirements if fed twice a day (total intake 4 L) and about 75% if fed three times a day (total intake approximately 6 L). The energy contents of various oral electrolyte solutions are presented in Fig. 20-8.

MILK WITHDRAWAL. Milk withdrawal can reduce the severity of diarrhea and depression in severe scours. This is because malabsorption exacerbates diarrhea through the osmotic effect of unabsorbed milk nutrients and promotes bacterial overgrowth and possibly malfermentation with production of organic acids. Milk also has a trophic effect on epithelial cells and maintains higher gastrointestinal tract enzyme activities as well as providing protein for repair of damaged intestinal epithelium.[518] In experimental trials, continued feeding of milk maintained weight gain; however, when calves were fed enough milk to fully meet their requirements and the undrunk milk was tube fed, calves initially had greater inappetence.[520,533] Withdrawal of milk without a high-energy alternative can rapidly result in cachexia and malnourishment.[520] In many calves, particularly the less severely affected, there is often a considerable degree of residual absorptive capacity—enough to support body weight gain if limited amounts of milk are fed. Milk withdrawal is recommended if the calf is depressed and not interested in sucking. In most cases electrolyte therapy will restore a calf's vigor and sucking drive within 1 to 2 days. Milk can then be reintroduced in small amounts (e.g., 1 L given bid or qid). However, forced feeding (by tubing or drenching), causing dysfunction of the reticular groove reflex, or reflux of abomasal contents, may result in ongoing acidosis as a result of production of D-lactate from fermentation of carbohydrates entering the reticulorumen.[143] If the calf is not interested in drinking or gets depressed when reintroduced to milk, a high-energy oral electrolyte preparation can be tried instead. Studies indicate that diarrheic calves have a generalized malabsorption rather than specific lactose intolerance.[133] Thus, it may be more important to manage calves with milk intolerance by giving smaller amounts of milk in each feed rather than by changing carbohydrate source. There is little point in withdrawing milk from calves that remain alert and interested in nursing, because it is unlikely to result in clinical improvement. This is particularly likely to be the case when the calf receives whole cow's milk in frequent small quantities (i.e., by natural sucking of the dam).

Role of Antimicrobials

Some controversy exists regarding the use of antimicrobials for the treatment of calf scours. Reports questioning the use of antimicrobial therapy are derived from lack of efficacy, the potential for adverse effects, the potential for violative residues, and selection for antimicrobial resistance. Conversely, there are reports describing attenuation of clinical disease, reduced pathogen shedding, and lower mortality following the use of antimicrobials to treat scouring calves.

THERAPEUTIC TARGETING. Bacterial pathogens associated with neonatal calf diarrhea include *Salmonella* and *E. coli*. During disease outbreaks caused by these pathogens, antimicrobial use may be targeted at the specific pathogen. Beneficial responses to antimicrobial therapy have also been reported in field trials involving undifferentiated pathogens.[534,535] Calves with diarrhea often have increased coliform bacterial numbers in the small intestine, regardless of etiology,[536-538] and this colonization is associated with altered small intestinal function, morphologic damage, and increased susceptibility to bacteremia.[538] Calves with diarrhea are more likely to have failure or partial failure of passive transfer, and this group of calves, in turn, is more likely to be bacteremic.[21,539] Blood cultures indicate that gram-negative bacteria account for approximately 80% of bacterial isolates; *E. coli* is the most common bacteria isolated.[17,18,539] In a study of 190 recumbent calves on a large calf-raising facility, 31% were determined to be bacteremic. *E. coli* accounted for 51% of the isolates; other gram-negatives, 25%; gram-negative anaerobes, 5.9%; gram-positive cocci, 11.8%; and gram-positive rods, 5.9%.[539]

Antimicrobial therapy may therefore be targeted at a specific bacterial enteric pathogen isolated from sick calves or in severely ill calves (as manifested by reduced suckle reflex, greater than 6% dehydration, weakness, inability to stand, or clinical depression) and used prophylactically to manage the risk of bacteremia. This application emphasis should be directed toward gram-negative organisms, particularly *E. coli*.

ANTIMICROBIAL SUSCEPTIBILITY. Antimicrobial susceptibility testing of fecal isolates is not a good predictor of clinical outcome. Three studies have reported no correlation between in vitro antimicrobial susceptibility of fecal *E. coli* and *Salmonella* spp. isolates and clinical response to antimicrobial treatment.[540-542] Antimicrobial

Updated table based on Naylor JM. 1999. Oral electrolyte therapy. Vet Clin North Am Food Anim Pract 15:487. Calculated from information listed in the Compendium of Veterinary Products, 2007, and product labels. Additional information obtained from Jones C, Kehoe S, Heinrichs J. Comparison of some available oral rehydration products. Pennsylvania State University, 2006, Department of Dairy and Animal Science. Available at http://www.das.psu.edu/pdf/electrolytetable.pdf.

Note: Concentrations of calcium, magnesium, phosphate, and sulfate not included. Molarities assume that all compounds dissociate completely in solution. Where a maximum and minimum value for a compound was provided, the mean value has been used.

*Contain maltodextrins (glucose polymers). It has been assumed that these will be completely digested to provide glucose.

?, Published information insufficient to provide reasonable estimate.

VetBooks.ir

efficacy is best evaluated by the clinical response of a number of calves to treatment, with calves randomly assigned to treatment groups, rather than the results of in vitro antimicrobial susceptibility testing performed on fecal *E. coli* isolates.[543]

Antimicrobial susceptibility testing has more clinical relevance for predicting the clinical response to antimicrobial treatment when applied to bacteria isolated from blood or tissues of bacteremic calves because the minimal inhibitory concentration break points are based on achievable antimicrobial concentrations in human plasma and MIC_{90} values for human *E. coli* isolates, which provide a reasonable approximation to achievable MIC values in calf plasma and MIC_{90} values for bovine *E. coli* isolates.[543] Even within a given herd, there will be a diversity of bacteria isolated from bacteremic calves, so the collection of blood cultures and assessment of antimicrobial susceptibility does not necessarily provide information applicable to the next case.

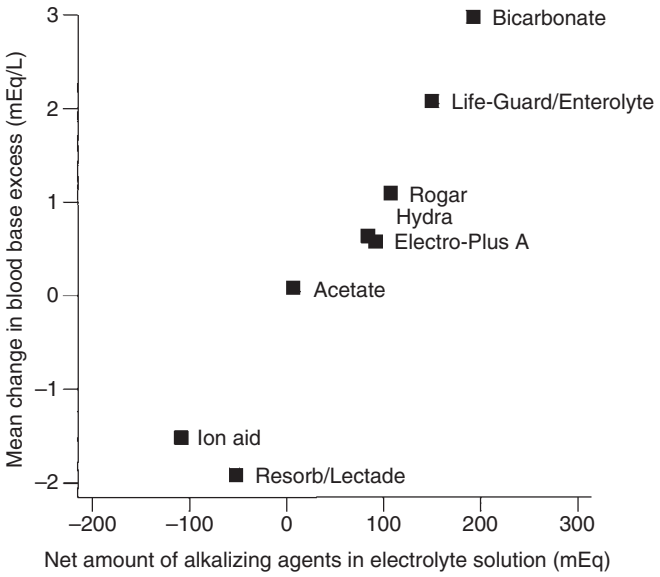

FIG. 20-7 Comparison of the alkalizing abilities of various oral electrolyte solutions. The Y axis shows the mean alkalizing effect after administration of one treatment (1.9 to 2.25 L) of the fluid to healthy calves, and the X axis shows the net amount of alkalizing agents in the solution. Bicarbonate and acetate are experimental solutions. (Life-Guard/Enterolyte manufactured by SmithKline Beecham Labs, Hydra manufactured by Vetrepharm, Electro-Plus A manufactured by Pitman-Moore, Ion Aid manufactured by Syntex, and Re-Sorb manufactured by Beecham. Rogar is Rogar STB's electrolyte powder.) *(Modified from the Proceedings of the 14th World Congress for Diseased Cattle, 1986, 1:362.)*

ANTIMICROBIAL SAFETY. A number of antimicrobials have been demonstrated to produce deleterious effects when administered orally to healthy milk-fed dairy calves. The addition to milk replacer powder of procaine penicillin (2 to 60 mg/kg of milk replacer) increased the incidence and duration of diarrhea and decreased growth rate compared with untreated controls in a total of 36 milk-fed calves.[544] Penicillin is not labeled for treatment of calf scours and has an inappropriate antimicrobial spectrum to prevent or treat calf scours. Administration of neomycin sulfate (300 mg PO q24h for the first 4 days of life) tended ($P = .060$) to increase the proportion of calves developing diarrhea (99/233 = 43%) compared with the proportion in an untreated control group (58/174 = 33%).[545] Administration of neomycin sulfate (25 mg/kg PO q6h, n = 10), ampicillin trihydrate (12 mg/kg PO q8h, n = 6), or tetracycline hydrochloride (11 mg/kg PO q12h, n = 6) for 5 days increased the occurrence of diarrhea and decreased glucose absorption through unknown mechanisms compared with untreated controls (n = 6).[546] Two other studies did not observe adverse side effects in calves administered tetracycline hydrochloride (40 mg PO q12h; 11 mg/kg PO q12h).[547,548]

EFFICACY OF ORAL ANTIMICROBIAL THERAPY. The response to oral antimicrobial therapy is variable with many formulations failing to demonstrate a beneficial effect.[543] Apramycin administered orally at either 20 or 40 mg/kg significantly decreased mortality.[535] Trials with orally administered neomycin reduced the duration of diarrhea but did not reduce mortality.[549,550] Similarly, trials with orally administered ampicillin failed to demonstrate a significant reduction in mortality.[551] The results of trials with orally administered trimethoprim have been variable with no significant improvement in outcome observed in a large field trial[552] and a significant reduction in mortality observed in an experimental *Salmonella* challenge study where calves were administered trimethoprim 5 mg/kg and sulfadiazine 25 mg/kg PO daily for 5 days.[553] Orally administered amoxicillin trihydrate has been demonstrated to reduce mortality and the duration of diarrhea when administered at a dose of 10 mg/kg PO q12h.[122,554]

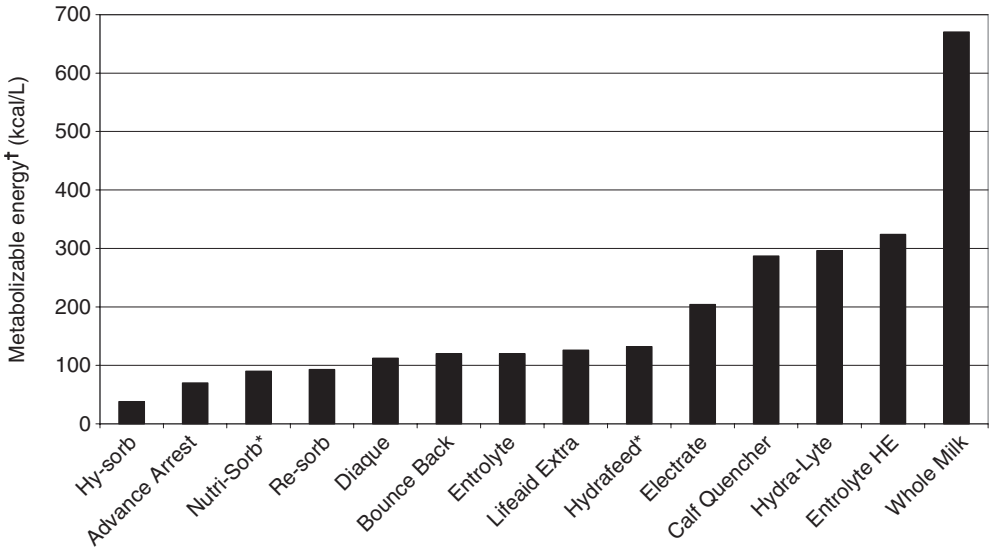

FIG. 20-8 Comparison of the energy contents of various oral electrolyte solutions. Milk is also shown for comparative purposes. This figure assumes electrolyte solutions are fed to neonatal calves prior to rumen development. (See text for manufacturers.) *ME estimated from water-soluble carbohydrate composition. †ME estimated from glucose and other water-soluble carbohydrate composition of as-fed electrolyte solution assuming 1 g (cry matter) of carbohydrate = 4 kcal.

VetBooks.ir

In an epidemiologic study of *Salmonella* in dairy calves conducted in the United States, feeding medicated milk replacer and hay to calves from 24 hours of age to weaning was associated with a reduced risk of *Salmonella* shedding.[555] This observation contradicts an experimental study in which feeding chlortetracycline in milk replacer increased the severity of disease and the rate and duration of *Salmonella* shedding.[556] Similarly, in another experimental trial, daily drenching of calves with 50 or 100 mg of chlortetracycline failed to alter the excretion pattern or the number of organisms excreted by calves infected orally with 10^6 *S.* Typhimurium.[557]

EFFICACY OF PARENTERAL ANTIMICROBIAL THERAPY. Antimicrobial drugs with an appropriate gram-negative spectrum of activity include third-generation cephalosporins (ceftiofur), potentiated penicillins (amoxicillin), trimethoprim sulfonamide combinations (TMS), aminoglycosides, sulfonamides, florfenicol, and tetracyclines. There is a paucity of efficacy data to support the use of aminoglycosides, tetracycline, nonpotentiated sulfonamides, and florfenicol.

Ceftiofur has an appropriate antimicrobial spectrum, and therapeutic drug concentrations can be maintained with once daily dosing. In an *S.* Typhimurium challenge experiment, intramuscular administration of ceftiofur hydrochloride (5 mg/kg q24h for 5 days) reduced the severity of clinical signs and reduced fecal shedding of *Salmonella*. The MIC of the challenge strain in this experiment was 1 μg/mL, and the therapeutic protocol maintained plasma concentrations above this concentration for the duration of therapy.[332]

Potentiated sulfonamides have been evaluated in enterotoxigenic *E. coli* and *Salmonella* challenge experiments. Mortality in 2- to 3-week-old calves medicated with trimethoprim sulfadiazine (in a 1:5 ratio) for 5 days 24 hours following *S.* Dublin oral challenge was reduced.[553] Administration of either sulfadiazine or trimethoprim alone did not reduce mortality.[553] TMS may be used to treat sepsis in neonatal calves, but its half-life rapidly declines as rumen function develops. In ruminating (6- to 8-week-old) calves, subcutaneous or oral administration of trimethoprim sulfa leads to high serum levels of sulfadiazine but little or no serum trimethoprim.[558]

Intramuscular administration of amoxicillin reduced mortality in *S.* Dublin–challenged calves.[559] In a comparative trial of amoxicillin and trimethoprim sulfadiazine, both drugs were found to have equal efficacy in reducing adverse clinical signs of disease when dosage regimens were based on the MIC of the pathogen.[560]

The frequency of bacteremia is sufficiently high such that treatment of calves with diarrhea that are severely ill (as manifested by reduced suckle reflex, greater than 6% dehydration, weakness, inability to stand, or clinical depression) should include routine treatment against bacteremia, with emphasis on treating potential *E. coli* bacteremia.[543] Parenteral administration of a broad-spectrum β-lactam antimicrobial—ceftiofur (5 mg/kg IM q24h), amoxicillin (10 mg/kg IM q12h), or trimethoprim sulfadiazine (20 mg/kg sulfadiazine with 5 mg/kg trimethoprim IV or IM, q24h for 5 days)—is recommended for treating calves with diarrhea and systemic illness. (Note that these are off-label doses and require an extended meat-withholding period.) Antimicrobial therapy is not recommended for calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever).[543]

Antiprotozoal Drugs

Drugs reported to have some efficacy against cryptosporidia in calves include halofuginone,[561-567] paromomycin,[568,569] azithromycin,[570] decoquinate,[571,572] and β-cyclodextrin.[573] Halofuginone appears to be the most efficacious. A meta-analysis of 15 cohort and clinical studies showed that prophylactic use of halofuginone delayed the shedding of *Cryptosporidium* with a lower prevalence of shedding at days 4 and 7 but a higher prevalence at day 21 when treated calves were compared with controls.[574] Prevalence of diarrhea was also lower on days 4 and 7 in treated calves. The efficacy of decoquinate is questionable with the only controlled clinical study failing to demonstrate a beneficial therapeutic effect with daily treatment at 2 mg/kg/day.[572] Lasalocid has been trialed for treatment of cryptosporidia. With a toxic dose of 8 mg/kg, it was found to reduce the shedding of cryptosporidia; however, the calves suffered adverse side effects. At a dose of 0.8 mg/kg, lasalocid was not effective.[575] The registered dose for preventing coccidiosis in calves is 1 mg/kg/head/day.

Coccidiosis is uncommon in calves less than 6 weeks of age. In hand-reared calves, coccidiostats (lasalocid, amprolium, or decoquinate) may be added to milk replacer. Prophylactic options for beef calves are restricted to coccidiostat-medicated pellets (monensin, lasalocid, amprolium, or decoquinate) or water (amprolium or sulfonamides). Therapeutic options include amprolium or sulfonamides such as sulfadimidine.

Both fenbendazole (5 mg/kg once daily for 3 days PO) or albendazole (20 mg/kg once daily for 3 days PO) have been shown as effective treatments for *Giardia*.[288,369,576] Because of the high level of subclinically affected animals, all cows and their dams need to be treated and reinfection is likely to occur unless calves are removed from environmental sources of infection.

Antiinflammatory Drugs

The benefit of routine administration of an NSAID could be due to their analgesic, antiinflammatory, or antipyretic properties. Meloxicam has been shown to increase feed intake, hydration score, and fecal consistency and to decrease signs of visceral pain when given at the onset of diarrhea.[577,578] A nonstatistical trend toward decreased morbidity has been reported in a study evaluating the benefits of a single or double injection of flunixin meglumine in scouring calves.[579] The routine administration of a corticosteroid to calves with diarrhea is not recommended because corticosteroids suppress the immune system and diarrheic calves have been shown to have high levels of plasma cortisol compared with healthy calves.[580]

Probiotics

Probiotics are a food or drug containing live microbes that are expected to confer beneficial physiologic effects to the host animal through microbial actions. Bacterial and fungal species included in these products include *Enterococcus faecium, Lactobacillus acidophilus, Lactobacillus delbrueckii* subsp. *bulgaricus, Lactobacillus plantarum, Lactobacillus rhamnosus, Bifidobacterium bifidum, Enterococcus faecium, Streptococcus salivarius* subsp. *thermophilus, Aspergillus oryzae,* and *Candida pintolopesii*. General mechanisms of action that have been prescribed to probiotics include competition for receptor sites on the intestinal surface, immune system stimulation, excretion of antimicrobial substances, and competition with pathogens for intraluminal nutrients.[581]

The number of controlled clinical trials evaluating probiotic formulations in calves is limited. In one report feeding antimicrobial-resistant *Streptococcus faecalis* to calves reared on an antibiotic-containing diet reduced *Salmonella* intestinal colonization of calves.[582] An improvement in weight gain and a reduction in diarrhea have been reported when calves were fed either 3×10^9 *Bifidobacterium pseudolongum* or *Lactobacillus acidophilus* daily from 1 to 56 days of age or a cell mixture containing 10^{10} colony-forming units (cfu) of *Bacillus thermophilum,* 10^{10} cfu of *E. faecium,* and 10^9 cfu of *L. acidophilus* for 28 days.[583]

OLIGOSACCHARIDES. Oligosaccharides are sugar polymers that are present in cows' milk and competitively bind to K99 fimbriae from enterotoxigenic *E. coli*.[584] The prophylactic addition of exogenous oligosaccharides to milk replacer resulted in similar fecal scores seen in calves fed milk replacer–containing antibiotics.[585] Overall, there are insufficient data to recommend the routine administration of oligosaccharides to calves with diarrhea.

Intestinal Protectants

A number of products that include intestinal protectants are marketed for treatment of calves with scours. Intestinal protectants

include bismuth subsalicylate, kaolin or pectin, and activated charcoal. No efficacy data are available regarding the use of kaolin in scouring calves. Suggested advantages of bismuth subsalicylate are its neutralization of bacterial toxins and antisecretory effect through its local antiprostaglandin activity.[586,587] The results of one prospective study indicated that the aforementioned nonantibiotic treatments for calf diarrhea resulted in a longer duration of treatment and increased morbidity and mortality when compared with medicated milk replacer and parenteral antibiotic treatment.[588]

GASTROINTESTINAL MOTILITY MODIFIERS. Drugs that inhibit gastrointestinal motility (such as hyoscine *N*-butyl-bromide) are contraindicated because reduction in intestinal motility potentially leads to the buildup of pathogenic bacteria and toxins.

Prognosis

The prognosis for recovery decreases with the severity of depression. Severe hypothermia and the presence of intercurrent disease are grounds for a guarded prognosis.[589-591] An initial examination should be performed. Calves with a primary problem of septicemia carry a guarded prognosis.

Summary

Calf scours is caused by a variety of infectious agents. At the present time, the need to make a definitive diagnosis of enterotoxigenic *E. coli* and salmonella infections has been established; these diseases can be controlled by antibiotics and prevented by vaccination.[592] There are public health implications to the diagnosis of cryptosporidiosis and salmonellosis. Vaccination may help control rotavirus and coronavirus infections. Treatment of neonate diarrhea is primarily based on correcting dehydration and acidosis through the use of oral and intravenous electrolytes. Only in the case of bacterial infections can direct action be taken against the invading organism, but antibiotics may still be useful in preventing secondary bacteremias. Good colostrum management helps reduce the risk of neonatal diarrhea. Management is very important in the control of diarrhea, and since infectious agents are almost always present at some exposure level, the underlying theme is to minimize the level of pathogen exposure and stress on the calf. In approaching a problem of neonatal death losses, the areas to be examined should include calf immunoglobulin status, calf feeding, calf housing, cleanliness of environment, calving area, cow vaccinations, diagnosis of specific infectious agents, and treatment protocols.

Lameness and Reluctance to Walk

John K. House

Septic Arthritis

Septic arthritis may result from direct trauma or contamination of the joint, by extension from periarticular infection, or via hematogenous spread from another site. Systemic sites of infection include enteritis, pneumonia, and inflamed umbilical structures. FPT increases the risk of sepsis. Destruction of the epiphysis and extension of infection into the joint may be primary in some cases, rather than starting as a primary synovial membrane infection that spreads to the epiphysis/physis. The most common pathogens isolated from septic joints of neonatal calves are enteric organisms including *E. coli* and *Salmonella* spp. *Streptococcus* spp., *Staphylococcus* spp., and *Trueperella pyogenes* are less common isolates. *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) is the most frequently isolated organism from the joints of older calves.[593-595] Vertebral body osteomyelitis is another manifestation of hematogenous bacterial spread with localization of bacteria in the vertebral veins. The presumed origin of the bacteremia most frequently is from pulmonary or umbilical infections in calves and tail docking wounds in lambs.[596] The etiologic agent usually is *T. pyogenes* or *Fusobacterium necrophorum,* alone or as part of a mixed infection.[597] The clinical signs vary depending on location of the compressive abscess. Affected animals often have clinical signs pertaining to other body systems (e.g., coughing, diarrhea, decreased weight gain compared with herdmates) before the onset of neurologic signs. The diagnosis of vertebral osteomyelitis is made by history, clinical signs, laboratory findings suggestive of chronic infection (elevated fibrinogen, globulin, and neutrophil count), and radiographs that demonstrate the affected vertebrae. Spinal fluid analysis is variable, but in most cases, it is normal or has a pleocytosis (macrophages and some neutrophils) caused by chronic inflammation of the dura mater.[596]

Bacteria commonly isolated from septic joints in lambs include *Streptococcus* spp., coliforms, *Trueperella pyogenes, Erysipelothrix rhusiopathiae,* and *Fusobacterium necrophorum*.[455] Predisposing factors include poor docking hygiene and contaminated sheep dip. Sporadic outbreaks of polyarthritis in lambs, kids,[61,598,599] and calves[600] are associated with *Chlamydia* and *Mycoplasma* spp. infections. Chlamydia infections may occur in utero or postnatally; mycoplasma infections often result from ingestion of mycoplasma-contaminated milk.

Diagnosis of septic arthritis is based on the combination of clinical signs, radiographic examination, bacterial culture, and cytologic analysis of synovial fluid. A bacterium is isolated in only 60% of cases of septic arthritis in bovine medicine.[601] Synovial fluid cytologic analysis is useful for the differentiation between infectious and noninfectious arthritis. Trauma is the chief differential. Lambs and kids with septic arthritis often fail to nurse and may present with significant weight loss. Typically polyarthritis caused by *Mycoplasma* spp. and *Chlamydia* is associated with high fevers and respiratory and occasionally neurologic disease. High morbidity and mortality are common. Conjunctivitis is commonly observed with chlamydial infections.[598] Cytologic findings consistent with septic arthritis include a synovial fluid total protein concentration greater than 4.5 g/dL, a nucleated cell count greater than 25,000 cells/mL, a polymorphonuclear cell count greater than 20,000 cells/mL, and percentage of polymorphonuclear cells of greater than 80%.[602] Chlamydial inclusions may be found in Giemsa-stained smears of synovial cells and the organism isolated from joint fluid or plasma in early cases.[598] Isolation of *Mycoplasma* spp. requires specific media (Hayflick media) and microaerophilic conditions. Normal synovial fluid does not rule out septic physitis or osteomyelitis, because the infection may be in the physis or small tarsal bones.

Careful examination of high-quality radiographs is important for the detection of bone lysis indicating infection. Initial radiographs may be normal because the degree of damage is often not detectable for 10 to 14 days after initial infection occurs. Radiographic features of septic arthritis include soft tissue swelling, widening or collapse of the joint space, osteoporosis, and osteosclerosis. Ultrasound may be used to confirm involvement of the joint and rule out periarticular or tenosynovial infection to avoid iatrogenic contamination of the joint during arthrocentesis. Joint distention and hyperechogenic fragments in the synovial fluid are suggestive of septic arthritis. Normal synovial fluid is anechoic.

Acute septic arthritis in neonatal ruminants may be treated effectively via joint lavage combined with systemic and local antimicrobial treatment. Typically, however, neonatal ruminants are presented with a chronic disease process. Treatment options include joint lavage or arthrotomy to remove destructive inflammatory products and long-term antimicrobial therapy. Joint lavage is rarely efficacious in the treatment of chronic septic arthritis in calves because accumulation of fibrin and pocketing of purulent material often make adequate joint drainage impossible.[603] Joint lavage may be facilitated via use of a rigid arthroscope or, in the case of simple joints (elbow and stifle), arthrotomy.[604] Empirical antimicrobial therapy should include a

VetBooks.ir

VetBooks.ir

gram-negative and gram-positive spectrum. Culture of synovial fluid facilitates antimicrobial selection.

Therapeutic synovial concentrations of penicillin, oxytetracycline, ampicillin, and cefapirin can be attained in inflamed and normal joints of calves following systemic administration.[605-608] The distribution of trimethoprim sulfadiazine, penicillin, oxytetracycline, and cefapirin in joints is not enhanced or reduced by inflammation.[605-607] Penicillin, trimethoprim, and sulfadiazine equilibrate in 0.5 to 1 hour, and oxytetracycline in 4.5 to 6 hours.[606] The subsequent decline in antibacterial drug concentration in synovial fluid parallels that in serum.[605] Synovial inflammation accelerates distribution of antimicrobial drugs into joints[606] but has little effect on the peak drug concentration achieved in synovial fluid.[605,606] The peak concentration of ampicillin in synovial fluid following a single intramuscular injection of ampicillin trihydrate at a dosage of 10 mg/kg is higher in normal and inflamed synovial fluid than in sera.[608] There is a paucity of bovine derived data regarding the distribution of the newer generation antimicrobials into synovial fluid following systemic administration. Studies in other species suggest that most classes of antibacterial drugs are capable of crossing the synovial membrane. Synovial tissue is very vascular and does not have a basement membrane. In humans, synovial fluid concentrations of most antibacterials generally average at least 60% to 70% of serum drug concentrations at the time of peak serum concentrations and frequently exceed those in serum immediately before the subsequent systemic dose in patients with septic arthritis.[609] Antimicrobial dosing is targeted to achieve a peak antibacterial concentration that exceeds the MIC of the infecting organism by fivefold to tenfold.[609] The duration of therapy is dependent on the antimicrobial sensitivity of the pathogen and the immune status of the patient; prolonged (4 to 8 weeks) antimicrobial therapy is commonly required.

In a review of 81 cases of septic arthritis in cattle, a 72% recovery was achieved with a combination of surgical treatment (opening of the joint capsule; débridement; and excision of the synovium, infected cartilage, and bone), joint immobilization, and systemic antibiotic therapy. Of cattle treated conservatively with systemic and intraarticular antimicrobials, 43% recovered.[610]

Noninfectious Lameness

Neonatal ruminants with nutritional myodegeneration often have a stiff, stilted gait. Lambs and kids may have difficulty nursing if they are unable to lift their head and may cry with pain when assisted to stand (see Chapter 42).

Contracture of joints or tendons of the limbs produces difficulty in movement and predisposes to FPT by impeding the ability to adequately nurse. Degree of contracture varies from mild to severe and may be associated with scoliosis and/or torticollis. Conservative therapy consisting of splinting the front limbs to induce tendon laxity may be helpful. Calves with severe digital flexor tendon contractures often require surgical resection of one or both digital flexor tendons, followed by bandaging or casting and stall rest for 3 to 4 weeks.

Peripheral nerve injuries may occur as a result of dystocia, trauma, or injection site reactions causing damage to peripheral nerves in the proximity of the injection site. The femoral nerve and brachial plexus are more commonly affected in calves. Femoral nerve damage is usually a result of stretching the nerve during a "hip lock" dystocia. Clinical signs of femoral nerve paralysis include the inability to extend the stifle and advance the limb and analgesia of the medial aspect of the limb down to the tarsus. Atrophy ("dished-out appearance") of the quadriceps is noticeable in 7 to 10 days if there is complete tearing of the femoral nerve.[596] Atrophy of the quadriceps predisposes to patella luxation. Complete or partial avulsion of the brachial plexus has also been observed in calves following dystocia.[611] The clinical presentation will depend on the severity of the injury. Clinical signs include abnormal positioning of the limb, abnormal locomotion, paresis, muscle atrophy, hyporeflexia, and sensory loss.[596]

Umbilical Enlargement

The umbilicus consists of three types of structures and undergoes functional and anatomic changes at birth. Two umbilical arteries connect internal iliac arteries to the placenta. These later regress and become the round ligaments of the bladder. One umbilical vein connecting the placenta to the liver and porta cava regresses to become the round ligament of the liver within the falciform ligament. The urachus connects the fetal bladder to the allantoic cavity.

Patent Urachus

Patent urachus is a persistence after birth of the tubular connection between the bladder and umbilicus. The urachus drains the bladder into the allantoic sac during gestation. Urine flow should gradually change, with some urine entering the amniotic sac through the urethra in later gestation. At birth, with umbilical cord rupture the urachus should be closed, and urine should be voided through the urethra. Neonates with a patent urachus may dribble urine from the urachus during or after urination or may simply present with a constantly wet umbilical stump.

Differentials include concurrent infection of the navel (omphalophlebitis). Ultrasound may assist the diagnosis and determine the involvement of umbilical arteries or vein. Moist hairs around the umbilicus and visualization of fluid coming from the navel are diagnostic. A complete physical examination should be performed. If abnormalities are noted, serum IgG, complete blood cell count, and urinalysis are helpful for detecting susceptibility to infection and presence of systemic or urinary tract infection. Surgical resection of the urachus to the tip of the bladder is the treatment of choice. Associated arteries and veins should be ligated and removed if they are infected or necrotic. Merely ligating the exterior stump can trap organisms and cause infection.

Omphalitis

Omphalitis is inflammation of umbilical structures that may include the umbilical arteries (omphaloarteritis), umbilical vein (omphalophlebitis), urachus, or tissues immediately surrounding the umbilicus. Umbilical abscess or infection of any of the three components of the umbilicus may produce local infection or be a source of septicemia. The source of infection is most commonly the external environment, coupled with failure of passive transfer. Bacteria isolated from calf umbilical cord remnant infection include *T. pyogenes, E. coli,* and *Proteus* and *Enterococcus* spp. The urachus is the most commonly affected structure in calves and the umbilical arteries the least.[612] Omphalophlebitis may extend the length of the umbilical vein into the liver and result in liver abscessation.

When the umbilicus is enlarged and draining purulent material, infection is easily noted. When the urachus is fixed to the abdominal wall, calves are prone to cystitis and may show signs of pollakiuria and dysuria. In other cases the umbilicus may be dry and larger in diameter than expected. In addition, neonates may have a completely normal-appearing, dry external navel and be severely ill from infection of the urachus, umbilical arteries, or vein. In a septic neonate without external signs of infection, involvement of the umbilicus can be difficult to determine. Abdominal palpation of the umbilical vein and arteries is a useful simple effective means of assessing their size and for detecting pain associated with these structures. Inflamed structures may be identified by standing behind the neonate and pressing the hands together above the umbilicus. Ultrasound is also a useful ancillary diagnostic aid.[613] Persistent dilation of the umbilical vein or arteries with a hypoechoic-to-echogenic fluid, intraluminal gas, and wall thickening are findings consistent with infection. In calves the urachus normally retracts up into the abdomen at birth, and ultrasonographic identification of a urachal remnant is abnormal.[614]

Overt signs of infection are heat, swelling, purulent discharge, or pain. Concurrent signs of systemic infection such as joint infection,

VetBooks.ir

pneumonia, diarrhea, meningitis, or uveitis may be noted. Calves with urachal abscesses may show signs of dysuria or pollakiuria.[615,616] Infection in more than one umbilical vessel in the neonate is common, and urachal involvement is frequent. Umbilical abscessation that is walled off and does not involve deeper structures is a less severe problem and may be treated with drainage without surgical removal of the entire umbilicus.

Early treatment with antibiotics and supportive care may allow resolution before development of abscessation and distention of the urachus or the umbilical arteries and vein. Established infection usually requires surgical removal of involved structures in addition to medical therapy.[612] When omphalophlebitis extends into the liver, the umbilical vein may be marsupialized to facilitate drainage and flushing.[617] Prognosis is improved when adequate passive transfer of colostral immunoglobulins has occurred and when joints or other structures are not involved. Sequelae such as renal abscessation, joint or bone infection, peritonitis, and other complications described for septicemia may develop if therapy is started too late or discontinued prematurely.

Anemia

Anemia in the neonate should be interpreted in the context of the realization that normal hematologic values of the neonate may vary from those of the adult. In calves the incidence of anemia (hemoglobin <10 g/dL) is quite high, ranging from 15% to 30% in many herds, and is normocytic, normochromic, and poikilocytic.[618,619] Anemia is reported to be a result of iron deficiency.[618,619] Potential causes are reduced amounts of iron in milk, poor placental transfer of iron, or decreased intestinal absorption. Anemic calves with poikilocytosis have similar levels of serum iron, total iron binding capacity, and marrow iron and plasma copper levels compared with normal calves.[620] Anemic calves do not appear to have an increased incidence of disease or decreased growth rates.[621] An overall higher plane of nutrition versus iron supplementation alone produces higher PCVs and hemoglobin levels.[620] Calves less than 6 weeks of age have three types of hemoglobin in various amounts: adult, 28%; fetal, 40%; and neonatal, 25%. The poikilocytosis may be a function of erythrocyte membrane defects or maturation transitions.[620]

In addition to frank blood loss from an injury, diseases causing anemia in the neonate include neonatal isoerythrolysis (NI), non-NI immune-mediated hemolytic anemia,[622] blood loss caused by gastric ulcer, anemia resulting from bone marrow necrosis, and anemia of chronic disease associated with localized infections. Hemolytic disease of newborn calves is uncommon but has occurred after vaccination of pregnant cows against anaplasmosis or babesiosis. The presence of red cell antigens in the vaccine causes the production of antierythrocyte antibody, primarily against the A and F systems.[623] Cows mated to bulls carrying these red cell antigens may have hemolytic disease develop in their A- and F-positive calves after ingestion of colostrum-containing alloantibodies.

Hemolytic disease processes produce signs of weakness, pale or jaundiced mucous membranes, fever, and depression. Blood loss produces weakness and pale mucous membranes. Intestinal parasitism does not normally lead to anemia during the neonatal period. Intravascular hemolysis may produce hemoglobinuria and hemoglobinemia. Icterus develops when the ability of the liver to conjugate bilirubin is exceeded. Mainly, indirect bilirubin is elevated. Anisocytosis is observed in responsive anemias. Nonspecific stimulation of bone marrow may produce a leukocytosis. Anemia has also been reported in calves infected with BVDV as a result of bone marrow necrosis.[624]

Determination of the nature of the anemia may allow specific treatment. Blood transfusion may be indicated when anemia develops rapidly or PCV drops below 14%. Associated conditions such as metabolic acidosis and hypoglycemia should be corrected. Anemia of chronic disease requires correction of the primary disease condition.

Fever

Differentials for fever in neonates include bacterial or viral infections, excitement, seizures with subsequent generation of heat by muscular overactivity, and environmentally induced hyperthermia. Fever is an unreliable indicator of sepsis in neonatal calves.[19] Septic neonates often have a normal or subnormal temperature. Older ruminants with localized infection such as in joints or bone are more likely to have fever. Fever may be beneficial. The need to administer antipyretics to the febrile neonate is controversial. Body temperatures lower than 40.8° C (105.4° F) are not considered detrimental unless they are associated with heat stroke or seizures,[625] in which case cooling and antipyretics are indicated. Because many antipyretics are antiprostaglandins that can cause deleterious gastrointestinal and renal effects, these agents should be used judiciously. Correction of the initiating cause and maintenance of fluid balance are also important.

Cyanosis

Cyanosis is the purple-blue coloration observed on mucous membranes or skin caused by reduced or poorly oxygenated hemoglobin in blood.[626] Cyanosis may be caused by congenital heart disease, respiratory impairment, or any circulatory condition producing a right-to-left shunt (Box 20-4). The degree of cyanosis depends on the arterial oxygen saturation, hemoglobin concentration, pH, peripheral circulation, and temperature of the neonate.[626] Shock and hypothermia are important causes of peripheral cyanosis. The affinity of hemoglobin for oxygen is reflected in the standard oxyhemoglobin dissociation curve. This curve is similar for neonates but is affected by the amount of 2,3-diphosphoglycerate (DPG) in the erythrocyte. Calves' erythrocytes have higher levels of 2,3-DPG, but the higher levels do not affect the affinity of hemoglobin for oxygen. A separate fetal hemoglobin exists in calves to increase affinity for oxygen.[627] Severe hypothermia and acidosis cause the oxygen dissociation curve to shift to the right and therefore contribute to tissue hypoxia.

BOX 20-4

Causes of Cyanosis

Cardiovascular Origins

Tetralogy of Fallot
Tricuspid atresia
Truncus arteriosus
Pentalogy of Fallot
Double outlet right ventricle
Single ventricle
Eisenmenger complex
Ventricular septal defect
Patent ductus arteriosus

Respiratory Causes

Alveolar hypoventilation
Drug-induced central nervous system (CNS) depression
CNS trauma or hemorrhage
Hypoglycemia or hypocalcemia
Altered neurologic function of spinal nerves (of respiratory muscles)
Thoracic cage abnormalities: pneumothorax, fractured ribs
Diaphragmatic hernia
Upper airway obstruction
Restrictive pleural space disorders: hemothorax, pleuritis
Hypoplastic lung

Impaired Diffusion

Pulmonary: pneumonia, edema, atelectasis
Shunting
Anatomic (congenital heart defects)
Pathologic: pulmonary hypertension
Ventilation-perfusion mismatch

VetBooks.ir

Cyanosis can be either central or peripheral.[626] Peripheral cyanosis results from increased peripheral extraction of oxygen from normally saturated blood or a significant decrease in the perfusion to an extremity.[626] In the neonate, causes include septic shock and severe hypothermia. Central cyanosis is more common in neonates and is related to congenital heart disease that causes right-to-left shunting or severe respiratory conditions that result in hypoxia. Examination and clinical pathologic evaluation for metabolic causes of cyanosis, hypothermia, and cardiac abnormalities should be conducted. History, medication use, auscultation, thoracic radiographs, and arterial blood gases are useful in determining the degree of the respiratory component to cyanosis. Echocardiography may be required for identification of cardiac anomalies.

Heart Murmur

Heart murmurs in the neonate may be heard normally before physiologic closing of the ductus arteriosus during the first 1 to 5 days of life. Other causes for murmurs include congenital anomalies, severe anemia, or infectious valvular disease. Physical examination for other signs of heart disease helps determine the severity of the murmur. Jugular pulse, weak or irregular arterial pulse, and palpable thrill indicate a serious condition. Dyspnea, cyanosis, tachypnea, and failure to gain weight are common signs of congenital heart disease in calves. Timing and location of the heart murmur should be determined. Thoracic radiography may aid in determining heart size and in detecting pulmonary edema or distended pulmonary vessels. Echocardiography may reveal atrial or ventricular enlargement, thickened ventricular walls, anomalous orientations of outflow tracts, or ventricular septal defects (VSDs).

Patent ductus arteriosus produces a continuous murmur localized over the left heart base. The diastolic component may not be heard with auscultation over other parts of the heart. As pulmonary hypertension develops, the murmur is shortened to a holosystolic type with normal arterial pulse. Large shunting of blood produces a bounding arterial pulse caused by wide fluctuations of systolic and diastolic pressures. Radiographs may reveal an enlarged heart with increased vascularity caused by left-to-right shunting of blood. Echocardiography may reveal an increased left atrial and left ventricular diastolic dimension/volume and hyperdynamic septal and left ventricular wall systolic motion (depending on the degree of right-to-left shunt).

VSD produces a large, harsh, holosystolic murmur that is heard loudest on the right cranial region of the thorax and is softer over the left heart base. Radiography may reveal heart size increase, left atrial enlargement, and dilated pulmonary vasculature. Two-dimensional echocardiography may show aortic and septal discontinuity. Injection of saline bubbles into the left ventricle and observation of bubbles in the right atrium or ventricle document a left-to-right shunting of blood. Tetralogy of Fallot or other types of complex malformations often produce loud murmurs and are associated with cyanosis, weakness, fatigue, and stunted growth. Tetralogy of Fallot produces a systolic ejection murmur heard at the left heart base. Echocardiography may reveal a thickened right ventricular wall, septal echo dropout in the area of the VSD, rightward displacement of the aortic root, and an abnormal pulmonary outflow region. Saline injection into the jugular vein demonstrates right-to-left flow from the right ventricle to the left ventricle or the aorta.

Icterus

Icterus is a relatively uncommon finding in neonates; it may be observed with sepsis, anorexia, liver disease, and hemolytic anemia. Liver disease in the neonate may be caused by exposure to hepatotoxins, by sepsis-producing bacterial hepatitis, or as a result of hypoxia. *C. perfringens* type A has been implicated in an enterotoxemic condition in nursing lambs, kids, and calves characterized by icterus, hemoglobinuria, anemia, and intravascular hemolysis.[88]

Failure to Thrive: Cachexia and Weak Calf Syndrome in Beef Calves

John Maas

In calves the weak calf syndrome has been reproduced by feeding low-protein diets to prepartum cows that subsequently calved in environments in which the temperature was well below the thermoneutral zone for calves.[628] The dietary recommendation for crude protein (CP) intake for third-trimester pregnant cows and heifers is 0.9 kg (2 lb) of total CP/day. This is particularly important for heifers and cows calving early in the spring calving season when temperatures well below freezing can occur. Cold rains, however, can also produce the hypothermic conditions that aid in precipitating this syndrome.

Cows weighing 450 kg (1000 lb) therefore need to consume 9.9 kg (20 lb) dry matter of good- to excellent-quality hay that is 10% CP or more. A quadratic equation has been developed to predict CP intake of the dams if their serum total proteins, urea nitrogen, and creatinine are known.[629] This equation predicts the daily CP intake on a continuing basis.

$$\text{Daily CP consumption (kg)} = 0.1806 + 0.04327\,(\text{BUN}) - 0.33497\,(\text{creat}) + 0.06963\,(\text{TP}) - 0.00025\,(\text{BUN})^2 + 0.06049\,(\text{creat})^2 - 0.00666\,(\text{BUN} \times \text{creat})$$

where *BUN* is serum urea nitrogen (mg/dL), *creat* is serum creatinine (mg/dL), and *TP* is serum total protein (g/dL).

Also, the use of this formula could predict CP intake for pregnant heifers and pregnant cows. This relationship may prove to have important clinical applications when weak calf syndrome or protein-calorie malnutrition is suspected and the gestation diet of the dams is not available for analysis (as under some range conditions). Supplements such as molasses licks that contain urea may tend to overestimate CP intake.[630]

Colostrum and Milk Replacers

SANDRA GODDEN and ROBERT E. JAMES, *Consulting Editors*

The goals of colostrum and milk feeding programs for preweaned calves and small ruminants are to achieve optimal rates of gain, support and develop a strong immune system, maximize health, and stimulate ruminal development—all in a cost-effective manner. Although feeding high-quality, clean maternal colostrum and whole milk may be considered by many to be gold standards, the use of high-quality colostrum replacement products and milk replacers may be attractive to producers for a variety of reasons, including for consistency, for convenience, as a means of breaking the transmission cycle of some infectious diseases, or simply to capture economic efficiencies. This chapter reviews important considerations in the manufacture, selection, and use of high-quality colostrum replacement and milk replacer products.

Colostrum Supplements and Replacements

The principles of colostrum management are reviewed in Chapter 19. Although feeding 3 to 4 L of clean, high-quality maternal colostrum shortly after birth remains the gold standard, farms can experience periods when an adequate supply of high-quality fresh or stored maternal colostrum is not available. Also, it may not always be practical or convenient to harvest first milking colostrum from fresh cows within a timely manner after calving (<1 to 2 hours). Contributing to this shortage, some producers may discard colostrum from cows testing positive to such pathogens as *Mycobacterium avium* subsp. *paratuberculosis* or *Mycoplasma bovis*.[1-3] Under such circumstances, feeding commercially available colostrum supplement (CS) or colostrum replacement (CR) products may offer a simple, consistent and convenient means of delivering the necessary immunoglobulins (Ig) to newborn calves while reducing the risk of pathogen exposure. The following section discusses types of CS and CR products, manufacture and licensing, evaluation of product efficacy (e.g., IgG dose, efficiency of IgG absorption, passive transfer levels, calf health and performance), impact of Ig source on antibody profiles, monitoring of passive transfer, and use of CR or CS products in minor species. Although some studies have demonstrated that supplementation of the milk diet with Ig from either maternal colostrum or CS may reduce the severity of rotavirus or coronavirus scours occurring during the first 14 days, the current discussion is limited to use of CS and CR products in the first 24 hours after birth.[4-6]

Colostrum Supplements versus Colostrum Replacements

Colostrum supplements, which typically cost between $9 and $18 USD per dose, are designed to provide exogenous IgG to calves to supplement poor-quality maternal colostrum (colostral IgG < 50 g/L).[7] Most CSs provide between 25 and 60 g of IgG per dose, which is reconstituted in 1 to 2 L of water. Feeding one dose of a CS will not provide a sufficient mass of IgG to prevent failure of passive transfer (FPT) in young calves, nor will it provide sufficient levels of nutrients necessary for calf survival or optimum growth.[7,8] By comparison, CR products, which typically cost between $25 and $40 USD per dose, are designed to be fed instead of maternal colostrum. They should provide a minimum of 100 g of IgG per dose and should provide sufficient levels of nutrients to the calf. It is recommended that CS or CR products be mixed in water, according to the manufacturer's label directions, and fed as a separate meal after any natural colostrum has been fed.[9]

Manufacturing

Immunoglobulins in commercial CR and CS products are most often derived from spray-dried bovine colostrum or spray-dried bovine serum. For colostrum-derived CR products, fresh-frozen bovine colostrum is collected from grade A dairies and assembled at a manufacturing plant where it undergoes testing for IgG concentration, pooling, heat treatment, spray drying, and then packaging. The concentrations of most non-Ig colostral components (e.g., nutrients, hormones, growth factors), with the exception of cellular fractions (i.e., leukocytes, bacteria), will be similar in colostrum-derived CR products compared with maternal colostrum. For serum-derived CR or CS products, blood is collected from abattoirs under USDA inspection, centrifuged to separate plasma and/or serum from red blood cells, ultrafiltered, spray dried to produce a concentrated powder containing approximately 20% Ig, and then mixed with other ingredients (e.g., lactose, dry fat blend, dextrose, vitamin/mineral premix). The final product may be irradiated. Exact manufacturing methods will vary among manufacturers and products.

Is the Colostrum Replacer or Colostrum Supplement Licensed?

In Canada, it is required that all CR products are licensed through the Canadian Food Inspection Agency (CFIA) Center for Veterinary Biologics (CVB, Ottawa, Ontario, Canada).[10]

Serum- or plasma-derived CR or CS products are not permitted in Canada. In the United States, only some manufacturers have acquired a license through the U.S. Department of Agriculture (USDA) Center for Veterinary Biological Products (CVB, Ames, IA). To attain a CVB license and label for prevention or treatment of FPT of Ig, the IgG in U.S. CR products must come from bovine colostrum collected from grade A dairies, must be processed by heat treatment or ionizing radiation using accepted protocols, and must undergo regular purity, potency, and efficacy testing.[11,12] Purity requirements allow a specified total bacteria count. However, coliforms, *Salmonella* spp., and fungi may not be present. Potency tests require a minimum IgG content for FPT products as determined by a validated radial immunodiffusion (RID) kit or assay. Efficacy testing for FPT products requires that, in 90% of animals, the increase in IgG concentration (pretreatment vs. 24-hour posttreatment) must be at least equal to concentration of the IgG Species Standard approved by the USDA's Animal and Plant Health Inspection Service (APHIS) (e.g., ≥10 mg/mL serum IgG for neonatal calves) (USDA: 9CFR 113.450; 9CFR 113.499).[11] Samples of product from every serial release (batch) are

VetBooks.ir

submitted to a central CFIA or USDA laboratory for testing. Also, the overseeing regulatory body completes annual site inspections to review processes and records. As such, licensed products can guarantee safety, potency, efficacy, and traceability. Table 21-1 (Section A) lists CVB-licensed products currently available in Canada and the United States.

Although products that do not have a USDA Veterinary Biologics license are not legally able to claim to supply IgG or to purport to be used as either CS or CR for prevention of FPT, their use for this purpose is widespread in the United States. The Ig in nonlicensed products is technically not considered a feed but is being used in feeds. As such, these products fall under Association of American Feed Control Officials (AAFCO) guidelines (www.aafco.org). Under AAFCO guidelines, every state (i.e., local State Department of Agriculture) adopts and regulates its own animal feed per its applicable laws and regulations. Feed testing programs are in place and regulated in Canada. In the United States, there is a system to identify feed products, but there currently is no system to regulate them through the USDA, FDA, or the State Departments of Agriculture. Although all U.S. manufacturers of non-CVB licensed CR and CS products will conduct some kind of internal quality control testing, these programs are at the manufacturer's discretion. External product testing or plant inspections by regulatory authorities (e.g., State Department of Agriculture) are not typically completed for non-CVB licensed products unless a problem or complaint is brought to their attention. Table 21-1 (Sections B and C) lists some of the many non-CVB licensed CR and CS products available in the United States.

Evaluating the Efficacy of Colostrum Replacement Products

Producers are strongly encouraged to select CR or CS products that have undergone independent evaluation of efficacy in controlled field studies. Evaluating efficacy should ideally consider passive transfer of adequate IgG, nutritional support, and calf health and performance. Passive transfer of IgG will be primarily determined by the dose of IgG (in grams) administered as well as the efficiency of absorption of IgG. Each product must be independently evaluated, since differences in manufacturing processes can have a significant impact on both apparent efficiency of absorption percentage (AEA %) and final dose of IgG in a package.[13,14] Head-to-head studies are necessary to make valid comparisons among products. Table 21-2 presents the results of field efficacy studies for commercially available CR and CS products that were mixed and fed according to label directions.

DOSE OF IgG PROVIDED. Although experts originally estimated that producers should feed a minimum mass of 100 g of IgG in the first colostrum feeding, more recent studies have shown that at least 150 to 200 g of colostral IgG must be fed to consistently achieve acceptable passive transfer (APT) rates (serum IgG ≥ 10 mg/mL) in the majority (≥90%) of calves.[15-18] This dose effect was demonstrated in one study wherein three groups of calves fed either 100 or 200 g of IgG in a colostrum-derived CR product or 3.8 L of fresh maternal colostrum achieved a mean serum IgG concentration at 24 hours of 9.6 mg/mL (46% with FPT), 19.0 mg/mL (0% with FPT), or 20.7 mg/mL (9% with FPT), respectively (see Table 21-2).[18] Although many CR products are packaged to provide 100 to 130 g IgG per dose, some CR products now provide a larger mass of IgG per dose and/or provide label directions that suggest feeding increased masses of IgG.

APPARENT EFFICIENCY OF ABSORPTION (AEA %) OF IGG. Grams are more important than percentages; under most circumstances, the total dose (g) of IgG fed will be the most important predictor of APT in calves fed CR products. That said, simply examining the mass of IgG provided by the CR is not an adequate predictor of product efficacy.[19] There can be significant differences in AEA % among products resulting from, but not limited to, such factors as manufacturing methods and quantity, the type of other nutrients or additives, and the age (in hours) at which the calves were fed. The apparent efficiency of absorption (AEA %) is the percentage of IgG administered that is absorbed systemically.[13] To calculate AEA %, one needs to know the serum IgG (mg/mL is equal to g/L), the grams of IgG originally fed (estimated from testing the maternal colostrum or indicated on the label of the CR or CS fed), and the weight of the calf (in kilograms) from which the plasma volume is estimated (e.g., plasma volume in liters = 9.1% of body weight in kg). The serum IgG (g/L) is multiplied by the plasma volume (L) to calculate the total grams of IgG in the blood. This is then divided by the total grams of IgG fed, and then multiplied by 100 to express efficiency as a percentage. For example, a 43-kg calf has an estimated 3.9 L of plasma (43 kg × 0.091). If the serum IgG concentration of the calf is 10 g/L (10 mg/mL), then the calf has 39 g of IgG in the blood (10 g/L × 3.9 L). If that calf was originally fed 100 g of IgG from maternal colostrum or a CR product, then the AEA would be 39% (39 g/100 g × 100%). Controlled field studies using commercially available CR or CS products, mixed and fed according to label directions, have reported widely varying AEA % values (see Table 21-2). The AEA % reported for CS products has ranged from 16% to 28%.[20,21] The AEA % reported for CR products has ranged from 14% to 51%.[18,22-29] By way of comparison, the AEA % of IgG reported for calves fed 3 to 4 L of fresh maternal colostrum within 6 hours of birth has ranged from 21% to 36%.[18,20,21,27,29]

The debate continues over whether the IgG in colostrum- or serum-based CR or CS products is more efficiently absorbed. However, relatively few head-to-head field trials exist to investigate this question. In one early CS study in which calves were fed two doses of a colostrum-derived CS (50 g IgG), two doses of either 60 g or 90 g IgG of serum-derived CS, or 3.8 L of maternal colostrum, the AEA % reported for the colostrum-derived CS (16%) was inferior to that of the two serum-derived CS products (24% or 28%) and to maternal colostrum (22%) (see Table 21-2).[20] However, because all three CS products delivered an insufficient dose of IgG as compared with maternal colostrum, all three CS products failed to provide APT to calves. Thus far, only two head-to-head controlled field studies have compared the AEA % of commercially available serum- versus colostrum-derived CR products. In one study calves fed 150 g of a lacteal-derived CR had significantly improved AEA % and serum IgG concentrations (AEA = 38.2%; IgG = 14.7 mg/mL) as compared with calves fed 130 g of a serum-derived CR (AEA = 28.4%; IgG = 9.6 mg/mL) (see Table 21-2).[26] In this study the improved final serum IgG values for the colostrum-derived CR group were attributed both to increased dose fed (in grams) and improved AEA %. In another recent study, calves fed 150 g of a serum-derived CR had inferior AEA % (21.6%) compared with calves fed 100 g of a colostrum-derived CR (38.8%).[30]

PASSIVE TRANSFER LEVELS, AND HEALTH AND PERFORMANCE OF CALVES FED COMMERCIAL CS OR CR PRODUCTS. If given alone, CSs will result in significantly lower serum IgG concentrations and a high risk of FPT in calves as compared with feeding 3 to 4 L of maternal colostrum (see Table 21-2).[19-21,31,32] There is no added benefit to feeding a CS if feeding 3 to 4 L of high-quality maternal colostrum.[33,34] Although an opportunity may exist for producers doing on-farm testing of colostrum, using such instruments as the Brix refractometer, to supplement poor-quality colostrum with a CS, the effectiveness of this strategy requires further study.[35,36]

Studies have demonstrated that several commercially available CR products, when administered at a high enough dose (150 to 200 g IgG) within a few hours after birth, can provide acceptable–to–very good serum IgG concentrations and APT rates in calves (goal of ≥ 90% of calves with serum IgG ≥ 10 mg/mL) (see Table 21-2).[18,23-26,28,29,32] Relatively few studies have been designed with sufficient sample sizes to evaluate the effects of feeding CR on health and performance outcomes in calves. In one early study of 457 calves on 12 upper Midwest dairy farms, there was no significant difference

VetBooks.ir

in morbidity or mortality in 218 calves assigned one dose of a serum-derived CR product providing 125 g Ig, as compared with 239 calves fed 3.8 L of fresh maternal colostrum, despite the fact that the CR group had lower serum IgG concentrations and higher FPT rates than calves fed maternal colostrum (see Table 21-2).[37] A companion study reported that calves fed the CR program at birth were at significantly reduced risk to test positive for infection with *Mycobacterium avium* subsp. *paratuberculosis* as adults (7.6% test positive; odds ratio 0.52 [0.27 to 1.003]), as compared with control calves fed maternal colostrum (11.9% test positive), thus demonstrating that CR products may be a useful management tool for dairy herds attempting to reduce the prevalence of Johne's disease.[38] This study also reported that the colostrum treatment group had no overall effect on longevity, milk production, or reproductive performance during the first three lactations.[39] Preliminary results from a more recent study of 568 calves on one California dairy reported higher serum IgG concentrations, very good APT rates, and improved health in calves fed 200 g of IgG in a colostrum-derived CR product, as compared with calves fed 3.8 L of very-poor-quality maternal colostrum (only 80 g IgG fed from maternal colostrum) (see Table 21-2).[29]

Does Immunoglobulin Source Affect the Antibody Profile in CR or CS Products?

Veterinarians frequently ask if the antigen-specific antibody profile in CR products will complement the antigen profile on their clients' dairy farms. Because the colostrum used to manufacture CVB-licensed colostrum-derived CR or CS products is collected from cows living on commercial North American grade A dairy farms, this author considers it a safe assumption that these cows will have been exposed to, and therefore produce colostral antibodies against, most of the common pathogens endemic on most commercial dairies (e.g. *Escherichia coli, Salmonella* spp., rotavirus, coronavirus, *Cryptosporidium*), either through natural exposure and/or through vaccination programs. However, published studies to verify this hypothesis are extremely limited as relates to colostrum-derived CR products, and lacking entirely for serum-derived CR products. One recent Alabama field study reported that calves fed 200 g IgG in a colostrum-derived CR had greater levels of BVDV-neutralizing antibodies in serum, and similar levels of antibodies to BHV-1, BRSV, and PI3V in serum, as compared with calves fed 3.8 L of maternal colostrum.[40] Additional studies are needed to describe antigen-specific antibody concentrations, particularly to enteric pathogens, found in CR or CS products.

Another frequent question asks whether the antibody profile in colostrum-derived CR products is superior to that of serum-derived products. Although the concentrations of the subclasses IgG_1 and IgG_2 are approximately equal in serum (50:50 ratio, or 50% IgG_1), IgG_1 occurs in much higher concentrations than IgG_2 in colostrum (7:1 ratio, or approximately 90% IgG_1) as a result of the selective transfer of IgG_1 into the mammary secretion of cows.[41-43] IgG is the main class of Ig secreted into the bovine intestinal tract.[44-46] Furthermore, IgG_1 is the predominant Ig subclass secreted into the bovine intestinal tract, lung, nasal secretions, vaginal secretions, and saliva.[47-49] Studies have demonstrated that secretion of serum IgG_1 rotavirus immunoglobulin into the intestinal lumen, if in sufficient quantity, provides protection against rotavirus infection.[44,46,47,50-52] In a review of this topic, Thornsberry and Wood[13] stressed the importance that newborn calves consume a sufficient mass of IgG_1 prior to closure of intestinal absorption of Ig molecules. All else being equal, one could theorize that the increased proportion of IgG_1 found in colostrum-derived CR products (90% IgG_1) should result in improved calf health, as compared with serum-derived CR products (50% IgG_1). However, studies are as yet lacking to investigate this hypothesis. It has been argued that the relative content of IgG_1 in a CR may be immaterial for consideration (provided that a sufficient total mass of IgG is provided), because studies have demonstrated that both colostrum- and serum-derived CR can achieve desired goals of calf production.[13]

Monitoring Passive Transfer Rates When Feeding CR or CS Products

Measurement of serum total protein (STP) by handheld refractometer offers a convenient, simple, rapid, and inexpensive method by which producers can monitor the colostrum program. For calves fed maternal colostrum, STP test endpoints of 5.0 or 5.2 g/dL yield the most accurate results in estimating the adequacy of passive transfer (serum IgG ≥ 10.0 mg/mL; sensitivity > 0.80; specificity > 0.80; proportion classified correctly > 0.85).[53,54] However, are the same STP cutpoints accurate when feeding a CR or CS? Three studies of colostrum-derived CR products have reported that an STP cutpoint of 5.0 or 5.2 g/dL most accurately predicts APT.[26,30,32] However, a significant association was not found between STP and serum IgG in one study wherein calves were fed a colostrum-derived CS product.[32] For serum-derived CS or CR products, the relationship between STP and serum IgG in calves may be very different depending on the source, level of inclusion, and/or degree of absorption of non-Ig proteins. Studies of different serum-derived CS or CR formulations have reported widely varying STP cutpoints ranging between 4.2 and 5.4 g/dL.[14,26,30,37,55] Given the large variation in predicted STP cutpoints, particularly for the serum-derived products, veterinarians are encouraged to use refractometry to monitor the effectiveness of a CR feeding program only if studies are available describing the relationship between STP and serum IgG for the specific commercial CR product in use on the farm. If such studies are not available, veterinarians are advised to periodically submit frozen serum samples for serum IgG analysis using direct methods such as the zinc sulfate turbidity test, radial immunodiffusion, turbidimetric immunoassay, or enzyme-linked immunosorbent assay.[53,56,57]

Use of Colostrum Supplements or Replacements in Minor Species

Although most CS and CR products target calves, products exist for minor species including goat kids, lambs, foals, llama or alpaca cria, pigs, fawns, and elk calves (see Table 21-1). Although most products available for minor species are not licensed, CVB-licensed products do exist for goat kids and lambs, meeting CFIA and USDA standards, thus guaranteeing purity, potency, efficacy, and traceability (see Table 21-1, Section A).[58] Because the dose of IgG required for multispecies CR or CS products will vary by species, producers should follow individual product label directions for feeding.

Summary

High-quality CR products can offer a consistent and convenient source of Ig for newborn calves for when high-quality, clean maternal colostrum is not available; they may also be a useful management tool to help break the transmission cycle of some infectious diseases (e.g., Johne's disease). Additional controlled field studies are needed to further describe and compare efficacy among various CR products, and particularly to describe the effects of feeding CR on short- and long-term health and performance outcomes. However, studies conducted to date demonstrate that, fed a large enough dose (150 to 200 g IgG) of a high-quality CR product within a short period of time after birth, calves can achieve at least equal passive transfer levels and health outcomes as compared with fresh maternal colostrum. Given the significant differences in quality and efficacy among various commercially available products, producers may want to consider whether a product is CVB-licensed, and they are strongly encouraged to select CR or CS products that have demonstrated efficacy in independently conducted controlled field studies.

Milk Replacers

The digestive anatomy of the newborn calf consists of a four-compartment stomach like that of the adult, but the abomasum predominates with 60% of the total stomach capacity. During the first weeks of life, the calf is essentially monogastric because milk is shunted directly to the abomasum by closure of the esophageal

VetBooks.ir

groove. Closure is stimulated as a behavioral response associated with milk feeding by bottle or bucket. During this time the calf depends upon the consumption of highly digestible nutrients provided by food grade feedstuffs because it depends upon enzymatic digestion of proteins, fat, and simple sugars in the form of lactose. The consumption of limited quantities of dry feed along with free-choice water stimulates rapid colonization of the stomach with ruminal microorganisms and rapid differential growth of the stomach tissue, which enables it to digest more complex carbohydrates and vegetable proteins. The impact of diet on rumen development is depicted by Heinrichs.[61]

There are multiple goals in feeding the preweaned calf, which require a degree of compromise. Ultimately, the goal should be to provide the conditions that enable the calf to achieve its genetic growth potential with minimal health problems at a reasonable cost. There are different philosophies in what constitutes a successful calf rearing program. A goal favored in more traditional programs has been limit feeding of the liquid diet to encourage dry feed intake as well as early weaning. This practice reduces feed costs during the preweaning period, and there has been the perception that digestive disturbances could be substantially reduced by transitioning the calf to a dry diet as soon as possible. This feeding program provides only enough energy from the liquid diet to meet maintenance requirements with little remaining to support growth. More recent research supports calf feeding programs that provide nutrients to encourage more biologically normal growth rates of 700 to 1000 g/day during the preweaning period. These programs cost more per day, but frequently result in lower costs per unit of gain. Studies have also demonstrated that higher protein and energy intake result in lower morbidity and mortality, particularly during the winter months.[62] Ultimately, the goal for the milk-feeding program should be to foster the growth of the animal, which results in the most economical lifetime performance, rather than the lowest daily rearing cost during the preweaning period.

Liquid Diets for the Dairy Calf

Calves can grow well on whole milk, waste milk, or milk replacers. Although the most recent NAHMS[62a] survey indicates that over 60% of calves are fed milk replacer, there is increased interest in the use of waste milk for calves, particularly on larger farms that pasteurize it prior to feeding to reduce risk of disease and improve acceptability. Pasteurized waste milk has been viewed as a means of increasing nutrient intake and reducing feed cost. However, the manager must be aware of the challenges involved in these feeding systems.[63,64]

Milk replacers were first developed in the early 1950s with the goal of reducing costs and increasing the convenience of feeding dairy calves. These milk replacers resembled gruels and frequently resulted in poor calf performance. The challenge in using milk replacers is to provide sufficient nutrients to encourage acceptable growth at less cost than feeding whole milk. Table 21-3 compares the nutrient content of one gallon of either average quality whole milk with a typical 20% protein:20% fat milk replacer diluted to approximately 12.5% solids. These milk replacers fed in the limited amounts shown here allow lower daily feed costs, encourage early starter intake but at reduced rates of gain and possibly impaired health. More recent research has been directed toward achieving gains more similar to whole milk feeding programs. The quality of milk replacers and expected performance are influenced by ingredients used and manufacturing practices and quality control.

Ingredients Used in Milk Replacers

Ingredients used in milk replacers providing the protein, fat, carbohydrate, and minerals should be of high digestibility for the young calf. Traditionally, these ingredients originate as products from the processing of milk as shown in Fig. 21-1. The skim milk and cream

Spray dried whole egg	95	41-47	39-41.5			3.5-3.65	

portions, although highly desirable, are generally too expensive to be considered in milk replacer manufacture.

PROTEIN SOURCES. Common proteins used in the manufacture of milk replacers can be classified as either milk or alternative proteins. Most milk-derived proteins used in milk replacers have originated from the whey fraction. Whey can be processed through evaporation or filtration to separate the lactose and minerals from whey proteins to yield ingredients commonly used in milk replacers. The nutrient value of these different fractions is shown in Table 21-4.

Many feeding trials have evaluated the nutritional value of different protein sources on calf growth, health, and feed efficiency. Variation in nutrient content and digestibility of whey proteins is due to the type of cheese that is being manufactured and efficacy of the different processes used. Special care must be taken during the drying process to prevent denaturation of the protein. Digestibility of whey-based ingredients generally exceeds 85% and more commonly exceeds 90%. One concern with the use of whey-based proteins is that unlike casein in skim milk protein, these proteins do not form a clot in the abomasum shortly after being consumed. It would seem that the failure to clot would impair protein digestion and utilization by the calf. However, Terosky and colleagues[68] formulated milk replacer diets containing 0%, 33%, 67%, and 100% replacement of skim milk protein with whey protein concentrate. During the 8-week experiment, daily gains were similar, although calves in which 100% of the protein was from whey protein concentrate experienced a slightly lower incidence of scouring.

The value of whey protein concentrate has increased from approximately $0.34/lb in 1985 to as much as $1.50/lb in 2012. This occurred due to the increased use of whey proteins as nutritional supplements and high-protein snack bars for human consumption. As a result, the study of the use of alternative proteins in milk replacers has been an active field of research. The nutritional content of milk-derived and alternative ingredients found in milk replacers is shown in Table 21-4. There are two major concerns with the use of alternative proteins. One is the digestibility by the calf, particularly for the calf less than 2 weeks of age. Research on the alternative proteins has shown a wide range in digestibility of these proteins from as low as 54% to more than 90%. Variation is due to the processing and the age of the calf receiving the liquid diet. Soy proteins probably offer the greatest promise. Untreated soybean protein is strongly antigenic, causing infiltration of the lamina propria of the small intestine with T and B lymphocytes, hypersensitivity reactions, villous atrophy, and decreased intestinal absorptive ability.[69] Soybeans are treated to remove the fat and all or part of the carbohydrate and reduce these antigenic properties. Soy flour represents the least processing whereas isolated soy protein is the result of extensive processing with an alkali wash, acid precipitation, alkali resolubilization, and drying. A trial reported by Tomkins and colleagues[67] noted that feed conversion by calves 1 to 14 days of age that were fed soy protein concentrate containing milk replacers was reduced by as much as 30%. However, more recent research has shown improved responses. Unfortunately, because of extensive processing, the cost of isolated soy protein is not always economically feasible.

Wheat gluten is protein derived from wet milling of wheat after separation of the starch. The protein is rather insoluble and has antigenic properties that cause reactions by intestinal tissue. However, acid treatment to partially hydrolyze the wheat protein increases its solubility and reduces antigenicity. Although the digestibility of wheat gluten is comparable to whey proteins, it is deficient in lysine. Wheat gluten proteins have found wide use in veal-type diets, but research has shown that growth in replacement heifers less than 14 days of age is seriously depressed. At higher rates of feeding the depression in average daily gain becomes ever more evident.[69]

Animal plasma proteins from porcine or bovine blood have been used in milk replacers. The protein has an excellent amino acid profile that compares well with skim milk protein. Several studies[70,71] have shown that calves fed milk replacers in which 25% of the whey proteins had been replaced with plasma proteins grew at a slightly lower rate during the first 28 days. However, growth rates were similar over a 56-day feeding period.

Spray dried whole egg is an undesirable alternative protein in milk replacers because incorporation at levels above 5% of the total dry matter results in depressions in calf growth.[72]

Other proteins, including, pea, lupine, potato, fish, red blood cells, meat solubles, yeast, and bacterial proteins, have shown to be unacceptable sources of proteins for milk replacers because of poor solubility, low digestibility, or inadequate amino acid content.[73]

Research appears to support the supplementation of vegetable protein–based milk replacers with lysine and methionine.[74] At the present time there does not appear to be merit in supplementing milk protein–based milk replacers with amino acids.

CARBOHYDRATES. The intestine of the young calf has limited carbohydrase activity except for lactase during the first weeks of life. The only carbohydrates usable in large amounts are lactose, glucose, or galactose. Lactose from whey is the main carbohydrate source in milk replacers. Whole milk contains approximately 29% lactose, 29% fat, 20% casein, 5% whey protein, and about 5% ash on a dry matter basis. The most popular milk replacers containing 20% protein and 20% fat would have substantial space for the addition of more lactose than is present in whole milk given that high levels of ash are undesirable. Consumption of higher amounts of lactose from milk replacer than might be present in whole milk does not appear to be a concern.[66] The inclusion of starch and other carbohydrates in milk replacers is not advised for calves less than 2 to 3 weeks of age because of limited amylase and maltase activity. Toullec and colleagues[75] suggest limits of 2% to 3% starch in dry matter intake for younger calves.

LIPIDS. Milk fat is highly digestible; however, it is too expensive to be included in milk replacers. Tallow, lard, choice white grease, and coconut and palm oil are the primary sources for fat used in

VetBooks.ir

TABLE 21-5

Fatty Acid Composition of Milk Replacers Based on Different Sources Compared with Whole Milk[76]

Fatty Acid (% total fat)	Animal Fat Source	Coconut Oil	Palm Oil*	Whole Milk

TABLE 21-6

Classification of Protein Sources Used in Milk Replacers Suitable for Young Calves[73]

Acceptable	Acceptable	Marginal	Not Acceptable
Dried whey protein concentrate	Soy protein isolate	Soy flour	Meat solubles
Dried skim milk	Protein modified soy flour		Fish protein concentrate
Casein	Soy protein concentrate		Wheat flour
Dried whey	Animal plasma		
Dried whey product	Wheat gluten or isolate		

Other alternative protein sources continue to be researched and yield mixed results (egg protein).

milk replacers. A comparison of the fatty acid composition of a tallow-based milk replacer with one based on coconut oil to whole milk is shown in Table 21-5. Although the digestibility of tallow and lard is somewhat lower than that of milk fat, performance is adequate. In general, highly unsaturated vegetable oils are poorly tolerated by the young calf.

Two fat sources that have been used, particularly in Europe, are palm and coconut oil. These fats are higher in medium chain fatty acids found in milk fat. Mills and colleagues[76] studied the effect of adding medium chain fatty acids at rate of 32% of the fat as coconut oil or oil high in caprylate. No differences were found in body composition intake or fecal score between the animal fat–based milk replacer or coconut oil treatments. Empty body fat was about 5% higher and livers contained 15% more fat for heifers fed coconut oil than those containing animal fat. Calves fed milk replacers in which part of the animal fat was replaced by low levels of coconut oil or blends of coconut and canola oil had higher average daily gains and less scouring than calves fed diets with only animal fat.[77,78] The formulation of milk replacers with special attention to fatty acid composition is an active field of research.

VITAMINS AND MINERALS. Vitamins and minerals are generally added to milk replacers to provide levels similar to those found in whole milk. The most recent (seventh) edition of the National Research Council (NRC)[79] recommended a substantial increase in vitamin A from 4000 to 9000 IU/kg of DM. Vitamin E recommendation was increased from 40 to 50 IU/kg of milk replacer DM. These levels are sufficient to prevent deficiencies under stressful conditions of digestive or respiratory disease and to avoid a toxic response with higher levels of milk replacer observed with more intensive feeding programs. Recommended vitamin D is 600 IU/kg of DM. Water-soluble vitamin and trace mineral recommendations are also described in the latest edition of Nutrient Requirements of Dairy Cattle.[79] Osorio and colleagues[80] evaluated the impact of supplementing organic trace minerals to calves fed diets formulated for a low or high plane of nutrition (568 g vs. >1000 g milk replacer solids/day). Calves fed at a high plane but not a low plane of nutrition responded with increased growth. This suggests that growth of calves on a lower feeding rate was limited by factors other than trace mineral nutrition.

Recommended Protein and Fat Levels in Milk Replacers

The most important factors influencing the price of a milk replacer are the protein and fat content and the source of each. Replacers labeled as all milk will usually contain blends of dried whey, delactosed whey, and whey protein concentrate. Those milk replacers with alternative proteins will have some of the whey proteins (up to 50%) replaced by soy, wheat, or animal plasma proteins. Table 21-6 represents industry classifications of the suitability of protein sources for milk replacers.

It should be noted that dried skim milk and casein are rarely present in milk replacers in significant amounts to impact nutrient content or quality as a result of their high cost. For the calves less than 3 weeks of age, digestibility and amino acid content of milk-derived proteins tend to be more suitable.

Commercially available milk replacers contain between 18% and 28% protein. The level of protein and fat depends upon the desired performance and conditions of the calf's environment. The seventh edition of the NRC[79] continues to recommend limited feeding of milk and milk replacer solids to calves (454 g/day) to encourage the early intake of calf starter and early weaning. At this level of intake, 18% to 20% protein is adequate with minimal rates of daily gain. However, more recent work that has focused on the nutritional requirements of calves growing to their genetic potential has resulted in the manufacture of milk replacers with higher protein content fed in amounts as high as 1.1 kg of milk or milk replacer solids/day.[81-83] Work by Blome and colleagues[81] suggests that lean tissue growth is optimal between 26% and 28% CP at higher feeding rates.

Calf milk replacers usually contain between 10% and 25% fat. This is lower than the level found in cow's milk, which would be in excess of 28% with milk containing 3.6% fat on a liquid basis. The impact

VetBooks.ir

of the fat content of the milk replacer upon body composition and calf growth depends upon the feeding rate and environmental conditions. At lower feeding rates (454 g solids/day), body fat deposition increases as the level of fat increases in the milk replacer. The optimal level of body fat for the preweaned calf has not been determined. Body fat at birth is heavily dependent upon the body condition of the dam. During the end of the first week of life it is not uncommon for calves to have less than 2% body fat.[84] This is probably an inadequate reserve should the calf become ill, decrease dietary energy intake, and have increased energy requirements as a result of environmental temperature or the response to disease. Therefore, there is probably some benefit to the calf experiencing accretion of body fat, especially during the first weeks of life. As fat percentage and daily fat intake from milk replacer increases, calf starter grain intake is delayed or occurs at a lower rate. Most milk replacers contain approximately 10% to 20% fat, which is adequate over a wide range of intake levels and protein percentages. Research by Bascom and colleagues[84] suggested that smaller calves would benefit from higher levels of fat in the diet during periods when the environment is below the thermoneutral zone. However, during warmer months, there appears to be little benefit to milk replacers with more than 15% fat. Milk replacers specially formulated to contain desired fatty acid composition with 10% fat provide sufficient energy for desired growth during summer months.

Manufacturing Milk Replacers

Production of milk replacers begins with procurement of quality ingredients and having a strict quality assurance program in effect at the plant.[69,85] Whey products are monitored for protein, fat, ash, pH, sodium, moisture, color, solubility, dispersibility, bacterial growth, lactic acid production, and evidence of overheating. With fats and oils, color, melting point, odor, peroxide, free fatty acid content, and fatty acid profile are considered. Most manufacturers rely on supplier histories as each incoming load of ingredient is tested. The main variables influencing the nutritional value of whey proteins are the type of cheese produced, heating history, length of storage, and sanitation. Sanitation factors are critical since they influence microbial load and peroxide addition to the final product. Standard plate count must be less than 30,000 cfu/g, less than 10 cfu coliforms/g, less than 10 mold or yeast colonies/g, and no detectable *Salmonella*. Excessive heating can lead to denaturation of the protein, whereas underheating contributes to excessive microbial growth. Reputable manufacturers only use ingredients that are edible by humans rather than feed grade.

The next process in producing a milk replacer is to combine the ingredients into a product that has good wettability and mixability characteristics and does not separate. *Wettability* is a measure of how fast the powder breaks water tension and drops below the surface of the water. A test used is the amount of the powder that drops below the surface of the liquid within 60 seconds. This is related to ingredients used and the amount of surfactant that is added. *Mixability* is how completely the powder goes into solution and stays in suspension. Although wettability appears to make the product more convenient, mixability is more important in regard to the calf. *Separation* is how much the ingredients separate from the rest of the solution, including those that float to the surface and those that sink to the bottom. Ingredients low in fiber (e.g., milk proteins, plasma, wheat gluten, and soy isolate) have better mixing characteristics than soy protein concentrate or flour. A powder that has all of the nutritional characteristics of a desirable milk replacer must also have physical characteristics that enable the calf to consume a uniform, digestible, and palatable product.

Several methods are used in manufacturing milk replacer powders: dry blending, chilling towers, and agglomeration. Each method can provide a finished product of desirable nutrient content. However, differences in the three characteristics mentioned previously may impact the nutrients consumed by the calf. Dry blending is the simplest because the dry protein and fat sources are mixed together with additional liquid fat sprayed on later. The issue with dry blended products is getting fat into suspension since it is very hydrophobic. The nature of the fat product greatly determines how this is accomplished. Some fats used in milk replacers have protein sprayed on their surface, which improves mixing, whereas others use higher amounts of emulsifiers. Milk replacers may also be agglomerated to enhance wettability and mixability. These processes result in encapsulation of difficult ingredients such as fat with more hygroscopic ingredients and increase particle size, resulting in a powder that goes into solution quicker and stays in suspension. The process of agglomeration generally provides a finished product that is easiest to mix on the farm. Ideal mixing temperature for a milk replacer is heavily dependent upon the ingredients and processing method used. Excessive temperature can result in disruption of the agglomerated product and separation of the fat and protein. Low temperatures will result in inadequate mixing. One must closely follow the recommendations for mixing temperature provided by the manufacturer. Typically dry blended milk replacers require higher mixing temperatures.

Another small but important detail is how milk replacer powder is mixed. Ideally, about 50% to 70% of the total water needed for a batch is added, followed by the powder, and then they are mixed. Remaining water is added to obtain the final desired volume. During cold weather, temperature should be warmer because the liquid will cool prior to feeding, especially in slower feeding systems. A thermometer should always be used to check mixing temperatures (see manufacturer recommendations) and feeding temperature (37.8° to 40.6° C [100° to 105° F]).

Ideally, both the water and powder should be weighed for each batch of milk replacer liquid. Most milk replacer powders are approximately 96% to 97% dry matter. When powder is diluted, the final solution should be fed at a solids concentration of 10% to 15%. The influence of solids level on calf performance is relatively small within this range. However, formulation of liquid diets with higher DM percentage permits delivery of more nutrient solids within a given volume. Delivery of more nutrients can be challenging with feeding systems using two quart/liter bottles and twice daily feeding. Under such systems, it is difficult to deliver more than 454 g/day to calves. Feeding milk replacer at solids levels as high as 20% has been associated with increased scouring in calves, especially if free choice water is not available. For this reason, many calf operations have switched to the use of three quart/liter bottles.

A degree of confusion exists in many operations on how to calculate the level of milk solids in a liquid feeding system. Adding 150 g of powder to 1 L of water does not result in a 15% solids solution because 150 g of powder + 1000 g of water = 1150 g of final weight, or 150/1150 = 13.04% solids.

Acidification of Milk Replacers

Workers in Canada[86] have described a system of free-choice feeding either cold milk or milk replacer treated with formic acid, which lowers the pH of the liquid to approximately 4.5. This system results in higher levels of intake of liquid diet and lower initial calf starter intake, but noticeable improvements in gains and labor efficiency. However, at the present time, formic acid is not permitted as a feed ingredient in the U.S. dairy industry. Nocek and Braund[87] observed more gain in calves fed ad libitum to 35 days compared with limit-fed calves offered a non-acidified milk replacer. However, there were not significant differences in scouring, and calves of both treatments reached 136 kg of body weight in the same number of days, likely because of weaning challenges and postweaning diets that were not adjusted for body weight differences. Jaster and colleagues[88] compared calves fed twice daily at 10% of body weight either "sweet" or acidified milk replacers containing 12.5% solids. Citric acid was used to decrease the pH to 5.3. No differences were found in gains with a slight reduction of scours in calves fed the acidified replacer. Acidified milk replacers using combinations of organic acids other than formic acid are commercially available. Cold liquid feeding systems will reduce feed efficiency because of the impact of liquid temperature on the energetic requirements of the calf.

VetBooks.ir

TABLE 21-7

Commonly Used Milk Replacer Medications

Medication	Use Level	Statement	Withdrawal
Oxytetracycline/Neomycin 1:1 ratio[72a]	To provide 0.05 to 0.1 mg/lb of body weight daily (10/20g/ton of milk replacer powder)	For increased rate of weight gain and improved feed efficiency	None
	To provide 10 mg/lb of body weight daily (500-2500 g/ton of milk replacer powder). Can be fed as a treatment for 7 to 14 days in calves up to 250 lb body weight	For treatment of bacterial enteritis caused by *E. coli* and bacterial pneumonia caused by *P. multocida* susceptible to OTC; treatment and control of colibacillosis caused by *E. coli* susceptible to Neomycin	5 days before slaughter
Decoquinate[73]	12.9 to 90 g/ton to provide 22.7 mg decoquinate/100 lb body weight	For prevention of coccidiosis in calves and cattle caused by *Eimeria bovis* and *Eimeria zuernii*	None
Lasalocid[73]	1 mg lasalocid per 2.2 lb body weight	For control of coccidiosis caused by *Eimeria bovis* and *Eimeria zuernii*	None

Additives to Milk Replacers

Prior to 2010, neomycin (400 g/ton) and oxytetracycline (200 g/ton) were added to milk replacers to aid in the control of bacterial enteritis. Beginning in late 2010, this policy was changed to limit the continuous feeding of these antibiotics to inclusion rates of 10 to 20 g/ton neomycin and 10 to 20 g/ton oxytetracycline with a label to increase weight gain and improve feed efficiency. Therapeutic inclusion rates of 1600 g/ton neomycin and 1600 g/ton oxytetracycline are limited to 14 days of continuous feeding. Commonly used milk replacer medications are shown in Table 21-7.

Additional additives used in milk replacers include yeast products, probiotics, and fermentable fibers. Heinrichs and colleagues[89] found similar performance of calves fed a milk replacer diet with no additives or supplementation with the pre-2010 level of oxytetracycline/neomycin or 4 g/day of mannan oligosaccharide (MOS). Addition of either the antibiotic or MOS reduced scours. Calf starter intake increased at a faster rate for those calves fed MOS. Inclusion of fermentable fibers from psyllium to a milk replacer powder at 1.1% of the dry matter intake increased populations of bifidobacteria and lactobacilli in the rumen and reticulum of preweaned dairy calves. It also increased the mass of the gastrointestinal tract.[90] Daily addition of probiotics in the form of *Lactobacillus acidophilus* had no effect on body weight over a 6-week trial, but calf health and growth were improved during the first 2 weeks of life.[91] The study of the efficacy of additives continues as the milk replacer industry seeks to find replacements for antibiotics in milk replacers.

Feeding Recommendations for Dairy Calves

Traditional calf feeding programs consisted of daily consumption of 454 g of milk or milk replacer solids in 4 L of liquid divided into two daily feedings. These recommendations existed solely to encourage calves to begin consumption of dry feed and promote early weaning. There is little evidence to support this from a biological perspective because such limited intake during the first 2 to 3 weeks of age barely provided sufficient energy and protein to meet maintenance requirements in calves under thermoneutral conditions between 10° C and 25° C. During periods of cold stress, intake of milk or milk replacer should increase by 30% to 50%. More recently, research has shown the benefits of "accelerated" or "intensive" calf-feeding programs in which liquid diet intake of milk or milk replacers with up to 28% protein are fed at rates up to 1 to 1.2 kg of solids per day. These terms are probably misnomers, since the intake of milk or milk replacer is more similar to liquid feeding programs for sheep, pigs, and beef cattle. Ollivett and colleagues[92] showed that calves challenged with *Cryptosporidium parvum* recovered faster and gained weight shortly after challenge if fed this more appropriate plane of nutrition while controls fed the traditional diet continued to lose weight. The seventh edition of the Nutrient Requirements[79] for dairy cattle uses the factorial approach to estimate requirements for growth and maintenance with consideration for environmental temperature. More progressive calf feeding programs encourage enhanced growth, higher feed efficiency, and more economical gains, especially during the first 3 weeks of life when calf starter intake is minimal. One concern expressed is that calf starter intake is delayed. However, calves quickly adjust, and weaning by 6 weeks of age is achievable.

Laboratory data are discussed here in relation to case management. The focus is on interpretation of an abnormal finding in the typical clinical situation. An in-depth pathophysiologic explanation of these alterations is beyond the scope of this section. Should additional information be required, a textbook on veterinary clinical pathology should be consulted.[1,2]

All samples should be submitted with specific objectives in mind. In general, these objectives fall into one of the following categories:

- Evaluating organ system involvement or functional impairment
- Confirming a diagnosis or ruling out a disease condition
- Directing therapy formulation
- Assessing response to therapy
- Formulating a more accurate prognosis

Submission of Laboratory Samples

Veterinary Diagnostic Services

The clinician must be aware of inherent limitations of laboratory evaluation in certain clinical settings. In general, veterinary diagnostic laboratories are preferred to general medical laboratories because human medical laboratories may be less familiar with animal diseases and the responses of animals to disease. There may also be differences in test methodology and interpretation. These species differences can cause confusion when results are evaluated on the basis of human criteria that may not apply to animals.

Various desktop or portable handheld point-of-care devices are available to veterinarians for determination of serum chemistry, electrolytes, and acid-base balance. Many of these devices use self-contained strips, cartridges, or rotors and thus reduce errors associated with the maintaining, measuring, and mixing of reagents. In addition, some of these devices can use whole blood rather than serum or plasma. Some devices require refrigerated storage of reagent cartridges, which must then be warmed to room temperature for use. There are relatively few independently published data comparing the results obtained with these point-of-care devices and those obtained with standard laboratory procedures. A widely used handheld device (iSTAT) has been shown to yield comparable results for blood electrolyte concentrations and acid-base balance in dogs and horses.[3] However, it was noted that the correlation between results from this device and from standard laboratory techniques was poor for sodium in the dog and for hematocrit in the horse. A study using the same handheld device in cattle, horse, and sheep showed that except for sodium concentration and hematocrit in horses and sheep, correlation was good or excellent for most variables reported.[4] Portable point-of-care devices can provide rapid, accurate, and relatively inexpensive results. As technology continues to improve, wider and more general application of these devices in many large animal practice settings can be anticipated. Important requirements are the establishment of normal values with these devices for our large animal species of important age or production groupings as well as clear definition of the limitations and possible idiosyncratic reactions in certain species or clinical settings.

Selection of Procedures

Selection of specific laboratory tests fosters logically integrated thinking and concentrates on evaluation of the primary medical problems. However, the sophisticated autoanalyzers used by large commercial laboratories can perform a wide battery of tests quickly and efficiently with little additional cost. These panels may be broadly defined (e.g., a general large animal health panel) or may offer a more focused evaluation of a specific organ system (e.g., liver, kidney, or muscle). The clinician must ensure that the panel selected contains all the appropriate tests for a thorough evaluation of the individual patient's medical problems.

The following recommendations for diagnostic panels are intended to provide a clear indication of organ damage and/or dysfunction. The most directly applicable diagnostic procedures are listed under "Recommended," and additional procedures that may be of benefit in certain circumstances are listed under "Optional."

GENERAL PANEL. The broadly based general chemistry panel should provide a balanced evaluation of the most likely medical problems.

Ionized calcium
Ionized magnesium

MUSCLE PANEL. The muscle panel should detect active skeletal and cardiac muscle injury (rhabdomyolysis) and the degree of secondary renal damage. The possible causative factors are evaluated as optional procedures, depending on the history, clinical findings, or special circumstances. Muscle biopsy with special staining may be critical to the diagnosis of specific muscle diseases such as polysaccharide storage myopathy, immune mediated myopathy, and mitochondria myopathy. Special tests for muscle function and the genetic basis for some myopathies are discussed in the chapters on muscles and genetic tests (see Chapters 42 and 52).

Recommended
CK
AST
Muscle biopsy
Urinalysis
BUN or creatinine

Optional
Myoglobin
Blood selenium
Venous blood gases
DNA analysis (HYPP, PSSM)
Calcium (ionized and total)
Magnesium (ionized and total)
Fractional excretion of:
- Sodium
- Potassium
- Chloride
- Myoglobin

LIVER DISEASE PANEL. The liver panel should detect active damage to the hepatic parenchyma, involvement of the biliary system, and alteration in hepatic function.

Recommended
SDH
AST
GGT
ALP
BUN
Bile acids
Blood glucose
Fibrinogen
Total protein
Albumin
Globulin
Bilirubin (direct, indirect, and total)
Complete urinalysis

Optional
Liver ultrasound
Liver biopsy/culture
Blood ammonia
Clotting panel
BSP clearance test (BSP $t_{1/2}$)

RENAL DISEASE PANEL. The kidney panel should provide a rough quantitative estimation of compromised renal function and should indicate the location and nature of the damage to the urinary tract.

Recommended
BUN
Creatinine
Na
K
Cl
Calcium
Phosphate
Protein
Albumin
Complete urinalysis

Optional
Renal ultrasound
Renal biopsy
Urine culture
Urine/plasma osmolality ratio
Urinary CK/creatinine ratio
Fractional excretion of:
- Sodium
- Potassium
- Chloride
- Endogenous creatinine clearance
- Sodium sulfanilate clearance

GASTROINTESTINAL DISEASE PANEL. The gastrointestinal disease panel should include evaluation of acid-base status, fluid and electrolyte balance, and renal function, which are common complicating features of gastrointestinal diseases. Additional optional or special diagnostic procedures may be necessary in calves or foals with neonatal diarrhea, in horses with colic, and in ruminants with gastrointestinal stasis or displacement.

Recommended
Packed cell volume (PCV)
Total plasma protein (TPP)
Sodium
Potassium
Chloride
Calcium (ionized and total)
Venous blood gases, pH, bicarbonate
Anion gap
BUN
Creatinine
Glucose
Peritoneal fluid cytology
Peritoneal fluid protein
Fecal occult blood
Fecal parasites
Ruminal fluid pH and analysis
Rumen fluid chloride

Optional
Peritoneal fluid (glucose and pH)
Serum immunoglobulin

VetBooks.ir

Plasma lactate (D and L forms)
Fecal protozoa
Fecal culture
Fecal *Clostridium difficile* toxin testing
Fecal cytology
Rectal biopsy (histology, culture)
Absorption test:
- Glucose
- D-Xylose
- Oral lactose tolerance test

Metabolic Profiling

The health status and productivity of dairy cattle, swine, and other food animals maintained in large confined groups involve a fragile balance between metabolic events, nutrition, agents of disease, management, and environmental factors. In these production units, the health status of the herd as a whole is of paramount importance. Subclinical disease or nutritional imbalance may contribute to suboptimal productivity. Most productivity problems in these settings are multifactorial. Defining and finding solutions to these problems can be a difficult and complicated task. Sequential assessment of weight gains, body condition scores, milk quality (fat and protein concentrations), and milk production are useful measures of the presence of subclinical production disorders but do not identify the cause. Metabolic profiling is a tool that has been used in some situations. Blood samples are drawn from a number of randomized individuals as representative of the group as a whole. Some have recommended the submission of pooled serum samples from representative individuals, much like the use of bulk tank tests as a reflection of the general level of mastitis in a herd. Sampling may be done routinely and sequentially (longitudinally). In dairy cattle this may be done during gestation or lactation but frequently focuses on the periparturient period when a combination of nutritional and metabolic events often contributes to costly production disorders.

Metabolic profiles might include most of the parameters listed under the recommended general panel with the addition of magnesium, total cholesterol, nonesterified fatty acids (NEFA), and β-hydroxybutyrate (BOHB). BOHB, NEFA, and cholesterol may provide an indication of energy balance, whereas BUN, creatinine, total protein, albumin, and CK may be helpful in assessing protein status along with urea levels in milk. In certain settings, trace minerals or fat-soluble vitamin concentrations may be important indicators of underlying nutritional problems. Metabolic profiling is not a substitute for careful clinical examination, analysis of husbandry practices, and ration analysis, but it may play a useful role in some modern large-scale operations in which a variety of subclinical problems can quickly translate into financial disaster.

Sources of Variation in Normal Values

Laboratory

One of the most commonly overlooked sources of variation in clinicopathologic data is the difference in results obtained by different laboratories. This can result in fivefold to tenfold differences in the normal range of certain enzyme activities among laboratories using similar but not identical methodologies. In the past there was marked variation in the units of measure used to express the activities of different serum enzymes. The standard method of representing serum enzyme activity is in international units per liter (IU/L), which is used in this text. Correction factors for converting the commonly used but older units of measure to international units are given in Table 22-1. The normal values given in Tables 22-2 and 22-3 are those currently used at the Ontario Veterinary College or are from the literature.[2] It is always best and crucial to use normal values and reference intervals established for the species, age, and production type by the diagnostic laboratory to which samples are submitted.

Species

There is relatively modest variation among species for most clinicopathologic parameters. Notable exceptions are plasma electrolyte concentration, erythrocyte potassium concentration in some breeds of sheep, and serum bilirubin concentration, which is higher in horses than in other species. Urea nitrogen (UN) is a less reliable indicator of renal function in ruminants and horses than creatinine because UN can be metabolized by the intestinal microflora. Donkeys and burros have a much higher GGT level than horses and cattle. Calves will have very high GGT levels compared with other species because of increased concentrations of this enzyme in bovine colostrum.

Breed

Significant differences in hematologic parameters exist between hot- and cold-blooded horses. Hot-blooded horses include most of the athletic breeds of horses (Thoroughbred, Quarter Horse, Standardbred, and Arabian breeds). Cold-blooded horses include the pony and draft breeds. Cold-blooded horses have lower red blood cell (RBC) values both at rest and after exercise and maintain a slightly lower leukocyte count; they also have lower resting and fasting indirect bilirubin concentrations.

Age

Several important differences in hematologic and clinical chemistry exist between neonatal and adult animals within species. The effects of age have been studied most carefully in horses and cattle. In comparison to adult animals, suckling neonatal animals tend to have lower BUN, slightly lower total protein and globulin, moderately higher GGT and phosphate, and markedly greater alkaline phosphatase. Creatinine in foals can be a bit higher in well-muscled foals (up to 2.5 mg/dL) and occasionally very high (up to 8 mg/dL) shortly after birth and returning to normal values within 24 hours, and it is thought to be due to defective placental transfer.[3]

Sex

With the obvious exception of sex hormone concentrations, there are few recognized differences in clinical chemistry values between sexes. In most domestic animals the intact male tends to have a slightly higher erythrocyte count, hemoglobin concentration, and PCV than the female or neutered male. This sex-related difference has been demonstrated most clearly in the horse.

Factors Influencing Results or Their Interpretation

Many factors influence the reliability and interpretation of results obtained by laboratory analysis. Sample collection and handling are very important factors. The sample collection site (e.g., jugular vein, mammary vein, tail vein, cephalic vein, lateral thoracic vein, ear vein or carotid artery, transverse fascial artery, metatarsal artery) can have an important effect on the results of tests such as blood gas evaluation, glucose, or ketones. The choice of anticoagulants depends on whether the samples are to be submitted for serum, plasma, or whole blood analyses. The specific sample requirements for the most commonly ordered clinical chemistry determinations are listed in Table 22-4. Serum is required for most chemistry parameters, and serum separator tubes work very well in most settings. There have been some indications that results of some serum hormone assays may be influenced by collection of blood in serum separator tubes. Sodium or lithium heparin is the anticoagulant of choice for most chemical determinations requiring plasma. Historically fluoride-oxalate was the anticoagulant of choice for blood glucose determination because it did halt glycolysis by the RBCs. However, fluoride may interfere with certain chemical procedures (specifically the glucose oxidase method for blood glucose determination) and should be used only for blood lactate determination or in selected circumstances in which glucose determinations are required and samples must be held for some period of time without refrigeration. Citrate is the anticoagulant of choice for clotting tests and blood typing.

kPa, Kilopascal; P_{O_2}, partial pressure of oxygen; P_{CO_2}, partial pressure of carbon dioxide; T_{CO_2}, total carbon dioxide.

Ethylenediaminetetraacetic acid (EDTA) is the anticoagulant most often used for hematologic evaluation. Both citrate and EDTA are chelating agents, which may interfere with a wide variety of chemical analyses.

Samples should be submitted as soon after collection as possible, but circumstances may require storage of some samples for 12 to 24 hours. For collection of serum, whole blood should be allowed to clot before refrigeration. Serum should be separated from the RBCs immediately after clot formation and then kept refrigerated. Samples should be stored in clean containers free from exposure to sunlight, medications, or chemicals. If whole blood is left at room temperature for longer than 60 minutes, blood glucose will be falsely low as a result of RBC glycolysis. Storage of whole blood may result in in vitro hemolysis, with the potential for misleading increases in the serum or plasma enzymes AST and lactate dehydrogenase (LDH) and potassium and phosphorus concentrations as a result of hemolysis. In addition, failure to separate serum or plasma from the RBCs within an hour of collection may lead to leakage of erythrocyte potassium and a falsely elevated serum or plasma potassium concentrations.

Stress, transportation, excitement, and handling produce physiologic responses in animals that affect a variety of hematologic and biochemical parameters. This is most evident in the horse, which shows marked increases in RBC mass and to a lesser extent plasma protein concentration in response to excitement, exercise, or catecholamine administration. The RBC count, hematocrit, and hemoglobin concentration can increase by as much as 50%, whereas plasma protein concentration may increase by 1 to 2 g/dL. Leukocytosis mainly seen as neutrophilia is induced as the marginating leukocyte pool is mobilized into the general circulation. Prolonged stress results in the release of endogenous corticosteroids, which produce the typical "stress response" in the leukogram. A similar leukogram is found in racehorses some 4 to 6 hours after racing. The combination of catecholamine and glucocorticoid release associated with stress, transport, and excitement, as well as with many gastrointestinal catastrophes, may result in markedly elevated blood glucose concentrations (up to 400 mg/dL). Modest elevations (twofold to fourfold increase) in muscle-derived enzymes occur in association with prolonged transport or endurance exercise.

Large losses or compartmentalization of sodium-containing fluid accompanies many systemic disorders, particularly digestive problems such as diarrhea, colic, displacement of viscera, excessive sweat losses, and some urinary tract diseases. These forms of dehydration lead to decreases in plasma volume, which are indicated by moderate-to-marked increases in the PCV and TPP concentration. The concentration of other compounds dissolved in the plasma may also increase as a result of decreases in the plasma volume. The concentrations of compounds that are largely protein bound, such as calcium, are generally closely related to albumin concentration. More than 50% of serum calcium is bound to albumin. Increases or decreases in plasma protein concentration normally result in proportional changes in total serum calcium concentration, whereas the physiologically active ionized calcium may remain unchanged.

TABLE 22-4

Recommended Anticoagulants for Hematologic or Clinical Chemistry Evaluation

Anticoagulant	Specimen	Test or Procedure
Ethylenediaminetetraacetic acid (EDTA)	Whole blood	Complete blood count, cross-match, platelet count
	Whole blood	Blood selenium
	Plasma	Refractometric protein and fibrinogen
	Peritoneal fluid	Fluid analysis
	Bone marrow	Hematologic evaluation
	Synovial fluid	Fluid analysis
Heparin	Whole blood	Blood pH, blood gases
	Plasma	Electrolytes, osmolality
	Synovial fluid	Mucin clot test
Fluoride and oxalate	Plasma	Lactate
Citrate	Whole blood	Blood typing
	Plasma	Coagulation tests (PT, PTT, factor analysis)
None, serum separator tubes	Serum	Most chemistries, electrolytes, osmolality
		Protein electrophoresis
		Hormones (cortisol, T_3, T_4)
		Immunoglobulins (IgG, IgM, IgA)

Modified from Brobst DF, Parry BW. 1987. Normal clinical pathology data. In Robinson NE (ed), Current therapy in equine medicine, ed 2. Saunders, Philadelphia, PA.
PT, Prothrombin time; *PTT,* partial thromboplastin time; *T_3,* triiodothyronine; *T_4,* thyroxine.

Diseases that cause a reduction in effective circulating fluid volume often also cause alterations in renal function. This so-called prerenal azotemia results in moderate to marked elevation in BUN and creatinine. Although this is generally considered primarily a prerenal azotemia, real pathologic changes in the kidneys often are associated with the systemic processes initiated by these disorders. Longitudinal reevaluation of renal function (urinalysis, serum BUN, and creatinine) in these patients during the course of disease is important because it affects prognosis, response to fluid administration, and the potential for nephrotoxicity and systemic toxicity of a variety of chemotherapeutic agents used in such patients.

Fasting laboratory data are important for evaluation of many disease conditions in human and small animal patients. Truly fasting conditions are rather difficult, given the large and complex gastrointestinal tract of most herbivores and are thus seldom used. The feeding of animals in relation to sample collection, however, can have an impact on the data obtained. Hay-feeding in horses is reported to affect sodium, potassium, and protein concentrations within the first few hours after feeding. Animals feeding on lush green pasture or large amounts of silage may have slightly different parameters from those fed high-concentrate rations. The anion-cation balance of the ration has an impact on relative serum electrolyte concentration, acid-base balance, and urine pH and urinary electrolyte excretion. Lactescent (cloudy) plasma may be observed in samples from nursing foals or calves. The fluid intake of the normal nursing neonate may range from 100 mL/kg/day to more than 250 mL/kg/day. This high fluid intake is reflected by a commensurately high output of urine with a low specific gravity and low osmolarity.

The administration of certain medications may have an impact on some laboratory parameters. Tranquilization may be necessary for restraint and safe sample collection. The practitioner should be aware that tranquilizers often decrease RBC mass and plasma protein concentration. This is particularly true of the phenothiazine-derivative tranquilizers when used in the horse. Xylazine administered to large animals produces a modest catecholamine release, which may be evidenced by the slight sweating response seen in many horses sedated with this drug. Glucose concentration will increase modestly in response to the xylazine-induced catecholamine release. Repeated intramuscular injections with certain antibiotics (especially erythromycin and tetracycline) or other preparations that are locally irritating may produce slight-to-moderate elevations in muscle-derived serum enzyme activities. Intravenous administration of certain drugs and compounds such as dimethyl sulfoxide (DMSO) can produce intravascular hemolysis and hematuria. The amount of hemolysis in these circumstances is relatively small and of little consequence, except that it can cause confusion as to why hemoglobinuria occurred.

VetBooks.ir

Fluid and Electrolyte Balance

Packed Cell Volume and Total Plasma Protein

PCV and TPP concentration are simple and convenient indicators of acute fluid alterations. Changes in the plasma volume generally are reflected by changes in the PCV and the TPP concentration. In dehydrated humans, changes in the PCV are believed to be the more reliable guide to changes in plasma volume because substantial protein fluxes into and out of the circulation have been shown to occur. However, in most animal species the range of normal for the PCV is much wider than for the TPP concentration. This is particularly true of horses, in which excitement, pain, or catecholamine release can produce variable mobilization of splenic erythrocytes, making it difficult to obtain a truly resting PCV. For these reasons, precise quantitative estimation of a change in plasma volume using these parameters is more complex and less reliable in large animal species. As plasma volume increases or decreases, the change in the PCV is always less than the change in the TPP concentration. However, a large disparity in the changes in the PCV and the TPP concentration in a patient with a history of loss of sodium-containing fluid and clinical evidence of reduced effective circulating fluid volume suggests blood or protein loss. Marked increases in the PCV with a normal-to-low TPP concentration frequently are encountered in animals with acute protein-losing enteropathies such as salmonellosis or equine toxic enteritis, or enterocolitis. In horses undergoing treatment for diarrhea, the excessive administration and retention of sodium-containing fluids is a key factor in the development of edema and hypoproteinemia. Blood loss generally results in a decrease in both PCV and TPP concentration with a lag time of up to 24 to 48 hours.

Serum Sodium

The serum sodium concentration is a function of the exchangeable cation content (i.e., the exchangeable sodium [Na] in the extracellular fluid [ECF] volume plus the exchangeable potassium [K] in the intracellular fluid [ICF] volume relative to total body water). The ECF *sodium* content determines the ECF volume, whereas the ICF volume is a function of ICF *potassium* content.

Changes in the sodium concentration reflect the net changes in this relationship and often do not represent accurately the changes in sodium balance. Changes in water balance are thus primarily responsible for changes in the serum sodium concentration and one should always consider the hydration status of the patient for sodium concentration interpretation. Hyponatremia is an indication of a relative water *excess,* whereas hypernatremia is an indication of a relative water *deficit*.

Dehydration is defined as a loss of body water (fluid volume contraction). It occurs in a variety of clinical circumstances. The serum sodium concentration provides a means of categorizing dehydration in a physiologically meaningful way. Hypertonic dehydration, which occurs when water losses exceed the losses of sodium and potassium, is indicated by hypernatremia (free water loss or hypotonic fluid losses). The response of horses to feed and water deprivation is an example of this form of dehydration. Isotonic dehydration occurs with a balanced loss of water and electrolytes—that is, approximately 140 to 150 mEq of sodium plus potassium (Na + K) for each liter of water lost. Because the relative water balance has not changed, the serum sodium concentration remains unchanged despite the accumulation of what may have been a substantial body sodium deficit. The early stages of acute diarrhea and the dehydration of heavily sweating endurance horses are examples of isotonic dehydration. Hypotonic dehydration occurs when the losses of exchangeable cations (Na + K) exceed the net change in water balance; this condition is indicated by hyponatremia. Hypotonic dehydration often is seen in animals with subacute or chronic diarrhea that develop substantial water and electrolyte deficits but then replace part of the water deficit through water consumption. Fig. 22-1 shows the compartmental distribution of fluid between the ECF volume and the ICF volume in four situations.

HYPONATREMIA. Hyponatremia results from retention of free water or excess loss of sodium. It is often but not invariably associated with conditions that cause sodium depletion such as vomiting, diarrhea, excessive sweat losses, and adrenal insufficiency. The fluid losses in these conditions are most often hypotonic or isotonic, and initial fluid and electrolyte deficits do not result in hyponatremia until water intake, renal water retention, or both disturb the balance between the remaining exchangeable cations and the total body water.

The accumulation of sodium-containing fluid in body cavities or the gut lumen caused by ascites, peritonitis, or rupture of the bladder or by displacement, torsion, or volvulus of the gut is referred to as a *third-space problem.* When such accumulations develop rapidly, the plasma volume is reduced, and the serum sodium concentration subsequently may decrease as compensating renal responses cause

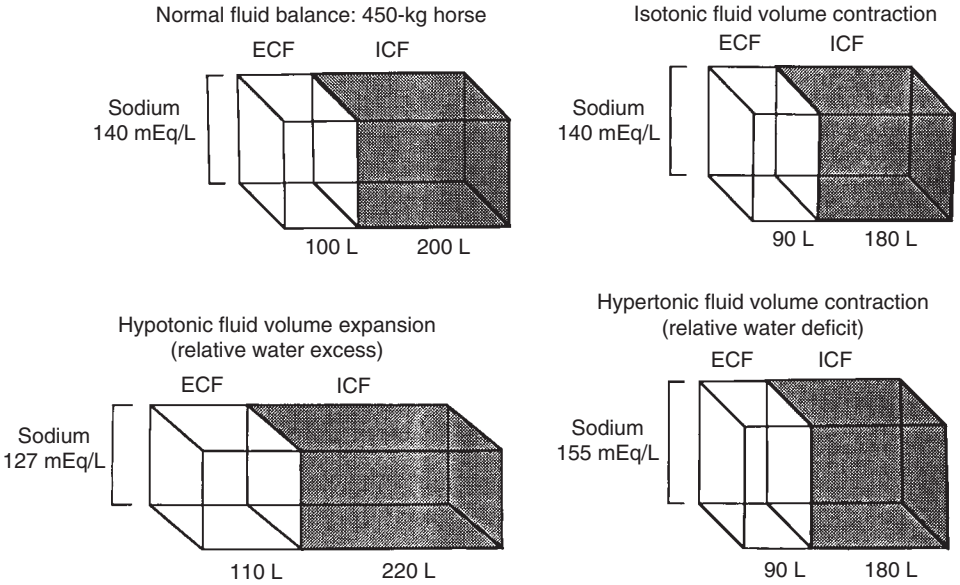

FIG. 22-1 Compartmental distribution of fluid between the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume in a 450-kg horse with normal fluid balance, with isotonic fluid volume contraction, with hypotonic fluid volume expansion, and with hypertonic fluid volume contraction. *(Modified from Kaneko JJ, Harvey JW, Bruss ML, eds. 2008. Clinical biochemistry of domestic animals, ed 6. Elsevier Academic Press, New York.)*

VetBooks.ir

BOX 22-1

Causes of Hyponatremia

Common Causes

- Relative water excess
  - Loss of sodium-containing fluid (decreased effective circulating volume)
    - Diarrhea
  - Excessive sweating
  - Blood loss
  - Fluid drainage
    - High-volume gastric reflux
    - High-volume pleural drainage
- Adrenal insufficiency
- Sequestration of fluid (third-space problems)
  - Peritonitis
  - Ascites
  - Pleuritis
  - Ruptured bladder
  - Torsion or volvulus of the gut
  - Excessive administration of 5% dextrose to patient with renal disease
- False hyponatremia
  - Hyperlipidemia
  - Hyperproteinemia
  - Hyperglycemia

Uncommon Causes

- Water retention with normal effective circulating volume
  - Psychogenic polydipsia
  - Renal disease
  - Inappropriate antidiuretic hormone secretion
  - Use of diuretics

BOX 22-2

Causes of Hypernatremia

Common Causes

- Pure water losses
  - Panting
  - Water deprivation
- Sodium excess (water restriction)
  - Salt poisoning
  - Feeding only electrolytes, no free water

Uncommon Causes

- Water loss exceeds electrolyte loss
  - Vomiting
  - Diarrhea
  - Burns
  - Intrinsic renal disease
  - Diuretics
  - Diabetes insipidus
    - Central
    - Nephrogenic
  - Hypertonic saline or sodium bicarbonate administration
  - Mineralocorticoid excess

water retention. Rupture of the bladder in neonatal foals is associated with marked hyponatremia and hypochloremia. As fluid intake continues and dilute urine accumulates in the abdomen, sodium, chloride, and other ions are drawn from the rest of the ECF into this accumulating fluid. No sodium or chloride has been lost from the body, and the observed decreases in the electrolyte concentration are caused by changes in the relative water balance ("water follows solute"). The neurologic signs seen in these foals are largely caused by the effects on the central nervous system of the rapidly developing and marked hypotonic hyponatremia. Progressively severe neurologic disturbances may be seen as the serum sodium concentration falls below 115 mEq/L and then below 100 mEq/L. The severity of the neurologic abnormalities is a function of both the rate at which hyponatremia develops and the absolute degree of hyponatremia. Neurologic disturbances can occur iatrogenically if excessive amounts of free water (usually given as 5% dextrose) are administered to patients with altered renal function.

Mastitis results in an increased loss of sodium in the milk, and a low-grade mastitis problem in a dairy herd on a marginal dietary salt intake may result in sodium depletion and medullary washout. Decreased milk production, polyuria, hyposthenuria, and a low urine sodium level may be noted, although the serum sodium concentration may remain within the lower range of normal.

The most common causes of hyponatremia are listed in Box 22-1. Marked hyperlipidemia or hyperproteinemia produces a falsely low sodium concentration value because lipid or protein occupies a significant volume in the serum or plasma sample and because sodium is present only in the aqueous phase. This potential cause of hyponatremia is indicated by an increase in the osmolar gap between measured and calculated osmolality. The use of direct ion-selective electrodes (direct potentiometry; all modern blood gas machines) for electrolyte determinations avoids this potential cause of a falsely low sodium concentration value.

Marked hyperglycemia causes a reduction in the measured serum sodium concentration of approximately 1.6 mEq/L for every 100 mg/dL increase in the glucose concentration. Increases in the plasma glucose concentration generate osmotic forces that result in the movement of cellular water into the ECF, diluting the plasma sodium concentration.

HYPERNATREMIA. Hypernatremia can develop if water is lost in excess of sodium or if sodium is ingested in excess of water. Hypernatremia can occur in the initial stages of diarrhea, vomiting, or renal disease if water loss exceeds electrolyte loss (Box 22-2). When water losses are replaced by increased water consumption, enhanced renal water retention, or both, the serum sodium concentration decreases. Food and water deprivation in normal horses and cattle is associated with substantial reduction of renal and fecal output, but continued cutaneous and respiratory insensible water loss may result in hypernatremia (primary water loss). Hypernatremia may occur transiently as a result of sodium excess after administration of hypertonic saline or hyperosmolar sodium bicarbonate if water intake is restricted or impaired. Hypernatremia has been reported in calves fed an inappropriately mixed oral electrolyte replacement solution as their only fluid intake.[5] The hypernatremia observed with salt poisoning in cattle and swine is the result of water restriction in animals that have been maintained on a high-salt intake.

Serum Potassium

Potassium is the major intracellular cation. Between 60% and 75% of total body potassium is found within muscle cells and in bones. Only 5% is in the ECF and not always a reflection of total body potassium. The serum potassium concentration is influenced by factors that alter internal balance (the distribution of potassium between the ECF and the ICF) and those that change external balance (potassium intake and output). Potassium is higher in foals compared with adult horses. Generally, herbivores have a net positive intake in potassium, which is usually carefully regulated by the renal system. Serum potassium concentrations correlate relatively well with total body potassium content in cattle but not in horses. Changes in the serum potassium concentration occur in a wide variety of clinical circumstances and have profound neuromuscular effects that are largely the result of changes in cell membrane potential. The responses to dehydration and acid-base imbalance often complicate the evaluation of the potassium concentration. For example, calves with acute diarrhea often develop body potassium depletion because of excessive losses and inadequate intake, but the serum potassium concentration of these animals is usually normal to increased as the result of renal shutdown and the metabolic acidosis induced by dehydration,

BOX 22-3

Causes of Hypokalemia

Common Causes

Altered External Balance*

Vomiting
Vagal indigestion with internal vomiting
Diarrhea
Third-space problems (gut or abomasal torsion or volvulus; peritonitis)
Excessive sweat losses
Dietary deficiency
Prolonged anorexia

Altered Internal Balance

Metabolic alkalosis

Uncommon Causes

Altered External Balance

Mineralocorticoid excess
Use of corticosteroids with mineralocorticoid activity
Diuretics
Renal tubular acidosis
Postobstruction diuresis

Altered Internal Balance

Excessively rapid sodium bicarbonate administration
Insulin and/or glucose administration
Catecholamine administration or endogenous release

*External balance refers to the relative changes in potassium intake and output; internal balance refers to the distribution of potassium between the extracellular and the intracellular fluid compartments.

BOX 22-4

Causes of Hyperkalemia

Common Causes

False hyperkalemia
- In vitro hemolysis
- Prolonged storage of blood (over 6 hours) without separation of serum or plasma

Altered external balance
- Hypovolemia with renal shutdown

Altered internal balance
- Metabolic acidosis
- Vigorous exercise

Uroperitoneum

Uncommon Causes

False hyperkalemia
- Markedly elevated leukocyte or platelet count

Altered internal balance
- Hyperkalemic periodic paralysis in Quarter Horses
- Diabetes mellitus
- Tissue necrosis
- Renal disease
- Addison disease

sodium depletion, and hypovolemia. Hypokalemia may become evident only as other fluid and electrolyte losses are replaced.

Measuring the erythrocyte potassium concentration is relatively easy and has been suggested as an aid in assessing the need for potassium supplementation in racehorses with recurrent muscle disease or in alert downer cows early postpartum. However, experimental studies in horses indicate that the erythrocyte potassium concentration does not always accurately reflect potassium deficits.

HYPOKALEMIA. Hypokalemia increases resting membrane potential, resulting in muscle weakness, impaired urine concentration ability, and arrhythmias. Hypokalemia may result from depletion of the body's potassium stores or from a redistribution of potassium from the ECF into the ICF space (Box 22-3). Hypokalemia is most commonly seen with altered intake and absorption and with excessive potassium losses from the gastrointestinal tract caused by vagal indigestion, torsion of the abomasum, ileus, or diarrhea. Excessive renal loss may result from mineralocorticoid excess, certain diuretics, or altered renal function, as reported in horses with renal tubular acidosis. Marked hypokalemia develops when reduced dietary intake caused by anorexia is associated with excessive potassium losses (e.g., causing muscle paresis in dairy cows early postpartum).

Hypokalemia without potassium depletion results from the movement of extracellular potassium to the intracellular space. This form of hypokalemia occurs in response to an acute alkalosis and to the administration of insulin or glucose. Overzealous and rapid administration of sodium bicarbonate can produce an alkalosis with a profound and rapidly developing hypokalemia. Animals with moderate potassium deficits that are vigorously treated with sodium bicarbonate to correct a coexisting mild metabolic acidosis may be particularly prone to this problem. The initial response to catecholamine administration is a modest, transient increase in potassium caused by α-adrenergic stimulation, which is often followed by hypokalemia caused by β-adrenergic receptor responses.

Pseudohypokalemia is seen in severe lipemia with potassium measured with indirect potentiometry (e.g., automated profile chemistry analyzers).

HYPERKALEMIA. Hyperkalemia may develop in vitro as a result of hemolysis or leakage of erythrocyte potassium after storage of whole blood (Box 22-4). The release of potassium from leukocytes or platelets into the serum after clot formation is a potential cause of hyperkalemia if marked leukocytosis or thrombocytosis is present. Hyperkalemia also results from renal potassium retention in Addison disease, acute renal failure (ARF), and renal shutdown. A number of factors contribute to the movement of intracellular potassium into the ECF, resulting in hyperkalemia. Hyperkalemia is often associated with metabolic acidosis, particularly when the acidosis results from volume depletion and is complicated by renal shutdown. Hyperkalemia has been reported in animals with massive muscle necrosis, but neither hyperkalemia nor metabolic acidosis is a common feature in horses with exertional rhabdomyolysis. Vigorous short-term exercise of horses at high intensity results in a marked but transient hyperkalemia (9 to 10 mEq/L) that may be associated with the profound lactic acidosis seen with anaerobic workloads.[6] Potassium returns to normal within minutes, and often a modest hypokalemia occurs later in the recovery period. Episodic hyperkalemia and muscular weakness are associated with the condition of hyperkalemic periodic paralysis (HYPP).[7] HYPP is inherited as an autosomal-dominant trait in horses, with a specific Quarter Horse lineage having a sodium channel defect[8] (see Chapter 42 for a more complete discussion of this disorder). The disease is the result of a single DNA base pair substitution that leads to the production of an abnormal voltage-regulated sodium channel at the cell membrane.[9] Sudden marked increases in the serum potassium concentration, up to 8 to 9 mEq/L, are the result of transcellular movement of potassium and are associated with profound electrocardiographic abnormalities and fluid shifts.

In drug-induced hyperkalemia, trimethoprim has been associated with hyperkalemia by inhibiting normal sodium reabsorption in the cortical renal collecting duct.

Serum Chloride

Chloride is a major ECF anion and very important with sodium for osmolality and acid-base balance. Together with sodium it is the main component of the strong ion difference (SID). Alterations in the chloride concentration are usually associated with nearly

BOX 22-5

Causes of Hyperchloremia

With Proportional Increase in Sodium

Common Causes

- Relative water deficit
  - Panting
  - Water deprivation
  - Salt poisoning

Uncommon Causes

- Vomiting
- Diarrhea
- Burns
- Intrinsic renal disease
- Diuretics
- Diabetes insipidus
  - Central
  - Nephrogenic
- Hypertonic saline administration
- Mineralocorticoid excess

Without Proportional Increase in Sodium

Common Causes

- Hyperchloremic metabolic acidosis
- Renal tubular acidosis

Uncommon Cause

- Compensation for respiratory alkalosis

BOX 22-6

Causes of Hypochloremia

With Proportional Decrease in Sodium

Common Causes

- Relative water excess
  - Diarrhea
  - Excessive sweating
  - Blood loss
  - Fluid drainage
  - High-volume gastric reflux
  - High-volume pleural drainage
  - Sequestration of fluid (third-space problems)
    - Peritonitis
    - Ascites
    - Ruptured bladder
  - Renal disease
- False hypochloremia
  - Hyperlipidemia
  - Hyperproteinemia
  - Hyperglycemia

Uncommon Causes

- Psychogenic polydipsia
- Inappropriate antidiuretic hormone secretion
- Adrenal insufficiency

Without Proportional Decrease in Sodium

Common Causes

- Metabolic alkalosis
  - Exhaustive disease syndrome
  - Abomasal torsion
  - Vagal indigestion with internal vomiting
  - Response to furosemide in horses

Uncommon Cause

- Compensation for respiratory acidosis

proportional changes in the sodium concentration as the result of changes in relative water balance. In addition, the chloride concentration tends to vary inversely with the bicarbonate concentration; therefore, when disproportionate changes in the chloride concentration relative to sodium occur, significant acid-base imbalances should be anticipated. Disproportionate increases in chloride are associated with a normal-to-low anion gap hyperchloremic metabolic acidosis, but they also are seen as a result of the compensating responses for a primary respiratory alkalosis (Box 22-5). A striking hyperchloremic metabolic acidosis has been reported in horses with renal tubular acidosis.[10,11] Iatrogenic hyperchloremic acidosis can be induced by overzealous NaCl fluid treatment.[12]

Disproportionate decreases in chloride relative to sodium are characteristically seen in metabolic alkalosis, but also may be seen as part of the compensating response for chronic primary respiratory acidosis (Box 22-6). Hypochloremic metabolic alkalosis is a common feature in many digestive disorders of ruminants and is caused by loss of chloride-rich fluids or sequestration of such fluids in the abomasum and forestomachs. It is also seen in horses with diarrhea as chloride is absorbed in the ileum and colon. Horses treated with diuretics (e.g., furosemide-induced metabolic alkalosis) may show hypochloremia.[13] Heavy sweating in horses is associated with hypochloremic metabolic alkalosis.

Osmolality

ECF osmolality is maintained around 300 mOsm (isotone). Measurement of the serum osmolality provides an indication of relative water balance in much the same way the serum sodium concentration does. In most circumstances these parameters are closely correlated. Comparing the measured osmolality with the calculated osmolality, as determined from the measured concentrations of the major solutes in serum (sodium, chloride, glucose, and urea), provides a means of determining if the serum water content deviates widely from normal or if foreign, low-molecular-weight substances are present in the blood. The difference between the measured osmolality and the calculated osmolality is called the *osmolar gap.* Decreases or increases in the osmolar gap could indicate laboratory error, but increases of more than 10 mOsm/kg generally are the result either of a decrease in the serum water content (caused by hyperlipidemia or hyperproteinemia) or of the presence of abnormally high concentrations of low-molecular-weight substances in the serum. These substances can include a variety of exogenous and potentially toxic compounds such as mannitol, ethanol, methanol, propylene glycol, ethylene glycol, isopropanol, ethyl ether, acetone, trichloroethane, and paraldehyde. All hypernatremic animals are hyperosmolal. Hypo-osmolality is always associated with hyponatremia, but not all cases with hyponatremia are hypo-osmolal (e.g., concurrent hyperglycemia).

Serum Calcium

Calcium plays a vital role in many of life's processes, including maintenance of neuromuscular excitability, permeability of cell membranes, conduction of nerve impulses, muscle contraction, and blood clotting. For these reasons the serum calcium concentration or, more correctly, the ionized calcium concentration is normally maintained within a relatively narrow range, despite wide variation in intake and output. Calcium metabolism is regulated by dietary factors, vitamin D and its active metabolites, and the hormones parathormone and calcitonin. Compared with ruminants in horses, a relatively larger percentage of calcium is excreted in the urine. The serum calcium concentration is maintained by adjusting intestinal absorption, renal excretion, and mobilization of available calcium from the large stores in bone. Calcium exists in the serum in three forms: ionized calcium, complexed calcium, and protein-bound calcium. Ionized calcium, which normally constitutes 40% to 60% of the total calcium, is the physiologically active form of calcium. Protein binding can cause confusion (protein-bound calcium normally constitutes 40% to 50% of the total calcium and most of it is bound to albumin). Hyperalbuminemia may result in a modest hypercalcemia, whereas hypoproteinemia, especially hypoalbuminemia, regularly results in a moderate

VetBooks.ir

BOX 22-7

Causes of Hypocalcemia

Common Causes

Parturient paresis (milk fever)
Grass tetany
Hypoalbuminemia (decreased total calcium; ionized calcium may remain unchanged)
Fat necrosis
Lactation tetany
Transport tetany
Synchronous diaphragmatic flutter
Blister beetle toxicosis (cantharidin)
Acute renal failure
Anorexia in lactating cows
Colic in horses

Uncommon Causes

Acute toxemia and associated anorexia in lactating dairy cows
Hypoparathyroidism
Exertional rhabdomyolysis
Malignant hyperthermia
Pancreatic disease
Oxalate toxicity
Tetracycline administration
Furosemide administration
Alkalosis induced by excessive bicarbonate administration

BOX 22-8

Causes of Hypercalcemia

Common Causes

Chronic renal failure in horses
Hypervitaminosis D
- Excessive dietary supplements
- Plant intoxication
  - *Cestrum diurnum* (day blooming jasmine)
  - *Solanum malacoxylon*

Excessive or too rapid intravenous administration of calcium

Uncommon Causes

Neoplasia (pseudohyperparathyroidism)
- Lymphosarcoma
- Gastric squamous cell carcinoma

Hyperparathyroidism

hypocalcemia. The ionized calcium concentration, usually measured with ion selective electrodes, generally remains within normal limits, despite increases or decreases in total calcium associated with the change in protein concentration. The acid-base balance has additional influence on the amount of ionized and protein-bound calcium. Alkalosis reduces ionized calcium and increases protein binding, whereas acidosis produces the opposite effect. Ion-specific electrodes are available for determining the ionized calcium level, which can be very useful if blood samples are handled appropriately. Most diagnostic laboratories provide the total serum calcium value, which is composed of ionized, complexed, and protein-bound calcium.

HYPOCALCEMIA. Large increases or decreases in the serum calcium concentration generally are the result of a failure in the normal mechanisms of calcium homeostasis rather than a reflection of absolute calcium deficits or calcium-phosphorus imbalances. Hypocalcemia occurs with some frequency in domestic animals, particularly in high-producing dairy cattle at the onset of lactation. In cattle the serum calcium concentration normally decreases to less than 8 mg/dL with the stress of parturition and the onset of lactation (Box 22-7). Failure to mobilize sufficient calcium to maintain serum calcium results in the clinical syndrome of parturient paresis (see Chapter 41 for a more detailed discussion of this syndrome). Most animals are recumbent with a calcium level of 6 mg/dL or less, and fatalities may occur if the level drops below 4 mg/dL. Parturient paresis is associated with a normal to increased serum magnesium level, hypophosphatemia, and hypocalcemia. Change in the cation-anion balance in the diet (increased proportion of strong anions) of dairy cattle during the periparturient period has modest effects on the acid-base balance and enhances calcium mobilization from storage sites, thus reducing the incidence of milk fever in cows at high risk. Grass tetany is associated with marked hypomagnesemia and modest hypocalcemia, whereas the inorganic phosphorus level remains within the normal range.

Systemic diseases resulting in anorexia (e.g., traumatic reticuloperitonitis, ketosis, and displaced abomasum) or acute toxemic conditions (e.g., coliform mastitis, septicemia, or aspiration pneumonia) that produce anorexia in lactating cattle frequently result in hypocalcemia. Hypocalcemia is also seen in sheep on marginal rations if stressed by inclement weather or when being moved. Hypocalcemia is seen in cattle with fat necrosis, presumably as the result of incorporation of calcium with the fat as a form of soap. Horses sweating or with exhaustive disease syndrome or transit tetany often develop decreases in ionized calcium with resultant muscle cramps and synchronous diaphragmatic flutter, which generally respond to intravenous calcium and electrolyte administration. Horses, cattle, and sheep usually respond initially to acute renal tubular damage with mild hypocalcemia and hyperphosphatemia. Idiopathic hypocalcemia, which may exist in foals 4 to 5 days old, has poor prognosis and a cause is not established.[14] Transport tetany and lactation tetany of horses are associated with hypocalcemia. In lactation tetany of mares, this is correlated with high milk production.

HYPERCALCEMIA. Marked hypercalcemia, with a serum calcium level ranging from 14 to 20 mg/dL, and modest hypophosphatemia are frequently observed in horses with chronic renal failure (CRF) that are fed a high-calcium diet such as alfalfa hay (Box 22-8). In these horses, blood samples collected in standard EDTA tubes may actually clot. This occurs because the serum calcium concentration is so high that there is insufficient EDTA to bind all the calcium, and some free calcium is available to complete the clotting process. Vitamin D intoxication can develop as a result of excessive dietary supplementation or the ingestion of certain plants such as *Cestrum diurnum* (day blooming jasmine) and *Solanum malacoxylon,* which contain toxic quantities of vitamin D analogs. Primary hyperparathyroidism is exceedingly rare in large animals, but pseudohyperparathyroidism with hypercalcemia occasionally can develop in animals with tumors that produce protein substances with parathormone-like biologic activity. This has been reported in a few animals with lymphosarcoma or gastric squamous cell carcinoma.

Serum Phosphorus

Phosphorus is found primarily in the skeleton and teeth in close association with calcium in the intricate and dynamic crystalline structure of bone. Intracellularly, phosphate plays an essential role in the degradation and synthesis of many compounds. Also, in the forms of adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP), it is the primary form of energy storage and transfer required for almost all of life's processes. Phosphorus in the ECF exists primarily in the organic and inorganic form specifically as the "buffer" pair H_2PO^{-3} and HPO^{-4} and plays a role in acid-base balance. Like calcium, phosphorus is regulated by dietary factors, the active metabolites of vitamin D, and the hormones parathormone and calcitonin. Imbalances of calcium and phosphorus or the presence of compounds that bind these substances in the gut can produce serious imbalances that are not always evident on analysis of serum samples. Measurement of urinary output or creatinine clearance ratios for calcium and phosphate are simple and helpful procedures. They provide an indication of an imbalance while more definitive procedures such as ration analysis are contemplated.

BOX 22-9

Causes of Hypophosphatemia

Common Causes

Chronic renal failure in horses
Parturient paresis in cattle
Postparturient hemoglobinuria

Uncommon Causes

Brassica toxicity
Inadequate dietary intake
Starvation or chronic wasting diseases
Hyperparathyroidism, pseudohyperparathyroidism

BOX 22-10

Causes of Hyperphosphatemia

Common Causes

Acute renal failure
Nutritional secondary hyperparathyroidism (excess phosphate intake)
Endurance exercise in horses
Higher normal range in neonates

Uncommon Causes

Acute rhabdomyolysis
Vitamin D toxicity

HYPOPHOSPHATEMIA. Serum phosphorus concentrations are not always an accurate guide to phosphate balance, but dietary deficiencies of phosphorus are frequently manifested by hypophosphatemia. Hypophosphatemia is a common feature in cattle with parturient paresis (see also Chapter 41) and horses with CRF (Box 22-9). It has been reported in animals with experimental oxalate toxicity, in chronic wasting states, or with starvation. Postparturient hemoglobinuria is a disorder of cattle, primarily lactating dairy cattle, that often is associated with diets low in phosphorus. Although marked hypophosphatemia is often reported, it is not an invariable feature of this disorder.

HYPERPHOSPHATEMIA. Age-related differences exist in the normal range of serum phosphorus concentration. Young animals have much higher values than adults, with values for neonates commonly up to 7 to 9 mg/dL. The serum phosphate concentration declines progressively with age. Hyperphosphatemia is seen in animals with vitamin D toxicity, transiently in horses after long-distance endurance rides, and initially in horses with ARF (Box 22-10).

Serum Magnesium

Between 20% and 30% of magnesium is bound to mostly albumin and 60% is free (ionized) or bound to phosphorus or other components. Free magnesium can be measured with ion-selective electrodes. Disturbances of magnesium metabolism occur principally in cattle and sheep. Complex nutritional and environmental interactions contribute to a variety of clinical syndromes attributed to magnesium deficiency and the onset of tetany in grazing animals.

HYPOMAGNESEMIA. Hypomagnesemia is reported in cattle with grass tetany, transport tetany, winter tetany, and in sheep with grass staggers (Box 22-11) (see also Chapter 41). A serum magnesium level below 1.8 mg/dL is considered low; values below 1 mg/dL are considered severe and are likely to be associated with clinical signs. Hypomagnesemia caused by dietary magnesium deficiency has been reported in calves reared in confinement and fed a milk diet exclusively (milk tetany). In chemistry panels of normal horses, hypomagnesemia (total serum magnesium) is often reported to be close to or below 1 mg/dL without clinical signs and is mostly considered irrelevant by the clinician.

BOX 22-11

Causes of Hypomagnesemia

Common Causes

Grass tetany
Winter tetany
Grass staggers
Calves on a milk-only, magnesium-deficient diet
Endurance exercise
Fatty liver syndrome

Uncommon Cause

Undernutrition

BOX 22-12

Causes of Hypermagnesemia*

Epsom salt ($MgSO_4$) overdose given orally or as an enema
Intravenous administration of magnesium in excessive amounts
Use of $MgSO_4$ IV

*Hypermagnesemia is an uncommon condition in large animals.

TABLE 22-5

Acid-Base Imbalances and Compensatory Responses

Disorder	pH	$[H^+]$	Primary Imbalance	Compensatory Response
Metabolic acidosis	↓	↑	↓ $[HCO_3^-]$	↓ P_{CO_2}
Metabolic alkalosis	↑	↓	↑ $[HCO_3^-]$	↑ P_{CO_2}
Respiratory acidosis	↓	↑	↑ P_{CO_2}	↑ $[HCO_3^-]$
Respiratory alkalosis	↑	↓	↓ P_{CO_2}	↓ $[HCO_3^-]$

$[HCO_3^-]$, Bicarbonate concentration; P_{CO_2}, partial pressure of carbon dioxide.

HYPERMAGNESEMIA. Hypermagnesemia occurs infrequently but may be seen with overzealous administration of Epsom salts ($MgSO_4$), either orally as a drench by means of nasogastric intubation or as an enema for the treatment of digestive disorders (Box 22-12). Intravenous administration of magnesium produces muscle relaxation but does not alter consciousness, and hypertonic $MgSO_4$ solutions are not considered a humane means of euthanasia.

Acid-Base Imbalance (Traditional Approach)

Using the traditional approach to acid-base balance, the four primary acid-base imbalances and their compensating responses are presented in Table 22-5. Acidosis is associated with an increase in the hydrogen ion concentration (decreasing pH), whereas alkalosis is caused by a decrease in the hydrogen ion concentration (increasing pH). When the primary imbalance is associated with a change in the bicarbonate concentration, the acid-base imbalance is called a *metabolic disorder.* The compensating response for a metabolic acid-base imbalance is mediated by the respiratory tract, which alters the partial pressure of carbon dioxide (P_{CO_2}) to counterbalance the primary imbalance and to partly restore the pH toward normal, but this mechanism has a very limited capacity quantitatively to correct bicarbonate concentrations back to normal values (maximum only about 2 mEq/L) (Fig. 22-2). Primary respiratory imbalances are related to changes in alveolar ventilation, which result in an increased

VetBooks.ir

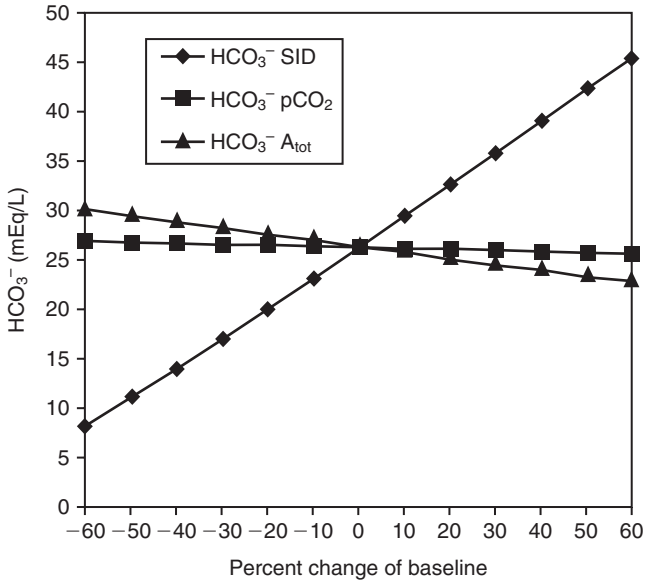

FIG. 22-2 Spider plot graphically showing the dependence of plasma bicarbonate (HCO_3^-) concentration on changes in the three independent variables (SID, P_{CO_2}, and A_{tot}). The spider plot was obtained by systematically varying one independent variable while holding the other two independent variables at their reference values (y axis values at 0 on the x axis) for plasma. Please note how little changes in P_{CO_2} affect concentrations of HCO_3^-.

P_{CO_2} in respiratory acidosis and a decreased P_{CO_2} in respiratory alkalosis. The compensating response for these primary respiratory acid-base imbalances is mediated by the kidneys through presumed alterations in the excretion or retention of hydrogen ions and bicarbonate. Heparinized blood samples for acid-base evaluation must be drawn anaerobically and sealed immediately. Arterial blood samples should be submitted for evaluation of primary respiratory disorders and for evaluation of ventilation in patients under general anesthesia. Venous blood samples are easier to obtain and provide reliable data for most primary metabolic acid-base abnormalities.

Blood gas analysis should be performed as soon after collection as possible. However, appropriately collected blood samples yield reliable results for as long as 4 hours if held in ice water. The patient's rectal temperature should be provided to the laboratory so that corrections can be made for variation in body temperature. Changes in body temperature have a major impact on the partial pressure of oxygen (P_{O_2}) as well as the P_{CO_2}, but relatively little effect on estimations of bicarbonate or base balance. During brief exercise at maximal intensity, the temperature of the central venous blood may exceed the rectal temperature by as much as 3° C. In these circumstances, the central blood temperature is more appropriate than the rectal temperature for correcting blood gas determinations. The blood sampling site (arterial, venous, or capillary blood) has a significant impact on the blood gas values obtained.[15] Arterial blood samples yield higher values for pH and lower values for P_{CO_2} than venous blood, but the bicarbonate is higher in venous blood. The use of blood gas data for evaluation of acid-base imbalances in animals has been reviewed.[16,17] In addition, a review of the traditional and nontraditional approaches to evaluation of acid-base balance as related to fluid therapy in small animals has application to many large animal situations and is well worth reading.[18]

Metabolic Acidosis

Metabolic acidosis is characterized by a decrease in pH and bicarbonate concentration. Metabolic acidosis is traditionally thought to be produced by the addition of hydrogen ions or the loss of bicarbonate ions. The most common causes include the lactic acidosis of ruminal overload, hypovolemia associated with loss or compartmentalization of sodium-containing fluid, ketoacidosis in ketosis and pregnancy toxemia, loss of sodium bicarbonate–rich saliva with oral diseases or esophagostomy in cattle, gastrointestinal loss of sodium bicarbonate as a result of diarrhea, and renal failure, which may result in decreased ability to excrete hydrogen and thus to retain bicarbonate (Box 22-13). Other causes include ingestion of certain drugs or toxic compounds such as salicylate, methanol, ethylene glycol, or paraldehyde (very rare in large animals). Increased ventilation provides a respiratory response for metabolic acidosis, and a decline in the P_{CO_2} generally begins within minutes. This temporarily minimizes the fall in blood pH, but long-term correction of metabolic acidosis requires classically explained renal bicarbonate retention and enhanced acid excretion. Complete correction of metabolic acidosis may be difficult in patients with intrinsic renal disease or those with diseases such as renal tubular acidosis that impair the ability of the kidneys to excrete acid or retain bicarbonate, or both.

BOX 22-13

Causes of Metabolic Acidosis

Common Causes

Rumen overload (lactic acidosis)
Ketosis
Pregnancy toxemia
Hypovolemic shock
Acute diarrhea
Colic with strangulated bowel
Strangulating abomasal torsion
Peritonitis
Uroperitoneum (ruptured bladder)
Exercise above anaerobic threshold (normal response in horses)

Uncommon Causes

Renal failure
Renal tubular acidosis
Urea toxicity
Salicylate toxicity
Methanol toxicity
Paraldehyde toxicity
Ethylene glycol toxicity

Metabolic Alkalosis

Metabolic alkalosis is characterized by an increase in pH and bicarbonate. It occurs fairly commonly in domestic animals, particularly in association with digestive disturbances in ruminants. An initiating process capable of generating alkalosis is necessary and must be coupled with additional factors to maintain metabolic alkalosis. Generation of metabolic alkalosis is traditionally thought to be caused by excessive hydrogen loss, bicarbonate retention, or contraction alkalosis (Box 22-14). Contraction alkalosis occurs when the ECF volume is reduced because of loss or sequestration of fluids high in sodium and chloride but without proportionate loss of bicarbonate, which really contradicts electroneutrality of watery solutions. This is thought to be traditionally a contributing mechanism for the generation of the metabolic alkalosis reported in heavily sweating endurance horses and in response to the diuretic furosemide in the horse. The most common causes of increased hydrogen ion loss are the gastrointestinal losses caused by salivary secretions in ponies after surgical esophagostomy[19]; massive gastric reflux associated with anterior enteritis, ileus, or small bowel obstruction in horses; and sequestration of fluid in the abomasum and forestomach associated with a variety of gastrointestinal displacements or functional disturbances (vagal indigestion) of ruminants. Continuous salivary losses in horses after surgical esophagostomy result in transient metabolic acidosis followed by progressive metabolic alkalosis. Most of these disorders cause significant dehydration and sodium, chloride, and potassium deficits.

The factors responsible for maintaining metabolic alkalosis involve classically explained impaired renal bicarbonate excretion. These factors are associated with the renal response to decreases in

VetBooks.ir

BOX 22-14

Causes of Metabolic Alkalosis

Common Causes

Sequestration of fluid in the abomasum and forestomach in ruminants (internal vomiting for abomasal reflux)
Gastric reflux in horses with ileus
Massive sweat loss in horses (endurance horses)
Chloride depletion
Potassium depletion
Contraction alkalosis (extracellular fluid volume contraction without bicarbonate loss)
Salivary loss of chloride in horses with esophagostomy
Use of diuretics (especially furosemide)
Functional pyloric stenosis

Uncommon Causes

Excessive bicarbonate supplementation or therapy
Mineralocorticoid excess

BOX 22-15

Causes of Respiratory Acidosis

Common Causes

Primary pulmonary disease
- Obstruction of the upper airway
- Laryngeal edema
- Aspiration pneumonia
- Pneumonia
- Pneumonia and pleuritis complex
- Pneumothorax
- Chronic obstructive pulmonary disease

Depression of the respiratory center of the central nervous system
- General anesthesia with inappropriately assisted ventilation
- Drugs
  - Opiates
  - Anesthetics
  - Tranquilizers

Central nervous system diseases

Uncommon Causes

Cardiac arrest
Muscle weakness or dysfunction
Tetanus
Botulism
Myasthenia
Severe hypokalemia
Neonatal respiratory distress syndrome

the effective circulating fluid volume, chloride depletion, or potassium depletion. Renal tubular sodium resorption is enhanced in response to hypovolemia. Maintenance of electroneutrality requires that sodium resorption in the proximal tubule be accompanied by a resorbable anion, whereas in the distal tubule, sodium resorption is associated with the secretion of another cation, usually hydrogen or, to a lesser extent, potassium. Chloride is the only resorbable anion normally present in appreciable quantities in the proximal tubular fluid. In metabolic alkalosis, plasma bicarbonate is increased and the chloride concentration is generally decreased as a result of disproportionate chloride losses. The relative lack of the resorbable anion chloride in the proximal tubule thus allows a larger amount of sodium to reach the distal tubule, where aldosterone and other factors enhance hydrogen or potassium loss into the tubular lumen in exchange for sodium. Potassium depletion reduces or eliminates potassium exchange as a means of sodium retention, thus classically explained placing greater emphasis on hydrogen ion exchange, which stoichiometrically and quantitatively is very difficult to explain. Because renal hydrogen excretion is linked with bicarbonate resorption, the excess bicarbonate cannot be eliminated, and metabolic alkalosis is maintained. Thus the traditional explanation is the reason for the paradoxic aciduria seen in some patients with metabolic alkalosis, and it is the reason these patients respond when given intravenous fluids containing sodium, chloride, and potassium. The compensating respiratory response to metabolic alkalosis is hypoventilation, resulting in an increase in the P_{CO_2}. Excessive sodium bicarbonate administration is an additional potential cause of metabolic alkalosis. Most normal animals can tolerate large doses of sodium bicarbonate, and excesses are rapidly eliminated by renal excretion.[20] However, patients with decreases in effective circulating fluid volume, particularly when coupled with potassium or chloride deficits, may not tolerate a bicarbonate load because renal clearance of excess bicarbonate is likely to be impaired. Attempts to alter the acid-base balance, and thereby affect the athletic performance of racing horses, by prerace administration of high doses of sodium bicarbonate–containing "milkshakes" have become a major concern around the world. This has stimulated substantial research on the acid-base balance of horses before and after racing. In many racing jurisdictions stringent prerace or postrace standards for blood pH or bicarbonate or T_{CO_2} levels (or both) have been enacted to control this practice. The prerace administration of the diuretic furosemide is allowed in several racing jurisdictions of North America. This drug results in a mild metabolic alkalosis with increased bicarbonate, and allowances for this may be included in some regulations. Racing supplements (which may contain sodium bicarbonate), bicarbonate precursors, and diets that supply a high positive cation-anion balance also have the potential to produce a significant metabolic alkalosis.

Respiratory Acidosis

Respiratory acidosis is characterized by a decrease in pH and an increase in P_{CO_2}, which develop because of decreased effective alveolar ventilation. CO_2 diffuses through the lungs much more readily than oxygen; thus, diseases that compromise ventilation normally result in decreases in P_{O_2} before significant increases in P_{CO_2} develop. The most common causes are acute upper respiratory obstruction and primary pulmonary diseases, including pneumonia, pneumothorax, pulmonary edema, and chronic obstructive pulmonary disease (Box 22-15). Diseases or drugs that affect the respiratory center of the central nervous system may also produce respiratory acidosis, as can general anesthesia. The compensating response for respiratory acidosis is classically thought to be renal retention of bicarbonate. This response requires days to develop and is seen only in chronic respiratory acidosis. Exogenous bicarbonate does not correct respiratory acidosis and should not be administered to affected patients.

Respiratory Alkalosis

Respiratory alkalosis is caused by hyperventilation, which may be stimulated by hypoxemia associated with pulmonary disease, congestive heart failure, severe anemia, or neurologic disorders (Box 22-16) or residence or extended stay at high altitudes. The initial compensating response to acute respiratory alkalosis is a modest decline in the ECF bicarbonate concentration—the result of cellular buffering. Subsequent renal responses result in a decrease in the ECF bicarbonate concentration through reduced renal bicarbonate resorption. The decline in bicarbonate may be offset by chloride retention; thus, hyperchloremia and decreased P_{CO_2} may be associated with compensated respiratory alkalosis, as well as with compensated metabolic acidosis. Compensating renal responses for chronic respiratory alkalosis that lasts several weeks actually may be sufficient to return pH to normal.[21]

Mixed Acid-Base Imbalances

Mixed acid-base disorders occur when several primary acid-base imbalances coexist. Metabolic acidosis and alkalosis can coexist, and either or sometimes both may occur with either respiratory acidosis or respiratory alkalosis. The following factors should be considered when evaluating possible mixed acid-base disorders:

VetBooks.ir

BOX 22-16

Causes of Respiratory Alkalosis

Common Causes

Hypoxemia
- Pulmonary diseases
- Congestive heart failure
- Severe anemia

Stimulation of the respiratory center of the central nervous system
- Psychogenic hyperventilation
- Excitement, fear, transport, pain
- Gram-negative septicemia
- Neurologic disorders

Uncommon Causes

After correction of metabolic acidosis
Inappropriate mechanical ventilation
Salicylate toxicity

- Compensating responses to primary acid-base disturbances do not result in overcompensation.
- Compensating responses, except for long-term renal compensation, rarely correct pH to normal. A normal pH in a patient with an acid-base imbalance is an indicator of a mixed acid-base disturbance.
- A change in pH in the opposite direction to that predicted for a known primary disorder indicates a mixed disturbance.
- Bicarbonate and P_{CO_2} always deviate in the same direction with primary acid-base disturbances. If these parameters deviate in opposite directions, a mixed abnormality exists.
- If the change in the anion gap does not approximate the change in bicarbonate, a mixed acid-base imbalance should be suspected.

Mixed acid-base abnormalities occur with some frequency in domestic animals and often are overlooked. The practitioner must be aware of the potential for mixed acid-base imbalances to correctly interpret blood gas data in complex clinical situations.

Anion Gap

The anion gap can be an extremely helpful tool for categorizing causal factors in acid-base imbalances and may prove a useful prognostic guide in animals with serious digestive disorders. The anion gap can be calculated as the difference between the major cations (sodium plus potassium) and the measured anions (chloride plus bicarbonate). The anion gap normally is 12 to 16 mmol/L and provides an approximation of the so-called unmeasured anions. These are anions that are not measured routinely in the clinical laboratory; they include "physically" the anionic equivalents of plasma proteins (debatably albumin in particular; ≈95% of total anion gap in normal adult animals), sulfate, phosphate, lactate, ketones, and a variety of inorganic anions. Significant differences exist in the normal range of the anion gap among species, and there may also be age-related differences. Foals are reported to have a larger anion gap than do adult horses.

Hypoproteinemia and hyperchloremic metabolic acidosis are the most common causes of a decrease in the anion gap. The cause of normal to low anion gap hyperchloremic metabolic acidosis often can be differentiated on the basis of the serum potassium concentration. Animals with hyperchloremic metabolic acidosis associated with gastrointestinal fluid losses or renal tubular acidosis most often manifest hypokalemia, whereas hyperkalemia generally is seen in patients with decreased mineralocorticoid secretion (Addison disease) or renal failure with renal shutdown. Decreases in the anion gap also result from overhydration caused by decreases in the protein concentration and changes in the relative concentration of plasma sodium and chloride.

Most commonly, high anion gap acidosis is associated with accumulation of a metabolizable acid, most commonly lactic acid associated with anaerobic exercise, grain overload, acute gastrointestinal accidents, or hypovolemic shock (e.g., diarrhea in young calves). The commonly used laboratory procedures (mostly automated blood gas machines) for the determination of lactate only measure the L form of lactate. Microbial fermentation in the gastrointestinal tract may result in the production of both the D and L forms of lactate. Recent studies have shown in milk-fed calves and kids that accumulation of D-lactate is a major factor in the profound acidosis associated with certain digestive disorders.[22,23] Unfortunately, at present, determination of D-lactate requires special procedures, which are now available only in special diagnostic commercial kits. Ketoacidosis, uremic acidosis, and poisoning with a variety of anionic poisons result in increases in nonmetabolizable acids that are also causes of an increased anion gap (rare in large animals). When a high anion gap metabolic acidosis is found, a thorough search for the potential causes of the accumulated unmeasured anions is indicated. The anion gap is also useful for identifying mixed acid-base imbalances. A mixed metabolic acid-base imbalance should be suspected when the change in the anion gap does not approximate the change in bicarbonate. Increases in the anion gap can be associated with dehydration and contraction alkalosis caused by changes in the protein concentration and the relative concentration of plasma sodium and chloride.

Bicarbonate and Total Carbon Dioxide

Bicarbonate accounts for approximately 95% of the measured CO_2; thus, the total CO_2 (T_{CO_2}) or "CO_2 content" of serum or plasma provides a measure of metabolic changes in the acid-base balance. Most automated chemistry profiles now provide the bicarbonate level directly, whereas some may still provide the T_{CO_2}. Bicarbonate or T_{CO_2} is decreased in metabolic acidosis and increased in metabolic alkalosis. However, the bicarbonate or T_{CO_2} values provide only a crude indication of acid-base status. When acid-base abnormalities are suspected, appropriate samples should be submitted for blood gas and electrolyte determination run on the same analyzer. It should be pointed out that bicarbonate levels are always calculated on automated measuring systems.

Buffer Base, Standard Bicarbonate, and Base Excess or Base Deficit

The terms *buffer base, standard bicarbonate,* and *base excess* (or *base deficit*) represent derived calculated estimates of the metabolic component of acid-base balance and do not really physically exist. The buffer base indicates the sum of all the buffer anions in blood under standardized conditions. The standard bicarbonate is the plasma bicarbonate concentration that would be found under specific conditions that eliminate respiratory influences on the values obtained. The base excess or base deficit is often supplied in routine assessment of acid-base balance; it indicates the deviation of bicarbonate from normal. The calculated base deficit provides a means of estimating the amount of bicarbonate required to correct metabolic acidosis. The conundrum is that bicarbonate cannot be given without a cation (mostly Na). The bicarbonate estimate is calculated by multiplying the base deficit by the probable sodium bicarbonate space (about 30% to 50% of body weight), as in the following equation:

$$\text{mEq } NaHCO_3^- \text{ needed} = \text{mEq base deficit} \times \text{kg body weight} \times 0.3 \text{ or } 0.5$$

It should be pointed out that normal ranges of plasma bicarbonate concentrations are different in humans and large animals, with normal large animals being an average of 4 to 5 mEq/L higher compared with normal humans. Modern blood gas machines providing base excess calculations most commonly will use human equations with normal bicarbonate concentrations of 24 mEq/L. When given clinical interpretations of values of base excess, this should be taken into consideration when applying the above equation to calculate $NaHCO_3^-$ deficits. The factor of 0.3 to 0.5 actually represents the sodium space in adult and young animals encompassing the ECF compartment.

VetBooks.ir

STRONG ION-CENTERED APPROACH TO ACID-BASE BALANCE. In the strong ion-centered approach (also known as the Stewart approach or physicochemical approach), acid-base balance is determined by three independent variables: strong ion difference (SID), the partial pressure of CO_2, and the total concentration of nonvolatile weak acids (A_{tot}), the principal components of which are plasma proteins and, to a lesser extent, inorganic phosphate.[18,24] Bicarbonate and pH are dependent variables determined by these three independent variables. Briefly, this approach is a quantitative approach applying physical laws of chemistry of watery solutions to calculate parameters involved in determining acid-base equilibria and disequilibria. These laws include electroneutrality (Σ cations = Σ of anions), dissociation equilibria, and mass conservation. If one of the independent variables (strong electrolytes, proteins, or PCO_2) changes the other dependent variables, pH, bicarbonate, and weak electrolytes adjust. Several studies have adapted the physicochemical approach for practical application in human and veterinary medicine.[17,24-29] Experimentally determined species-specific A_{tot} and Ka data are now available for horses, cattle, dogs, and humans.[30-33]

Strong Ion Difference

Strong electrolytes are completely dissociated in aqueous solution and chemically nonreactive. The SID is simply the difference between the total concentration of strong cations (sodium, potassium, calcium, and magnesium) and the total concentration of strong anions (chloride, sulfate, lactate, acetoacetate, and β-hydroxybutyrate) with sodium, potassium, and chloride normally being quantitatively the principal determinants of SID. In fluids with little or no protein, such as cerebrospinal fluid (CSF), bicarbonate concentration is the same as the SID, but it should be noted that the chloride concentration is higher (≈10 to 11 mEq/L) and SID is lower compared with blood; thus, normal acid-base equilibria in such fluids are different from acid-base equilibria of blood. Abnormalities in PCO_2 are viewed in essentially the same manner in both the traditional and nontraditional approaches to acid-base balance. Plasma albumin debatably makes up the majority of A_{tot}. The A_{tot} exists in both dissociated A^- and undissociated forms. A decrease in A_{tot} (A^-) resulting from hypoalbuminemia causes an alkalosis with an increase in bicarbonate, whereas hyperalbuminemia has the opposite effect. Increases in A^- can cause an increase in anion gap, whereas decreases in A^- result in a decrease in anion gap. A change in protein concentration has effects on acid-base balance. The literature describes hyperproteinemic acidosis or hypoproteinemic alkalosis.[25] Details are outlined in Figs. 22-2 and 22-3.

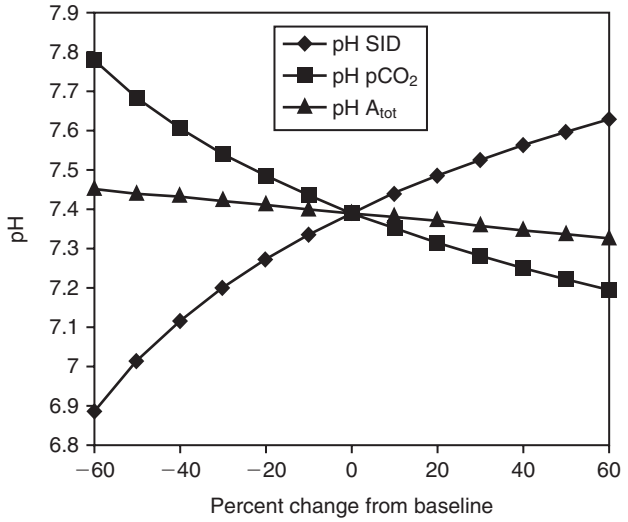

FIG. 22-3 Spider plot graphically showing quantitatively the dependence of plasma pH concentration on changes in the three independent variables (SID, PCO_2, and A_{tot}). The spider plot was generated by systematically varying one independent variable while holding the other two independent variables at their reference values (y axis values at 0 on x axis) for plasma.

When protein and inorganic phosphate remain within the normal range, acid-base balance is controlled by changes in PCO_2 mediated by the respiratory system, and changes in SID, which are largely under the control of the kidneys. Heavy sweat loss in an endurance horse, displaced abomasum in a cow (trapping of chloride in abomasum), or the prerace administration of the diuretic furosemide (chloruresis) in a racehorse produces metabolic alkalosis (mainly observed abnormalities are decreases in serum chloride concentrations). In each case the alkalosis is the result of a disproportionate loss of chloride relative to sodium, yielding hypochloremia and an increase in SID. The dissociation of serum bicarbonate concentrations will adjust to fulfill electroneutrality requirements of watery biologic solutions. Correction of the alkalosis is brought about by the provision of relatively more chloride relative to sodium, generally as sodium chloride or potassium chloride. This results in changing SID to more normal concentrations and thus a return of bicarbonate and pH toward normal. Metabolic acidosis with a large base deficit is generally treated with sodium bicarbonate with sodium being the strong cation added to the ECF and bicarbonate adjusting according to its dissociation equilibrium and sodium added without a strong anion. Other metabolizable anions (short-chain fatty acids such as lactate, acetate, gluconate, and propionate, added with Na as the cation) could be substituted for bicarbonate and achieve similar effects. Short-chain fatty acids are quickly metabolized to glucose and ATP as sources of energy for the body; in physicochemistry, this will result in a relative increase of the SID.

Calculation of SID is simple and provides useful insight in patients with metabolic acid-base disturbances. Factors that influence SID range from changes in free water, to sodium-chloride imbalances that result from excessive losses or disproportionate retention of sodium or chloride, to the accumulation of strong organic anions (most commonly lactate). Organic acidosis can be produced by the accumulation of exogenous as well as endogenous anions. The anion gap does not always accurately predict the presence of unmeasured strong anions. Mathematic methods have been developed as a means for the detection of unmeasured anions[23,34] and for the calculation of the simplified strong ion gap.[35]

Both the traditional and the nontraditional or strong ion approaches to acid-base balance have proven useful to address practical problems in both research and medical settings. The traditional approach to acid-base balance is more widely accepted and user-friendly. The strong ion approach may provide a better understanding as to why the bicarbonate concentration is changing as it integrates acid-base and electrolyte disorders. The strong ion approach has recently gained wider acceptance from members of the human critical care community, who have found it useful for the analysis of the complex fluid, electrolyte, and acid-base problems of patients in intensive care units. Several easy-to-use computer or calculator programs have been developed for the mathematically challenged that facilitate implementation of the strong ion approach to acid-base balance.

Serum Enzymes

Serum enzyme levels are proportional to their cell or tissue concentrations and activity. A number of variables affect the appearance in serum or plasma. The amount of any single enzyme in serum depends on concentration in the cell, total tissue mass, magnitude of cell/organ damage, normal death of the cell, apoptosis, degradation rate of the enzyme in serum or its half-life, and whether the injury is single or continuous.[2] Some of the common and less common causes of elevated serum enzyme activity are listed in Box 22-17.

Sorbitol Dehydrogenase

Sorbitol dehydrogenase (SDH) reversibly oxidizes D-sorbitol to D-fructose with the cofactor NAD. It is a liver-specific enzyme in all large animal species. Increases in this enzyme indicate hepatocellular damage and leakage of enzymes. Increases in SDH are also seen with

VetBooks.ir

BOX 22-17

Causes of Elevated Serum Enzymes

Elevation of Sorbitol Dehydrogenase (SDH)

Common Causes

Severe anoxia
Acute liver failure
Liver abscess
Secondary to damaged bowel
- Strangulating intestinal lesion
- Acute toxic enteritis

Chronic liver failure

Less Common Causes

Acute and severe anemia
General anesthesia
Anoxia

Elevation of γ-Glutamyltransferase (GGT)

Common Causes

Acute liver failure
Chronic liver failure
Pyrrolizidine alkaloid toxicity
Aflatoxicosis
Cholangiohepatitis
Cholelithiasis
Liver flukes

Uncommon Causes

Higher normal range in young animals
Fatty liver

Elevation of Alkaline Phosphatase (ALP)

Common Causes

Acute liver failure
Chronic liver failure
Pyrrolizidine alkaloid toxicity
Cholangiohepatitis
Cholelithiasis
Liver flukes

Uncommon Causes

Higher normal range in young animals
Fatty liver

Elevation of Creatine Kinase (CK)

Common Causes

Exertional rhabdomyolysis (azoturia, myositis, tying-up)
Polysaccharide storage myopathy
Streptococcus equi–associated myopathy
Nutritional myodegeneration (selenium, vitamin E deficiency)
Post-endurance ride multisystemic disorder
Alert downer cow syndrome (muscle crush syndrome)
Malignant hyperthermia
Malignant edema
Prolonged recumbency with inability to rise

Uncommon Causes

Normal postexercise modest increase
Acute cardiomyopathy
Purpura hemorrhagica
Equine influenza
Sarcosporidiosis
Local irritation from intramuscular injections

Elevation of Lactate Dehydrogenase (LDH)

Common Causes

Muscle disease
- Exertional rhabdomyolysis (azoturia, myositis, tying-up)
- Polysaccharide storage myopathy

Streptococcus equi–associated myopathy
- Nutritional myodegeneration (selenium, vitamin E deficiency)
- Post-endurance ride multisystemic disorder

- In vitro hemolysis

Uncommon Causes

Hemolytic anemia
Acute cardiomyopathy
Purpura hemorrhagica
Equine influenza
Sarcosporidiosis
Local irritation from intramuscular injections
Fatty liver

obstructive or strangulating gastrointestinal lesions and with acute toxic enteritis as a result of liver damage associated with absorption of bacteria or their toxins (or both) from the damaged bowel into the portal circulation. This enzyme is a sensitive indicator of liver damage, and modest increases may be seen with anoxia, acute anemia, or general anesthesia. The half-life of SDH in the circulation is short (a matter of hours), and elevations indicate active and ongoing liver damage. This enzyme is not stable when stored at room temperature (only for 5 hours), but refrigerated samples may yield useful results up to 24 to 72 hours if frozen.

Creatine Kinase

Creatine kinase (CK) is present in high concentrations in the cytoplasm of myocytes; it catalyzes the reversible phosphorylation of creatinine to form creatinine phosphate, which is a major storage of high-energy phosphate in the muscle. It is a "leakage" enzyme and a

VetBooks.ir

highly sensitive and specific indicator of muscle damage in domestic animals. Normal values of CK activity vary according to physical activity, restraint, age, and sex. Although CK is found in both cardiac and skeletal muscle, elevations of this enzyme most commonly are associated with exertional myopathies (rhabdomyolysis) and are seen as musculoskeletal manifestations of systemic disease. Intramuscular injections, vigorous exercise, or prolonged shipping may result in modest releases (up to a fourfold increase over resting values) of CK into the circulation without producing histologic evidence of muscle damage. Endurance exercise may lead to moderate elevation of CK (2000 to 15,000 IU/L) in some horses that show no recognizable sign of exertional myopathy. The half-life of this enzyme in the circulation is very short (2 hours in horses and 4 hours in cattle); its activity peaks at 6 to 12 hours and even marked elevations in CK may return to normal within 24 hours after a single muscle insult. Although marked elevation of CK can be a guide to the extent of muscle damage, the short half-life and the potential for continuing myonecrosis have a marked influence on the enzyme activity observed at any point in time. A persistent elevation of CK suggests a process resulting in active and continuing muscle damage and provides grounds for resting athletic horses; it can also be used as a prognosticator in downer cows (>3500 IU/L carries a guarded prognosis). Elevated CK provides no information on the factors responsible for the rhabdomyolysis; more precise information regarding the etiology can be obtained by muscle biopsy and its histologic and histochemical examination. Hemolysis or delayed separation of serum from clot may produce falsely high values for CK as a result of inadvertent muscle penetration during venipuncture.

Aspartate Aminotransferase

Aspartate aminotransferase (AST) is found in high concentrations in a variety of tissues, including skeletal and cardiac muscles, the erythrocytes and kidneys, and the liver. AST enzyme catalyzes the transfer of the α-amino group of aspartic acid to α-ketoglutaric acid resulting in formation of oxaloacetic acid and glutamic acid. This enzyme is a nonspecific indicator of tissue damage and tends to be less sensitive to mild insults than the tissue-specific enzymes SDH and CK. The half-life of AST in the circulation is relatively long (more than 2 days in large animals), and elevations may persist for as long as 10 days after an episode of myonecrosis or liver damage. As a general rule, extensive muscle necrosis tends to produce much higher elevations of AST than severe liver necrosis. This enzyme is most useful when compared with the tissue-specific enzymes as determined sequentially over the time course of a disease process. Elevations of CK and AST indicate muscle damage, whereas elevations of SDH and AST indicate liver damage. Marked but transient elevations of CK and SDH are associated with a single insult to the muscles and liver, respectively, whereas AST increases gradually and remains elevated for a much longer time. Thus, a moderate to marked increase in AST in an animal with progressively declining SDH or CK indicates that some tissue damage occurred within the past 7 to 10 days, but also that the process may no longer be active. This often is a favorable prognostic indicator. Persistent elevation of or a progressive increase in CK or SDH and AST over time indicates an active, continuing process of tissue damage, and the prognosis is more guarded. AST is relatively stable at room temperature, but hemolysis or lipemia may interfere with the assay.

γ-Glutamyltransferase

γ-Glutamyltransferase (GGT) is a membrane-bound enzyme that functions in the γ-glutamyl cycle where it catalyzes the transfer of γ-glutamyl groups from γ-glutamyl peptides. It is important in glutathione metabolism, amino acid absorption, and protection against oxidant injury. This enzyme is found in the biliary tract from where it derives the serum activity in health and disease, therefore making it an important marker of hepatobiliary disorders and cholestasis in large animals. GGT is also found in the pancreas, gastrointestinal tract, urinary tract, mammary gland, and reproductive tract; it does not increase in serum in disorders involving these organs. GGT is quite stable, and reliable results can be obtained from samples submitted several days after blood samples have been drawn, provided the serum is refrigerated. The half-life of GGT activity in blood is not known, but it has been suggested to be a half-life of 3 days in horses. The activity of this enzyme is highest in the cells of the periportal region of the liver, in the pancreas, and in the renal tubular cells. Pancreatic diseases resulting in inflammation and necrosis are relatively rare in large animal species. Damage to the renal tubular cells leads to a release of GGT into the tubular lumen and the urine. Because this enzyme is a relatively large molecule, it is not resorbed into the systemic circulation, and renal tubular damage does not result in elevated serum GGT activity. Increases in GGT relative to creatinine in the urine have been used as an index of acute renal tubular damage. However, the validity of the normal range for this ratio in horses has been questioned.

In large animal species, an elevation in serum GGT is one of the more reliable indicators of damage to the liver and biliary obstruction. Disease processes such as pyrrolizidine alkaloid intoxication (in subclinical liver diseases showed a 75% sensitivity and 90% specificity); chronic active hepatitis, cholangiohepatitis, and cholelithiasis produce liver damage, primarily in the periportal region, leading to marked and persistent elevation of GGT activity in the serum.[36] In these instances, elevations in serum ALP activity are generally associated with the increase in GGT. Two syndromes—fatty liver syndrome in dairy cows and hyperlipemia syndrome of periparturient mares of pony and miniature horse breeds—are associated with liver damage, which is often reflected by elevation of GGT.

Most suckling neonatal large animals, except horses, have high levels of GGT activity in their serum. This is the result of absorption of maternal GGT, which is present in relatively high levels in the colostrum, making its serum levels a sensitive indicator of passive transfer. Elevation of GGT in neonates should be regarded as a normal finding unless it is associated with other evidence of liver disease. The normal range of serum GGT activity for burros, donkeys, and asses may be substantially higher (two to three times) than the normal range of serum GGT activity for horses. Caution should therefore be used when evaluating this enzyme in these species. Elevation in serum GGT activity has been reported in Thoroughbred racehorses that are performing below expectations. The reasons for the increase in GGT are not known, but horses often respond to a period of rest or reduction in workload. These horses show little histologic evidence of liver damage, and other indices of liver damage and dysfunction usually are within normal limits. The stress of training may be associated with an elevated GGT. Certain trainers, often highly successful trainers, appear to have a disproportionately large number of horses with elevations of this enzyme. The normal range for GGT of Thoroughbreds in race training may be slightly higher than that of normal sedentary horses.

Alkaline Phosphatase

Alkaline phosphatase (ALP) is used in most species as a marker for intrahepatic or extrahepatic obstruction of the biliary system. The enzyme is also released by osteoblasts from metabolically active bone. This may be the reason that young, rapidly growing animals normally have high levels of serum ALP. Elevations in ALP are also reported in cases of rickets and healing fractures. The intestinal isoenzyme of ALP is very similar to the ALP isoenzyme found in neutrophils. Elevations in the ALP activity of abdominal fluid in horses with intraabdominal disease may reflect the release of this enzyme from the neutrophils rather than being a specific marker of damage to the bowel.

ALP has been useful for evaluating liver disease in large animals, particularly in horses with pyrrolizidine alkaloid intoxication, chronic active hepatitis, and cholangiohepatitis, and in some patients with cholelithiasis. A profound elevation in ALP activity is thought to reflect periportal liver damage and biliary obstruction in these patients. A moderate to marked elevation in ALP may be observed in a wide range of disorders resulting in hepatic necrosis and intrahepatic cholestasis. Because this enzyme is not organ specific in large

VetBooks.ir

animals, elevations in ALP activity must be interpreted in relation to more organ-specific enzymes such as SDH and GGT.

Other Enzymes

LDH is a metalloenzyme that hydrolyzes many types of phosphate esters at an alkaline pH in the presence of zinc and magnesium ions. It is found in relatively high concentrations in a variety of organs and tissues of the body from the heart, liver, muscle, and kidney to the erythrocytes and leukocytes. An elevation in serum LDH enzyme activity must be evaluated in relation to other, more organ-specific enzymes. LDH isoenzyme analysis can be helpful in differentiating organ system damage, but the analysis is time consuming and not always available. An elevation in LDH activity is expected in hepatic necrosis and serves as an indicator of an active disease process. Extensive muscle damage and rhabdomyolysis tend to result in a more massive release of enzyme and much higher serum enzyme activity. A modest elevation in LDH may be seen in some hemolytic disorders and some cases of leukemia. Blood samples must be handled with care, because hemolysis results in falsely elevated serum LDH activity.

Glutamic dehydrogenase (GLDH) and ornithine carbamoyltransferase (OTC) are two enzymes that are reported to be sensitive indicators of hepatic necrosis in ruminants. GLDH is a mitochondrial enzyme that catalyzes the conversion of glutamate to 2-oxoglutarate. Injury to the hepatocyte has to be severe enough to damage the mitochondria. It is suggestive of either hepatocyte death or sub-lethal hepatocyte injury. In large animals, it is more liver specific than AST and has better storage stability than SDH. OTC is a hepatic-sensitive enzyme that catalyzes the reaction between ornithine and carbamoylphosphate-forming citrulline and inorganic phosphate. OTC has been used mostly to evaluate fatty liver in cattle and as a prognostic indicator in abomasal displacement and fatty liver.[37] Alanine aminotransferase (ALT) is an important liver-specific enzyme that has wide application in small animals and is often included in automated chemistry profiles. This enzyme has not been useful for evaluation of liver disease in large animal species, and occasionally horses with marked rhabdomyolysis and no other evidence of liver disease show an elevation in serum ALT activity.

Bilirubin

Bilirubin is a breakdown product of the heme component of the hemoglobin molecule and to a lesser extent to the breakdown of other porphyrin-containing compounds (e.g., myoglobulin, cytochrome P_{450}, peroxidase, catalase). Bilirubin exists in the serum in two forms and is responsible for the yellow color known as *icterus,* or *jaundice,* of the mucous membranes. Unconjugated, prehepatic, albumin-bound bilirubin is also known as *indirect-reacting bilirubin,* which used to be determined by the van den Bergh reaction; currently total bilirubin is measured by the 2,5-dichlorophenyldiazonium (DPD) method, and direct bilirubin is determined by the method of Jendrassik and Grof.[38] Indirect-reacting bilirubin must be taken up by the liver cells, where it is conjugated and then excreted in the bile. Conjugated bilirubin is known as *direct-reacting bilirubin,* as determined by the van den Bergh reaction. Horses normally have a much higher serum bilirubin level than ruminants, and hot-blooded horses have a higher bilirubin level than cold-blooded horses of the pony and draft breeds. The horse also differs from ruminants in that horses often develop moderate icterus in response to fasting or anorexia associated with many systemic diseases. The increase in the bilirubin concentration in these horses is caused almost entirely by an increase in unconjugated (indirect-reacting) bilirubin, and within a few days the bilirubin can increase from the normal range up to 6 to 8 mg/dL. Therefore, the total serum bilirubin concentration is of little diagnostic value in the ill horse unless both the direct- and indirect-reacting bilirubin values are determined. However, in general terms unconjugated hyperbilirubinemia occurs when there is increased production of bilirubin or when either hepatic uptake or conjugation of bilirubin is diminished.

BOX 22-18

Causes of Elevated Serum Bilirubin

Elevation of Total Serum Bilirubin

Common Causes

Hemolytic anemia
Liver failure
Secondary to systemic disease or anorexia in horses

Uncommon Cause

Elevation of Indirect-Reacting Bilirubin

Common Causes

Secondary to systemic disease or anorexia in horses
Liver failure
Hemolytic anemia

Uncommon Cause

Chronic liver failure in cattle

Elevation of Direct-Reacting Bilirubin

Common Causes

Liver failure
Cholelithiasis
Cholangiohepatitis
Neonatal isoerythrolysis

Uncommon Cause

Hemolytic anemia

Conjugated hyperbilirubinemia is caused either by intrahepatic cholestasis or extrahepatic bile duct obstruction.

Total serum bilirubin is elevated in animals with hemolytic anemia, and this increase is caused largely by an increase in indirect-reacting bilirubin (Box 22-18). The degree to which bilirubin is elevated in hemolytic anemia is a function of the rate of RBC destruction and the capacity of the liver to excrete the newly formed bilirubin. The total bilirubin rarely exceeds 10 mg/dL in hemolytic anemia. An exception is the hemolytic anemia of neonatal isoerythrolysis in newborn foals, which is often associated with marked clinical icterus. In these foals the serum bilirubin may exceed 25 mg/dL, a variable but substantial proportion of which (40% to 60%) is likely to be direct-reacting bilirubin causing kernicterus in some cases.

The second major cause of clinical icterus and increased serum bilirubin is liver failure. Liver failure results in impaired uptake and excretion of bilirubin. Acute liver failure caused by hepatic necrosis results in marked to moderate increases in both direct- and indirect-reacting bilirubin. In horses with acute liver failure, bilirubin often exceeds 10 mg/dL, and this increase is caused primarily by increases in indirect-reacting bilirubin. Direct-reacting bilirubin rarely exceeds 25% of the total bilirubin in the horse, and increases of this magnitude suggest an intrahepatic or extrahepatic biliary obstruction. With chronic liver failure, icterus is more variable, and total bilirubin rarely exceeds 10 mg/dL. Liver failure in ruminants, particularly chronic liver failure, is associated with a much less striking elevation in serum bilirubin than occurs in horses. In the absence of hemolytic anemia, a bilirubin value above 2 mg/dL indicates impaired hepatic function in ruminants. Hyperbilirubinemia without clinical icterus may be observed in cattle and in sheep with fatty liver associated with ketosis/acetonemia; in such cases, the predominant pigment is unconjugated bilirubin. In horses, unconjugated hyperbilirubinemia can occur a few days after prolonged halothane anesthesia.[39]

Glucose

Blood glucose concentration represents an equilibrium among dietary intake, hormonal interactions (insulin, glucagon, gluco-

Causes of Hyperglycemia

Common Causes

Acute severe colic in horses
Stress and excitement
Cushing syndrome
Glucocorticoid administration
Xylazine administration

Uncommon Causes

Overly rapid administration of dextrose
Diabetes mellitus

corticoids, catecholamines, and growth hormone), and biochemical pathways (glycogenolysis, gluconeogenesis, and glycolysis). Glucose is an essential substrate for brain cells and for erythrocytes. Major storage sites for glucose in the body are skeletal muscles and liver in the form of glycogen.

Hypoglycemia

Hypoglycemia is either the result of poor sample handling, pathologic states, or fasting. Delayed separation of serum from the blood cells may allow time for these cells to consume glucose, thus causing false low glucose levels. Fasting usually does not result in hypoglycemia except in neonatal animals (Box 22-19). Newborns have limited energy reserves, and any disease (mainly septicemia and diarrhea), injury, congenital defect, maternal rejection, agalactia, or management error that limits energy intake can result in marked hypoglycemia associated with profound depression, even coma. In calves with acute severe diarrhea, blood glucose may fall below 40 mg/dL (2.2 mmol/L) in 30% to 50% of cases.[40] One study has shown that 34% of critically ill foals are hypoglycemic.[41] Hypoglycemia may also be seen in animals with acute toxic enteritis, coliform mastitis, septicemia, and colic associated with strangulated bowel, as well as in the later stages of endotoxemia and in some horses with exhaustion after prolonged exercise, hepatic insufficiency, islet B cell neoplasia, hepatocellular carcinoma, and surreptitious injections of insulin. Hypoglycemia is a reasonably consistent feature with primary ketosis and fat cow syndrome in cattle, with pregnancy toxemia in sheep and goats, and in hyperlipemia syndrome, which is seen primarily in pregnant or lactating ponies. Rapid, semiquantitative field tests for blood glucose (Dextrostix, Boehringer Mannheim Diagnostics, Inc., Indianapolis, Ind.) or handheld human glucometers provide a practical means of early recognition of this problem. It should be pointed out that this method reads glucose concentrations slightly low compared with standard laboratory procedures by 10% to 15%.[42]

Hyperglycemia

Hyperglycemia may be seen with excitement, transportation, or stress and probably is mediated by increases in catecholamine and glucocorticoid hormones (Box 22-20). The stress and pain of acute severe colic in horses frequently results in hyperglycemia occurring in approximately 50% of the colic cases, and elevations of blood glucose above 250 mg/dL are associated with a poor prognosis in such cases. In a recent study all the animals with colic that did not survive had a mean glucose level of 234 mg/dL.[43] Endotoxemia initially results in a transient hyperglycemia that may be followed by marked hypoglycemia in the terminal stages of the toxemia. The later stages of Cushing syndrome in horses are generally associated with a non–insulin-responsive hyperglycemia and glycosuria. Similar changes can be induced transiently when exogenous glucocorticoid hormones are administered at a high dose rate. Insulin-responsive diabetes mellitus rarely occurs in large animals but has been reported in association with destructive pancreatic lesions. Hyperglycemia in large animals has also been associated with iatrogenic hyperadrenocorticism, pheochromocytomas, after strenuous exercise, after prolonged halothane anesthesia, administration of xylazine or detomidine, during administration of glucose, endotoxemia, proximal duodenal obstruction in cattle, and pituitary pars intermedia dysfunction in horses.

Creatinine

Creatinine is generated by muscle metabolism and is derived from the cyclic use of phosphocreatine—the muscle energy store—resulting in the production of inorganic phosphate and creatine that degrades into creatinine. In the resting animal, this process occurs at a relatively constant rate. The absolute muscle mass and level of physical activity may influence the rate of creatinine production and thus the serum concentration. Starvation, with loss of muscle mass, may result in a slightly reduced serum creatinine level, whereas serum creatinine may be slightly higher in muscular, athletic individuals compared with sedentary animals. Creatinine is distributed throughout the body water and is not reused. Creatinine is normally excreted by the kidneys, primarily by glomerular filtration, and is not normally reabsorbed in the tubules. In azotemic patients a substantial part of creatinine is metabolized and excreted by nonrenal routes. Serum or urine creatinine concentrations determined by the standard alkaline picrate reaction may be falsely elevated by the presence of noncreatinine chromogenic compounds in the serum. These chromogens include glucose, fructose, ascorbic acid, hippuric acid, urea, ketones, cephalosporins, amino acids, and several other compounds. The contribution of these compounds can be reduced or eliminated, and most automated chemical laboratories use such methodology. However, if inappropriately high creatinine is reported in patients without other evidence of renal failure, the method of creatinine measurement should be ascertained.

The serum creatinine concentration provides a crude measure of the glomerular filtration rate. However, serum creatinine, like BUN, is not a very sensitive or early indicator of changes in renal function. Alterations in renal blood flow caused by decreases in effective circulating fluid volume (hypovolemia) produce an elevation in serum creatinine and BUN; this can be considered a prerenal azotemia (Box 22-21). It occurs with some frequency in animals with acute enteritis, peritonitis, acute heart failure, massive blood loss, and some forms of colic and in horses with exhaustive disease syndrome. An important point is that many of these disorders initiate the release of inflammatory mediators, which may cause renal damage and impaired renal function above and beyond that associated with impaired renal blood flow and hypovolemia. Prerenal azotemia is usually seen in animals that are dehydrated and volume depleted and that have a history of loss or compartmentalization of sodium-containing fluid. Prerenal azotemia often can be marked (creatinine level above 6 mg/dL), but if uncomplicated, it generally responds rapidly to fluid replacement therapy. Urine production, the urine sodium concentration, and the fractional excretion of sodium are usually low, and the urine specific gravity is usually elevated. The ratio of urine to plasma urea or creatinine, as well as the urine-to-plasma ratio of osmolality, is reported to be higher in horses with

VetBooks.ir

BOX 22-21

Causes of Elevated Creatinine

Common Causes

Prerenal azotemia
- Reduced renal perfusion
- Hypovolemia
- Congestive heart failure
- Dehydration after endurance exercise

Renal azotemia
- Acute renal failure
- Chronic renal failure

Postrenal azotemia
- Urolithiasis
- Renal calculi
- Ureteral calculi
- Urethral calculi

Ruptured bladder

Uncommon Causes

False azotemia
- Noncreatinine chromogens in serum or plasma

Perirenal abscess
Renal carcinoma
Renal dysgenesis
Carcinoma of the bladder
Post-exhaustion multisystemic syndrome in horses
Severe exertional rhabdomyolysis with myoglobinuria
Severe intravascular hemolysis with hemoglobinuria
Intoxication or poisoning
- Heavy metal poisoning
- Nonsteroidal antiinflammatory drug intoxication
- Aminoglycoside intoxication

prerenal azotemia compared with renal azotemia.[16] In ruminants, creatinine is a more reliable indicator of renal failure than is BUN. Urea nitrogen can be secreted in saliva and metabolized by the ruminal microflora; this frequently results in a disparity between BUN and creatinine levels in ruminants with renal failure.

Although small increases in creatinine may be seen with progressively compromised renal function, nearly two thirds to three fourths of the nephrons must be nonfunctional before the serum creatinine level clearly exceeds the normal range. Both ARF and CRF are usually associated with elevated creatinine. ARF, especially in animals with anuria or oliguria, is usually associated with progressive daily changes in blood parameters. In contrast, blood parameters of animals with CRF tend to remain relatively constant. A transient but markedly elevated serum creatinine has been observed in some newborn foals that have no other evidence of compromised renal function. Many of these foals are born to mares that had medical problems before parturition. Alterations in placental function may allow the accumulation of creatinine in the foal's circulation. In most of these otherwise normal foals, this marked elevation in serum creatinine resolves within the first few days of life. There is no clinical significance to decreased serum creatinine levels.

Blood Urea Nitrogen

The term *blood urea nitrogen* (BUN) is ingrained in the veterinary literature, despite the fact that urea nitrogen determinations usually are performed on serum (SUN) or plasma samples. This is of little consequence, because the actual difference in urea concentrations of whole blood and serum or plasma is relatively small. Urea provides a nontoxic means of excreting ammonia generated by amino acid catabolism and the intestinal microflora. It is distributed throughout the body water. In the intestine, urea is broken down by urease, which is produced by the intestinal microflora, and the nitrogen, as ammonium ion, is recycled to the liver. Urea is excreted by the kidneys, primarily by glomerular filtration, intestine (in high concentration in horses), saliva, and sweat. Ruminants excrete urea into the gastrointestinal tract where it is converted to ammonia and amino acids that result in protein production.

BOX 22-22

Causes of Decreased Blood Urea Nitrogen

Common Causes

Liver failure
Neonatal animals (blood urea nitrogen is normally lower than in adults)

Uncommon Causes

Low-protein diet
Anabolic steroid administration

BOX 22-23

Causes of Increased Blood Urea Nitrogen

Common Causes

Prerenal azotemia
Reduced renal perfusion
- Hypovolemia
- Congestive heart failure
- Dehydration after endurance exercise

Renal azotemia
- Acute renal failure
- Chronic renal failure

Postrenal azotemia
- Urolithiasis
- Renal calculi
- Ureteral calculi
- Urethral calculi

Ruptured bladder

Uncommon Causes

Gastrointestinal bleeding
Perirenal abscess
Renal carcinoma
Renal dysgenesis
Carcinoma of the bladder
Postexhaustion multisystemic syndrome in horses
Severe exertional rhabdomyolysis with myoglobinuria
Severe intravascular hemolysis with hemoglobinuria
Intoxication or poisoning
- Heavy metal poisoning
- Nonsteroidal antiinflammatory drug intoxication

Aminoglycoside intoxication

Urea production occurs almost exclusively in the liver and is synthesized by hepatocytes from ammonia derived from amino acid catabolism. Blood or serum urea is dependent on hepatic urea production and renal tubular flow rate. Urea excretion is not solely determined by GFR, because once in the tubules, at rapid flow rates, 40% of the urea is reabsorbed. However, at slow flow rates as occurs in hypovolemia, 60% is reabsorbed, thus increasing urea levels in serum or blood. Liver failure is frequently associated with a decrease in BUN (Box 22-22). Urea nitrogen tends to be low in nursing animals because of their high fluid intake and urine output and their anabolic state of rapid growth. Urea nitrogen may be reduced slightly in animals given anabolic steroids or fed diets low in protein but of adequate calorie content.

Starvation or other processes that result in rapid tissue catabolism such as fever, burns, exercise, and increased protein digestion (e.g., hemorrhage in the gastrointestinal tract) decreases GFR, or corticosteroid administration may result in modest increases in BUN (Box 22-23). BUN, along with creatinine, provides a crude index of altered

VetBooks.ir

renal function in most animal species. BUN is influenced more directly by dietary factors than is creatinine, and creatinine is generally a better guide to renal failure. This is particularly true in ruminants, in which BUN may remain within normal limits in animals with marked impairment of renal function.

The BUN/creatinine ratio has been used to try to aid in differentiating prerenal azotemia and intrinsic renal azotemia based on the proportion of increases of each substance in the ratio. However, given the wide variation in BUN and creatinine concentration along with the differences of species, it is not a reliable indicator. In the horse a BUN/creatinine ratio of less than 10:1 is expected with ARF; when it exceeds 15:1, CRF is more likely. With these considerations in mind, the discussion of prerenal, renal, and obstructive causes of azotemia in the creatinine section apply to BUN.

Serum Protein

The serum or plasma proteins consist of albumin and globulin fractions. These are discussed in detail in Chapter 26.

Urinalysis

Urinalysis can be an extremely useful diagnostic tool, providing information on many systemic disorders. Ideally urine is collected at the same time as blood for clinical chemistry and before any treatment is administered. The interpretation of certain abnormalities in urine (e.g., glucosuria, ketonuria) is facilitated by concurrent knowledge of chemistry results. Urinalysis is essential in the evaluation of primary renal disease. Urine normally is collected as a voided sample or after catheterization. Voided urine samples are safe and easy to collect but are easily contaminated. Catheterization is preferred for bacteriologic evaluation, but the resultant mild trauma may result in a slight increase in urine RBCs and protein. Because of the urethral diverticulum at the level of the pelvis, it is difficult to successfully catheterize male ruminants. Urethral obstruction is common in male small ruminants, and percutaneous aspiration may be the only way to obtain a urine sample in affected animals. Urinalysis should be performed as soon after collection as possible (within 30 minutes) to avoid degeneration of cellular elements, changes in pH, or bacterial overgrowth (cytolysis, crystallization). If this is not possible, samples should be refrigerated but brought back to room temperature before tests. Urine volume and composition are influenced by feed and water intake, salt supplementation, environmental factors, exercise, stress, systemic disease, and drug administration. Urine samples collected after administration of a diuretic are dilute and unsuitable for routine urinalysis. The tranquilizer xylazine, which is often used to assist in the catheterization of male horses, may alter the results of the urinalysis because it produces diuresis as a result of glycosuria and specifically also kaliuresis.

When urinalysis is performed, the color should be noted along with the organoleptic characteristics of the urine such as the fact that an adult horse's urine has a lot of mucus and becomes cloudier at the end of urination.

Specific Gravity

Specific gravity is defined as the weight of urine relative to the weight of distilled water (=1 at 4°C [60°F]). The normal specific gravity of serum is approximately 1.008 to 1.012. The urine specific gravity is an indicator of renal function, because it reflects the action of the renal tubules and collecting ducts on the glomerular filtrate by providing an estimation of the number of particles dissolved in the urine (e.g., whether the urine is concentrated or diluted via serum). It is usually measured by refractometry on urine supernatant. Urine dipsticks with reagent pads for estimating the urine-specific gravity in humans should not be used for this purpose in domestic animals, because a poor correlation has been reported compared with refractometry in large animals.[44] Normal animals have the capacity to dilute their urine specific gravity to less than 1.010 and to concentrate to greater than 1.050. The normal range reported for most adult large animals is 1.020 to 1.050. Suckling neonatal animals normally produce a very dilute urine with a specific gravity below 1.010. Although this could represent immature renal function, it more likely reflects their high-volume fluid intake, because normal neonates can concentrate their urine if fluids are withheld.

Failure to produce a concentrated urine, as reflected by a specific gravity below 1.020, in the face of dehydration is an indication of altered renal function, which may be caused by primary renal disease, diabetes insipidus, medullary washout, or nephrogenic diabetes insipidus. With severe and chronic sodium depletion, tubular sodium may be insufficient to sustain normal countercurrent mechanisms for water resorption. This process is called *medullary washout* and has been reported as a cause of polyuria in lactating dairy cattle on a salt-deficient diet. At least 50% of renal function must remain for highly concentrated urine to be produced. Isosthenuria, a urine-specific gravity that remains around 1.010 despite variation in hydration, occurs when renal disease progresses to the point at which renal function is reduced to less than a third of normal. Altered renal function in these animals is usually reflected by a moderate to marked elevation in BUN and creatinine levels and by other changes in the urinalysis. Hyposthenuria occurs when the specific gravity remains below 1.010; this indicates altered release of or response to antidiuretic hormone, which occurs with diabetes insipidus, medullary washout with chronic sodium depletion, nephrogenic diabetes insipidus, psychogenic polydipsia, and chronic liver failure in some horses. Hypersthenuric urine occurs when SG is greater than 1.030-1.035, and it occurs commonly in states of dehydration. It is also common in horses fed a high percentage diet of hay and in those living in hot environments.

pH

The normal range of urine pH for adult herbivores is alkaline, with values ranging from 7 to 9. Neonatal foals tend to have a slightly acid urine with a pH below 7. Aciduria in adults may be seen in postrace samples collected from racehorses, after prolonged fasting, with ketosis in ruminants, or in response to metabolic acidosis. A paradoxic aciduria is seen in ruminants with hypochloremic, hypokalemic metabolic alkalosis and has been recently attributed to K concentration changes in the urine.[45] Urine pH is also influenced by the cation-anion balance of the diet. The SID of urine, specifically the potassium concentration, has the strongest influence on urinary pH in dairy cattle and most likely in horses as well.[45]

Protein

Protein normally is not detected in urine, although a false-positive protein reaction may be noted on urine dipsticks if the sample is strongly alkaline. Urine with a positive reaction for protein on dipsticks should be checked for protein by a chemical method. Proteinuria should be evaluated in relation to the other findings in the urinalysis. Persistent and strongly positive reactions for protein in the absence of leukocytes, RBCs, bacteria, or casts suggest glomerular protein loss, as in glomerulonephritis or amyloidosis. The presence of bacteria and leukocytes with proteinuria suggests sepsis in the urinary tract, whereas hemorrhage or inflammation in the urogenital tract is often associated with proteinuria. A transient postexercise proteinuria is observed in performance horses at submaximal or maximal levels of exertion.

Glucose

Glucose is not found in the urine of normal large domestic animals unless the blood glucose level increases above the renal threshold, which is thought to be approximately 100 to 140 mg/dL in ruminants and approximately 160 to 180 mg/dL in horses. The causes of hyperglycemia and glycosuria were described in a previous section; they include Cushing syndrome, stress, and catecholamine or glucocorticoid hormone release. Hyperglycemia and glycosuria can be created iatrogenically when glucose-containing fluids are administered at

VetBooks.ir

an excessive rate. Glycosuria is a fairly consistent finding in sheep with enterotoxemia type D (pulpy kidney). The presence of glycosuria without hyperglycemia strongly suggests renal tubular damage resulting from a toxic or ischemic insult.

Occult Blood

Both myoglobin and hemoglobin give a positive reaction on urine occult blood dipsticks. In most instances proteinuria shows a positive result as well. A tentative clinical impression sometimes can be formed to differentiate myoglobin from hemoglobin in dark urine if the sample is shaken vigorously in a closed, transparent container. Myoglobin tends to produce a brown foam, whereas hemoglobin produces a reddish foam. Hemoglobinuria caused by intravascular hemolysis is generally associated with clinical and hematologic evidence of a hemolytic anemia. Hematuria may result in a positive occult blood reaction if lysis of some of the intact RBCs has occurred. This is likely to happen if the urine is very dilute or if it is held at room temperature for an extended period before analysis. False-positive reactions can occur if microbial peroxidase or oxidizing contaminants are present. Hematuria should be confirmed by cytologic examination of the urine sediment.

Myoglobin

Myoglobinuria should be associated with clear clinical and clinicopathologic evidence of extensive muscle damage. The ammonium sulfate precipitation method of differentiating hemoglobin from myoglobin is imprecise and frequently fails to detect myoglobin in the dark, coffee-colored urine of horses with severe rhabdomyolysis. Accurate differentiation of these compounds in urine requires more sophisticated procedures.

Cells

Cytologic evaluation of urine is deemed essential in cases of unexplained fever, hyperfibrinogenemia, weight loss, and complicated neurologic disease. The normal range for cells is generally considered to be up to five RBCs or leukocytes per high-power field. An increased number of erythrocytes indicates hematuria, which may be caused by neoplasia, trauma, inflammation, or coagulopathy. Pyuria, an increase in urine leukocytes, indicates an inflammatory process; when associated with bacteriuria, it indicates a septic process in the urinary tract. The presence of sheets or rafts of transitional cells suggests neoplasia. Foal's urine has relatively more epithelial cells compared with urine of adult animals.

Casts

Casts are accumulations of protein and cellular material that form in the renal tubules, and when present in the urine, they indicate renal damage or tubular disease. Casts can consist of erythrocytes, leukocytes, or renal tubular cells. As cellular degeneration proceeds, the cell type is more difficult to determine, and the casts become granular and then waxy. Hyaline casts are noncellular and are formed from mucoprotein. They may be seen with glomerulonephritis, fever with passive congestion, or severe dehydration with altered renal blood flow. However, casts are soluble in alkaline pH, which is the usual urine pH of large animals, thus making their documentation in urine sediment difficult. If present, they indicate tubular involvement.

Crystals

The crystalline structures in the urine of large animals are those usually associated with an alkaline urine. Calcium carbonate crystals normally are found in abundance in horse urine, particularly if the horse has been fed alfalfa hay. Triple phosphate and calcium oxalate crystals are frequently observed in relatively small numbers. In foals calcium oxalate crystals are more prevalent. The major crystals involved in urolithiasis of feedlot cattle is struvite ($MgNH_4PO_4 \cdot 6H_2O$). In the western United States, silicate stones are most common in livestock under range conditions. Carbonate and oxalate stones are common causes of urolithiasis in small flocks of backyard sheep and goats fed alfalfa hay.

Bacteria

Bacteria sometimes are seen in small numbers in voided urine samples and may represent surface contaminants. Bacterial infections of the urinary tract are usually associated with significant pyuria. When this is noted, a catheterized sample (horse) or clean midstream catch (ruminant) should be obtained for Gram stain, culture, and sensitivity testing. Results from ruminant samples must be carefully interpreted, because male ruminants routinely urinate within the prepuce, thus heavily contaminating samples. Fortunately, urinary tract infections in male ruminants and horses are rare.

Urine Creatinine Clearance Ratio[46]

Urinary electrolyte excretion is affected by a variety of factors, including dietary intake, alterations in renal function, and specific hormones that regulate renal electrolyte excretion. Determination of electrolyte concentrations from randomly collected urine samples is easily done and can be clinically useful when these concentrations are compared with serum concentrations. The presence of substantial amounts of sodium in the urine of an animal with hyponatremia suggests excessive renal sodium loss caused by altered renal function or hormonal control. However, marked variation in the rate of urine production can lead to serious problems in the interpretation of urine electrolyte concentrations. The standard physiologic methods of determining renal electrolyte clearance are complicated by the need for quantitative urine collection and are not well suited to most practical clinical situations. One means of overcoming these difficulties is expression of the renal electrolyte clearance relative to the endogenous creatinine clearance. Expression of the renal clearance as a ratio eliminates the need for quantitative urine collection. This derived value is known as the *creatinine clearance ratio* or the *fractional excretion* (FE), and it is calculated by the following formula:

$$\mathrm{FE} = \mathrm{Urine}/(\mathrm{X})\mathrm{Serum}/(\mathrm{X}) \times \mathrm{Serum}/(\mathbf{C})\mathrm{Urine}/(\mathrm{C}) \times 100$$

where *X* represents the electrolyte concentration and *C* represents the creatinine concentration.

The FE fluctuates somewhat during the day in relation to physical activity and feed and water intake. However, under standardized conditions, there is close agreement between the FE determined from single random samples of blood and urine and that based on samples quantitatively collected during a 12- to 24-hour period.[16] The FE of electrolytes has a very wide range of normal values. The principal sources of this variation are differences in dietary intake and environmental or experimental conditions. The FE of electrolytes has been useful for detecting specific dietary deficiencies or imbalances. Dietary salt deficiency is associated with an extremely low FE of sodium and chloride, whereas the plasma concentration of these ions generally remains within normal limits. In a similar fashion, dietary calcium and phosphorus imbalances seldom are reflected by the serum concentrations of these ions. Calcium deficiency and phosphorus excess are relatively common dietary problems in large animals and result in a low FE for calcium and a high FE for phosphorus. There are technical problems with the determination of the urine calcium concentration in horses because of their normally alkaline urine and the resultant precipitation of calcium carbonate in the urine. Mixed urine samples from horses must be acidified (hydrochloric acid can be used) to solubilize the calcium. It has favored the use of fractional excretion of phosphorus to diagnose nutritional secondary hyperparathyroidism in horses.

Increases in the FE of sodium are noted with renal tubular damage and impaired sodium resorption. The sodium FE increase has been a useful indicator for the differential diagnosis of prerenal azotemia, which almost invariably results in a low sodium FE, from the azotemia caused by primary renal disease, in which the FE for sodium often is markedly increased. Specific criteria of interpretation in horses have been suggested. In the case of the FE_{Na+}, the reference range varies between 0.01% and 1.0%. A level lower than 0.02% indicates Na^+ conservation by the kidney; an increase may

result from excess of dietary intake, Addison disease, and more commonly tubular insufficiency. FE_{K+} normal values are considered between 15% and 80%; values below 15% have been associated with potentially recurrent myositis and chronic laminitis. FE_{Cl-} has not been reported with a diagnostic value. FE_{Ca++} normal values are between 0% and 33% when used in association with FE_P. The reference values for FE_P have been reported up to 0.5% and as a sensitive diagnostic indicator of calcium and phosphorus balance in horses. An increase above 0.5% is mainly considered an indicator of possible nutritional secondary hyperparathyroidism, renal tubular disease, or pseudohyperparathyroidism.

Collection and Submission of Samples for Hematologic and Cytologic Evaluation

CATHERINE J. BENSON and JED A. OVERMANN, *Consulting Editors**

Proper test choice and sample acquisition, preparation, and submission of specimens to a reference laboratory are crucial to making diagnostic decisions to aid in patient care and treatment. Numerous preanalytical factors such as incorrect labeling of samples, presence of interfering substances, use of incorrect collection tubes for a certain test, sampling the wrong tissue for cytologic evaluation, and samples with low cellularity can all impact data results and interpretation. Hematologic and cytologic sample quality can also be affected by the ambient storage temperature and the time interval between collection and evaluation. Care should be taken to eliminate or minimize sources of preanalytical errors to ensure high-quality laboratory results. Hematologic data and cytologic results should always be interpreted in light of the clinical history, physical examination findings, and other diagnostic testing such as imaging or histopathology results. If there are questions regarding sample collection, submission, or handling, contact the reference laboratory.

Venipuncture Site and Technique

Venipuncture site should be based on where it is safe to access a vein that will not collapse when blood is withdrawn.[1] In horses and goats, the jugular vein is most commonly used for blood collection. Alternative but often less recommended sites for venipuncture in horses resulting from safety concerns include the facial sinus, cephalic vein dorsal to carpus, and the saphenous veins. In cattle, the jugular and coccygeal (tail) vein can be accessed. Less often, the mammary vein is used due to the risk of personal injury and of hematoma formation at the blood draw site. Depending on the venipuncture site, species, and size of the animal, an 18- to 22-gauge needle and syringe or a double-ended needle and sheath or Vacutainer system (Becton Dickinson and Co., Franklin Lakes, NJ) with collection tube can be used to collect blood after the site of venipuncture is cleaned with an absorbent and 70% isopropyl alcohol and the vein is digitally occluded. After venipuncture, digital pressure should be applied over the site where the needle is removed to prevent hematoma formation.[2] Good technique is important because traumatic venipuncture can result in platelet activation and clumping of platelets. This can falsely decrease the measured platelet count generated by hematology analyzers.

*Contributions to previous editions by Debra Deem Morris are acknowledged.

Handling and Transportation of Samples

Samples for complete blood cell counts (CBCs) should be submitted in ethylenediaminetetraacetic acid (EDTA) tubes, filled to the proper amount indicated on the container, and inverted several times to ensure proper mixing of the blood with the anticoagulant. Too little blood may result in a falsely decreased pack cell volume (PCV) caused by shrinkage of red blood cells (RBCs). When collecting for both a CBC and serum biochemical profile, blood should first be put in an EDTA tube and then in a serum tube that does not contain anticoagulant. Care must be taken to avoid contaminating the blood remaining in the syringe with retrograde flow of EDTA blood, since this can alter calcium and potassium values on the serum biochemistry.[1] Samples for coagulation testing (prothrombin time and activated partial thromboplastin time) should be placed in a sodium citrate tube at a proportion of 1:9 with blood. Concurrently sending blood from a clinically healthy animal can serve as a control to help assess artifacts if there is a delay in sample transit. Samples for plasma fibrinogen concentration can be submitted either as whole blood in EDTA tubes or in sodium citrate tubes.[3] Consultation with the reference laboratory is advised because the technique used by a specific laboratory will dictate how the sample should be submitted.

Blood smears for microscopic evaluation should be made immediately to minimize artifacts from deterioration of cells. Blood smears should also routinely be made for manual differential counting and to evaluate for hemoparasites and atypical cells that would otherwise not be detected. Hematologic results are affected by the ambient storage temperature and the time interval between collection and evaluation. If samples cannot be run immediately on a hematology analyzer, they should be refrigerated. In cattle and goats, if blood samples are handled appropriately, hemoglobin concentration, RBC count, and total white blood cell (WBC) count are stable for the first 24 hours after collection. PCV is stable for up to 12 hours with mild increases at 24 hours.[4] Blood should not be frozen because this will rupture the cells.[1] Shipping and packaging of samples for hematologic and cytologic evaluation should follow guidelines from the reference laboratory.

General Principles for Submitting Cytology Samples

Proper labeling of slides will help ensure accurate record keeping and help minimize error. Slides that have one edge that is frosted should be labeled with a pencil with the patient identification and sample

VetBooks.ir

site before the sample is put on the slides. This is preferred to "permanent" ink marking pens because the preparation stains and fixatives used in the staining process will often wash off the ink.[5] When submitting samples to a diagnostic laboratory, it is important to fill out a complete history including the patient signalment, tissue sampled, location, duration of the mass or illness, a description of the mass or lesion (color, three-dimensional size for masses, shape, texture, consistency, etc.), other important clinical findings (bloodwork, surgical, imaging results), and differential diagnoses. Minimizing the amount of blood present on slides is also important, especially in cases in which inflammation is suspected. In these cases, cytologic findings may need to be interpreted in conjunction with CBC data to aid in determining if inflammation is present or if leukocytes are blood associated. Samples can be obtained by fine needle aspirate, impression smears, scrapings, and swabs of lesions. Depending on the sample, blood smear, squash, or roll preparations can be made to spread cells on the slide. Once air-dried samples are made, they can be stained with Romanowsky type stains (Wright-Giemsa, Diff-Quik, etc.). Although stained slides may be submitted, it is also important to include some unstained slides when submitting samples to a diagnostic laboratory. Keep unstained cytology samples away from formalin when histopathology samples are also being prepared and submitted because the formalin fumes can render cytology samples nondiagnostic.[5]

Bone Marrow Aspirates and Core Biopsy Samples

Please refer to Chapter 28.

Lymph Node Aspirates

Lymph nodes should be manually stabilized and aspiration or non-aspiration techniques as have been previously described can be used to collect cells.[6] In both techniques, the needle should be maintained within the lymph node, and it can be redirected to obtain cells from multiple areas. Peripheral lymph node samples tend to be highly cellular because the lymphocytes tend to exfoliate well and blood contamination is often mild. As a result, it is very important to spread the cells out well, which can be done by the squash preparation or blood smear technique. Evaluation of poorly stained thick areas should be avoided. Lymphocytes are often very fragile and are prone to lysis; it is therefore important to be gentle when making the preparations. Evaluate only intact lymphocytes because ruptured lymphocytes can appear larger than normal, leading to the misdiagnosis of lymphoma.

The main differential diagnoses for lymph node aspirates include normal lymph node, reactive lymph node, various inflammation (lymphadenitis), lymphoma, and metastatic neoplasia.[6] Normal lymph nodes are composed of mostly small lymphocytes with fewer medium and large lymphocytes. Low numbers of plasma cells, macrophages, eosinophils, non-degenerate neutrophils, and rare mast cells can also be seen. In reactive lymph nodes, small lymphocytes still predominate, but there are increased numbers of medium and large lymphocytes and plasma cells. Reactive lymph nodes are a relatively nonspecific finding in animals with antigenic stimulation, inflammation, or neoplasia. Increased numbers of degenerate or non-degenerate neutrophils, macrophages, or a combination of these two cell populations should prompt evaluation for an underlying infectious organism (bacteria or fungus) and for metastatic neoplasia. Eosinophilic inflammation can be seen with parasitic disease, with some fungal diseases, and with allergic conditions.[6]

General Principles for Various Body Fluids

Fluid should be collected in both EDTA tubes and in tubes without anticoagulant. EDTA tubes are best for cell counts, cytologic examination, and total protein measurement, whereas tubes lacking anticoagulant are used for biochemical and microbiological analysis. At least 1 mL of fluid should be collected in each tube if possible.[7] It is recommended to consult with a reference laboratory for the most current guidelines regarding sample collection, storage, and transport for culturing abdominal, pericardial, thoracic, cerebrospinal, and synovial fluids. Direct preparations of highly cellular turbid fluid or concentrated preparations of low cellularity clear fluid should be made as soon as possible, especially when a delay in transportation cannot be avoided. Cytologic findings that may be seen with delayed processing of fluid samples include erythrophagocytosis, vacuolization of large mononuclear cells, and pyknosis. Bacterial overgrowth can also impair interpretation.[8]

Body Fluid Analysis

Abdominocentesis, thoracocentesis, and pericardiocentesis techniques have been previously described in horses[2,7,9,10] and cattle.[2,11] Gross impressions such as the amount of fluid, color, and consistency should be evaluated. Normal fluid should be light straw-colored and clear.[11] Samples from thoracic, abdominal, and pericardial fluid should be evaluated based on total nucleated cell counts (TNCC) and total protein concentration (TP). The TNCC and TP together aid the clinician in classification of the fluids into the broad categories of transudate, modified transudate, and exudate. However, microscopic analysis should always be performed to evaluate the cellular differential and to assess for neoplastic cells, organisms, or evidence of chronic hemorrhage. In adult horses, samples from the thoracic cavity are generally transudates if they have fewer than 5000 cells/μL and a total protein of less than 2.5 g/dL, are modified transudates with 5000 to 15,000 cells/μL and a total protein of 2.0 to 5.0 g/dL, and are exudates if the TNCC is greater than 10,000 to 15,000 cells/μL and have a TP of greater than 3.0 to 3.5 g/dL.[12] Samples from the peritoneal cavity are similar except that modified transudates can have a TNCC of 1500 to 10,000 cells/μL and a TP of 2.5 to 3.5 g/dL.[8] TNCC and TP interpretations vary widely in cattle, and appropriate references should be consulted.[11] Further information can be obtained in Chapters 30, 31, and 32.

Synovial Fluid Analysis

Collection of synovial fluid should be aseptic, and a full description of techniques is found in other sources.[13,14] Synovial fluid should be placed in an EDTA tube for cytologic analysis as well as in a serum tube or heparinized tube if a mucin clot test is desired.[13] The gross and microscopic appearance of the synovial fluid, the total nucleated cell count, protein concentration, viscosity, and mucin quality (assessed via the mucin clot test) are all important features to analyze when making interpretations of joint fluid.[14] Normal joint fluid is clear to pale yellow, does not clot, and is highly viscous. Although there is some variability in the TNCC obtained from normal joints from various locations, generally, synovial fluid samples are of low cellularity (often < 1000 cells/μL). Hemarthrosis should be distinguished from blood contamination and the overall differential cell count should be interpreted in light of the degree of blood contamination. Overall, the percentage of neutrophils in normal joint fluid should not be greater than 10% in the absence of significant blood contamination. Large mononuclear cells and small lymphocytes predominate in normal joint fluid. Neutrophilic inflammation can be due to septic inflammation, immune-mediated disease, or acute trauma. Bacterial cultures and sensitivities are recommended to rule out infectious organisms. Immune-mediated diseases affecting joints are relatively uncommon in the horse.[13]

Alterations in the Erythron

LESLIE C. SHARKEY and JED A. OVERMANN, *Consulting Editors**

VetBooks.ir

MAJOR ALTERATIONS

Hematocrit, 376
Packed cell volume, 376
Hemoglobin, 376
Red blood cell count, 376
Mean cell volume, 376
Mean cell hemoglobin concentration and mean cell hemoglobin, 376
Erythrocyte morphology, 377
Agglutination of RBCs, 377
Coombs test, 377
Anemia, 377
Blood loss, 379
Hemolysis, 379
Decreased erythrocyte production, 379
Erythrocytosis (polycythemia), 379

The erythron is defined as the total mass of circulating erythrocytes and their precursors within the bone marrow. Alterations in the erythron are common in clinical practice and developing an approach to interpreting these abnormalities is important. Initial assessment of the erythron is generally accomplished through evaluation of a complete blood cell count (CBC). Major alterations include anemia and erythrocytosis. Based on the results of the CBC, clinical history, and physical examination, additional diagnostic tests can then be selected to further characterize these abnormalities in an attempt to identify a specific underlying pathophysiologic process.

Erythropoiesis

Erythrocytes are produced in the bone marrow, largely under the influence of erythropoietin (EPO), with increased erythropoiesis occurring in response to blood loss or hemolysis. Horses are unique in that equine erythrocytes generally remain in the bone marrow until fully mature before they are released into circulation. As a result, peripheral indicators of regeneration used in other species such as polychromasia and reticulocytosis are typically absent or unreliable in the horse. Detection of relatively low numbers of reticulocytes in the peripheral blood of anemic horses, however, has been described using an automated hematology analyzer, which may be a more sensitive means of detecting these cells than the manual methods used previously.[1,2]

Laboratory Evaluation of Erythrocytes

General reference intervals are presented for common erythrocyte parameters in large animals (Table 24-1); however, laboratory- or instrument-specific reference intervals should be used whenever possible. A complete discussion of age- and breed-related influences on erythrocyte parameters is found elsewhere.[3-5] What follows is a brief review of common laboratory evaluators of the erythron.

Hematocrit, Packed Cell Volume, Hemoglobin Concentration, and RBC Count

Hematocrit (HCT), packed cell volume (PCV), hemoglobin (Hgb) concentration, and red blood cell (RBC) count are all ways of quantifying the erythrocytes in peripheral blood, and these measures tend to increase (erythrocytosis) or decrease (anemia) together. HCT and PCV are similar in that they are describing the percentage volume of whole blood occupied by erythrocytes. The HCT is a calculated value and is a function of the mean cell volume and RBC count, whereas the PCV is determined by centrifugation of whole blood in a microhematocrit tube. The Hgb concentration and RBC count are measured values generated by hematology analyzers.

Mean Cell Volume

The mean cell volume (MCV) is directly measured by most hematology analyzers and represents the average erythrocyte volume. An increased MCV can be the result of a regenerative anemia in the ruminant and occasionally in the horse. Decreased MCV is seen with iron-deficiency anemia (also copper) and can also be seen in healthy calves and foals.[3,4]

Mean Cell Hemoglobin Concentration and Mean Cell Hemoglobin

The mean cell hemoglobin concentration (MCHC) is the cellular Hgb concentration per average erythrocyte and is calculated from the Hgb concentration and HCT. A decreased MCHC can be seen in ruminants with regenerative anemias, but this would not be expected in the horse. Both horses and ruminants can have decreased MCHC as the result of iron-deficiency anemia. A low MCHC has also been reported in calves (<5 weeks) as an age-related change.[6] Increased MCHC values are almost always false increases and can be seen with hemolyzed, severely icteric, or lipemic samples, or those with large numbers of Heinz bodies present.

Mean cell hemoglobin (MCH) is the amount of hemoglobin per average erythrocyte (in picograms). This is a calculated value based on the Hgb concentration and the RBC count. In general, MCH is affected in a similar manner to MCHC. MCHC, however, is considered more useful since it takes into account cell volume and is thus preferred over MCH when evaluating the erythron.

Erythrocyte Morphology

ANISOCYTOSIS. Anisocytosis is variation in erythrocyte size. A mild to moderate degree of anisocytosis can be seen in healthy ruminants, whereas mild anisocytosis can be seen in healthy horses. Increased anisocytosis can be the result of a regenerative anemia in ruminants and occasionally in horses. The RBC distribution width (RDW) provides an index of the variation in erythrocyte size.

POLYCHROMASIA. Polychromatophilic erythrocytes are slightly immature, macrocytic cells that appear blue-gray on a Wright-stained blood smear because of their retained cytoplasmic RNA. An increase in these cells in the peripheral blood is indicative of a regenerative response in ruminants. Increased polychromasia is not expected

TABLE 24-1

Reference Intervals for Ruminants and Horses

	Cattle*	Sheep*	Goats*	Horses (Hot-Blooded Breeds)†	Horses (Cold-Blooded Breeds)†
PCV/HCT (%)	22-33	27-45	22-38	32-53	24-44
Erythrocytes ($\times 10^6/\mu L$)	5.1-7.6	9-15	8-18	6.8-12.9	5.5-9.5
Hemoglobin (g/dL)	8.5-12.2	9-15	8-12	11-19	8-14
MCV (fL)	38-50	28-40	16-25	37-58.5	—
MCHC (g/dL)	36-39	31-34	30-36	31-38.6	—
Reticulocytes	—	0	0	—	—

*From George JW, Snipes J, Lane M. 2010. Comparison of bovine hematology reference intervals from 1957-2006. Vet Clin Pathol 39:138.

†From Jain NC. 1986. Schalm's veterinary hematology, ed 4. Lea & Febiger, Philadelphia, PA.

in horses because in this species erythrocytes complete maturation in the bone marrow prior to release into circulation. Polychromatophilic erythrocytes are relatively analogous to reticulocytes; however, not all reticulocytes will be viewed as polychromatophilic erythrocytes on a peripheral blood smear. Thus, a reticulocyte count is considered a more objective and sensitive means of detecting a regenerative response, particularly if performed by an automated hematology analyzer. If a reticulocyte count is not available, a moderate to large degree of polychromasia observed on a peripheral blood smear is a good indicator of a regenerative response in ruminants.

HOWELL-JOLLY BODIES. Howell-Jolly bodies are small, dark, circular structures consisting of nuclear material within erythrocytes. These can be present in small numbers in healthy horses. Increased numbers can be associated with regenerative anemias and splenic dysfunction. Note that in cattle Howell-Jolly bodies can appear similar to *Anaplasma marginale* and can be difficult to differentiate from these organisms in some cases.

NUCLEATED ERYTHROCYTES. Nucleated erythrocytes (nRBCs) are not normally seen in the peripheral blood of healthy horses or ruminants. In ruminants, small numbers associated with regenerative anemias can sometimes be present, but should be accompanied by a significant degree of polychromasia. Bone marrow damage (e.g., toxic damage, hypoxia, neoplasia) can also result in circulating nRBCs. The presence of nRBCs and basophilic stippling in the absence of significant anemia should prompt consideration of lead toxicity (more common in ruminants).

BASOPHILIC STIPPLING. Basophilic stippling is seen as multiple small basophilic inclusions within erythrocytes and is the result of staining of ribosomal aggregates. Basophilic stippling is often seen in association with regenerative anemias in ruminants. As described previously, it can also be seen in cases of lead toxicity.

HEINZ BODIES. Heinz bodies form in erythrocytes as a result of oxidative damage that leads to precipitation of Hgb. They are recognized on Wright-stained blood smears as rounded, pale pink staining structures that protrude from the edge of erythrocytes. Heinz bodies can be confirmed by visualizing them with use of a new methylene blue stain that stains Heinz bodies as dark, rounded structures associated with the erythrocyte membrane. Ingestion of oxidants such as wilted red maple leaves, onions, and garlic; phenothiazine; *Brassica* spp.; and copper toxicity can result in Heinz body formation in large animals. Heinz body formation causes affected erythrocytes to be more susceptible to both intravascular and extravascular hemolysis.

ECCENTROCYTES. Eccentrocytes also form as a result of oxidative damage. In the case of eccentrocytes, oxidative damage results in partial fusion of the erythrocyte membrane causing displacement of Hgb contents to one side of the erythrocyte. Oxidants listed as causes of Heinz bodies can also result in eccentrocyte formation. Eccentrocytes have also been reported in horses with glucose-6-phosphate dehydrogenase deficiency and flavin adenine dinucleotide deficiency. Both are rare erythrocyte enzyme deficiencies that result in the affected animal's erythrocytes being more susceptible to oxidative damage by endogenous or exogenous sources.[7]

ROULEAUX. Rouleaux formation is seen as linear stacking of erythrocytes on a peripheral blood smear. Rouleaux formation is common in healthy horses. A consequence of rouleaux formation is that equine blood samples tend to have a relatively high erythrocyte sedimentation rate, and as a result, whole blood samples should be thoroughly mixed before evaluation. Rouleaux formation is uncommon in healthy ruminants but can be seen with increased plasma proteins such as fibrinogen and immunoglobulins. Increases in these plasma proteins can also enhance rouleaux formation in horses. In any species, care should be taken to differentiate rouleaux from erythrocyte agglutination.

AGGLUTINATION. Agglutination is the result of surface-associated antibody on erythrocytes causing clumping. When viewed microscopically on a peripheral blood smear, aggregation produces clumps of erythrocytes that are described as having the appearance of "clusters of grapes." Agglutination is significant in that it is indicative of immune-mediated hemolytic anemia (IMHA). In some cases it may be difficult to differentiate prominent rouleaux from agglutination. A saline dilution test can be done to confirm true agglutination. This test is accomplished by diluting whole blood with saline and evaluating a wet preparation. Rouleaux will disperse with dilution, whereas true agglutination will persist. Generally a 1:2 to 1:4 dilution will disperse rouleaux; however, occasionally higher dilutions are needed. Agglutination confirmed by a saline dilution test is generally considered to preclude the need for Coombs testing. Agglutination in the horse has also been described as a result of treatment with unfractionated heparin.[8]

Erythrocyte Parasites

A variety of erythrocyte parasites can be detected by review of peripheral blood smears. Examples include *Mycoplasma* spp., *Anaplasma* spp., *Theileria* spp., and *Babesia* spp.[9]

The Coombs Test

The Coombs test or direct antiglobulin test is used to detect erythrocyte surface-associated antibody. Positive Coombs test results support a diagnosis of IMHA (including neonatal isoerythrolysis). A negative Coombs test result, however, does not rule out IMHA because this test is known to have a relatively low sensitivity (i.e., many false negatives).

Evaluation of the Anemic Patient

Anemia develops from one or more of three main pathophysiologic mechanisms: blood loss, hemolysis, and decreased production of erythrocytes. More specific causes are often categorized in terms of these three main mechanisms (Boxes 24-1 and 24-2). Specific causes of anemia are also sometimes grouped in terms of whether they cause a regenerative or non-regenerative anemia. Anemias that are the

VetBooks.ir

BOX 24-1

Causes of Anemia in the Horse

Common Causes

Blood Loss

Trauma
Surgery
Ectoparasites (lice, ticks)
Intestinal parasites (strongyles)
Gastrointestinal bleeding (ulcers, neoplasia)
Immune-mediated thrombocytopenia
Equine purpura hemorrhagica

Hemolysis

Neonatal isoerythrolysis
Red maple leaf toxicosis
Equine infectious anemia

Decreased Erythrocyte Production

Anemia of inflammatory disease (chronic inflammation, neoplasia)
- Chronic abscessation
- Chronic pneumonia or pleuritis
- Lymphoma

Less Common Causes

Blood Loss

Bleeding diathesis associated with disseminated intravascular coagulation (DIC)
Guttural pouch mycosis
Hematuria
Hemoabdomen
Moldy sweet clover toxicosis
Rodenticide toxicity (brodifacoum)
Congenital coagulation factor deficiencies (hemophilia A)
Platelet function disorders (von Willebrand disease, Glanzmann thrombasthenia)

Hemolysis

Fragmentation (DIC, vasculitis)
Immune-mediated hemolytic anemia (idiopathic)
Immune-mediated hemolytic anemia (secondary)
- Clostridial infections
- Penicillin therapy
- Lymphoma

Theileriosis/Babesiosis
Onion toxicosis
Phenothiazine toxicosis
Glucose-6-phosphate dehydrogenase deficiency

Decreased Erythrocyte Production

Anemia of chronic renal failure
Bone marrow neoplasia (leukemia, metastatic neoplasia)
Myelofibrosis
Aplastic anemia (idiopathic, drugs including phenylbutazone)

BOX 24-2

Causes of Anemia in Ruminants

Common Causes

Blood Loss

Trauma
Intestinal parasites *(Haemonchus)*
Ectoparasites (lice, ticks)
Abomasal ulcers

Hemolysis

Anaplasmosis
Brassica spp. toxicosis
Leptospirosis
Onion toxicosis
Clostridial infections
Chronic copper toxicosis

Decreased Erythrocyte Production

Anemia of inflammatory disease (chronic inflammation, neoplasia)
- Chronic pneumonia
- Chronic abscessation
- Johne's disease
- Chronic bovine virus diarrhea infection
- Lymphoma

Less Common Causes

Blood Loss

Hemorrhagic enteritis
Hemoabdomen
Bleeding diathesis associated with disseminated intravascular coagulation (DIC)
Moldy sweet clover toxicosis
Caudal vena cava syndrome
Severe acute pyelonephritis

Hemolysis

Babesiosis
Theileriosis
Mycoplasma spp. infection
Postparturient hemoglobinuria
Immune-mediated hemolytic anemia

Decreased Erythrocyte Production

Anemia of chronic renal failure
Bracken fern toxicosis (also hemorrhage in enzootic hematuria)
Radiation toxicosis
Myelofibrosis (pygmy goats)
Myelophthisis

result of blood loss or hemolysis are typically regenerative, whereas those that are the result of decreased erythrocyte production will be non-regenerative.

A regenerative response in the ruminant is best identified by a moderate to marked degree of polychromasia or a reticulocytosis. Note that following an acute episode of hemorrhage or hemolysis in ruminants, it takes 2 to 4 days for the bone marrow to respond by beginning to release increased numbers of polychromatophilic cells/reticulocytes into circulation. Peak bone marrow response generally occurs within 7 days. This time frame must be kept in mind when assessing peripheral blood for indicators of regeneration. Other findings that can support the regenerative nature of an anemia would be an increased MCV, a decreased MCHC, basophilic stippling, nRBCs, increased numbers of Howell-Jolly bodies, and increased anisocytosis. It may take 2 to 4 weeks or more in ruminants for the HCT to return to normal after an episode of hemorrhage or hemolysis.

As noted previously, classifying an anemia as regenerative or non-regenerative is more difficult in the horse because of the relative absence of peripheral indicators of regeneration (e.g., polychromasia, reticulocytosis). In these patients, serial CBCs can be performed to detect increasing HCT over time. Similar to ruminants, it takes about 4 days for the bone marrow to begin to respond to an episode of hemorrhage or hemolysis. Mild increases in the MCV can be seen in some horses with regenerative anemias. The bone marrow response to anemia in horses is relatively sluggish compared with other species, and it may take up to 1 to 2 months following severe hemolysis or 2 to 3 months following severe hemorrhage for HCT values to return to normal.[10] In both horses and ruminants, the regenerative response to hemolysis is generally considered to be somewhat more vigorous than the response to hemorrhage. It is suggested that this may be in part due to the fact that in hemolysis, iron (from Hgb) is not lost from that body and is then made available for production of new erythrocytes. Evaluation of bone marrow can also be performed in horses to evaluate for a regenerative response. Enumeration of polychromatophilic cells and reticulocytes in the bone marrow, assessment of overall cellularity, and calculation of the myeloid to erythroid ratio (M:E) are used to determine if a regenerative response is

present. Excessive hemodilution of the bone marrow sample and the variable M:E ratios present in normal animals, however, can complicate interpretation in some cases.

Blood Loss

Immediately following an episode of acute blood loss, the HCT and plasma protein concentration are generally within the reference interval. The HCT in horses can actually increase mildly above baseline in some cases as a result of splenic contraction. It is only after fluid shifts have occurred from the interstitial space into the vasculature that the HCT and plasma protein concentration begin to decrease. Increased thirst and renal conservation of free water contribute to the fluid shifts that will continue to occur over a 24- to 48-hour period as vascular volume is restored. Hypoproteinemia concurrent with anemia is supportive of hemorrhage as the cause, assuming there are no other significant sources of protein loss (e.g., gastrointestinal [GI] or renal). Evidence of regeneration should also be present if sufficient time has passed since the episode of blood loss. In some cases, the source of blood loss is obvious (e.g., trauma, surgery, severe epistaxis), whereas in other cases more cryptic sources of blood loss must be investigated. Evaluation of the patient for endoparasites, ectoparasites, hematuria, GI blood loss (e.g., ulcers, neoplasia), and hemoabdomen is warranted in these instances. Chronic blood loss, commonly from parasitic causes, GI ulcers, or GI neoplasia, can result in an iron deficiency anemia. Supportive findings for iron deficiency anemia are decreased MCV, decreased MCHC, hypochromic erythrocytes, and a mild degree of erythrocyte fragmentation (i.e., schistocytes and keratocytes). Iron-deficiency anemia is initially regenerative but, if ongoing, can become poorly regenerative to non-regenerative. Hypoproteinemia may be present; however, protein concentration is within the reference interval in some animals because protein loss is compensated by increased production by the liver. Iron deficiency anemia can also occur in young foals and calves as a result of low dietary intake.[11] An iron panel can be performed to confirm iron deficiency.

Hemolysis

Hemolysis results in a regenerative anemia often with a normal to increased plasma protein concentration. Erythrocyte morphology should be assessed for evidence of Heinz bodies, eccentrocytes, schistocytes, erythrocyte parasites, and agglutination. Hemolyzed plasma and hemoglobinuria are supportive of an intravascular hemolytic process, whereas icterus and hyperbilirubinemia support extravascular hemolysis. Hemoglobinuria, however, should be differentiated from hematuria and myoglobinuria, and liver disease and anorexia (in the horse) should be ruled out as causes of the icterus and hyperbilirubinemia. Feed and/or pasture should be evaluated if ingestion of an oxidant is suspected. Additional diagnostics to consider in cases of hemolytic anemia are Coombs testing (IMHA) and Coggin testing (equine infectious anemia).

Decreased Erythrocyte Production

Anemia of inflammatory disease, often the result of infection, inflammation, or neoplasia, is the most common cause of a mild to moderate non-regenerative anemia. An inflammatory leukogram and hyperfibrinogenemia would be supportive of the presence of a systemic inflammatory response. Chronic renal failure can also result in a non-regenerative anemia of variable severity (moderate to severe) and can initially be assessed by a serum biochemical profile and urinalysis. Feed and/or pasture conditions and drug history should be determined to prioritize other causes of anemia resulting from decreased erythrocyte production. Bone marrow evaluation is indicated to investigate unexplained non-regenerative anemias, especially when other cytopenias are present.

Erythrocytosis

Erythrocytosis (polycythemia) refers to an increased RBC count, Hgb concentration, and HCT. Erythrocytosis can be either relative or absolute in nature (Box 24-3). In general, relative erythrocytosis is far more common than absolute, and these causes should be considered or ruled out first. With relative erythrocytosis, there is no actual increase in total body erythrocyte mass; however, hemoconcentration or splenic contraction causes apparent increases in these measures in the peripheral blood. Hemoconcentration is most often due to dehydration and loss of plasma volume (e.g., diarrhea, excessive sweating, water deprivation, diuresis). Endotoxic shock can also result in hemoconcentration because of increased vascular permeability and subsequent fluid shifts from the intravascular to extravascular space. In both cases, plasma volume is decreased, effectively concentrating the erythrocytes in circulation. With dehydration, increased plasma protein concentration and clinical evidence of dehydration (e.g., skin tent, tachy mucous membranes, sunken eyes) would be supportive. Epinephrine-mediated splenic contraction as the result of excitement, pain, fright, or vigorous exercise can also cause a relative erythrocytosis as a result of redistribution of relatively high HCT splenic blood into the peripheral circulation. This is most often seen in the horse. Plasma protein concentration is not expected to increase with splenic contraction as compared with dehydration. Erythrocytosis caused by splenic contraction is a transient change and typically normalizes within a few hours if the inciting stimulus has been removed.

BOX 24-3

Causes of Erythrocytosis in Large Animals

Relative Erythrocytosis

Dehydration
Endotoxic shock
Splenic contraction

Absolute Erythrocytosis

Primary

Primary erythrocytosis

Secondary Appropriate

Chronic pulmonary disease
Right-to-left cardiovascular shunting
Residence at high altitude

Secondary Inappropriate

EPO-secreting neoplasms
Renal pathology causing local hypoxia

Absolute erythrocytosis occurs when there is a true increase in total erythrocyte mass as a result of increased erythropoiesis and can be primary or secondary in nature. Absolute erythrocytosis is considered secondary when it is in response to increased erythropoietin (EPO) levels or activity. This can be an appropriate physiologic response to chronic hypoxemia (e.g., chronic pulmonary disease, right-to-left cardiovascular shunting, or animals living at high altitude); however, tumor production of EPO or EPO-like substances or renal pathology causing local tissue hypoxia can result in a secondary erythrocytosis in the absence of systemic hypoxemia. Primary absolute erythrocytosis is considered a chronic myeloproliferative disease (primary erythrocytosis or polycythemia vera) where erythropoiesis occurs independent of EPO. There are rare reports of primary erythrocytosis in the horse.[12] Absolute erythrocytosis of unknown cause has also been described in a herd of Jersey calves and in a Japanese black heifer.[13]

Clinical evaluation of animals with an erythrocytosis should first begin by considering causes of relative erythrocytosis, since these are much more common. If dehydration, shock, and splenic contraction are ruled out and if the increased HCT persists over time without response to fluid therapy, then the erythrocytosis may be considered absolute. Arterial blood gas, thoracic radiographs, and echocardiography can help to identify decreased cardiorespiratory function and systemic hypoxia as the cause. Neoplasia (e.g., lymphoma,

VetBooks.ir

VetBooks.ir

hepatoblastoma, hepatocellular carcinoma) and renal disease should also be ruled out before considering the erythrocytosis primary in nature.[14-18] Bone marrow aspiration and biopsy are generally not helpful in differentiating causes of absolute erythrocytosis (i.e., primary vs. secondary) because erythroid hyperplasia would be expected in both cases. Serum EPO concentrations would be expected to be normal to low in primary absolute erythrocytosis and increased in secondary absolute erythrocytosis. This assay, however, is not widely available, and there is likely some overlap in EPO levels among patients with primary and secondary absolute erythrocytosis, making interpretation difficult in some cases.

Alterations in the Leukogram

LESLIE C. SHARKEY and JED A. OVERMANN, *Consulting Editors**

■ MAJOR ALTERATIONS

Neutrophilia, 382
Neutropenia, 383
Eosinophilia, 384
Basophilia, 384
Lymphocytosis, 384
Lymphopenia, 384
Monocytosis, 384

Interpretation of the leukogram in the context of the clinical history, physical examination, and the rest of the minimum laboratory database (complete blood cell count, serum biochemical data, and urinalysis) can provide valuable insights into the diagnostic process in large animal species. Often, leukogram data are used to evaluate patients for the presence of inflammation or hematopoietic neoplasia. Careful attention to sample collection and handling (see Chapter 23) will help ensure high-quality results. Key components of the leukogram include the total white blood cell count (WBC), differential cell counts including the absolute numbers of each leukocyte type, and a microscopic evaluation of the blood film. Blood film evaluation is necessary to visually verify the WBC, to generate the differential, and to evaluate the leukocytes for important morphologic abnormalities that contribute to the diagnostic interpretation of the quantitative data. Although the newer automated hematology analyzers will generate leukocyte differentials for numerous species, the Clinical Laboratory Standards Institute still considers the manual differential cell count to be the reference standard.[1] Microscopic examination of the blood film for the presence of toxic change, band neutrophils, reactive changes in lymphocytes, neoplastic cells, and organisms is required for a full characterization of the leukogram. The concurrent measurement of acute phase proteins can augment the diagnostic interpretation of leukogram data.

When evaluating the leukogram, clinicians should remember that each data set is a snapshot in time of a dynamic system in which the numbers of cells in the circulation reflect a balance between the release of cells from the bone marrow and egress of cells into the tissues. Serial monitoring of patients often provides more information than a single time point. It is also important to keep in mind that the numbers of cells trafficking in the circulation may not be reflective of the tissue content of cells; therefore, cytology or biopsy of tissues may be necessary to confirm the presence of inflammation or hematopoietic neoplasia.

Leukocytes

Leukocytes are partitioned into granulocytes (neutrophils, eosinophils, basophils) and mononuclear cells (lymphocytes, monocytes). In postnatal life, the main source of hematopoiesis is the bone marrow, except for lymphocytes, which migrate from the bone marrow to tissues such as the lymph nodes, spleen, and mucosal-associated lymphoid tissue after birth. The following sections will briefly describe the biology of each type of leukocyte, as well as the interpretation of high and low values and common morphologic abnormalities. Note that the reference intervals for some leukocyte subtypes encompass zero, making the detection of low values difficult and therefore the interpretation of questionable clinical significance (Table 25-1). Although reference intervals are provided here for guidance, clinicians should use laboratory-specific reference intervals because of the potential effect of instrumentation and geographic variation on leukocyte parameters. Other factors that influence reference intervals in large animal species include age, reproductive and lactation status, and other husbandry issues that are explored in further detail elsewhere.[2-4]

Neutrophils

Neutrophils develop from hematopoietic stem cells in a process that usually takes about 6 days under the influence of an array of cytokines. Some species can accelerate the process in situations of increased demand, but that capacity appears to be limited in cattle.[5] There is a storage pool of neutrophils in the marrow; however, once that is depleted, earlier precursors, including band neutrophils and sometimes metamyelocytes or even myelocytes, may be observed in the peripheral circulation in a phenomenon known as a "left shift." Neutrophils circulate for only a few hours after release, existing in either the circulating pool where they can be measured, or in the marginal pool along the endothelial surface where they are not recovered during blood sample collection. Shifts between the circulating and marginal pools in response to hormonal mediators can result in rapid changes in neutrophil numbers measured in the leukogram.

Neutrophils migrate into tissues, especially the gastrointestinal and respiratory tracts and the skin, through selectin-mediated rolling followed by integrin-mediated adhesion of neutrophils to the endothelium. Transmigration between or through endothelial cells allows neutrophils to enter the tissues, where they will bind to chemokines that direct them toward targets in the tissue. Receptor-mediated phagocytosis of bacteria and other particulate matter is followed by proteolytic digestion and/or the respiratory burst using granule contents. Neutrophils also amplify local inflammation and interact with cells of the adaptive immune response.[6] These mechanisms can result in damage to normal tissues in addition to the killing of infectious agents, contributing to acute respiratory distress syndrome and multiple organ failure. Senescent neutrophils undergo apoptosis in tissues and are cleared by tissue macrophages.

Some of the morphologic abnormalities that can be relevant to the interpretation of the leukogram in large animals include toxic change, Pelger-Huët and pseudo–Pelger-Huët anomalies, and the

presence of intracellular organisms including *Anaplasma phagocytophilum*. The common components of toxic change include cytoplasmic basophilia and vacuolization and the presence of Dohle bodies in the cytoplasm of neutrophils; rarer manifestations include nuclear abnormalities, toxic granulation, and increased cell size. Toxic change is subjectively evaluated during the blood film evaluation and graded as 1+ to 4+. These changes occur in the neutrophil cytoplasm during the development in the marrow and signal the likelihood of inflammation; toxic change may be accompanied by a left shift. Pelger-Huët anomaly is an incidental asymptomatic congenital condition in which a defect occurs in the segmentation of leukocyte nuclei, giving the impression of a severe left shift in the absence of toxic change or other signs of inflammation.[7] In contrast, pseudo–Pelger-Huët is pathologic hyposegmentation that occurs as a result of severe inflammation and is accompanied by toxic change and inflammatory disease. *Anaplasma phagocytophilum* is a tick-borne bacteria common to humans as well as small and large animal species that survives in neutrophils by avoiding the bactericidal mechanisms.[8] Organisms are most likely to be identified microscopically in acute infection, when serologic methods for detection may still be negative.

Eosinophils

Eosinophil development in the marrow is very similar to that of neutrophils, although it occurs under the influence of distinctive cytokines. Normally, eosinophils spend a short time in the circulation before entering the tissues using similar mechanisms to neutrophils, although the numbers in the peripheral blood are usually quite small. The tissue survival time of eosinophils is usually short; however, they may persist in tissues for longer periods if appropriate survival factors are present. Recirculation is even possible under some conditions. Although eosinophils have the capacity for phagocytosis, more prominent functions include defense against parasites by externalization of granule contents and modulation of inflammation, particularly allergic and hypersensitivity disorders. Eosinophils are primarily tissue dwelling cells, so numbers in the circulation may not accurately reflect tissue eosinophilia.

Basophils

Basophil development largely parallels that of eosinophils, although it is associated with a specific growth factor repertoire. Basophils are the least numerous leukocyte in the peripheral blood under most conditions, where, like other granulocytes, they circulate briefly before entering tissues through similar mechanisms. With even less phagocytic and bactericidal potential than eosinophils, basophils are important in hypersensitivity responses and allergic conditions, which they mediate through release of their granule contents into the local environment. The accuracy of basophil counts by automated analyzers has been questioned.

Lymphocytes

Lymphocytes encompass a heterogeneous group of mononuclear leukocytes fundamental to the adaptive immune response, although some, like natural killer cells, are aligned with innate immunity. Circulating lymphoid cells are generally divided into natural killer cells, B-cells, and T-cells, with an expanding number of T-cell varieties being characterized, each with a specific function. Advanced diagnostic techniques such as flow cytometry are required to identify cells from different lymphocyte subsets, which are not routinely distinguished during blood film evaluation. All originally derive from bone marrow stem cells; however, T-cells complete maturation in the thymus and participate in cell-mediated immunity, whereas B-cells develop in the marrow and other peripheral tissues to eventually disperse throughout the body to effect humoral immunity. Unlike most leukocytes in the peripheral blood, lymphocytes have significant potential for proliferation. Lymphocytes continually recirculate among tissues in a process called "trafficking," which is most relevant for T-cells because B-cells release antibodies that are carried by the circulation to relevant sites. At any given time, only a tiny fraction of an animal's lymphocytes are present in the circulation, so the peripheral blood lymphocyte count is not reflective of total body lymphoid activity. Likewise, advanced diagnostic techniques are required to characterize the lymphocyte subsets in circulation, which may change with different pathologic processes.

Monocytes

Monocytes develop in the bone marrow and enter the circulation, where they persist longer than other leukocytes. Like other leukocytes, monocytes migrate into tissues; however, they have the potential to differentiate into a variety of macrophage subtypes (e.g., Kupffer cells, alveolar macrophages, microglial cells) depending on the local microenvironment. Monocytes can re-enter the circulation from the tissues. Unlike mature granulocytes that are post-mitotic, monocytes have a limited capacity for replication in tissues. The major functions of macrophages once in the tissues include inhibiting the growth of intracellular pathogens, antigen processing, removal of dead cells and debris, control of iron metabolism, and complex regulation of the inflammatory response. Depending on the stimuli, macrophages can develop into proinflammatory M1 macrophages or antiinflammatory M2 cells.[9]

Principles of Leukogram Interpretation

As noted previously, the absolute numbers of leukocyte subtypes are interpreted in the context of appropriate reference intervals. If there are questions about the validity of available reference intervals, clinicians should consider the option of submission of samples for comparison from one or more age- and sex-matched unaffected individual(s) sharing the husbandry conditions and genetics of the patient of interest. Although individual abnormalities are discussed in the following sections, integration of all of the leukogram data to identify diagnostic patterns is often the best approach.

Neutrophilia

Although bacterial infection is the most common cause of neutrophilia in large animal species, noninfectious inflammatory processes such as traumatic tissue damage, surgery, and immune-mediated hemolytic anemia can also cause increased neutrophil concentrations (Boxes 25-1 and 25-2).[10] A left shift and toxic change provide

Septic metritis
Septic (coliform) mastitis
Diffuse peritonitis
Ruptured uterus with peritonitis
Ruptured abomasal ulcer
Acute salmonellosis
Acute pneumonia
Toxemia- or toxin-induced bone marrow suppression
Fat cow syndrome (fatty liver)
Clostridial infection

Uncommon Causes

Bovine virus diarrhea
Bracken fern toxicosis
Trichloroethylene toxicosis
Radiation toxicosis
Idiopathic aplastic anemia

additional evidence of an inflammatory cause for neutrophilia, but they may not always be present, especially with mild or chronic compensated inflammation. In fact, normal neutrophil numbers do not exclude infectious or inflammatory diseases because the numbers of circulating cells do not reflect tissue activity in all conditions. Neutrophilia can signal the presence of otherwise difficult-to-detect processes such as extrapulmonary *Rhodococcus equi* infection in foals,[11] musculoskeletal *Corynebacterium pseudotuberculosis* infection,[12] meningitis/meningoencephalomyelitis in horses,[13] and liver abscesses in dairy cattle.[14] Stress resulting from causes such as transport and changes in housing can be another important cause of neutrophilia in cattle.[15] Marked neutrophilia occasionally follows a period of neutropenia induced by inflammation (overshoot effect), and very rare genetic causes such as bovine leukocyte adhesion deficiency have been documented. Some authors advocate the use of a neutrophil:lymphocyte ratio to augment the interpretation of absolute neutrophil and lymphocyte numbers on the basis that ruminants have been described to have greater numbers of lymphocytes than neutrophils in the circulation under normal circumstances. Recent information on bovine leukocyte reference intervals suggests that clinicians should exercise caution with that approach and consider laboratory- and herd-specific information when interpreting the ratio.[16]

Neutropenia

Endotoxemia results in rapid redistribution of neutrophils from the circulating pool to marginal pool and tissues. Neutropenia resulting from bone marrow depletion is often observed in large animal species during the first 24 to 48 hours of an acute inflammatory episode, especially in cattle (Boxes 25-3 and 25-4).[17] Persistent neutropenia is a poor prognostic sign or may indicate bone marrow pathology if other peripheral cytopenias are present. Transient viral infections in cattle such as bovine viral diarrhea virus and bluetongue virus can cause neutropenia, as can some tick-borne diseases. As for any species, toxic damage to the marrow or bone marrow necrosis,

fibrosis, or neoplasia can result in generalized peripheral cytopenias, including neutropenia. Alloimmune neonatal neutropenia has been reported in horses.[18]

Eosinophilia

Eosinophilia is not common in large animal species, even when parasitism can be demonstrated (Boxes 25-5 and 25-6). This may be related to the tissue predilection of eosinophils and the relatively short transit time from marrow to target tissue. Rare hypereosinophilic syndromes have been described that are accompanied by peripheral eosinophilia, such as idiopathic chronic eosinophilic pneumonia in horses.[19] Paraneoplastic eosinophilia resulting from lymphoma has been reported in multiple species. Although eosinopenia may characterize the corticosteroid response in most species, it is difficult to recognize because the lower limit of the reference interval is often zero.

Basophilia

Basophilia is rare in large animal species and is often attributed to hypersensitivity responses; basopenia is not recognized as clinically significant.

Lymphocytosis

Lymphocytosis characterizes an epinephrine response (especially in young horses), as well as antigenic exposure (Boxes 25-7 and 25-8). The lymphocytosis caused by antigenic stimulation may be accompanied by morphologic changes in lymphocytes, including reactive lymphocytes that have increased amounts of cytoplasm, cytoplasmic basophilia, increased azurophilic granules, or larger cell size. Spontaneous lymphoid leukemias are described sporadically in horses, whereas bovine leukemia virus causes persistent lymphocytosis in a third of infected cattle and leukemia in approximately 4%.[17]

Lymphopenia

The most common cause of lymphopenia in large animal species is corticosteroid effects, although the acute phase of systemic infectious diseases may also be associated with a transient period of lymphopenia (Boxes 25-9 and 25-10). Rarely, congenital combined immunodeficiency syndromes, especially in Arabian and Arabian-cross foals, cause severe lymphopenia and global depletion of lymphoid tissues.

Monocytosis

Monocytosis can be seen with inflammation, tissue necrosis, or occasionally as part of a stress leukogram. Because the reference intervals for monocytes approach or include zero, monocytopenia is not a diagnostically useful observation (Box 25-11).

VetBooks.ir

Approach to Interpretation of the Leukogram in Horses

Reference intervals for equine patients are often wide due to the inclusion of a range of ages and breeds; the benefits of using more specific reference intervals must be balanced against the preference for reference intervals generated by the laboratory performing the testing.[20] As an approximation, 20,000 leukocytes/μL indicates a moderate leukocytosis, 30,000/μL is marked, and greater than 30,000/μL is considered extreme. Marked rebound neutrophilia can be observed after an episode of neutropenia resulting from neutrophil depletion caused by acute inflammation/endotoxemia. Foals often have greater absolute numbers of neutrophils and lower numbers of lymphocytes than adult horses for the first several months of life. Variable effects of training on leukocyte counts have been reported.

Epinephrine-mediated (physiologic) leukocytosis is observed more frequently in horses than in many other species, particularly in young warm and hot bloods and horses that are not habituated to transport or handling. This type of leukocytosis is typically characterized by a mild mature neutrophilia and a moderate lymphocytosis that persists for about 20 to 30 minutes. In contrast, the corticosteroid leukogram is less age or breed specific and includes a moderate mature neutrophilia with no left shift or toxic change, lymphopenia, eosinopenia, and inconsistent monocytosis. Corticosteroid leukograms are more persistent than physiologic leukocytosis and can frequently be superimposed on inflammatory leukograms because of the stress of illness.

Leukemias are rare but have been reported in horses. Lymphocytic leukemia is the most common, frequently associated with high lymphocyte counts and/or immature lymphocytes. Other forms of myeloid leukemia may present with large numbers of atypical cells originating from any myeloid lineage. Disruption of the hematopoietic microenvironment by proliferating neoplastic cells often suppresses the production of other cell lines.

Approach to Interpretation of the Leukogram in Ruminants

Most sources report that neutrophils predominate in neonatal calves and lambs, with a reversal of this ratio about a week after birth.[17] One study examining reference interval data in Holstein cows longitudinally from 1957 through 2010 suggests that over time, mean neutrophil counts have increased while other leukocyte counts have dropped.[16] A survey of other laboratories suggested that this observation had been made elsewhere but was not universal. Potential causes hypothesized include genetic selection, changes in management practices, and decreased prevalence of viral pathogens such as bovine viral diarrhea and bovine leukosis virus. Because a predominance of neutrophils compared with lymphocytes regardless of whether absolute cell counts deviate from the reference intervals has been used as an indicator of inflammatory disease in cattle, these findings may be significant to ruminant leukogram interpretation. In light of these findings, clinicians should be especially attentive to the source of reference intervals provided by laboratories.

Corticosteroid leukograms are relatively common in ruminants, as opposed to the changes associated with excitement, which are rare. Stress leukograms are commonly observed in cattle, sheep, and goats in the periparturient period. Stress leukogram changes are often superimposed on inflammation. As described previously, cattle have a sluggish marrow response to increased demand for neutrophils, resulting in the frequent observation of neutropenia in the first 24 to 48 hours after an acute inflammatory stimulus. Persistent neutropenia of more than 3 to 4 days indicates marrow suppression or inability of the marrow to respond to excessive tissue demands. As in the horse, rebound neutrophilia may ensue, often accompanied by a significant left shift that may include myelocytes and metamyelocytes in addition to band neutrophils. The left shift will resolve as neutrophil numbers increase with marrow compensation for increased demand. In chronic or low-grade inflammation, there may be no abnormalities in the leukogram, in which case evaluation of acute phase proteins may be helpful. The leukogram responses of sheep to inflammation generally mirror the bovine, whereas goats tend to respond more like small animal species with less frequent periods of leukopenia in response to inflammation.

MAJOR ALTERATIONS

Hyperproteinemia, 387
Panhyperproteinemia, 387
Hyperglobulinemia, 388
Acute phase response, 388
Hypoproteinemia, 390
Hypoalbuminemia, 390
Panhypoproteinemia, 391

Serum or plasma protein measurements constitute a vital component of laboratory diagnostic evaluations. Globulin and total protein measurements will be higher in plasma than serum because of the presence of coagulation proteins, particularly fibrinogen. It is vital to use appropriate reference intervals for the sample type. The following measurement techniques are widely used (units for the following serum or protein measurements are g/dL or the SI unit g/L):

Refractometry: The total protein concentration of serum, plasma, or body fluids can be determined via refractometry. The principle of measurement is that the degree of light refraction by a solution is proportionate to the concentration of solids. Refractometers are calibrated under the assumption that the solids are entirely proteins. However, other substances can increase the refractive index of a solution and falsely increase the total protein reading (e.g., marked hyperglycemia with glucose concentration of 700 mg/dL or azotemia with blood urea nitrogen concentration of 300 mg/dL can falsely increase the protein reading by 0.6 g/dL).[1] Hemolysis does not alter refractometer protein readings. The effect of marked icterus is unclear.[2]

Biuret reaction: Serum protein is commonly measured via modified biuret testing on automated analyzers. The principle involves basic spectrophotometry measuring color change following copper binding to peptide bonds. Depending on the specific assay, hemolysis can cause a positive interference (e.g., hemoglobin of 400 mg/dL can cause a 12% positive bias).[3] This method is not sensitive to very low protein concentrations (e.g., in cerebrospinal fluid).

BCG albumin binding: Albumin concentration in serum or plasma is usually measured via the bromocresol green (BCG) reaction. The principle involves basic spectrophotometry measuring color change when BCG binds to albumin. Nonspecific BCG binding to globulins can artifactually inflate the albumin value, particularly with a very low albumin concentration.[4] Plasma albumin values can be increased over serum values because of nonspecific plasma globulin binding. Also, heparin interference can increase or decrease an albumin reading depending on the assay.[5] Globulins are typically calculated by subtracting the albumin value from the total protein value.

Protein electrophoresis (PE): Serum or plasma proteins can be separated into albumin and globulin fractions electrophoretically. The principle of measurement is that an electrical charge is applied to a cellulose acetate or agarose gel matrix, allowing serum/plasma proteins to migrate through the matrix and separate into bands based on their charge and size. The acetate or gel is stained to detect the protein bands and read via densitometry to generate a tracing. Albumin has a low molecular weight (roughly 66 kD), is highly anionic, and migrates the farthest to form a band near the anode. The identical nature of all albumin molecules and therefore their migration to a single band generates a single sharp, narrow-based peak on the tracing. Globulins are divided into α-, β-, and γ-globulin regions in ruminants. In horses, globulins are further divided into α_1-, α_2-, β_1-, β_2-, and γ-globulin regions (Fig. 26-1). The heterogeneity of globulin fractions results in broad-based peaks for each, as the diverse proteins in each region migrate slightly differently. Rarely, a narrow-based peak will be seen in the γ-globulin region (see Hyperglobulinemia section). The presence of coagulation proteins will cause higher globulin peaks on protein electrophoresis of plasma (PPE) versus serum (SPE). In particular, fibrinogen will migrate into either the "late-beta" peak or the β-γ junction, and in rare cases might obscure the presence of a monoclonal peak.[6,7] Both α- and β-globulins include many acute phase proteins (see later), whereas immunoglobulins (antibodies), primarily IgG, comprise the γ-globulins. IgA and IgM are immunoglobulins that migrate in the β_2 or β-γ junction regions, but they are not detected in health via PE testing.

Immunoelectrophoresis: Immunoelectrophoresis is a specialized technique for quantification of each immunoglobulin subtype (e.g., IgG, IgM) via electrophoresis followed by immunoprecipitation using subtype-specific antibodies. Units are usually given in mg/dL. Other immunoglobulin measurements are designed specifically for detection of IgG in neonatal samples and are discussed under failure of passive transfer (see Chapters 19 and 53).

Reference values for proteins vary by species (Table 26-1). When evaluating protein concentrations in a patient, some clinicians use the ratio of albumin to globulins (A:G ratio). However, it is often simpler to evaluate albumin and globulins separately because the A:G ratio can change with alterations in one or both parameters.

Biologic variation with life stage: Transfer of immunoglobulins from the dam to the neonate via colostral ingestion is a key process that determines the neonate's subsequent immunocompetence and is often reflected in serum globulin levels in the first few weeks of life. In addition, neonates generally have lower serum albumin levels; for example, calves had decreased albumin values in the first 8 days of life.[8] Total protein levels in calves are decreased at birth, rise immediately following colostrum intake, then fall below the reference interval again at about 2 weeks of age and remain subnormal for some time.[8] IgG measurement also reflects

*Contributions to previous editions by Debra Deem Morris and Janet K. Johnson are acknowledged.

VetBooks.ir

the combined presence of maternal and neonatal proteins (Fig. 26-2). Studies in cows found gradually increasing plasma globulin levels during pregnancy until 4 weeks pre-parturition, then a steady drop until parturition.[9] IgG_1 production is greatly increased at parturition and the half-life is decreased, corresponding with transfer to colostrum.[10] Serum total protein steadily increased during lactation in Danish landrace goats.[11] In pregnant and lactating mares, significant differences in albumin, globulins, and total protein were not found at any stage.[12] Aging can be associated with alterations in some laboratory parameters. However, no significant differences in biochemical parameters or specific concentrations of IgG, IgA, or IgM were found in aged horses, despite alterations in lymphocyte populations.[13,14]

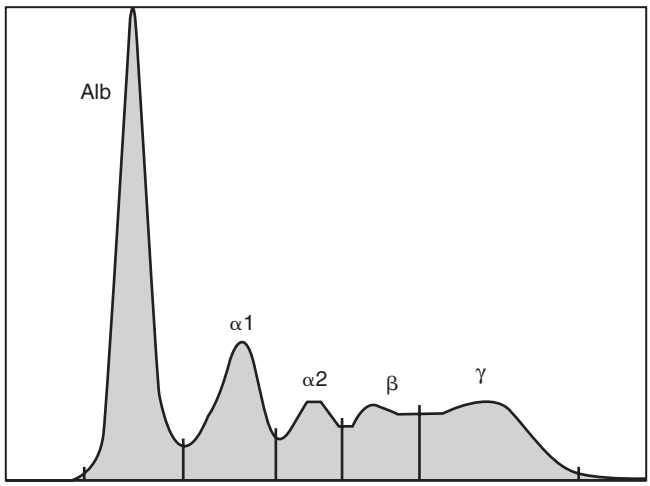

FIG. 26-1 Normal equine serum protein electrophoresis. *alb,* Albumin.

Hyperproteinemia

Hyperproteinemia can result from an increase in both albumin and globulins (panhyperproteinemia) or only globulins (hyperglobulinemia) (Boxes 26-1 and 26-2).

Panhyperproteinemia

An increase in the concentration of all blood proteins results from hemoconcentration. Dehydration (resulting from decreased fluid intake, excessive fluid loss, or both) causes panhyperproteinemia with an associated increase in packed cell volume (PCV). This is due to a relative increase in protein and RBC concentrations as they become more concentrated in blood. True hyperalbuminemia (i.e., increased albumin synthesis) does not occur. Hyperalbuminemia is an insensitive indicator of dehydration. If the true albumin level is decreased, a dehydrated patient may have a normal albumin result, masking effects of hemoconcentration. Similarly, a dehydrated, anemic animal may have hyperproteinemia with a normal or decreased PCV. In an animal with a plasma protein concentration of 7.0 g/dL in health, a 10% decrease in plasma volume (severe dehydration) will result in a plasma protein concentration of 7.8 g/dL.[2] As with albumin measurement, the total plasma protein measurement will underestimate the degree of dehydration if the patient is losing protein along with fluid. This is relatively common in renal disease, in protein-losing enteropathy with diarrhea, and in third-space loss when fluid and protein accumulate in the thoracic and/or abdominal cavity. Dehydration alone can result from GI fluid sequestration, including intestinal obstruction, vagal indigestion with internal vomiting, and grain engorgement. Less common causes of dehydration include polyuria with renal failure, exudation from extensive skin wounds, and excessive sweating. Physiologic responses to dehydration include increased urine concentration and decreased urine output, increased fluid absorption from the gastrointestinal (GI) tract, and increased thirst.

BOX 26-1

Causes of Hyperproteinemia in Horses

Panhyperproteinemia-Dehydration

Common Causes

Acute toxic colitis of unknown cause
Acute salmonellosis
Potomac horse fever
Intestinal clostridiosis
Intestinal strangulating obstruction
Proximal enteritis
Gram-negative sepsis, endotoxemia
Botulism
Choking (esophageal obstruction)

Less Common Causes

Chronic renal failure
Chronic hepatic disease
Guttural pouch mycosis with dysphagia
Equine protozoal myelitis
Salt toxicity
Toxins, poisonous plants
Lead toxicity
Yellow star thistle poisoning (dysphagia)
Dysphagia of unknown cause

Hyperglobulinemia

Common Causes

Abdominal (mesenteric) abscess (including "bastard" strangles)
Pulmonary abscess
Chronic pleuritis
Purpura hemorrhagica
Equine infectious anemia

Less Common Causes

Chronic hepatic disease
Strongylosis
Lymphoma
Immune-mediated cytopenia

BOX 26-2

Causes of Hyperproteinemia in Ruminants

Panhyperproteinemia-Dehydration

Common Causes

Ruminal acidosis (grain overload)
Abomasal torsion
Acute salmonellosis
Peritonitis
Sepsis, toxemia (mastitis, metritis)
Intussusception
Vagal indigestion
Oral or pharyngeal foreign body with dysphagia
Coccidiosis
Diarrhea, undifferentiated
Salt toxicity
Toxins, poisonous plants

Less Common Causes

Renal amyloidosis
Lymphoma
Pregnancy toxemia
Rabies

Hyperglobulinemia

Common Causes

Abdominal abscess (traumatic reticuloperitonitis, uterine tear, other)
Chronic pneumonia
Umbilical abscess
Lymphoma
Caseous lymphadenitis (sheep and goats)
Other abscess

Less Common Causes

Parasitism
Pregnancy

Hyperglobulinemia

The most common cause of hyperglobulinemia with normal hydration status (i.e., without hemoconcentration) is inflammation resulting in increased production of numerous globulins, including many acute phase proteins (see Acute Phase Response section). Chronic inflammation frequently results in a nonspecific increase in γ-globulins *(polyclonal gammopathy)* resulting from production of different immunoglobulins by plasma cells in response to chronic antigenic stimulation. A broad-based peak will be seen on SPE in the γ region, and can extend into the β region as a result of production of IgM and/or acute phase β-globulins. An increase in both β- and γ-globulin fractions (β-bridging) can occur with intense antigenic stimulation, chronic active hepatitis, or lymphoma. Increased IgG in the γ-globulin fraction is termed *hypergammaglobulinemia* and can be seen in a range of chronic inflammatory diseases, including internal abscessation, chronic hepatitis, immune-mediated diseases (e.g., immune-mediated hemolytic anemia or thrombocytopenia), and lymphoma. Infection with the agent of epizootic bovine abortion triggered significant increases in IgG in clinically affected heifers.[15]

Increased production of a single immunoglobulin by a clonal population of B lymphocytes/plasma cells is known as a *monoclonal gammopathy.* On SPE, the monoclonal peak is as narrow-based and sharp as the albumin peak as a result of the identical migration of the monoclonal immunoglobulins (also known as paraproteins). Monoclonal gammopathies are usually the result of neoplasia of B lymphocytes or plasma cells, including B-cell lymphoma, multiple myeloma, and B-cell lymphocytic leukemia. Increased susceptibility to hemorrhage can occur with monoclonal gammopathy as a result of impaired platelet function caused by immunoglobulin coating, and it can be exacerbated by hyperviscosity syndrome.

Acute Phase Response

Acute inflammatory processes can trigger an acute phase response. Infectious causes are common but many noninfectious causes (e.g., trauma, strenuous exercise) are also documented. The body's response to the inflammatory insult is altered liver production of many proteins, termed *acute phase proteins* (APPs). A few proteins are negative APPs and their production decreases with acute inflammation. Albumin is the most prominent negative APP, and levels will decrease in circulation proportionate to its half-life in each species. For example, the albumin half-life is 19.4 days in horses and 16.5 days in cattle, so hypoalbuminemia caused by inflammation will take several weeks to develop in these species.[4,16] Transferrin and transthyretin (prealbumin) are other negative APPs, as is apolipoprotein A-1 (see following sections on specific APPs). The presumed role of decreased production of certain proteins is to shift available amino acids to the synthesis of proteins that are useful in host defense.[17]

Most reactants are positive APPs, meaning production increases with inflammation. They migrate in the α- and β-regions on SPE or PPE. The positive APPs are a diverse group including proteins involved in coagulation, opsonization, iron regulation, and limiting of tissue injury. Protein electrophoresis can reveal increased globulin fractions that are comprised largely of APPs. Some diseases cause fairly specific alterations (e.g., internal parasitism in diarrheic horses caused increased β-1 globulin levels that were significantly higher than those in diarrheic horses with other disorders).[18] Nonprotein assays are also used to diagnose an acute phase response (e.g., serum iron outperformed plasma fibrinogen as an indicator of acute inflammation in horses).[19]

Measurement of individual APPs can be useful diagnostically and is not limited to blood; assays for APPs in milk and saliva have also proven useful.[20-22] The following is a list of major APPs in large animals.

VetBooks.ir

BOX 26-3

Causes of Hyperfibrinogenemia in Horses

Abscess (abdominal or other)
Chronic peritonitis
Pleuritis
Pneumonia
Osteomyelitis
Septic arthritis
Cholelithiasis
Neoplasia with inflammatory response
Vasculitis (equine purpura hemorrhagica)
Cellulitis
Gastrointestinal inflammation
Salmonellosis

BOX 26-4

Causes of Hyperfibrinogenemia in Ruminants

Acute mastitis, especially coliform
Abscess
Traumatic reticuloperitonitis, pericarditis
Salmonellosis
Gastrointestinal inflammation
Pyelonephritis
Endocarditis
Pleuritis
Pneumonia
Chronic peritonitis
Necrotic rumenitis
Lymphoma
Septic arthritis
Cellulitis
Omphalophlebitis
Osteomyelitis

TABLE 26-2

Useful Acute Phase Proteins (APPs) in Large Animal Species

APP	References for Use in Each Species

Fibrinogen

Fibrinogen is a useful marker of inflammatory disease in large animals. Increased plasma fibrinogen, termed *hyperfibrinogenemia,* can occur in a myriad of conditions. Fibrinogen is semiquantitatively measured via the heat precipitation method, along with total plasma protein, as part of the routine CBC. Serum samples cannot be used to measure fibrinogen. The heat precipitation method cannot be used to detect hypofibrinogenemia (see Chapter 27).

As for other proteins, fibrinogen can be increased as a result of dehydration. Calculating the plasma protein : fibrinogen (PP : F) ratio is useful when fibrinogen is increased. If the PP : F is greater than 15, hyperfibrinogenemia is due to dehydration. If the PP : F is less than 10, the patient has true hyperfibrinogenemia (caused by inflammation).[23] Severe inflammatory disease in horses and ruminants consistently causes hyperfibrinogenemia, although the increase in fibrinogen may not be proportionate to the degree of inflammation. Increased fibrinogen often precedes development of an inflammatory leukogram in ruminants, particularly in cattle.[23] Hyperfibrinogenemia can persist for a period of time postoperatively. In one study, more than half of horses undergoing subchondral bone cyst removal still had hyperfibrinogenemia 15 days postoperation[24]; in another, fibrinogen remained increased through day 11 following laparotomy and other procedures.[25]

In adult horses, a number of conditions including colic, sterile inflammation, surgical intervention, and chronic internal abscessation are all associated with hyperfibrinogenemia (Box 26-3).[24,26-28] Vaccination of horses induces an acute phase response including increases in both fibrinogen and serum amyloid A.[29] Fibrinogen response in foals is more variable. In healthy neonatal foals, fibrinogen levels are initially lower than adult values and then equilibrate within a few weeks of age.[30,31] Hyperfibrinogenemia lags behind leukocytosis as an indicator of inflammation.[30,32] Fibrinogen was an unreliable marker of foal sepsis in one study,[33] although marked hyperfibrinogenemia of 900 to 1500 mg/dL had utility as a diagnostic marker of foal osteomyelitis.[34] Fibrinogen may be useful as an indicator of foal pneumonia resulting from *Rhodococcus equi;* one study found that hyperfibrinogenemia had greater specificity than leukocytosis, but another reported better diagnostic performance (encompassing both sensitivity and specificity) for leukocytosis over hyperfibrinogenemia.[35,36]

Fibrinogen is a particularly useful indicator of inflammation in cattle and other ruminants as they develop substantial hyperfibrinogenemia in response to inflammation (Box 26-4).[37] A number of inflammatory diseases in cattle are associated with hyperfibrinogenemia including peritonitis, mastitis, and pneumonia. Lymphoma and uncomplicated displaced abomasum (without peritonitis) did not present with hyperfibrinogenemia.[37] Fibrinogen is reportedly low to undetectable in neonatal calves.[38] One study of healthy calves reported a peak in fibrinogen at postnatal day 6 (mean value 400 mg/dL), then a gradual decline until reaching a mean nadir of 250 mg/dL at day 50 followed by a slight rise; values always remained within the reference interval for adult cattle.[8] Fibrinogen was significantly increased in calves with suspected septic shock.[39]

Other Acute Phase Proteins

The usefulness of individual APP measurement in diagnosis of inflammatory disease varies by species (Table 26-2). The following APPs have proven utility in one or more large animal species.

Haptoglobin

When haptoglobin enters the circulation, it immediately binds hemoglobin to form a complex that is then internalized by hepatic Kupffer cells.[40] Increased haptoglobin during the acute phase response occurs as a result of transcriptional activation. Haptoglobin may regulate and modulate the immune response during inflammation.[41] Haptoglobin is increased in the first week postpartum in dairy cows.[42] Measurement of haptoglobin in milk is superior to measurement in serum for diagnosis of mastitis, although serum measurement is also useful.[20,43] Haptoglobin performs well as an acute phase marker in sheep, with increases found during inflammatory diseases including bacterial metritis and pneumonia.[44,45]

C-Reactive Protein

In health, C-reactive protein (CRP) is present in trace amounts in circulation. Inflammation and tissue necrosis can markedly upregulate CRP levels.[46] The role of CRP in the acute phase response may be clearance of endogenous or exogenous substances (e.g., microorganisms, cellular debris), but it may also worsen inflammatory tissue damage via complement activation.[47] Dairy cattle have increased CRP levels during lactation that are highest at peak lactation and

VetBooks.ir

decline thereafter; mastitis and other inflammatory diseases caused further increases (e.g., a threefold increase in CRP levels in mastitic cows compared with healthy lactating cows).[48] Increased CRP has been associated with pneumonitis, enteritis, and arthritis in horses.[49]

Serum Amyloid A

The serum amyloid A (SAA) protein family of apolipoproteins includes both constitutively expressed proteins and acute phase reactants that are markedly upregulated during inflammation.[50] The induced proteins chemotactically recruit leukocytes and are implicated in the pathogenesis of chronic inflammation, since they are precursors of the amyloid A protein in amyloidosis. As with haptoglobin, SAA is increased in the first postpartum week in dairy cows, and measurements of milk SAA levels are superior to serum levels to diagnose mastitis, although both are useful.[20,42,43]

Apolipoprotein A-1

Apolipoprotein A-1 (Apo A-1) is a negative acute phase reactant in humans and domestic animals. Apo A-1 is associated with high-density lipoproteins. A role as a constitutive antiinflammatory factor has been posited for Apo A-1.[51]

Ceruloplasmin

Ceruloplasmin (CP) plays a key role in iron metabolism, and CP-bound copper accounts for 95% of plasma copper concentration. CP interacts with several proteins including ferritin, neutrophil myeloperoxidase, and lactoferrin.[52] Equine CP increases with sterile inflammation and surgical manipulation. Transient changes in CP occur in mares immediately before and after foaling.[53]

α2-Antiplasmin

α2-Antiplasmin (α2-AP) is a fibrinolytic inhibitor via its specific inactivation of plasmin. Measurement of increased plasmin α2-AP complexes is one indicator of fibrinolysis. α2-AP is increased in horses with colic, as is plasminogen, and may reflect a role as an acute phase biomarker.[28,54]

Pig Major Acute Phase Protein

Pig major acute phase protein (pigMAP; ITIH4) is the porcine homolog of a human kallikrein-sensitive protein and is a useful indicator of inflammatory diseases.[55,56] The related proteins in humans, pigs, and rats have been designated collectively as ITIH4, a new member of the inter-α-trypsin inhibitor (ITI) protein family with unknown biological function. Recently the utility of ITIH4 as an acute phase reactant in cattle was also described.[57]

Ferritin

Ferritin is an iron storage and transport protein. Ferritin levels can markedly increase during infectious and other inflammatory disorders, presumably to sequester iron and limit availability to microbes.[58] Species-specific assays are generally needed to measure ferritin. An equine-specific assay is available and has some cross-reactivity with other species.[59] Ferritin has shown usefulness as a biomarker in horses. Strenuous exercise also causes an increase in ferritin that persists for up to 2 days.[60]

α1-Acid Glycoprotein

Also known as orosomucoid, α1-acid glycoprotein (α1-AG) is a carrier of basic substances including therapeutic drugs and steroids. Increased α1-AG values have been found in cattle with various inflammatory disorders, including mastitis and traumatic pericarditis.[61]

Hypoproteinemia

Hypoalbuminemia

Albumin is the most abundant of the plasma proteins. It accounts for approximately 75% of plasma colloidal oncotic pressure (COP), and in turn its synthesis is primarily regulated by COP. Albumin is a nonspecific transport protein for a number of substances including calcium, lipids, and hormones and serves as an amino acid source for body tissues. Hypoalbuminemia is caused by a decrease in albumin production and/or an increase in albumin loss, most commonly renal or GI loss (Boxes 26-5 and 26-6). As described previously, decreased albumin synthesis is a common component of the acute phase inflammatory response. Overall hypoproteinemia does not occur, partly because the decrease in albumin is usually mild and partly because of the corresponding increase in globulins.

Albumin production can decrease with chronic insufficient intake of amino acids. In particular, protein-energy malnutrition can lead to hypoalbuminemia more quickly than total starvation.[62] Hypoalbuminemia is an indicator of chronic malnutrition given albumin's relatively long half-life, and clinical signs relating to hypoalbuminemia develop over a prolonged period. GI disorders that disrupt normal protein digestion and absorption can lead to decreased protein synthesis and are discussed as follows under protein-losing enteropathies.

BOX 26-5

Causes of Hypoproteinemia in Horses

Hypoalbuminemia

Common Causes

Parasitism
Glomerulonephritis
Pyelonephritis
Idiopathic granulomatous enteritis
Intestinal lymphosarcoma
Parasitism
Salmonellosis
Equine ehrlichial enterocolitis (Potomac horse fever)
Colitis
Clostridiosis
Nonsteroidal antiinflammatory drug toxicosis

Less Common Causes

Chronic hepatic fibrosis (pyrrolizidine alkaloid toxicity and other causes)
Hepatic neoplasia
Chronic hepatitis
Amyloidosis
Tuberculosis
Histoplasmosis
Chronic eosinophilic gastroenteritis
Starvation/malnutrition

Panhypoproteinemia

Common Causes

Excessive fluid therapy or water intake
Acute blood loss
Gastrointestinal ulceration
Strangulating gastrointestinal obstruction, infarction
Protein-losing enteropathy (chronic granulomatous bowel disease)
Acute severe peritonitis
Nonsteroidal antiinflammatory drug toxicity
Glomerulonephritis

Less Common Causes

Blood-sucking gastrointestinal or external parasites
Intestinal lymphosarcoma
Urinary blood loss
Congenital vascular disorders: renal trauma
Renal calculi
Pyelonephritis
Neoplasia
Cystic calculi
Disseminated intravascular coagulation
Immune-mediated thrombocytopenia
Congestive heart failure

VetBooks.ir

BOX 26-6

Causes of Hypoproteinemia in Ruminants

Hypoalbuminemia

Common Causes

Protein malnutrition, starvation
Amyloidosis
Pyelonephritis
Glomerulonephritis
Salmonellosis
Johne's disease
Trichostrongylus infection

Less Common Causes

Chronic liver failure
Intestinal lymphangiectasia
Intestinal lymphoma

Panhypoproteinemia

Common Causes

Excessive intravenous fluid therapy or water intake
Acute blood loss
Abomasal ulceration
Blood-sucking gastrointestinal or external parasites
Gastrointestinal ulceration

Less Common Causes

Ingestion of caustic chemicals
Strangulation, infarction of intestine
Congestive heart failure
Pyelonephritis
Urinary tract blood loss

Although albumin is produced by the liver, synthesis generally does not decrease in acute liver disease. Chronic, diffuse liver diseases such as chronic hepatitis, fibrosis, and hepatic neoplasia may cause hypoalbuminemia. Because the half-life of albumin is longer in horses and cattle than in dogs and humans, hypoalbuminemia is uncommon in large animal hepatic disease but can occur in conditions such as chronic hepatic lipidosis or chronic pyrrolizidine alkaloid toxicosis. In one study, 6% of horses with acute liver disease and 18% of those with chronic liver disease were hypoalbuminemic; increased globulins were found in 64% of all horses with liver disease.[63] Decreased albumin and increased globulins can indicate a poorer prognosis in horses with liver disease.[64] A potentially more useful indicator of liver disease in horses than hypoalbuminemia is a post-albumin shoulder (a small hump on the right [cathodal] side of the albumin peak) on SPE; this shoulder can also appear with acute inflammatory disease or severe hypoalbuminemia.[23,65]

Excessive albumin loss usually occurs through the urinary and GI tracts. Less common causes include chronic blood loss (acute blood loss is associated with panhypoproteinemia) and burns or other exudative skin disease. Normal urine contains little or no protein as a result of resorption of filtered small proteins in the proximal tubule. Transient physiologic proteinuria, sometimes referred to as "functional proteinuria," can occur with exercise, stress, seizures, and excessive protein intake, as well as following colostrum ingestion in neonates. These are (mostly) prerenal sources of proteinuria and do not cause hypoproteinemia.[66]

Renal proteinuria arises as a result of diseases of the glomeruli and/or proximal tubules; hemorrhage or inflammation within the kidney is another cause but is often categorized under postrenal proteinuria. Albumin is readily filtered through defects in the glomerular basement membrane because of its lower molecular weight. Proteinuria caused by glomerular lesions consists largely of albumin and can result in hypoalbuminemia and overall hypoproteinemia, whereas tubular proteinurias do not produce hypoalbuminemia.[66] Glomerulonephritis, amyloidosis, and less commonly pyelonephritis are top differentials for glomerular disease leading to proteinuria and hypoalbuminemia.[67]

Protein-losing enteropathy (PLE) is a GI condition resulting in net loss of protein from the body, as a result of abnormal loss of protein from the GI tract and/or inability of the GI tract to absorb proteins. PLE is not a disease itself; it is a manifestation of numerous GI disorders. The diagnosis of PLE includes ruling out urinary protein loss, body cavity effusion, increased protein catabolism, and decreased synthesis resulting from liver disease. The clinically important mechanisms of PLE are defective lymphatic transport, increased mucosal permeability, GI parasitism, exudative inflammation, and/or ulcerative blood loss. Hypoalbuminemia can be useful both diagnostically and prognostically in PLE. In a study of horses with diarrhea, albumin was lower in horses that died than in those that survived, likely reflecting albumin leakage across inflamed intestinal mucosa.[18]

In horses, the most common cause of PLE is idiopathic granulomatous enteritis, one of the chronic inflammatory bowel diseases of the horse.[12] Other causes of equine PLE include acute enterocolitis including bacteria-associated disease; GI lymphoma and other GI neoplasia; nonsteroidal antiinflammatory drug (NSAID) toxicity, including phenylbutazone; GI parasitism; and other conditions in the chronic inflammatory bowel disease group, including intestinal tuberculosis, histoplasmosis, and eosinophilic gastroenteritis. Proliferative enteritis of foals or yearlings caused by *Lawsonia intracellularis* infection often presents with hypoalbuminemia or panhypoproteinemia.[68,69]

The most common cause of chronic PLE in ruminants is infection with *Mycobacterium avium* subsp. *paratuberculosis,* or Johne's disease. Intestinal protein loss in Johne's disease arises both from mucosal lesions and secondary intestinal lymphangiectasia.[70] Other differentials include parasitism such as *Trichostrongylus* infection, intestinal lymphangiectasia, and GI lymphoma.

In addition to the previously mentioned causes of decreased albumin production and increased albumin loss from the body, hypoalbuminemia can also arise from dilution within the body. Redistribution of albumin into subcutaneous tissues and higher-protein body cavity effusions can result in hypoalbuminemia. Edema and peritoneal effusions may be contributory to the severe acute hypoalbuminemia described in fescue toxicity in horses.[71] Some edematous and effusive disorders such as congestive heart failure (see next section) can cause either hypoalbuminemia or panhypoproteinemia.

The clinical sequelae of hypoalbuminemia relate to the decrease in COP and subsequent fluid shift. Severe hypoalbuminemia (e.g., from protein-losing nephropathy or chronic liver disease) can cause a very low-protein effusion called a *transudate*. Other clinical signs of hypoalbuminemia include edema of the limbs, head, and ventrum. The albumin level generally must be below 1.5 g/dL in horses and below 1 g/dL in ruminants before clinical signs occur. A correlate of the longer albumin half-life in large animals is that albumin replacement is also slower, resulting in more clinically significant edema resulting from hypoalbuminemia.[65]

Panhypoproteinemia

Vigorous fluid therapy or excess water intake can cause dilution of plasma proteins and subsequent relative panhypoproteinemia. Panhypoproteinemia resulting from both dilution and increased GI protein loss occurs frequently in patients with acute GI disease receiving intravenous fluid therapy.

Acute blood loss with subsequent interstitial fluid shift into the vasculature, as well as volume expansion during pregnancy, can also cause relative panhypoproteinemia. Acute blood loss results in loss of all plasma proteins; interstitial fluid then rapidly shifts into the intravascular space to help maintain volume. This dilution effect is intensified by increased water intake that commonly occurs after acute blood loss. Acute hemorrhage resulting from trauma, severe epistaxis, or internal vascular rupture should be ruled out in a hypoproteinemic, anemic animal.

VetBooks.ir

GI disorders can lead to panhypoproteinemia via loss of either blood or protein alone. Differentials for GI blood loss include abomasal or gastric ulcers, blood-sucking parasites (e.g., *Haemonchus contortus* in ruminants), viral or bacterial infection, azotemia, neoplastic invasion, or exposure to caustic chemicals. NSAID toxicosis and strangulating GI obstructions or infarctions can result in mucosal necrosis and leakage of plasma proteins into the gut lumen. Although protein-losing enteropathy usually initially causes hypoalbuminemia, panhypoproteinemia often develops over time. Proliferative enteropathy of young horses (described previously) often results in panhypoproteinemia.[68] Acute severe peritonitis with massive protein exudation caused by GI rupture can also quickly lead to hypoproteinemia.

Other conditions resulting in clinically significant blood loss include urinary tract disorders caused by congenital vascular disorders, renal trauma, renal or cystic calculi, pyelonephritis, and renal neoplasia. Coagulopathies, including disseminated intravascular coagulation (DIC) or immune-mediated thrombocytopenia, may cause either external blood loss via the GI or urinary tract or internal bleeding into body cavities.

Congestive heart failure may cause either hypoalbuminemia or panhypoproteinemia via several mechanisms including dilutional effects from plasma volume expansion, protein loss into ascitic fluid and the interstitium, and decreased albumin synthesis caused by hepatic congestion and/or concurrent inflammation.[72]

Alterations in Hemostasis

JENNIFER L. JOHNS, *Consulting Editor**

MAJOR ALTERATIONS

Thrombocytopenia, 393
Thrombocytosis, 394
Platelet function defects and von Willebrand disease, 395
Prolonged prothrombin time, 395
Prolonged activated partial thromboplastin time, 396
Increased fibrin and fibrinogen degradation products, 397
Decreased plasma antithrombin III, 397
Hypofibrinogenemia, 398
Other tests of hemostatic function, 398

The standard diagnostic test panel to evaluate coagulation in large animals includes platelet count, plasma fibrinogen, prothrombin time (PT), partial thromboplastin time (PTT), and serum fibrin and fibrinogen degradation products (FDPs). Proper collection and preparation of blood samples are paramount in obtaining accurate results (see Chapter 23). Platelet counts are routinely performed as part of the complete blood cell count (CBC). Citrated blood is required for coagulation testing and can also be used for platelet analysis. It is critical to have a 1:9 ratio of citrate to whole blood. The patient's hematocrit can affect coagulation results when whole blood is used. When the hematocrit is over 55%, correction to a lower citrate volume is recommended to prevent overcitration and prolonged coagulation times.[1] If the laboratory does not have reference intervals for a particular species, plasma from two or more healthy animals should be collected and assayed in a similar manner for comparison. Table 27-1 shows reference values for platelets and fibrinogen, but laboratory-specific values are preferable for these analytes and are necessary for other coagulation parameters.

Platelet Parameters

The platelet count is technically the platelet concentration in whole blood. Units = [platelets] × 10^3/μL; SI units = [platelets] × 10^9/L. Automated analyzers are routinely used to generate a platelet count. A rough estimate can be made via manual smear review: at 100× oil objective, the total number of platelets in 10 fields is counted. This count is then divided by 10 to yield an average number. This average is multiplied by a 15,000 to 20,000 conversion factor to yield [platelets]/μL.[2] Both this estimate and the automated platelet count will be artifactually decreased if platelet clumps are present. Cattle normally average around 8 to 10 platelets per 100× oil objective field, and horses normally have 5 platelets or more per field.[2]

Mean Platelet Volume

The mean platelet value (MPV) is the mean or average platelet volume and is measured in femtoliters (fL). This value is an average and does not represent the range of platelet volumes. Increased MPV is consistent with increased release of large/giant platelets and usually indicates a platelet regenerative response. The measurement of reticulated platelets (analogous to reticulocytes) may become widely accepted as another index of platelet regeneration.

*Contributions to previous editions by Debra Deem Morris are acknowledged.

Platelet Distribution Width

The platelet distribution width (PDW) is a calculated range of platelet volumes (representing anisocytosis), analogous to the red blood cell (RBC) distribution width. It is expressed as a percentage, and a higher percentage indicates a greater variation in platelet volume. The PDW in combination with the MPV value can indicate whether there are increased numbers of smaller and/or larger platelets.

Thrombocrit

Also called the platelet-crit, the thrombocrit value is a function of the platelet count and the mean platelet volume. It is a better indicator of the total platelet functional potential than the platelet count, as a result of the greater functional capacity of larger platelets.[3]

Thrombocytopenia

A decrease in the circulating platelet count is termed *thrombocytopenia*. Thrombocytopenia is caused by one of three basic mechanisms: platelet sequestration, decreased platelet production, and decreased platelet lifespan caused by consumption or destruction (Boxes 27-1 and 27-2). Spurious thrombocytopenia occurs occasionally in horses when blood is collected into EDTA anticoagulant, causing in vitro platelet clumping.[4] Platelet clumps are visible in the stained blood smear and may be indicated by error messages on an analyzer. Collection of a second sample into sodium citrate can yield an accurate platelet count and confirm a suspicion of spurious thrombocytopenia. Heparinized samples are not recommended for platelet counts because heparin-induced clumping can occur in any species. If citrated samples are used for platelet counts, the count must be corrected for citrate dilution (i.e., multiplied by 1.1).

Splenic platelet sequestration can occur as a result of splenomegaly. Splenomegaly occurs due to various disorders including infiltrative diseases such as lymphoma, leukemia and multiple myeloma, and infectious and other inflammatory diseases such as immune-mediated hemolytic anemia that result in splenitis, lymphoid hyperplasia, and/or splenic extramedullary hematopoiesis. In addition, congestive splenomegaly occurs when the venous outflow is occluded by torsion, intestinal displacements, or congestive heart failure. Platelet sequestration is a relative thrombocytopenia resulting from redistribution (vs. an absolute thrombocytopenia), is reversible, and does not result in increased bleeding tendency.

Decreased platelet production can occur with various bone marrow disorders, including myelophthisis (replacement of normal marrow). Myelophthisis is often due to marrow infiltration with neoplastic cells (e.g., plasma cells in multiple myeloma) and can result in

BOX 27-1

Causes of Thrombocytopenia in Horses

Common Causes

Disseminated intravascular coagulation
Immune-mediated thrombocytopenia (drugs: penicillin, trimethoprim-sulfadoxine)
Endotoxemia, septicemia (e.g., acute toxic colitis, intestinal strangulating obstruction, neonatal septicemia)
Equine infectious anemia
Equine anaplasmosis *(Anaplasma phagocytophilum)*
Lymphoma

Less Common Causes

Salmonellosis
Equine viral arteritis
Equine influenza
Myeloproliferative disease (myelogenous leukemia)
Plasma cell myeloma
Aplastic anemia
Stachybotryotoxicosis
Neonatal alloimmune thrombocytopenia

BOX 27-2

Causes of Thrombocytopenia in Ruminants

Common Causes

Disseminated intravascular coagulation
Bracken fern *(Pteridium aquilinum)* toxicosis
Septic mastitis or metritis (endotoxemia)

Less Common Causes

Salmonellosis
Gram-negative sepsis
Trichloroethylene-extracted soybean meal
Lymphoma
Plasma cell myeloma
Immune-mediated thrombocytopenia
Stachybotryotoxicosis
Myelofibrosis (pygmy goats)

pancytopenia. Familial myelofibrosis was reported in pygmy goats and resulted in marked pancytopenia, including thrombocytopenia with myelophthisis.[5] Toxic damage to the marrow (e.g., from bracken fern toxicosis or nonsteroidal antiinflammatory drug administration) can result in myelosuppression and potentially aplastic anemia. Immune-mediated destruction of megakaryocytes, a variant of immune-mediated thrombocytopenia, causes decreased platelet production and release. Infectious agents can cause decreased platelet production via either indirect effects on megakaryocytes (e.g., equine infectious anemia virus) or by direct infection of megakaryocytes (e.g., acute bovine viral diarrhea infection).[6,7] Evaluation of a bone marrow aspirate and core biopsy is indicated to evaluate megakaryocyte numbers and assess for dysplasia in a patient that is either persistently thrombocytopenic without evidence of peripheral consumption or destruction, or pancytopenic.

Blood loss is a rare cause of thrombocytopenia; it is more likely that any concurrent bleeding is the result rather than the cause of severe thrombocytopenia. Studies in dogs found that acute severe blood loss induces a mild to moderate thrombocytopenia, with up to 50% reduction in platelet count.[2] Rapid dilution of the blood volume with aggressive fluid therapy can decrease the platelet count as well as other hemostatic elements. The decrease is generally mild to moderate.

Platelet lifespan can be reduced by destruction of platelets or by platelet consumption in widespread coagulation. Immune-mediated platelet destruction is a common cause of thrombocytopenia in horses. Immune-mediated thrombocytopenia (IMT) can be either idiopathic or a result of various etiologies including viral and bacterial infections, drug administration, and hemic neoplasia.[7-10] Thrombocytopenia caused by idiopathic IMT is often marked, in contrast to thrombocytopenia from other causes. The thrombocytopenia of equine anaplasmosis resulting from infection with *Anaplasma phagocytophilum* is apparently multifactorial; an element of IMT is possible but not supported by experimental studies.[11,12] Neonatal alloimmune thrombocytopenia has been reported in horses, mule foals, and pigs and is caused by colostral antibodies against foreign (paternal) epitopes on the neonate's platelets.[2]

Excessive consumption of platelets occurs with disseminated intravascular coagulation (DIC). DIC is a clinical condition of disordered hemostasis that arises as a result of severe trauma; infectious or other inflammatory diseases, including septicemia; and disseminated neoplasia.[13] Examples include DIC in horses with colic, calves with septic shock, and pigs with spontaneous heatstroke.[14-17] The diagnosis of DIC in most species relies on finding evidence of both platelet and coagulation factor consumption (thrombocytopenia with one or more coagulation test abnormalities, described later) along with evidence of increased fibrinolysis (see the Increased Fibrin and Fibrinogen Degradation Products section). Snake envenomation directly causes platelet destruction in the absence of typical DIC as some snake venoms contain platelet-activating factors. Endothelial damage or necrosis (e.g., resulting from equine viral arteritis infection) can also result in platelet destruction with or without concurrent DIC.[18]

Clinical Signs of Thrombocytopenia

Thrombocytopenia is characterized by petechial or ecchymotic hemorrhages on the oral, nasal, and/or vaginal mucous membranes and the nictitans, sclerae, pinnae, and ventral abdomen. Epistaxis, melena, hyphema, and/or hematuria may occur, although spontaneous hemorrhage is rare unless the platelet count drops below 10,000 to 20,000/μL. Concurrent inflammation can increase a thrombocytopenic patient's propensity for spontaneous hemorrhage.[19] Prolonged bleeding from injections or wounds and a propensity to form hematomas with minor trauma are relatively common with a platelet count below 40,000/μL.

Thrombocytosis

Thrombocytosis is an increase in platelet count over the reference interval. A physiologic increase in platelet count can occur at high altitude.[2] Relative thrombocytosis resulting from redistribution from splenic and other tissue stores can occur with exercise or epinephrine

VetBooks.ir

release. Splenectomy can result in thrombocytosis for several weeks because of both increased production as well as decreased platelet sequestration and destruction in the absence of the spleen.[2]

Absolute thrombocytosis can occur in a number of conditions as a secondary reactive change. Thrombocytosis resulting from any cause does not result in increased risk of thrombosis or any other clinical abnormalities; it is a reflection of the underlying disease(s). Many infectious and other inflammatory disorders including immune-mediated diseases can cause reactive thrombocytosis, as can surgery, neoplasia, and other inflammatory disorders. One infrequent cause of thrombocytosis in some species is iron deficiency, but this is not well documented in large animal species; chronic blood loss can be associated with thrombocytosis, and iron deficiency may be one factor. Administration of vincristine or vinblastine can result in thrombocytosis. Thrombocytosis can also occur as a rebound effect following prior thrombocytopenia. A rare cause of persistent severe thrombocytosis is primary thrombocythemia or other chronic myeloproliferative disease; bone marrow evaluation is indicated in this situation.

Platelet Function Defects and Von Willebrand Disease

Defects in platelet function have been described in large animals, but diagnosis can be challenging. The template bleeding test is routinely performed in small animals to assess primary hemostasis (e.g., platelet number/function and von Willebrand factor [vWF] function), but it is criticized for poor reproducibility in both humans and animals, including horses.[20] Template bleeding tests have been useful for monitoring effects on aspirin therapy on hemostasis in horses, and may be suitable for serial monitoring of a patient if other factors such as platelet count remain constant. Aggregometry is considered a gold standard assay for platelet function but can be cumbersome; automated platelet function analysis with the PFA-100 device has become a standard platelet function assay in human medicine and is emerging as a valuable assay in veterinary medicine. More specific assessment of platelet function can require specialized assays.

Glanzmann's thrombasthenia is a disorder resulting in poor platelet aggregation and clot retraction in humans and animals, and it is caused by one or more defects in quantity or quality of platelet surface glycoprotein IIb/IIIa. A Peruvian Paso mare was diagnosed with hereditary Glanzmann's thrombasthenia; the mare was 17 years old at the time of diagnosis.[21] Other hereditary thrombopathias are infrequently described in animals. Chediak-Higashi syndrome is reported in Hereford, Japanese Black, and Brangus cattle. The bleeding diathesis associated with this syndrome is defined by substantial impairment of platelet aggregation in response to collagen.[22] A hereditary thrombopathy in Simmental cattle is characterized by impaired platelet aggregation, with clinical signs including periodic epistaxis and severe hemorrhage following surgical procedures.[23] Inheritance of this thrombopathy appears to be multigenetic, and aggregometry was not useful at differentiating carrier versus clear animals. A variant form of von Willebrand disease has also been described in a Simmental calf.[24] Von Willebrand disease has been reported in Quarter Horses and consisted of a deficiency in high-molecular-weight multimers of vWF, consistent with type 2 von Willebrand disease in other species.[25]

Acquired defects in platelet function are common as a result of drug administration. Drugs that impair platelet function include aspirin, phenylbutazone, sulfonamides, estrogens, and phenothiazines.[14] Several underlying medical conditions can also negatively affect platelet function, including uremia and liver disease. Production of high levels of immunoglobulins, particularly IgM, in monoclonal gammopathies hinders platelet function via protein coating of platelet surfaces.

Prolonged Prothrombin Time

The PT, or one-stage prothrombin time, is a measure of the extrinsic (tissue factor) and common pathways of coagulation (Fig. 27-1). The assay tests the time after the calcium-thromboplastin reagent is added to the plasma sample until formation of a fibrin clot. The PT is prolonged when the fibrinogen level drops below 100 mg/dL or with a marked deficiency of one or more coagulation factors in the common pathway (factors II [prothrombin], V, and/or X) or the tissue factor pathway (VII).

Acquired defects in coagulation factors are much more common than inherited defects and generally involve deficiencies in multiple rather than single coagulation factors. Causes of acquired defects include hepatic disease, vitamin K antagonism (e.g., moldy sweet

Anticoagulant/rodenticide toxicosis
Hepatotoxins (pyrrolizidine alkaloids, rubratoxins, aflatoxins, bitterweed)
Hereditary fibrinogen deficiency

clover poisoning), and increased consumption via DIC (Boxes 27-3 and 27-4). The PT is usually the first abnormal coagulation test with decreased coagulation factor production in chronic liver disease.[14] Widespread coagulation and consumption in DIC also causes a prolonged PTT and thrombocytopenia, along with increased fibrinolysis. In addition to quantitative deficiencies, coagulation factors may be functionally impaired by increased FDPs or circulating anti-factor antibodies.

Vitamin K is necessary for hepatic production of functional coagulation factors II, VII, IX, and X as well as anticoagulant proteins C and S. The action of vitamin K is inhibited by coumarin compounds acquired via moldy sweet clover hay or anticoagulant rodenticide ingestion, or by therapeutic administration (e.g., warfarin in horses). Vitamin K inhibition results in deficient carboxylation of coagulation factors and a resulting inability to bind endothelium stably. These incompletely carboxylated factors are termed PIVKAs (or proteins induced by vitamin K antagonism/absence). A modified PT assay called the thrombotest PT is specific for defects in factors II, VII, and/or X and can be used in cases of suspected coumarin toxicosis; specific tests for PIVKAs are not available for domestic animals.

Clinical signs of coagulation factor deficiencies include spontaneous hemorrhage (e.g., epistaxis, melena, and hematuria) or prolonged bleeding after trauma, diagnostic procedures, or surgery. Hematomas or hemarthroses are common after minor trauma or normal exercise, and bleeding into body cavities can occur. Coagulation times are designed primarily for screening purposes and are very insensitive to minor defects of one or more factors (e.g., the PT was prolonged with factor VII levels ranging from 16% to 39% in one study).[1] Less severe coagulation defects may require specific factor assays for diagnosis.

Prolonged Activated Partial Thromboplastin Time

The partial thromboplastin time (PTT) is a measure of the intrinsic (contact activation) and common coagulation pathways (see Fig. 27-1). The activated PTT is now the only test used and measures time from the addition of calcium to plasma with partial thromboplastin reagent and a surface activator until clot formation. The PTT is prolonged with deficiencies or defects in factors XII, XI, IX, and VIII:coagulant (VIII:C) as well as prekallikrein (PK). Most PTT assays detect PK deficiency, and the assay can be corrected to prove that a PK abnormality is the cause of prolonged PTT. The activated coagulation time (ACT) is a simplified variation of the PTT that can be tested by mixing whole blood with activator and calcium. It is less sensitive to factor defects, since prolonged ACT may not occur until a single factor is at 5% to 10% of normal function, and it can be prolonged also with severe thrombocytopenia.[1] As with all tests, reference values vary by species; for example, alpacas have substantially shorter PTTs normally than horses or cattle.[26] Age may also play a role, since healthy newborn foals have PTTs and PTs that are longer than adult reference values.

The most common cause of a prolonged PTT is increased consumption of clotting factors induced by DIC (Boxes 27-5 and 27-6). Liver failure and vitamin K antagonism prolong both the PTT and PT. Single factor defects will prolong the PTT and not affect the PT. Inherited deficiencies of factors VIIIa (the precursor form of VIII:C), IX, and XI, as well as PK, have been described in horses.[27-31] Congenital factor VIIIa deficiency (hemophilia A) is sex linked and males are clinically affected; carriers cannot be detected via PTT as factor levels are insufficiently decreased. The level of factor VIIIa must drop below 5% of normal before spontaneous bleeding occurs. Clinical signs of coagulation factor deficiencies are those of hemorrhagic diathesis as described in the previous section. Inherited factor XI deficiency is transmitted in Holstein cattle by an autosomal recessive trait.[32] Cattle deficient in factor XI rarely demonstrate bleeding tendencies.

Although both the PT and PTT can be prolonged during DIC, it is not uncommon for only one test to be abnormal initially. Serial analyses should reveal a trend toward prolongation of both tests along with decreasing platelet count. When a persistently prolonged

PTT is the only laboratory abnormality, hereditary factor deficiency should be suspected. As with PT, the PTT is a relatively insensitive screening test. The assays generally have prolonged times when at least one factor is decreased to 30% or less of normal function. Both the PT and PTT can be shortened (times will be below reference interval) with increased fibrinogen, factor V, and/or factor VIII (PTT only). These shortened times are not reliable indicators of clinical hypercoagulability.

Increased Fibrin and Fibrinogen Degradation Products

FDPs can be comprised of fragments of fibrin and/or fibrinogen. Assays are either serum or plasma specific, since fibrinogen present in plasma can react to the polyclonal antibody of the serum assays, and are relatively species specific. A study in horses found that two FDP assays, one serum based and one plasma based, had low sensitivity for FDPs in horses with colic.[33] At the same time, a plasma D-dimer assay was a useful adjunct test. D-dimer (one form of FDP) is a cross-linked fibrin fragment and is therefore specific for fibrinolysis, whereas FDPs as a group are less specific. When measurable, increased levels of FDPs and/or D-dimer generally indicate increased fibrinolysis in response to excessive coagulation (Box 27-7). In addition to DIC, localized intravascular fibrin deposition following surgery, internal hemorrhage, sepsis, and other severe inflammatory processes may cause increased FDP levels. Plasmin perturbations may occur with snake envenomation, heat stroke, surgery, or administration of plasminogen activators and can lead to fibrinogenolysis and increased FDPs.[1] Decreased FDP clearance caused by hepatic or renal disease can also lead to increased FDP levels.

Increased serum FDPs can contribute in turn to hemorrhagic clinical manifestations of DIC by interfering with thrombin activity, fibrin polymerization, and platelet aggregation. Interpretation of FDP or D-dimer tests depends on evaluation of the other components of the hemostasis profile (platelet count, PT, PTT) in concert with the patient's history and clinical signs. Serum FDP levels over 40 µg/mL or plasma levels over 20 µg/mL most often occur with DIC; lower values do not exclude DIC. Horses have measurable D-dimer concentrations in health, so an upper cutoff value must be used to report abnormal values.[33] In one study, horses with clinical evidence of DIC resulting from colic had decreased D-dimer levels consistent with hypofibrinolysis during hypercoagulation.[17]

Decreased Plasma Antithrombin III

The physiologically most important inhibitor of coagulation is antithrombin or antithrombin III (ATIII). This low-molecular-weight glycoprotein primarily neutralizes activated factors IX, X, and II (thrombin) along with other coagulation proteins. Heparin is a necessary cofactor to potentiate ATIII and enable its rapid inhibitor activity. ATIII is measured via chromogenic assays to evaluate functional activity; activity is expressed as the percent relative to a species-specific plasma pool from healthy animals. Plasma ATIII levels may be reduced by decreased liver production, excessive use, loss from the intravascular compartment, or increased catabolism. Inherited ATIII deficiency is not reported in animals. Newborn foals normally have lower ATIII levels than adult horses.[34]

Chronic liver disease may result in failure to produce ATIII and a number of other important plasma proteins. However, horses with chronic liver disease were shown to have increased plasma ATIII levels.[35] These findings suggest that ATIII may behave as an acute-phase protein in horses, since some horses also had increased fibrinogen levels. A second group of horses in the study with acute diarrhea/colitis had decreased ATIII levels. ATIII is variably reported as a positive or negative acute phase protein in animals.[1,35] Estrogens may contribute to ATIII deficiency because of negative effects on synthesis.[1]

In conditions such as DIC, ATIII is consumed and can be decreased as a result of binding to activated coagulation factors and subsequent hepatic clearance of the ATIII-factor complexes. Any pathologic activator of coagulation including trauma, neoplasia, or sepsis may cause reduction of plasma ATIII (Boxes 27-8 and 27-9). ATIII can be reduced as a component of coagulopathy as a result of endotoxemia in foals.[36] Administration of unfractionated or low-molecular-weight heparin leads to decreased ATIII levels via increased activity and subsequent clearance of ATIII.[37]

Diseases that cause massive proteinuria or protein-losing enteropathy result in loss of ATIII in addition to other plasma proteins. Because of the small size of ATIII, it is lost in approximately the same proportion as albumin. Nephrotic syndrome in humans and animals may lead to secondary hypercoagulability and thrombotic disease caused by urinary ATIII loss and other complicating factors; hypoalbuminemia can be a useful predictor of thrombotic risk given concurrent loss of ATIII and albumin and may also play a contributory role.[38,39]

The major clinical sequela of ATIII deficiency is a tendency to develop venous thrombosis. Thrombosis in nephrotic syndrome was discussed earlier. Venous thrombosis is commonly recognized in horses with severe toxic colitis or endotoxemia, but the potential role of ATIII deficiency is unknown. Decreased ATIII has been documented in nonsurviving horses with colic and horses with strangulating obstructions.[40] The contribution of ATIII consumption in DIC to

VetBooks.ir

the clinical manifestations is complex and difficult to evaluate; however, use of ATIII concentrates in human patients with acute DIC has improved survival in some instances.[35] As with all components of the hemostatic system, plasma ATIII must be evaluated in combination with other hemostasis values.

Hypofibrinogenemia

Decreased fibrinogen concentration, termed *hypofibrinogenemia,* can be detected via a modified thrombin time (TT) test, the Clauss TT, or via immunoassay using anti-fibrinogen antibodies. Heat precipitation is useful to detect increased fibrinogen but is too insensitive to detect hypofibrinogenemia. Plasma fibrinogen levels represent the balance between fibrinogen production and degradation, an important concept in large animals because fibrinogen production is often increased as a result of inflammation and increased consumption may be masked. Pregnancy can also cause increased fibrinogen.[41]

Hypofibrinogenemia may result from impaired hepatic synthesis, increased consumption with DIC, or uncompensated loss during massive hemorrhage (Boxes 27-10 and 27-11). Decreased plasma fibrinogen is uncommon in liver disease of large animals; increased production caused by concurrent inflammation appears to be more common. With DIC and fibrinolysis, decreased fibrinogen concentration caused by consumption is expected in most species. However, hypofibrinogenemia is not common in horses with DIC. Horses with colic in one study had evidence of increased coagulation postoperatively, including decreased ATIII and increased D-dimer, with concurrent hyperfibrinogenemia.[42] Hypofibrinolysis has also been shown in horses with DIC.[17]

Hereditary afibrinogenemia has been described in a family of Saanen dairy goats with a hemorrhagic diathesis in newborn kids that included umbilical bleeding and recurrent hemarthroses.[14] Fibrinogen was undetectable in the affected animals, while heterozygotes had hypofibrinogenemia.

Other Tests of Hemostatic Function

Other tests of hemostasis may be indicated in specific disease situations and include the following tests.

Thrombin Time

The standard thrombin time test measures the rate of fibrinogen to fibrin conversion and can be a useful assay for the effects of FDPs, heparin, and paraproteins (e.g., a prolonged thrombin time can indicate the presence of FDPs that interfere with fibrin polymerization). This test also evaluates for the presence of hypofibrinogenemia, but the Clauss thrombin test (described earlier) is a better assay for that purpose because any interference effect from FDPs, heparin, and other factors is largely eliminated.

BOX 27-10

Causes of Hypofibrinogenemia in Horses

Acute hepatic necrosis
Acute severe disseminated intravascular coagulation
Severe hepatic fibrosis

BOX 27-11

Causes of Hypofibrinogenemia in Ruminants

Uncommon Causes

Hereditary afibrinogenemia (goats)
Acute severe disseminated intravascular coagulation

Specific Factor Assays

Specific factor assays are generally indicated for the diagnosis of hereditary factor deficiencies. Prolonged PTT values along with the signalment, history, and clinical picture may indicate that specific factor assays are needed. In DIC, specific factor analysis is unlikely to be useful.

α_2-Antiplasmin

α_2-Antiplasmin (α_2-AP) binds plasmin to cleave and inactivate it, and then the complexes are cleared from circulation. In humans, α_2-AP is decreased by severe liver disease (reduced production) and with DIC (consumption). Experimental studies in ponies suggest that α_2-AP may be reduced with chronic DIC.[43] Conversely, increased α_2-AP is reported in horses with colic as part of the acute phase response (see Chapter 26).

Protein C

The protein C pathway provides the second major anticoagulant mechanism that regulates hemostasis. Protein C is activated by thrombin complexed to thrombomodulin and subsequently inactivates factors Va and VIIIa via proteolysis and using the cofactor protein S. In humans, decreased protein C can occur in liver failure or DIC, increasing risk of thrombotic disease, and decreased protein C is reported in horses with severe colic.[40]

Collection and Analysis of Bone Marrow

ANDREA A. BOHN, *Consulting Editor*

The hematopoietic system is composed of erythrocytes, leukocytes, and platelets, their precursor cells, and the tissues that support the continuous cycles of cell differentiation required for maintenance of oxygen delivery, protection from infectious agents, and hemostasis. A single multipotent stem cell is the precursor for all hematopoietic cells. From this cell arise progenitor cells directed toward various cell lineages. Postnatally, hematopoiesis to replenish circulating erythrocytes, granulocytes, monocytes, and platelets predominantly occurs in the bone marrow. Although lymphocytic precursor cells continue to travel from the bone marrow to the thymic cortex and enteric mucosa for differentiation postnatally, most circulating lymphocytes are associated with the extramedullary lymphoid organs.

Constantly replenishing blood cells, the bone marrow is one of the most active tissues in the body. Blood cell turnover is rapid; for example, neutrophils have a circulatory half-life of approximately 10 hours. The lifespan of platelets, on average, is approximately 7 to 10 days, and the lifespan of large animal erythrocytes is approximately 5 months, with slightly shorter half-lives reported in some breeds.[1-3] Readers are referred to a veterinary hematology textbook for more in-depth information on the hematopoietic system.[4]

Indications for Bone Marrow Aspiration or Biopsy

Bone marrow evaluation provides important diagnostic information on the hematopoietic status of an animal; it is typically performed to evaluate hematopoiesis and to detect evidence of neoplastic or infectious disease (Box 28-1). The complete blood cell count (CBC) is the most common method used to evaluate the hematopoietic system, but a more comprehensive evaluation includes bone marrow aspiration and/or biopsy. Bone marrow aspiration is commonly used to evaluate the cause of cytopenia. Unexplained nonregenerative anemia, neutropenia, thrombocytopenia, and pancytopenia are indications for bone marrow aspiration. In these cases, bone marrow evaluation is used to determine if the cytopenia is more likely a result of lack of production or of consumption or destruction of the cell in question. If an animal's clinical presentation and other laboratory data provide a reasonable explanation for cytopenia, a decision to perform the procedure may not be justified. For example, if another disease process is present that could explain nonregenerative anemia, such as a chronic inflammatory disease or chronic renal failure, bone marrow aspiration is not indicated in most cases.

Another common reason for bone marrow aspiration is the observation of atypical cells, unexplained immature cells, or abnormal blood cell morphology on a peripheral blood film. In these cases bone marrow is evaluated for the diagnosis of leukemia, myelodysplastic syndromes, and infiltrative disease. Potential infiltrative disease is sometimes detected radiographically, and the presence of lytic or proliferative bone lesions can also be an indication for bone marrow aspiration. Because abnormalities within the bone marrow are not always reflected in the peripheral blood, it may be prudent to perform bone marrow aspiration if a neoplastic or infectious process is clinically suspected but cannot be found elsewhere. This suspicion may arise from finding cytopenias or detecting an unexplained hypercalcemia or monoclonal gammopathy, conditions that are often associated with neoplasia; identifying a fever of unknown origin; or recognizing the probability of an infectious agent that may have bone marrow involvement.

Even though complication rates are low, bone marrow aspiration should not be performed indiscriminately; as for all testing, the clinician should consider what question is being asked and if bone marrow evaluation is the appropriate diagnostic test for answering that question. Examination of a peripheral blood film often provides clues as to the necessity of bone marrow evaluation. In general, cytopenia should be persistent and confirmed before bone marrow evaluation is performed. Rechecking a low cell count by drawing a new blood sample, especially if initial results do not fit with the clinical presentation of the animal, is recommended. An ethylenediamine tetraacetic acid (EDTA)-associated pseudothrombocytopenia has been reported in horses,[5] which can be ruled out by drawing blood into a heparin or sodium citrate tube for platelet counts. A low platelet count can also be artifactual if platelet aggregation occurs during blood collection. The presence of clumped platelets on a peripheral blood film is an indication that platelet aggregation has occurred and that a low platelet count should be viewed with skepticism. Repeated CBCs can also be used to assess persistence of an abnormality. It can take up to 5 days for the bone marrow to respond to acute anemia and for regeneration to be evident in the peripheral blood. Bone marrow aspiration is typically not indicated when there is evidence of regeneration in the peripheral blood. Evidence of erythroid regeneration in the peripheral blood includes an increase in the number of reticulocytes or polychromatophilic cells, basophilic stippling, and macrocytosis. Because the changes typically associated with regenerative anemia are rarely seen in horses, bone marrow aspiration is often the only way to assess erythropoiesis in this species.

BOX 28-1

Indications for Bone Marrow Evaluation

To assess regeneration in anemic horses
To investigate cause of cytopenia
- Unexplained nonregenerative anemia
- Unexplained neutropenia
- Unexplained thrombocytopenia
- Pancytopenia

To investigate for neoplasia
- Atypical cells in peripheral blood
- Lytic or proliferative bone lesions
- Hypercalcemia
- Monoclonal gammopathy

To investigate for infectious disease
- Fever of unknown origin

Lytic or proliferative bone lesions

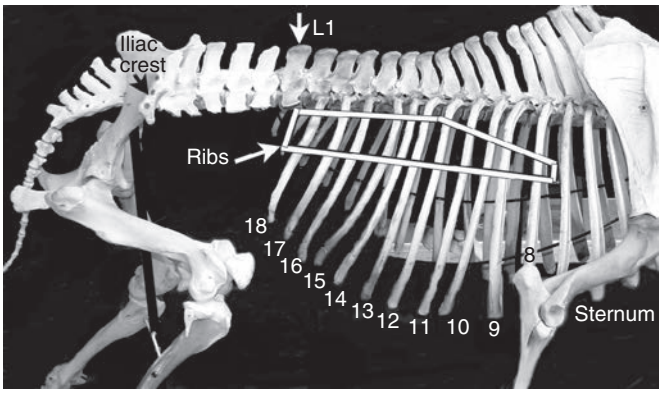

FIG. 28-1 Equine skeleton depicting sites for bone marrow aspiration: the sternum, iliac crest, vertebral ends of ribs 8 to 18, and first lumbar vertebra.

(See Color Plate 28-1, *A-D,* for an example of erythroid hyperplasia in a horse.) Evidence of regeneration in granulocytes includes the presence of a left shift and toxic changes.

Cytologic evaluation of a bone marrow aspirate is more commonly performed than core biopsy because results can be attained more quickly and the morphology of the cells is superior, allowing a more accurate assessment of cell types. The disadvantage of an aspirate versus biopsy is that architecture cannot be assessed with an aspirate and it can be impossible to confirm whether a poorly cellular sample is a result of a pathologic process or an unsatisfactory sampling. The core biopsy provides a better assessment of bone marrow cellularity and is necessary for the confirmation of myelofibrosis, generalized bone marrow suppression, or necrosis. (See Color Plate 28-2, *A-D,* for core biopsy samples of generalized bone marrow hypoplasia from a bovine.) The core biopsy also provides a more accurate assessment of metastatic neoplasia because architecture can be assessed. When collecting a bone marrow sample for cytologic evaluation, some clinicians will also collect a core biopsy to store in formalin in the event that histologic evaluation is later recommended.

If a bone marrow sample is being submitted for evaluation, it is recommended to always submit a concurrent peripheral blood sample for a CBC because interpretation of the bone marrow is dependent on CBC results and changes can occur quickly in the blood.

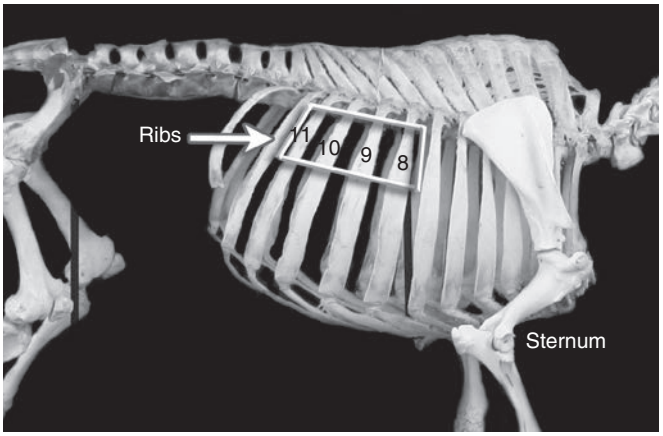

FIG. 28-2 Bovine skeleton depicting sites for bone marrow aspiration: the sternum and vertebral ends of ribs 8 to 11.

Bone Marrow Collection

Sites

Hematopoietically active bone marrow is most consistently found in the flat bones (sternum, ribs, pelvis, vertebrae) and proximal ends of long bones (humerus, femur). The most commonly described sites for bone marrow aspiration in large animals are the sternum, ribs, and iliac crest (Figs. 28-1 and 28-2). Which location is chosen may depend on species, age, and temperament of the animal as well as available facilities.

The ventral sternum is the preferred site in adult horses, small ruminants, and camelids (Figs. 28-3 to 28-6). It is one of the preferred sites in cattle (Fig. 28-7). The advantages of the sternum are that it is covered by only a thin layer of bone, it has areas not covered by thick muscles, and samples can be reliably obtained from the site. The disadvantages of the sternum are that it is near vital organs and that the operator is in an awkward position when working on a standing animal. A procedure for sampling the cranial aspect of the sternum has also been described in horses[6] (see Fig. 28-3). This approach involves going through more muscle.

The ribs are one of the preferred sites for bone marrow aspirates in cattle. The dorsal ends of ribs 8 to 11 can be accessed for sequential aspirations (see Fig. 28-2).[7] Ribs can also be used in the horse, but the needle slips off the bone more easily. In calves, sheep, and goats,

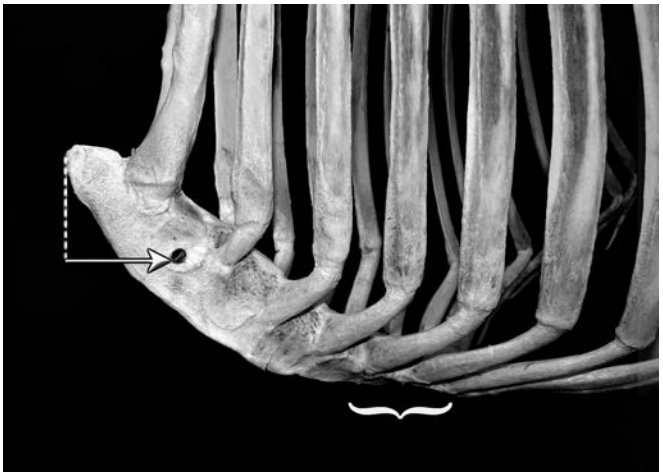

FIG. 28-3 Lateral view of equine sternum. The ventral sternum is the most popular site for sampling bone marrow in the adult horse *(bracket),* but the cranial sternum can also be used. The aspirate site of the cranial sternum is reached by going one hand width below *(dotted line)* and one hand width lateral to its cranial tip. From there, the needle is advanced in a horizontal plane at a 45-degree angle to the longitudinal axis of the horse *(arrow).*

the marrow cavity of the rib is small and more difficult to hit,[8] and in camelids the rib marrow is less consistent in location than the sternum.[9] Successful collection from ribs has been described in camels, with the fifth to eighth ribs as the best sites.[10]

The iliac crest is the site often used in foals for bone marrow sampling and can also be used in young adult horses up to a couple

FIG. 28-4 Ventral view of equine rib cage and sternum. *Arrows* depict optimal sites for sternal bone marrow aspiration or biopsy, on midline between the elbows of the horse.

FIG. 28-5 Cross-section of sheep sternum. The needle is entering the second sternebra. The second through fourth sternebrae are recommended as optimal sites for bone marrow collection.

of years in age[11] (Fig. 28-8). Samples can also be obtained from older horses at this site, but the needle must be inserted more deeply, needle placement is more critical, and it becomes difficult to obtain a successful sample in horses more than 9 years old.[12] The wing of the ilium is generally considered too thin for bone marrow aspiration

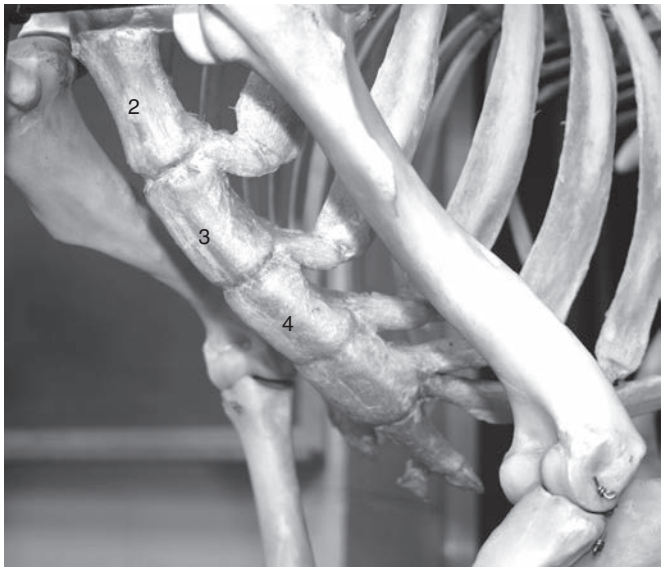

FIG. 28-6 Llama sternum. The llama sternum can be sampled at ventral midline, inserting the needle vertically through the callosity, or from a lateral approach, inserting the needle dorsal to the callosity.

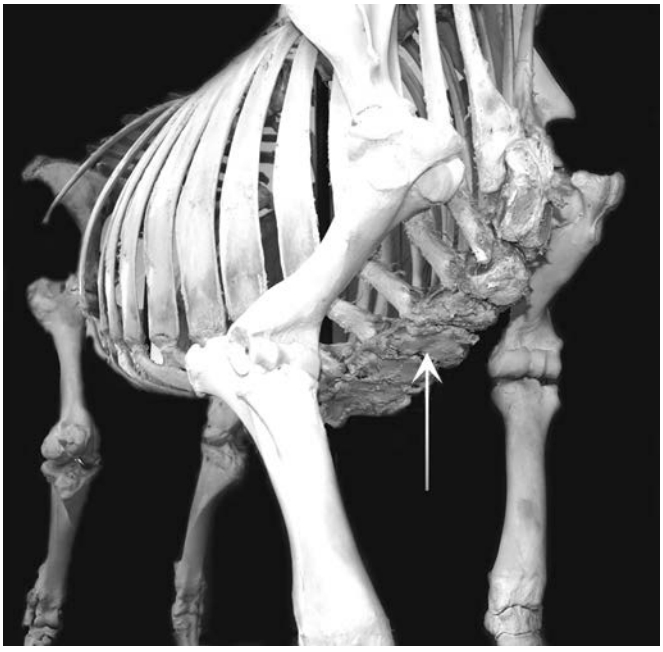

FIG. 28-7 Bovine sternum. The third and fourth sternebrae are recommended for bone marrow collection. The *arrow* is pointing to the fourth sternebra.

in camelids,[9] although successful bone marrow aspiration from the iliac crest of a 2-year-old alpaca has been reported[13] (Fig. 28-9). The iliac crest can also be used in sheep (Fig. 28-10).

Another site informally described for horses is the spinal process of the first lumbar vertebra (Fig. 28-11). It is usually vertical, whereas the adjacent processes tend to be more angled. The tip of the process is wider than the shaft and has a thin layer of bone. The needle is advanced straight down into the marrow cavity, which is narrow, but if the needle is close to correct placement, the walls of the process help guide the needle into the marrow cavity. The advantage of this site is that the operator is not working under the horse. The spinal process is reported to be a poor site to sample in the cow.[14]

APPROACH TO THE STERNUM. In the horse, bone marrow aspiration is typically performed in the standing animal. Sedation or a twitch may be used if necessary. The preferred site is on the ventral

VetBooks.ir

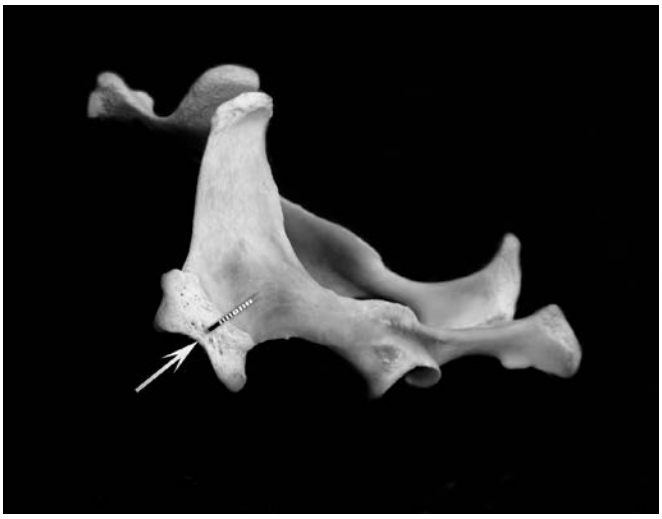

FIG. 28-8 Equine pelvis. To obtain bone marrow, the needle should be placed near the center of the tuber coxae *(arrow)* and advanced toward the opposite coxofemoral joint *(dotted line)*.

FIG. 28-9 Llama pelvis. The wing of the ilium *(arrows)* is generally considered too thin for easy bone marrow collection in camelids.

FIG. 28-10 Bone marrow aspirate from the ileum of a sheep. This sheep was undergoing necropsy, and the wing of the ileum has been dissected out.

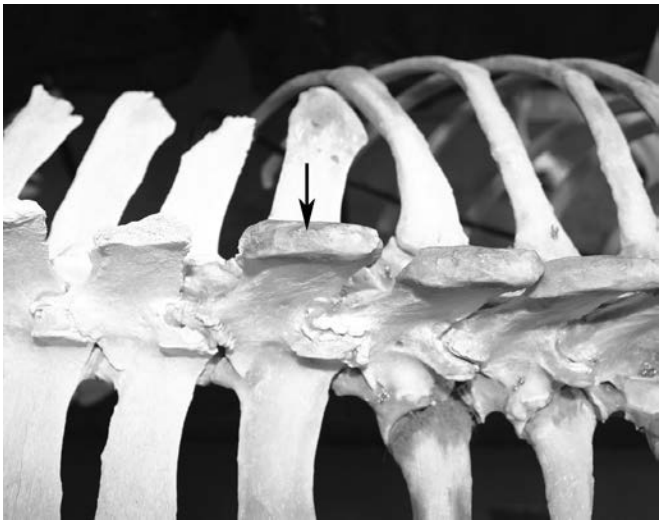

FIG. 28-11 First lumbar vertebra of a horse. Although not widely used, the spinal process of L1 *(arrow)* is another site from which bone marrow can be obtained in the horse.

midline in the cleavage between the deep pectoral muscles where a line connecting the points of the elbows would cross[15] (Figs. 28-4 and 28-12). The manubrium of the sternum can also be sampled in horses by finding the cranial end of the sternum and going one hand width below and one hand width laterally from the end (see Fig. 28-3). From this spot the needle is advanced through the muscle in a horizontal plane at a 45-degree angle to the longitudinal axis of the horse.[6]

Sternal bone marrow can be sampled from adult cattle standing in stocks or a squeeze chute. It may be necessary to use techniques to prevent kicking, such as jacking the tail, or sedation. Unruly adult cattle and large calves can be cast and held in lateral recumbency. The upper front leg of the cast animal is held extended along the neck, exposing the sternum, after the other legs are secured with a rope.[16] Calves that weigh less than 300 lb can be placed in dorsal recumbency and secured by assistants or with ropes.[8] The needle should be placed on the midline and inserted perpendicular to the third or fourth sternebra. The appropriate sternebra is located by palpating the third or fourth rib and following it to the sternum.

For the sternum of a small ruminant to be sampled, the animal is placed in dorsal recumbency with legs secured, or it can be restrained in a sitting position with an assistant standing behind, supporting the animal and holding a foreleg in each hand.[8] The location of the appropriate site is midline, between the front legs. The second through fourth sternebrae can be used in sheep (see Fig. 28-5). A prominence may be felt between the first and second sternebrae. The appropriate sternebrae can also be located by palpating ribs and following them to their articulations.[17] In sheep, the needle will advance approximately 0.5 cm into the bone (2.5 to 3.8 cm from the skin) before entering the marrow cavity.[17]

The sternum of llamas can be sampled with the animal either standing in a chute or lying in left lateral recumbency, usually while sedated[18] (see Fig. 28-6). The sample can be taken by inserting the needle perpendicularly through the callosity on the ventrum of the

VetBooks.ir

FIG. 28-12 Bone marrow aspiration in a horse. The animal was placed in a stock and sedated. **A,** The ventral sternum between the horse's elbows is clipped and surgically scrubbed. **B,** After local anesthetic, a stab incision is made on midline. **C,** A spinal needle is inserted to collect marrow.

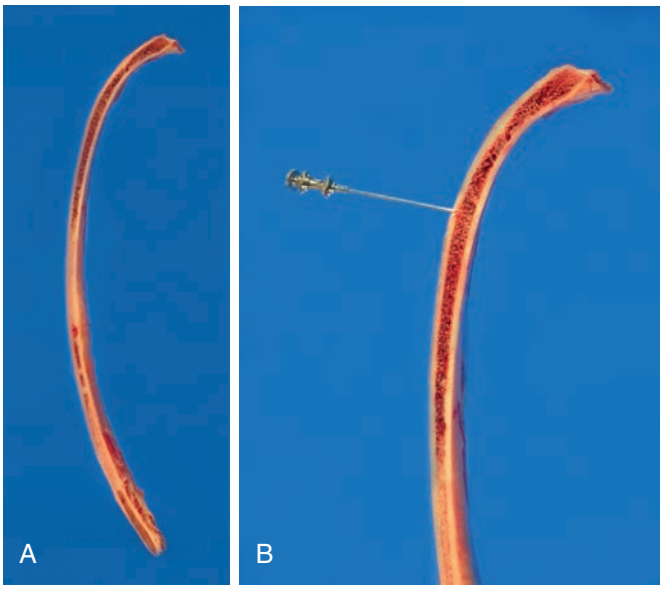

FIG. 28-13 Cross-section of bovine rib 10. **A,** Bone marrow is more consistently present in the vertebral end. **B,** A Rosenthal bone marrow needle is inserted into the rib approximately 3 inches below the costovertebral junction.

sternum or with a lateral approach, approximately 3 to 4 cm dorsal to the callosity with the needle directed medially and slightly dorsally to engage bone.[9] Marrow will be approximately 2.5 cm deep in an adult. The sample is normally more dilute with blood than in other species.[9]

When the ventral sternum is sampled, unless a lateral approach is used, the needle should be placed on the midline, as near to the center of the bone as possible, and advanced perpendicular to the bone. A sudden reduction of resistance may be felt when the marrow cavity is entered, but because the sternal cortex is so thin, especially in horses, there may be no obvious change. Care needs to be taken to not enter the thoracic cavity. Because a change in resistance may not be felt, once the tip of the needle is firmly seated in the bone, an aspiration attempt should be made.

APPROACH TO THE RIB. The vertebral end of the rib more consistently contains marrow than the sternal end of the bone[19,20] (Fig. 28-13). Palpation can be used to find the rib that has the least amount of fascia covering it. In the horse, the eighth to eighteenth ribs can be used, going as high as possible but below the latissimus dorsi and serratus posticus muscles[19] (see Fig. 28-1). In cattle, place the needle approximately 3 inches ventral to the ninth or tenth costovertebral junction[14] (Figs. 28-2 and 28-14). The needle should be inserted perpendicularly at the middle of the rib, midway between the anterior and posterior borders (see Fig. 28-14, *A*). To help keep the needle from sliding off the bone, a scalpel can be inserted first until it touches the bone to be used as a guide.[11]

APPROACH TO THE ILIAC CREST. The iliac crest is often used in foals (see Fig. 28-8). The needle should be placed midway between the two tuberosities of the tuber coxae and somewhat toward its posterior border. With regard to angle, the needle should be pointing at the coxofemoral joint of the opposite side. Bone marrow will be hit when the needle is inserted approximately ⅛ inch for foals, whereas in adult horses bone marrow may be more than 2 inches deep. The main benefit of using this method is that there is no risk of inadvertently entering the thoracic cavity.[12]

Preparation for Bone Marrow Aspiration or Biopsy

Bone marrow aspiration should be performed as a sterile procedure. After the animal has been restrained and the site of approach identified, hair should be clipped and the area surgically scrubbed (see

VetBooks.ir

FIG. 28-14 Bone marrow aspirate of a cow. The animal was placed in a head-gate and sedated, and a tail jack was applied. **A,** The area over the vertebral end of rib 11 has been clipped and surgically scrubbed. The cranial and caudal edges of the rib are palpated approximately 3 inches down from the costovertebral junction, and the midpoint of the rib is identified for aspiration location. **B,** At the chosen aspiration site, lidocaine is injected from skin to periosteum. **C,** After a stab incision has been made and the Jamshidi-type bone marrow needle inserted through the skin, the needle is forcibly pushed forward through cortical bone as it is rotated alternately in a clockwise–counterclockwise motion. **D,** After a decrease in resistance is felt, the stylet is removed. **E,** A syringe is attached to the needle, and a few sharp pulls on the plunger are needed before the sample is noted in the hub of the syringe.

VetBooks.ir

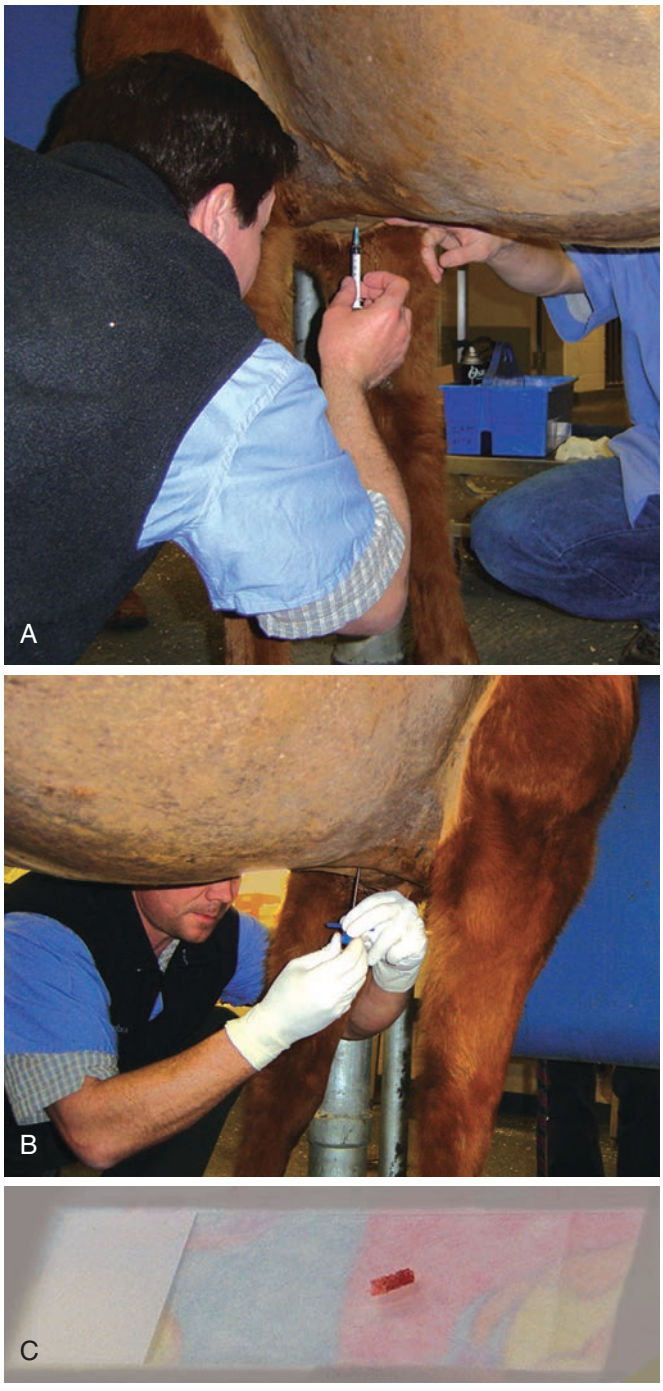

FIG. 28-15 Core bone marrow biopsy of a horse. The animal was placed in a stock and sedated; the ventral sternum between the elbows was clipped and surgically scrubbed. **A,** Lidocaine is injected from the skin to the periosteum. **B,** After a stab incision, the Jamshidi bone marrow biopsy needle is advanced into cortical bone. Here the stylet is about to be removed before the needle is advanced further. **C,** Core biopsy sample.

Fig. 28-12, *A*). Local anesthetic is injected at the site where the needle will be inserted, from the skin to the periosteum (see Figs. 28-14, *B*, and 28-15, *A*). A small stab incision is typically made with a scalpel to aid the needle's approach to the bone (see Fig. 28-12, *B*). If the rib is to be sampled, the scalpel blade can be held in place to act as a guide for the needle. It is important to be organized and have all supplies ready so that the procedure will flow smoothly and the sample will not clot before it can be processed (Box 28-2; Fig. 28-16).

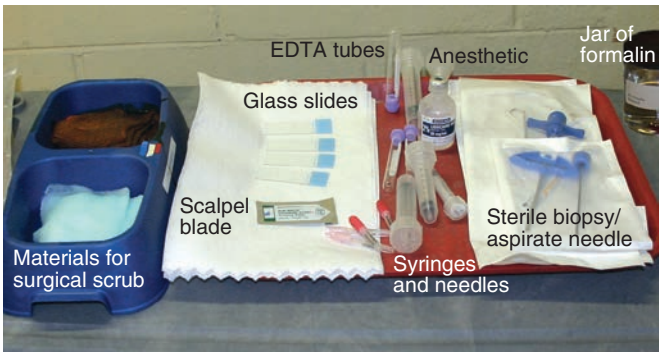

FIG. 28-16 Supply table is set up and ready for bone marrow aspiration. Sterile gloves were opened on an adjacent table. *EDTA,* Ethylenediamine tetraacetic acid.

BOX 28-2

Supply Checklist for Bone Marrow Collection

Clippers
Surgical scrub
Lidocaine
    Syringe and needle
Sterile gloves
Scalpel blade (no. 15 adequate)
Bone marrow needle
    ≥16 gauge, 1½ inches
10- to 20-mL sterile syringe
Glass slides
Jar of formalin for core biopsy
Optional:
    Anticoagulant
    EDTA blood tubes
    Petri dish or watch glass

EDTA, Ethylenediaminetetraacetic acid.

How the sample will be ultimately handled will dictate some of the available supplies needed: glass slides, Petri dish, EDTA blood tubes, and/or anticoagulant. One option is to prime the syringe that will be used for aspirating the sample with anticoagulant. To prevent clotting, 1 to 2 mg of EDTA is recommended per milliliter of blood. One to two drops of a 3% to 15% EDTA solution should be adequate. The EDTA solution can be aspirated from a purple-topped blood tube. Priming the syringe with anticoagulant, although it adds a preparatory step, decreases the worry that the sample will coagulate and allows more time for processing the sample. If the syringe is not primed, as soon as the sample is seen in the syringe hub, the syringe needs to be disconnected immediately from the needle and the sample quickly processed before it has a chance to clot. If a reticulocyte count is to be performed to assess erythroid regeneration, supravital stains, such as new methylene blue and brilliant cresyl blue, require mixing with a portion of anticoagulated, liquid sample before slides are made; therefore, placing at least some of the bone marrow sample in an EDTA tube is recommended.

The sample in the syringe may be processed by expressing it directly onto several clean glass slides, into an EDTA blood tube, or into a Petri dish or watch glass. The Petri dish or watch glass must contain anticoagulant if no anticoagulant was used in the syringe. The anticoagulant commonly used is EDTA, which can be used in solution or as a salt, but other anticoagulants such as sodium citrate are also effective. Samples placed in an anticoagulant should be gently mixed immediately.

Collecting the Sample

The goal of bone marrow aspiration is to obtain a good sample of hematopoietic cells with minimal blood contamination.

VetBooks.ir

FIG. 28-17 Bone marrow needles with stylets separated. On the *left* is a 14-gauge, 2¾-inch Rosenthal needle. On the *right* is an 11-gauge, 4-inch Jamshidi needle.

Anatomically, within the bone marrow, hematopoietic cells are extravascular and found in spaces dissected by venous sinuses and a central vein.[21] To collect the sample, a bone marrow or spinal needle with stylet should be used. Commonly used needles include Rosenthal, Illinois sternal-iliac, and Jamshidi bone marrow needles (Fig. 28-17). Some needles come with a guard that can be adjusted to prevent deeper penetration than desired. The needle used should be 16 gauge or larger and at least 1½ inches long. Larger needles may be needed, depending on the site of aspiration and the age and size of the animal.

After an animal has been properly prepared, the bone marrow needle is inserted through the skin, perpendicular to the bone (see Fig. 28-12, *C*). Once the needle contacts bone, it can be advanced using manual pressure and a clockwise-counterclockwise twisting motion (see Fig. 28-14, *C*). One hand can be used to stabilize the needle angle and placement while the other hand is on the needle hub pushing and turning the needle.[15] If the needle is going through dense bone, a wood mallet can also be used to advance it.

Once it is suspected that the needle has entered the marrow cavity, either because of detection of a sudden reduction in resistance or because of needle depth, the stylet should be removed and an aspiration attempted (see Fig. 28-14, *D*). In dense bone, pliers may be helpful in removing the stylet.[8] After the stylet is removed, a 10- to 20-mL sterile syringe is securely attached to the needle, and the plunger of the syringe is pulled back quickly and sharply, creating negative pressure in order to dislodge bone marrow particles (see Fig. 28-14, *E*). Suction can be repeated two or three times. As soon as blood is seen in the hub of the syringe, suction should be discontinued, the needle and syringe removed from the animal, and the sample processed promptly. Additional suction will likely only result in hemodilution of the sample. The first drop of blood is the most cellular, and further aspiration results in lower cellularity of the sample.[22]

If the initial aspiration does not obtain any material, remove the syringe, replace the stylet, and carefully advance the needle a little further. If a sample still cannot be obtained after additional advancement of the needle and repeated suction, slowly withdraw the needle while applying suction to the syringe. Ultimately, repositioning the needle to a different site, such as moving a couple of centimeters cranially or caudally, may result in a successful aspiration.[9]

Processing the Sample

Whether the bone marrow sample is directly applied to glass slides or expressed into a Petri dish or watch glass, processing needs to proceed rapidly to prevent clotting or drying out of the sample. When on the slide, if the sample contains a lot of excess blood, the slide can be briefly tilted so that the fluid portion can run off into an absorbent surface, leaving behind adherent particles for spreading (Fig. 28-18, *C*; Fig. 28-19, *A*). If the sample is placed into an EDTA tube or Petri dish with anticoagulant, spicules (small grayish particles) can be transferred out of the bloody sample using a pipette and placed on a glass slide[23] (see Fig. 28-18).

To spread the sample on a slide, place a second glass slide flat on top of the sample, allowing the sample to form a thin layer between the slides (see Fig. 28-19, *B*). Without additional pressure other than the weight of the slide, gently pull the slides apart from each other horizontally and without vertical separation, which can create suction and rupture cells (see Fig. 28-19, *C*). This typically results in a nicely spread sample with intact particles and nice monocellular layers for evaluation. Several slides should be made. After slides are made, they should be allowed to air dry, kept away from formalin fumes, and stored at room temperature until staining.

Some bone marrow slides are stained with a Romanovsky-type stain (Wright, Giemsa, Diff-Quick) for cytologic examination, and some should be left unstained in the event that special staining procedures are wanted. It is highly recommended to stain at least one slide right away for microscopic examination in order to determine sample quality and to make sure bone marrow elements are present while the animal is still available and prepped, in the event that the first aspiration is nondiagnostic and additional attempts will be needed (Fig. 28-20). If a hemodilute sample without spicules is obtained, it may be possible to acquire diagnostic information by centrifuging the sample in Wintrobe hematocrit tubes and making smears from the buffy coat. Staining for reticulocytes requires that an anticoagulated, liquid bone marrow sample be mixed and incubated with a supravital stain before slides are made.

If a core biopsy sample is obtained, the tissue can be gently rolled on a slide to make an impression smear for cytologic evaluation. The biopsy tissue should then be placed in 10% neutral buffered formalin for preservation. A larger gauge needle (10 to 13 gauge) is generally recommended for core biopsy. The Jamshidi needle, designed so that the distal tip tapers to help retain the sample, is the most popular needle for biopsy. The needle and stylet are initially inserted as for aspiration (see Fig. 28-15, *B*). Once the needle enters the bone marrow, the stylet is removed and the needle advanced farther with the same twisting motion. Ideally, the needle is inserted at least an additional 1 to 2 cm, but this may be limited by location. After the needle is advanced to obtain the core, it is rotated and rocked forcibly to help break the core at its base for successful removal. Once the needle is removed from the animal, a probe is inserted into its lumen at the distal tip, pushing the sample out the hub end (see Fig. 28-15, *C*).

Often, bone marrow aspirates are placed into an EDTA blood tube for submission to an outside laboratory. In this case it is still recommended to make slides of the sample to submit along with the fluid sample. If the sample is left in the fluid phase, cells can deteriorate during transit, and it is always helpful for the cytologist to have a freshly prepared sample to examine (of both bone marrow and peripheral blood). In addition, a slide can be stained and evaluated for diagnostic quality before the sample is shipped.

If repeated aspirates all result in samples of low cellularity, a core biopsy may be indicated. Cytologically, it is usually impossible to differentiate low cellularity caused by a pathologic process from that resulting from poor sampling; therefore, a biopsy may be needed for the evaluation of cellularity.

VetBooks.ir

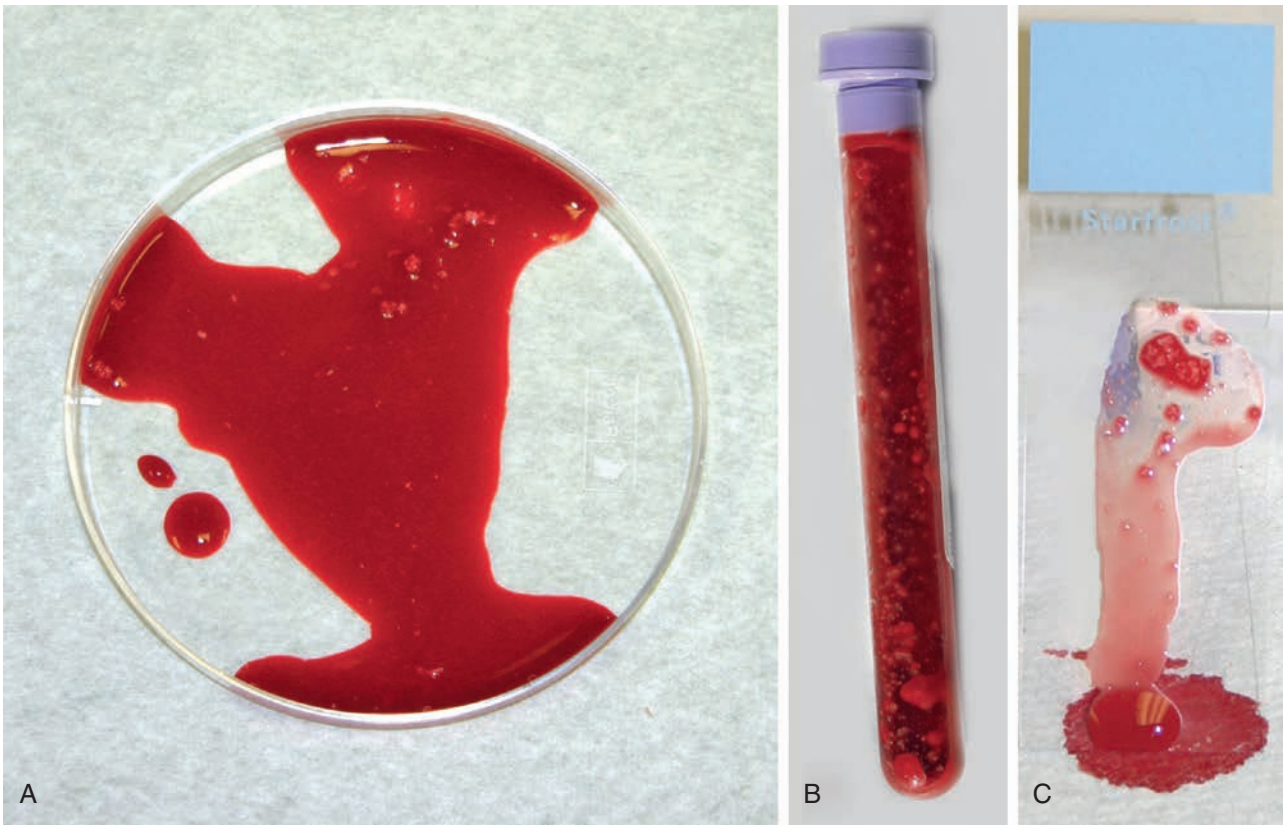

FIG. 28-18 Bone marrow spicules (small grayish particles) should be seen in the aspirated sample. **A,** Particles can be picked out of background blood from a Petri dish. **B,** Particles can be seen adhering to the sides of an EDTA blood tube. **C,** Particles will adhere to a glass slide while excess blood runs off.

Bone Marrow Evaluation

Bone marrow evaluation requires expertise (advanced training and experience), and in most cases it is anticipated that samples will be sent to a trained cytologist for evaluation. To obtain the most information from a bone marrow aspirate, it is important to have a good-quality sample. Even if not reading the sample oneself, it is recommended to stain a slide to confirm that a diagnostic sample was obtained (stain the worst slide; if it is acceptable, one can expect the others to also be acceptable). Recent CBC results and freshly made blood films are also essential for full interpretation of a bone marrow sample. Relative changes among different cell lines are assessed in the evaluation of hematopoiesis because absolute cell counts are unreliable in bone marrow aspirates.[22] Knowledge of the peripheral blood picture is necessary to assess whether changes (or lack of changes) in the bone marrow are consistent with normal hematopoiesis. Freshly made blood films are important to have when comparing the morphology of cells in the bone marrow with the morphology of those in the peripheral blood. Results from cytologic evaluation of bone marrow should ultimately be correlated with history, clinical presentation, and other laboratory data.

Cytologic Examination

In general, the evaluation of bone marrow includes assessment of the following parameters. On low magnification the cellularity and quality of the sample as a whole are assessed, as well as the cellular density of bone marrow particles. Iron stores are evaluated within the particles. Megakaryocyte numbers are also best assessed at low magnification. On high magnification the sample is evaluated for the presence of myeloid and erythroid cell lines. The cell lines are evaluated for orderly maturation, and cell morphology is assessed for evidence of dysplastic changes. The relative proportion of myeloid to erythroid cells is determined by subjective assessment or by counting cells to derive a myeloid-to-erythroid (M:E) ratio. The sample is also evaluated for the presence of other cell types or infectious organisms. Results from the bone marrow evaluation are then interpreted in accordance with peripheral blood abnormalities.

Cellularity of bone marrow spicules is subjectively determined by assessing how much area of a particle is composed of cells versus fat. Cellularity of normal marrow can vary according to the age of an animal, with higher cellularity in younger animals and lower cellularity in older animals. Examples of differing cellularities are depicted in Fig. 28-21. Iron stores are assessed within spicules and typically described as *present, decreased,* or *increased* (Fig. 28-22).

Maturation of bone marrow cell lines follows somewhat of a pyramidal pattern, with cells dividing as they mature, resulting in higher numbers of cells in the more mature cell stages (Figs. 28-23 and 28-24). In bone marrow of healthy animals, rubriblasts and myeloblasts will typically comprise at most a small percentage of the total cell population. Twice as many prorubricytes and promyelocytes may be seen. Numbers of cells in each stage increase up to polychromatophilic rubricytes and metamyelocytes, after which there are relatively stable numbers between the subsequent maturational phases. In general, for each blast there are 16 mature granulocytes or erythrocytes. Mitotic figures are normally present in low numbers.

The M:E ratio is most accurately determined by counting a minimum of 500 cells. Nucleated cells of all maturational stages are included in the count and categorized as myeloid or erythroid. The ratio is calculated by simply dividing the total number of myeloid cells by the total number of erythroid cells. It is important to include several different areas of the sample to make it as representative of the whole sample as possible. Blood contamination can also affect the M:E ratio, especially if leukocytosis is present. Reported M:E ratio ranges for healthy animals of different species have been variable. In some sources the M:E ratio in cattle is listed as less than 1, although ranges from 0.27 to 2.59 have been reported.[7,20,24-26] The range of M:E

VetBooks.ir

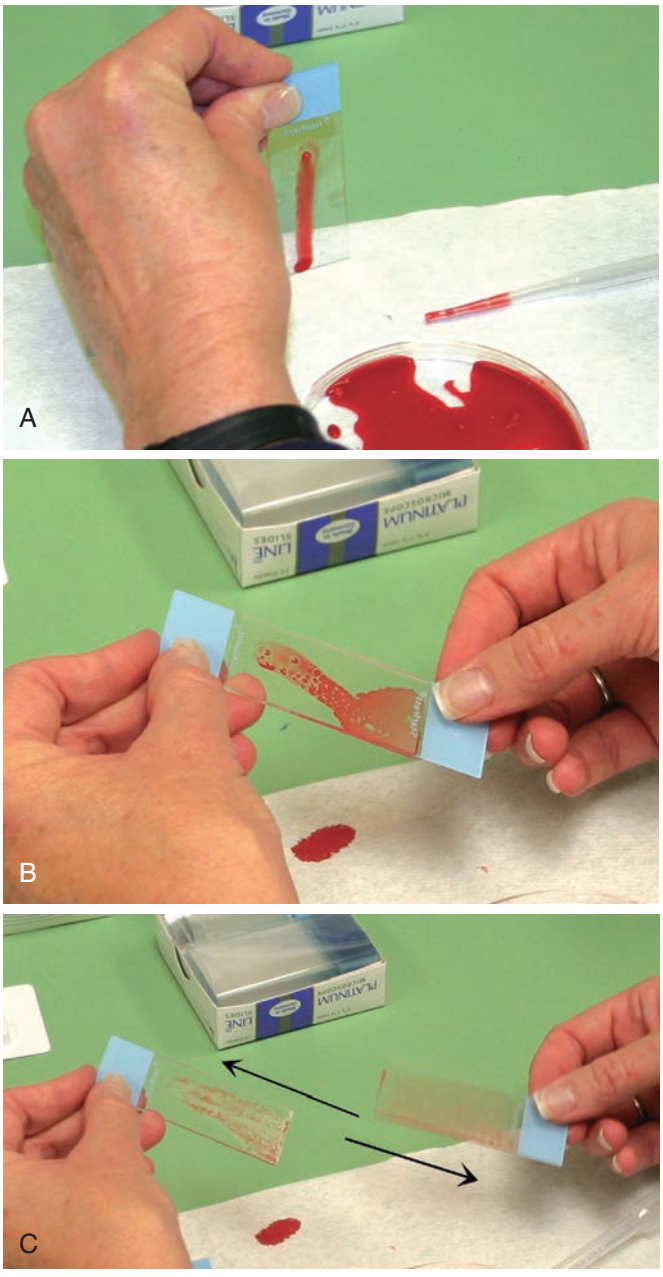

FIG. 28-19 Making slides of a bone marrow sample. **A,** Excess blood is allowed to run off the slide onto an absorbent surface while the spicule stays adhered to the slide. **B,** A second slide is laid on top of the sample, causing the sample to spread out between the slides. **C,** The slides are horizontally pulled apart, then allowed to air-dry.

ratios in ten 3- to 6-year-old pregnant sheep was reported as 0.77 to 1.68.[17] The reported range for the M:E ratio in a low number of llamas is 0.9 to 2.9.[18] Llama, alpaca, and vicuña have a lower M:E ratio at high elevation (4200 m) versus low elevation.[2] M:E ratios in horses generally range from 0.5 to slightly greater than 1, with 1.5 sometimes reported as the upper value.[6,27-29]

Evidence of dysplastic changes in hematopoietic cells includes asynchronous maturation between the cytoplasm and nucleus, large cell forms, and abnormal nuclei, such as ring-shaped nuclei. Cell types other than hematopoietic cells should be evaluated as to their presence and proportion of the total cell population. Low numbers of macrophages (<1%), plasma cells (<2%), and small lymphocytes (<10%) are commonly seen in bone marrow samples.

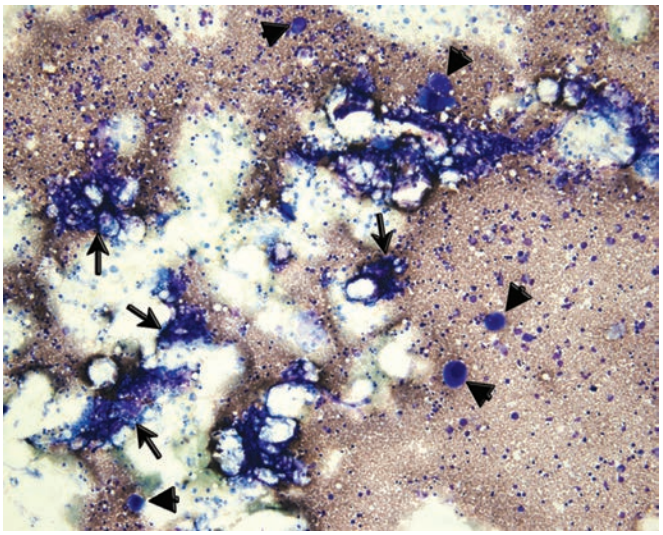

FIG. 28-20 Stained slide of adequate bone marrow aspirate sample. Megakaryocytes *(arrowheads)* and particles *(arrows)* are present. There is also increased cellularity compared with peripheral blood. (Wright-Giemsa stain, 10× objective.)

Interpretation

It is easy to make a conclusion about bone marrow cellularity if the sample is highly cellular, but a poorly cellular sample is more difficult to interpret if adequate particles are not present. A core biopsy may be needed to differentiate between a poorly cellular marrow and a nonrepresentative sample. In general the bone marrow will become more cellular in a hyperplastic or regenerative response.

In many cases it is adequate to describe iron stores as being present without quantification. When assessing the cause of anemia, an abnormality in iron stores may provide useful diagnostic information. Lack of iron stores would suggest iron deficiency, whereas abundant iron stores are associated with anemia of chronic inflammation. Perl's iron stain (Prussian blue reaction) can be used on bone marrow slides to confirm low iron stores. Llama bone marrows normally contain abundant iron.[18]

No definitive criteria for megakaryocyte numbers have been determined. If thrombocytopenia is not present, any number of megakaryocytes is acceptable. Many megakaryocytes are expected to be seen within individual particles when there is regeneration associated with thrombocytopenia. Higher numbers of immature megakaryocytes may also be seen; these will be smaller cells (still larger than other bone marrow cells) with a higher nuclear-to-cytoplasmic ratio, deeper basophilic cytoplasm, and fewer lobes to the nucleus. If megakaryocytes are not frequently seen in the bone marrow from an animal with thrombocytopenia, this suggests hypoplasia or destruction of megakaryocytes.

When assessing bone marrow for normal, progressive maturation of cell lines, it is expected that all developmental stages will be present, with greater numbers of the more mature cells. Variation from normal can be seen for a variety of reasons, often reflected by a shift to the left or what appears to be a maturation arrest. A shift to the left is the situation in which all maturation stages are represented but there is a higher proportion of the less mature cells (the proliferating pool) than normal. *Apparent maturation arrest* is a term used when maturation appears to terminate at a particular stage; the earlier maturation stages are present, but later stages are poorly represented. Suppression of hematopoiesis can result in abnormalities in maturation progression but often is reflected by a decrease in all stages of maturation. If the number of cells within a cell line is too low, progression of maturation can be difficult to evaluate. Destruction of cells, such as with immune-mediated disease, at a particular maturation stage will result in decreased numbers of cells of the affected type as well as cells at all later stages, which can appear

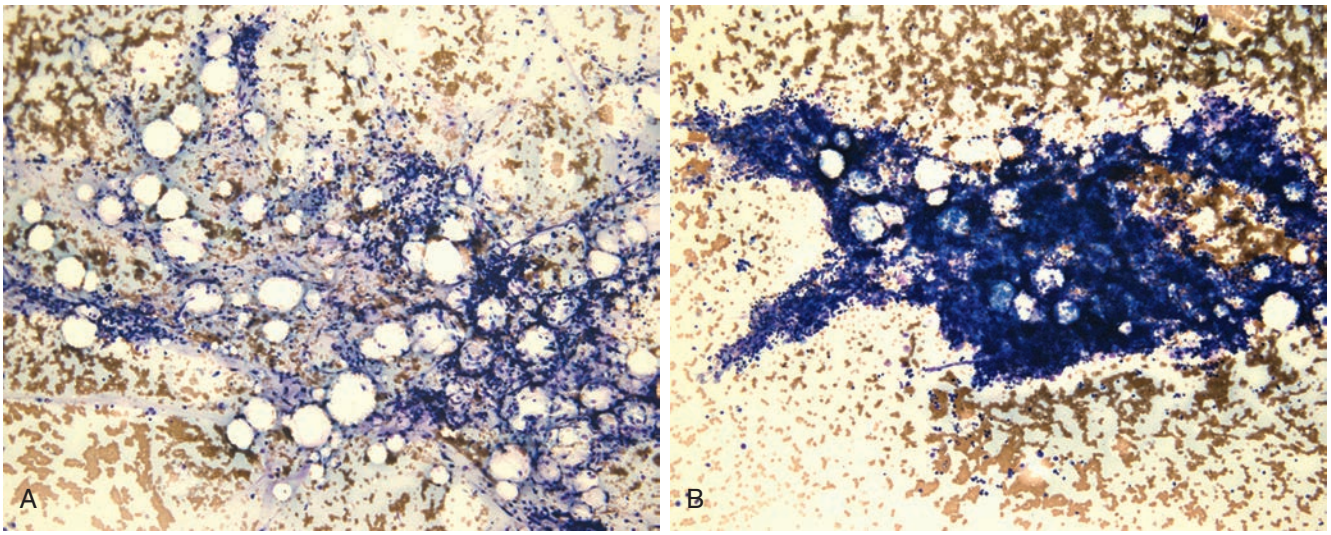

FIG. 28-21 Bone marrow particles. The particle in **A** is of low cellularity. Only a small proportion of the particle is composed of nucleated cells. The particle in **B** is of high cellularity. At least 75% of the particle is composed of nucleated cells. (Wright-Giemsa stain, 10× objective.)

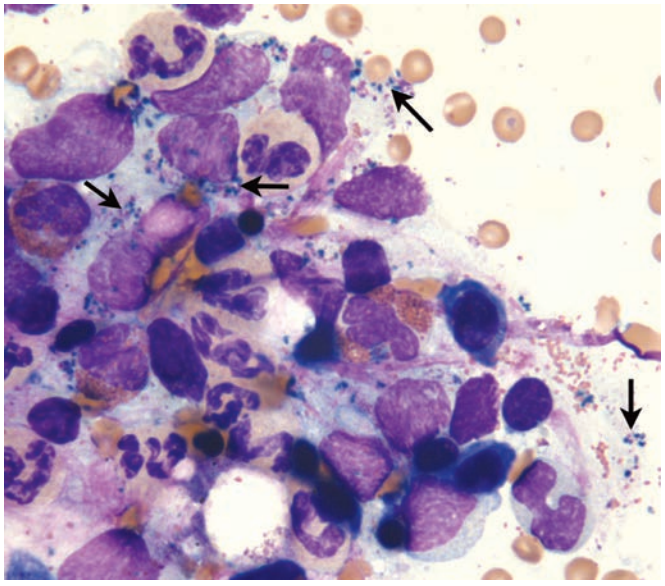

FIG. 28-22 Bone marrow aspirate. The blue-black granules visible extracellularly and within macrophages represent iron stores *(arrows)*. Iron stores can also be seen as brown crystalline material within particles. (Wright-Giemsa stain, 100× objective.)

as a maturational arrest. If a disease process results in large demand or rapid mobilization of cells out of the bone marrow, depletion of the more mature cell stages can appear as a maturational arrest. In such cases a left shift also is often associated with the increased demand. Acute leukemia is typically reflected as an apparent maturational arrest or left shift. Therefore, it can be difficult to differentiate between hyperplastic marrow in which there has been rapid mobilization of mature cells out of the marrow and a myeloproliferative disorder on cytologic examination alone. In some instances sequential bone marrow aspirations can be useful in helping to determine disease pathogenesis. Abnormalities in maturational progression may also be reflected by the presence of dysplastic changes.

The M:E ratio is used to help determine if the erythrocyte or myeloid cell lines are hypoplastic or hyperplastic. An equal number of nucleated erythroid and myeloid cells will result in an M:E ratio of 1. An M:E ratio greater than 1 (or greater than the reference interval) often indicates that granulocytic production exceeds erythroid production, but it could also indicate a decrease in erythropoiesis. Likewise, an M:E ratio less than 1 (or less than the reference interval) often indicates that erythropoiesis exceeds granulopoiesis, but it could also indicate suppression of the latter. Determining which interpretation is appropriate requires knowledge of concurrent CBC results. An increase in the M:E ratio would be appropriate in an animal with neutrophilia, but if the neutrophil count is normal and anemia is present, it would indicate erythroid hypoplasia. In the face of anemia, a decrease in the M:E ratio would indicate erythroid hyperplasia and regeneration, but a decrease in a neutropenic animal that is not anemic would indicate myeloid hypoplasia. In some disease states both the myeloid and erythroid series may be affected, which could potentially exacerbate or mask alterations.

Whereas most species readily reflect an erythroid regenerative response in the peripheral blood, horses do not. Reticulocytes are rarely seen in equine peripheral blood, and in one investigation it took several days of severe anemia (PCV of 13% to 14%) in horses before a reticulocytosis of 1% to 2% was seen.[30] An increase in mean corpuscular volume (MCV) may be detected in the peripheral blood of horses with chronic anemia or acute, massive hemolytic or hemorrhagic anemias,[29-32] but the best way to assess erythropoiesis in horses is to examine the bone marrow. The number of reticulocytes significantly increases in the bone marrow of horses with regenerative anemia. In the study of acute blood loss in which only 1% to 2% of reticulocytes were seen in peripheral blood, bone marrow reticulocytes went from 4.1% (before blood loss) to as high as 66.5%.[30] Reticulocytes typically comprise less than 2% of erythrocytes in normal bone marrow, and a regenerative response is considered present if reticulocytes comprise greater than 5%.[11] Determining the number of reticulocytes per 1000 erythrocytes after staining with a supravital stain such as new methylene blue is the most reliable method, but an estimate can be made by counting the number of polychromatophils per 100× oil objective field in a Wright-stained smear (assuming the field of view includes approximately 100 cells; this can vary with the microscope). In the face of anemia, greater than 5 polychromatophils/oil field is considered a good regenerative response, and less than 2 is indicative of erythropoietic suppression.[33] Care should be taken not to dilute the sample with peripheral blood, since this will dilute the number of reticulocytes from the bone marrow.

Other bone marrow parameters that indicate erythrocyte regeneration in horses include a decreased M:E ratio (<0.5) and a left shift of erythroid precursors.[29,33] Depending on the type of blood loss, it could take several weeks to reduce the M:E ratio below the reference interval.[34] With regeneration, a doubling of the proliferating pool of

VetBooks.ir

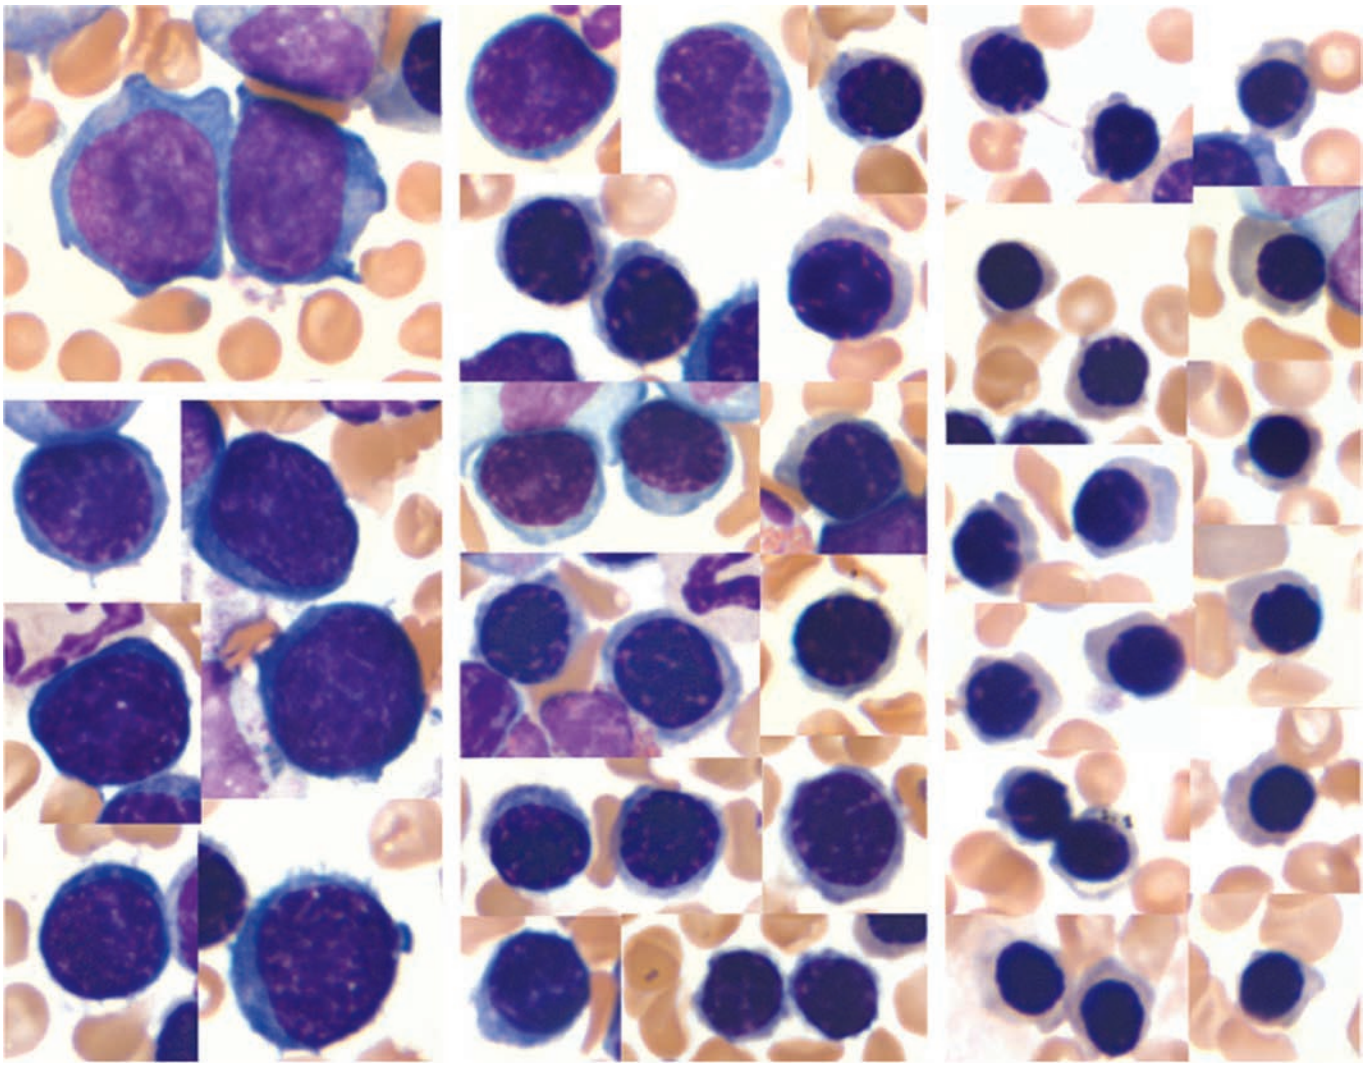

FIG. 28-23 Maturational stages of erythrocytes within the bone marrow. The *left panel* contains rubriblasts in the upper square with prorubricytes below. Rubriblasts are large cells with large nuclei containing coarse-grained chromatin and nucleoli; a perinuclear halo is present within scant deeply basophilic cytoplasm. Prorubricytes have a more mature nucleus; chromatin condensation begins, and no nucleoli are present. The *middle panel* contains basophilic and polychromatophilic rubricytes; chromatin condensation is distinct and the cytoplasm is paler, grayer, or polychromatic. The *right panel* contains metarubricytes with dark, intense chromatin condensation and pink cytoplasm. (Wright-Giemsa stain, 100× objective.)

erythrocyte precursors can occur within 3 days of an acute severe hemorrhage, with maximal response at 9 days.[35] The proportion of basophilic and polychromic rubricytes can reach 39% to 55% of all cells in the regenerative equine bone marrow.[29]

Atypical cell populations in the bone marrow can represent a myeloproliferative disorder, an infiltrative neoplastic process, inflammation, or antigenic stimulation. Atypical cell populations can be a result of significant increases in cell numbers of types normally seen in the marrow. Blast cells normally constitute only a small percentage of total cells in the bone marrow. A diagnosis of acute leukemia is typically associated with blast cells that constitute greater than 20% to 30% of cells within the bone marrow. Cytologic results need to be correlated with other clinical data because granulopoiesis characterized by a marked left shift in bone marrow precursor cells with rapid mobilization of more mature cells from the bone marrow can resemble a myeloproliferative disorder.

Another cause of increased numbers of cells normally residing in the bone marrow is inflammation. Suppurative inflammation can be seen, typically associated with septicemia. Histiocytic or granulomatous inflammation is characterized by increased numbers of macrophages. Both suppurative and histiocytic inflammation can be associated with infectious or noninfectious disease processes. If inflammation is present, the sample should be thoroughly inspected for organisms, and culture may be indicated.

Increased numbers of lymphocytes and plasma cells can be seen with antigenic stimulation or with neoplasia. In general, it is rare to see the proportion of lymphocytes or plasma cells exceed 20% with antigenic stimulation. The morphology of lymphocytes and plasma cells should be well differentiated if they are associated with nonneoplastic processes. Cells associated with neoplasia can also appear well differentiated; therefore, cell morphology alone may not be useful in establishing a diagnosis. Clinical presentation and ancillary testing (e.g., serum protein electrophoresis, flow cytometry) can be helpful in interpreting lymphocytoses and plasmacytoses.

The presence of cells not typically seen in the bone marrow or cells exhibiting a high degree of pleomorphism or other criteria of malignancy should raise suspicion of a neoplastic process. Neoplasia can arise from within the bone marrow or can metastasize to the bone marrow from other sites.

VetBooks.ir

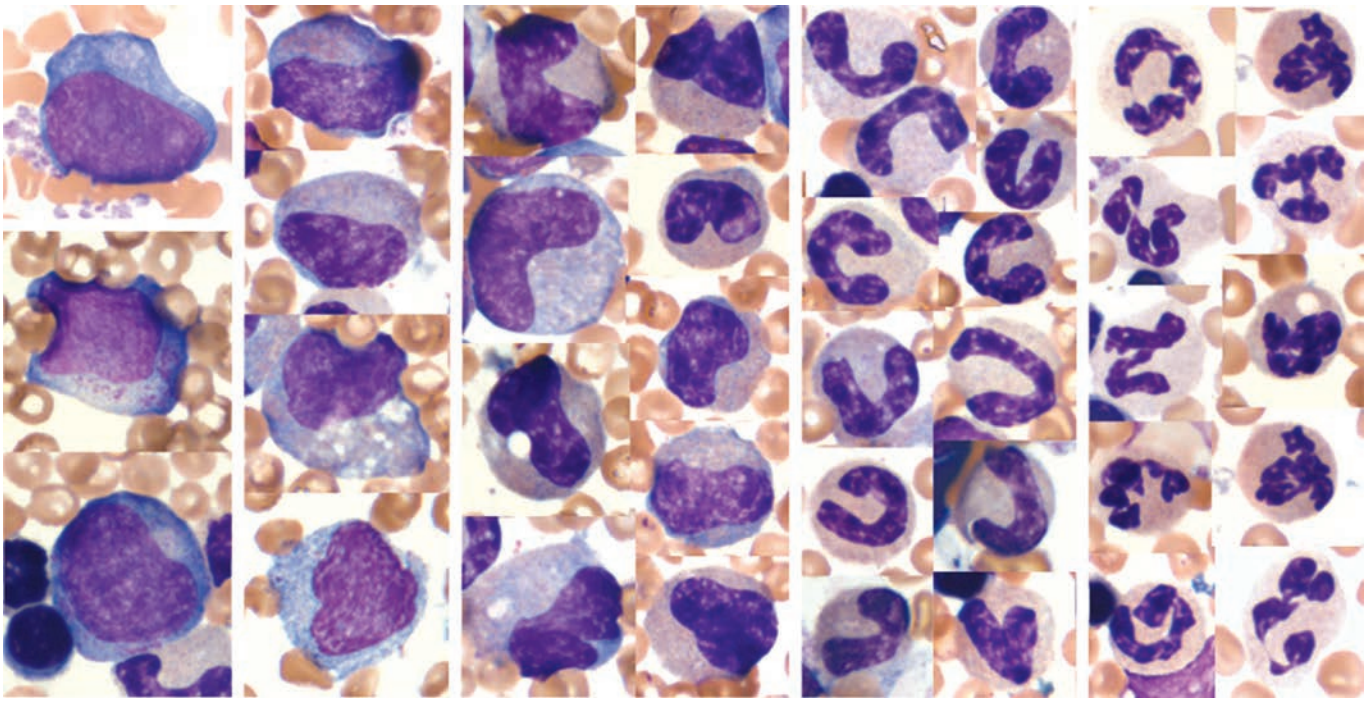

FIG. 28-24 Maturational stages of granulocytes within the bone marrow. The *left panel* contains a myeloblast in the upper square with promyelocytes below. Myeloblasts are large cells with large nuclei containing fine reticular chromatin and nucleoli; the cytoplasm is basophilic and agranular. Promyelocytes contain coarse cytoplasmic granulation; nuclear chromatin is beginning to condense, and nucleoli are present. *Subsequent panels,* moving to the right, contain myelocytes, metamyelocytes, band neutrophils, and segmented neutrophils. Myelocytes have a lower nuclear : cytoplasmic ratio and contain fewer and finer cytoplasmic granules; the nucleus is round to kidney shaped and contains no nucleoli. As maturation progresses, the cells become smaller, the cytoplasm becomes more eosinophilic, the chromatin becomes more condensed, and the nucleus indents and segments.

Degenerative cells or amorphous proteinaceous debris suggests bone marrow necrosis. This can occur as a result of infarction, neoplasia, or inflammation. Degenerative cells are often unidentifiable.

After cytologic evaluation of bone marrow and correlation with CBC results, a determination can be made as to whether any of the cell lines are hypoplastic or hyperplastic and whether there is evidence of maturational arrest, dysplasia, neoplasia, or inflammation. This information can then be correlated with the clinical information to determine appropriate differential diagnoses and likely disease pathogenesis.

Molecular Diagnostics in Large Animals

NICOLA PUSTERLA and CHRISTIAN M. LEUTENEGGER, *Consulting Editors*

Molecular Diagnostics in Large Animals

Christian M. Leutenegger • Nicola Pusterla

Of the four classes of organic molecules that compose the basic physical structure of all living beings, nucleic acids are the only molecules that carry replicable instructive information. Nucleic acids differentiate themselves from lipids, carbohydrates, and even proteins in their ability to organize the basic unit of life, the cell. Even minor alterations in DNA and RNA molecules can disrupt the fine balance between health and disease. The field of molecular diagnostics seeks to elucidate the variations and mutations in genetic material that can cause disorder in the otherwise intricately organized body.

The amplified era of molecular diagnostics for infectious diseases began in 1983 when Dr. Kary Mullis of Cetus Corporation first conceptualized the polymerase chain reaction (PCR). He went on to win the Nobel Prize in Chemistry for this revolutionizing technology 10 years later.[1,2] Since the inception of PCR technology, infectious disease diagnostics has been at the forefront of molecular medicine, with the promise of detecting contagious pathogens in a safer and more sensitive way to aid in controlling their spread. Infectious disease testing is expected to continue to dominate the molecular diagnostic market for large animals in the foreseeable future. The use of amplified and nonamplified tests to assay the molecular makeup of the host rather than the pathogen is growing. Whereas cancer diagnostics is in its infancy for large animal testing, parentage and forensic testing together with single-nucleotide polymorphism (SNP) detection using in situ hybridization (ISH), fluorescent in situ hybridization (FISH), and sequencing technologies is gaining importance in assessing the presence and prognosis of genetic diseases.

The ability of molecular diagnostic assays to sensitively and specifically detect the primary cause of a disease, with short turnaround time, is giving significant advantages to disease diagnostics. Molecular tests are able to detect a specific unknown. Such tests are binary by nature; they provide a yes-or-no answer. However, certain tests when used quantitatively provide more insight into the medical manifestation induced by *Clostridium perfringens* toxins, for example. The clinically valuable information rests in determining the presence or absence of a specific pathogen in a biological sample derived from an animal. Because detection of viral, bacterial, rickettsial, fungal, or parasitic nuclear material in a biological sample gives clinically important information, molecular tests have direct clinical utility. However, the clinical context is always important to consider when making an interpretation on a molecular test. Determining the presence of a gene sequence per se without the clinical context does not necessarily correlate with a given clinical action, since diseases are generally multifactorial. In contrast, establishing the presence of the neuropathogenic form of equine herpesvirus (EHV)-1 in an equine patient's blood sample has direct association with EHV-1 infection, whether this translates into a symptomatic stage or not. The binary nature of molecular tests, which establishes the presence or absence of genetic material in a sample with a high degree of accuracy, has an accepted clinical value for infectious disease diagnostics because of its correlation with clinical signs.

Rapid results have tremendous clinical value in curtailing infection. Molecular methods can provide results in hours compared with days for culture-based or alternative technologies. The high sensitivity and specificity of molecular testing is particularly valuable in early determination of infection and makes it advantageous compared with antibody and antigen testing without amplification techniques. In most cases pathogens enter the host and replicate exponentially; early detection provided by the higher sensitivity allows for earlier clinical intervention and a better prognostic outlook. Molecular tests have been shown to produce fewer false-positive and false-negative results compared with other test platforms. Therefore, molecular tests are becoming the gold standard in the laboratory in terms of sensitivity and specificity. Key features for the adoption of molecular diagnostics for infectious agents are as follows:

- Superior sensitivity and specificity compared with most immunoassays
- Automated platforms that significantly increase throughput
- Quantitative assessment of viral load, which is clinically useful
- Fast turnaround time that speeds detection and reduces overall costs
- Simultaneous analysis of multiple analytes
- Standardized environment with the potential for full comparability across lab systems
- Ability to tightly quality control and monitor all aspects of the test workflow, including sample quality, DNA and RNA quantity, contamination situation during extraction and in the lab in general, presence of inhibition, and performance of the PCR test and reagents.

Technological Superiority of Molecular Tests

The relative technological superiority of molecular methods makes them likely to partially replace other types of more conventional methods such as culture-based tests or certain direct antigen and antibody tests to determine the presence of an infectious pathogen in a sick animal. Whereas antibody testing is more of a broad

VetBooks.ir

screening tool, molecular diagnostics allow accurate detection of the genome of a pathogen in a clinically sick animal. Culture-based tests have a turnaround time of days and are labor intensive. In addition, certain infectious agents are difficult to culture or biohazardous for laboratory personnel (e.g., *Mycobacteria* species, fungi, *Mycoplasma* species, *Lawsonia intracellularis*). In such instances, molecular detection of selected pathogens has already supplanted conventional culture.

Rapid and High-Throughput Applications Promote Molecular Tests

Rapid and specific detection of infectious disease agents is crucial for the prevention or containment of outbreaks. In the case of avian flu, the rapid detection of H5N1 strains of that virus is critical for containment. The avian flu pandemic concerns necessitate rapid and high-throughput molecular tests to maintain the well-being of animal and human community health. Similarly, West Nile virus (WNV) screening of mosquito pools and birds as well as screening for exotic Newcastle disease are additional examples of high-throughput applications with predominance for molecular tests.

Increasing Adoption of Molecular Tests by University and Commercial Laboratories

Since the advent of molecular platforms in the diagnostic laboratory, most molecular tests in veterinary medicine are performed by several commercial and public laboratories (Table 29-1). Unlike the market in human molecular diagnostics, which is dominated by four large players (Roche, Bayer, Gen-Probe, and Abbott), veterinary molecular diagnostics shows significant fragmentation in particular with many university diagnostic laboratories. However, the transition to the more advanced real-time PCR platform within the past 5 to 7 years and the abandonment of conventional PCR tests by many laboratories has led somewhat to a concentration process in the veterinary diagnostic landscape for a good reason: real-time PCR is the more advanced method and is considered a fully matured technological platform with great incentives for automation, operational efficiency, and affordability.

Simultaneous Testing of Multiple Pathogens

Parallel testing of multiple infectious agents in highly standardized platforms is a central advantage of molecular assays; it essentially allows several tests for both DNA and RNA pathogen targets to be performed simultaneously on a single sample, therefore condensing the medical message obtained on a given diagnostic sample. This development is a noteworthy driver for molecular diagnostics because it allows acquisition of more meaningful data from a single sample. This so-called panel strategy allows an efficient workup of complex clinical syndromes with general symptomatology that do not allow etiologic diagnosis based on clinical signs. These clinical cases are complex for the decision-making process for the veterinarian dealing with patients unable to communicate the pain matrix. In complex organ-related problems with general or unspecific symptomatology, multiple infectious agents can be responsible for a clinical picture or aggravate other primary events in the differential workup. Even though veterinarians tend to make a single-pathogen diagnosis, it has become more evident in recent years that many syndromes are caused by multiple infections present at a given time. Panel testing on a large scale will uncover unknown co-infections in animals, which can diffuse the clinical picture. It has long been speculated, for example, that seemingly clinically irrelevant EHV-2 infections in horses may be a predisposing factor for *Rhodococcus equi* pneumonia in foals. More characteristic examples include respiratory infections in companion animals, often initiated by subclinical viral or bacterial infections that lead the way to secondary infections. In addition, many vectorborne pathogens have a high tendency to persist in infected animals and therefore may facilitate viral infections or aggravate preexisting conditions such as feline immunodeficiency virus or feline leukemia virus infection. Sepsis caused by infectious agents is expected to become an important segment for equine molecular diagnostics, especially in neonatal medicine. Molecular diagnostics enable fast turnaround time with rapid initiation of treatment. In the future, panel testing for the most important sepsis-inducing agents could be complemented by the addition of assays targeting antimicrobial resistance genes. This would allow the modification of treatment regimens in case antimicrobial resistance is detected.

Indications for Use of Polymerase Chain Reaction Assays for Infectious Diseases

Diagnostic tests such as PCR assays offer the potential for fast and accurate determination of the presence of an infectious agent, which can lead to an improved clinical outcome because of the faster initiation of more etiologic-based treatment and the possibility for quantitative treatment monitoring. Even if molecular-based tests are more expensive than more traditional diagnostic assays, their overall impact will lead to reduction in treatment costs.

Key indications for use of a molecular test are the speed and accuracy of molecular assays. In comparison with traditional culture for bacteria, rickettsial organisms, fungi, and viruses, molecular testing offers direct detection of the target pathogen within a fraction of the time. Owing to its speed, PCR assays have the potential to replace traditional culture methods for infectious agents that are difficult to culture or not cultivable at all.

Compared with serology testing, molecular tests offer the advantage of detecting an infectious agent before an immune response occurs and a detectable antibody titer is developed. Immunoglobulin M (IgM) analysis in certain applications (such as WNV) can alleviate this problem; however, molecular testing methods are more reliable in picking up early virus replication and allow a faster epidemiologic assessment and earlier patient treatment.

In certain instances, for the discrimination of a clinically relevant EHV-4 infection from a latent infection, the detection of viral DNA is not informative. In such cases the quantitative assessment of viral loads is necessary.[3] Similarly, the choice of RNA or DNA affects the ability to distinguish disease (active virus replication and production of viral transcribed RNA) from nondisease (viral DNA of latently infected cells) status.

Molecular Biology Technologies

The main methodologies used for molecular diagnostics include the following:

- Nucleic acid capture, probe hybridization
- ISH, FISH
- Isothermal amplification of nucleic acids[4]
- Transcription-based amplification methods
- Signal amplification by branched-chain DNA
- Qualitative pathogen identification using nucleic acid amplification
- Quantitative assays
- Genotyping assays
- Genotype sequencing assays
- Multianalyte testing panels

Genotyping assays are usually used to test for known mutations associated with inherited genetic conditions such as hyperkalemic periodic paralysis (HYPP) in horses, an autosomal dominant condition that causes potassium-induced attacks of skeletal muscle paralysis. Many of these assays depend on sequence-specific probes designed to hybridize with known genetic variations. For infectious agents, genotyping or speciation is achieved by using highly specific PCR- or hybridization-based assays or by restriction enzyme fragment length polymorphism (RFLP) assays. In these assays, amplified material is digested with a certain restriction enzyme that characterizes the difference between two target sequences.

The Polymerase Chain Reaction in Veterinary Molecular Diagnostics

Because of its predominance in research and diagnostic applications, PCR assays will be discussed in more detail in later chapters. To give practitioners guidance about what to look for when PCR-based molecular diagnostic assays are offered, we will discuss some aspects such as design guidelines, differences between traditional and real-time PCR assays, sampling, controls, and interpretation of results in greater depth.

PCR testing in its pure form is a three-cycle event: denaturation of double-stranded target (or in later cycles PCR products), annealing of target and primers, and extension of the DNA strand from the primer.

Comparing Real-Time Polymerase Chain Reaction with Traditional Polymerase Chain Reaction Testing for Diagnostic Applications

Real-time PCR testing was introduced into the marketplace in 1996 and replaced the tedious gel electrophoresis step to detect PCR products after amplification. In one survey, 98% of equine veterinarians knew about PCR testing and 79% of equine veterinarians at universities knew the difference between conventional and real-time PCR testing.[5] During gel electrophoresis, the PCR products are separated by size and visualized using a dye (ethidium bromide) that intercalates with the double-stranded DNA. Real-time PCR detects the PCR products by using an internal probe that is labeled with two fluorescent dyes: a reporter dye and a quencher dye. The fluorescent activity of the reporter dye is absorbed (quenched) by the quencher dye. The probe binds to the PCR products between the two PCR primers. If the primers are extended by the DNA polymerase, the 5′ nuclease activity of the DNA polymerase digests the internal probe (hence hydrolysis probe) and releases the quenched fluorescence. Alternatively, hybridization probes can be used that are not digested during amplification and that allow melting curve analysis. This single change in the protocol regarding how to detect the PCR products revolutionized the use of PCR testing for both research and diagnostic applications. Most of the advantages resulting from this principle originate from the fact that the PCR tube does not have to be opened after a PCR assay for analysis. This principle is called *closed-tube detection.* The advantages are as follows:

1. Because of the closed-tube detection format, PCR products cannot escape from the PCR reaction containers. If escape occurs, it leads to the contamination of the PCR laboratory and subsequently the next PCR reactions. The consequence is false-positive PCR results. Real-time PCR efficiently eliminates this risk of PCR product carryover. There is also a second safety system called AmpErase UNG (Invitrogen, Grand Island, NY),[6] which eliminates contaminating PCR products.
2. Real-time PCR is a kinetic PCR principle, underlining the fact that PCR product accumulation is measured during every single PCR cycle in real time. Because of this fact, real-time PCR is a quantitative method.
3. The real-time PCR platform introduced in 1996 consisted of a laser-based thermocycler, software to design real-time PCR assays, reagents, disposables, and protocols. Because of its integrated design, PCR assays generated with the new system were highly standardized.
4. Data analysis is run on an attached computer that collects fluorescent data points. This principle eliminates all laboratory steps after the real-time PCR cycling is finished. Because of the computer-formatted end analysis, results can be fed directly into the information and management systems of diagnostic laboratories. Real-time PCR has also enabled rapid cycling to finish the PCR process in less than 1 hour. Real-time PCR results therefore can be turned around significantly faster than with traditional PCR testing (normally within a 24-hour period).
5. Because of the probe used to detect the PCR products, real-time PCR is also a more specific assay than single-round traditional PCR. Only specific PCR products are detected by the probe. Real-time PCR testing, essentially a liquid-based hybridization method, is considered as specific as Southern blotting, which is a solid-based hybridization method.
6. Because real-time PCR incorporates hot-start enzymes, the specificity is even greater than with regular non–hot-start DNA polymerases. Hot-start enzymes are inactive at ambient temperatures and have to be heated to 95° C for 20 seconds to 10 minutes in order for the DNA polymerase activity to begin. Because of the hot-start nature, nonspecific binding of primers does not lead to unspecific PCR products and results in an overall increased specificity of the assay.
7. In combination, real-time PCR is described to be as sensitive as or more sensitive than double-round (nested) traditional PCR. Analytic sensitivity and limit of detection using real-time PCR testing is normally in the single molecule range, whereas the limit of quantitation with traditional PCR testing is in the range of 10 to 20 molecules.

Preanalytic Variables

In general, molecular diagnostic laboratories provide strict recommendations for sample collection, including shipping instructions. These instructions include specimen type, volume, anticoagulant, and specimen transport, storage, and handling. The sample type is largely influenced by the pathogenesis of the disease and plays a key role in the performance and interpretation of the test results. Veterinarians are advised to adhere to these recommendations, because the quality of the result is directly correlated to the quality of the sample and preservation of the nucleic acid content. Molecular assays often offer the convenience of using a small specimen acquired with a minimally invasive procedure. The diagnosis of herpesviruses is a classic example in which culture and neutralization assays have been largely replaced by PCR testing on a small volume of aspirate or swabs from mucosal surfaces. Molecular tests can detect the presence of small numbers of organisms, and the probability of detection increases when a larger volume of specimen is added to the amplification reaction. Because molecular assays do not need viable organisms for testing, more flexibility in specimen transport is possible than with culture methods.

Appropriate specimen collection and transport conditions are important to ensure successful extraction of intact nucleic acid and to prevent cross-contamination. Specimen transport and storage conditions are likely to vary among specimen types and between RNA and DNA tests. RNA is more susceptible to degradation but in general, molecular diagnostic samples should be cooled in order to slow the nucleic acid degradation within the sample. Because of the difficulty of maintaining a freeze chain, molecular diagnostic samples should only be cooled throughout the collection, storage, and transportation process in order to minimize sample deterioration. Detailed storage and shipping instructions are crucial for a successful molecular diagnostic workup. Practitioners should be aware of these recommendations and consider using appropriate cooling containers when samples are collected in the field. Such samples maintain stability if stored appropriately in a cooled environment. Freezing and in particular the thawing process often adversely affects the quality and should be avoided if not otherwise instructed by the laboratory.

Sampling errors are among the many preanalytic variables that can affect the outcome of the results. It is therefore recommended to have the appropriate labeling material available for blood containers or other sample types. Blood or body liquid contamination on the outside of the containers is an obvious cause of sample cross-contamination before the samples are manipulated in the laboratory. Proper collection procedures are essential to prevent these kinds of artifacts.

Nucleic Acid Extraction

Many commercially available manual and automated methods have been successfully applied to infectious disease testing using a variety

VetBooks.ir

of clinical materials. Especially in veterinary molecular diagnostics, the variety of sample types can be challenging for processing through a single platform but can be achieved by validating sample type specific pretreatment procedures in order to create a lysate of similar viscosity and nucleic acid concentration, which maximizes the extraction efficiency. Automated or semiautomated platforms are rapid and usually require only a small volume of specimen. In general, these systems are total nucleic acid extraction systems and support the parallel analysis of DNA and RNA pathogens from the same sample in a panel configuration. In addition, commercially available automated systems can reduce hands-on labor requirements and speed up the process significantly, leading to even shorter turnaround times. Most systems can accommodate sample volumes ranging from 100 to 500 µL and even 1 mL of specimen lysate. Nucleic acid binding capacity varies and can be as high as 200 µg per individual extraction position, which allows the maintenance of a good limit of detection even when many infectious agent targets are analyzed in parallel for a given panel.

Interpretation of Results

Interpretation of results obtained with molecular assays for infectious diseases requires understanding of the pathogenesis and biology of the target organisms. Some challenges are unique to molecular tests and are different from considerations in interpreting other microbiologic tests. Such differences are related to the distinction of viable from nonviable organisms and the correlation of nucleic acid detection with presence of disease or disease association.

Interpretation of a negative result includes information about the sensitivity and nucleic acid extraction efficiency. A false-negative result may be caused by a degraded or unstable sample. Insufficient volume or inappropriate sample type, inadequate sampling procedures, and transport problems are additional sources for potentially false-negative results. Sample-specific internal positive controls targeting endogenous genes such as the universal 18S rRNA (ssrRNA) or glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene help to identify these problems. These so-called internal positive controls allow the quantification of the sample specific nucleic acid (both DNA and RNA) and allow validation of a diagnostic sample for its use in PCR; samples below a certain quantity of DNA are at risk of being called false negative; therefore, repeat collection can be recommended. In addition, inhibition phenomena originating from difficult sample matrixes such as feces, urine, or environmental samples contaminated with trace amounts of soil (humic acid) have to be controlled with internal positive controls to assess the inhibitory effects.

The factors requiring consideration for the interpretation of positive results include assay specificity and contamination issues. PCR testing or any other target amplification method is subject to these considerations. Real-time PCR testing using closed-tube detection procedures reduces the risk of PCR product carryover as a source of false-positive results and the availability of systems, which mark the PCR products when produced with certain types of nucleotides (uracil instead of thymidine), allows the specific degradation of contaminating PCR products before the next PCR amplification is taking place (AmpErase UNG system). Combined with air movement control in the molecular diagnostics lab (overpressurized clean lab and negative-pressurized sample preparation lab) and limited access to trained laboratory technicians, great safety can be achieved, leading to valid results.

In general, molecular assays do not provide information about the viability of an infectious agent. Exceptions to this are DNA viruses, bacteria, and parasites analyzed for transcribed genes instead of their genomic DNA. This approach allows the assessment of the replication competence of a target and therefore is highly correlated with viability. Examples are toxin quantification, differentiation of vaccination versus infection, and herpesvirus quantification in order to differentiate between lytic (acute) and chronic (latent) infection, which has immediate implications to the ability of the virus to cause or contribute to clinical signs. In addition, spliced RNA occurs only if viral genes are actively transcribed and provides a means for obtaining information about the replication activity of a virus and the stage of infection. In other cases, targeting the ribosomal RNA of parasites such as *Toxoplasma* and *Cryptosporidium* is a means for obtaining viability information and also may increase the analytic sensitivity.[7]

Detection of the nucleic acid of a pathogen does not necessarily ensure that the organism is the cause of the disease. A primary example is herpesvirus infections (EHV-1 and EHV-4), in which the detection of DNA may indicate the presence of lytic, non-replicating, or latent virus. Studies indicated that high viral loads of EHV-4 DNA allow the formulation of a cutoff value to differentiate between lytic and latent infection.[8] In this particular case, high viral loads were associated with the presence of clinical signs and the presence of viral RNA transcripts. Therefore, quantitative real-time PCR testing can provide a means to obtain much improved disease association and invalidates the notion that PCR "just detects dead DNA."

Reporting of Molecular Results

Reporting results for qualitative assays in infectious disease monitoring is simple: a sample either does or does not contain the nucleic acid of a target organism. Further relevant information includes the nucleic acid extraction efficiency, nucleic acid stability, and sample integrity determined with the various quality controls.

Reporting results for quantitative molecular infections is more complex. For veterinary medicine, some quantitative applications have been established and are progressively phased into diagnostic routine analysis. Such quantitative PCR tests combined with fully standardized protocols will continue to expand within the veterinary diagnostic market as our understanding of the biology and pathology of infectious agents grows.

Regulatory Considerations of Molecular Laboratories

Veterinary molecular diagnostics is an emerging market with a growing level of regulation. Standards such as those defined by the American Association of Veterinary Laboratory Diagnosticians (AAVLD; http://www.aavld.org), Molecular Diagnostic Methods for Infectious Diseases (NCCLS; www.nccls.org), or MIQE (minimum standard guidelines for fluorescence-based quantitative real-time PCR experiments) are adopted by commercial laboratories aiming to provide a comprehensive diagnostic service. Other sources for guidelines are U.S. Food and Drug Administration (FDA) guidelines (www.fda.gov) for the detection of nucleic acids; ASTM guidelines (*Standard Guide for Detection of Nucleic Acid Sequences by the Polymerase Chain Reaction Technique;* www.astm.org); and the Association for Molecular Pathology (AMP) (*Recommendations for In-House Development and Operation of Molecular Diagnostic Tests;* www.ampweb.org).

Guidelines for Clinicians to Select Molecular Diagnostic Laboratories

Veterinarians can use a variety of guidelines to select laboratories for molecular diagnostics. However, there are some major factors worth considering before samples are submitted. First, it is worthwhile to obtain information about the nature of the PCR test (traditional vs. real-time). Second, questions addressing the quality control and quality assurance system within a particular laboratory should be asked. Third, turnaround time, pricing, and the level of guidance with result interpretation and availability of consulting resources are additional factors worth investigating before samples are submitted.

Summary

As with any methodologies, quantitative PCR is a work in continuous progress and development and improvement. Although all of the methods described in this review use the Nobel Prize–awarded PCR process, the advantages and disadvantages of subtle differences in

VetBooks.ir

assay format, accuracy, and reliability of quantitation have to be rigorously compared. The next generation of quantitative real-time PCR processes will be increasingly automated, standardized, and miniaturized. The time for nucleic acid preparation and PCR amplification will be further reduced by using small microtiter-formatted microfluidic cards or silicon-based chip technology.[9-11] Amplification time has been brought down to several minutes by using an advanced nucleic acid analyzer (ANAA) consisting of a battery-powered array of silicon-based PCR microchips with thin-filmed resistive heaters, thus enabling ultrafast amplification, further pushing the technological possibilities in order to improve the diagnostic results output.[10]

How will these new systems be incorporated in routine veterinary diagnostics? Veterinary medicine will experience a broad adoption of many quantitative assays for infectious agents and genetic abnormalities in the near future. The ability to standardize assays will allow high-throughput applications that have not been possible with traditional molecular methods. For this reason, applications for veterinary medicine may experience not only quantitative but also qualitative growth. These assays will help improve patient management and client satisfaction.

Molecular Testing for Infectious Diseases in Horses

Nicola Pusterla • Christian M. Leutenegger

The ready availability of a correct etiologic diagnosis, particularly in contagious infections, enables the veterinarian to make early decisions regarding the patient's care and management, address appropriate treatment, and allow timely notification and discussion of management issues pertaining to the prevention of disease spread. The past two decades have seen a revolution in the understanding, management, diagnosis, control, and prevention of infectious diseases.[1,2] This period has encompassed the discovery of emerging equine agents, antimicrobials and vaccines, as well as a wealth of improved diagnostic tests for equine practitioners. Despite these advances, infectious diseases remain a leading cause of equine morbidity and mortality, with resurgence of certain infections (e.g., West Nile virus), an increasing population of elderly, more susceptible horses, and an increasing international equine commerce, expanding the geographic distribution of pathogens.[3,4] The focus of rapid diagnosis of infectious diseases has also shifted during this time. The most obvious change has been the appearance and increasing importance of nucleic acid (NA) amplification-based techniques, primarily the polymerase chain reaction (PCR), at the expense of traditional methods of clinical microbiology.[5] The PCR has become an increasingly important tool in microbial diagnosis in recent years, mainly because of its rapidity, high sensitivity, and high specificity. These superior characteristics have propelled the field of PCR-based molecular diagnostics into the arena of applied diagnostics for infectious agents. Because the number of published and offered PCR assays is steadily rising, there is a need for critical evaluation, comparison of performance, and eventually standardization of methods to enable equine practitioners to select the optimal methodology.

Sample Submission

Nucleic acid (NA) techniques to detect the presence of infectious agents in biological specimens require stringent quality guidelines. These guidelines aim to ensure the stability of NAs (both genomic DNA and total RNA), which are the target for molecular-based diagnostic methods. Whole blood samples are collected aseptically into evacuated blood tubes containing EDTA; body fluids (e.g., thoracic, abdominal, joint, cerebrospinal, tracheal wash, bronchoalveolar, and guttural pouch lavage fluid) and tissues should be collected into serum tubes without additives; nasal or nasopharyngeal secretions should be collected with rayon- or Dacron-tipped swabs and are best kept in a sterile serum or conical tube (virus transport medium is recommended for the detection of viruses); fecal material should be collected into small fecal cups or serum tubes (Table 29-2; Fig. 29-1). All samples must be sent cooled on blue ice by express mail overnight to the laboratory. Freezing of samples should be avoided. Short-term storage for a period of 2 to 3 days before shipment (over a weekend) should be done in a refrigerated compartment. Each sample should be properly labeled and accompanied by a submission form containing information pertaining to the patient, owner, veterinarian, sample, and pathogen (s) to be tested (most submission forms can be downloaded from the respective laboratory website). The laboratory should be notified in advance and inquiry should be made about the availability of the offered tests as well as turnaround time and associated costs. Incoming samples normally are processed the same day and PCR results usually are available within 24 to 48 hours if the NA passes quality control.

TABLE 29-2

Tissue Samples Commonly Used for the Molecular Detection of Common Equine Pathogens

Pathogen	Tissue Submission
Anaplasma phagocytophilum	Whole blood
Babesia caballi	Whole blood
Clostridium difficile (antigen and toxin A and B)	Feces
Corynebacterium pseudotuberculosis	Aspirate from abscess, body fluid
Cryptosporidium spp.	Feces
Equine arteritis virus	NPS, uterine swab, placenta, aborted fetus
Equine coronavirus	Feces
Equine herpesvirus 1	NPS, whole blood, TW, BAL, CSF, CNS, uterine swab, placenta, aborted fetus
Equine herpesvirus 2	NPS, whole blood, TW, BAL
Equine herpesvirus 4	NPS, TW, BAL
Equine herpesvirus 5	NPS, whole blood, TW, BAL
Equine influenza virus	NPS, TW, BAL
Equine rhinitis A virus	NPS, urine
Equine rhinitis B virus	NPS
Equine rotavirus	Feces
Lawsonia intracellularis	Feces, intestinal biopsy
Leptospira spp.	Urine, blood, uterine swab, placenta, aborted fetus
Neorickettsia risticii	Whole blood, feces
Neospora hughesi	CSF, CNS
Rhodococcus equi	TW, BAL, feces
Sarcocystis neurona	CSF, CNS
Streptococcus equi subsp. *equi*	NPS, NPL, GPL, lymph node aspirate
Salmonella spp.	Feces
Theileria equi	Whole blood
West Nile virus	Whole blood, CSF, CNS

BAL, Bronchoalveolar lavage fluid; *CNS,* cerebrospinal tissue; *CSF,* cerebrospinal fluid; *GPL,* guttural pouch lavage; *NPL,* nasopharyngeal lavage; *NPS,* nasal/nasopharyngeal swab; *TW,* tracheal wash fluid.

Clinical Applications

An array of NA amplification techniques may be offered by laboratories in order to establish an etiologic diagnosis of equine infectious diseases. Several published studies have shown the benefit of NA amplification techniques in comparison to conventional microbiological techniques. Current efforts are aimed at improvement of the diagnostic efficiency of molecular techniques, both for common and less common infections. To facilitate a decision on which pathogens should be evaluated for a specific case, some laboratories offer panels covering specific organ systems (e.g., respiratory, gastrointestinal, neurology, bloodborne). Such panels test several common pathogens for each organ system. Some of the diagnostic PCR applications most

VetBooks.ir

relevant for equine practice are presented as follows, along with their advantages and potential pitfalls.

Respiratory Pathogens

Respiratory pathogens are often contagious, and infections must be diagnosed rapidly in order to prevent a disease outbreak and institute the appropriate management plan. The short turnaround time and reliability of PCR makes this molecular technology an ideal tool for the diagnosis of respiratory pathogens.

Equine influenza is commonly diagnosed by virus isolation or detection from nasopharyngeal swabs collected from horses during the early febrile stage of the disease. Virus can be grown from nasopharyngeal swabs by inoculation and incubation of embryonated chicken eggs or passage through Madin-Darby canine kidney cells. Although isolation of the virus is essential to allow antigenic and genetic characterization of the strain, this technology is time consuming and successful isolation is, at best, to be expected in 50% of the cases. Further, since mutations have been reported to occur during the process of viral culture, recovered isolates must be viewed critically. In recent years new methods for virus detection, such as antigen-detection enzyme-linked immunosorbent assays (ELISAs) and PCR, have been described. Collectively these detection methods have shown higher sensitivity than virus isolation and antigen-capture ELISAs (Table 29-3).[6-9] Amplification of the single-stranded RNA of equine influenza viruses is performed by reverse transcription-PCR (RT-PCR) technology, using either a one-step, nested, or real-time approach. The hemagglutinin, nucleoprotein, and matrix gene are the commonly targeted genes for these molecular assays. Unfortunately, comparison of the different PCR assays is precluded by the use of different technologies, the lack of standardization among the assays, and variation in targeted genes. Nucleotide and deduced amino acid sequences of portions of the hemagglutinin gene are now routinely used for phylogenetic characterization of outbreak strains. Further, novel real-time assays can be used as a viable replacement for the more traditional methods of quantifying equine influenza virus in vaccine efficacy studies. Another advantage of assays such as antigen-detection ELISAs and PCR is their ability to detect nonviable virus, a situation that may occur when nasopharyngeal samples are frozen or not adequately stored and/or shipped to a diagnostic laboratory, allowing a rapid diagnosis in the acute phase of infection. The commercially available Directigen Flu A (Becton, Dickinson and Company, Franklin Lakes, NJ) detects nucleoprotein, one of the type-specific antigens of type A influenza viruses, and was designed for use in cases of human influenza infection. Although this assay has the shortest turnaround time of all antigen tests (i.e., 15 minutes), its sensitivity decreases when low titers of virus are present, for example, in a partially immune horse with subclinical signs or in a clinical case past the acute onset of disease. In recent years, PCR-based assays have been described for the identification of equine influenza.

Equine herpesvirus (EHV)-1 and EHV-4 are important, ubiquitous equine viral pathogens that cause important economic losses in the equine industry. Both are double-stranded DNA alphaherpesviruses that affect the equine respiratory tract and can establish lifelong latent infection after primary exposure. Traditionally, virus isolation has been the gold standard for diagnosing EHV-1 and EHV-4 infections. The sample of choice is a nasal or nasopharyngeal swab, which should be taken early in the febrile phase of the disease. The swabs should be kept in viral transport medium and shipped on ice to a veterinary diagnostic laboratory. Because of the lymphotropism of EHV-1, virus isolation can also be attempted from citrated or heparinized whole blood. Virus isolation requires the maintenance of specific cell culture lines, making this process relatively expensive and time consuming. EHV-1 can be propagated in a broad range of cell lines; however, EHV-4 only grows in cell lines of equine origin. Virus isolation is often hampered by the fragility of the virus, intermittent viral shedding, and the interference with local antibodies. PCR offers an alternative to virus isolation and has proven to be a sensitive method of detecting EHV-1 and EHV-4 in respiratory secretions, peripheral blood lymphocytes, and other tissues.[10-12] Many conventional PCR assays have been established to study the pathophysiology and improve the diagnosis of these viruses. Conventional one-step or nested PCR assays do have inherent risks of carry-over contamination as a result of post-amplification steps required to detect the PCR products. Novel molecular platforms such as the real-time PCR have strongly reduced the risk of contamination. PCR assays used in routine diagnostics are based on the detection of viral genomic DNA and are therefore unable to distinguish between lytic, dead, or latent virus. Alternative molecular approaches have recently been established using the real-time PCR to allow discrimination among the different viral states in horses naturally infected with EHV.[13,14] Discrimination among the different viral states is now possible by (1) targeting several genes (e.g., glycoprotein, latency-associated transcripts), (2) detecting viral genomic DNA and transcriptional activity of the target genes at the messenger RNA (mRNA) level, and (3) using absolute quantification (Table 29-4). Viral threshold loads are used in selected human infectious diseases (i.e., HIV, HCV) to determine disease stage and response to antiviral therapy. A similar

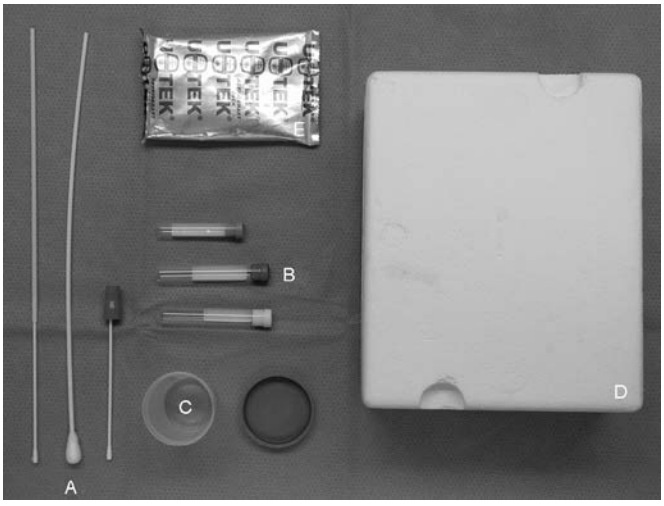

FIG. 29-1 Collection and shipping material routinely used to submit equine tissue samples for molecular detection. **A,** Three sterile swabs of different lengths. **B,** Three sterile, evacuated tubes with and without additives. **C,** A sterile cup with lid. **D,** A Styrofoam shipping container. **E,** A cooling element to keep the samples cooled.

concept is used diagnostically for EHV-1– or EHV-4–infected horses in order to discriminate between lytic and non-replicating virus, to determine their infectious risk based on viral load in nasal secretions, and to monitor their response to treatment.[13,14]

Streptococcus equi subsp. *equi (S. equi)* infection is rarely associated with detection difficulties when using conventional cultures in clinically affected horses. Culture of nasal swabs, nasal or guttural pouch washes, or exudates aspirated from an abscess remains the gold standard for the detection of *S. equi*. Culture, however, may be unsuccessful during the incubation, and early clinical phases of infection and the presence of other β-hemolytic streptococci, especially *S. equi* subsp. *zooepidemicus,* may complicate interpretation of cultures. Available PCR assays are designed to detect the DNA sequence of the *S. equi* M protein (SeM) gene, the gene for the antiphagocytic M protein of *S. equi*. This gene offers enough nucleotide variations between the two *S. equi* subspecies to allow full discrimination in clinical specimens. The test can be completed in a few hours and results may be available on the same day that samples are taken. One of the pitfalls of PCR has been its inability to distinguish between non-viable or live organisms; therefore, positive results have in the past been considered presumptive until confirmed by culture. Nowadays, the viability issue can be addressed by quantitation of the SeM gene or detection of transcriptional activity of the SeM gene at the RNA level. In several studies, PCR proved to be up to three times more sensitive than culture (Table 29-5).[15-17] PCR accompanying culture on a nasal swab or guttural pouch lavage may be used in a control program to select possible carrier animals, because PCR is capable of detecting *S. equi* DNA in guttural pouch lavages for weeks after disappearance of live organisms. Such is not the case for the nasopharynx, in which the efficient mucociliary apparatus removes organisms and DNA at the same time. PCR should be considered to detect asymptomatic carriers, establish the *S. equi* infection status of asymptomatic horses, and determine the success of elimination of *S. equi* from the guttural pouch. A particular problem in the management of strangles outbreaks is the lack of a suitable assay to differentiate between wild-type and vaccine *S. equi* strains. Recent studies have shown gene variations in the N-terminal region of the SeM gene of various field isolates, allowing epidemiologic analysis of disease transmission.[18] Further, a deletion in the *aroA* gene of a live attenuated strangles vaccine marketed in Europe (Equilis StrepE, Merck Animal Health, Walton Manor, Walton, Milton Keynes, UK) has allowed the development of a PCR assay able to differentiate between wild-type and vaccine strains.[18] Such assay has, however, not yet been developed to differentiate between the intranasally applied attenuated live vaccine marketed in North America (Pinnacle I.N., Zoetis, Overland Park, KS) and field isolates. However, when needed for forensic reasons, differentiation can be done via the morphology of colonies, biochemical analysis, genotyping, and restriction digest.[19] Together, these assays allow differentiating between wild-type and vaccine/ancestor strains.

Rhodococcus equi is an important cause of chronic suppurative bronchopneumonia with extensive abscessation in foals 3 weeks to 6 months of age. Culture of the organism from tracheal wash (TW) fluid currently is considered the gold standard for diagnosis.[20] However, it can be difficult to reliably grow *R. equi* from a single TW sample, possibly because of prior antimicrobial administration or overgrowth by multiple pathogenic bacterial species.[21,22] Hillidge[23] reported that only 62% of foals with positive *R. equi* cultures at necropsy and 64% of those with radiographic evidence of lung abscessation yielded *R. equi* on culture of TW fluid. PCR has been evaluated in order to increase the diagnostic sensitivity of TW fluid samples. Strains of *R. equi* isolated from sick foals uniformly contain an 85- to 90-kb plasmid that carries the gene responsible for expression of a 15- to 17-kDa antigen (vapA) of undetermined function.[24,25] Environmental strains of *R. equi* not associated with disease do not contain this plasmid. Therefore, detection of the vapA gene of *R. equi* in a TW fluid sample from a foal with pneumonia can be considered diagnostic. Both culture and PCR, however, may detect environmental contaminants of *R. equi* in TW fluid, but PCR has the ability to distinguish between virulent and avirulent strains. Foals, however, may have virulent or avirulent strains of *R. equi* present as contaminants in their airways that are not responsible for clinical signs of pneumonia. This situation may be more likely on farms in which *R. equi* problems are endemic. In a study evaluating the sensitivity of conventional culture, PCR and serology from 53 foals with pneumonia, PCR of TW fluid was found more sensitive and specific for the diagnosis of *R. equi* pneumonia than the other two available diagnostic tests.[26] PCR should be used in conjunction with standard culture because of the probability of the presence of multiple bacterial pathogens and the inability of PCR to determine antimicrobial sensitivity

VetBooks.ir

of *R. equi*. PCR with its higher sensitivity and specificity may be useful to rule out *R. equi* pneumonia in culture-negative foals that have failed to improve with standard antimicrobial therapy and have clinical signs consistent with *R. equi* pneumonia. It may also be useful in monitoring response to therapy and deciding when to discontinue therapy in foals that are confirmed to have *R. equi* pneumonia. In clinical situations in which the severity of the respiratory signs of the patient prevents the collection of TW fluid, feces have been shown to be a sensitive surrogate specimen for the molecular detection of *R. equi*.[27] The study determined that fecal PCR had a similar diagnostic accuracy as that of culture of TW fluid samples, and that false-negative fecal PCR results for *R. equi* were associated with prior use of antimicrobials.

Equine rhinitis A and B virus and equine arteritis virus, although less commonly associated with infectious upper respiratory disease (IURD), should also be considered as target pathogens during respiratory outbreaks.[28-30] The role of EHV-2 and EHV-5 in nasal secretions of horses with IURD is still unclear.[31] Because of their high prevalence in horse populations and in order to avoid dilemmas with the interpretation of PCR results, the testing of gamma herpesviruses is at this time not recommended. Infection with EHV-5 has been associated with equine multinodular pulmonary fibrosis, a novel pathogenic entity with characteristic gross and histopathologic pulmonary lesions.[32] In such cases, antemortem diagnosis can be supported by the PCR detection of EHV-5 in bronchoalveolar lavage or pulmonary biopsy tissue samples.[33]

Neurologic Pathogens

Although highly sensitive and specific PCR assays have been developed for detection of viral and protozoal genomes in the cerebrospinal fluid (CSF) of neurologic patients, these methods are often of limited value in the routine diagnosis of these diseases because viremia is often very short-lived or the pathogen has no affinity to the cells of the CSF. Consequently, pathogens are usually no longer detectable at the onset of systemic or central nervous system (CNS) signs.

Equine protozoal myeloencephalitis (EPM), caused by the protozoal apicomplexa parasites *Sarcocystis neurona* and *Neospora hughesi,* represents one of the greatest diagnostic challenges for equine practitioners. Detection of the parasite at necropsy is considered the gold standard. Therefore, clinical diagnosis is based on clinical findings, exclusion of other neurologic diseases, and the use of serologic assays (e.g., Western immunoblot, indirect immunofluorescent assay) on serum and CSF.[34-36] Molecular diagnostics have also been investigated but their sensitivity was found to be low.[37]

Apparently, intact merozoites rarely enter CSF and free parasite DNA is destroyed rapidly by enzymatic action.[38] Based on its low sensitivity, PCR testing of CSF should not be recommended for routine diagnosis of EPM. In contrast, PCR testing of neural tissue has been shown to be useful as a postmortem test.[39] Sequence analysis is routinely used to identify *S. neurona* and *N. hughesi* isolates and to determine the heterogeneity and evolutionary relatedness within these and related species.[40,41] Detection and isolation of *S. neurona* from peripheral blood has only been reported in experimental studies.[42,43] Therefore, molecular detection of *S. neurona* in blood is very insensitive and should not be used in order to document or rule out EPM in a neurologic horse.

Diagnosis of West Nile virus (WNV) encephalitis in horses currently is based on observation of compatible clinical signs (e.g., ataxia, paresis, paralysis, hyperesthesia, muscle fasciculation, seizures, fever) and one or more of the following: isolation of WNV from blood, CSF, or tissue; a fourfold increase in plaque reduction neutralization test antibody titers on paired serum samples taken 2 weeks apart; or the detection of IgM antibody to WNV by IgM-capture ELISA.[44,45] Given the nonspecificity of the IgM ELISA (i.e., does not differentiate between disease and exposure) and the time required to serologically confirm WNV infection, alternative tests able to rapidly detect WNV in clinical specimens are important. RT-PCR using either a one-step, nested, or real-time approach has been evaluated to investigate antemortem cases of suspected WNV encephalitis in horses and humans using blood. The diagnostic sensitivity of WNV RT-PCR using either serum or whole blood was very low.[46-48] However, 57% to 70% of CSF samples from human beings with serologically confirmed WNV infection tested positive by real-time RT-PCR.[46,47] The reduced ability to detect WNV in CSF or serum from patients with serologically confirmed WNV infection is likely due to the short-lived viremia in dead-end hosts, and it emphasizes the fact that in order to detect WNV in blood or CSF, the sample should be collected early during the disease process. Investigation of the sensitivity of RT-PCR on CSF from horses with WNV encephalitis has not yet been reported. RT-PCR has also been shown to accurately identify WNV in field-collected mosquito pools, avian tissues, and human and equine brain tissue samples with a degree of sensitivity approaching that of virus isolation in Vero cells.[47-49]

Myeloencephalopathy is an uncommon presentation of EHV-1 infection and should always be considered as a differential diagnosis when a horse develops sudden neurologic signs (e.g., ataxia, paresis, urinary incontinence), especially if multiple horses on the premises are involved or when a recent history of fever, abortion, or viral respiratory disease in the affected horse or herdmates is reported.[50] Diagnosis is often based on history, clinical signs, and xanthochromia and elevated total protein concentration in CSF resulting from vasculopathy. Attempts to isolate virus from the blood or CSF of patients are often unsuccessful because the peak of viral shedding has usually passed by the time neurologic signs appear.[51] However, affected horses can shed the virus in nasal secretions and thus represent a risk of infection for unaffected in-contact horses. This outcome has been reported in a hospital setting in which horses developed neurologic disease after having been exposed to horses with EHV-1 myeloencephalopathy.[52] Therefore, it is imperative to determine the risk of shedding in a suspected horse in order to initiate an appropriate infectious disease control protocol. PCR, as previously shown for viral respiratory diseases, is a fast and sensitive molecular diagnostic tool and should be performed on blood and nasal or nasopharyngeal swabs to document viremia and nasal shedding, respectively.[39,53,54] The dilemma as to whether the virus is in a lytic, non-replicating, or latent state can be addressed by using absolute quantitation or transcriptional activity of the target gene similar to the approach used for EHV-4.[13] Research groups have recently identified a region of variation in the genome of different EHV-1 strains that correlates directly with their ability to cause neurologic disease.[55]

A single nucleotide polymorphism at position 2254 of the DNA polymerase gene (ORF 30) has been associated with a higher risk of EHM development. Rapid PCR assays have been established to allow differentiation between neuropathogenic and non-neuropathogenic strains.[56-58] However, such assays have moderate specificity, since 76% of EHV-1 strains associated with EHM have been shown to be of the neuropathogenic genotype.[59] Therefore, these assays should be used judiciously and the results should always be interpreted in the context of clinical presentation. Further, these assays should be coupled with additional assays targeting conserved regions of the EHV-1 genome.

Gastrointestinal Pathogens

The detection of equine gastrointestinal pathogens using conventional or molecular tests is often very challenging because these pathogens either are difficult to grow in cell culture systems or can be present in pathogenic or non-pathogenic forms, making interpretation of positive results difficult. Furthermore, the use of fecal material for molecular diagnostics has been associated with false-negative results because of the presence of inhibitory substances in the feces that can interfere with NA extraction or amplification.[60] However, development and use of specific extraction kits (DNA Stool Mini Kit, QIAGEN, Valencia, CA) have improved the yield of NA from feces.[61]

Neorickettsia risticii is the rickettsial agent responsible for Potomac horse fever (PHF), a serious enterocolitis of horses. Because of the nonspecific nature of the clinical signs, a provisional diagnosis of PHF is often based on the presence of typical clinical signs and the seasonal and geographic occurrence of the disease. A definitive

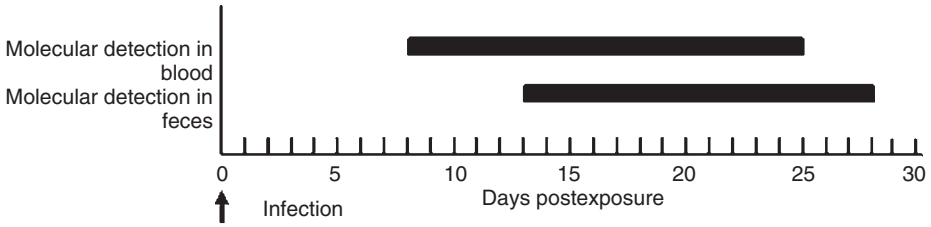

FIG. 29-2 Molecular detection period of *Neorickettsia risticii* in blood and feces of experimentally infected horses. *(From Pusterla N, Madigan JE, Leutenegger CM. 2006. Real-time polymerase chain reaction: a novel molecular diagnostic tool for equine infectious diseases. J Vet Intern Med 20:3. Reprinted with permission of the American College of Veterinary Internal Medicine.)*

diagnosis of PHF, however, should be based on isolation or detection of *N. risticii* from blood or feces of infected horses.[62] Isolation of the agent in cell culture, although possible, is time consuming and not routinely available in many diagnostic laboratories. The recent development of *N. risticii*–specific PCR assays has greatly facilitated the diagnosis of PHF.[63-64] These molecular assays have contributed to the investigation of the epidemiology of PHF, allowing the discovery of helminthic vectors and intermediate and definitive helminthic hosts as well as determining the natural route of infection.[65-67] Nucleic acid of *N. risticii* can be detected in the blood and feces of naturally or experimentally infected horses, but the detection period does not necessarily coincide between the two sample types (Fig. 29-2). Based on these results, we recommend analyzing both blood and feces from suspected horses in order to enhance the chance of molecular detection of *N. risticii*. Another application of PCR has been the recent description of the first equine cases of PHF from Nova Scotia using formalin-fixed and paraffin-embedded colon tissue.[68]

An emerging equine gastrointestinal pathogen, *Lawsonia intracellularis,* has been described in young horses.[69] This obligate intracellular bacterium is the causative agent of proliferative enteropathy (PE), a transmissible enteropathy known to affect a wide range of domestic and wild animal species.[70] This disease has a worldwide distribution and likely is underrecognized in horses. Antemortem diagnosis can be challenging and is based on interpreting clinical signs (e.g., lethargy, anorexia, fever, weight loss, subcutaneous edema, diarrhea, colic), clinicopathologic results (e.g., hypoproteinemia resulting from hypoalbuminemia), ultrasonographic findings (e.g., thickened small intestinal walls) and excluding other causes of similar gastrointestinal findings.[71] Currently, culture of the organism is difficult and is not routinely offered by laboratories. Antemortem diagnosis relies on serology and PCR.[72,73] The combination of both tests as well as repeated fecal sampling for PCR from target animals will increase the chance of diagnosing the disease. Novel PCR assays, such as the real-time PCR, have increased the sensitivity of molecular detection, compared with initial conventional assays.[74,75] PCR has the advantage of being fast and can yield positive results in the early stage of disease, when antibodies are not yet measurable. Prior use of antimicrobials can negatively affect the molecular detection of *L. intracellularis* in feces. Therefore, in a suspected case, fecal collection for PCR testing should be performed prior to the institution of any antimicrobial treatment.

In recent years, PCR assays for the detection of *Salmonella* spp. in fecal samples from horses admitted to veterinary hospitals have been evaluated.[76-80] Collectively, these studies have shown an unquestioned higher analytic sensitivity for the detection of *Salmonella* spp. PCR assays when compared with conventional microbiological culture. The higher detection rate of *Salmonella* by PCR has been attributed to the detection of nonviable organisms and of previously undescribed *Salmonella*-like bacterial organisms. The use of novel virulence target genes for the molecular detection of *Salmonella* spp. has considerably improved the performance and accuracy of such assays. More and more veterinary hospitals across North America are switching from conventional microbiological culture to PCR for the testing of *Salmonella* as part of their infectious disease control program. In such instances, PCR is performed on fecal and environmental samples following a 24-hour selective enrichment step. The use of PCR is very cost effective and has the potential to reduce contamination risks and turnaround time, with results being available within 22 to 28 hours from sample collection (18 to 24 hours enrichment time, 4 hours for DNA purification and amplification). Further, the use of absolute quantitation allows assessment of the infectious nature of hospitalized animals and may be an excellent alternative to conventional culture methods for surveillance and research studies.[80] Although PCR for *Salmonella* spp. is an accurate and fast screening test, one must still consider microbiological culture to confirm positive molecular results and to determine the serovar and antibiogram of the isolated *Salmonella* spp.

The detection of equine coronavirus (ECoV) by PCR in the feces of foals with fever and diarrhea is difficult to interpret because ECoV has also been detected in the feces of healthy foals. Healthy foals have been found to be infected mostly by ECoV in a single infection without any other co-infecting agents, whereas ECoV was found exclusively in association with other co-infecting agents in sick foals.[81] This is in agreement with coronaviruses in other species, where the virus may not have enough pathogenic potential to cause disease but causes local immune suppression, allowing secondary infections to take place more efficiently. In adult horses ECoV causes a self-limiting disease characterized by depression, anorexia, fever, and less frequently changes in fecal character and colic.[82,83] More epidemiologic studies are needed to better understand the impact of this emerging disease.

Equine rotavirus poses a challenge each foaling season to farm managers and veterinarians in intensive horse-breeding areas throughout the world. A quick and reliable diagnosis is essential in order to separate affected foal with diarrhea and reduce the spread of this virus. The diagnosis of rotavirus infection has in the past relied on direct virus detection using a rapid antigen-capture ELISA. Recently developed PCR assays have shown high analytic sensitivity, specificity, and accuracy in the diagnosis of equine rotavirus infection[81] and will likely replace the less sensitive ELISA test in the near future.

Miscellaneous Pathogens

Equine granulocytic anaplasmosis (EGA) is caused by *Anaplasma phagocytophilum,* a rickettsial pathogen transmitted by *Ixodes* spp. ticks. Diagnosis is often based on awareness of the geographic area for infection, typical clinical signs, abnormal laboratory findings, and identification of characteristic pathogen inclusions in the cytoplasm of neutrophils and eosinophils in a peripheral blood smear. PCR has been used for many years to study several aspects of the epidemiology and pathophysiology of EGA.[84,85] For clinical purposes, the material of choice is whole blood. PCR has been shown to be a very sensitive and specific tool, supporting the diagnosis especially during the early and late stage of the disease, at times when the number of organisms is too small to be detected via microscopy (Fig. 29-3).[86]

Corynebacterium pseudotuberculosis is a common cause of external and internal abscesses in horses from arid regions of North America.[87] The epidemiology has been investigated with the help of PCR, and flies have been identified as potential vectors.[88,89] *Corynebacterium pseudotuberculosis* is easy to grow on culture and use of PCR on clinical samples is restricted to specific situations (e.g., culture-negative aspirates or body fluids).

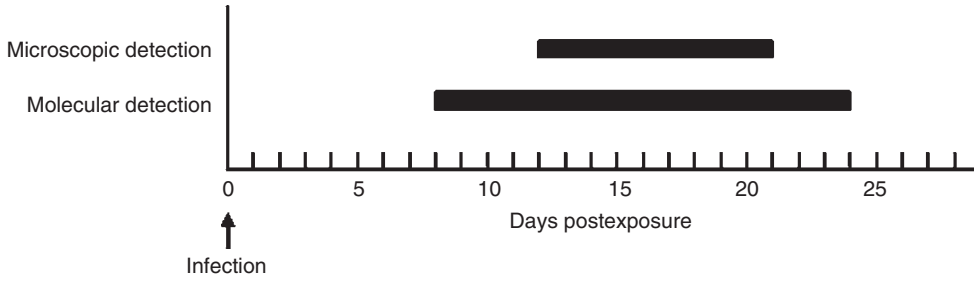

FIG. 29-3 Microscopic and molecular detection period of *Anaplasma phagocytophilum* in the blood of horses experimentally infected with *Ixodes scapularis. (From Pusterla N, Madigan JE, Leutenegger CM. 2006. Real-time polymerase chain reaction: a novel molecular diagnostic tool for equine infectious diseases. J Vet Intern Med 20:3. Reprinted with permission of the American College of Veterinary Internal Medicine.)*

Additional PCR assays for *Borrelia burgdorferi* sensu lato, *Leptospira* spp., *Mycobacterium* spp., *Mycoplasma* spp., *Babesia caballi, Theileria equi, Clostridium difficile* (antigen and toxin A and B), toxigenic *Clostridium perfringens, Cryptosporidium* spp., and methicillin-resistant *Staphylococcus aureus* have been developed and are being used in the research setting.[81,90-100] These assays will likely be offered in the near future for diagnostic purposes when additional epidemiologic information has been evaluated and accuracy of the tests has been validated using clinical samples from infected horses.

Molecular Testing for Infectious Diseases in Cattle, Sheep, and Goats

Beate M. Crossley • Sharon K. Hietala

The availability of molecular-based diagnostic technologies designed to identify infection or genetic conditions by detecting specific genome targets in the host or agent DNA or RNA have expanded logarithmically in the past decade. Diseases and genetic conditions affecting cattle, sheep, and goats are now commonly studied and diagnosed using a variety of molecular techniques and, in particular, polymerase chain reaction (PCR) assays and genome sequence analysis. Molecular-based approaches, which by nature can be extremely sensitive for the detection of infectious agents, were once considered useful only in research laboratories based on concerns ranging from the risk of laboratory contamination and false-positive findings to high per-assay costs. With the commercial availability of specialized instrumentation, reagents, and technical training, the criticisms have largely been overcome. Molecular technologies are now generally available for routine diagnostic services provided by state and federal diagnostic laboratories, university laboratories, and commercial laboratories. The technical complexity of molecular-based diagnostics, paired with the wide range of assays available to diagnose genetic and infectious diseases of food animals, means that no single laboratory can feasibly provide comprehensive testing for all species and all diseases. Instead, laboratories tend to focus on the diseases or genetic conditions of primary significance to their allied industries, and use the technologies that provide the most rapid, reproducible, and economic results for their particular group of clients. Largely based on this specialization within laboratories, molecular-based assays may be developed and put into use without significant effort toward assay standardization and validation. The list of PCR-based assays available for detection of infectious agents, in particular, has grown significantly in the past decade, although with no guarantee that the assays have been suitably designed, tested in the field, or clearly advertised as to their "fitness for purpose." For PCR-based assays, the selection of the genetic sequence (DNA or RNA) used as the target of the diagnostic assay is heavily dependent on the proposed use of the test and on the availability of known genomic sequence(s) for development of the assay. All genomes accumulate mutations over time, with some genes being highly mutable to allow evolutionary advantage, such as those genes that encode antimicrobic resistance or protein conformations for evading the host immune system. Other genes such as those encoding specific functions (e.g., replication) tend to remain highly conserved and stabile to protect the survival of the organism. Assays used to detect a specific agent, such as bovine viral diarrhea (BVD) virus, can be designed to target a conserved region of the genome that is shared by all members of the species. Alternatively, assays used to characterize or subtype particular strains or isolates, such as BVD virus type 1b, can be designed to target regions with significantly more mutability or sequence variation. Assays designed as "fit" for surveillance testing must often sacrifice the ability to discriminate closely related pathogens, such as BVD virus from the genetically related Border disease virus, in order to have the needed surveillance sensitivity to detect the broad range of potential BVD virus isolates. Similarly, assays designed for test and cull, or related disease control programs, must have a high diagnostic specificity for detecting only the agent or trait of interest. These assays tend to sacrifice diagnostic sensitivity or detection level in order to minimize the risk of false-positive results. Although molecular diagnostics provide a powerful and rapidly advancing tool, the clinician is advised to use molecular-based assays with appropriate awareness of their individual strengths and weaknesses, including the designated use or "fitness for purpose." Unquestionably, molecular technologies will continue to be developed and implemented in veterinary medicine. Although it can be expected that some technologies will replace existing procedures, it should be expected that other molecular tools will be no more than a supplement to traditional diagnostic approaches.

Sample Submission

As with any diagnostic technology, the specimen used must be appropriate for the disease or genetic condition and take into consideration the timing and pathogenesis of the disease process and availability of the intact genetic material being targeted by the diagnostic assay. Among the important criteria in the selection and use of molecular-based assays are onset and duration of agent replication in the host, specific tissue(s) affected, and the relative abundance of target DNA or RNA over the course of the infection. In addition to tissues obtained from postmortem investigation or surgical sampling, antemortem diagnostic testing can target genetic material recovered from swabs of mucous membranes; blood, urine, milk, or skin scrapings; or fecal material as appropriate to the disease process.

Since all molecular-based diagnostics detect genomic material in one form or another, the isolation and purification of nucleic acids (DNA or RNA) from the diagnostic specimen is critical to the success of the assays. Dependent on the tissue or specimen used for diagnostic testing, recovery of sufficient quantities and quality of nucleic acid can be problematic. Common sources of assay failure include substances in the sample that can interfere with the chemistries used in detection or PCR-based amplification steps. Examples include, but are not limited to, heparin, iron, peroxidases, hemoglobin, and myoglobin, as well as the relative abundance of total DNA or RNA associated with the different specimen types. This type of assay error is controlled in some PCR assays by the inclusion of internal controls

VetBooks.ir

VetBooks.ir

prior to initiating the assay in order to monitor for specimen-based interference or related-assay failure. Another common source of assay failure is destruction of target nucleic acids in the specimen prior to testing, commonly as a result of enzymes associated with postmortem autolysis. Because of the complexities of nucleic acid recovery and target nucleic acid detection, assays developed for use with one matrix, such as whole blood, may not be suitable for use with other matrices, such as milk or feces. Appropriate sample collection buffers, storage temperatures, and shipping requirements are available from the laboratories performing the specific testing.

Molecular-Based Diagnostic Technologies

Nucleic acid fragments, either DNA or RNA, can be detected by binding to a complementary fragment of nucleic acid that has been marked with a reporter dye or enzyme. The short strands of DNA or RNA, generally chemically synthesized and referred to as oligonucleotides, are identified as *hybridization probes* when marked with a reporter dye or enzyme. Radioactively labeled probes, although once the standard, have largely been replaced by enzymatic tags, such as avidin-biotin, peroxidase, or chemiluminescent tags. Target nucleic acids can be detected directly in the diagnostic specimen when sufficiently abundant, or they may be detected following PCR-based amplification of the nucleic acid target.

Southern Blots, Northern Blots, and Dot-Blots

There are a variety of techniques used to immobilize genetic material prior to detection steps, with or without prior PCR amplification. As a group, the techniques are referred to as "blots." Dot-blots and Southern blots refer to DNA bound to nitrocellulose membranes, whereas Northern blotting is the terminology used when RNA is immobilized onto membranes. In Southern and Northern blots, nucleic acid fragments are first separated by size using an electric current running through a semi-solid gel, a technique referred to as gel electrophoresis. The nucleic acid detection step for DNA and RNA blots may include a specific hybridization probe or may simply use the molecular weight of the DNA or RNA fragment. Related terminology includes Western blot, which describes protein immobilized on a membrane, and immunoblot, referring to detection of the immobilized protein using specific antibody as an immunologic marker. Variations of this approach, using proteins or capture antibodies immobilized on specialized paper strips, form the basis for lateral flow ("dip-stick") pen-side tests, including those developed for the rapid field detection of foot-and-mouth disease virus.

The laboratory technique referred to as in situ hybridization allows for localization and observation of a DNA or RNA target within a histologic tissue section.[1-4] The hybridization probes are typically end-labeled with a radioactive or enzymatic reporter molecule. Fluorescent in situ hybridization (FISH) is a relatively new staining approach showing promise for future rapid diagnostic applications. In situ hybridization using RNA probes (riboprobes) is another rapidly advancing technology, with improved detection sensitivity compared with DNA probes, although to date it has been used primarily for studying viral infection and gene expression rather than for diagnostic applications. In situ hybridization technology can be applied to frozen or formalin-fixed tissues, with best results provided when the tissue is fixed as soon as possible postmortem to avoid loss of target nucleic acids during tissue autolysis. Nucleic acids from veterinary pathogens have been shown to be stable in formalin-fixed, paraffin-embedded tissues for up to 15 years.[1,5] Because of technical complexity, in situ hybridization is not yet widely applied to routine diagnostics, but appears to be rapidly advancing in that direction.

Polymerase Chain Reaction

PCR is the most commonly applied of the molecular technologies and can be grouped roughly into standard PCR and the more rapid real-time or quantitative PCR. Both techniques amplify minute quantities of target DNA to levels that are detectable using laboratory instrumentation or special staining procedures. The principal difference in the two approaches is that standard PCR is divided into two major processes in the laboratory: (1) the amplification of the DNA target, followed by (2) the detection of the amplified target DNA. Real-time PCR combines the two steps, so that target detection occurs during the DNA amplification process. The advantages of PCR over standard isolation and identification techniques is the significantly reduced time required to obtain a result, with PCR results generally provided in hours instead of days. Real-time PCR results can be reported as dichotomous results (positive, negative) or on a continuous numeric scale, generally as a cycle threshold (Ct) with the lower numeric values correlating with higher concentrations of the target pathogen or genetic marker. Diagnostic caution is generally needed in interpreting "weak positive" real-time PCR results caused by technical limitations and the nature of how real-time PCR results are captured in the laboratory. PCR-based technologies are a particularly powerful tool when designed to detect the presence of organisms that are extremely slow growing or difficult to culture, such as the *Mycobacterium avium* subsp. *paratuberculosis* (Johne's disease) bacterium, *Leptospira* spp., and bluetongue virus, among others. Since PCR-based assays detect nucleic acids, they do not require that the organism is viable in the sample. This is considered an advantage for those agents that may be easily destroyed during sample transport to the laboratory but a disadvantage where fragments of a pathogen's genome may persist for weeks or months after the animal has become noninfectious. An excellent example of this is the bluetongue virus, in which PCR can detect non-replicating viral genome adherent to red blood cells for several weeks after live virus can be recovered from the blood. With the proliferation of PCR assays being developed in research laboratories, state diagnostic laboratories, and commercial laboratories, it is often difficult for the practitioner to know which genetic marker or gene fragment was used in the design of a particular assay. This is of particular diagnostic importance because different gene segments in an individual pathogen's genome may favor screening assays (high detection sensitivity, greater risk of cross-reactivity with lower diagnostic specificity) versus confirmatory assays (high specificity for the target, but lower detection sensitivity). The number of different assays, often identified by just the name of the agent, creates confusion and frustration for those faced with selecting the appropriate assay to use. It is important when selecting and interpreting results of PCR assays to remember that not all assays targeting a specific pathogen will have the same genomic target, or are even designed to have equivalent sensitivity in detecting an infection, making direct comparison of results between laboratories difficult. Quality diagnostic laboratories will be able and willing to discuss the assays performed in their laboratory, including the designated diagnostic purpose of the specific assay, as well as the benefits and pitfalls identified during the assay validation process.[6,7]

STANDARD PCR. Standard PCR is used for detection of DNA or RNA and can be applied to mammalian, microbial, or viral genomes. The PCR technique is based on the natural cross-linking of complimentary (matching) nucleic acids to form double-stranded DNA. When DNA is sufficiently heated, double-stranded DNA separates into single strands, each of which can then be used as a template for chemically (or biologically) generating an exact copy. Specific heat-stabile polymerase enzymes are used in the laboratory for the process of DNA replication. The PCR reaction amplifies DNA using multiple cycles of heating double-stranded DNA to generate a single-strand template and cooling sufficiently to allow the polymerase enzyme to generate a new double-stranded DNA made up of the original strand and its test-tube synthesized copy. For diagnostic assay purposes, it is necessary to copy only a small but diagnostically characteristic fragment of any particular genome. This fragment is generally referred to as the PCR target or target sequence. PCR primers are short chemically synthesized fragments typically 10 to 30 nucleic acids in length that are used to mark the beginning and end of the selected target sequence, and, as their name implies, are used to prime or start the initial PCR amplification process. The choice of

VetBooks.ir

target sequence as well as appropriate primer design is critical to the accuracy and efficiency of PCR-based diagnostic assays. For detecting target RNA, as is needed for the PCR diagnosis of an RNA virus, the technique of reverse transcriptase PCR (RT-PCR) is used. The reverse transcriptase enzyme converts target RNA into DNA, identified as cDNA or copy DNA for use in the PCR steps. The PCR amplification process typically takes 2 to 6 hours to complete and is followed by detection steps that require additional hours to days to complete. Detection of the amplified DNA fragment, often referred to as an amplicon, uses techniques that identify the DNA fragment by molecular weight, by marking a specific target sequence in the amplified DNA with hybridization probes, or by a combination of both (PCR/probe). PCR amplification followed by hybridization probe detection offers increased specificity, thus less chance of a false-positive finding, and often provides a tenfold or greater increase in detection sensitivity. Dependent on the stringency designed into the assay by balancing such measures as temperature, length of replication cycles, and enzyme concentrations, false-negative results will occur when the sequence of the primers or probe does not precisely match the sequence of the target. In some cases, PCR assays are very precise and designed to recognize a single nucleic acid polymorphism (SNP analysis) in the target sequence, and in other cases are intentionally designed with lower stringency to allow some degree of variability among isolates or strains being detected by the assay. Because RNA viruses in general lack the proofreading enzymes found in DNA viruses, bacteria, and protozoa, they are at greater risk for appearance of random mutations at primer or probe sites. PCR false-negative results associated with primer or probe mismatches resulting from random genomic mutations at the primer or probe binding sites are of particular concern for RNA viruses, and they provide ample justification for a laboratory to investigate with alternative or additional technologies when negative PCR-assay results clearly do not match a clinical or epidemiologic pattern of disease.

NESTED PCR. Nested PCR is a PCR technique modification generally used to increase the detection sensitivity of an assay.[8] During nested PCR, an initial PCR reaction amplifies a selected fragment of DNA, which is then used as a template in a second round of PCR. The second or nested PCR reaction targets one or more unique fragments of DNA within the initially amplified region. The two-step process has the advantages of increasing detection sensitivity and detection specificity and of diluting the impact of interference from potential PCR inhibitors found in some tissues and clinical materials. Nested PCR assays have been described for West Nile virus, malignant catarrhal fever virus, and *Chlamydia* spp., among others. The significant disadvantage of the two-step process comes from handling the first round of amplified DNA in the laboratory. With the high concentrations of target DNA available following PCR amplification, laboratories must take rigorous precautions to mediate the risk of contaminating laboratory workspaces, equipment, and reagents with the amplified DNA. The significant risk and associated costs of laboratory contamination and resulting false-positive results is used in many diagnostic laboratories as justification for charging additional fees or for not offering nested PCR techniques.

Diagnostic assays originally developed using standard PCR approaches are increasingly being converted to real-time PCR and real-time quantitative PCR (qPCR) technology, to take advantage of the speed, technical efficiency, and cost reduction often associated with this approach.[9] Because real-time PCR technology completes both amplification and detection in the same reaction tube or well, there is no need for the laboratory to handle amplified DNA and risk workspace contamination. This noteworthy modification to PCR technology has been responsible for a significant expansion in use and general availability of PCR-based diagnostic assays. More importantly, the combination of amplification and detection in a single reaction vessel has allowed expansion of PCR-based assays into high-throughput, portable, and on-site formats as described for foot-and-mouth disease virus, anthrax detection, and others. Real-time PCR offers an additional advantage of supporting quantitative approaches to amplification and detection of the original target in the sample tested. Quantitative PCR answers a frequent criticism of standard PCR, specifically that detection limits, potentially as low as a single cell or viral particle, may produce a positive finding that is biologically irrelevant to clinical disease. Quantitative PCR allows the relative amount of target nucleic acid to be correlated with the associated clinical presentation.

MULTIPLEX PCR. Multiplex PCR expands the use of PCR or real-time PCR-based detection from a single target to multiple targets simultaneously from a single specimen.[10-12] The ability to include multiple genome targets for a single virus or bacteria in a PCR assay minimizes the risk of a PCR false negative as a result of genetic diversity within the agent of interest. Inclusion of targets for multiple closely related viruses has been used to differentially detect related pathogens, such as the closely related sheep and wildebeest-associated forms of malignant catarrhal fever, to subtype BVD viruses, and to differentially detect virulent *E. coli*. Multiplex PCR also has broad application in syndrome-based testing where several pathogens may produce very similar to identical clinical pictures. A single diagnostic specimen could theoretically be used in a multiplex format to detect one or more agents associated with a particular clinical presentation, such as the multiple viral and bacterial agents in shipping fever complex. Prototypes of this approach have been developed, but are not yet widely deployed, and there are technological limits to the number of PCR assays that can be combined without significant loss of assay performance. In real-time PCR formats, three to five unique assays have been the practical limit, based on the technical limitations of commonly available equipment and detection dyes.

Isothermal Amplification

These techniques use alternate chemistries to PCR and are carried out at a single temperature. Among the isothermal amplification technologies that have been used for the detection of veterinary pathogens are nucleic acid–based amplification (NASBA), loop-mediated isothermal amplification (LAMP), rolling circle amplification, and direct signal amplification systems.[13,14] None of these technologies has seen widespread diagnostic application, possibly as a result of the complexity in initial assay design, but they may offer future PCR alternatives that can be more automated, portable, or developed as fully integrated self-contained testing units.

Arrays of DNA or RNA fragments, variously referred to as genechips and microarrays, consist of thousands of oligonucleotides attached in a specific pattern to a solid surface, typically a glass slide or silica chip.[15-21] The sample nucleic acids compete with fluorescently labeled competitor oligonucleotides for binding to the chip. A fluorescent detector and computer software are then used to analyze the patterns of fluorescence, indicating where nucleic acids have (or have not) been bound to the chip. Microarrays have been used primarily as research tools focused on detecting and understanding gene expression. The practical application to veterinary medicine includes studies such as the evaluation of genetic resistance to naturally occurring nematode infections, including *Hemonchus, Trichostrongylus,* and *Ostertagia* in sheep. Microarray technology has not seen wide use in veterinary diagnostic laboratories, largely because of the large initial investment required for equipment. However, examples of diagnostic microarrays have shown promise, and it is expected that once established, the technology will be cost effective on an individual animal basis. In human diagnostic medicine, microarrays designed with genetically conserved sequences for all major groups of microorganisms have been used to identify or "mine" for unknown pathogens. This approach was used to detect and identify the SARS virus, before it was initially recovered and characterized by virus isolation techniques. Alternately, genotyping arrays have been designed to target specific virulence-associated genes, allowing differentiation of disease-associated subtypes of organisms from other members of the same or closely related species, such as enterotoxigenic *E. coli* and multi-drug–resistant *Salmonella* strains.

An alternative to genechip technology is liquid array technology, in which the nucleic acids are captured by oligonucleotide probes bound to a microbead, rather than to a flat surface. Bead sets are internally labeled with different colored dyes used to distinguish the specific agents being measured. Liquid array systems use flow cytometry, laser technology, and signal processing to recognize the internal color of the beads and measure associated surface-binding of a target-specific fluorescent hybridization probe. The bead-based modification to microarray technology allows a laboratory to create a flexible diagnostic-test panel in a single assay by adding or removing target beads based on the unique clinical presentation, diseases suspected, or species specificity of interest. In theory, 100 different targets are detectable in a single assay.

Molecular techniques provide a valuable tool for genotypic characterization or subtyping of viral, bacterial, and parasitic agents. Subtype characterization[22-25] is essential for, among other things, taxonomic classification, differential detection of virulent strains, identification of genetic sources of antimicrobic resistance or virulence factors, recognition of vaccine escape mutants, epidemiologic investigation of disease outbreaks, and identification of inter species transmission of specific pathogens. Restriction fragment length polymorphism (RFLP) is a technique useful for subtyping of pathogens based on genetic sequence variation within specific genes.[26] Target DNA, which may or may not previously have been PCR amplified, is digested using one or more well-characterized restriction enzymes. Characteristic profiles or patterns produced by the different-sized DNA fragments remaining after enzyme digestion are detected by gel electrophoresis. RFLP has been used to investigate interspecies transmission of enterotoxigenic *Staphylococcus aureus* associated with intramammary infections in cattle, sheep, and goats.[27] Random amplified polymorphic DNA (RAPD) analysis is a technique that has proved useful in detecting genetic variation and for strain typing.[28] Rather than amplifying a specific region of a genome, RAPD relies on random amplification of genomic DNA using short arbitrary sequences as PCR primers. RAPD does not require prior knowledge of an organism's DNA sequence for specific primer design and can be applied to very small amounts of template DNA. The RAPD technique has been applied, for example, to rapid differentiation of pathogenic from non-pathogenic coccidia of sheep, including *Toxoplasma gondii and Sarcocystis* spp. Identification of non-culturable, slow-growing, and atypical bacterial species using sequence analysis of the 16s ribosomal RNA (rRNA) gene has become recognized as a valuable diagnostic tool in recent years. The basis of the 16s RNA typing technique is the highly conserved nature of the 16s rRNA gene within bacterial species, as well as among species of the same genus.[12,29,30] Automation developed to support 16s rRNA amplification, sequencing, and data analysis is available to and currently in place in selected veterinary diagnostic laboratories. Although the technique is not currently cost effective for routine identification of all microbial isolates in a clinical setting, the technology is used for identification of atypical, slow-growing, and rarely encountered species.[31] Because 16s rRNA databases continue to be updated to include pathogens of veterinary and zoonotic interest, it is likely that the technology will see broader application.

Nucleic acid sequence analysis is used to identify and compare the exact nucleic acid sequence of a gene fragment, gene, or possibly entire genome for forensic purposes, to investigate disease outbreaks, to track evolutionary changes in rapidly mutable microorganisms, or for precise phenotype or genotype analysis of animals or organisms. The technology used for sequence analysis is progressing exponentially since initially introduced in the 1970s. Equipment and computational strength used for sequence analysis were once limited to specialized research laboratories and reference centers, but they are increasingly available in well-equipped diagnostic laboratories. Next-generation, also called second-generation, sequence analysis approaches use bench-top commercialized equipment based on DNA synthesis, ligation, or ion semiconductor technology for the rapid and highly accurate genome sequencing of pathogens. The complete genomic sequence of individual pathogens can be completed within a matter of hours to days using Next Generation Sequencing technologies. For diagnostic purposes sequencing may be paired with PCR amplification of specific genetic markers or regions of known pathogens, or may be used in *de novo* applications which determine the genetic sequence and identity of an unknown or previously uncharacterized pathogen.[19,20] Sequence analysis is most commonly used to confirm the identity of a pathogen testing positive in a PCR assay, to detect genetic variants or diagnostically important mutations in a pathogen's genetic makeup, and for forensic investigation into the source of an agent or disease outbreak based on specific genetic markers in the recovered pathogens. Nucleic acid sequencing of the sheep prion protein (PrP) gene allele has been used as a flock management tool associated with scrapie control.[32]

Genetic Diseases

Diseases that are linked to genetic mutations in specific breeds, such as bovine leukocyte deficiency (BLAD) and complex vertebral malformation (CVM) in Holstein cattle, β-mannosidosis in cattle or goats, and spider-lamb syndrome in sheep, can be controlled by selective breeding using PCR-based testing to identify carriers of the defective gene. Similarly, susceptibility to certain diseases has been linked to specific genetic haplotypes that can be detected by molecular analysis.[33] Although at times controversial, rapid PCR-based genotyping of sheep has been used for selective breeding programs targeting the genetic alleles associated with "scrapie resistance." DNA testing for genetic selection, parentage confirmation, coat color, and related management purposes is also available for cattle, sheep, and goats. For genetic testing, the appropriate sample is typically whole blood, from which genomic DNA is extracted, the gene of interest is amplified by PCR, and then mutations are detected by sequence analysis, microsatellite target testing, and restriction enzyme analysis to identify the mutations in the gene of interest.[34,35]

Summary

For molecular diagnostics, as with any new technological advance, there was initial hesitation or mistrust of the techniques, followed by a rush to take advantage of new diagnostic tools. With routine implementation of PCR, sequence analysis, and associated molecular diagnostic techniques have come significant advantages in diagnostic sensitivity and specificity, in the speed that a laboratory diagnosis can be reached, and in the potential for in-depth genome-level investigation of disease occurrences. At the same time, molecular techniques have introduced a new level of complexity to diagnostic medicine. The use and interpretation of molecular-based diagnostic results require sufficient understanding of the techniques used in order to judge the reliability and the relevance of the findings. Molecular techniques have become, and will continue to grow as, an extremely valuable diagnostic tool, but like any tool in diagnostic medicine, they must be used with caution and with a clear understanding of their strengths, limitations, and appropriate applications to specific clinical investigations.

SHEILA M. MCGUIRK

Performing the Electrocardiogram

No single electrocardiographic lead system has been universally accepted for use in large animals. Bipolar leads (I, II, III, base-apex, X, Y, and Z of the orthogonal lead system) and unipolar leads (aV_F, aV_R, aV_L, thoracic) have been described, but the amplitude, duration, and configuration of the different waveforms vary widely depending on an animal's breed, size, body type, and sex. In addition, there is lability of certain waveforms within each animal depending on the level of exercise, excitement, or organic heart disease. Large animals have a deeply penetrating Purkinje system, and depolarization from the ventricular endocardium to the epicardium occurs explosively and in many directions at once. This period of ventricular activation is responsible for the electrocardiographic criteria that indicate ventricular enlargement in small animals but contributes little to generating the QRS complex of large animals. Establishing specific diagnostic criteria for chamber enlargement in large animal species has been difficult because changes in the QRS complex are not sensitive or specific for ventricular enlargement.

The electrocardiogram (ECG) is used primarily to detect cardiac arrhythmias. For this purpose a single-channel machine can be used, and the lead system chosen can be any that generates distinctive P, QRS, and T complexes. If an arrhythmia is detected, another lead should then be obtained to further characterize the QRS and T complexes and confirm their origin. The lead system should be easy to apply, and the tracing free of artifacts created by muscle tremors, skin movement, shifting of weight, and changes in limb position. Two such leads commonly used to obtain a rhythm strip for the diagnosis of cardiac arrhythmias are the base-apex lead[1] and the Y lead of the orthogonal lead system.[2] The base-apex lead is attached by placing the positive electrode from one of three standard bipolar leads (lead I, II, or III) on the left thorax in the fifth intercostal space at the level of the elbow or at the location where the apex beat is most readily palpable. The negative electrode is attached to the skin of the right jugular furrow two thirds of the way from the ramus of the mandible to the thoracic inlet or at the top of the right scapular spine. The ground electrode can be attached to any site remote from the heart. Electrical contact is improved by clipping hair or wetting the skin with alcohol. The base-apex lead ECG is recorded by switching the machine to the bipolar lead that has been attached to the horse and recording the ECG (Table 30-1). Lead Y is attached by placing the positive electrode over the xiphoid and the negative electrode cranially to the front of the chest.

Continuous electrocardiographic recording over a 24-hour or longer period (Holter monitoring) or with radiotelemetry is also useful for evaluating horses with arrhythmias. Continuous ECG recording can be performed with contact electrodes covered with moist sponges to maintain contact, electrode patches that are held against the skin with a surcingle, or electrode patches attached to shaved skin with a cyanoacrylate adhesive and protected underneath a surcingle.[3,4] With bipolar contact electrodes using a single lead system, the positive electrode is placed over the left cardiac silhouette or over the sternum and the negative electrode is placed over the dorsum to the left of the withers where the electrode will lie flat and remain in contact with the skin.[3] The electrodes are kept moist with alcohol and are then held in position with a tight surcingle. With electrode patches the electrodes are taped to a small square of cardboard to provide them with some rigidity. The best recording with a three-lead system is usually obtained with the left arm electrode placed on the sternum, the right leg electrode on the right side in the fifth intercostal space at the level of the point of the shoulder, and the right arm electrode placed on the left side in the fifth intercostal space at the level of the point of the shoulder. These electrodes are then held in position with a tight surcingle after removal of the plastic that covers the conducting material overlying the electrode. The electrodes are connected to a digital recorder that records the animal's heart rhythm for the entire monitoring period (Holter monitor) or a telemetry device that sends the ECG signal back to the receiver to be displayed on a monitor. The entire recording or monitoring period can be stored on a smart card for subsequent analysis. The continuous 24-hour Holter ECG is useful for diagnosing arrhythmias that occur intermittently or for monitoring cardiac rhythm during exercise for later analysis. Radiotelemetry electrocardiography is useful for real-time cardiac rhythm monitoring during treatment or exercise.

In the base-apex lead the P wave is positive in most horses and ruminants. The P wave is most frequently bifid in horses. In many horses a T_a wave, indicative of atrial repolarization, occurs as a negative deflection after the P wave (Fig. 30-1). The QRS complex begins with a small positive deflection (rS) and is followed by a large negative deflection that terminates in the ST segment. The T wave is variable and can be positive, negative, or biphasic in horses and ruminants. Frequently the appearance of the T wave is variable within one recording. Fig. 30-2 illustrates a typical base-apex ECG recorded from both a cow and a horse at a 25-mm/s paper speed with the gain set at 10 mm/mV.

When a systematic approach is used to analyze the ECG, diagnosing arrhythmias is not difficult. The following step-by-step approach can be used:

1. Identify all the QRS complexes. Each QRS complex should be followed by a T wave, and the QT interval should be similar for

VetBooks.ir

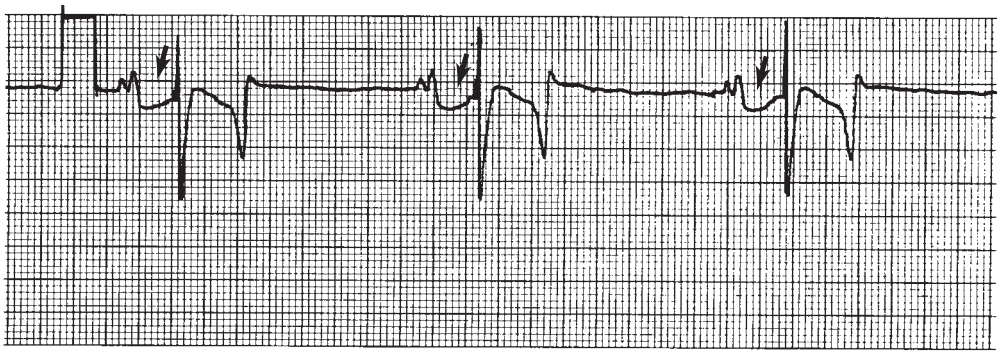

FIG. 30-1 Base-apex lead ECG recorded from a horse. *Arrows* point to the atrial repolarization wave (Ta) frequently seen in normal horses. It follows the notched P wave and precedes the QRS complex. Paper speed 25 mm/s, calibration 1 cm/mV.

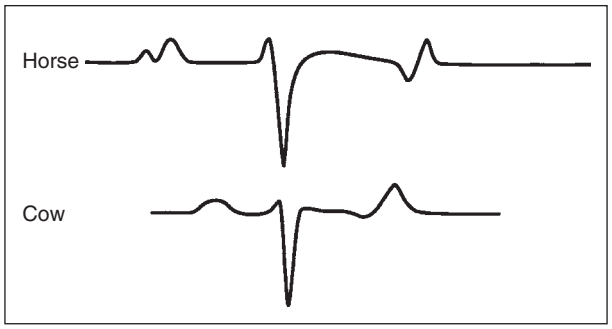

FIG. 30-2 Schematic representation of a typical base-apex lead ECG recorded from a cow and horse. In horses the P and T waves may be variable in appearance.

TABLE 30-1

Standard Bipolar Electrocardiographic Leads

Lead	Positive Electrode	Negative Electrode
I	Left arm	Right arm
II	Left leg	Right arm
III	Left leg	Left arm

all QRS configurations unless there is a marked change in heart rate. Identify the remaining complexes. Are P waves, "F" (flutter) waves, or "f" (fibrillation) waves present? Are there any artifacts?

2. Determine the atrial and ventricular rates. Are they identical? Is one too fast or too slow? This determines whether there is a tachycardia or bradycardia.
3. Are the P-P and R-R intervals regular? Determine whether an irregular rhythm has underlying regularity that is interrupted by irregular intervals or whether the rhythm is consistently irregular. Second-degree atrioventricular (AV) block and atrial and ventricular premature beats are arrhythmias with underlying regularity, whereas atrial fibrillation, sinus arrhythmia, and sinus arrest are truly irregular rhythms.
4. Are P waves present? If so, is there a P wave preceding every QRS complex? If not, there are premature depolarizations, escape beats, or atrial fibrillation. Are all P waves followed by QRS complexes? If not, second-degree AV block may be present. Is the resultant P-R interval constant? If not, there may be a wandering pacemaker or first-degree AV block.
5. Are all P waves and QRS complexes identical or normal in contour? If not, this signifies more than one pacemaker, premature depolarizations, or escape beats.

Use of Echocardiography in Large Animals

Echocardiography is a noninvasive diagnostic tool that uses sound waves in the range of 1.5 to 10.0 MHz to visualize the heart in motion, using either a single icepick (M-mode) or a two-dimensional (2D; B-mode) image. Noninvasive evaluation of blood flow in the heart and great vessels is performed with pulsed wave, color flow, and continuous wave Doppler echocardiography. Precise localization of abnormal flow within the heart and great vessels is performed with pulsed wave and color flow Doppler echocardiography, whereas continuous wave Doppler echocardiography is used to determine the peak velocity of blood flow and to noninvasively estimate pressure gradients. In contrast to M-mode and 2D echocardiography, in which the best image is obtained with the ultrasound beam perpendicular to the structures being imaged, optimal Doppler signals are obtained with the ultrasound beam parallel to the blood flow being evaluated. For accurate peak blood flow velocities to be recorded with continuous wave Doppler echocardiography, the ultrasound beam should be as close to parallel as possible (<20-degree angle) to the direction of blood flow being measured. This alignment is difficult or impossible to achieve in most large animals with valvular heart disease, so accurate peak blood flow velocities often cannot be obtained from large animals with valvular heart disease. Noninvasive estimations of pressure gradients are inaccurate in these instances. Alignment of the ultrasound beam parallel to shunt flow is possible with most ventricular septal defects (VSDs) because of the typical location of the VSD in the membranous or perimembranous portion of the interventricular septum. A more extensive review of the theory and application of echocardiography in horses and cattle has been published.[5-11] More recently, tissue Doppler imaging (TDI) has been used in horses to evaluate atrial and ventricular myocardial wall motion.[12-17]

Echocardiography is particularly useful in evaluating large animals with cardiovascular disease, because the examination is noninvasive and can be performed in a timely fashion in most standing unsedated animals. Diagnostic criteria for valvular, myocardial, pericardial, and congenital lesions of the heart are well established, and the information obtained assists the practitioner in confirming a diagnosis, assessing the extent of the disease, determining the severity of cardiac dysfunction, monitoring the response to treatment, and providing an accurate prognosis. Large animal echocardiographic equipment should provide satisfactory resolution of images at depths of 26 cm or greater. Portable ultrasound machines are available that can display depths of up to 40 cm for equine and bovine cardiology. These machines are available with pulsed, continuous wave, and color flow Doppler. However, Doppler echocardiography is used mainly in specialty practices and referral institutions because performing and interpreting the echocardiogram, including Doppler, requires a significant amount of training and expertise. In addition, state-of-the-art color flow and tissue Doppler equipment remains fairly expensive, although it has decreased in price.

VetBooks.ir

Echocardiographic examination is performed in a systematic way, using standardized images to obtain information about chamber size, wall thickness, myocardial function, valve appearance, valve function, great vessels, blood flow, and presence of abnormal structures or echodensities. The standard equine or bovine echocardiogram is performed from the right parasternal window (right fourth intercostal space in horses and third intercostal space in ruminants) with a 2.5-MHz or lower frequency transducer. Higher-frequency transducers should be used to examine younger or smaller animals, South American camelids, and small ruminants. Both long- and short-axis views of all cardiac structures should be evaluated. The cardiac valves should be carefully examined for any abnormalities of structure or function (dysplasia, thickening, prolapse, ruptured chordae tendineae, fenestrations, flail valve leaflet, vegetative lesion, or high-frequency vibrations). The relative size, shape, and relationship of the cardiac chambers and great vessels should be assessed, and an evaluation of myocardial function and blood flow performed. Standard measurements of left ventricular internal diameter, left ventricular free wall thickness, interventricular septal thickness, and right ventricular internal diameter should all be obtained at end diastole and peak systole from the M-mode echocardiogram. The diameter of the aortic root and left atrial appendage, the distance between the interventricular septum and the peak opening of the septal leaflet of the mitral valve (septal to E point separation), and the left ventricular ejection time (ET) should also be determined. End-diastolic measurements are obtained at the Q wave of the ECG, whereas peak systolic measurements are made from the peak downward deflection of the interventricular septum. Calculations of fractional shortening (FS) and ejection fraction (EF) can then be performed to assess left ventricular function using the following formulas:

$$FS = \frac{LVID_d - LVID_s}{LVID_d} \times 100$$

$$EF = \frac{LVID_d - LVID_s}{LVID_d} \times ET \times 100$$

in which $LVID_d$ is the left ventricular internal diameter at end diastole (cm), $LVID_s$ is the left ventricular internal diameter in systole (cm), and *ET* is the left ventricular ejection time (seconds).

Echocardiograms should also be performed from the left cardiac window when the entire heart cannot be successfully imaged from the right side; atrial fibrillation is present; abnormalities of the mitral valve, aortic valve, pulmonic valve, aorta, pulmonary artery, left atrium, left ventricle, or outflow portion of the interventricular septum are suspected or detected; or murmurs originating from the mitral, aortic, or pulmonic valves are detected or a pericardiocentesis is planned. The maximal diameter of the left atrium should be obtained at peak systole from the left cardiac window at the level of the left coronary artery, parallel to the mitral valve (Fig. 30-3). The diameters of the aorta and pulmonary artery should be measured from similar locations in the vessel on the 2D echocardiogram and compared. Echocardiography should be considered a useful diagnostic test to evaluate patients with the following complaints, physical examination findings, or tentative diagnoses:

1. Cardiac murmur, to determine the etiology of the murmur
   a. Any grade 3/6 or louder holosystolic or pansystolic murmur on the left side of the thorax
   b. Any grade 4/6 or louder holosystolic or pansystolic murmur on the right side of the thorax
   c. Any holodiastolic decrescendo murmur
   d. Any continuous machinery murmur
2. Congenital heart defects, especially atrial septal defects (ASDs) and VSDs
3. Acquired valvular heart disease
4. Cardiac enlargement
5. Cardiac arrhythmias not associated with high resting vagal tone
6. Unexplained exercise intolerance or collapse or exercise intolerance attributed to cardiac causes

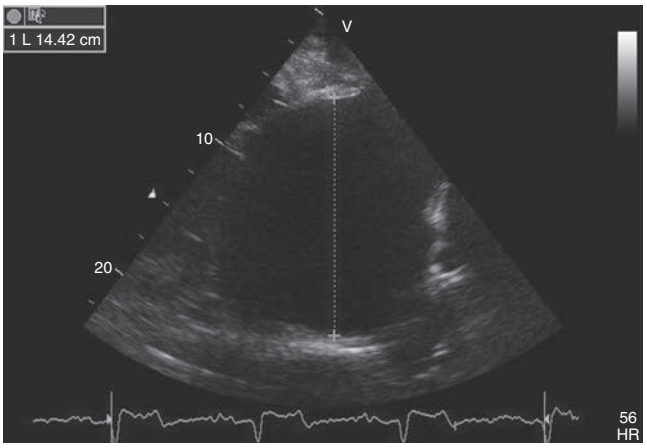

FIG. 30-3 Two-dimensional echocardiographic image of the left atrial diameter obtained from the left parasternal long-axis window in a horse with mild left atrial enlargement secondary to cardiomyopathy and mitral regurgitation.

7. Muffled heart sounds, pericardial friction rubs, or pericardial effusion
8. Myocarditis or myocardial dysfunction
9. Congestive heart failure (CHF)
10. Pulmonary hypertension
11. Cardiovascular neoplasia
12. Aortic rupture or other abnormalities of the great vessels
13. Ionophore toxicity or exposure to other myocardial toxins

Color flow or pulsed wave Doppler echocardiography should be used to map the size and location of a turbulent jet associated with an intracardiac or extracardiac shunt, valvular regurgitation, or stenosis (rare) and to semiquantitate its severity.[18,19] Continuous wave Doppler echocardiography can then be used to measure the peak velocity of blood flow in the jet, estimating (noninvasively) the pressure difference between cardiac chambers using the Bernoulli equation and assessing the hemodynamic significance of the lesion. This can be accurately performed in most patients with a VSD but is difficult to impossible to accurately perform in many patients with valvular insufficiencies because of the limited windows available for interrogating blood flow in large animals and the inability to align the ultrasound beam to within 20 degrees of the abnormal blood flow. This poor alignment of the ultrasound beam with the regurgitant jet results in an underestimation of the peak regurgitant jet velocity. Contrast echocardiography, a technique involving microbubble-laden injections of saline, carbon dioxide, or indocyanine green, can also be used to demonstrate valve dysfunction and the direction of intracardiac shunts (VSDs, ASDs) and extracardiac shunts (patent ductus arteriosus [PDA], truncus arteriosus). TVI should be performed to look for left atrial dysfunction (left atrial stunning) post conversion of atrial fibrillation.[16] TVI is also useful in identifying ventricular myocardial dysfunction.[13]

Cardiac Catheterization in Large Animals

Cardiac and great vessel catheterization can be performed in standing unsedated large animals to determine the following data:

- Pressure and waveforms (shape of the pressure curve)
- Oxygen tension, oxygen saturation, oxygen content
- Cardiac output and other indicators of ventricular size and function

Cardiac catheterization is also used for special diagnostic studies such as angiocardiography, nuclear angiocardiography, and indicator dilution studies. These data are used to determine the direction and size of intracardiac and extracardiac shunts, chamber size and contractility, and valvular and myocardial function. Much of this information is now obtained noninvasively with echocardiography, minimizing the need for more invasive techniques.

VetBooks.ir

Cardiac catheterization is usually reserved for specialty practices and referral institutions, owing to the equipment needed and skills required for acquiring and interpreting accurate data. Results are not always specific, but catheterization can add quantitative measurements that increase diagnostic and prognostic accuracy for certain cardiac conditions and may provide a direction for therapy.

Blood Pressure Measurements

Normal blood pressures for cattle and horses are listed in Table 30-2.[20-23] The values for horses represent a summary of data from numerous authors as cited in the references given. Accuracy of pressure recordings is greatly influenced by the choice of catheter and the recording equipment used. Pulmonary artery wedge pressure (PAWP) is an indicator of left atrial mean pressure so long as balloon inflation of the catheter occludes flow in the segment of the pulmonary artery that is catheterized. PAWP is superior to central venous pressure (CVP) as a monitor of left ventricular function and fluid therapy.

The shape of the pressure curve in the ventricles, aorta, or pulmonary artery may have diagnostic significance in conditions like constrictive pericardial disease (Fig. 30-4); pulmonic stenosis (giant A wave), rare as an isolated defect in large animals; or tricuspid or mitral valve regurgitation (large V wave). These conditions are more commonly assessed by echocardiography. An abnormal rise in pressure going from one chamber to the next indicates a stenotic lesion (uncommon in large animals) at the level of the pressure gradient. The size of the pressure gradient can be used to determine the severity of the lesion.

TABLE 30-2

Cardiac Pressure Measurements in Normal Horses and Cattle*

	Horses[20]	Cattle[21]
RA	12 to 28/22 to 5 (4 to 10)	(5)
RV	30 to 59/24 to 14 (9 to 25)	42 to 56/0 to 1 (19 to 28)
PA	34 to 48/14 to 22 (16 to 30)	33 to 46/19 to 21 (24 to 31)
PAW	13/3 (8)	(5 to 21)[22]
LV	140 to 148/15 to 17	(120 to 144)[23]
AO	131 to 144/86 to 100 (110 to 115)	
CA	142 to 157/98 to 119 (113 to 124)	160 to 208/110 to 147 (135 to 175)

*Pressure ranges are reported as systolic/diastolic (mean) in mm Hg unless otherwise designated. *AO,* Aorta; *CA,* carotid artery; *LV,* left ventricle; *PA,* pulmonary artery; *PAW,* pulmonary arterial wedge; *RA,* right atrium; *RV,* right ventricle.

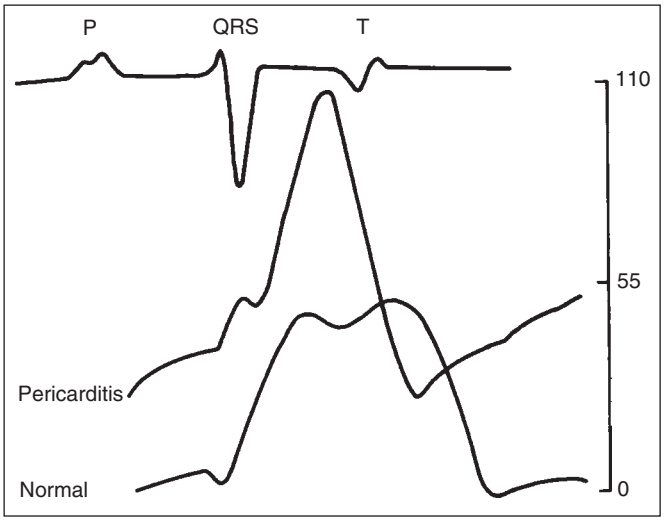

FIG. 30-4 Schematic representation of ventricular pressure curves recorded from a normal horse and a horse with pericarditis, showing the relationship between pressure changes and the ECG. With pericarditis, the ventricular end-diastolic and systolic pressures are elevated and pressure declines sharply in early diastole.

Blood Oxygen Measurements

Blood oxygen measurements are taken from the chambers on the right side of the heart to detect abnormal elevations indicative of a left-to-right shunt (ASD, VSD, PDA). Criteria for oxygen step-ups have not been established for large animals, but human guidelines have been accepted for qualitative assessment of shunts.[24,25] In humans, oxygen content step-ups of the following magnitude are considered abnormal and indicative of a left-to-right shunt[26]:

- ≥1.9 volume percent from the superior vena cava to the right atrium
- ≥0.9 volume percent from the right atrium to the right ventricle
- ≥0.5 volume percent from the right ventricle to the pulmonary artery

Because oxygen content depends on hemoglobin concentration, oxygen saturation, which is independent of hemoglobin concentration, may be a more accurate indicator of shunts in anemic or polycythemic patients. Changes in the animal's physiologic status during sampling (cardiac output, ventilation, oxygen consumption), incomplete mixing of shunted blood, and variable time intervals between sampling can be potential sources of error. Several samples within a single chamber improve reliability of results. Small shunts and shunts in animals with low systemic arterial oxygen tension may not be detected by this technique.

Shunt calculations can be made once oxygen saturation or content has been measured in each of the right heart chambers, the pulmonary artery, and a systemic artery. For a left-to-right shunt, the pulmonary flow/systemic flow ratio (QP/QS) is determined as follows:

$$QP/QS = \frac{SAO_2 - MVO_2}{SAO_2 - PAO_2}$$

in which SAO_2 is the arterial blood oxygen content, MVO_2 is the mixed venous blood oxygen content, and PAO_2 is the pulmonary artery oxygen content. A 2:1 QP/QS represents a 50% left-to-right shunt, indicating that 50% of the pulmonary flow is from the left side of the heart. For a right-to-left shunt, the QP/QS is determined as follows:

$$QP/QS = \frac{SAO_2 - MVO_2}{PVO_2 - MVO_2}$$

in which PVO_2 is the pulmonary venous oxygen content (assumed to be 98% of oxygen capacity plus 0.3 mL of dissolved oxygen).[27]

Cardiac Output and Ventricular Function Assessment

Cardiac output is determined by indicator dilution methods (usually by dye dilution or thermodilution or, more recently, by lithium dilution), by the Fick method, or by using 2D or Doppler echocardiography. The Fick method requires use of a face mask and simultaneous determination of mixed venous and arterial blood samples. Dye dilution and thermodilution results are comparable when 30 to 40 mL of 5% dextrose are injected rapidly at 32°F (0°C).[25] Lithium dilution compares favorably with thermodilution in anesthetized horses and foals.[28,29] Volumetric echocardiography using the Bullet method achieves results similar to those obtained with the lithium dilution method in anesthetized foals.[30] Transthoracic Doppler echocardiography was closely correlated with thermodilution in standing horses.[31]

Cardiac output values in the resting horse range from 32 to 40 L/min.[32] Cardiac index is the cardiac output divided by a measure of body size (body weight in kilograms) and is expressed in mL/kg/min.[32] The normal cardiac index for the adult horse ranges from 72 to 88 mL/kg/min.[32,33] Cardiac output values of 20.9 to 23.6 L/min have been reported in normal anesthetized horses.[28] In cattle a

VetBooks.ir

cardiac index of approximately 110 mL/kg/min has been reported.[23] Cardiac output measurements in clinical patients vary with heart rate, excitement, hydration, and many other factors and are best determined in the pulmonary artery. Electronic integration and computation of area under the curve by means of battery-powered units that can display results instantly provide the most reliable results.[34]

Cardiac output results or indicator dilution curves can provide quantitative and qualitative assessment of cardiac shunts. Characteristic changes in the temperature-time curve (thermodilution methods) or dye concentration-time curve indicate the presence of a left-to-right, right-to-left, or bidirectional shunt. Calculation of the cardiac output in the chamber just proximal to the shunt and distal to it can give a quantitative estimate of the size of the shunt.[25]

Angiocardiography

Angiocardiography is used in neonates or animals small enough to have the entire cardiac silhouette visualized on a single radiograph cassette. The contrast medium must be injected rapidly, and in most cases this is done with a pressure injector. Specialized radiographic requirements include rapid film change capabilities, rapid image sequence acquisition, or cineradiography. Angiocardiography is used to confirm the presence of an intracardiac shunt (ASD, VSD) or extracardiac shunt (PDA, truncus arteriosus) or valve dysfunction, to visualize chamber size, or to estimate contractility. Angiocardiography is performed in anesthetized animals.

Nuclear Angiocardiography

In nuclear angiocardiography, specialized equipment captures sequential digitized images of the right side of the heart, lung, and left side of the heart after rapid injection of radiographic tracer into peripheral circulation. A more extensive review of this subject has been published.[35] Nuclear angiocardiography can be used to confirm valvular dysfunction, which is manifested by chamber enlargement or prolonged washout of affected vessels or cardiac chambers and is quantitated by the regurgitant fraction. It also can reveal enlargement of chambers and prolonged washout resulting from cardiac failure. The presence of intracardiac or extracardiac shunts can be demonstrated by the simultaneous visualization of left- and right-side cardiac chambers or slow washout downstream of the shunt. In addition, nuclear angiocardiography can be used to calculate cardiac output and ejection fraction (EF) and other indices of cardiac function.

Congenital Cardiovascular Disease

The cause of congenital cardiac defects has not been established, although hereditary factors may be responsible for some defects. In humans, additional factors such as maternal infection, age, and nutritional status have been identified; fetal anoxia from placental insufficiency, fetal infection or metabolic dysfunction, or other causes may contribute to the development of congenital cardiac defects. The same factors may apply in animals. Congenital cardiac defects in large animals can occur alone or in combination. The most commonly reported is VSD.[18,24,36-39] Multiple cardiac anomalies including PDA,[40,41] tetralogy of Fallot,[42,43] truncus arteriosus,[44,45] total anomalous pulmonary venous connection,[46] and Eisenmenger complex in calves[47] have been reported. Congenital anomalies of the tricuspid,[44,48-50] mitral,[51] and pulmonic valves[44,52,53] are uncommon. Congenital abnormalities of the aorta are reported in calves and foals but are also uncommon.[39,54,55] ASD occurs more commonly in calves than in foals and is frequently accompanied by other defects.[39,45,56,57] Hypoplasia of the left and right ventricles has been infrequently reported in calves and foals.[39,58,59]

Congenital cardiovascular disease should be suspected in a young patient if examination reveals a holosystolic (pansystolic), holodiastolic, or continuous murmur or a murmur with a palpable thrill or wide radiation over the thorax. Cyanosis at rest or with exercise in a patient with a cardiac murmur warrants consideration of a right-to-left cardiac shunt, obstructive pulmonary disease, or severe stenosis of the structures of the right side of the heart. The presence of any of these findings in a young animal with a history of lethargy, weakness, or failure to thrive constitutes grounds to suspect congenital cardiovascular disease.

Ventricular Septal Defect

Definition and Etiology A VSD is an opening in the interventricular septum that creates a communication between the left and right ventricles. In large animals most defects occur in the perimembranous septum and are imaged ventral to the right and/or noncoronary leaflet of the aortic valve and cranioventral to the septal leaflet of the tricuspid valve, including or adjacent to the fibrous part of the interventricular septum.[18,24,37,39] VSD can occur as a single defect or as part of a complex anomaly. Many cardiac malformations such as tetralogy and pentalogy of Fallot, truncus or pseudotruncus arteriosus, common atrioventricular canal defect, tricuspid atresia, and double outlet right ventricle include a VSD. The cause of VSD is unknown, although it has been documented to be a heritable defect in Limousine[39] and possibly Hereford[60] cattle. VDSs are more common in Welsh Mountain ponies (Section A) and in the Arabian, Standardbred, and Quarter Horse breeds, suggesting a possible hereditary predisposition.[61,62] The defect is thought to result either from failure of fusion of a part of the endocardial cushion and the muscular ventricular septum or failure of fusion of the truncal and conal septa.[63]

Clinical Signs and Differential Diagnosis The clinical signs of an isolated VSD vary and depend on the size of the defect, direction of the shunted blood, and presence of concurrent valvular or myocardial disease. In isolated VSD the blood flow is shunted from the left ventricle to the right ventricle through the defect in the interventricular septum. The size of the shunt depends on the size of the defect and the pressures in the left ventricle, right ventricle, and pulmonary artery.

VSD is suspected when there is a loud, harsh, plateau-shaped pansystolic murmur with its point of maximal intensity (PMI) in the tricuspid valve area, and a slightly softer, more crescendo-decrescendo holosystolic murmur that is loudest in the pulmonic valve area. The murmur on the left side has its PMI in the pulmonic valve area, associated with a relative pulmonic stenosis (increased blood flow across a normal pulmonic valve). A palpable cardiac thrill usually is present over the tricuspid valve region, and occasionally there is splitting of the second heart sound. The murmur may be the only clinical sign identified if the defect is small. On the other hand, poor growth, lethargy, dyspnea, exercise intolerance, and signs of CHF can be exhibited by animals with a moderate to large VSD. This usually develops by the time the animal is 5 years old. Occasionally there is a diastolic murmur of aortic insufficiency associated with a large VSD, the location of which compromises the support of one of the aortic valve cusps.[9,18,38] Cardiac arrhythmias, particularly atrial fibrillation, may be associated with VSD when there is cardiac enlargement or failure.

If the systolic murmur is loudest on the left side of the thorax, a subpulmonic VSD or a complex anomaly with pulmonic stenosis (or some form of right ventricular outflow tract [RVOT] obstruction) should be suspected.[9,18,38,64] The pulmonic murmur is usually louder than the tricuspid murmur in large animals with tetralogy of Fallot. Large animals with tetralogy of Fallot may have cyanosis at rest (uncommon in horses) or with exercise or exertion. Cyanosis is also a distinguishing feature of Eisenmenger complex, a defect in which right-sided heart resistance to blood flow causes the shunt associated with VSD to become right to left. Congenital abnormalities of the mitral and tricuspid valves cause a loud systolic murmur audible on both sides of the thorax. The PMI of the left-sided systolic murmur is more caudally located (in the mitral to aortic valve area) than the relative pulmonic stenosis murmur. Usually the murmur of mitral regurgitation is the louder of the two murmurs. In addition, congenital mitral or tricuspid valve dysplasia is rare in large animals. An innocent flow murmur of neonates can usually be distinguished from

VSD by its crescendo-decrescendo shape, PMI at the left heart base, lack of radiation, and low to moderate intensity.

Clinical Pathology Echocardiography is the diagnostic technique of choice for identifying a VSD. With 2D echocardiography the VSD can be imaged directly (Fig. 30-5) and the shunt size, location, and direction demonstrated with pulsed wave Doppler, continuous wave Doppler, color flow echocardiography, or injection of microbubbles. Careful scanning of the interventricular septum should be performed with 2D echocardiography to directly image the VSD and measure its maximal diameter in two mutually perpendicular planes.[9,18,38] The typical perimembranous VSD (≤2.5 cm in both planes) is missed if the long-axis view of the left ventricular outflow tract (LVOT) is not examined. The membranous VSD is located underneath the right and/or noncoronary leaflet of the aortic valve and ventral to the septal leaflet of the tricuspid valve. If a perimembranous defect is not found, the entire septum should be carefully scanned in all imaging planes to detect the VSD. The subpulmonic location, more common in calves, is easy to miss. This defect is usually best imaged in the short-axis view, scanning the interventricular septum between the LVOT and RVOT. With a left-to-right shunt a high-velocity turbulent jet is depicted from the right parasternal window, originating in the left ventricle, traversing through the defect in the interventricular septum into the right ventricle with color flow Doppler echocardiography (blood flow toward the transducer), whereas a negative contrast jet is imaged in the right ventricle with a right-sided injection of microbubbles.[9,18,38] M-mode echocardiography should reveal septal discontinuity when traversing the interventricular septum from the apex of the heart to the aortic root (septal dropout). Moderate to large VSDs show left atrial and left ventricular enlargement, right ventricular enlargement, and pulmonary artery dilation. The left atrial–to–aortic root ratio is increased. Aortic valve prolapse and aortic regurgitation may also be detected because of loss of support of the aortic root from the VSD, more likely with larger VSDs and VSDs with malalignment of the ascending aorta with the upper portion of the interventricular septum. Myocardial dysfunction and subsequent CHF may occur with a large VSD. Most horses with VSDs that are compatible with a normal life expectancy ultimately develop mitral regurgitation secondary to the chronic left atrial and ventricular volume overload. Continuous wave Doppler echocardiography can be used to noninvasively assess the hemodynamic significance of the shunt (see Fig. 30-5, *B*). A peak shunt flow velocity of 4.5 m/s or greater indicates a restrictive VSD with normal or near-normal right ventricular pressures.[62] Nuclear angiocardiography can also be used to demonstrate simultaneous opacification of the left and right ventricles. The radiographic presence of cardiomegaly and increased vascularization of the lungs provide only nonspecific evidence of VSD. If polycythemia is found, a complicated VSD should be suspected.

Cardiac catheterization can be used for qualitative and quantitative assessment of the VSD but has largely been supplanted by echocardiographic diagnosis. Elevated cardiac pressures provide qualitative evidence of a VSD. Right ventricular systolic pressure elevation is most common and may equal left ventricular pressure with a large VSD. Pulmonary artery pressure can be increased as a result of increased blood flow from the left-to-right shunt or increased pulmonary vascular resistance and decreased flow (restrictive pulmonary hypertension). Elevation of left or right ventricular diastolic pressure provides evidence of cardiac failure in the patient with VSD. Oximetric data (oxygen content or oxygen saturation) can be used to locate the shunt and provide some evidence of the size of the defect. A step-up in oxygen content or saturation between the right atrium and the pulmonary artery suggests a moderate or large VSD. Because most VSDs are located high in the RVOT, there may be inadequate mixing of shunted blood in the right ventricle to detect the shunt in this chamber unless the catheter is directed to the outflow tract for sampling. When the oxygen step-up is detected first in the pulmonary artery, a PDA cannot be ruled out. A small shunt may be missed by oximetry as described earlier under oxygen sampling.

By using the indicator dilution methods described previously, the shape of the concentration-time or temperature-time curve can be used to demonstrate the left-to-right shunt of a VSD. A comparison of the cardiac output measured in the right ventricle with the cardiac output measured in the pulmonary artery can give an estimation of the percent of pulmonary blood flow coming from shunted blood and therefore an estimation of the size of the defect.[25]

Angiocardiography can be performed in the anesthetized neonate and can definitively demonstrate VSD if there is simultaneous opacification of the left and right ventricles when dye is injected into the left ventricle.

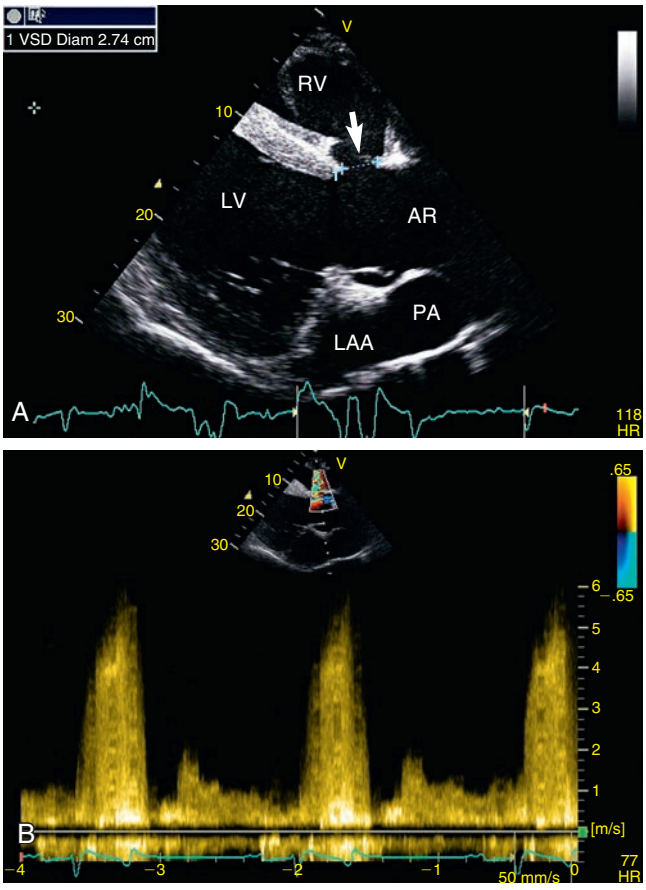

FIG. 30-5 Two-dimensional echocardiographic image **(A)** and continuous wave Doppler spectral tracing **(B)** of a ventricular septal defect (VSD) *(arrow)* in a Thoroughbred gelding who presented for poor racing performance. The VSD is located just underneath and cranial to the septal leaflet of the tricuspid valve and just ventral to the noncoronary and right coronary cusp of the aortic valve and measured 2.74 cm in this view. There is significant left ventricular enlargement in this gelding. The right ventricle *(RV),* left ventricle *(LV),* left atrial appendage *(LAA),* aortic root *(AR),* and pulmonary artery *(PA)* are all visible in this view. The spectral tracing shows a peak shunt velocity of over 5 m/s in systole. Some turbulent flow (spectral broadening) is also detected in diastole, with a peak flow velocity of approximately 1.75 m/s.

Pathophysiology A small VSD may provide enough resistance to flow that the left-to-right shunt is minimal and the patient remains asymptomatic. Horses can race successfully with small VSDs (≤2.5 cm in diameter with peak shunt velocities ≥ 4.5 m/s), although they are not usually successful as elite racehorses.[9,18,62] In smaller horses and ponies or very large horses, a VSD-to–aortic root ratio that exceeds 0.3 is likely to be hemodynamically significant.[61,62] VSDs produce a left-to-right shunt because the pressure in the left ventricle exceeds the pressure in the right ventricle. A peak shunt velocity of 3.5 to 4.5 m/s indicates an increased right ventricular pressure and a less restrictive VSD, but the defect is usually compatible with a normal life expectancy. A peak shunt velocity of less than 3.5 m/s is

VetBooks.ir

VetBooks.ir

indicative of a large shunt that is hemodynamically significant. These animals usually develop CHF by 5 years of age. Occasionally the VSD is so large that the pressure between the two chambers is equalized. The right ventricle, pulmonary circulation, left atrium, and left ventricle must compensate for this volume overload, which generally results in dilation of cardiac chambers and development of pulmonary hypertension.

Simultaneous pulmonary disease or left-sided heart failure due to chronic volume overload can increase pulmonary vascular resistance. In addition to volume overload, the right ventricle is subjected to a chronic pressure overload that may be sufficient to reverse the direction of the shunt (Eisenmenger complex, more common in cattle than horses). Because of the pressure and volume overload with moderate to large VSDs, patients with this condition run a greater risk of developing CHF.

Considerable turbulence associated with left-to-right shunts and endocardial damage increase the risk of endocarditis in patients with VSD.[65] Because the VSD is usually located high in the LVOT, structural support of the aortic valve cusps may be lost, especially with large VSDs and/or malalignment VSDs, and aortic insufficiency may develop.[9,18,62] Significant aortic regurgitation adds to the left ventricular volume overload caused by the VSD.

Epidemiology The true incidence of VSD in large animals is unknown, although it is recognized as the most common congenital cardiac defect. In one study, 36 calves had 78 congenital cardiac defects, of which 11 were VSDs.[39]

Necropsy Findings VSD is usually located high in the interventricular septum just ventral to the right or noncoronary cusp of the aortic valve in the left ventricle and underneath the septal leaflet of the tricuspid valve or caudal or ventral to the crista terminalis in the right ventricle.[62] It can be an isolated defect or accompanied by other cardiac or organ anomalies. If the defect is moderate or large, there is right ventricular, left atrial, and left ventricular enlargement and pulmonary artery dilation. Increased pulmonary blood flow can lead to lung congestion, and secondary pneumonia is not uncommon. If pulmonary vascular resistance is increased, right ventricular hypertrophy may be present. There may be secondary endocarditis (infrequent in large animals)[65] or endocardial lesions as a result of turbulent blood flow across the defect.

Treatment and Prognosis There is no practical treatment for VSD in large animals. A complete echocardiographic examination is indicated to identify the presence and significance of a VSD. The size of the VSD, peak shunt velocity through the VSD, degree of left atrial and left ventricular volume overload, presence of aortic valve prolapse, detection of aortic or mitral regurgitation and myocardial function all have to be assessed to determine the VSD's significance. It is important to identify those animals with moderate to large defects, because the prognosis for normal production or function is poor. Horses with large defects (>3.5 cm or VSD/aortic root ratio >0.3) and peak shunt velocities through the defect of less than 3.5 m/s are likely to develop CHF early in life and have a shortened life expectancy. Animals with small defects may remain asymptomatic throughout life. Very rarely, spontaneous closure of the VSD may occur.[66] It is important to recognize that small defects, which provide a large resistance to flow, can produce loud murmurs, so murmur intensity is not a good predictor of defect size.

VSDs may be heritable in some breeds, and because of the increased risk of heart failure and other cardiac complications, breeding animals with this defect is not advised. As a general rule, bull studs do not accept animals with this defect into a breeding program.

Patent Ductus Arteriosus

Definition and Etiology A PDA is persistent patency of the vessel (normally present in the fetus) that connects the pulmonary arterial system to the aorta. The ductus arteriosus fails to close at birth when breathing begins and placental circulation is removed. Closure of the ductus arteriosus occurs in response to decreasing pulmonary vascular resistance and increased systemic vascular resistance.

A PDA can occur as a single defect (rare in large animals) or with other cardiac anomalies. In large animals the most common other defects reported with PDA are tetralogy of Fallot and pseudotruncus arteriosus.

Clinical Signs and Differential Diagnosis The clinical signs of PDA depend on the length and diameter of the ductus arteriosus, direction of the shunted blood, and presence of other cardiac defects. A PDA should be suspected when a continuous high-pitched murmur, frequently referred to as a "machinery murmur" because of its alternating intensity, is auscultated. The murmur may be heard on the left and right sides of the thorax but is usually loudest in the left third or fourth intercostal space at the level of the point of the shoulder. The intensity of the murmur increases with increased heart rate, exercise, or excitement. The arterial pulses are usually bounding because of the runoff of blood from the systemic to the pulmonary circulation. Occasionally the PDA is manifested by a holosystolic murmur,[67] because the diastolic component is barely audible except at the left heart base. Large PDAs can exist without producing a murmur. In the animal with increased pulmonary vascular resistance and reversal of the shunt, there may be cyanosis of the caudal parts of the body if the PDA enters the aorta caudal to the brachiocephalic trunk. Stunting of growth may also occur.

Other causes of a continuous murmur in large animals are extremely rare, but detecting a continuous machinery murmur should lead the veterinary clinician to suspect a complex congenital cardiac defect that includes a PDA, rather than an isolated defect. In older horses an aorticocardiac fistula should be suspected, particularly if the machinery murmur is of recent onset and is loudest on the right side of the chest. A systolic and diastolic murmur can be present in young animals with a large VSD causing aortic insufficiency. A similar murmur is possible with vegetative endocarditis of one of the atrioventricular or semilunar valves, producing insufficiency and stenosis of the affected valve. These latter conditions should not have the machinery murmur characteristic of the PDA. A loud systolic ejection murmur, which is confused with a PDA, frequently can be heard at the left heart base of foals shortly after closure of the PDA. This murmur may persist for 2 to 3 months.[40]

Clinical Pathology No characteristic clinicopathologic changes are associated with a PDA. Radiography may show enlargement of the cardiac silhouette and pulmonary overcirculation in an uncomplicated PDA. Pulmonary venous congestion, interstitial pulmonary edema, and alveolar edema are evidence of a large PDA with left-sided heart failure. These signs are not specific for PDA and can be present with any congenital heart defect that results in a left-to-right shunt. No consistent electrocardiographic pattern has been identified with PDA. Echocardiographic detection of an enlarged left atrium and left ventricle, with a pattern of left ventricular volume overload and increased values for the ratio of the left atrial to aortic root dimension, are diagnostic.[9,38,67,68] Direct visualization of the ductus arteriosus is difficult with echocardiography but is most successful when performed from the left cardiac window. A PDA arising from the pulmonary artery has been imaged echocardiographically in an 11-month-old Friesian-Holstein heifer.[41] High-velocity turbulent flow in the pulmonary artery and ductus arteriosus is detected throughout the cardiac cycle with pulsed wave, continuous wave, or color flow Doppler echocardiography.[9]

Cardiac angiocardiography and nuclear angiocardiography using a selective aortic angiogram provide definitive evidence of a PDA. Oximetric data show a step-up in oxygen content or saturation in the pulmonary artery proportional to shunt size. Indicator dilution methods also provide evidence of a left-to-right shunt occurring in the pulmonary artery in cases of an uncomplicated PDA. Pulmonary arterial and right ventricular pressures may be increased with a large PDA.

VetBooks.ir

Pathophysiology Normally the ductus arteriosus narrows near term and constricts rapidly after birth in response to lowered pulmonary vascular resistance, increased systemic vascular resistance, increased blood volume, and increased left ventricular pressure when breathing begins and the placental circulation is removed. If the ductus arteriosus is large or the resistance to flow across the ductus is minimal, there is a significant left-to-right shunt that produces a large left ventricular volume overload. The left ventricular response may be failure or, with time, dilation (primarily) and hypertrophy. Pulmonary hypertension and congestion result. The right ventricle can be affected by the pulmonary pressure load, and right ventricular hypertrophy can also develop. If the pulmonary resistance equals or exceeds the systemic vascular resistance, a right-to-left shunt occurs.

Epidemiology Normal foals may have a PDA for a few days after birth, but functional closure of the ductus arteriosus is expected by 96 hours of age.[67] Normal ruminants rarely have a PDA after birth, and if one is present it is considered abnormal. Functional closure may precede anatomic closure of the PDA. This defect is uncommon in older animals. No evidence suggests that this is an inherited defect in horses or cattle.

Necropsy Findings The ductus arteriosus can be of variable length and diameter but is patent between the aorta and pulmonary artery. The PDA often enters the aorta caudal to the origin of the brachiocephalic trunk. Changes in the left and right ventricles and lung and pulmonary vasculature are variable and depend on the size of the shunt. When the PDA is large, there may be cardiomegaly with left atrial and left ventricular dilation, right ventricular hypertrophy, pulmonary congestion, and edema.

Treatment and Prognosis There is insufficient evidence on which to base a prognosis for animals with PDA. The condition can be corrected surgically in neonates, but future performance has not been documented. Animals with small defects may remain asymptomatic throughout life. The prognosis is poor if the defect is large, because the risk for left (primarily) and right ventricular failure is increased. Pharmacologic closure of the PDA using inhibitors of prostaglandin synthesis has been successful in humans but is not without risk of complications and recurrence. The efficacy of prostaglandin inhibitors has not been evaluated in large animals.

Tetralogy and Pentalogy of Fallot

Definition and Etiology Tetralogy and pentalogy of Fallot are characterized by biventricular origin (overriding) of the aorta, VSD, obstruction of pulmonary arterial flow, and secondary right ventricular hypertrophy. When there is an associated ASD, the anomaly is referred to as *pentalogy of Fallot*. The defect is caused by abnormal development of the conal septum in the embryonic heart, which leads to narrowing of the right ventricular infundibulum (pulmonic stenosis), an inability of the conal septum to participate in closure of the interventricular foramen (VSD), and overriding of the aorta. Right ventricular hypertrophy due to pulmonary outflow obstruction develops.

Clinical Signs and Differential Diagnosis Tetralogy of Fallot is one of the more common congenital cardiac defects that cause cyanosis in large animals. Resting cyanosis is rare in horses, although it may be detectable after exercise. Cyanosis of the oral and nasal mucosa, tongue, vaginal mucous membranes, and occasionally the nose and skin of light-colored animals is noticed when more than 5 g/dL of hemoglobin are reduced (unoxygenated). Exercise intolerance is often marked and is characterized in most cases by dyspnea or collapse. Frequently the owner complains of slow growth or small size. A loud pansystolic murmur associated with a palpable thrill is loudest in the left third to fourth intercostal space. The murmur may be a crescendo-decrescendo murmur of pulmonic stenosis or the harsh, plateau-shaped murmur of a VSD; one of these usually predominates. A harsh band-shaped pansystolic murmur is also auscultated in the tricuspid valve area but is usually one or two grades softer than the pulmonic stenosis murmur. Excitement of the animal may result in auscultation of a gallop rhythm or an early systolic ejection click. A continuous machinery murmur associated with continuous shunting through the PDA can be auscultated in some patients.

Tetralogy and pentalogy of Fallot must be distinguished from other causes of cyanosis in young animals. Respiratory distress syndrome of neonates can be distinguished by the presence of tachypnea, dyspnea, and abnormal lung sounds in the absence of a cardiac murmur. Cyanosis caused by central nervous system disease has other neurologic manifestations. Cyanosis from congenital cardiac disease may be caused by a right-to-left shunt or by heart failure with pulmonary edema. Cyanosis resulting from heart failure or respiratory disease improves with oxygen administration, whereas the patient with a right-to-left cardiac shunt fails to improve. Right-to-left cardiac shunting does or can occur with tetralogy and pentalogy of Fallot, reverse PDA or VSD, tricuspid valve or right ventricular atresia, left ventricular hypoplasia, persistent truncus arteriosus, pseudotruncus arteriosus, and other complex congenital cardiac disease, all of which may occur with cyanosis and a cardiac murmur. A complete echocardiographic examination using a segmental approach to cardiac anatomy is necessary to accurately diagnose the correct congenital cardiac malformation, and has widely supplanted other methods of diagnosing complex congenital cardiac disease in large animals. Radiography and cardiac catheterization provide supplemental information that may be helpful in distinguishing among the causes of right-to-left cardiac shunting.

Clinical Pathology Increased packed cell volume (PCV), red blood cell count, and hemoglobin concentration (polycythemia) may be present in some animals with tetralogy and pentalogy of Fallot.[43] However, polycythemia is uncommon in foals with cyanotic congenital cardiac disease and is usually less than 45% in most calves. The degree of arterial hypoxemia is variable, depending upon the amount of right-to-left or bidirectional shunting. Electrocardiographic changes are usually nonspecific, but a right-axis deviation may be detected.[43] Radiographs of the lungs may show decreased vascularity. Echocardiography easily visualizes the four components of tetralogy of Fallot. The VSD and overriding aorta are usually clearly visible with 2D echocardiography. The malalignment VSD is usually large and located just below the right cusp of the aortic valve, separated from the pulmonic valve by the crista supraventricularis. The aortic root is usually large, dextroposed, and overrides the septal defect. Echocardiography shows increased thickness of the right ventricular wall, ventricular septal hypertrophy, paradoxical septal motion, and similar left and right ventricular internal dimensions. Narrowing of the RVOT, pulmonic stenosis, or a hypoplastic pulmonary artery (most common) may be imaged as the cause of the RVOT obstruction. Pulsed wave and color flow Doppler echocardiography can be used to further characterize the abnormalities of blood flow associated with tetralogy of Fallot, in particular the severity of the RVOT obstruction. Contrast echocardiography also nicely demonstrates the path of blood flow with a peripheral venous injection. Contrast echoes are imaged entering the right ventricle from the right atrium, and then simultaneous opacification of the pulmonary artery, left ventricle, and aorta occurs.

Cardiac catheterization can be used to demonstrate equalization of ventricular pressures and a pressure gradient between the right ventricle and pulmonary artery. Oximetry should demonstrate decreased oxygen content in the left ventricle compared with the pulmonary vein. Angiocardiography demonstrates simultaneous filling of the right ventricle, left ventricle, and overriding aorta, with decreased pulmonary artery filling and increased right ventricular trabeculation (hypertrophy).

Pathophysiology The VSD is usually large, resulting in equalization of pressures in the two ventricles and the aorta. The degree

VetBooks.ir

of shunting is controlled by the resistance across the stenotic RVOT compared with the resistance across the aortic valve. If the RVOT is severely obstructed, the clinical signs of cyanosis are more marked. Excitement, drugs, or increased myocardial contractility from any cause decreases right ventricular volume and worsens clinical signs. Right ventricular failure usually is not a consequence of the pressure overload because of equalization of the ventricular pressures.

Epidemiology The prevalence of tetralogy and pentalogy of Fallot in large animals has not been documented, but these defects seem to be more common in calves than in foals. There is no evidence that these disorders are inherited.

Necropsy Findings Examination of the heart reveals a rounded apex caused by right ventricular enlargement. A high, usually large VSD, a dextroposed overriding aorta that straddles the VSD and the left and right ventricle, right ventricular hypertrophy, and septal hypertrophy are present. There is usually right ventricular infundibular narrowing and a hypoplastic pulmonary artery, although there may be valvular pulmonic stenosis with a poststenotic dilation. The right and left atria may be enlarged.

Treatment and Prognosis There is no practical treatment for tetralogy and pentalogy of Fallot in large animals. When cyanosis or exercise intolerance is present or growth is stunted (the latter two are common findings in affected animals), the prognosis for long-term survival, production, or performance is poor. Affected foals should not be used for performance or broken to ride if they live long enough. As with many congenital cardiac diseases, the intensity of the murmur is not a good predictor of the severity of the condition, and further diagnostic tests are indicated.

Other Congenital Cardiac Defects

ATRIAL SEPTAL DEFECT. ASD is a connection between the left and right atria at the septal level. The most common type of defect is the ostium secundum defect, of which patent foramen ovale (PFO) is seen most frequently. PFO is relatively common in calves and is due to failure of the septum primum, the valve of the foramen ovale, to become adherent to the crista dividens after birth, when changes in left and right atrial pressures produce functional closure of the foramen ovale. PFO is frequently associated with PDA in calves.[39]

Animals with an ASD are frequently asymptomatic, but a holosystolic crescendo-decrescendo murmur may be heard at the left heart base. The shunt is usually left to right, and the murmur is the result of increased volume being ejected across the pulmonic valve. If the defect is large, right atrial, right ventricular, and left atrial dilation may be present. Differential diagnostic considerations are a functional murmur, pulmonic stenosis, VSD, or PDA. A definitive diagnosis can be made by 2D echocardiography, in which an enlarged right atrium, right ventricle, and left atrium are imaged. Pulsed wave Doppler, color flow, or contrast echocardiography can be used to demonstrate the shunt through the ASD.

PULMONIC VALVE STENOSIS. Pulmonic valve stenosis is uncommon as a single defect but has been reported in a foal with VSD and as one of multiple defects in calves and foals.[9,39,53] Clinical signs of cardiac murmur, cyanosis, and polycythemia are variable and depend largely on the other cardiac defects present. Characterization of the severity of the pulmonic stenosis and other associated cardiac defects can be performed with a complete echocardiographic examination.

TRICUSPID VALVE ATRESIA. Tricuspid valve atresia has been reported in foals[44,48-50] in conjunction with other cardiac defects. The abnormalities associated with tricuspid atresia include PFO, VSD, small right ventricle, large left ventricle, and large mitral valve orifice. The foals showed cyanosis and a crescendo-decrescendo or band-shaped holosystolic or pansystolic murmur audible over the left and right heart base. Tachycardia, tachypnea, and weak peripheral pulses also were present. Polycythemia was commonly reported. Echocardiographic diagnosis of tricuspid atresia in foals has been reported.[44,49] A thick echo in the region of the tricuspid valve that does not separate in diastole (absent tricuspid valve), an ASD (usually PFO), a VSD, a small right ventricle, a large left ventricle, and a large mitral valve orifice are the echocardiographic findings in tricuspid atresia. Blood flow (right to left) through the PFO into the left atrium and left ventricle, followed by simultaneous opacification of the aorta and right ventricle, is detected with contrast echocardiography. Affected foals rarely live past weanling age. Necropsy showed tricuspid atresia, along with ASD, VSD, small right ventricle, and large left ventricle. Pulmonic valve stenosis and dextropositioning of the aorta have also been reported.

MITRAL VALVE DYSPLASIA. Mitral valve dysplasia is a rarely reported early developmental anomaly in the horse.[9,51,69] The affected foals had a grade 3 to 5/6 holosystolic decrescendo or coarse-type murmur loudest in the mitral to aortic valve area. On echocardiography, the mitral valve leaflets appeared thickened, bright, and irregularly nodular in the foal with mitral valve dysplasia. A cleft was imaged in the midportion of the free wall leaflet, with small papillary muscles and shortened, unevenly thickened chordae tendineae.[51] The other foal was missing the right papillary muscle, and the parachute configuration of the mitral valve was readily imaged echocardiographically.[69] One foal died, and the foal with the parachute mitral valve was humanely euthanized because it was stunted and had a poor prognosis. Other congenital variation in the configuration of the mitral valve leaflets resulting in mild mitral regurgitation occurs more frequently in horses, usually compatible with a normal life expectancy.

VENTRICULAR HYPOPLASIA. Ventricular hypoplasia has been reported in foals and calves.[39,58] The defect may be present with other cardiac defects and is usually associated with early death. The defect was present in three closely related Holstein calves, suggesting possible genetic factors.[39]

TRUNCUS OR PSEUDOTRUNCUS ARTERIOSUS. *Persistent truncus arteriosus* refers to the condition in which one arterial vessel leaves the heart above a VSD. The coronary and pulmonary arteries and aorta arise from this vessel. Persistent truncus arteriosus has been diagnosed in foals and calves.[45] Subclassifications of this condition have been applied to humans, depending on the origin of the pulmonary trunk or arteries. Pseudotruncus arteriosus has also been described in foals and a calf and is characterized by the presence of a remnant of an atretic pulmonary trunk.[44,70] With pseudotruncus arteriosus, the pulmonary blood supply comes from bronchial arteries or a PDA. Clinical manifestations of these conditions include tachycardia, exercise intolerance, and a cardiac murmur. The murmur may be a continuous machinery murmur if a PDA is also present, holosystolic and crescendo-decrescendo and loudest at the left heart base, or the coarse murmur of the VSD may be auscultated, although the relative pulmonic stenosis component is absent. Cyanosis, dyspnea, or syncope may be seen with exercise or excitement. CHF and stunted growth may be noticed. Polycythemia was detected in a calf with a pseudotruncus arteriosus.[70] The presence of cyanosis with the cardiac murmur helps differentiate this condition from a simple VSD or PDA. Definitive diagnosis may be made by echocardiography, angiocardiography, or nuclear angiocardiography. These foals and calves have a guarded to grave prognosis. Their life expectancy depends upon the magnitude of their pulmonary blood flow.

AORTIC ANOMALIES. Dextropositioning or transposition of the aorta are the most common aortic anomalies of foals and calves and are seen most frequently with other defects. Other aortic anomalies of foals and calves are persistence of the right aortic arch and double aortic arch, which may cause esophageal compression. The clinical presentation is one of esophageal obstruction. Interruption of the aortic arch in two foals with VSD, ASD, and PDA has been reported.[55]

VetBooks.ir

The foals showed weakness, lethargy, cyanosis, and tachycardia. The murmur was pansystolic and plateau shaped, with the PMI on the right side of the thorax. Radiology showed cardiomegaly and increased vascularization of the lungs. Cardiac catheterization showed left ventricular failure.

Bicuspid and quadricuspid cusps of the aortic and pulmonic valves occur in large animals and usually result in both stenosis and valvular insufficiency. An aneurysm of the sinus of Valsalva was detected in a 3-year-old Thoroughbred gelding as an incidental finding.[71] Occasionally a diastolic murmur may be associated with aortic insufficiency in horses with sinus of Valsalva aneurysms.[72] These sinus of Valsalva aneurysms usually rupture later in life, and the horse develops acute distress, colic, and uniform ventricular tachycardia (VT). A continuous machinery murmur associated with the presence of an aorticocardiac fistula is usually present on the right side of the thorax.

EISENMENGER COMPLEX. Eisenmenger complex has been described in a stunted 24-month-old Holstein heifer that had a loud, crescendo-decrescendo, pansystolic murmur heard best over the pulmonic valve.[47] The heifer had a prominent gallop rhythm from a loud fourth heart sound, exercise intolerance without cyanosis, and polycythemia. Cardiac catheterization showed increased pressures in the right atria, right ventricle, and pulmonary artery, with normal left-sided pressures. The echocardiogram was characterized by a VSD, overriding aorta, and dilation of the pulmonary trunk, a feature that distinguished this from tetralogy of Fallot. Left ventricular function was decreased, and at necropsy the heart was enlarged and rounded with a dilated pulmonary trunk and small aorta. The right ventricle was dilated and hypertrophied, whereas the left atria and ventricle were only mildly dilated.

ECTOPIA CORDIS CERVICALIS. Ectopia cordis cervicalis is a relatively common defect of cattle.[39,54] Although this defect usually results in the heart being in the cervical region, a few animals may have the heart in the pectoral region (14%) or abdomen (3%).[54] Various defects are associated with ectopia cordis cervicalis, including defects of the heart, great vessels, neck (torticollis), ribs, and sternebrae. The heart is usually contained within the pericardium under the muscles of the skin in the ventral cervical area, with the double apex of the heart pointing craniodorsally. The ligaments of the pericardium are most frequently attached to the mandibles and the parotid fascia cranially, the cervical fascia laterally, and the first rib or manubrium caudally. The lung may lack the cardiac notch and often protrudes to the base of the heart. Although the prognosis for a productive life is poor, some calves lived until about 1 year of age.

MISCELLANEOUS CARDIAC DEFECTS. Other cardiac defects can occur, but either the significance of the lesion is questioned or the defect has been recorded infrequently. Complete atrioventricular canal defect has been reported in several foals.[56,57,73] Anomalous coronary artery development has been reported at postmortem examination in both calves and horses and has been thought to be the cause of death in most cases.[74,75,76] Congenital hematomas of the atrioventricular valves also have been noted, but the significance is unknown.[39] Endocardial fibroelastosis, an anomalous development of the endocardium associated with left ventricular hypertrophy, is usually a severe defect resulting in death of the animal. The frequency of this defect in large animals is not established.

Valvular Heart Disease

Definition and Etiology In adult animals, disorders of the tricuspid, pulmonic, mitral, or aortic valves are usually acquired and most commonly result in insufficiency of the affected valve. These disorders may be the result of degenerative changes, infection (bacterial or viral endocarditis or myocarditis), inflammation (valvulitis), trauma, myocardial disease (cardiomyopathy), or unknown causes. They are usually manifested by a cardiac murmur, most frequently of valvular regurgitation, with the PMI at the location of the affected valve or in the direction of the regurgitant blood flow. The mitral and aortic valves are the most common location of degenerative valve disease in horses.[77] Chronic active infection such as foot abscesses, rumenitis, reticular abscess, or other septic process may lead to sustained or recurrent bacteremia, predisposing the animal to the development of bacterial endocarditis, particularly in cattle, or a nonvegetative valvulitis, probably more common in horses. Experimentally, valvular vegetative endocarditis can be induced by intravenous (IV) administration of bacteria without preliminary damage to a valve.[78] Rupture of a valve leaflet or chordae tendineae can cause valvular heart disease, as can dilation of a cardiac chamber from any cause or rupture of the aortic root or of a sinus of Valsalva aneurysm.[72,79-81] In rare cases neoplasia, primarily lymphosarcoma of cattle, can cause valvular heart disease. Congenital valvular heart disease in adult animals is rare. The most common bacterial isolates from equine and bovine endocarditis cases are streptococci and *Pasturella* or *Actinobacillus* spp. and *Trueperella pyogenes* (formerly *Arcanobacterium [Actinomyces] pyogenes*) in horses and cattle, respectively, although a wide variety of organisms has been isolated from large animals with endocarditis.[82-89]

Clinical Signs and Differential Diagnosis Most animals with valvular heart disease have no clinical signs, but a cardiac murmur is detected during a routine examination. Clinical signs vary depending on lesion severity and its rate of development. Murmurs of valvular heart disease are frequently holosystolic (Fig. 30-6), pansystolic, or holodiastolic (Fig. 30-7). They radiate from the PMI in the direction of the abnormal blood flow; are coarse and band-shaped, crescendo or honking (if systolic), or decrescendo and blowing or musical (if diastolic); and are usually moderate to loud in intensity (≥grade 3/6) but may be softer if holodiastolic. All these characteristics help distinguish these murmurs from functional or innocent murmurs, which generally occur early or late in systole or diastole but can be holosystolic; are soft and blowing or crescendo-decrescendo in quality; are localized to a small area; do not radiate; and are soft to moderate in intensity (≤3/6). Murmur intensity is not a reliable indicator of lesion severity except in horses with tricuspid regurgitation, in which the longer, louder murmurs are associated with a larger jet of tricuspid regurgitation.[90] In cattle in particular, severely involved valves (usually in cattle with endocarditis) commonly have faint or no audible murmurs.

The location of the PMI of the murmur is helpful in distinguishing which valve is involved, although more than one valve can be

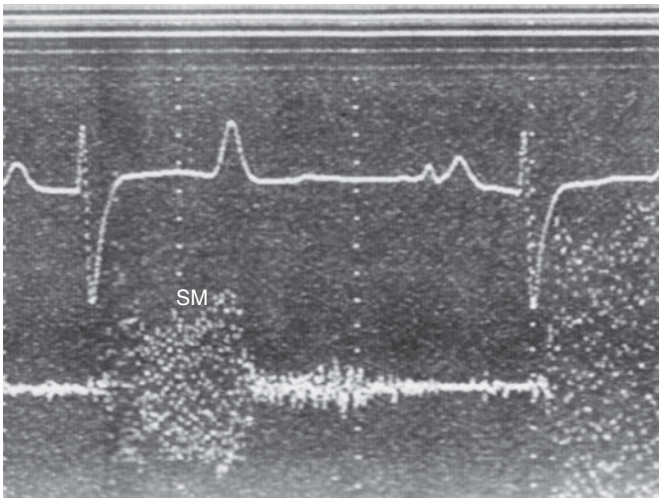

FIG. 30-6 Phonocardiogram obtained from a horse with a ruptured mitral valve chorda tendineae. A loud plateau-shaped holosystolic murmur *(SM),* which is variable in intensity, occurs when the free wall leaflet of the mitral valve is prolapsing into the left atrium.

affected in the same animal. The PMI for lesions of the mitral valve is often in the mitral valve area, although murmurs of mitral regurgitation usually radiate dorsally toward the left heart base and aortic valve area. Therefore loud systolic murmurs with the PMI in the aortic or mitral valve area in horses are usually mitral regurgitation murmurs. Disorders of the tricuspid valve commonly have the PMI on the right side of the thorax (third to fourth intercostal spaces [horses] or second to third intercostal spaces [cattle]). Infrequently the murmur may also be heard on the left side of the thorax cranial to the pulmonic valve location in the second intercostal space. Aortic and pulmonic valve lesions produce murmurs with the PMI at the left heart base in the fourth or third intercostal space, respectively. Acquired valvular lesions of the mitral and tricuspid valves produce primarily systolic murmurs.[19,82,83,85,90-95] Diastolic tricuspid flow murmurs have been reported, however, and may be associated with right-sided mural or valvular masses in horses[65] or may be physiologic, associated with normal blood flow across the atrioventricular valves.[96,97] Lesions of the aortic and pulmonic valves may produce diastolic murmurs, systolic murmurs, or both,[82,98-100] but diastolic murmurs of regurgitation are most common in large animals. Aortic regurgitation associated with degenerative valve disease is most common in horses, whereas pulmonic regurgitation associated with bacterial endocarditis is more common in cattle. Aortic valve lesions in horses have primarily holodiastolic, decrescendo, musical murmurs (see Fig. 30-7) but can also be decrescendo, soft, and blowing. Aortic regurgitation murmurs are accompanied by a water-hammer or bounding arterial pulse if the aortic regurgitation is associated with a significant left ventricular volume overload.[19,82,101] The musical quality of the murmur (harmonic) indicates that some part of the aortic valve is vibrating during diastole. The arterial pulse quality becomes more bounding as the aortic regurgitation becomes more severe, and is a good clinical indicator of the degree of left ventricular volume overload. Ventricular premature beats and atrial fibrillation may also be detected in horses with significant aortic regurgitation.

Besides the cardiac murmur, animals with valvular heart disease may have exercise intolerance, arrhythmias, weight loss, or signs of CHF evidenced by tachycardia, coughing, respiratory distress, jugular venous distention, subcutaneous edema, and ascites (uncommon in large animals, especially horses). In adult cattle, mammary vein distention is another sign of CHF.[83] Cardiac enlargement may be noted as an increased area of auscultation and/or percussion or caudal dislocation of the apical impulse of the heart. Atrial fibrillation may be present. This development is usually an indicator of atrial enlargement in animals with valvular heart disease. If tricuspid valve regurgitation is present, there may be abnormal systolic jugular venous pulsations. If mitral regurgitation is present there may be tachycardia, tachypnea, poor recovery to resting respiratory rate after exercise, coughing, and frothy pulmonary edema (uncommon). Lung sounds may be harsh at rest and on deep inspiration may include crackles or moist bubbly sounds (both of the later auscultatory findings are rare). Most horses with pulmonary edema have only harsh breath sounds that are detected at rest and on deep inspiration.

One of the clinical signs of bacterial endocarditis is a cardiac murmur, the PMI and timing of which depend on the valve or valves affected. Other signs may include tachycardia, arrhythmias, auscultation of prominent heart sounds, tachypnea, coughing, recurring fever, anorexia, weight loss, or signs of CHF. Evidence of disseminated sepsis such as pneumonia, hematuria, or pyuria is usually present. Shifting leg lameness and swollen joints or tendon sheaths are common but usually have an immune-mediated cause, although a horse with bacterial endocarditis and septic tenosynovitis has been reported.[86] Mastitis and decreased milk production are common in cattle. The presence of weight loss, fever, and signs of recurring sepsis help distinguish bacterial endocarditis from other forms of acquired valvular disease.

The clinical signs of a major mitral valve chordal rupture (major chorda tendineae) or its characteristic murmur distinguish this disease from other mitral valve diseases. The murmur is usually a widely radiating murmur of mitral valve regurgitation (see Fig. 30-6) with a distinctive honking quality (the honking quality is consistent with vibration of the mitral valve chorda tendineae or leaflet with blood flow in systole). However, the honking quality may be absent and replaced by a band-shaped pansystolic murmur. There may be evidence of acute hemodynamic collapse. Acute onset of respiratory distress with coughing and expectorating foamy pulmonary edema fluid (this fluid is also detected at the external nares) is a relatively consistent feature with rupture of a major chorda tendineae. Signs of right-sided heart failure (jugular venous distention, subcutaneous edema, and ascites) may develop rapidly. Atrial arrhythmias, most frequently atrial fibrillation, often develop secondary to atrial enlargement. Supraventricular arrhythmias have also been reported in foals with a ruptured mitral chorda tendineae.[93] Acute onset of respiratory distress, along with a honking systolic murmur, distinguishes mitral valve chordal rupture from other causes of mitral regurgitation. The honking systolic murmur of a ruptured mitral valve chorda tendineae can also be heard in the absence of any clinical signs in horses with a minor chordal rupture. The murmur of mitral valve prolapse is also a distinctive murmur and should be suspected in horses whenever a mid- to late-crescendo systolic murmur is auscultated with the PMI over the mitral valve area.[19,102] A similar murmur is frequently auscultated in horses with tricuspid valve prolapse. Murmurs of mitral or tricuspid valve prolapse can be detected in horses with all degrees of valvular insufficiency. Most frequently, however, only small amounts of valvular regurgitation are associated with valvular prolapse. An increased prevalence of mitral and tricuspid regurgitation has been reported in young horses in training.[103-106]

Clinical Pathology Diagnosis of valvular disease is best performed with a complete echocardiographic examination including M-mode, 2D, and Doppler echocardiography. Two-dimensional echocardiography is superior to M-mode for detection of valvular abnormalities (Figs. 30-8 and 30-9), measurement of valvular masses (see Fig. 30-9, *B*), and global assessment of ventricular function, but chamber enlargement, high-frequency vibrations of the valve leaflets, and shortening fraction (an indication of ventricular systolic function) can be determined by both. Pulsed wave, continuous wave, and color flow Doppler echocardiography can be used to semiquantitate the severity of valvular regurgitation and should be performed from both sides of the thorax, interrogating the left atrium in multiple imaging planes.[9,102,107,108] The size of the regurgitant jet at its origin and the extent of the jet within the left atrium detected with pulsed wave and/or color flow echocardiography are two indicators of the severity of the valvular insufficiency.[19] Detection of proximal flow convergence indicates hemodynamically significant mitral regurgitation. The duration of the mitral regurgitation jet is also important in

assessing severity. Clinically insignificant jets of regurgitation are detected only just behind the valve when it is closed. Valvular insufficiency is mild when the jet occupies one third or less of the receiving chamber, moderate when the jet occupies greater than one third but less than two thirds of the receiving chamber, and severe when the jet occupies greater than two thirds of the receiving chamber. The intensity and shape of the spectral Doppler tracing of the mitral regurgitation jet also provide information about its severity. Severe

mitral regurgitation is associated with an intense triangular rather than parabolic signal that increases rapidly at the onset of systole.

Echocardiographic signs of mitral regurgitation are increased left atrial (Fig. 30-10; also see Fig. 30-3) and left ventricular dimensions, rounding of the left ventricular apex, and a pattern of left-sided volume overload. Left ventricular function may be normal (if mitral regurgitation is mild) or the FS may be increased (if there is a significant left ventricular volume overload associated with acute moderate to severe mitral regurgitation), unless there is concomitant myocardial disease. Normal or decreased contractility is present with chronic severe mitral regurgitation. A round, turgid left atrium with bulging of the interatrial septum toward the right is another indication of hemodynamically severe mitral regurgitation. A larger-than-normal pulmonary artery (larger than the aortic root) is compatible with severe pulmonary hypertension and left-sided heart failure. A smaller-than-normal aortic root is detected echocardiographically in horses in low-output left-sided heart failure.[9,19,93,94,102]

The cause of the valvular regurgitation can often be determined. Endocarditis (see Fig. 30-9), ruptured mitral valve chordae tendineae (see Fig. 30-8), a flail valve leaflet, valvular prolapse, or thickening of the valve leaflet are readily imaged echocardiographically.[94] The regurgitant jet detected with pulsed wave or color flow Doppler echocardiography usually originates from the site of the valvular abnormalities detected with 2D echocardiography. In some animals, the lesion responsible for the valvular insufficiency is not visualized with 2D echocardiography, but the regurgitant orifice is detected with pulsed wave or color flow Doppler echocardiography.[5,9,108] A ruptured mitral valve chorda tendineae is diagnosed by finding a mobile linear echo everting into the left atrium (see Fig. 30-8) or a flail leaflet that may prolapse into the left atrium during systole, systolic and chaotic diastolic mitral valve flutter, rapid mitral valve opening with increased excursion of the affected leaflet, and lack of coaptation of the mitral valve in systole. The asynchronous movement of any portion of the valve leaflet during any phase of the cardiac cycle indicates the presence of a flail valve leaflet.[9,19,91,94]

Tricuspid regurgitation may produce echocardiographic evidence of right atrial and right ventricular enlargement with paradoxical septal motion. Frequently the cause of tricuspid valve regurgitation in cattle is bacterial endocarditis, and the incompetent valve can be visualized. In cattle, neoplasia of the right atrium, tricuspid valve, or right ventricle can usually be visualized when present.[109] Tricuspid regurgitation is common in horses with no obvious valvular lesion.[97,104,110]

Aortic valve regurgitation is diagnosed echocardiographically by observing left ventricular dilation, increased aortic root diameter (Fig. 30-11), increased left ventricular FS (if the aortic regurgitation is moderate to severe and left ventricular function is normal), diastolic fluttering of the septal mitral valve leaflet (see Fig. 30-7), or less

frequently by observing high-frequency vibrations of the interventricular septum or aortic valve in diastole (Fig. 30-12).[9,19,99,101,111] Rarely, premature closure of the mitral valve is detected. Thickening of the left cusp of the aortic valve is frequently detected echocardiographically, but prolapse, fenestration, and tears of the aortic cusps also occur.

Acquired pulmonic valve lesions are uncommon in large animals and when present are usually associated with bacterial endocarditis.[100,112] Diagnosis is established by finding the mass associated with the pulmonic valve. Severe pulmonic regurgitation associated with pulmonic valve rupture has been reported in one horse.[113] Pulmonic regurgitation is most common in horses with pulmonary hypertension and CHF but is rarely detected clinically.

Lesions of bacterial endocarditis (see Fig. 30-9) may have a shaggy, ragged, or cystic appearance on 2D echocardiography.* Occasionally the only abnormality noticed is valve thickening, with ventricular hyperkinesis and enlargement of the chambers on the side of the affected valve. Acoustic reverberation and production of microbubbles have also been associated with valvular bacterial endocarditis.[93,96] Other laboratory evidence of bacterial endocarditis includes anemia, neutrophilia (a left shift may be present), an increased serum globulin concentration, and hyperfibrinogenemia. Liver enzymes are frequently mildly elevated, and a urinalysis sometimes shows hematuria or pyuria. Positive blood cultures taken during febrile episodes confirm the diagnosis when associated with these findings, but many times culture results are negative in large animals with bacterial endocarditis. Other laboratory evidence of disseminated sepsis includes neutrophilic response in peritoneal, tracheal wash, or joint fluid. Ventricular arrhythmias are frequently detected electrocardiographically in individuals with mitral or aortic valve endocarditis. Radiographic or sonographic evidence of disseminated pneumonia also may be found with bacterial endocarditis, usually in large animals with a right-sided lesion.

Other laboratory evidence of valvular heart disease is nonspecific. The ECG is not reliable for detecting chamber enlargement associated with valvular incompetence, but is valuable for documenting cardiac arrhythmias occurring secondary to chamber enlargement or the underlying myocardial disease. Radiographic findings of cardiac enlargement, increased pulmonary vascular pattern, or pulmonary edema are also nonspecific. Cardiac catheterization can be performed, and pressure measurements help determine the degree of cardiac dysfunction. Nuclear angiocardiography shows cardiac enlargement or prolonged washout of contrast material. Time-activity curves can be helpful in accurately documenting ventricular dysfunction and the valvular regurgitant fraction.[35]

Pathophysiology

Acquired valvular heart disease that is slow in onset or gradually progressive may be asymptomatic at first, but cardiac changes occur that eventually may lead to CHF. Valvular incompetence from endocarditis, degenerative changes, chordal rupture, or other causes results in volume overload of the recipient chamber. Initially the output of the chamber is increased to maintain forward output, but the increased end-diastolic volume of the recipient chamber leads to compensatory dilation and a mild elevation in end-diastolic pressure. Compensatory hypertrophy may also result. In the later stages of valvular regurgitation, contractile function of the volume-overloaded chamber may diminish, leading to further elevation of end-diastolic pressure and decreased compliance. In the case of severe aortic and mitral regurgitation, this causes elevation of left atrial pressure and eventually pulmonary venous hypertension. PAWP is higher at rest and during exercise in horses with moderate mitral regurgitation.[115] With severe tricuspid regurgitation, right atrial pressure or CVP increases. Increased myocardial oxygen consumption is a natural sequela, and biventricular failure can ensue.

If valvular heart disease is acute in onset, as with major chordal rupture of the mitral valve, the regurgitation and volume overload are imposed on the left atrium, which cannot dilate and adapt acutely to the increased diastolic filling. The sudden hemodynamic change leads to pulmonary venous hypertension and acute pulmonary edema. However, most horses with mitral regurgitation do not have acute fulminant pulmonary edema. Instead, chronic pulmonary hypertension leading to subtle respiratory signs associated with interstitial pulmonary edema and the subsequent development of right-sided CHF are common in horses with severe mitral regurgitation.[94] In one study, 12 of 14 horses with CHF had jugular distentions or pulsations, 10 had abnormal lung sounds (crackles), and 9 had a cough.[116]

Bacterial endocarditis of the mitral or tricuspid valve may lead to rupture of the chordae tendineae. Mitral chordal rupture has been reported in adult horses and foals with bacterial endocarditis, leading to acute left-sided CHF.[93] In addition to the hemodynamic load placed on the heart from an incompetent valve, bacterial endocarditis also results in disseminated sepsis. The vegetations are made up of layers of fibrin, blood cells, necrotic tissue, and bacteria and are relatively resistant to short-term antimicrobial therapy. Disseminated sepsis may be the cause of death or the reason for culling of the animal. Myocardial necrosis of a papillary muscle was associated with mitral chordal rupture in one foal.[93]

Epidemiology

Acquired valvular heart disease is common in large animals, involving 356 of 1557 horses (22.9%) in one abattoir survey.[77] Endocarditis, one form of valvular heart disease, was

*References 65, 85, 87, 88, 93, 99, 100, and 114.

VetBooks.ir

reported in 4% of cattle in another study.[117] Bacterial endocarditis most commonly affects the tricuspid valve in cattle but has been reported on the pulmonic, mitral, and aortic valves as well.[83,95,99,100] Most cases of tricuspid valve bacterial endocarditis have been reported in horses with septic jugular vein thrombophlebitis.[82,85,118] Tricuspid valve endocarditis has also been reported in a horse with a VSD.[65] Aortic and mitral valve endocarditis are most common in horses, occurring with nearly equal frequency.[84,85] In the largest survey of acquired valvular heart disease in horses, the aortic valve was affected most commonly with degenerative valve changes, followed by the mitral valve, tricuspid valve, and (uncommonly) pulmonic valve.[77] Not all valvular lesions are associated with incompetency of the valve. Degenerative valvular changes, particularly changes involving the aortic valve, are seen more commonly in older horses.

Necropsy Findings Acquired valvular disease is associated with finding nodular thickening, fibrous bands, valve fenestrations, rupture of mitral valve chordae tendineae, fibrinous masses typical of endocarditis, or combinations of these lesions on postmortem examination. There may be associated or secondary changes varying from enlargement of a chamber or vessel to degeneration, inflammation, and fibrosis. Enlargement (primarily dilation) of the chamber receiving the regurgitant flow, in addition to enlargement (primarily dilation) of the chamber or vessel from which the regurgitant flow arises, is commonly detected. Jet lesions, usually found in the receiving chamber, are associated with the high-velocity turbulent regurgitant blood flow.

Subcutaneous edema, congestion and mottling of the liver, and increased pericardial, pleural, or peritoneal fluid may be present and indicate CHF. Ascites associated with CHF is uncommon in large animals, particularly in horses. A primary source of chronic or active infection, along with evidence of bacterial embolization, may be seen in cattle with endocarditis but is rare in horses.

Treatment and Prognosis Treatment and prognosis of acquired valvular heart disease depend on the cause, onset, duration, and severity of the lesion. In general, the prognosis is guarded to poor when evidence of valvular incompetence includes tachycardia, exercise intolerance, signs of CHF, or echocardiographic evidence of severe chamber enlargement. Degenerative valve disease may be asymptomatic except for a cardiac murmur, or it may be mild, but it generally is slowly progressive and therefore historically has been given a guarded prognosis. A more accurate prognosis for horses with murmurs can now be obtained from a complete echocardiographic examination, including Doppler echocardiography.[9,19] The valve affected, the lesions detected on the valve leaflets, the degree of chamber enlargement and volume overload detected, the echocardiographic assessment of myocardial function, and the severity of the regurgitation determined with Doppler echocardiography, coupled with the animal's age and intended use, can be used to formulate a prognosis.[9,19] Valvular regurgitation associated with no detectable abnormalities, valvular prolapse, and mild valvular thickening usually has a fair to good prognosis if the amount of valvular regurgitation is small.[9,19,119,120] Individuals with ruptured chordae tendineae, flail valve leaflets, and marked valvular thickening usually have moderate to severe regurgitation, which is likely to progress more rapidly and usually warrants a guarded to poor prognosis.[9,19,94,121] Mitral regurgitation is the most likely valvular insufficiency to be associated with clinical signs of cardiovascular disease, whereas primary aortic regurgitation and tricuspid regurgitation infrequently result in the development of CHF or the death of the animal, except in horses with severe aortic regurgitation. Bacterial endocarditis has a guarded to grave prognosis, even with long-term antibiotic therapy, and frequently results in sudden death of the animal, although bacteriologic cures have been reported.

Despite the guarded long-term prognosis, palliative therapy can be applied for most forms of acquired valvular heart disease. Bacterial endocarditis is treated with long-term administration (ideally intravenously) of bactericidal antimicrobials, the choice of which is based on blood culture and sensitivity results. Continuous IV infusion of antimicrobials is the ideal initial treatment when feasible. In cattle, initial therapy is directed at the likelihood of a gram-positive infection. Combination antibiotic therapy consisting of penicillin and an aminoglycoside is recommended for broad-spectrum coverage in a horse until the results of culture and sensitivity testing are available. Using rifampin at an oral (PO) dose of 5 mg/kg twice daily in combination with another antibiotic with appropriate spectrum has improved the short-term outlook for large animals with bacterial endocarditis. Aspirin (100 mg/kg/day PO, ruminants; 10 mg/kg/day, horses) and subcutaneous (SC) low-dose sodium heparin (30-40 units/kg twice daily, ruminants and horses) may be used in patients with valvular endocarditis in an attempt to prevent platelet adhesion and increased size of the valvular mass. Early diagnosis and aggressive treatment with the appropriate antimicrobials for a prolonged period are important for successful treatment of bacterial endocarditis. The long-term outcome for successfully treated cases is still poor because the scarring that results as the endocarditis lesion heals may lead to severe valvular regurgitation and death of the animal, particularly with left-sided bacterial endocarditis lesions.[19,85-87,122] Compliance and economics are also major drawbacks in treating endocarditis.

The hemodynamic consequences of valvular heart disease (volume overload or CHF) may be improved by using diuretics. Furosemide has been used most commonly at a dose of 1 mg/kg as needed. With the low bioavailability of PO furosemide, IV administration is preferred to obtain the maximal diuretic effect.[123] Digoxin can be used to improve contractility when CHF has occurred. Conditions such as aortic valve or mitral valve regurgitation may show little or no long-term improvement, although many individuals improve for 2 to 6 months before the CHF becomes refractory to treatment. Administration of a maintenance dose of digoxin at 2.2 µg/kg IV twice daily or 11 µg/kg PO twice daily has resulted in therapeutic plasma digoxin concentrations and clinical improvement in horses with CHF, with no significant adverse effects (Box 30-1).[124] Loading doses are rarely used, because of problems with digoxin toxicity.[125] An IV loading dose of 12 to 14 µg/kg can be used in horses but must be divided into three administrations, followed by a maintenance dose of 6 to 7 µg/kg daily.[126] Digoxin is administered IV to cattle at a loading dose of 22 µg/kg followed by a maintenance dosage of 11 µg/kg three times daily or, preferably, at an infusion rate of 0.86 µg/kg/h.[127] Although the 11 µg/kg IV tid dosing may slightly increase the risk of digoxin toxicity, it is more practical than the q4h administration of 3.4 µg/kg IV. Horses appear to benefit from the use of vasodilators, as do other species. Clinical and echocardiographic improvement has been seen in numerous horses with moderate mitral or aortic regurgitation treated with angiotensin-converting enzyme (ACE) inhibitors. Quinapril at 120 mg/horse/day resulted in an increase in stroke volume and cardiac output that was statistically significant after 8 weeks of treatment in horses with mitral regurgitation.[128] Clinical and

BOX 30-1

Guidelines for Digoxin Therapy in Horses and Cattle

Horses

Priming dose IV: 4.4-7.5 µg/kg q12h for 2 doses (rarely used)
Maintenance dosage IV: 2.2 µg/kg q12h (most commonly used)
-3.75 µg/kg q12h
Maintenance dosage PO: 11 µg/kg q12h (most commonly used)
-17.5 µg/kg q12h

Cattle

Priming dose IV: 22 µg/kg
Maintenance dosage IV: infusion of 0.86 µg/kg/h, or give 11 µg/kg tid

IV, Intravenous; *PO,* by mouth; *tid,* three times daily.

VetBooks.ir

echocardiographic improvement has been seen in horses with CHF. Although the ACE inhibitor enalapril appeared to be effective in horses with moderate to severe mitral or aortic regurgitation and in horses with CHF, at a dose of 0.5 mg/kg PO twice daily, oral enalapril (single dose or once-daily administration) did not significantly reduce ACE activity in normal horses and ponies.[129,130] Ramipril at 50 µg/kg daily PO was beneficial in treating one horse with CHF.[131] Benazepril at 0.5 mg/kg PO once daily has recently been shown to be the most effective at inhibiting serum ACE activity in healthy horses.[132] Clinical improvement has been seen with hydralazine at 0.05 to 1.5 mg/kg PO twice daily. Although the short-term outlook may be improved with use of cardiovascular drugs, the prognosis is guarded for long-term survival or production.

Prevention and Control Many causes of acquired valvular heart disease cannot be controlled. Appropriate therapy for chronic active infections and careful attention to asepsis with IV medication and other invasive procedures may help prevent endocarditis and possibly nonvegetative valvulitis. Effective parasite control measures may eliminate some predisposing causes of valvular heart disease such as trauma to heart valves, microembolism, or infarction in horses.

Brisket Disease, Cor Pulmonale, and Pulmonary Hypertension

Definition and Etiology *Cor pulmonale* is a term used to refer to the effect of lung dysfunction on the heart and is therefore a secondary form of heart disease. Regardless of the cause, the underlying feature is pulmonary hypertension that leads to right ventricular hypertrophy, dilation, or failure. The primary cause of cor pulmonale in cattle is high-mountain disease (HMD, also called *high-altitude disease* or *brisket disease*), which leads to hypoxic vasoconstriction from high-altitude dwelling. Some cattle are resistant to developing cor pulmonale when grazed at high altitudes, but others are genetically much more susceptible.[133,134] Pneumonia, lungworm, and prolonged exposure to cold temperatures contribute to the development of HMD. The disease is worsened by ingestion of locoweed (*Oxytropis* and *Astragalus* spp.).[135,136] Chronic pulmonary disease such as bronchopneumonia or lungworm infection in cattle can also result in cor pulmonale.[137] In the horse, right-sided heart dysfunction (e.g., decreased cardiac output, increased right ventricular end-diastolic pressure, increased right atrial pressure or CVP, jugular venous distention, or subcutaneous edema) associated with chronic pulmonary disease is rare but may be more common than previously recognized. However, right-sided heart dysfunction associated with pulmonary hypertension and left-sided heart dysfunction is a common cause of CHF.

Clinical Signs and Differential Diagnosis Frequently the primary presenting clinical sign of brisket disease is subcutaneous edema of the brisket, ventral thorax, submandibular area, and occasionally the limbs. Lethargy, weakness, bulging eyes, diarrhea, collapse, and death occur.[133] Jugular venous distention or pulsations may be present. Dyspnea and tachypnea are frequently exhibited. Tachycardia is present, and a gallop rhythm may be auscultated. Splitting of the second heart sound (S_2) is a variable finding. Pulmonary hypertension may accentuate the separation of the aortic and pulmonic valve closures, producing audible splitting of S_2 that is most noticeable during inspiration. In some horses with moderate or severe recurrent airway obstruction (RAO) and increased vascular impedance, however, pulmonic valve closure occurs early and only a single S_2 is audible.[138]

A cardiac murmur may be auscultated, caused either by tricuspid insufficiency or a pulmonic valve ejection murmur. The murmur of tricuspid insufficiency, which is secondary to right ventricular dilation, is regurgitant or plateau shaped, with the PMI over the right thorax or, less frequently, the left second intercostal space. The pulmonic valve ejection murmur, found less commonly, is audible as a crescendo-decrescendo murmur at the left heart base.[5] Pleural or pericardial effusion is not common with cor pulmonale.[139] In horses with RAO leading to cor pulmonale, tachypnea, labored breathing, coughing, and exercise intolerance are common complaints. Wheezes are usually auscultated bilaterally in the thorax of affected horses.

These clinical signs are not specific for brisket disease (cor pulmonale) and largely reflect right-sided heart failure. Other considerations when signs of right-sided heart failure are present should be bacterial endocarditis or tricuspid insufficiency from any cause, cardiomyopathy, cardiac lymphosarcoma or other thoracic neoplasms, traumatic reticulopericarditis or other causes of pericarditis, left-sided heart failure, pleuritis or pleural effusion, and congenital pulmonic valve stenosis (rare). With pericarditis, heart sounds may be muffled, or the characteristic "washing machine murmur/rub" may be audible. Left-sided heart failure is frequently accompanied by pleural effusion, pulmonary edema, and weak peripheral pulses. In horses, however, expectoration of pulmonary edema fluid occurs only with sudden onset of severe left-sided heart failure. In horses with chronic left-sided heart failure, tachypnea, coughing, poor recovery after exercise, and harsh lung sounds may be all that is detected.

Clinical Pathology A complete blood cell count (CBC) may reveal a neutrophilia in cases of cor pulmonale caused by primary lung disease. Radiography of the thorax reveals primary pulmonary disease such as bronchopneumonia, bronchiectasis, or chronic bronchitis in cattle that have developed this disease at low altitudes. Radiographic findings in horses with RAO usually reveal an interstitial pattern. Arterial blood gases demonstrate the presence of hypoxia and may also show hypercapnia. Transtracheal wash fluid cytology and bacterial culture may provide evidence of the cause of the primary lung disease. Fecal sedimentation helps rule out parasitic bronchitis or pneumonia. Electrocardiographic findings are not specific. An echocardiogram may provide further evidence of pulmonary hypertension and right-sided heart dysfunction by showing right ventricular hypertrophy and dilation, increased septal thickness, and abnormal septal motion (Fig. 30-13).[140,141] Dilation of the pulmonary artery is also detected with 2D echocardiography and is a sensitive indicator of pulmonary hypertension or increased flow through the pulmonary artery. A dilated pulmonary artery has been reported in horses with cor pulmonale and in horses with acute pulmonary obstruction from RAO.[141,142] Cardiac catheterization reveals elevated pressure in the pulmonary artery, right ventricle, and right atrium. Elevation of right ventricular end-diastolic pressure is a sign of right ventricular failure.

Pathophysiology Pulmonary arteriolar constriction is the response to hypoxia from high-altitude dwelling or pulmonary disease. The response to hypoxia varies depending on the amount of smooth muscle in the pulmonary arteries. In cattle, increased pulmonary vascular resistance and pulmonary hypertension frequently develop. Chronic pulmonary artery hypertension causes a pressure overload on the right ventricle, which responds to the increased workload with hypertrophy, dilation, or failure, depending on the speed with which the condition develops. The disease is progressive, and at some stage the right ventricular myocardium is unable to compensate, dilates, and fails. With failure come the typical signs of jugular venous distention and development of subcutaneous edema. Chronic right-sided heart failure may result in diastolic dysfunction of the left ventricle.

Epidemiology The disease is more common in cattle than in other animal species, especially when cattle are kept at altitudes over 6000 feet, where the incidence has been estimated at 0.5% to 5% in cattle native to high altitude.[133,134] In cattle adapted to low altitude and moved to higher altitude for grazing, however, the incidence is much higher.[133,134,143] Mainly calves and yearlings are affected. A genetic predisposition to develop pulmonary arterial constriction when

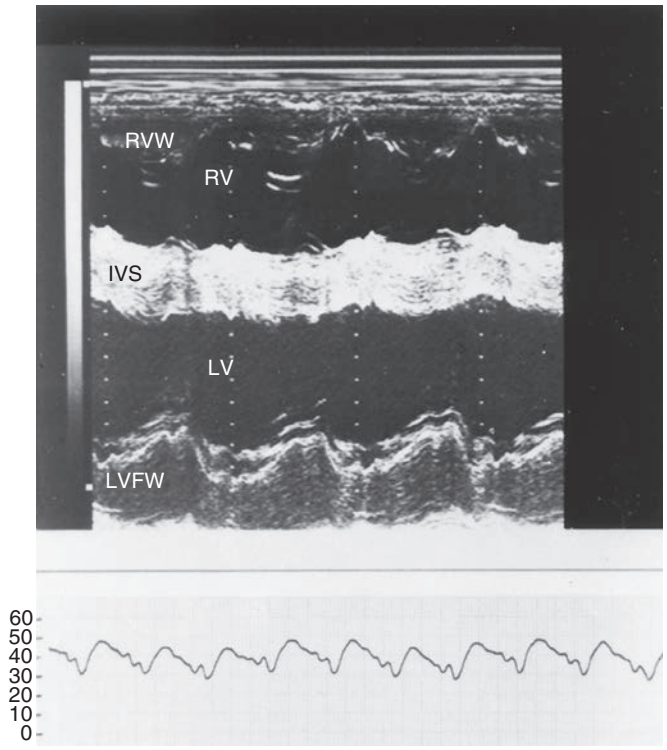

FIG. 30-13 M-mode echocardiogram and pulmonary artery pressure curve obtained from a cow with pulmonary hypertension and cor pulmonale. The echocardiogram shows mild thickening of the right ventricular wall *(RVW)* and interventricular septum *(IVS),* dilation of the right ventricle *(RV),* and abnormal septal motion. *LV,* Left ventricle; *LVFW,* left ventricular free wall. The pulmonary artery pressure curve demonstrates elevated systolic and diastolic pressures. (Pulmonary artery pressure curve in millimeters of mercury [mm Hg].)

subjected to hypoxia at high altitude is present in many breeds. Some breeds and pedigrees within breeds are more resistant than others to the effects of high altitude, and the inheritance appears to be complex.[133,134] More cases of HMD are detected in the fall and winter and are due to cold weather exacerbating pulmonary hypertension.[134] Ingestion of swainsonine contained in locoweed (*Oxytropis* and *Astragalus* spp.) also predisposes cattle to right-sided heart failure at high altitudes by causing toxic myocardial damage.[135] Pulmonary hypertension has also been detected in cattle fed ionophores at high altitude.[133]

Necropsy Findings There is evidence of right-sided heart failure (e.g., subcutaneous edema) in the submandibular area, brisket, and ventral abdomen. Findings include dilation and hypertrophy of the right ventricle, congestion of the liver, and ascites. Perirenal edema, mesenteric edema, and pleural effusion are often present. The lung may have evidence of concurrent pneumonia, bronchitis, bronchiectasis, or emphysema. Lesions of locoweed toxicity may be found in other organs in cattle.[135] Lesions of chronic interstitial pulmonary disease are found in horses with RAO.

Treatment and Prognosis Removing the animal from high altitude, treating the primary lung disease, and administering oxygen may help eliminate the hypoxia and thus the pulmonary hypertension. Cor pulmonale from high altitude is potentially reversible when the animal is returned to a lower altitude. However, cattle with other lung disease and a mean pulmonary artery pressure (PAP) of 50 to 55 mm Hg rarely have their mean PAP return to an acceptable level for high-altitude living.[133] The heart failure can be treated with digoxin and diuretics. Beneficial effects of vasodilator therapy have not been documented. Once heart failure signs have developed, the prognosis is guarded even with appropriate treatment. Removing the horse from the environment inducing RAO is critical to treating the cor pulmonale. A more detailed discussion of the treatment and management of horses with RAO can be found in Chapter 31.

Prevention and Control Selection of breeding stock with low or normal pulmonary arterial pressures at altitudes above 5000 feet (mean PAP < 35 mm Hg) helps eliminate the predisposing genetic susceptibility to the effects of hypoxia of high altitude.[133,134,143] Recently, more specific guidelines have been formulated for the selection of cattle to be kept at high altitudes.[133] Cattle older than 12 months of age with a mean PAP of less than 41 mm Hg at over 5000 feet elevation are good to select for breeding stock for high altitudes and should have a low risk of HMD. Cattle with a mean PAP of 49 or higher at any elevation are at high risk for developing HMD and should not be selected as high-altitude breeding stock.[133] Cattle with a mean PAP in between these two guidelines are at risk and should be used with caution at high altitudes.[133] The disease can also be controlled by removing susceptible animals from high altitude and preventing locoweed ingestion. Herd health practices such as avoiding crowding and poor ventilation and using appropriate vaccinations to reduce the incidence of pulmonary disease help reduce the incidence of other causes of cor pulmonale.

Myocardial Disease: Myocarditis and Cardiomyopathy

Definition and Etiology *Myocarditis* is inflammation of the myocardium caused by bacterial, viral, or parasitic organisms or thromboembolic disease caused by these organisms. In large animals, recognized bacterial causes include *Staphylococcus aureus, Streptococcus equi, Clostridium chauvoei,* and *Mycobacterium* spp. Myocarditis can also occur after bacteremia, septicemia, pericarditis, or endocarditis, regardless of the causative agent. Known viral causes of myocarditis include foot-and-mouth disease, equine infectious anemia, equine viral arteritis, equine influenza, and African horse sickness. Parasitic causes of myocarditis may include strongylosis[144] or onchocerciasis in horses, and toxoplasmosis, cysticercosis, or sarcocystic infection in ruminants.[145,146] Currently it is thought that infection with the spirochete *Borrelia burgdorferi* may be a cause of myocarditis in domestic animals, as it is in human beings.[147] Cardiomyopathy is a subacute or chronic disease of the ventricular myocardium that occurs without anatomic valvular disease, congenital malformations of the heart or vessels, or pulmonary disease. In large animals, dilated cardiomyopathy is the only cardiomyopathy of known significance. Dilated cardiomyopathy is associated with ventricular dilation, increased ventricular mass, and decreased systolic function. Although the cause is frequently undetermined,[109,148,149] several conditions have been related to or identified with cardiomyopathy. An inherited cardiomyopathy thought to be linked to the red Holstein gene has been found in Holstein-Friesian cattle in Canada, Japan, Australia, the Netherlands, and Switzerland.[150-153] There is also a cardiomyopathy associated with a curly hair coat in polled Herefords.[154] Cardiomyopathy has been associated with ingestion of monensin, lasalocid, salinomycin, gossypol, *Cassia occidentalis,* and *Phalaris* spp. Vitamin E and selenium deficiency, copper deficiency, excessive molybdenum, or high sulfates (secondary copper deficiency) may cause cardiomyopathy.[155-165] Myocardial infiltration by neoplasia such as lymphosarcoma or fibrosarcoma also may cause cardiomyopathy. A fibrofatty infiltration of the right ventricle and interventricular septum that appears to be similar to arrhythmogenic right ventricular dysplasia has been reported in horses.[166-168] The most common cause of cardiomyopathy in horses is probably myocarditis, although the inciting insult is usually difficult to identify.

Clinical Signs and Differential Diagnosis The manifestations of myocarditis are highly variable depending on the extent of the disease, location of the inflammation within the myocardium, and associated systemic illness. Myocarditis can easily be missed because of the lack of specific cardiac signs or the predominance of

VetBooks.ir

VetBooks.ir

signs related to the organ system with primary involvement (e.g., strangles in horses or mastitis in cattle). Animals suspected of having myocarditis are often febrile or have a recent history of fever and may have tachycardia. The elevated heart rate may be caused by sinus tachycardia or other paroxysmal or sustained supraventricular or ventricular arrhythmias, because cardiac arrhythmias are common. Premature beats are also commonly detected in large animals with suspected myocarditis and may be present in animals with a normal or increased heart rate. Occasionally, acute myocarditis is associated with auscultation of a pronounced gallop rhythm or a cardiac murmur of either tricuspid or mitral valve insufficiency. Jugular venous distention, other signs of CHF such as peripheral edema, and signs of circulatory collapse may be present. Horses may show evidence of myalgia, reluctance to move, or exercise intolerance. With these signs it may be difficult to distinguish myocarditis from colic, respiratory disease, lameness, or septicemia. If signs are more clearly cardiac (e.g., murmur, arrhythmia, jugular venous pulsations), the practitioner should rule out endocarditis, cardiomyopathy, cardiac neoplasia, and CHF from another cause.

The clinical signs associated with dilated cardiomyopathy can also be variable but are usually more clearly associated with heart disease. Most animals have signs of cardiac failure such as peripheral edema and jugular venous distention or pulsations (Fig. 30-14). Auscultation frequently reveals tachycardia, gallop rhythm, muffled heart sounds, or a cardiac arrhythmia. Cardiac murmurs of tricuspid or mitral valve insufficiency are usually present secondary to the ventricular dilation. Breath sounds are increased, tachypnea is present, and percussion of the thorax frequently reveals signs of pleural or pericardial fluid. Occasionally, respiratory distress is evident with hyperpnea, dyspnea, coughing, and presence of a bloody froth at the nostril. Nonspecific signs of cardiomyopathy such as exercise intolerance, syncope, diarrhea, or anorexia may also be present. In cattle, decreased milk production and abomasal displacement have been associated with dilated cardiomyopathy.[150] Palpable liver enlargement has also been reported in cattle with cardiomyopathy.[151] Most affected cows develop clinical signs within 3 months of calving.[151]

FIG. 30-14 Holstein cow with cardiomyopathy showing signs of CHF (submandibular and brisket edema, jugular venous distention, and pulsations).

Sudden death can be a feature of myocarditis or dilated cardiomyopathy, and it frequently follows stress or exercise. Recumbency, collapse, and sudden death are common presenting signs in animals with ionophore toxicosis.[155-161,163,165] In many animals with inherited cardiomyopathy, death occurs within 6 months of age.[152,154] In Holstein-Friesian cattle with suspected inherited cardiomyopathy, heart failure and death may not occur until cattle are 2 to 4 years old.[150,151] Other acquired causes of cardiomyopathy can occur at any age.

When animals show clinical signs of dilated cardiomyopathy, many differential diagnoses should be considered. If the animal is young, other congenital heart defects, cor pulmonale, and nutritional myodegeneration should be considered. In adults, bacterial endocarditis, cardiac neoplasia, thoracic abscess, pericarditis, pleuritis, and diaphragmatic hernia may also have similar clinical manifestations. Although the cause of dilated cardiomyopathy may be difficult to determine, nutritional (vitamin E, selenium, or copper deficiency), toxic (monensin, gossypol, salinomycin, lasalocid, *Cassia* spp., or *Phalaris*), infectious (viral, bacterial, or parasitic), or drug-induced causes should be investigated.

Clinical Pathology Depending on the cause of the myocardial disease, the clinicopathologic findings may vary. Routine CBC may be normal, or a neutrophilic leukocytosis may be present. No consistent changes are expected in the serum chemistry profile, but serum albumin concentration may be slightly decreased, and serum urea nitrogen, creatinine, γ-glutamyltranspeptidase (GGT), sorbitol dehydrogenase (SDH), and bilirubin concentrations may be increased because of congestive liver disease when signs of CHF are present. Serum concentrations of creatine kinase (CK) and lactic dehydrogenase (LDH) may be elevated, but hepatic and skeletal muscle contribution to these elevations cannot be ruled out. Large elevations of the myocardial isoenzymes of CK (myocardial bound [MB]) and LDH (LDH_1) were detected in one outbreak of monensin toxicosis[158] and have been detected in other horses with myocardial necrosis of unknown etiology. A better indication of myocardial disease may be the elevation of cardiac troponin I (cTnI), which has been detected in horses with acute gastrointestinal (GI) disease as well as in many types of myocardial diseases.[169,170] Marked elevations of cTnI have been reported in a horse with multiform VT and myocardial necrosis of unknown cause,[171] and in a horse with VT and aortic septal rupture.[172] Elevations of cTnI were detected in horses following exposure to lethal and sublethal concentrations of monensin and lasalosid.[164,165,173] Analysis of pericardial or pleural fluid reveals a transudate with low protein concentration (<2.5 g/dL) and cellularity (white blood cell [WBC] count < 2500/μL), with the predominant cell type being mononuclear cells unless the myocarditis is an extension of pericarditis. Serum should be tested for serologic evidence of bovine leukosis (BLV) infection in adult cattle, α-tocopherol, glutathione peroxidase, and copper concentrations. Whole blood selenium levels should be determined. In infectious myocarditis or inherited cardiomyopathy, results of these tests will most likely be normal. A negative BLV test result essentially eliminates lymphosarcoma as a cause of the myocardial disease; a positive test result does not confirm a causal relationship. In horses, serum should be tested for serologic evidence of a variety of equine viruses, particularly influenza, equine viral arteritis, and herpesvirus. Hemoglobinuria, if present, suggests consideration of monensin, gossypol, or nutritional myodegeneration as the cause of myocardial disease. Arterial blood oxygen tension may be reduced below 80 mm Hg in animals with myocardial disease.

An ECG may demonstrate sinus tachycardia or other cardiac arrhythmias; the frequency and severity of these arrhythmias are best demonstrated with continuous ECG monitoring. There may be some evidence of conduction abnormalities in the base-apex lead, but these findings are not specific for myocardial disease. Echocardiography may be normal in animals with myocarditis, or the abnormalities detected may be caused by the arrhythmias present. A small left ventricular internal diameter, thickened left ventricular free wall and interventricular septum, small aortic root diameter, and decreased FS

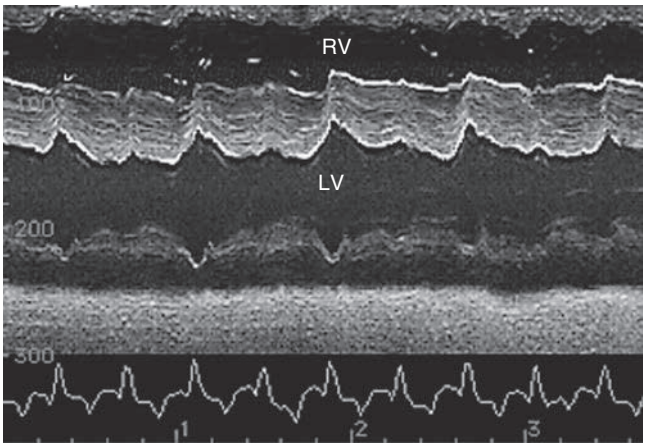

FIG. 30-15 M-mode echocardiogram of the left ventricle *(LV)* obtained from a mare with sustained uniform ventricular tachycardia. Note the small end-diastolic and end-systolic dimensions of the left ventricle and the little variation between systole and diastole in this dimension. *RV,* Right ventricle.

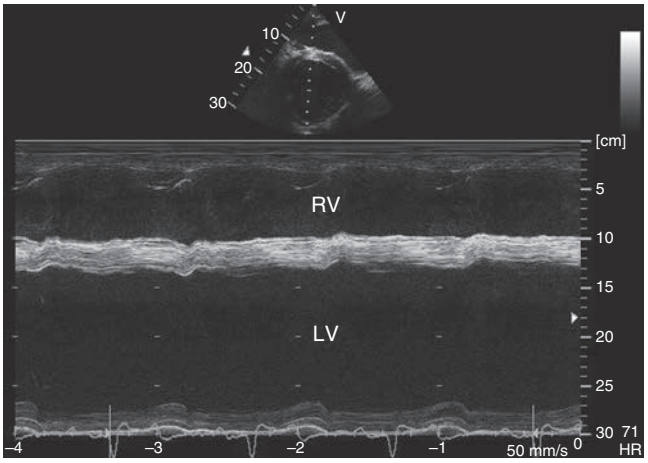

FIG. 30-16 M-mode echocardiogram of the left ventricle obtained from a mare with cardiomyopathy and severe left ventricular dysfunction. Note the large end-diastolic dimension of her left ventricle *(LV),* the thin interventricular septum and left ventricular free wall, and the poor left ventricular contractility. The fractional shortening in this mare varied from 2% to 8%. *RV,* Right ventricle.

may be detected in animals with sustained VT and decreased cardiac output (Fig. 30-15). More frequently, however, there is increased ventricular chamber size, decreased thickness of the interventricular septum and left ventricular free wall, and decreased myocardial function (decreased FS, decreased EF, and myocardial dyskinesis), especially in more severe cases of myocarditis and in animals with dilated cardiomyopathy (Fig. 30-16). In humans with myocarditis there may be evidence of abnormal left ventricular wall motion, paradoxical motion of the interventricular septum, or an echo-free pericardial space.[155] Additional echocardiographic features of dilated cardiomyopathy are increased end-systolic and end-diastolic dimensions of the left and right ventricles (see Fig. 30-16), increased left atrial size, and an increased left atrial–to–aortic root dimension ratio. There may be abnormal mitral valve closure (increased EF slope) and increased separation of the septal mitral valve leaflet and interventricular septum. A decreased aortic root diameter may be detected along with a shortened ET in animals with low-output left-sided heart failure. An enlarged pulmonary artery indicative of pulmonary hypertension (Fig. 30-17) may also be present.

Cardiac catheterization may reveal elevated intracardiac pressures (right atrial, right ventricular, pulmonary artery, pulmonary capillary wedge, and left ventricular end-diastolic) in animals with dilated cardiomyopathy. Horses with acute infectious myocarditis may show hypotension and a narrow pulse pressure. Nuclear angiocardiography

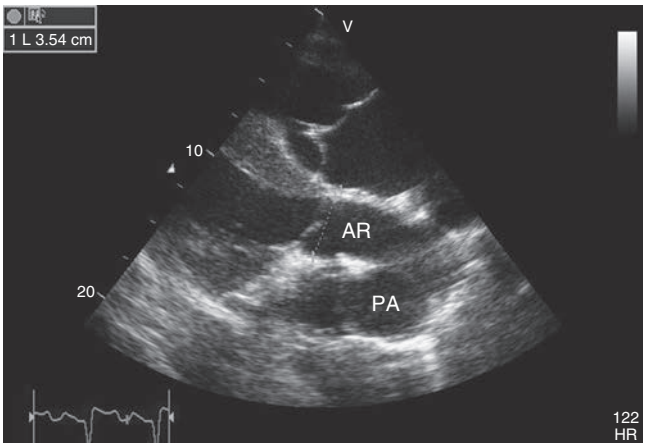

FIG. 30-17 Two-dimensional echocardiogram of the aorta *(AR)* and main pulmonary artery *(PA)* obtained from a foal with cardiomyopathy and severe mitral and tricuspid regurgitation. The pulmonary artery is larger than the aorta, indicative of pulmonary hypertension and impending left-sided CHF. The aorta measured 3.54 cm at its origin.

may be used to show decreased EF[35] in animals with myocardial disease.

Pathophysiology The pathophysiologic changes associated with myocardial disease depend on the specific nature and extent of the disease. Acute myocarditis or angiopathic myocardial lesions[144] may go on to develop into idiopathic dilated cardiomyopathy. It is speculated that changes in cellular metabolism occur with either acute myocarditis or dilated cardiomyopathy, resulting in ECG abnormalities and reduced myocardial performance (reduced cardiac output). In an attempt to compensate for reduced cardiac output, circulating fluid volume is increased by activation of the renin-angiotensin-aldosterone system, and arterial resistance is increased. These compensatory mechanisms frequently lead to only minor improvement in the cardiac output of the failing heart, and the increase in ventricular preload (venous return) and afterload (arterial resistance) may cause pulmonary edema and a further reduction in cardiac contractility. Ventricular dilation, further reduction in cardiac output, and signs of heart failure occur.

Epidemiology The prevalence of acute myocarditis is difficult to estimate because frequently the disease goes undiagnosed, is mild or masked by disease in another organ system, or the animal recovers spontaneously. Similarly, it is difficult to assess the clinical significance of postmortem findings of myocardial inflammation and fibrosis. The morbidity of myocarditis in large animals is probably underestimated because it is rarely the cause of mortality and is associated with viral, bacterial, and parasitic infections that manifest without specific signs of cardiovascular disease.

Inherited cardiomyopathy has been reported in cattle in Japan, Australia, the Netherlands, Canada, and Switzerland, with the incidence in inbred populations reaching 3% to 5%.[151] A familial form of dilated cardiomyopathy has also been reported in cattle in Sweden, Denmark, Australia, and the United Kingdom.[151] These cattle may be genetically linked by the presence of the red gene in Holstein-Friesian cattle.[150] Although in some cattle, inherited cardiomyopathy resulted in death by 6 months of age,[152,154] other cattle failed to show clinical signs until 2 to 6 years of age.[109,149,151,153] No sex predilection is recognized in inherited cardiomyopathy of cattle.

The morbidity and mortality from cardiomyopathy stemming from other causes in cattle and horses is not known. From the number of clinical reports, inherited cardiomyopathy seems to be more prevalent in cattle than in horses. Idiopathic dilated cardiomyopathy or cardiomyopathy secondary to viral or bacterial infections may be more common in horses and is a cause for the acute onset of CHF in horses of racing age.

VetBooks.ir

VetBooks.ir

Necropsy Findings There may be no gross lesions associated with myocarditis. Depending on the relationship between death and the occurrence of myocarditis, microscopic examination of the myocardium may show increased fibrous tissue in the interstitium in the absence of inflammation, or there may be foci of inflammatory cells (typically mononuclear cells), variation in the cross-sectional area of the cardiac myocytes, degeneration of adjacent myocardial fibers, myocardial necrosis, and fibrosis. Replacement of the myocardium by fibroadipose tissue has been reported in horses that experienced unexpected sudden death and were thought to have arrhythmogenic right ventricular cardiomyopathy at postmortem examination.[166-168] Focal interstitial nephritis and fibrosis were reported in eight of nine Holstein-Friesian cattle with dilated cardiomyopathy in Scotland.[151] Often the inciting cause of myocardial necrosis in horses is unknown.[171] Samples of gastric or ruminal contents should be obtained and submitted for analysis of ionophores if ionophore toxicosis is suspected. Feed samples should also be obtained and submitted for ionophore analysis in these cases.

On gross examination, the lesions of cardiomyopathy are recognized more easily as enlargement of the heart, which may be rounded to globose. Biatrial, biventricular, and pulmonary artery dilation are usually present. Patchy or uniform streaks of myocardial pallor may be detected. In rare cases, one of the chambers or major vessels (usually pulmonary artery) may rupture. Generalized edema is frequently found as ascites (uncommon in horses), pericardial or pleural effusion, and edema of the mesentery and subcutaneous tissues. There may be evidence of vascular congestion of the liver, lungs, and spleen. The kidneys may be pale and swollen and have an irregular, granular, pitted surface.

Microscopically the lesions of cardiomyopathy are characterized as myocardial vacuolation and degeneration with necrosis and fibrosis. Calcification may be associated with these lesions. Occasionally there is increased vascularization with proliferative regeneration of myofibers. Loss of cardiac myocytes and replacement by fibrofatty tissue has been described in horses with arrhythmogenic right ventricular cardiomyopathy.[166-168] In some cases of cardiomyopathy, no histopathologic abnormalities are found.

Treatment and Prognosis Treatment of myocarditis includes treating the underlying causative agent if it is recognized and controlling complications such as arrhythmias, CHF, or shock. Thromboembolism is rarely a complication recognized in animals. Prompt administration of vitamin E may be beneficial to the survivors in cases of ionophore toxicosis. Performance animals should be rested. Corticosteroids may be beneficial in animals with severe toxemia, complicated arrhythmias, or intractable heart failure, but their use in early cases of myocarditis or in infections suspected of having a viral cause is controversial because viral recrudescence may occur. However, in many cases corticosteroids appear to have a beneficial effect. Prognosis is good if there are no signs of heart failure and if cardiac arrhythmias are managed successfully. Prognosis is guarded to poor if signs of CHF are present.

Therapeutic strategies currently used for treatment of dilated cardiomyopathy include positive inotropic agents (digoxin), diuretics, vasodilators, rest, and in some cases removal of pleural or abdominal fluid. The advantages of vasodilators (venodilators to relieve pulmonary edema and arterial dilators to reduce preload and afterload and improve contractility) in the treatment of cardiomyopathy are recognized in humans and small animals.[174]

Digoxin is the positive inotropic agent used almost exclusively in large animals but is contraindicated in animals with acute monensin toxicosis. A priming or loading dose can be used in horses with acute severe CHF, followed by a maintenance dose, or more frequently, the horse is started on a maintenance dose from the onset of therapy. In horses, the drug can be administered PO or parenterally. In cattle, low bioavailability limits its use to the IV route of administration.[158] Guidelines for the use of digoxin are given in Box 30-1.[124,175,176] In general, maintenance dosages are used because of the lowered risk of adverse reactions. A peak and trough serum digoxin concentration should be obtained 3 to 5 days after digoxin therapy is begun, and the dosage should then be adjusted accordingly. Ideally the peak and trough digoxin concentration should be 1 to 2 ng/mL.

Dehydration, acid-base imbalance, and electrolyte abnormalities should be corrected before digoxin therapy. The dose of digoxin should be decreased in animals with elevated creatinine or blood urea nitrogen (BUN) until these values return to normal. In horses, the IV loading dose of digoxin should be administered slowly or divided and given at a rate of one third of the loading dose hourly until completion.[175] Alternatively, therapy can be initiated with the maintenance dose. Close monitoring of body weight, appetite, electrolyte concentrations, creatinine or BUN concentration, and cardiac rhythm is essential during therapy. Therapeutic drug monitoring with digoxin plasma concentrations can be helpful during initial therapy, when the volume of distribution of the drug and the patient's body weight may be in a state of flux. Samples for determination of peak serum digoxin concentrations should be obtained 1 to 2 hours after digoxin administration and should not exceed 2.5 ng/mL.[124,177]

The diuretic used most commonly in large animals is furosemide. It is administered parenterally at the rate of 1 mg/kg twice daily or as needed to control edema. Oral absorption of furosemide is poor or variable in horses.[123] A continuous-rate infusion of furosemide is recommended in horses when rapid profound diuresis is needed.[178] The half-life and diuretic effect of bumetanide, a sulfonamide diuretic, are shorter than those of furosemide in horses.[179] Electrolyte concentrations and water consumption should be monitored closely in patients receiving diuretics.

The vasodilators used most frequently in horses include hydralazine and ACE inhibitors (enalapril, quinapril, ramipril, and most recently, benazepril). These vasodilators have resulted in clinical improvement in animals treated for CHF. Hydralazine is administered PO at a dose of 0.5 to 1.5 mg/kg twice daily. Enalapril has been used at a dose of 0.5 mg/kg PO twice daily in the management of horses with moderate to severe mitral or aortic regurgitation and in the treatment of horses with CHF. However, after a single 0.5-mg/kg oral dose of enalapril, neither enalapril or enalaprilat was detectable in the serum, and ACE activity was not significantly reduced.[129] Ramipril was reported to result in clinical and echocardiographic improvement of a horse with CHF at a dosage of 50 µg/kg daily PO.[131] The ACE inhibitor most commonly used in horses is quinapril at a dose of 0.25 mg/kg PO once daily. Quinapril has also been shown to increase stroke volume and cardiac output in horses with mitral regurgitation after 8 weeks of therapy.[128] However, benazepril at 0.5 mg/kg daily PO has recently been shown to be most effective at suppressing ACE activity in normal horses.[132]

Control of cardiac arrhythmias should be attempted in animals that are hemodynamically unstable or threatened with development of worsening arrhythmias. Quinidine is usually the drug of choice for control of atrial and ventricular arrhythmias in cattle and is one of the drugs of choice in horses. Procainamide, lidocaine, and propafenone have also been successful in treating ventricular arrhythmias in horses (Table 30-3). Although administration is limited to the IV route in cattle, oral or IV administration in horses results in adequate plasma concentrations to control arrhythmias. Quinidine is administered IV by infusion or by divided bolus injections as shown in Box 30-2.

When quinidine is used IV, concurrent IV administration of a balanced electrolyte solution at the rate of 3 to 4 mL/kg/h may be desirable to maintain blood pressure in animals with severely compromised cardiovascular status.

Prognosis for animals with dilated cardiomyopathy is poor. Echocardiography is useful in determining the severity of the myocardial dysfunction and in formulating a prognosis. The results of the initial echocardiographic examination were the best prognostic indicator of survival in a recent outbreak of monensin toxicosis.[158] Recovery of animals with cardiomyopathy is unusual, constant therapy is required for maintenance of animals with CHF, and sudden death can occur at any time. Some animals may have significant myocardial

TABLE 30-3

Drug Therapy for Ventricular Tachycardia

Drug	Usual Dose
Bretylium tosylate	0.5-5 mg/kg IV for life-threatening ventricular tachycardia or ventricular fibrillation
Dexamethasone	0.05-0.22 mg/kg, IV or IM
Furosemide	1-2 mg/kg IV as needed for pulmonary edema
Lidocaine	*Equine:* 0.25-0.5 mg/kg slowly IV every 10-15 min; repeat up to a total of 1.5 mg/kg *Bovine:* 0.5 mg/kg, slowly IV; can repeat in 15 min
Magnesium SO_4	IV infusion at 1 g/min to effect, up to a maximum of 25 g
Procainamide	1 mg/kg/min IV to a maximum of 20 mg/kg
Propafenone	2 mg/kg PO tid 0.5-1 mg/kg in 5% dextrose slowly IV over 5-8 min for refractory sustained ventricular tachycardia (not available in United States)
Propranolol	0.03 mg/kg IV
Quinidine gluconate (IV)	1-10 mg/kg IV; total dose in 0.25- to 0.5-mg/kg boluses 5-10 min apart

IM, Intramuscular; *IV,* intravenous; *PO,* by mouth; *tid,* three times daily.

BOX 30-2

Quinidine Administration in Horses and Cattle

Horses

IV: 1.5 to 2 mg/kg every 10 to 20 min until conversion or desired effect, not to exceed a total dose of 12 mg/kg

PO: 22 mg/kg (1 g/100 lb of body weight) q2h until conversion or desired effect, not to exceed a total dose of 132 mg/kg q2h. If quinidine plasma concentrations cannot be obtained promptly, a total dose of 88 mg/kg q2h should not be exceeded.

Cattle

IV: 48 mg/kg infused IV over a 4-hr period

IV, Intravenous; *PO,* by mouth.

dysfunction without CHF and are "cardiac cripples," comfortable at pasture but not safe to use for performance. These animals may later develop CHF.

Prevention and Control Maintenance of a good vaccination program may limit the bacterial and viral causes of myocarditis. Parasite control may also reduce myocardial injury that predisposes to myocarditis or cardiomyopathy in horses. Toxic myocardial diseases are prevented by proper mixing of feeds containing monensin, salinomycin, or lasalocid in feed mills in which horse feed is not made, by not shipping bulk horse feed in trucks in which medicated ionophore-containing feed has been transported, and by preventing horses from ingesting these medicated feeds. Gossypol toxicity can be prevented by feeding no cottonseed meal or cottonseed meal with low gossypol content, especially when feeding preruminants.[180] Feeding of cottonseed meal can be limited by providing more forage or additional protein sources in the diet of ruminants so that ingestion of gossypol is limited to concentrations of 1 to 2 g/kg or less of feed for adult cattle and 0.5 to 1 g/kg or less of feed for immature cattle.[181] Nutritional myocardial disease can be prevented by adequate feeding of vitamin E, selenium, and copper with supplementation as required. Inherited cardiomyopathy is controlled by avoiding breeding of known or suspected carriers of the polled Hereford and Holstein-Friesian breeds.

Pericarditis

Definition and Etiology *Pericarditis* is inflammation of the pericardium that results in accumulation of fluid or exudate between the visceral and parietal pericardium. Pericarditis in large animals can be caused by trauma from penetration of ingested foreign objects or external wounds, hematogenous spread (septicemia) of infection, extension of infection from the lung or pleura, viral infections such as equine viral arteritis or equine influenza, and neoplasia. Pericarditis has also been associated with the mare reproductive loss syndrome (MRLS), with *Actinobacillus* species isolated in the majority of these horses.[182] Idiopathic pericarditis, characterized by an aseptic inflammatory exudate, is not uncommon in horses and has recently been reported in cattle.[183-190] Autoimmune, hereditary, and metabolic causes of pericarditis have not been documented in large animals.

Clinical Signs and Differential Diagnosis The clinical presentation of pericarditis can vary depending on the volume and rate of development of the pericardial effusion and the cause. Nonspecific clinical signs—fever, anorexia, depression, or weight loss—may be the chief complaints, but more frequently, peripheral edema, jugular venous distention and pulsations, tachypnea, or dyspnea is the presenting clinical sign. Cattle may exhibit pain by an abnormal stance characterized by abducted elbows, a spontaneous or induced expiratory grunt, reluctance to move, or preference to stand with the forequarters elevated. Horses may show signs of colic or syncopal episodes.

The most consistent findings on auscultation are tachycardia, muffling of heart sounds, and absence of lung sounds in the ventral thorax. Dorsally the lung sounds are louder than normal. These findings are in contrast to pleuritis, an important diagnostic rule-out for pericarditis, in which lung sounds are muffled ventrally but heart sounds are not, and radiation of the heart sounds occurs over a wider area than normal.[191] In cattle, splashing sounds are frequently audible in the cardiac auscultation area, a sound some refer to as a "washing machine murmur or rub." This is attributed to accumulation of gas and fluid in the pericardium and is indicative of the presence of gas-forming (anaerobic) organisms and a grave prognosis. In cattle this murmur distinguishes pericarditis from cardiac neoplasia or other causes of CHF. The splashing sounds are absent in horses and muffled heart sounds are the rule, but pericardial friction rubs may be auscultated, especially after pericardial fluid accumulation has been relieved.[186] A gallop rhythm may be auscultated in either horses or cattle.

Mucous membranes may be congested and have a prolonged capillary refill time. Jugular venous distention and pulsations usually are present. Arterial pulses are weak. The latter findings may help distinguish pericarditis from primary pleuritis. Percussion of the thorax reveals ventral dullness, and pleural effusion is frequently present in horses with pericarditis. A concurrent pleuropneumonia or septic pleuritis is present in some horses.[188,192-195] Ascites is infrequently detected in horses with pericarditis, but concurrent peritonitis has been reported.[196]

Clinical Pathology CBC changes are nonspecific and depend on the cause of the pericarditis. There may be hemoconcentration if the animal is dehydrated or toxemic, or there may be a mild anemia associated with chronic infectious pericarditis. WBC count may be normal or increased. There may be an absolute neutrophilia or a lymphopenia. Frequently the fibrinogen concentration is elevated. Serum chemistries are usually normal except for albumin concentration, which may be low[185,186] and accompanied by an elevation in globulin concentration. Liver enzyme, bilirubin, serum urea nitrogen, and creatinine concentrations are frequently mildly elevated, consistent with the development of CHF. Laboratory evidence of dehydration (increased PCV, total protein, serum urea nitrogen, and creatinine concentrations) may be exaggerated when diuretics have been administered previously. Although total serum LDH concentration may be elevated, more specific information may come from

finding an increase in the cTnI or the myocardial isoenzymes CK and LDH. An elevated cTnI was reported in one cow with hemorrhagic pericarditis.[189] Electrolyte concentrations are frequently normal, but serum calcium and potassium concentrations may be low because of anorexia. Decreased sodium and chloride concentrations have been reported in horses with pericarditis.[186] No consistent abnormalities in arterial or venous blood gas concentrations have been reported in large animals with pericarditis.

Radiography is not a sensitive diagnostic test for pericarditis in horses, although an enlarged rounded cardiac silhouette is detected with large pericardial effusions. In cattle, traumatic pericarditis frequently results in fluid and gas accumulation in the pericardium that is detectable radiographically and relatively specific for this disease. A metallic foreign body is usually detected radiographically in the cranial reticulum or caudal thorax in cattle with traumatic pericarditis (Fig. 30-18). Radiographic changes may not be detected in early or uncomplicated pericarditis. If fluid accumulation is large and there is concurrent pleural effusion, changes are indistinguishable from those associated with pleuritis. An enlarged, rounded cardiac silhouette is not specific for pericarditis and can be seen with other causes of generalized cardiomegaly. An obscured cardiac silhouette, vena cava, and diaphragm, with dorsal displacement of the trachea, may be seen with pericarditis or pleuritis. The lungs, which may be aerated only dorsally, frequently have interstitial infiltrates.

FIG. 30-18 Lateral radiograph of the caudal thorax and cranial reticulum showing a wire *(arrow)* in a cow with traumatic reticuloperitonitis.

The ECG changes most commonly associated with pericarditis in large animals are decreased amplitude of the QRS complexes (<1.5 mV in the base-apex lead)[186,187,196] (Fig. 30-19), electrical alternans (altered configuration of the P, QRS, or T complexes on a regular basis), and ST-segment elevation or slurring.[185,186,192,196,197] A right-axis deviation in the standard limb leads may be apparent.[185,197] Cardiac arrhythmias (usually atrial or ventricular premature beats) may be detected in affected animals, suggesting a concurrent myocarditis (Fig. 30-20). In some animals, no ECG changes are evident.[198]

Echocardiography reveals findings specific for pericarditis and is used to confirm the diagnosis noninvasively. An echo-free space between the visceral and parietal pericardium is evident (Fig. 30-21) and apparent even with a minimum amount of fluid accumulation.[191,192] Frequently, hypoechoic to echoic strands that correspond to fibrin are imaged in the pericardial space, with a hypoechoic to echoic layer covering the epicardial surface of the heart in large animals with pericarditis (Fig. 30-22). The pericardial effusion is often anechoic to hypoechoic, but more echoic pericardial fluid is occasionally seen, consistent with a more exudative fluid. Bright hyperechoic pinpoint echoes representing free gas are often imaged in cattle with pericarditis (Fig. 30-23). Gas in the pericardial sac of cattle with splashy heart sounds may limit the ability to obtain an echocardiographic evaluation of all cardiac structures. The visualization of intrapericardial gas is a sensitive indicator of anaerobic pericarditis. Pericardial effusion is differentiated from pleural effusion by finding the fluid- or fluid and gas–filled space surrounding the right ventricle and left ventricular free wall within the pericardial sac. Pericardial effusion is rarely imaged behind the left atrium, whereas pleural fluid is frequently imaged there. Right ventricular diastolic collapse (see Fig. 30-22) and right atrial collapse are common

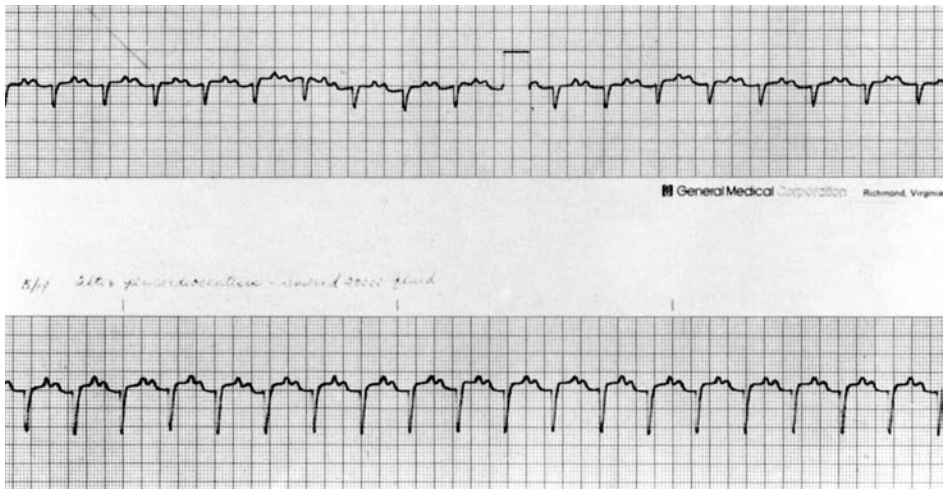

FIG. 30-19 Base-apex lead ECG taken from a cow before *(upper strip)* and after *(lower strip)* removal of 2 L of pericardial fluid. The markedly decreased amplitude (0.6 mV) of the QRS complexes is improved (1.2 mV) after pericardiocentesis.

FIG. 30-20 ECG (rhythm strip) obtained from a horse with pericarditis and junctional tachycardia. Note the P wave at the same place in the QT interval.

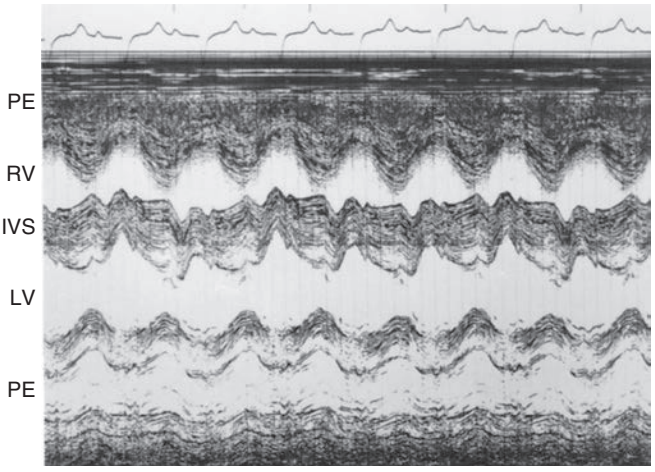

FIG. 30-21 M-mode echocardiogram obtained from a cow with traumatic pericarditis. There is a separation between the visceral and parietal pericardium cranial to the right ventricle *(RV)* and caudal to the left ventricle. The cranial pericardial effusion *(PE)* is echogenic, suggesting that fibrin or debris is present. The left ventricular *(LV)* dimension is reduced, and there is marked cranial motion of the interventricular septum *(IVS)* just before the QRS complex.

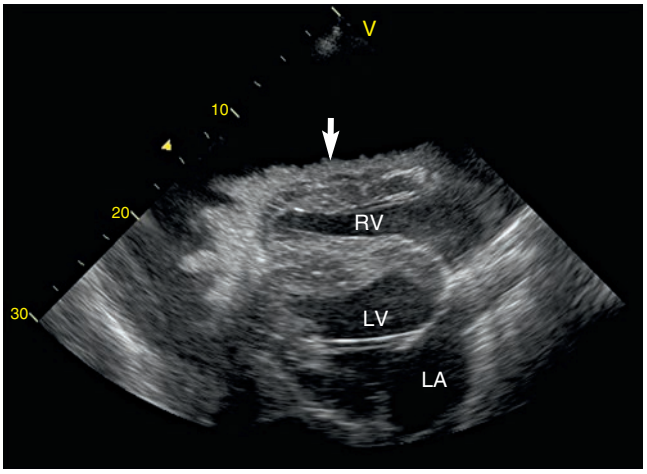

FIG. 30-22 Two-dimensional echocardiogram obtained from a horse with fibrinous pericarditis. Note the thick layer of echoic fibrin *(arrow)* covering the epicardial surface of the heart. There is a large anechoic pericardial effusion causing right ventricular *(RV)* collapse. The left atrial *(LA)* and left ventricular *(LV)* dimensions are reduced.

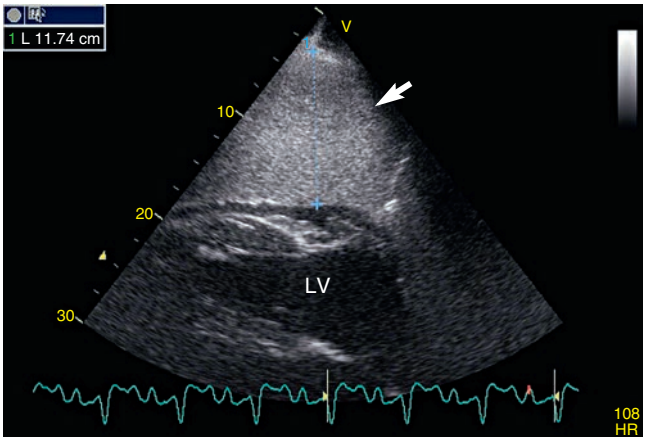

FIG. 30-23 Two-dimensional echocardiogram obtained from a cow with anaerobic pericarditis. Note the large amount (11.74 cm) of hyperechoic fluid *(arrow)* between the pericardium and left ventricle *(LV)* consistent with gaseous fluid.

FIG. 30-24 Insertion of a pericardial chest tube into the left fifth intercostal space for drainage and lavage of the pericardial space. Note that the left foreleg is being pulled forward, the clinician is inserting the large-bore Argyle chest tube into the left fifth intercostal space above the lateral thoracic vein, and the cow is wearing a radiotelemetry ECG system underneath the surcingle.

findings with large pericardial effusions and are an indication of the development of cardiac tamponade and hemodynamically significant pericardial effusion.[187] Other echocardiographic findings consistent with pericarditis are decreased left ventricular chamber dimension, decreased left ventricular free wall motion, and decreased parietal pericardial motion.[187,188,192,199] Increased (see Fig. 30-21) or paradoxical motion (cranial motion beginning before the QRS complex) of the interventricular septum may be apparent.[199]

The site for pericardiocentesis should be selected echocardiographically. Pericardial fluid is obtained most commonly from the left fifth intercostal space 2.5 to 10 cm dorsal to the olecranon, above the level of the lateral thoracic vein, the safest site for pericardiocentesis. When there is a large volume of pericardial effusion, pericardiocentesis can be productive from the right at about the same location. If at all possible, a pericardial catheter (large-bore Argyle tube) should be inserted into the pericardial space at the time the initial pericardiocentesis is performed to enable repeated drainage and lavage of the pericardial sac (Fig. 30-24). Fluid analysis and bacterial and viral culture results depend on the cause. In cattle with traumatic pericarditis, fluid analysis usually reveals elevated protein concentration (>3.5 g/dL) and an elevated WBC count (>2500/μL) composed primarily of neutrophils. The fluid is urine colored to slightly blood tinged and foamy, and it has a foul odor. A mixed population of gram-positive and gram-negative aerobic and anaerobic bacteria (GI flora) usually are present. Protozoa may be found in unusual circumstances. Hemorrhagic effusion has been reported in several cows with idiopathic pericarditis that responded favorably to pericardial drainage (usually with lavage) along with systemic antimicrobial therapy.[189] In horses, protein concentration of the pericardial fluid is elevated (≥2.5 g/dL) and the WBC count is normal or elevated with a population predominantly of neutrophils, although red blood cells, lymphocytes, eosinophils, mesothelial cells, and histiocytes have been observed.[185-187,192,196] Bacterial (aerobic and anaerobic) cultures and viral cultures may be negative. *Actinobacillus* organisms were frequently isolated from mares with pericarditis in association with the mare reproductive loss syndrome.[182] Paired serum may support a viral cause. Analysis of pleural and peritoneal fluid (when present) usually reveals fluid characterized as a modified transudate or that is mildly inflammatory.

Cardiac catheterization demonstrates an elevation in central venous or right atrial pressure, and the atrial and ventricular pressure curve may be abnormal in appearance. Right atrial, right ventricular, and pulmonary artery end-diastolic pressures may equilibrate.[197] In combination these findings are relatively specific for pericarditis.

■ ***Pathophysiology*** Accumulation of fluid in the pericardium occurs as a result of inflammation. The rate of fluid accumulation and

VetBooks.ir

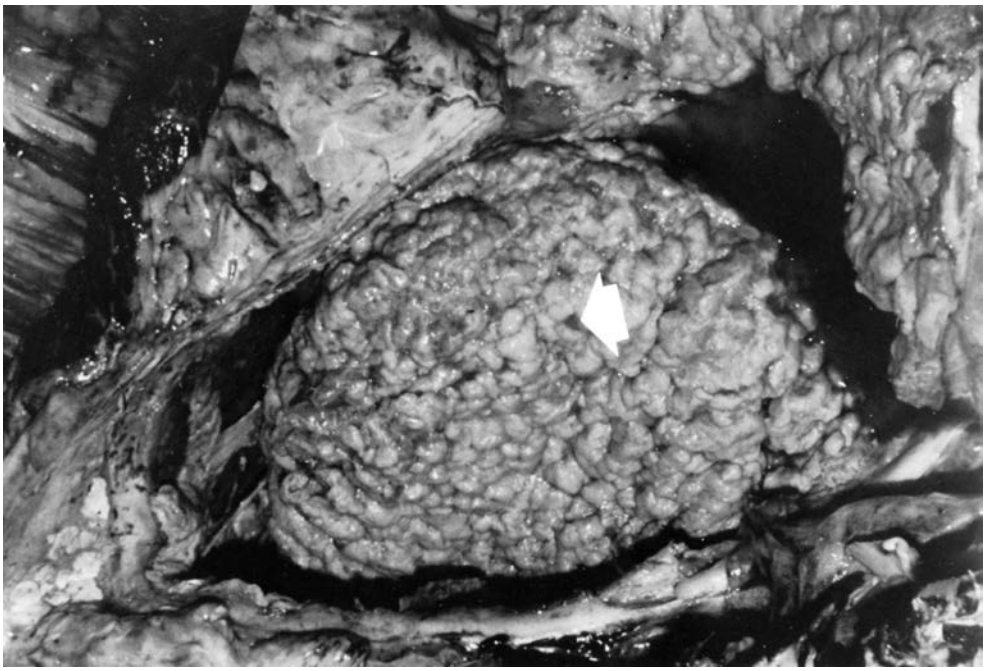

FIG. 30-25 Postmortem photograph of a cow with constrictive pericarditis. The pericardium is opened and reflected, revealing the epicardium *(arrow)* covered in fibrinopurulent exudate.

the degree to which the pericardial pressure increases determine the pathophysiologic consequences. Generally pericarditis results in decreased distensibility (increased ventricular end-diastolic pressure) of the heart, which impairs the ability of the heart to fill during diastole. The elevation in end-diastolic pressure and impairment of ventricular filling elevate atrial pressure and reduce venous flow or venous return to the heart and diastolic perfusion of the myocardium. The result is a depression of ventricular contractility, stroke volume, and consequently cardiac output. In addition, arterial pressure and renal blood flow are decreased. Initially, compensatory mechanisms consisting of vasoconstriction, increased heart rate, and sodium retention (increased vascular volume) may maintain cardiac output. Failure to maintain cardiac output results in circulatory collapse.

Pericarditis can be classified as primarily effusive, constrictive, or a combination of both.[197] The hemodynamic consequences of effusive pericarditis are primarily caused by the physical presence of pericardial fluid, whereas constrictive pericarditis is classified as such because the reduction in ventricular compliance is due to fibrinous or fibrotic involvement of the pericardium and epicardium. Removal of pericardial fluid results in improved cardiac performance in effusive pericarditis but is of limited usefulness in constrictive pericarditis.

Epidemiology

Pericarditis is uncommon in horses; when it does occur, it is most frequently idiopathic and can occur in a horse of any age. History of a recent respiratory tract infection is not uncommon. Exposure of horses to Eastern tent caterpillars was the greatest risk factor for the development of fibrinous pericarditis during the epidemic of mare reproductive loss syndrome.[200] Traumatic pericarditis has been reported in horses but is rare.[201] Traumatic pericarditis is not uncommon in cattle, but it occurs in less than 10% of cattle with traumatic reticuloperitonitis.[60] Most cattle are affected in late gestation or at parturition. Idiopathic pericarditis is rare in cattle. Several cows with idiopathic hemorrhagic pericarditis later developed cardiac lymphosarcoma.[183]

Necropsy Findings

Gross postmortem examination shows distention of the pericardial sac with serosanguineous or urine-colored fluid that is foamy and may be malodorous (cattle). There may be organization of fibrinous exudate and fibrosis that is also evident on the epicardium (Fig. 30-25) and may infiltrate the myocardium. Pleural effusion may be present. Other signs of CHF such as pulmonary congestion, pulmonary edema, and chronic passive congestion of the liver may be present. If the cause is traumatic, the offending object may be well contained in a fibrous tract located between the reticulum and the pericardium.

Histopathologic examination reveals pericardial, epicardial, and occasionally myocardial fibrosis and inflammation with neutrophilic, lymphocytic, eosinophilic, or plasma cell infiltrates. Bacteria may be visible. The liver may show diffuse centrilobular necrosis, fatty change, dilation and congestion of sinusoids, and perivenous fibrosis.

Treatment and Prognosis

Treatment of traumatic pericarditis in cattle is unrewarding and usually is addressed toward salvage or short-term survival to calving. Repeated pericardial drainage by means of pericardiocentesis or a fifth rib resection, lavage, or pericardiectomy may be useful for short-term survival, but the prognosis for return to normal function is poor because CHF results from involvement not only of the pericardium but also the epicardium and myocardium (see Fig. 30-25). Thoracotomy by a split-rib technique followed by pericardiectomy has been effective in treating some cattle with traumatic, restrictive pericarditis.[202]

Treatment of pericarditis not caused by trauma has been successful in horses, but the initial prognosis should be guarded. Aggressive treatment of horses with moderate to large pericardial effusions should include the placement of a large-bore indwelling chest tube into the pericardial sac under echocardiographic guidance and drainage and lavage of the pericardial sac, with local infusion of antibiotics in addition to the initial broad-spectrum antimicrobial therapy. Obtaining a sample for cytologic examination and culture and sensitivity testing via a pericardiocentesis should be postponed until an indwelling catheter can be safely inserted, because it is difficult to insert the catheter once the pericardiocentesis has been performed. The pericardial drainage and lavage, performed once or twice daily as needed, has been very effective in treating idiopathic or septic pericarditis in horses.[9,187,188,192,196] The indwelling tube should remain in situ until the fluid recovered at the time of drainage is consistently

VetBooks.ir

less than or equal to the volume instilled in the pericardial sac with antimicrobials 12 to 24 hours earlier. The ECG should be monitored because occasionally cardiac arrhythmias occur during the therapeutic procedure or during a routine pericardiocentesis. All horses with pericarditis should initially be treated for septic pericarditis with systemic broad-spectrum bactericidal antimicrobial drugs. The antimicrobial choice should be based on the most likely causative agents and modified as needed by the results of culture and sensitivity testing. Fibrinous pericarditis has been successfully treated in horses with broad-spectrum bactericidal antimicrobials when the amount of pericardial fluid detected echocardiographically was too small to safely obtain a sample for cytologic evaluation and culture and sensitivity testing. Treatment of idiopathic pericarditis with corticosteroids should be initiated only after the results of these studies demonstrate no evidence of sepsis. Pericardiotomy or (preferably) pericardiectomy are the treatments of choice if signs of constrictive pericarditis are present. However, the long-term prognosis for large animals following this surgery is guarded. A partial pericardiectomy was performed in one horse with constrictive pericarditis but was only transiently successful.[193]

In traumatic pericarditis the antibiotic selected must be capable of covering gram-positive and gram-negative aerobic and anaerobic bacteria. Nonsteroidal antiinflammatory drugs (NSAIDs) have been deemed useful as adjunctive therapy, as have corticosteroids if bacterial culture of the fluid is negative and no evidence of sepsis is detected cytologically.

Although diuretics are effective in eliminating the severity of peripheral edema, they further reduce venous return and preload in animals with pericarditis. The result is further compromise of cardiac output and worsening of heart failure.

Prevention and Control Traumatic pericarditis in cattle can be prevented by routine administration of magnets to heifers at the time of pregnancy diagnosis. At each subsequent pregnancy diagnosis, the cattle should be checked for the presence of the magnet in the reticulum. It is not beneficial to have more than one magnet present at one time.

Some types of infectious pericarditis in horses may be controlled by routine vaccination against the common respiratory pathogens.

Cardiac Tumors

Definition and Etiology The heart may be the primary site of neoplastic disease or be involved secondarily by tumors from adjacent structures such as the lungs, pleura, lymph nodes, or diaphragm. Cardiac neoplasia is uncommon in large animals. The most common primary cardiac tumor is lymphosarcoma. Mesotheliomas, fibrosarcoma, adenocarcinomas, lipomas, and other carcinomas, especially squamous cell carcinomas in horses, may involve structures adjacent to the heart and may extend to the heart or heart base, producing signs of heart disease.[203,204] An infiltrative cardiac lipoma has been reported in a horse, but no signs of cardiac disease were attributed to it.[205] A metastatic anaplastic pulmonary carcinoma caused signs of CHF in one horse,[204] and disseminated hemangiosarcoma with myocardial involvement was thought to be responsible for ventricular arrhythmias in another horse.[206] Primary pericardial hemangiosarcomas have also been reported in a horse.[207]

Clinical Signs and Differential Diagnosis The clinical signs of cardiac neoplasia are nonspecific and depend on the cardiac site involved and other sites of tumor manifestation. Nonspecific signs of neoplasia are common and include anorexia, depression, weight loss, and fever. These signs can be produced by any site of chronic disease, and in large animals pneumonia, peritonitis, enteritis, and liver and kidney disease are considered differential diagnoses, among others. If the tumor involves the pericardium, signs of pericarditis or pericardial effusion such as tachycardia, pain, jugular venous distention, peripheral edema, and weak arterial pulses may be seen. Myocardial involvement of the neoplasia, as is most common with lymphosarcoma, may result in cardiac signs that include tachycardia, cardiac arrhythmias, and cardiac murmur (atrioventricular valve insufficiency) or signs of CHF such as peripheral edema, ascites, and diarrhea. Clinical signs attributable to tumor involvement of the endocardium (e.g., obliteration of a cardiac chamber, valvular obstruction or damage, embolic showering) are rare in large animals.

Tumor involvement of other organ systems and tissues can be manifested by lymphadenopathy, peripheral edema, diarrhea, melena, dysphagia, tachypnea, pleural effusion, or rectal palpation of abdominal masses.

Clinical Pathology Cardiac tumors present no consistent clinicopathologic feature. The CBC from horses or cattle with lymphosarcoma may reveal neoplastic lymphocytes. The absence of leukemic changes does not rule out lymphosarcoma. Cattle with lymphosarcoma may test positive for fecal occult blood. A serum chemistry profile may reveal nonspecific changes such as hypoalbuminemia, hyperglobulinemia, or elevated liver enzyme concentrations, depending on the other organ systems affected by the tumor or the animal's debilitation. Diagnosis of the cardiac tumor is based on histopathology of tumor tissue. Tumor cells may be found in pericardial or pleural fluid or adjacent lymph nodes. Serologic evidence (agar gel immunodiffusion or radioimmunoassay) of BLV infection does not confirm a diagnosis of lymphosarcoma, but a negative test result virtually rules out the adult or enzootic form of lymphosarcoma in cattle. No evidence of BLV infection will be found in cattle with the thymic form of lymphosarcoma.

If electrocardiographic evidence of cardiac tumors is present, it is nonspecific. Cardiac tumors may produce cardiac arrhythmias, reduce amplitude of the QRS complexes, or alter the normal appearance of the P, QRS, and T complexes. Two-dimensional echocardiography or an ultrasound examination of the lungs or pleura may show evidence of the cardiac tumor by providing direct evidence of abnormal echogenic masses involving the heart or surrounding tissue, abnormal fluid accumulation, or myocardial functional changes. Ultrasound findings can determine whether any masses can be safely biopsied to confirm the diagnosis.

Radiographs may provide evidence of cardiac tumors by showing abnormal soft tissue densities in the thorax that obscure the cardiac silhouette or ventral lung borders.

Pathophysiology Lymphosarcoma, the most common cause of cardiac tumors in cattle, has a predilection for the right atrial myocardium. Right ventricular myocardial involvement is not uncommon; left atrial or left ventricular involvement is rarer. Involvement of the right side of the heart may result in little or no evidence of heart disease. More commonly the myocardial involvement results in dilation of the chamber involved. As a consequence, the tricuspid valve ring may be dilated, and tricuspid valve insufficiency occurs. Chamber enlargement or infiltration of the myocardial conduction system may cause cardiac arrhythmias. Myocardial function may be impaired, so that signs of right-sided heart failure become apparent, including tachycardia, peripheral edema, jugular venous distention or pulsations, pericardial or pleural effusion, hepatic congestion, and ascites.

Epidemiology Cardiac tumors are rare in large animals. The most common cause in cattle is lymphosarcoma. Although more than 50% of cattle in some parts of the United States are infected with BLV, only 1% to 5% develop lymphosarcoma.[208-210] In herds with more than 50% of cattle infected with BLV, the incidence of lymphosarcoma may be higher. Cardiac involvement is common in cattle with the adult or enzootic form of BLV, a disease that occurs most commonly in cattle over 4 years old.[211] Thymic lymphosarcoma, which is not associated with BLV infection, also involves the heart but is much less common, occurring in cattle under 30 months of age.

VetBooks.ir

FIG. 30-26 Postmortem photograph of a cow with lymphosarcoma demonstrating right atrial myocardial infiltration by a tumor and extension of the tumor into the atrial lumen.

FIG. 30-27 Postmortem photograph of a horse with pericardial mesothelioma. Note the huge heart base tumor mass, along with several smaller masses.

Lymphosarcoma, mesothelioma, and squamous cell carcinoma are probably the most common causes of neoplastic involvement of the equine heart, but the prevalence is not documented.

Necropsy Findings Necropsy findings depend on the type of cardiac tumor. Direct involvement of the myocardium with lymphosarcoma is associated with finding diffuse infiltration by a pale, tan, homogeneous tissue that frequently causes enlargement of the cardiac chamber. Involvement of the right atrium (Fig. 30-26) is the most common manifestation of adult enzootic BLV, but any area of the myocardium and pericardium may be involved. Intracavitary extension of the tumor may be evident (see Fig. 30-26). Histologic evaluation of the tumor shows diffuse infiltrates of lymphoblastic cells that obliterate the normal architecture of the myocardium.

Other tumors such as fibrosarcoma, squamous cell carcinoma, pulmonary carcinoma, thymic lymphosarcoma, and mesothelioma (Fig. 30-27) may involve the heart by extension or metastasis from other sites in the thorax.

Treatment and Prognosis No definitive treatment exists for neoplasias involving the heart, and the prognosis for survival is poor. Death can be expected within 6 months with most cardiac tumors. Lymphosarcoma of the heart in cattle has a grave prognosis and is usually associated with death within a few months. Short-term improvement has been achieved in cattle with lymphosarcoma treated with a combination of corticosteroids, L-asparaginase, and cytotoxin. Thoracoscopic pericardiotomy has been used as a palliative treatment in a cow with pericardial lymphoma.[212]

Prevention and Control Prevention and control of BLV can be accomplished by isolation of BLV-positive and BLV-negative animals; use of individual or sterilized supplies such as needles, rectal examination sleeves, tattooing, dehorning, and ear-tagging equipment on each animal; rigorous attention to a vector control program; and feeding colostrum from serologically negative cows only.[209,213] Frequent testing (at least every 6 months) and isolation of serologically positive animals over 6 months of age should be performed. Prevention and control of other cardiac tumors is not possible.

Vascular Disease: Aneurysms, Thrombosis, and Embolism

Definition and Etiology *Aneurysms,* which are vascular dilations, develop from weakening of the medial elastic coat of blood vessels. The medial weakness may be primary or caused by a progression of an intimal atherosclerotic lesion that has enlarged from hemorrhage, calcification, ulceration, and thrombus formation. The specific causes of aneurysms in large animals are unknown, but trauma (internal or external), sepsis, parasite migration, degenerative vascular disease, atherosclerosis, or aging changes (dilation, elongation, and loss of elasticity of blood vessels) may play a role.[214-216] Congenital aneurysms of the sinus of Valsalva have been reported in horses.[72,79-81] Hypertension can accelerate degeneration of the wall.

Thrombosis is the formation of a clot that obstructs blood flow in the circulatory system. The causes of thrombosis are numerous and include trauma, venous stasis, and catheterization for administering medication or fluids. Needle penetration, indwelling catheters,

VetBooks.ir

thrombogenic solutions, or bacterial contamination can cause thrombosis associated with catheterization. Secondary thrombosis can result from perivascular inflammation caused by cellulitis, lymphangitis, or other sources of bacterial invasion around the blood vessel. Mural thrombi, which occur in cardiac chambers associated with low-flow states and/or a coagulopathy, also may occur in large animals, although they have been rarely diagnosed antemortem.[217] Thrombosis usually occurs when intimal disease is present, but it may occur in arteries with no intimal disease when a hypercoagulable state exists, such as with dehydration, endotoxemia, anemia, hypotension, stress, or stasis.[218-220] This type of thrombosis is frequently a complication of acute infectious disease (particularly acute toxic enteritis or colitis), neoplasia, or any chronic debilitating disease.

An *embolism* is foreign material carried in the bloodstream. Emboli frequently arise from an arterial or venous thrombus, but unusual emboli include catheters and other foreign bodies inadvertently introduced into the circulatory system. In large animals, emboli occur most commonly in bacterial endocarditis, thrombophlebitis, omphalophlebitis, and parasitic arteritis. Aortoiliac thromboembolism has been reported as a complication of valvular endocarditis in a calf and mural endocarditis in a cow.[221,222]

Clinical Signs and Differential Diagnosis Sites of thrombosis associated with thrombophlebitis are likely to have pain, swelling, redness, and palpable thickening of the involved vein. These signs frequently occur within 12 to 24 hours after catheter removal when the thrombus is associated with catheterization. If there is bilateral jugular venous thrombosis, sudden, marked swelling of the head may occur. If the thrombosis involves the terminal aorta and iliac arteries in horses, the signs are frequently a vague hindlimb lameness, exercise intolerance, or poor performance. These nonspecific signs make it necessary to rule out lameness from other causes, cardiac disease, or respiratory problems. Failure to ejaculate has been reported in breeding stallions with aortoiliac thrombosis.[223] Aortoiliac thrombosis in horses also is characterized by heavy sweating after exercise, except over the hindlimbs, which are cool. With severe aortoiliac thrombosis the affected limb can be cool to the touch at rest or can be cold with no palpable femoral arterial pulse. Saphenous vein filling is slow or nonexistent in affected horses, and the metatarsal and other peripheral arterial pulses of the hindlimbs are weak. Rectal examination may be normal, or weak, absent, or asymmetric iliac pulses may be palpated. Fremitus of the iliac arteries or terminal part of the aorta may be palpated. The terminal part of the aorta may feel larger or firmer than normal, or an aneurysmal dilation may be detected. Similarly with verminous arteritis of the cranial mesenteric artery, a thickened, dilated cranial mesenteric artery or aorta may be palpated that may be firmer than normal and have a weak pulse, or fremitus may be palpated. In calves with aortic or aortoiliac thrombosis weakness, lameness, knuckling, paresis or paralysis of the hindlimbs, inability to rise, and cold hindlimbs lacking a femoral arterial pulse have been described.[221,224-226]

The signs attributable to embolism and thrombosis may be identical. Embolism usually is manifested by an acute episode of pain or fever, abnormal pulsation in a peripheral vessel, or a change in skin temperature. If there is peripheral vessel showering, superficial veins may be collapsed, and muscular weakness may be present. Embolic showering usually occurs in animals suspected of having or known to have thrombus formation.

Clinical signs associated with an aneurysm depend on its location and may vary from being asymptomatic to being a noticeable enlargement or mass associated with a blood vessel or causing colic, syncope, seizures, or sudden death on rupture. In a peripheral artery, a pulsatile expansile mass may be visualized or palpated. Other considerations for this finding are a false aneurysm and an arteriovenous fistula. A false aneurysm is clinically indistinguishable from a true aneurysm but can be distinguished ultrasonographically. A false aneurysm is caused by a break in the continuity of all three coats of the arterial wall rather than in the tunica media alone. This results in extravascular accumulation of blood in adjacent tissues. Signs attributable to low blood flow (e.g., lameness, colic, edema) may be present with arterial aneurysms. Aneurysms of the cranial mesenteric artery frequently manifest as chronic episodes of colic. With involvement of major cardiac vessels there may be pain, an auscultable heart murmur, rapid tachycardia, signs of CHF, acute onset of pulmonary edema, or sudden death when the aneurysm ruptures. The latter signs make aneurysms difficult to distinguish from the clinical signs of a horse with valvular heart disease or cardiomyopathy. One cause of an aorticocardiac fistula in horses is the result of rupture of an aneurysm of the sinus of Valsalva.[72,79-81]

Clinical Pathology Aneurysms or pseudoaneurysms may be visualized radiographically as soft tissue density masses continuous with a vessel wall (true aneurysm) or extending outward from a vessel wall (false aneurysm).[215,216] However, the majority of the aneurysms involving the aorta and aortic root are not visible radiographically. Echocardiography is useful in the diagnosis of aneurysms involving the aortic root (Fig. 30-28).[64,69-71] Angiography can be used in the diagnosis of peripheral vessel swelling or suspected thrombosis but is of little use in diagnosis of aneurysms of major vessels in adult animals. Ultrasonography may be used for the diagnosis of aneurysms or thrombosis of major arteries and peripheral vessels. In aortoiliac thrombosis of horses, ultrasound has been used to determine the origin of the thrombus and the extent of occlusion of the involved arteries (Fig. 30-29).[227] Abdominal ultrasonography of the

upper left flank dorsal to the left kidney has been used to diagnose aortoiliac thrombosis in calves.[224] Diagnostic ultrasound has been used to detect thrombi in the caudal vena cava in cattle.[228,229] Although the occluding thrombus is not imaged, detecting a distended oval or round caudal vena cava rather than the normal triangular vessel in the eleventh and twelfth intercostal spaces is consistent with this diagnosis in cattle. Thrombi have been detected ultrasonographically in the hindlimb in both horses and cattle.[230-234] Jugular vein thrombophlebitis has also been diagnosed ultrasonographically in both horses and cattle (Fig. 30-30).[235,236] Similarly, diagnostic ultrasound has been used to image the cranial mesenteric artery, its branches, and the aorta in horses with verminous arteritis.[237] Aneurysms appear as dilated vascular structures or vascular outpouchings continuous with the vessel wall,[71] whereas a thrombus is apparent as a hypoechoic to echogenic mass within a blood vessel.[236] Cavitation of an occlusive thrombus is suggestive of septic thrombophlebitis (see Fig. 30-30), whereas a nonseptic thrombus usually has a homogeneously hypoechoic to echoic appearance.[236] Complete occlusion of the vessel can be determined ultrasonographically, or flow within an aneurysm or alongside a thrombus determined. Doppler ultrasound provides a more sophisticated method for determining blood flow and vessel patency.

In the case of catheter-associated thrombosis, a positive catheter tip culture (>10^3 colony-forming units) along with a positive blood culture provides evidence of septic thrombophlebitis.[238] An aseptic ultrasound-guided aspiration of the cavitary lesion within a heterogeneous thrombus can be performed, and the aspirate submitted for culture and sensitivity testing.[236] Septic thrombophlebitis from any cause or embolic showering of septic thrombi may be accompanied by neutrophilic leukocytosis and elevation in fibrinogen concentration.

Pathophysiology

Irritation of the intimal lining of a blood vessel, stasis of blood flow, or existence of a hypercoagulable state triggers the clotting cascade and sets the stage for development of thrombosis. Further injury causes hemorrhage, more thrombosis, ulceration, and calcification. These in turn can compromise the media of the vessel, predisposing to aneurysm formation, and impinge on the lumen of the vessel, causing obstruction to blood flow. Either aneurysm or thrombosis can occlude blood flow to vital structures or organs, resulting in ischemia.

Thrombosis in any sizable vein causes venous hypertension, passive congestion, and subsequent edema and pain of the structure. As the thrombus matures, it adheres to the wall more, but with clot retraction and lysis, recanalization may occur. However, parts of the thrombus may protrude into the moving bloodstream and serve as the source of embolic showering, even during thrombus organization. The most common site for an embolus to lodge has not been established in large animals; the femoral and iliac arteries are common locations in humans. Emboli usually lodge at bifurcations, where the caliber of the artery is suddenly reduced.

The most common outcome of aneurysm of a major vessel is thought to be rupture. Rupture of sinus of Valsalva aneurysms into the right atrium, right ventricle, and interventricular septum has been reported in the horse.[79-81] VT often occurs with rupture of an aortic sinus of Valsalva aneurysm and dissection into the interventricular septum.[80,81] Unruptured aneurysms may have other complications such as thrombosis or embolization of the thrombus. The frequency of rupture or embolic showering from thrombosis is unknown in animals.

Epidemiology

The significance of thromboembolism in large animals is poorly defined. Spontaneous thromboembolism is commonly associated with parasitism in horses, and the aorta and cranial mesenteric arteries are the sites most frequently involved.[144] Aortoiliac thrombosis is also a recognized syndrome diagnosed most frequently in heavily exercised horses. Although historically parasitism has been associated with aortoiliac thrombosis in horses, other causes of this syndrome are probable but have not been elucidated. Thrombotic disease can occur in any animal having repeated IV injections or being catheterized for administration of medication or fluids, but it is particularly common in horses with acute toxic enteritis, colitis, or sepsis. Careful skin preparation and aseptic technique are important factors in minimizing the likelihood of the patient developing catheter-related thrombophlebitis. Low doses of heparin have been effective in limiting the development of catheter-related thrombophlebitis in cattle.[239] Large intestinal disease, hypoproteinemia, endotoxemia, salmonellosis, fever, diarrhea, and locally produced fluids have all been identified as risk factors for catheter-associated thrombophlebitis.[220,240,241]

Arteriosclerosis is recognized in horses and in cattle. In cattle the lesion is most frequently caused by excessive vitamin D_3 supplementation or ingestion of calcinogenic plants such as *Solanum malacoxylon, Cestrum diurnum,* or *Trisetum flavescens.*[242] In horses the arteriosclerotic lesions were caused by lesions induced by *Strongylus vulgaris.*[82]

Aneurysms are uncommon in large animals but have been documented as the cause of sudden death in breeding stallions and racing Thoroughbred and Standardbred horses.[81,82] Aneurysms of the sinus of Valsalva are one cause of aortic rupture in older horses and are probably congenital in horses, as they are in humans.[71,79-81] Aortic root rupture also occurs without the presence of a preexisting aneurysm and has been associated with medial necrosis of the aorta.

Necropsy Findings

Aneurysms are detected grossly as dilations of the involved blood vessel. Aneurysms of the sinus of Valsalva are characterized by an absent tunica media in the wall of the aorta, causing the aneurysmal dilation.[61,71] Rupture of a sinus of Valsalva aneurysm may occur into the right atrium, right ventricle (Fig. 30-31), or interventricular septum, resulting in an aortic cardiac fistula and volume overload.[61,71,72,80,81] Rupture through the tricuspid valve or chordae tendineae may also occur. Subendocardial dissection of blood down the interventricular septum may occur. Subsequent rupture into the left ventricle and of the mitral chordae tendineae have also been reported. Aneurysms of the major vessels leaving the heart may involve more than one vessel by dissection and hemorrhage. Aneurysms may contain thrombi or parasites, and there may be evidence of embolic showering of thrombi into peripheral vessels or other organ systems, especially the lungs. Histologically there may be necrosis and inflammation at the site of the aneurysm with foci of mineralization.

Thrombosis and arteriosclerotic lesions are recognized as rounded, well-demarcated fibrous plaques frequently located in the thoracic and cranial abdominal aorta (Fig. 30-32). The plaques may contain a central calcified core or parasitic larvae. Microscopically there is a thin layer of fibrin, platelets, and inflammatory cells in early lesions, whereas older lesions have a greater fibrous component. Thrombotic

lesions may be associated with proliferation of the underlying aortic intima. In horses, parasitic larvae may be found.

Treatment and Prognosis Aneurysms of major vessels carry a guarded to grave prognosis because surgical correction is rarely attempted and spontaneous rupture is thought to be relatively common. Intact aneurysms of the sinus of Valsalva can be detected echocardiographically, and once an aneurysm has been detected, the horse should be removed from all athletic competition because of the risk of rupture.[71]

Treatment of thrombosis consists of removal of the catheter, if present, and resting the affected vessel. Warm compresses or hydrotherapy may be helpful in some animals. Topical NSAIDs (diclofenac sodium) may also be useful. Support wraps may be useful to control swelling. The effectiveness of anticoagulant therapy (aspirin at 100 mg/kg once daily PO, ruminants; 10 mg/kg once daily, horses; or sodium heparin at 30-40 units/kg SC twice daily) or antiinflammatory drugs for dissolving a thrombus is questionable. Anticoagulant therapy may be useful in preventing additional thrombus formation or propagation of the existing thrombus. Ultrasonographic guidance can be used to obtain a sterile aspirate of the cavitated area of the thrombus for culture and sensitivity testing when septic thrombophlebitis is suspected.[236] Broad-spectrum bactericidal antimicrobial therapy should be instituted for suspected septic thrombophlebitis or when a cavitated thrombus is detected ultrasonographically and modified, if necessary, based on the results of culture and sensitivity testing.[236] Bacterial endocarditis, particularly involving the tricuspid valve, is a potential complication of septic jugular vein thrombophlebitis. With the exception of a jugular venous thrombus, surgical removal of an embolism or thrombus is rarely attempted in large animals. Surgical resection of a jugular vein with septic thrombophlebitis has been performed successfully when the surgeon could ligate the affected vein above and below the thrombus. Jugular vein thrombectomy with removal of the contents of the affected portion of the vein has been performed successfully in horses.[243] Although the prognosis for complete resolution of the thrombophlebitis is guarded, especially if the thrombus is infected, many veins do recannulate with complete resolution of the thrombus and without vascular stricture. However, the time course is slow, and persistent local induration and obstruction to blood flow may persist. The prognosis for non–racehorses to return to the same level of performance is good.[244] However, Standardbred racehorses in this same study had a decreased chance of returning to racing at the same level.[244]

The prognosis for horses and calves with aortoiliac thrombosis is guarded. Although most calves with aortoiliac thrombosis have died or were euthanized, two calves have survived. One calf received antithrombotic treatment with unfragmented heparin and aspirin, and the other was treated with ketoprofen, acepromazine, and local heat. A wide variety of medical treatments have been proposed for horses with aortoiliac thrombosis, including sodium gluconate, larvicidal deworming, phenylbutazone, and a controlled exercise program. Success has been variable. Surgical thrombectomy has also been successful in some horses.[245-247]

Prevention and Control Thrombosis and embolization from IV catheters can be prevented by aseptic insertion, stabilization of the catheter, use of topical antiseptics, application of a sterile dressing, daily inspection of the catheter and vein, and replacement of the catheter at another site (preferably in another vein) if phlebitis occurs. Dwell time is a significant factor in the development of thrombophlebitis, and catheters should be replaced by new ones at another site every 72 hours.[248] Attempts should be made to place long-term catheters in large peripheral or central veins where contact between the endothelium and catheter is minimized and medications administered are diluted by the large volume of blood flow. Catheters left in place for prolonged periods should be of silicone rubber or polyurethane.[238] Aspirin (100 mg/kg PO once daily, ruminants; 10 mg/kg/day, horses) and low-dose heparin (30-40 units/kg SC twice daily, ruminants and horses) therapy should be considered to prevent thrombus formation in septic or endotoxic patients. Horses are much more prone to jugular thrombosis than are ruminants.

Parasite control is important in the control of thromboembolic disease and aneurysm in horses. Aneurysms of the sinus of Valsalva may be detected by routine echocardiographic screening of horses but occur so infrequently that this is not practical. In cattle, arteriosclerotic lesions are prevented by proper calcium and vitamin D supplementation.

Atrial Fibrillation

Definition and Etiology *Atrial fibrillation* is a cardiac arrhythmia characterized by a lack of coordinated atrial electrical activity. It is caused by an abnormality of impulse conduction that results from multiple small rapid and random reentrant activation of the atria. High resting vagal tone, commonly found in horses, shortens the action potential duration in atrial myocardial cells, making atrial fibrillation more likely to occur. Atrial fibrillation can occur in the presence of atrial enlargement from atrial myocardial disease, atrioventricular valvular regurgitation, ventricular failure, myocarditis, endocarditis, autonomic nervous system imbalance, electrolyte or acid-base disturbances, anesthetic drugs or tranquilizer administration, unknown causes, or in the absence of underlying cardiac disease (lone atrial fibrillation).

VetBooks.ir

Clinical Signs and Differential Diagnosis Large animals with atrial fibrillation may be asymptomatic at rest, and atrial fibrillation may be detected as an incidental finding in an otherwise normal horse. Horses that perform in rigorous athletic events usually have a history of exercise intolerance or poor performance. Other complaints may be exercise-induced epistaxis, respiratory disease, weakness, syncope, myopathy, colic, or CHF. Cattle with atrial fibrillation usually have GI disease.[249,250] Atrial premature depolarizations have also been reported in cattle with GI disease and may be a prelude to the development of atrial fibrillation.[250] Foot rot, pneumonia, and endocarditis also have been associated with atrial fibrillation in cattle. Anorexia and decreased milk production are common in cattle with atrial fibrillation. Atrial fibrillation and the clinical signs associated with it in horses and in cattle can be paroxysmal. Paroxysmal atrial fibrillation usually lasts no more than 24 to 48 hours before spontaneous conversion to sinus rhythm occurs.[251] Spontaneous conversion usually occurs in horses with small atria and an otherwise normal heart or in cattle with correction of the underlying problem. Transient potassium depletion associated with the administration of furosemide is a common cause of paroxysmal atrial fibrillation in horses. Administration of bicarbonate "milkshakes" has also been implicated in horses with paroxysmal atrial fibrillation.

Animals with atrial fibrillation have an irregularly irregular cardiac rhythm. In horses with atrial fibrillation, there is a high degree of underlying periodicity.[252] Heart sounds vary in intensity, and no fourth heart sound is audible. The heart rate may be slow, normal, or elevated. In cattle with severe abdominal disease, the heart rate usually reflects the severity of the underlying disease. In horses the resting heart rate is usually normal to slightly elevated and is rarely above 50 beats/min unless there is underlying myocardial or valvular disease. During exercise, horses with atrial fibrillation develop abnormally high heart rates that are usually 40 to 60 beats/min higher than expected for each level of exercise, far exceeding the peak heart rate of 240 beats/min at maximal exercise.[253,254] The arterial pulse varies in intensity. A pulse deficit occurs when two beats occur in rapid succession and is infrequent unless the heart rate is elevated. Cardiac murmurs of grade 3/6 or louder are present in less than 50% of the horses and in even fewer cattle with atrial fibrillation.[255-257] Signs of CHF (peripheral edema, jugular venous distention) may be present in some animals, but they are not caused by the arrhythmia. In these cases, atrial fibrillation occurs secondary to the atrial enlargement that occurs with the underlying valvular or myocardial disease.

Absence of an auscultable fourth heart sound in the presence of an irregular cardiac rhythm with no underlying regularity distinguishes atrial fibrillation from other cardiac arrhythmias. Sinus arrhythmia, which is also an irregular rhythm, has an audible fourth heart sound. Ventricular and atrial ectopic beats usually occur with a relatively regular underlying rhythm. A complicated ventricular rhythm with more than one focus of activation may have characteristics similar to those of atrial fibrillation and must be distinguished from it by an ECG. Atrial tachycardia with varying degrees of atrioventricular block has similar auscultatory characteristics, and the underlying fourth heart sounds may be missed if the animal is auscultated in a noisy environment.

Clinical Pathology In cattle with atrial fibrillation, acid-base and electrolyte disturbances occur frequently and are most likely attributable to the underlying primary disease. Most cattle with atrial fibrillation have GI disease, and the most consistent acid-base disturbance is metabolic alkalosis.[257] Hypocalcemia, hypokalemia, and hypochloremia may also be seen in cattle with atrial fibrillation. Experimental induction of metabolic alkalosis with hypokalemia in cattle has been associated with development of atrial fibrillation.[258] Most horses with atrial fibrillation have normal electrolytes, although the fractional excretion of potassium may be low, particularly in horses that sweat excessively or are routinely receiving furosemide for exercise-induced pulmonary hemorrhage.

The diagnosis of atrial fibrillation is made by ECG. The arrhythmia is characterized by an irregular R-R interval. The ventricular response rate is low, normal, or high, depending on the presence of heart disease or the severity of the primary disease. The ventricular complexes have normal polarity and amplitude but vary slightly in appearance from beat to beat. Similarly, the QT interval and the appearance of the T wave vary. P waves are absent, replaced by fine undulations of the baseline called *fibrillation* or *f waves*. In some leads the f waves are barely visible, particularly in cattle (Fig. 30-33).

The echocardiogram is used to determine whether cardiac disease is present. The most significant change associated with the arrhythmia is a mild reduction in shortening fraction (≤24%) that occurs, in part, secondary to the loss of the atrial contribution to ventricular filling.[259] Absence of the second (atrial) opening of the mitral valve, corresponding to atrial contractions, is also detected with atrial fibrillation.[260] Conversion to sinus rhythm usually results in these echocardiographic findings returning to normal within several days if there is no underlying myocardial disease.[259,261] Similar improvement occurs in horses with mitral and aortic regurgitation after conversion to normal sinus rhythm.[261] In many large animals with atrial fibrillation, no evidence of heart disease can be detected echocardiographically; these animals are often considered to have "lone" atrial fibrillation. Abnormal echocardiographic dimensions, if detected, indicate that underlying heart disease is present. Measurement of the maximal left atrial dimension in the two-chambered view of the left atrium and left ventricle from the left cardiac window should be performed in peak systole to determine whether there is left atrial enlargement. This measurement is a more sensitive indicator of left atrial enlargement than the M-mode left atrium–to–aortic root ratio. In normal horses the left atrial diameter in this view should be

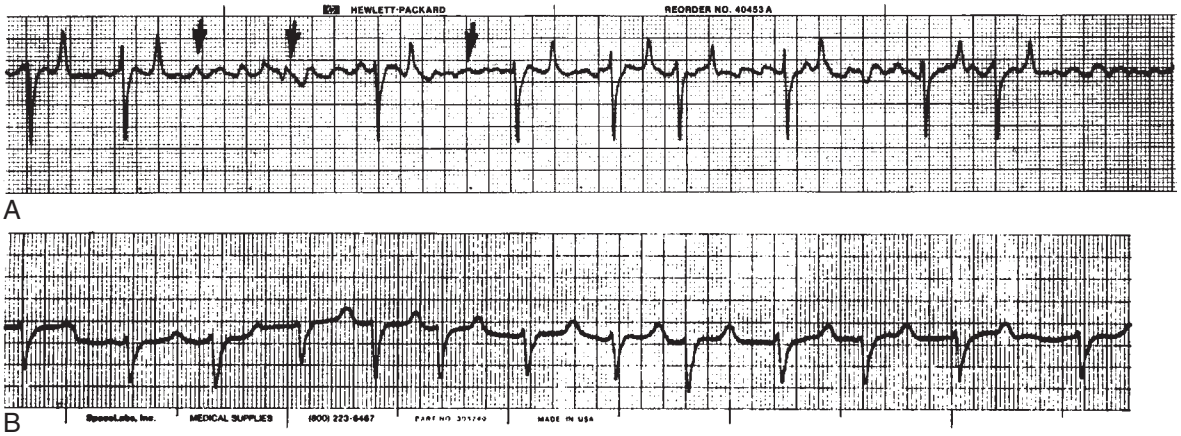

FIG. 30-33 ECGs showing atrial fibrillation in a horse **(A)** and cow **(B)**. The irregular QT intervals and absence of P waves are apparent. *Arrows* point to fibrillation waves, which are apparent only in **A.**

VetBooks.ir

13.5 cm or less. Measurement of the left atrium–to–aortic root ratio can be performed in the 2D short-axis view of the aorta across the maximal short-axis diameter of the left atrium to obtain additional information about left atrial size. Measurement of the maximal diameter of the left atrium can also be performed in the four-chambered view in peak systole if the heart can be imaged in its entirety.

Cardiac catheterization reveals normal cardiac output and blood pressure measurements in most awake horses with atrial fibrillation, but conversion to normal sinus rhythm may induce a reduction in mean right atrial, pulmonary arterial, and aortic pressures.[262] Similar studies have not been reported in cattle.

Pathophysiology

Experimentally, rapid stimulation of the atrium can initiate atrial fibrillation, which can be sustained if the animal has a large heart and sufficient vagal tone.[250,263-266] In horses and cattle the normal atria may be large enough to support atrial fibrillation once it is established. In addition, both species have a high vagal tone at rest. This combination of factors may be responsible for the large number of benign or functional cases of atrial fibrillation in large animals. The ventricular response during atrial fibrillation results from rate-dependent concealment of atrial fibrillation wavelets bombarding the AV node.[252] Cardiac diseases such as endocarditis, atrioventricular valvular regurgitation, and CHF that result in atrial enlargement and rapid stimulation of the atria provide a setting in which atrial fibrillation can develop and can be sustained naturally. Microscopic cardiac pathology might also create the proper setting for the development of conduction block and reentry.

During atrial fibrillation there is no coordinated contraction of the atria, so ventricular filling is passive. Although this might be expected to reduce cardiac output, there is no evidence this occurs in resting horses without concurrent mitral or aortic regurgitation.[262] In several horses with aortic regurgitation or aortic and mitral regurgitation, a decreased cardiac output was detected compared with horses without valvular insufficiencies before conversion.[261] The cardiac output increased significantly in warmblood horses with valvular regurgitation after conversion. During exercise, however, the heart rate of horses with atrial fibrillation exceeds normal limits, often by 40 to 60 beats/min for each level of exercise. This results in a decreased cardiac output and the resultant exercise intolerance that occurs in horses performing high-intensity athletic work.[253] Even higher heart rates were reported in warmblood horses during lungeing exercise, with the majority of these horses exhibiting QRS complexes with abnormal morphology during exercise.[267] Blood flow to other organs and viscera, although not studied, may be altered in large animals with atrial fibrillation, resulting in reduced GI motility, colic, reduced muscle blood flow, and poor milk production.

Atrial pressures are elevated in horses with atrial fibrillation.[262,268] Sustained high pressure is likely to produce dilation of the atria. With progressive dilation, secondary atrioventricular valve regurgitation may occur. During atrial fibrillation blood flow to the atrial myocardium is reduced, and progressive fibrosis can also be a consequence of chronic atrial fibrillation. Sustained atrial fibrillation may result in progressive cardiac disease, although it is usually well tolerated in the horse.

Epidemiology

Standardbred, Thoroughbred, and Draft horses have been reported to have the highest incidence of atrial fibrillation.[254-256] Racehorses have been diagnosed most frequently, but atrial fibrillation has been found in all types of horses.[255,256,261] Horses of all ages are susceptible to atrial fibrillation, but it occurs infrequently in ponies, foals, weanlings, and yearlings. Older horses, ponies, foals, weanlings, and yearlings with atrial fibrillation more frequently have underlying heart disease associated with the arrhythmia.

In cattle, atrial fibrillation is diagnosed more frequently in dairy cattle than in beef cattle, but there is no apparent breed predilection.[249,257] It is commonly associated with GI disease or abdominal pain in cattle.[249,250,257] Foot rot and pneumonia can also be associated with development of atrial fibrillation in cattle.

Necropsy Findings

Many cattle and horses have "lone" atrial fibrillation without apparent underlying heart disease, so the necropsy findings reflect the primary disease. Microscopic cardiac pathology has been found in horses with atrial fibrillation that consists of focal atrial myocardial fibrosis, microvascular alterations, and cardiac nerve abnormalities.[269-271] Multifocal or large areas of myocardial fibrosis were detected in dairy cows with idiopathic atrial fibrillation.[272] Whether these changes predisposed to the development of atrial fibrillation, were a consequence of atrial fibrillation, or were aging changes has not been established. A minority of horses and cattle have endocarditis, CHF, or valvular lesions, and the necropsy findings reflect these conditions. In horses with atrial fibrillation, mitral valve disease was the most common valvular lesion.[256] Pharmacologic and transvenous electrical cardioversion are both options for conversion of atrial fibrillation to normal sinus rhythm in horses.[256,273-284]

Treatment and Prognosis

Quinidine is the drug of choice to convert atrial fibrillation to normal sinus rhythm in horses and cattle. The drug is a negative inotrope at high dosages, causes systemic hypotension, increases the ventricular response rate, and can produce undesirable side effects and toxicity—it must be used with caution. In animals with CHF, quinidine therapy has considerable risk.[256] Because most large animals have little or no underlying cardiac pathology, treatment with quinidine is successful in restoring normal sinus rhythm. Treated animals should be monitored frequently by physical examination, with careful auscultation and ECG recording. Continuous ECG recording using radiotelemetry should be performed throughout treatment.[276] Animals should have normal acid-base balance and electrolyte concentrations before treatment. They should be adequately hydrated, allowed to drink and eat, or given additional oral fluids (horses) or IV fluids (cattle) during therapy. IV administration of quinidine gluconate is successful in converting horses with recent-onset atrial fibrillation to sinus rhythm.[277] Quinidine gluconate is most successful when administered to horses with atrial fibrillation of 2 weeks or less. However, quinidine gluconate had been successful in converting horses with atrial fibrillation of 2 to 4 weeks' duration. Horses with longer durations of atrial fibrillation should be treated with quinidine sulfate via nasogastric intubation. Quinidine is poorly absorbed after oral administration to cattle, so it must be given by IV infusion to obtain therapeutic concentrations. Cattle should be given IV fluids during quinidine infusion. Quinidine therapy should always be discontinued when conversion to normal sinus rhythm occurs.

Quinidine sulfate is the preparation most economically used in large animals, although quinidine gluconate has resulted in successful conversion of a cow with atrial fibrillation.[285] Before therapy, a baseline ECG is recorded. Horses are given a dose of 22 mg/kg of body weight (1 g/100 lb) in a suspension of water via nasogastric tube. At 2 hours (time by which blood concentration of quinidine should have peaked), they are evaluated closely for idiosyncratic or toxic reactions such as nasal edema, cutaneous reactions (urticaria or wheals), laminitis, colic, diarrhea, or ataxia. If no abnormalities are noticed, an ECG is recorded. If conversion to normal sinus rhythm has not occurred and the QRS duration is not greater than 25% of the pretreatment QRS duration, an additional dose is administered. Two hours after each dose administered via nasogastric intubation, an ECG is recorded. If there has been no conversion to normal sinus rhythm, another dose is administered, up to a maximum of four doses. A plasma quinidine concentration should be obtained 1 hour after the fourth dose administered every 2 hours to be sure the horse will be able to tolerate another dose without experiencing toxicity. If the QRS complex is prolonged by more than 25% of the pretreatment value, or if a fast (>80 to 100 beats/min) sustained supraventricular arrhythmia, ventricular rhythm, colic, diarrhea, ataxia, nasal edema or laminitis develops, therapy should be discontinued. Although laminitis is a frequently reported complication of quinidine sulfate therapy in the older literature, the actual incidence of laminitis associated with quinidine administration is rare.[276] Nasal

VetBooks.ir

mucosal edema, neurologic signs, and prolongation of the QRS duration to greater than 25% of the pretreatment value are all signs of quinidine toxicity; if detected, the drug should be discontinued. Colic associated with high dosages of quinidine should also prompt discontinuation of treatment (at least for this attempt at conversion). If conversion has not occurred after a total of four to six doses (one every 2 hours) or after a cumulative dose of 88 to 132 mg/kg of quinidine sulfate has been administered, treatment intervals should be prolonged to every 6 hours (approximate half-life of quinidine).[276] Only four doses of quinidine sulfate should be administered every 2 hours before switching to every 6 hours if plasma quinidine concentrations cannot be obtained in a timely fashion. The every-6-hour treatment can be continued until the horse converts or shows toxic or adverse side effects or the owner elects to discontinue treatment. The advantage of this treatment regimen is that steady-state plasma and myocardial concentrations of the drug are achieved. There is less quinidine toxicity, a lower total dose of quinidine sulfate is used, and horses that did not convert after the standard every-2-hour administration may convert with this treatment regimen. Digoxin at 11 µg/kg PO twice daily can then be added to the therapeutic regimen if conversion has not occurred in 24 to 48 hours; it appears to be helpful in some horses. Concurrent administration of digoxin and quinidine will result in an increased plasma digoxin concentration,[286] so to prevent digoxin toxicity, concentrations should be monitored beginning the second day of combined quinidine and digoxin therapy. If this is not possible, the horse should not receive more than 2 days of combined digoxin and quinidine therapy. Transvenous electrical cardioversion has been very successful in converting horses to normal sinus rhythm and is particularly useful in horses in which adverse or toxic reactions to quinidine prompted discontinuation of antiarrhythmic therapy with the result that conversion to normal sinus rhythm was not achieved.[281,284]

Quinidine sulfate at a dose of 48 mg/kg is suspended in 4 L of saline or lactated Ringer solution when cattle are treated for atrial fibrillation. This dose is administered at a rate of 1 L/h. IV fluids are administered simultaneously in the opposite jugular vein. Cattle should be monitored continuously during the infusion. Cattle frequently become depressed and develop diarrhea during the infusion of quinidine. These signs are side effects, and therapy can be continued. The infusion rate should be slowed if the ventricular response rate exceeds 100 beats/min. If the QRS complex is visibly prolonged or a fast (>120 beats/min) supraventricular arrhythmia or ventricular rhythm develops, therapy is temporarily discontinued. Just before conversion, some cattle have blepharospasm and are ataxic. The infusion should be discontinued as soon as conversion occurs. Therapy should be discontinued after the 4-L infusion even if conversion to normal sinus rhythm has not occurred.

During quinidine therapy the ECG shows predictable changes. The fibrillation waves become coarser and less frequent. The R-R interval becomes more regular as the heart rate increases. Before conversion there may be a rapid regular atrial rate with more than one saw-toothed flutter (F) wave or P wave for each QRS complex (atrial flutter or atrial tachycardia with atrioventricular block, respectively). At the time of conversion, a single P wave is present for each QRS complex. Frequently a large T_a wave is present and the ST segment is elevated. The ECG should be normal within 12 hours of conversion. A continuous 24-hour ECG is recommended in horses with atrial fibrillation after conversion to determine whether frequent atrial premature depolarizations are present. If the continuous ECG is normal and left atrial and ventricular function has returned to normal, the horse can be returned to training. If frequent supraventricular premature extrasystoles are detected or left atrial contractile dysfunction persists, the horse should be rested and treatment with corticosteroids considered. The horse should not be returned to work until the atrial premature depolarizations have resolved and left atrial contractile function has returned to normal. IV amiodarone and flecainide have been used to convert horses with atrial fibrillation,[279,280,282] but amiodarone is less successful than quinidine for this purpose.[279,282] Ventricular arrhythmias were common in horses given flecainide, limiting its usefulness as a treatment for atrial fibrillation in horses.[280]

Digoxin is used before quinidine therapy in horses and cattle with fast heart rates. The ventricular response rate should be less than 60 beats/min in horses and 100 beats/min in cattle before quinidine therapy. One or two doses of digoxin are administered before initiation of quinidine therapy in horses with only mild tachycardia. In horses with very labile heart rates or problems with rapid ventricular response rate during a previous conversion, digoxin is administered for up to 5 to 7 days before initiation of quinidine therapy. Digoxin should be administered at a dose of 11 µg/kg PO twice daily to horses. Cattle are given digoxin by IV infusion at 0.86 µg/kg/h or 11 µg/kg three times daily. The side effects of quinidine treatment (e.g., rapid ventricular response rate) may be decreased in animals pretreated with digoxin. Digoxin is also indicated as a pretreatment in horses with atrial fibrillation and very low FS (<24%), indicative of underlying myocardial disease. Transvenous electrical cardioversion should be considered in horses with high heart rate responses to stimulation or during prior quinidine therapy.

Because cattle with successfully treated primary GI disease frequently convert to normal sinus rhythm spontaneously—usually within 5 days of resolution of the primary problem—treatment is delayed for this period.[257] Cattle that do not convert spontaneously in 5 days, have chronic GI problems, or have atrial fibrillation with adverse hemodynamic effects (poor peripheral perfusion, weak arterial pulses, and/or pulse deficit) are selected for quinidine therapy. The prognosis for cattle with atrial fibrillation is good if the primary problem has been resolved and conversion to normal sinus rhythm occurs. Prognosis for cattle with chronic GI disease is guarded, but many show improved appetite and milk production when atrial fibrillation is resolved. Unless heart disease is present, few cattle experience a recurrence of atrial fibrillation. A small percentage of cattle fail to respond to quinidine therapy, and their prognosis is guarded to poor because milk production and appetite are intermittently poor and heart disease can be progressive.

Horses with paroxysmal atrial fibrillation have a good prognosis for return to performance, and few have a recurrence of the arrhythmia. If possible, predisposing factors such as transient potassium depletion should be removed by discontinuing furosemide administration or adding oral KCl to the diet. Oral bicarbonate milkshakes and thyroid hormone supplementation should be avoided. Horses with "lone" sustained atrial fibrillation have a good prognosis for conversion to normal sinus rhythm and a return to previous performance level.[255,256] Horses with sustained atrial fibrillation associated with mild to moderate valvular regurgitation and atrial enlargement often have a recurrence of atrial fibrillation but can usually be successfully converted when indicated. Horses with heart rates over 60 beats/min or with signs of CHF have a guarded to grave prognosis, and conversion to sinus rhythm is rarely warranted. Treatment of the underlying cardiac disease (if possible) is warranted, and the horse should be treated for CHF with digoxin, diuretics, and vasodilators as needed. Recurrence of atrial fibrillation and side effects of quinidine therapy are more frequent in horses that have had atrial fibrillation for longer than 4 months before treatment.[256] The recurrence rate for horses with atrial fibrillation of more than 4 months' duration increases from 25% to 60%. This may be the result of atrial remodeling and the associated microscopic cardiac lesions that developed with chronic atrial fibrillation.

Ventricular Tachycardia

Definition and Etiology *Ventricular tachycardia* is a cardiac arrhythmia characterized by a rapid rhythm originating in the ventricle. This rhythm originates below the bundle of His in the specialized conduction system, the surrounding ventricular myocardium, or both.[287] VT may be caused by disorders in impulse formation, impulse conduction, or a combination of the two.[287] Ventricular reentry is an important mechanism in the genesis of sustained VT,

VetBooks.ir

whereas abnormal automaticity is probably responsible for idioventricular rhythms and parasystole. Changes in autonomic tone may also be important in the genesis of VT. Early afterdepolarizations are thought to be the mechanism responsible for ventricular tachyarrhythmias associated with sympathetic stimulation. Late coupled ventricular complexes or a very premature ventricular depolarization are usually required to initiate VT. VT can occur when there is myocarditis, myocardial necrosis, fibrosis or neoplasia, bacterial endocarditis (especially involving the aortic or mitral valve), autonomic nervous system imbalance, hypoxia, ischemia, electrolyte or metabolic disturbances, anesthesia, drug administration, sepsis, endotoxemia, toxic myocardial injury, or aortic root rupture; or it may be associated with other, unknown causes.[80,206,220,288,289]

Clinical Signs and Differential Diagnosis The clinical signs detected depend on the ventricular rate, type of VT (uniform or multiform), duration of VT, and severity of the underlying cardiac disease.[289] Large animals with VT may be asymptomatic at rest if the rhythm is relatively slow and uniform, or they may have severe CHF with rapid uniform or multiform VT.[289] Exercise intolerance is common and may be so severe that the animal has frequent syncope. Other complaints include depression, weakness, colic, respiratory distress, coughing, ventral edema, and pulmonary edema. Acute viral or bacterial respiratory disease with high fever may precede development of VT in horses or may occur concurrently with it. Gastrointestinal disease and primary myocardial disease are common in horses with VT.[288,290] Horses with severe hemorrhage are also at increased risk for ventricular arrhythmias.[291] In cattle, VT occurs most frequently secondary to sepsis and toxemia. Anorexia and decreased milk production are common in affected cows.

Animals with sustained VT have a rapid heart rate with a regular (uniform) or irregular (multiform) rhythm.[292-295] Heart rates as high as 300 beats/min have been detected in horses with VT. Heart sounds vary in intensity, with some very loud booming sounds ("bruit de cannon"). Arterial pulse may be variable or uniform, with normal (slower rate) or weak (rapid rate) intensity pulses. Pulse deficits frequently occur, particularly with rapid or multiform VT. Jugular pulses are frequently detected in large animals with VT. The large pulse waves seen in the jugular vein are cannon "a" waves that occur when the right atrium and ventricle contract simultaneously. Cardiac murmurs are not commonly detected. Signs of CHF are usually present when VT is rapid and sustained but are uncommon in animals with slower or paroxysmal VT.[292-294] Signs of right-sided CHF (ventral edema, venous distention) usually predominate with sustained uniform VT and increase in severity the longer the duration and more rapid the rate of the arrhythmia. Signs of left-sided CHF (coughing, expectoration of foamy fluid, respiratory distress) usually predominate with multiform VT.

The presence of jugular pulses and bruit de cannon in an animal with a rapid regular rhythm helps distinguish VT from sinus or supraventricular tachycardia. Multiform VT can be difficult to distinguish from atrial fibrillation, because both arrhythmias have an irregular rhythm with heart sounds that vary in intensity. Jugular pulses may also be detected in large animals with atrial fibrillation but are usually less prominent than in animals with VT. Although large animals with multiform ventricular arrhythmias usually have more severe clinical signs, an ECG is necessary to distinguish these arrhythmias.

Clinical Pathology Electrolyte, metabolic, or toxic causes of VT may be present in large animals with primary GI disease. Hypomagnesemia and hypokalemia have also been associated with development of VT.[295] Serum creatinine and BUN may be elevated in horses and cattle in CHF associated with prerenal azotemia. Serum osmolality, BUN, and creatinine increase and urine osmolality decreases acutely in horses with experimental monensin toxicosis.[158] Initial decreases in serum potassium and serum calcium have also been reported in these animals. Marked elevations of cTnI have been seen in horses with VT.[171,172,290] In human beings, cTnI is a more sensitive indicator of myocardial injury and appears to have a similar sensitivity in the horse; cTnI is currently preferred for detection of myocardial injury in horses. Cardiac isoenzymes of CK and LDH are often elevated if there is recent myocardial injury associated with VT. Elevation of the myocardial fraction of CK (CK-MB) in excess of 5% of the total CK is compatible with myocardial injury in horses.[158] A neutrophilic leukocytosis and hyperfibrinogenemia may be detected in animals with infectious myocarditis or bacterial endocarditis or may be elevated owing to the primary underlying disease. In most large animals with VT, however, hematologic findings are normal.

The diagnosis of VT is made from the ECG. A series of four or more ventricular premature depolarizations is diagnostic of VT.[288,296] The electrocardiographic appearance of the ventricular premature depolarizations may be widened and bizarre, or the QRS duration and appearance of the QRS and T may be near normal, especially in horses (Fig. 30-34).[288,289] Although the duration of QRS complexes that are ventricular in origin is usually within the normal range reported for horses, it is usually longer than the QRS duration of the horse's normal sinus beats.[288] The major direction of the QRS complex is usually oriented opposite to that of the T wave. The R-R intervals may be regular or irregular. The morphology of the QRS complexes may be similar (uniform) or may vary widely with multiform VT (Fig. 30-35). Atrioventricular dissociation is usually present, with an atrial rate slower than the ventricular rate. Fusion beats and capture beats may be detected. VT can be sustained or paroxysmal.

The echocardiogram is used to determine whether cardiac disease is present. The echocardiogram is usually abnormal in large animals

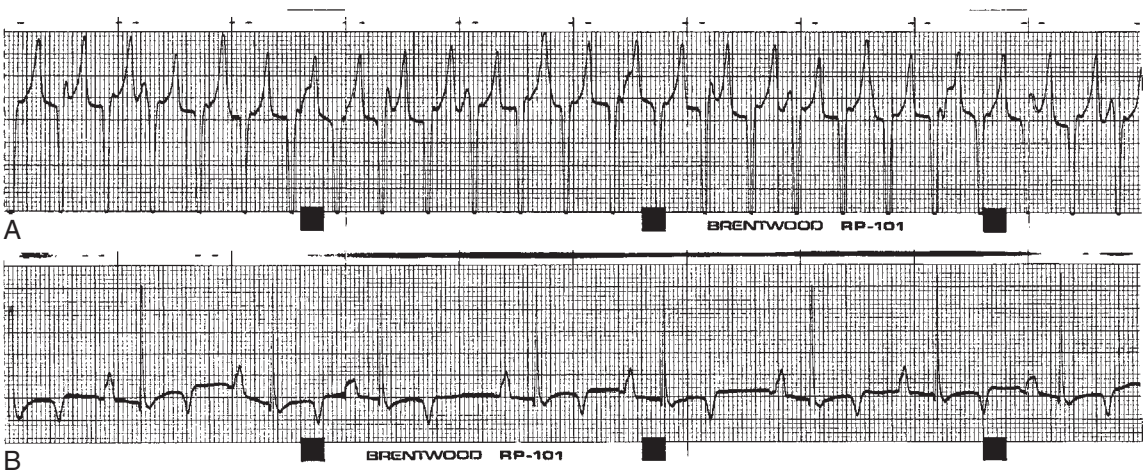

FIG. 30-34 Lead II ECG obtained from a horse with sustained uniform ventricular tachycardia and congestive heart failure before **(A)** and after **(B)** conversion to sinus rhythm. Note the abnormal QRS and T configuration and slower atrial rate during the sustained ventricular tachycardia.

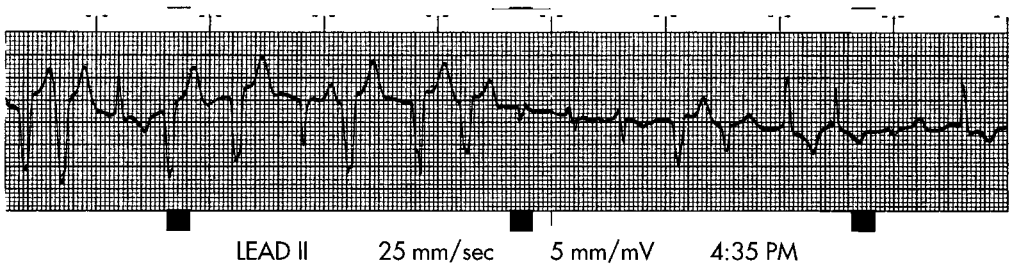

FIG. 30-35 Lead II ECG obtained from a horse with multiform ventricular tachycardia and acute onset of pulmonary edema. Note the multiple different QRS and T configurations and the elevated ventricular rate.

with primary myocardial disease and normal in large animals with secondary VT, except for the changes associated with the VT itself (see Fig. 30-15). Abnormal echocardiographic findings that may be detected in large animals with primary myocardial disease include myocardial dyskinesis, hypokinesis, and akinesis; abnormal myocardial echogenicity; decreased FS, ET, and EF; loss of the normal systolic and diastolic undulations of the aortic root; and detection of spontaneous contrast, small aortic root, and large pulmonary artery. Occasionally the echocardiographic abnormalities created by VT may be difficult to distinguish from those of primary myocardial disease. Rupture of the aortic root at the right sinus of Valsalva may be detected in horses with acute onset of uniform VT and colic.

Cardiac catheterization may reveal severe hypotension and low cardiac output. In healthy ponies with pacing-induced VT, stroke volume decreased significantly when the ventricle was paced at 150, 200, and 250 beats/min.[297] Mean left atrial pressure, mean pulmonary arterial pressure, and right ventricular systolic pressure increased significantly when the ventricle was paced at 220 and 250 beats/min. Aortic pressure and cardiac output decreased in these ponies at 250 beats/min, but the decrease from resting values was not statistically significant. Myocardial perfusion in the papillary muscles and subendocardium decreased significantly with pacing-induced VT at a rate of 250 beats/min. Decreases in cardiac output, arterial blood pressure, and myocardial perfusion are even more marked in animals with underlying myocardial disease or multiform VT, as are the changes in left atrial, pulmonary arterial, and right ventricular pressure.

Pathophysiology

VT is probably initiated spontaneously by late coupled ventricular complexes, whereas one very early ventricular premature depolarization can often initiate VT electrically.[287] Sympathetic stimulation may also provoke VT by increasing the amplitude of the early afterdepolarizations, culminating in a run of VT.[287] This may be the mechanism of some of the exercise-induced VT in horses. Reentry in the ventricle is an important cause of sustained VT, particularly in human patients with dilated cardiomyopathy and ischemic heart disease. The area of reentry is reportedly small (<1.4 cm^2).[287] Reentry is also thought to be an important mechanism in horses with sustained VT.[294,298,299] Delayed afterdepolarizations may trigger VT in humans and dogs and may be the mechanism for digitalis-induced VT.[287] Abnormal action potentials have also been demonstrated in ventricular myocardium resected from human beings with recurrent VT.[287] Depressed automaticity and afterdepolarizations have been associated with acute myocardial ischemia, whereas automaticity and afterdepolarizations are enhanced in Purkinje fibers surviving myocardial infarction. Idioventricular rhythms and parasystole may be caused by abnormal automaticity.

Cardiac diseases such as endocarditis may result in septic myocardial emboli and myocardial ischemia. Aortic root rupture and dissection of blood into the interventricular septum disrupts conduction and usually results in a uniform VT. Myocarditis, myocardial necrosis, and fibrosis also may result in abnormalities of impulse formation and conduction, leading to VT.[300] The excitement of the high-performance situation and the decreased myocardial perfusion that may occur at peak exercise may make exercise-induced VT more common in racehorses and other types of high-performance horses.

Epidemiology

VT has been reported in all large animals, although horses may have the highest incidence. VT leading to ventricular fibrillation is thought to be one of the leading causes of sudden death in horses when other causes of death cannot be found on postmortem examination.[299,301,302] Male horses are at increased risk for aortic root and sinus of Valsalva rupture and are usually at least 10 years old at the time of rupture. VT is also more likely in large animals of any age with primary GI disease and in horses following severe hemorrhage.

Necropsy Findings

If VT is not associated with primary myocardial disease, necropsy findings reflect the underlying disease. Gross and microscopic cardiac pathology has been found in horses with VT, although in some horses no cardiac pathology is found. Areas of myocardial necrosis, inflammatory cell infiltrate, fibrosis, infarction, microvascular alterations, and cardiac nerve abnormalities have been reported in horses with VT.[270,294,299,300] CHF is most likely in large animal patients with multiform VT and heart rates in excess of 180 beats/min. Bacterial endocarditis and secondary septic emboli dissemination through the coronary arteries as a result of VT occurs in a minority of large animal patients. Aortic root rupture and rupture of a sinus of Valsalva aneurysm with dissection of blood into the interventricular septum are infrequently detected in horses.

Treatment and Prognosis

Treatment and prognosis for VT depends on the suspected cause of the arrhythmia, severity of the animal's clinical signs, and electrocardiographic abnormalities detected.[288,289] Relatively slow, uniform VT often resolves or improves significantly with correction of the underlying electrolyte or metabolic imbalances, without requiring antiarrhythmic therapy. These animals usually have an excellent prognosis for conversion with correction of the underlying problem. Similarly, in large animals with sepsis or toxemia, hemodynamically and electrically stable VT often resolves with treatment of the underlying disease. Uniform, hemodynamically stable VT in animals with myocarditis may resolve with rest and/or corticosteroid therapy. A minimum of 4 to 8 weeks of rest is indicated in these patients before returning to work, once the VT has resolved.

Treatment with antiarrhythmics is indicated in any animal with hemodynamically unstable or life-threatening VT. Treatment with antiarrhythmics is indicated if clinical signs of CHF or cardiovascular collapse are present or if the rate of sustained VT is extremely high. In horses with sustained uniform VT, a heart rate in excess of 120 beats/min usually warrants antiarrhythmic therapy, whereas in cattle, antiarrhythmic therapy may not be indicated until the heart rate exceeds 140 beats/min or greater. Horses with rapid sustained uniform VT (≥120 beats/min) need antiarrhythmic therapy because signs of CHF will develop after several days or weeks with this arrhythmia, if not already present. Rapidity of CHF onset is related to heart rate and type of primary myocardial disease, if present. These horses usually have a good prognosis for conversion and return to their previous performance level with appropriate antiarrhythmic

VetBooks.ir

therapy (many times three or more antiarrhythmic drugs must be tried before conversion occurs) and rest before the horse is returned to work.

ECG findings associated with life-threatening VT include a multifocal origin for the ventricular premature depolarizations, torsades de pointes (wide ventricular tachycardia), and the presence of an R wave superimposed on the preceding T wave ("R on T"). Large animal patients with clinical signs of CHF and hemodynamic collapse with rapid (heart rate < 120 beats/min) multiform VT (±R on T) should be treated as a cardiovascular emergency; sudden death from ventricular fibrillation is likely without antiarrhythmic therapy. Large animals with multiform VT (±R on T) must be given a guarded to grave prognosis for survival, because most have severe underlying myocardial disease. Often conversion to sinus rhythm may not be successful before the animal develops ventricular fibrillation and dies. If successfully converted to sinus rhythm, many of these animals die or are euthanized because of the severity of the underlying cardiac disease.

Several antiarrhythmic choices are available to the large animal practitioner for correcting life-threatening VT (see Table 30-3). Lidocaine hydrochloride—the most readily available drug for most large animal practitioners—is rapidly acting, administered IV, and has a short duration of action and minimal hemodynamic effects. However, this drug has central nervous system side effects in horses (hyperexcitability and seizures) and must be used at a lower dosage than in cattle. Quinidine gluconate (or quinidine sulfate in cattle) is very effective in large animals but is less rapidly acting, has negative inotropic effects at large doses or if primary myocardial disease is present, causes hypotension, and can produce undesirable adverse or toxic reactions. Magnesium sulfate can cause hypotension but has no other recognized adverse cardiovascular effects. It is less rapidly acting than lidocaine, but in both normomagnesemic and hypomagnesemic patients it may be effective when other antiarrhythmics fail. IV procainamide, IV and oral propafenone, and IV flecainide have also been used successfully in horses with VT. IV propafenone is indicated for refractory VT and has been used successfully in several horses that did not respond to lidocaine, quinidine, procainamide, or magnesium sulfate. However, it is currently unavailable in the United States. Other antiarrhythmics such as propranolol have been used with less success but have converted large animals with sustained VT.

Diseases of the Respiratory System

PAMELA A. WILKINS and AMELIA R. WOOLUMS, *Consulting Editors*

Diagnostic Procedures for the Respiratory System

Kara M. Lascola and Pamela A. Wilkins, *Consulting Editors*

General Evaluation of the Patient with Respiratory Disease

History

As with any disease process, acquisition of an accurate and appropriate history is the first step undertaken in evaluating the patient with a complaint thought to be related to the respiratory tract. Animals with respiratory disease may have widely varied histories and it is important to gather as much information as possible. Age and breed may play a role in the development of respiratory disease, such as congenital defects or neoplastic disease, or in inherited or acquired immunodeficiency syndromes seen in certain breeds. The environment in which the animal is maintained can contribute to the development or severity of respiratory disease, heaves in horses for example, and respiratory disease may become manifest following a change to a new environment. The work horses are expected to perform can lead to important diagnostic clues, and recent events, such as long-distance transport, can predispose horses to diseases such as pleuropneumonia. It is important to know if certain diseases are either endemic or epidemic where the horse is kept or has recently moved from; diseases such as strangles and *Rhodococcus equi* bronchopneumonia of foals come to mind. Any recent traumatic or potentially traumatic event should be noted. If possible, a thorough vaccination history should be obtained, as should an accurate history of any administered treatments or supplements and the patient's response to those treatments.

Presenting Signs or Chief Complaints

There are many presenting signs or chief complaints that should lead to more thorough evaluation of the respiratory system, some more directly associated with either the upper or lower respiratory tract. Findings or complaints associated with respiratory disease include nasal discharge, either bilateral or unilateral. Respiratory noise at rest or during exercise is commonly associated with abnormalities of the upper airway, as may be inequalities of airflow present at the nares. Normal animals may periodically cough or sneeze, but an increase in either activity may indicate involvement of the respiratory tract. Exercise intolerance or apparent decrease in the ability of the animal to exercise should prompt evaluation of the respiratory system. Other clinical signs that indicate thorough evaluation of the respiratory tract include, but are not limited to, abnormal breathing patterns (tachypnea, hyperpnea, dyspnea), cyanosis, hemoptysis, epistaxis, unusual swellings (facial, pharyngeal, cervical), lymphadenopathy, ataxia or reluctance to move, foul smell to the breath, weight loss, and ventral abdominal, sternal, or limb edema.

Physical Examination

The initial physical examination occurs at some distance from the patient and involves evaluation of the demeanor, posture, mental status, and way of movement of the patient. It is important to note if the patient has an abnormal stance, such as standing with the head and neck extended. If the patient is unwilling to move or stands with elbows abducted, this suggests pleural pain is present. Ideally, the respiratory rate can be determined by observation as can the respiratory pattern. While some respiratory diseases are not manifest at rest, important clues can be gained from observation of the patient at rest in many others. The normal resting respiratory rate of an adult horse is between 8 and 16 breaths per minute, for adult cattle 15 to 35 breaths/min; and sheep and goats, 12 to 20 breaths/min. There is some small abdominal component during the expiratory phase, which is, along with inspiration, an active process for horses. The normal rate for neonates is up to 60 breaths/min at birth and less than 30 breaths/min by 1 month of age; respiratory rate decreases toward the adult rate with age. High ambient temperature, fever, and excitement can all increase respiratory rate. Normal breathing, which is quiet and apparently effortless, is termed *eupnea.* The term *dyspnea* is a breathing pattern that is inferred by the observer to reflect difficulty in breathing; the animal will appear distressed, and the work of breathing is obviously increased, although the actual rate may be within normal limits. Other terms used to describe breathing patterns include *tachypnea,* characterized by rapid rate and shallow depth or low tidal volume; *hyperpnea,* with increased frequency and depth of breathing (an example would be during postexercise recovery); and *apnea,* in which there is no discernible breathing. Two additional terms include *hypoventilation* and *hyperventilation,* both of which require a change in arterial carbon dioxide partial pressure as a component of their definitions. Hyperventilation is a pattern that increases alveolar ventilation and causes arterial hypocapnia, whereas hypoventilation alters gas exchange in such a way to cause arterial hypercapnia, or retention of carbon dioxide.

Closer examination can reveal some of the physical manifestations of presenting complaints listed previously. Beginning with the head, the clinician should determine that airflow is even from both nostrils, as differences can indicate either congenital or acquired abnormalities ranging from choanal atresia to the presence of upper airway masses. Abnormal respiratory sounds can sometimes be present at rest and may be heard at the nares. Abnormal breath odors

VetBooks.ir

may be prominent, particularly at the nares. The frontal and maxillary sinuses should be percussed; identification of abnormal resonance, usually dullness, may be made easier by performing this with the mouth held open. Palpation of the submandibular regions, larynx, and pharyngeal and cervical regions should be performed to identify any abnormal lymph node enlargement, masses, or areas of muscular atrophy. Both jugular veins should be checked for patency and the presence of any evidence of injection sites or infections that may contribute to abnormal upper airway function by interfering with normal recurrent laryngeal nerve or vagosympathetic trunk function.

Coughing represents a nonspecific irritation of receptors in the airway and can be induced by many mechanisms. It can be, and usually is, a normal protective reflex that allows the animal to clear material from the airway. Cough can be associated with increased mucus production, production of other respiratory secretions, or decreased mucociliary clearance. In older horses cough is most commonly associated with heaves, whereas in younger horses cough is associated with infectious diseases and small airway inflammatory disease. Normal animals should not cough when the larynx or trachea is palpated.

Nasal discharge can be unilateral or bilateral, scant or copious, clear, mucoid, mucopurulent, or even bloody. The nature and character of nasal discharge can provide some information about a possible source of the discharge, but this information should not be overinterpreted. Horses, for example, have a tendency to swallow excess airway secretions, and the volume of secretions may be underestimated. Whereas unilateral nasal discharge seems to suggest a source in front of the larynx, bilateral nasal discharge can be of either upper or lower airway origin. Skin depigmentation of the ventral nares or presence of mucoid material in feed or water containers is a clue to presence of nasal discharge.

Hemoptysis is the coughing up of blood from the airways or lungs. It is important to determine conclusively that the blood has come from the respiratory system. Epistaxis is defined as blood seen at the nares and often originates in the nasal passages, sinuses, turbinates, nasopharynx, or equine guttural pouches, although the lung can be, and is, a source on occasion, as in exercise-induced pulmonary hemorrhage (EIPH) or following lung biopsy. Bilateral epistaxis generally indicates bleeding caudal to the choanae. Because animals tend to swallow excessive respiratory secretions, bleeding can be occult and may not be seen unless the animal drops its head toward the ground. Significant blood loss can occur in this manner, unseen by owners.

Examination of the oral mucous membranes may reveal cyanosis, bluish discoloration of the oral, nasal, or vulvar mucous membranes. Cyanosis does not become apparent until 5 mg/100 mL of deoxygenated hemoglobin, about one third of the total normal hemoglobin, is present; this reflects a profound decrease in oxygen saturation of hemoglobin and is suggestive of severe hypoxemia. As it is the total quantity of deoxygenated hemoglobin that lends the mucous membranes the bluish color, very anemic patients may lack sufficient deoxygenated hemoglobin to appear blue, which makes appreciation of cyanosis impossible in these patients. One caveat is that all newborns are cyanotic for the first few breaths and only become pink when they have established neonatal, as opposed to fetal, cardiorespiratory circulation and have opened their lungs to allow for gas exchange.

It is important that auscultation of the thorax take place in as quiet an environment as possible. Additionally, auscultation of the lung fields should be performed under two breathing conditions: eupnea and hyperpnea, with hyperpnea induced by the use of a rebreathing bag. Some common misconceptions regarding the use of a rebreathing bag exist. Simply occluding the animal's nostrils is inadequate to fully examine the patient, as is using a rectal sleeve as a rebreathing bag. The purpose is to cause the animal to rebreathe its own expired carbon dioxide, not to necessarily deprive it of oxygen. Rebreathing expired carbon dioxide results in increased $PaCO_2$, which stimulates deeper and more frequent breathing efforts, making recognition of abnormal lung sounds simpler. The bag used should be large enough to accommodate 2 to 3 times the normal tidal volume of the animal and should be held in such a manner as to prevent the bag from occluding the patient's nostrils. Once the bag is removed, the animal will usually take several very deep breaths and the examiner should take advantage of these very large breaths to reexamine areas where suspicious sounds were heard during rebreathing. Animals with significant lung pathology will not tolerate the bag well, may cough when the bag is removed, and may require more time to return to baseline respiratory patterns when the bag is removed.

Normal breath sounds are those produced by turbulence within the tracheobronchial tree and may vary considerably depending on location within the lung, breathing pattern, and condition of the animal.[1] Only airways from the larynx to segmental bronchi contribute to sound generation; bronchial and vesicular sounds represent larger airway flow events. Vesicular sounds—the quietest sounds, heard over the middle and diaphragmatic lung regions—correlate best with regional ventilation and mainly represent segmental bronchial sounds; they do not represent air flow in terminal conducting airways and alveoli, which is silent due to the nature of its flow. Bronchial sounds are louder and heard best over the trachea and base of the lung. Common abnormalities found during auscultation include ventral areas of dullness if pleural effusion is significant, dorsal areas of dullness or hyperresonance with pneumothorax, and dorsal harsh lung sounds. The degree of variation in normal lung sounds is large, and auscultatory findings do not always correlate well with the degree of lung abnormality. That said, abnormal lung sounds are always potentially clinically important.

Adventitious lung sounds are divided into short discontinuous sounds called *crackles* and longer continuous sounds called *wheezes*, replacing the older terms *rales* and *rhonchi,* respectively. Crackles are most commonly generated by sudden pressure equalization when collapsed airway segments open. Although an air/fluid interface is required, crackles do not necessarily imply excessive secretions or pulmonary edema. They are often end-inspiratory and associated with reinflation of atalectatic lung. Crackles may be normal when auscultated in the previously down lung of a laterally recumbent neonate. Disease processes that generate crackles include pneumonia, interstitial fibrosis, chronic obstructive lung disease, congestive heart failure, and atelectasis.[2]

Wheezes commonly represent oscillation of airway walls before complete closing (expiratory) or opening (inspiratory). Intrathoracic airways are usually involved in expiratory wheezes and include the lower trachea, main, lobar, and segmental bronchi. Disappearance of a wheeze after coughing indicates secretory rather than tissue component origin. Disease processes responsible for wheezes include airway stenosis or external compression; airway lumen compromise by foreign body, purulent material, cyst, or neoplasm, and airway wall thickening as in chronic bronchitis; and bronchoconstriction. Expiratory wheezes are a hallmark of obstructive lung diseases such as heaves. Crackles and wheezes may be variably present. A final category of adventitious sounds is the "rubbing" or "creaking" sounds generated by sliding or stretching of inflamed pleural surfaces, commonly termed *pleural friction rubs*.

Percussion of the thorax is performed by methodical tapping over the intercostal spaces of the thorax using a variety of instruments, including plexors, pleximeters, spoons, fingers, neurologic hammers, and hands. It is an inexpensive and useful component of the physical examination and should be performed in all patients where the respiratory system is suspect. Percussion of the thorax can reveal hyporesonance (dullness) ventrally when pleural effusion is present, reveal hyperresonance dorsally in pneumothorax, and cause some patients to exhibit pleurodynia during the examination. Other conditions that can alter resonance of the thorax include, but are not limited to, diaphragmatic hernia with intrathoracic intestine, pericardial effusion, pulmonary and pleural abscessation, and consolidated lung. The point at which a change occurs from resonant to dull can be marked with adhesive tape. Thus the outline of aerated lung immediately beneath the chest wall is delineated. It is usually impossible

VetBooks.ir

to fully delineate the lung field cranially because of body fat and triceps musculature. There is a distinct region of cardiac dullness for all species on the left side.

Percussion allows delineation of pleural effusion and intrathoracic masses or consolidated lung up to 7 cm beneath the pleural surface, but cannot distinguish between them. The procedure should be performed whenever pleural effusion is suspected on the basis of auscultatory findings and in all ruminants as part of the physical examination to uncover occult pneumonia.[3]

Additional Diagnostic Evaluation of the Respiratory Tract

Endoscopy

The upper airway can be directly examined with the aid of an endoscope, the only limitations being the size of the patient, the patency of the airway, and the size of the available equipment. Standard flexible fiberoptic endoscopes, available to most practitioners and present now in virtually all referral hospitals, allow direct examination of the nasal passages, ethmoid turbinates, nasal maxillary opening of the sinuses, pharynx, guttural pouch openings, larynx, and cranial trachea (Fig. 31-1). Smaller (8 to 10 mm in diameter) endoscopes can be readily introduced into the equine guttural pouches, with the aid of a biopsy instrument, and longer endoscopes (more than 150 cm long with diameters greater than 10 mm) are commonly employed to examine main stem bronchi and their initial branches in large animals.[4] Smaller species, such as camelids, may require the use of a smaller diameter (3 to 5 mm) endoscope or bronchoscope. Small brushes, used for collecting exfoliated cells for cytologic study, and a variety of biopsy instruments can be used for sampling the airway.

Airway endoscopy in the horse has evolved to include dynamic endoscopy (e.g., treadmill, overland endoscopy) during exercise to evaluate the dynamic function of the upper respiratory tract.[3,4a] Objective measurements can be made by use of videoendoscopy with slow motion or freeze-frame features.[3] Treadmill endoscopy is available at specialty practices and typically is performed at high speed (12 to 14 m/s) using incremental standardized testing protocols. Overland endoscopy has recently become more readily available to certain specialty practices and is performed during ridden exercise in the field with endoscopy equipment that is attached to the horse.[4a] Advantages of overland endoscopy include the ability to evaluate the horse under saddle and in natural conditions. Standardizing exercise tests in the field may, however, be more challenging. Sedation/tranquilization will aid many standing endoscopic examinations, but examinations aimed at evaluating pharyngeal and/or laryngeal function are best performed without any form of chemical restraint that might alter function. Most horses will allow standing examination of the upper airway with only physical restraint, such as judicious use of a nose twitch. Introduction of the endoscope into the trachea may elicit coughing, particularly in horses but less so in cattle. Small ruminants, such as sheep and goats, may require local tracheal anesthetic administration in the form of 2% lidocaine administered through small tubing passed through the biopsy channel of the endoscope. If lidocaine is used, it must be diluted and must not reach a toxic dose in small ruminants. Diluted topical 2% lidocaine can similarly be used in horses and cattle, if need be, for evaluation of the distal trachea, main stem bronchi, and larger bronchial tree branches. Horses are more sensitive to tracheal and bronchial stimulation and are more likely to require topical anesthesia than are cattle.

Guttural pouch diseases and upper airway abnormalities, such as pharyngeal lymphoid hyperplasia, laryngeal hemiplegia, epiglottic entrapment by arytenoepiglottic folds, dorsal displacement of the soft palate, pharyngeal cysts, retropharyngeal masses, and epiglottic deformities, are best diagnosed by endoscopic examination. Direct tracheobronchoscopic examination is best for the diagnosis of EIPH if it is performed within a few hours of exercise. Bronchoscopy with a longer endoscope may be useful for evaluating additional lower airway abnormalities, such as recurrent airway obstruction in horses. The degree and nature of airway secretions accumulating in the trachea can be easily assessed with an endoscope, and accumulated secretions may be sampled by aspirating the secretions through small tubing introduced into the trachea through the biopsy channel. Because the endoscope has passed through the nonsterile upper airway, these samples are best suited for cytologic, not microbiologic, evaluation but may be fully compatible with evaluation using molecular diagnostic techniques.[5-8] Endoscopy has also been used to help remove foreign bodies from the airway, generally aided by the biopsy instrument.

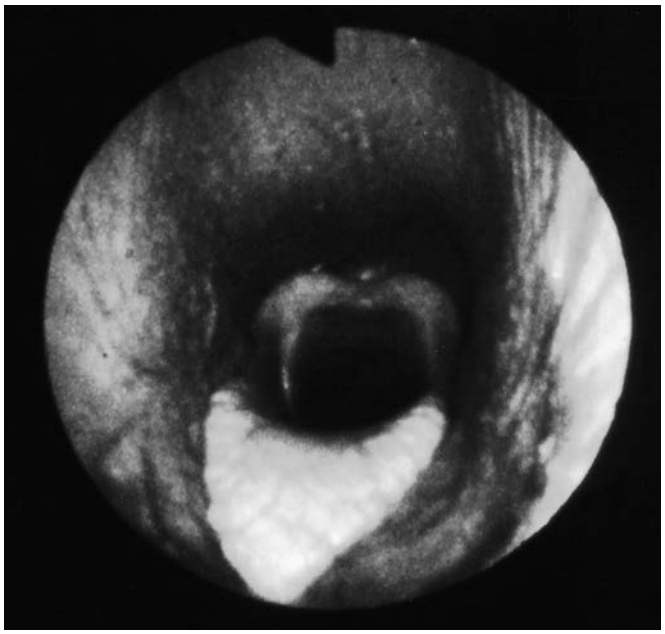

FIG. 31-1 Normal equine larynx. The larynx is directly visualized by endoscopy, with both structure and symmetry evaluated. *(Courtesy Dr. Corinne Sweeney, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

Radiography

Radiographs are indicated when the clinician suspects a congenital anomaly involving any thoracic structure; infectious disease of the pleura, pulmonary parenchyma, tracheobronchial tree, or mediastinum; pneumothorax or pneumomediastinum; thoracic neoplasia of any origin; or trauma. Radiographs are frequently performed along with thoracic ultrasonographic evaluation. If significant accumulation of pleural fluid is suspected based on physical examination findings, the ultrasonographic portion of the examination should be performed first and radiographs obtained following drainage of excess fluid, as fluid may obscure potentially important parenchymal disease. The equipment needed to perform radiographic evaluation of the upper airway is available in most private practices, while most large referral and university practices will have the equipment needed to perform thoracic radiography in larger patients such as adult horses and cattle. Conventional and digital radiography are available to most practitioners. Digital radiography has replaced conventional radiography in many practices and referral clinics because of recent improvements in affordability and the range of systems offered. Advantages to these systems include portability and speed of image processing along with a greater range of radiographic exposures and tools for image manipulation.[9] Because of its configuration, the thorax in adult horses and cattle is filmed as standing lateral, generally requiring a series of three to four separate but overlapping images; thus the benefit of the ventrodorsal view in which the two lungs may be compared is lost. Obtaining standing radiographs bilaterally may aid in localizing lesions to one hemothorax or the other. Neonates and small ruminants can be more readily handled and retained in recumbent positions, allowing for multiple recumbent views.

VetBooks.ir

Other imaging modalities, such as computed tomography (CT) and magnetic resonance imaging (MRI), are available at select referral practices and may aid in the characterization of certain upper airway disorders in large animal species. In horses, CT has been used in the diagnosis of sinonasal disease, particularly ethmoid hematomas,[10] and MRI has been used for the premortem diagnosis of laryngeal dysplasia associated with branchial arch abnormalities.[11] The application of CT and MRI toward routine use in the diagnosis of airway disease in large animal species is limited because of availability of equipment, cost of procedure, the need for general anesthesia in most instances, and size restrictions. Imaging of pulmonary disease is limited to immature animals or smaller species such as camelids.[12-14]

Skull and cervical radiographs offer diagnostic information for evaluation of the upper respiratory tract. For large animal species, standing lateral skull films are easily obtained, and, with practice and adequate sedation, ventrodorsal and oblique projections can be obtained in most patients. Certain difficult patients may require general anesthesia in order to obtain radiographs of diagnostic quality. Skull radiographs image the sinuses, pharynx, and larynx, allowing for assessment of anatomic dimensions of the pharyngeal and laryngeal structures. Sinuses affected by neoplasia or inflammation may show abnormal tissue density, a horizontal fluid line on a standing lateral film, bone lysis around the affected sinus, or alveolar periostitis. Thorough evaluation of the sinuses and nasal passages requires lateral, dorsoventral, and oblique views. Foreign bodies can be assessed in many cases. The equine guttural pouches are evident on lateral skull projection, and abnormal fluid accumulation, distortion by enlarged retropharyngeal lymph nodes, and emphysema can be radiographically apparent.

Radiographic assessment of the thorax of large animals remains preferable to ultrasonographic examination for detection of diffuse parenchymal diseases, such as interstitial pneumonia, pulmonary edema, equine multinodular pulmonary fibrosis (EMPF), fungal pneumonia, acute lung injury (ALI), acute respiratory distress syndrome (ARDS), chronic disorders, and deep parenchymal or mediastinal abscesses. Unfortunately, many radiographic changes in equine respiratory disorders tend to be nonspecific or, in certain diseases, such as EIPH, inflammatory airway disease, or heaves, minimal to nonexistent.

Four types of radiographic patterns are described for the thorax: alveolar (airspace), interstitial, bronchiolar, and vascular. Opaque areas coalesce and fully obliterate vessels and bronchi in the alveolar pattern, air bronchograms may be prominent, and this pattern is common in pulmonary edema, pulmonary hemorrhage, EMPF, ALI, ARDS, lung consolidation, and neoplasia. Interstitial patterns are the most common pattern noted in equine thoracic radiographs and are characterized by a blurring of the edges of pulmonary vessels, a diffuse increase in lung density, and variable reticular, linear, and nodular opacities. The reticular pattern is most commonly associated with more diffuse infectious lung diseases, pulmonary edema, interstitial pneumonia, and pulmonary fibrosis, whereas the irregular linear pattern is seen most commonly with resolving bronchopneumonia. A nodular pattern is seen with abscesses, granulomata, and neoplasms. It is rare to see a pure bronchial pattern in a horse; it is usually seen in association with an interstitial pattern. An exception is paired linear opacities or numerous small circular opacities (donuts) representing thickening of large or medium airways in equine bronchitis/bronchiolitis. The vascular pattern is seen in horses radiographed immediately after exercise or in animals with left to right cardiac shunts. Finally, extraparenchymal problems such as pleural effusions or free gas may be seen on thoracic radiographs of large animals. Thoracic radiology may be used for evaluation of potential rib fracture, but it is far less sensitive than thoracic ultrasonography in this regard.

Ultrasonography

Thoracic ultrasonography, a companion to thoracic radiography, is useful for diagnostic, therapeutic, and prognostic evaluation of the extraparenchymal thorax, the pleural space, and the peripheral (superficial) parenchyma of the lung. Unlike thoracic radiography, for which specialized equipment is needed to image the adult large animal, thoracic ultrasonography is an imaging technique readily available to most practitioners. In many instances it is superior to thoracic radiography as an imaging method; examples include evaluation of pleural effusions, assessment of thoracic trauma, evaluation of neoplasms or granulomata, detection of mediastinal masses/abscesses, and guidance of transthoracic lung biopsy.[15,16] Ultrasonography is considered greatly superior to thoracic radiography in the detection of rib fractures.[17] This imaging technique should be considered for complete evaluation of any large animal with suspected or diagnosed pulmonary disease.

Ultrasonography is generally performed with the patient standing, although in neonates lateral recumbency may be preferred or even necessary, and sound waves are generated by piezoelectric crystals, transmitted to the area of interest through a skin coupling gel with subsequently reflected echoes detected by the same crystal. Echo signals from all tissue interfaces are displayed on a screen, which can be photographed for a permanent record or stored digitally. Air trapped beneath the haired skin can interfere with the process, as can excessive skin dirt, so preparation of the acoustic window usually involves hair removal and cleansing in order to get the best image possible.

Although ultrasound waves will not penetrate the aerated portion of the lung, limiting the examination to extraparenchymal surfaces in normal horses, ultrasonography is superior to thoracic radiography for the evaluation of these areas of the chest. Small amounts of pleural fluid that would be missed on auscultation, percussion, or thoracic radiographs can be detected, and the amount and character of pleural effusion in each hemithorax can be evaluated separately.[15] Clear fluid is anechoic, but inflammatory cells, gas, and fibrin are echogenic, causing opacities that can be seen floating in pleural fluid and altering the general echogenicity of the fluid. Because of this, ultrasound is the method of choice for diagnosis and monitoring of pleural space disease. Ultrasonography should be used to guide catheter placement for drainage of accumulated fluid in the pleural space. The pleural surfaces are imaged well by ultrasound with thickened or roughened areas easily detected. Lack of normal independent movement of the visceral and parietal pleural surfaces during the respiratory cycle, suggestive of adhesion formation, can be readily monitored.[15,16]

Consolidated lung is a better acoustic medium than aerated parenchyma and can be well visualized. If there is pleuropneumonia with consolidation or atelectasis caused by compression of the ventral lung by pleural effusion, it will be evident. Pulmonary abscesses or masses extending to the lung surface can be imaged and ultrasound can be used for guidance during transthoracic biopsy.[15,16] Thoracic radiography remains superior to ultrasound in the diagnosis of pulmonary parenchymal disease and pneumothorax, but combined the two techniques will improve patient management diagnostically and therapeutically.

Nuclear Medicine Imaging

Nuclear medicine imaging is a very specialized technique available at a few university and private specialty referral practices. Gamma-emitting radioisotopes such as krypton-81m or technetium-99m can be used with an external detector (gamma camera) to assess regional pulmonary ventilation and perfusion in the horse. The procedure is safe and painless. Anesthesia is not needed, and the only requirement is that the patient stand quietly in front of the gamma camera. After the study, the patient must be kept in an isolated area to allow decay and excretion of the radiopharmaceutical (normally no more than 48 hours), and, of course, all pertinent radiation regulations must be strictly adhered to.

The radioisotope is bound to albumin aggregates of 10 to 15 micrometers in diameter. When injected into a peripheral vein, that is, the perfusion scan, the aggregates become trapped in the

VetBooks.ir

pulmonary arterial vasculature. Given even and thorough mixing in the right ventricle, the resulting image illustrates the perfusion distribution of the pulmonary arterial system. The ventilation scan is generated when the horse inhales aerosolized radioisotope particles through a closed circuit system.[18] The particles are small enough in diameter to be deposited in the alveoli and small conducting airways with the gamma camera recording the sites of deposition. Together, the ventilation and perfusion scans allow for evaluation of the ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio, important in evaluation of certain respiratory problems such as EIPH (high $\dot{V}/\dot{Q}$ areas), pulmonary thromboembolism (high $\dot{V}/\dot{Q}$ areas), and heaves (low $\dot{V}/\dot{Q}$ areas).[19] Additional uses are in the evaluation of deposition in the lung of aerosolized radiolabeled medications such as albuterol[19] and the evaluation of mucociliary clearance or tracheal mucus transport. In the latter, the time a bolus of radioisotope requires to cover a given tracheal distance is recorded in millimeters per minute and compared with normal ranges.[21]

Arterial Blood Gas Analysis

Arterial blood gas determinations are the most sensitive indicator of respiratory function readily available to the clinician. The most easily accessed arteries for sampling are the metatarsal, temporal, facial, and brachial arteries (Fig. 31-2). In cattle the coccygeal artery on the ventral aspect of the tailhead is easily accessible. Heparin is the only acceptable anticoagulant for blood gas samples, and all gas bubbles must be removed and the syringe capped to prevent equilibration of the sample with room air. Use a short (1-inch) small-gauge (25-gauge generally) needle and a 1- to 3-mL syringe for most samples. The syringe and needle can be purchased preheparinized especially for arterial blood gas samples, or regular syringes and needles may be heparinized by aspirating a small volume of heparin into the syringe via the needle and then forcefully expelling the air and heparin from the syringe three times. This minimizes the effect heparin might have on any reported values from the blood gas analyzer. Pulsation of blood from the needle, spontaneous filling of the syringe, and bright color of the blood all confirm a successful arterial puncture. If successful arterial puncture is questionable, then a comparison sample may be drawn from the jugular vein. Once the sample has been drawn, the vessel should be manually compressed for 2 to 5 minutes to prevent hematoma formation. If the sample will not be analyzed within 10 minutes, it should be placed on ice to slow metabolism of blood cells. The patient's body temperature at the time of sampling should also be recorded, as results are frequently reported at both 37° C and at the actual temperature of the patient, called *temperature-corrected values*, for pH, P_{O_2}, and P_{CO_2} as these values are known to be temperature variable. Clinically either set of values may be used for evaluating efficacy of treatment, but comparisons should only be made between samples reported similarly as either temperature corrected or not.

Portable arterial/venous blood gas analyzers have become relatively inexpensive. Because of their ease of use and rapid return of results, they are now making arterial blood gas analysis more practical for use in the field and the technique is no longer reserved for large institution or referral practices.[22,23] Awareness of potential device-, species-, or age-related differences in reference ranges, as well as awareness of any limitations in accuracy, is critical for proper interpretation of results. It is veritably impossible to manage severe respiratory disease without knowledge of arterial blood gas parameters. Pulse oximetry is also being more commonly employed in some institutions and referral centers. These monitors measure oxygen saturation of hemoglobin, useful for diagnosing severe hypoxemia or recognizing desaturation events, but provide no measure of actual arterial oxygen and carbon dioxide partial pressures. The most common abnormalities recognized with arterial blood gas analysis in an animal that is breathing room air are hypoxemia with normocapnia or hypocapnia and hypoxemia with hypercapnia. There are five primary means by which hypoxemia develops in any animal. For our purposes, hypoxemia is defined as decreased oxygen tension of the arterial blood (decreased Pa_{O_2}) and hypoxia is defined as decreased oxygen concentration at the level of the tissue, with or without hypoxemia. Hypoxia results from hypoxemia, decreased perfusion of the tissue bed in question, or decreased oxygen carrying capacity of the blood due to anemia or hemoglobin alteration.

Hypoxemia develops from (1) low partial pressure of oxygen in the inspired air, such as seen in high altitude or in an error mixing ventilator gas, resulting in lower than anticipated partial pressure of oxygen (altered Fi_{O_2}); (2) hypoventilation; (3) $\dot{V}/\dot{Q}$ mismatch; (4) diffusion limitation; or (5) intrapulmonary or intracardiac right to left shunting of blood. Mild to moderate hypoxemia is not an uncommon finding in neonates, but it must be evaluated in terms of the current age of the foal and its position. The difficulty in obtaining the sample must also be considered, as severe struggling can variably affect the arterial blood gas results. If the lung is significantly involved in the underlying pathology, such as with severe pneumonia, ALI, or ARDS, increased Pa_{CO_2} may very well be present, representing respiratory failure.

Hypoxemia is usually treated with intranasal humidified oxygen insufflation at 4 to 10 L/min for neonates and 10 to 15 L/min in adults. Hypercapnia is not easy to treat. It is important to try to distinguish between acute and chronic hypercapnia. Acute hypercapnia is usually accompanied by a relatively dramatic decrease in blood pH of 0.008 pH units for each 1-mm Hg increase in Pa_{CO_2}. This respiratory acidosis can promote circulatory collapse, particularly in the concurrently hypoxemic and/or hypovolemic patient. The effects of more chronic CO_2 retention are less obvious as the time course allows for adaptation. The pH change is less, about 0.003 pH units per 1-mm Hg increase in Pa_{CO_2}, as it is balanced by enhanced renal absorption of bicarbonate by the proximal renal tubule. Most patients with acute respiratory distress are in the acute stages of respiratory failure, but chronic adaptation will begin to occur within 6 to 12 hours and will be maximal in 3 to 5 days. An increase in bicarbonate will be noted, particularly if the acidosis is primarily respiratory in origin, and pH may be within the normal range.

Alveolar gas exchange is readily estimated by determining the alveolar-arterial (A-a) gradient for oxygen, computed by subtracting the Pa_{O_2} measured by the arterial blood gas from the calculated alveolar oxygen partial pressure (PA_{O_2}). The PA_{O_2} is effectively estimated using the partial pressure of inspired oxygen (Pi_{O_2}) as follows:[24]

$$PA_{O_2} = \frac{Pi_{O_2} - Pa_{CO_2}}{0.8}$$

The Pi_{O_2} equals the total barometric pressure (760 mm Hg) minus the partial pressure of water vapor (47 mm Hg) multiplied by

VetBooks.ir

TABLE 31-1

Normal Arterial pH and P_{CO_2} Values for Various Species (Nonneonate)

Species	Blood pH	P_{CO_2} (mm Hg)
Bovine	7.32-7.45	35-53
Ovine	7.32-7.54	37-46
Equine	7.32-7.44	38-46
Caprine	7.42-7.46	33-38

the fraction of room air that is oxygen (0.21) and thus equals 150 mm Hg for room air. For patients on supplemental inspired oxygen, the practitioner must remember to recalculate the P_{IO_2} with the new oxygen fraction (F_{IO_2}) (or, if at altitude, the P_{O_2} in the inspired gas), which is only possible in patients receiving inspiratory gas through a closed system. The P_{ACO_2} is obtained from the arterial blood gas measurement. The A-a gradient is normally only 4 to 10 mm Hg; an increase beyond this indicates impaired gas exchange within the lungs, most often the result of $\dot{V}/\dot{Q}$ mismatching. Only an estimate of the A-a gradient can be calculated in patients receiving intranasal insufflation of oxygen, as neither the F_{IO_2} nor the P_{O_2} is known.

A second useful measure is the P_{AO_2}/F_{IO_2} ratio, a component of most definitions of ALI and ARDS.[25] The P_{AO_2}/F_{IO_2} ratio equals the P_{AO_2} obtained from the arterial blood gas divided by the F_{IO_2}, the oxygen fraction in the inspired gases. The normal P_{AO_2}/F_{IO_2} ratio is greater than 300 mm Hg, a ratio less than 300 mm Hg is consistent with a potential diagnosis of ALI, and a ratio less than 200 mm Hg suggests ARDS, a more severe form of ALI. A consensus statement recently defined the conditions of equine neonatal acute respiratory distress syndrome and equine acute lung injury (EqNARDS and EqNALI).[26] Although similar to the definitions for ALI/ARDS in humans and adult veterinary species, the definition of EqNARDS and EqNALI account for the relative hypoxemia of normal neonatal foals compared with adults during the first week of life.[26] For this reason, over the first week of life the P_{AO_2}/F_{IO_2} increases from less than 115 mm Hg to less than 190 mm Hg in EqNARDS and from less than 175 mm Hg to less than 280 mm Hg in EqNALI.[26] The ranges of normal arterial blood gas values for various species are listed in Table 31-1.

Respiratory Function Testing

The major functions of the lungs are to transport gas from the periphery to the site of gas exchange (i.e., the "bellows" function) and to provide gas exchange with the blood, facilitating gas transport to the tissues. The first of these is assessed by means of pulmonary function tests, and the second by arterial blood gas evaluation, discussed above.

Historically pulmonary function tests have primarily been used in horses and in most cases as a research tool in veterinary teaching hospitals. Pulmonary function testing has also recently been described in awake adult llamas[27] and alpacas.[28] Portable technologies, such as flowmetric plethysmography, allow the use of noninvasive techniques in the field, and the awareness of their clinical utility to practitioners has grown.[29,30] Measurements of pressure, flow, and volume allow computation of a variety of ventilatory variables. Their ability to demonstrate airway obstruction and airway hyperresponsiveness[31] makes them clinically valuable in the diagnosis and characterization of inflammatory airway disease (IAD) and recurrent airway obstruction (RAO) in horses.[31] They may also provide an objective means with which to monitor response to therapy.[30-35] These techniques are described in greater detail in a later portion of this section.

Collection and Evaluation of Respiratory Secretions

TRACHEAL ASPIRATES AND BRONCHOALVEOLAR LAVAGE. Various spaces in the respiratory system can be aspirated or lavaged for diagnostic or therapeutic purposes. The most commonly performed procedure is the tracheobronchial aspirate. By aspirating from the airways caudal to the larynx, a sample without pharyngeal contamination is obtained.

In both the horse and the ruminant the procedure is performed with the animal standing. Sedation or restraint may be needed. A small area over the trachea in the middle third of the neck is clipped and routinely sterilely prepared. The skin is anesthetized using a local block of 2% lidocaine, generally less than 3 mL given as a "bleb" subcutaneously, and a small stab incision is made. A trocar or angiocatheter needle is introduced on the midline between muscle bundles, with the beveled edge facing ventrally to decrease the opportunity for inadvertent cutting of the tubing when it is introduced or manipulated, and the ventral tracheal wall is punctured between two cartilaginous rings. The distal end of the trocar or needle is then advanced distally in the trachea, with the bevel facing ventrally, taking care not to lacerate the dorsal tracheal mucosa. Sterile polyethylene tubing or the catheter from the angiocatheter is introduced through the trocar or needle for about 30 cm. A needle or sharp trocar should be withdrawn to prevent severing the tubing or catheter, but a cannula with rounded edges may be left in place. Approximately 20 to 30 mL of nonbacteriostatic sterile saline solution is introduced quickly. Intermittent aspiration is performed as the tubing is gradually withdrawn. The tubing can be advanced again if a guarding cannula has been left in place to prevent introduction of skin contamination. Additional saline solution aliquots can also be introduced. Once an adequate sample has been obtained, the tubing is completely withdrawn, followed by the withdrawal of any guarding catheter or trocar. Injectable antimicrobial solution or suspension can be infiltrated at the skin incision site if a septic sample is suspected, and in horses and small ruminants a sterile dressing can be applied for 24 hours if desired. Possible complications include subcutaneous emphysema (usually peritracheal but may extend into the mediastinum), local cellulitis, or cutting of the catheter at the needle and loss into the airway. The latter is usually resolved because the catheter is rapidly coughed up, but good technique should prevent this complication. If necessary, the severed catheter can be retrieved endoscopically. The sample should be cultured for aerobic bacteria. Anaerobic colonization is possible, and appropriate cultures should be made if these organisms are suspected (evidence of pleural effusion, consolidation, abscessation, fetid breath, history of aspiration). For patients with prior antimicrobial therapy, it is advised to discontinue antibiotics for 72 to 96 hours before culture, although a recent study has shown reliable recovery of bacteria using bronchoalveolar lavage fluid from foals receiving therapy.[6]

Airway aspiration can also be performed during routine endoscopy of the trachea using an aspiration catheter advanced through the endoscope biopsy channel, but there is potential for pharyngeal contamination. Results comparing culture from a protected aspiration catheter passed through an endoscope compared favorably with traditional percutaneous tracheobronchial aspirate.[5]

A direct smear and Gram stain can be used as an initial guide for antimicrobial therapy pending culture results. Cytologic evaluation can be extremely valuable in differentiating among infectious, allergic, parasitic, and neoplastic processes. Transtracheal aspirates from clinically normal horses contain columnar ciliated epithelial cells, a few neutrophils, and multiple mononuclear cells. Increased percentages of neutrophils and the presence of mast cells, eosinophils, giant cells, and hemosiderophages have been found in aspirates from normally performing Thoroughbred racehorses, indicating some airway inflammation in "normal" equine atheletes.[8] Mucus, large spores, and fungal hyphae may be found in the absence of airway disease and must not be overinterpreted. In cases of pneumonia, neutrophils may constitute 40% to 90% of the cellular sample. Bacterial pneumonia causes a more degenerate appearance of neutrophils, and intracellular bacteria may be found. Equine lungworm is characterized by the presence of large numbers of eosinophils and occasionally a larva. In ruminants the most important information gathered in patients with bronchopneumonia is usually the result of culture and antimicrobial sensitivity testing.

VetBooks.ir

Bronchoalveolar lavage (BAL) involves obtaining a sample from the terminal airways and alveolar region and is described in horses, cattle, and camelids.[28,36,37] BAL is performed using a long endoscope (2 to 3 m) or BAL (e.g., double-lumen or cuffed Bivona [Smiths Medical, Norwell, Mass.]) or MILA (MILA International, Elanger, Ky.) tubes introduced through the nares. Endoscopic BAL allows for more exact placement of the end of the endoscope, so a clear understanding of the anatomic location of the distal airway lavage is available. It also allows for the characterization of lower airway secretions and mucosal inflammation. Use of the BAL tube is a blind technique, but most frequently the dorsal lung of one hemithorax is sampled. BAL is contraindicated in horses that are expected to exercise within 24 hours of the procedure and in any animal demonstrating signs of respiratory distress, marked tachypnea, paroxysmal cough, or significant hypoxemia.

Proper sedation is critical for performing BAL. In horses, the addition of butorphanol may reduce cough that is typically associated with this procedure. Instillation of dilute 2% lidocaine, particularly when passing the tube into the trachea or past the level of the carina, may also decrease coughing associated with this procedure. Passage of the tube into the trachea can be facilitated by stretching the head horizontally. The endoscope or tube should be passed until it is wedged in the most distal bronchus. If using a cuffed BAL tube, the cuff should be inflated to seal the airway once wedged. In adult horses, it is recommended to infuse a total of 300 to 500 mL of warm (37°) sterile physiologic saline in aliquots of 60 to 250 mL. Smaller lavage volumes may be necessary in smaller animals. Fluid may be instilled via prefilled syringes or via a solution administration set using a pressure bag with fluid bag or pressure bulb with fluid bottle. The BAL sample is collected via continuous aspiration with syringes or a suction pump using low suction pressure. Aliquots should be pooled for analysis. The presence of surfactant (foam) and turbidity on gross inspection is suggestive of a properly obtained sample.

BAL has the advantage of sampling the airways nearest the parenchymal region, but only a limited area of the lung is sampled instead of the pooled secretions from a tracheobronchial aspirate. Thus bronchoalveolar lavage may be superior to tracheobronchial aspirate in evaluation of horses with diffuse chronic lung diseases of the peripheral airways, and molecular analysis of fluid is performed for identification of certain viral or bacterial species. Cytologic findings of BAL and tracheobronchial aspirates correlate poorly, and a tracheobronchial aspirate should be performed prior to a BAL if an infectious process is suspected. Bronchoalveolar lavage cytology is valuable in evaluation of fungal infections, inflammatory airway disease, and the assessment of therapeutic response. Normal cell distribution of BAL fluid in healthy horses reveals predominantly macrophages (50% to 70%) and lymphocytes (30% to 50%) with lower percentages of neutrophils (<5%), mast cells (<3%), and eosinophils (<0.1%). Macrophages are the predominant cell type (89%) in BAL fluid of healthy calves,[37] whereas alpacas may have a greater abundance of neutrophils (10%).[28]

Thoracocentesis

Aspiration from the pleural space is a simple, easily performed, inexpensive procedure that can be both diagnostic and therapeutic. In the horse with septic or neoplastic effusions, sedation is often unnecessary, because the procedure causes only minimal additional discomfort. Following ultrasonographic evaluation of the thorax, a point is chosen where drainage or fluid sampling would seem most appropriate, frequently found in the sixth or seventh intercostal space 10 cm dorsal to the olecranon and above the lateral thoracic vein. The area should be clipped, if it was not clipped for the thoracic ultrasound examination, and surgically prepared. Multiple sites may be needed in horses with loculated pockets of fluid in the pleural cavity and these sites should also be chosen using ultrasonography. The skin and intercostal tissue down to the pleura are anesthetized with lidocaine, and a stab incision is made. A sterile 2- to 3-inch teat cannula or bitch catheter is introduced immediately cranial to the rib border to avoid the intercostal nerve and vessel along the caudal aspect of the ribs. The cannula should be attached to sterile intravenous extension tubing and a three-way stopcock. While the cannula is advanced bluntly through the parietal pleura, a sudden loss of the force required to advance is felt. Aspiration should be attempted at this time. The orientation of the cannula can be varied to reach as much fluid as possible. Normally only a few milliliters of straw-colored fluid are obtained. In cases of pleural effusion, as much as 30 L may be removed from each side of the chest (Fig. 31-3). If fluid is excessive, the tubing can be extended over a bucket for gravity drainage, or a vacuum pump with a fluid trap can be attached. When the procedure is complete, a purse-string suture is placed around the stab incision and the cannula is withdrawn while the suture is tightened. In cases where the effusion is large and expected to continue forming for several days, the initial drainage can be performed by placing a chest tube instead of a puncturing the pleural space with a teat cannula. If a chest tube is to be left in place, it should be secured with a Chinese finger trap suture and the end covered by a Heimlich valve to prevent aspiration of air into the thorax through the tube. If the thorax is being drained rapidly, the patient should be watched carefully for signs of distress, as draining of large volumes can alter cardiovascular parameters significantly.

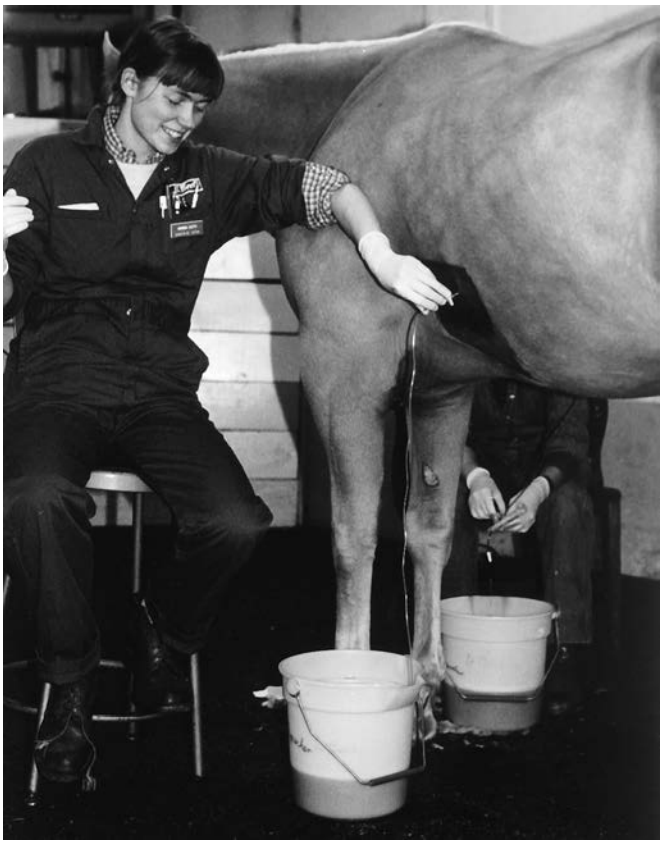

FIG. 31-3 Thoracocentesis and therapeutic drainage in the horse. Pleural effusion can be large and bilateral. Samples should be obtained for culture and cytologic examination at the time the chest is drained. *(Courtesy Dr. Corinne Sweeney, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

Increasing opacity, presence of fibrin clumps, and malodor of pleural fluid all suggest relative progression from transudate to septic exudate containing inflammatory cells and debris. A putrid odor suggests the presence of anaerobic bacteria. Samples should be cultured for aerobic and anaerobic organisms. A white blood cell (WBC) count of 10,000/mL or less is considered normal; fewer than 60% are normally neutrophils, the remainder being lymphocytes and macrophages. The proportion and total number of neutrophils increase with pleuritis. Erythrocytes are normally not present in the absence of a traumatic tap. The protein concentration is normally less than

VetBooks.ir

3.5 g/dL, and pH should be approximately 7.4. Additional metabolic values that give early indication of sepsis can be obtained on pleural fluid samples collected after filtration through a blood administration set to remove fibrin and debris potentially detrimental to analytic equipment. Pleural fluid pH, P_{CO_2}, and concentration of glucose, lactate, and bicarbonate can be directly compared with similar analysis of venous blood from the patient. A septic pleural exudate is acidic, with decreased glucose and bicarbonate but increased lactate and P_{CO_2} compared with venous blood concentrations or tensions, apparently reflecting metabolic activity of phagocytic cells and bacteria and development of an anaerobic environment.[38] Of these values, low pleural fluid glucose concentration (<40 mg/dL) has the best correlation with sepsis.[39]

Neoplastic cells may be found in cases of lymphosarcoma, adenocarcinoma, or other neoplasms. Equine gastric squamous cell carcinoma occasionally presents with neoplastic pleural effusion. If neoplastic effusion is suspected but diagnostic cells do not exfoliate into the pleural fluid, pleuroscopy under sedation and local anesthesia can be used directly to visualize and obtain biopsy samples of intrathoracic lesions. The technique of pleuroscopy is beyond the scope of this chapter.

Mediastinal fenestrations may be occluded by fibrin and cell debris; therefore each side of the thorax should be evaluated separately. In the horse a transtracheal aspirate for culture should also be performed because of the common association of pleuritis with bacterial pneumonia and pulmonary abscessation. Although identical organisms are generally isolated from both samples, this is sometimes not the case.

Sinus Trephination

Sinusitis is performed with some frequency in horses or ruminants. Clinical signs indicating a need for sinus trephination include foul-smelling purulent nasal discharge (the most consistent sign with dental disease or invasive tumors), facial malformation, exophthalmos, stertorous breathing, and epistaxis. Sinus cysts, neoplasms, or hematomas occur occasionally and result in serosanguineous discharge. When the physical examination, especially percussion, and radiographic findings indicate it, the sinus should be trephined for diagnostic aspiration, drainage, and flushing, if necessary. In some cases, sinoscopy may be indicated, particularly when the true extent of the disease process is difficult to determine or if biopsy samples are needed.

In the horse the frontal, sphenopalatine, and ethmoidal sinuses communicate with the posterior chamber of the maxillary sinus and drain through the nasal maxillary opening into the middle meatus. The anterior chamber of the maxillary sinus is separated by an osseous septum that often breaks down with infection, making the posterior chamber of the maxillary sinus the most productive site for diagnostic aspiration. A line is drawn from the medial canthus of the eye perpendicularly to the facial crest. After tranquilization and local anesthesia, the sinus is approached with a Steinmann pin midway on this line. Once the sinus has been entered, it should be aspirated by using a sterile 16-gauge needle or canine urinary catheter. One skin suture will suffice for closure. If purulent material or fluid within the sinus is under pressure, some leakage into the subcutaneous space may occur, with resulting cellulitis. The sample should be cultured for aerobic and anaerobic bacteria and examined cytologically for signs of septic inflammation or neoplastic cells.

The frontal sinus is trephined more often for flushing in chronic cases than for diagnostic purposes. The approach is 2.5 cm lateral to the midline of the face and 2.5 cm caudal to the point where the nasal bones begin to diverge.

In cattle the frontal sinus is most often affected with septic inflammation as a consequence of dehorning. Purulent material frequently accumulates in the postorbital diverticulum of the sinus. This site is approached for trephination 4 cm from the edge of the orbital cavity just dorsal to the temporal (lateral) canthus of the eye.

Postdehorning sinusitis in goats can be a severe condition, especially in animals dehorned when mature. The frontal sinus contains numerous septae, creating poor drainage; the bony plate protecting the brain is thin, so that septic necrosis of bone leading to meningitis may occur. Therefore, in mature goats with sinusitis, appropriate systemic antimicrobial therapy and vigorous curettage of the affected areas should be used. A bone flap similar to the technique used in chronic maxillary sinusitis may be required to expose the frontal sinuses to curettage adequately.

Guttural Pouch Catheterization

When indicated by radiography and/or endoscopy, the equine guttural pouches are easily catheterized for diagnostic sampling and lavage. Sampling can also be achieved by placing thin tubing through the biopsy channel of the endoscope, as for tracheobronchial aspiration, and directly aspirating or aspirating following introduction of sterile saline. Lavage can also be performed through the biopsy channel. The patient should be tranquilized so that the head drops, facilitating drainage of the secretions by gravity. A Chambers mare catheter can be passed through the ventral meatus into the pharynx if the endoscope is not to be used for the sampling or lavage. The curved end is directed beneath the flap of the medial lamina of the pouch ipsilateral to the nostril used for passage. Successful passage is indicated by lack of resistance while the catheter is inserted deeper than if it were in the pharynx. The position of the catheter tip in the pharynx can be observed through an endoscope placed up the opposite nasal passage. Once the catheter is within the pouch, it can be used to obtain a sample, to drain excessive secretions, or to act as a conduit for flushing. A self-retaining uterine catheter can be left in place for repeated flushing, but the Chambers catheter can be passed repeatedly with no complications.

Lung Biopsy

Lung biopsy is most often done in the horse and should be used in conjunction with other, less invasive diagnostic techniques such as ultrasonography, radiography, and transtracheal aspiration. Biopsy is indicated to obtain a histologic diagnosis or prognostic information primarily in cases of diffuse lung disease, because the sample obtained is generally very small. A more useful parenchymal sample is obtained by means of percutaneous rather than endobronchial biopsy; complications of percutaneous biopsy are uncommon but they do occur. Thoracoscopically guided pulmonary wedge resection is also an option for collection of a parenchymal sample and enables direct visualization of the lung prior to biopsy as well as collection of a larger tissue sample. The procedure is relatively safe but is more invasive and requires specialized equipment and expertise. For percutaneous biopsy a large gauge (14-gauge) 15-cm or longer biopsy needle, with a sample "slot" length of 22 mm, provides an excellent sample. Lung biopsy is easier and complications fewer with newer spring-loaded biopsy instruments than with the older hand-operated biopsy instruments. Discomfort is minimal, and sedation may or may not be needed. The site for biopsy should be determined following ultrasonographic evaluation for the thorax and should be performed away from common locations of major pulmonary vessels. Caudal and dorsal locations are generally chosen. The site should be widely clipped, surgically prepared, and infiltrated with local anesthetic down to the pleura. The biopsy needle is inserted through a stab incision just cranial to the rib, similar to catheter placement for pleural fluid sampling and drainage, and directed medially through the intercostal muscles and parietal pleura. The needle should be advanced the distance indicated by ultrasonographic measurement and then sharply advanced less than 1 cm to enter the lung parenchyma. The biopsy is obtained by "firing" the spring-loaded instrument; the biopsy instrument is then withdrawn. If no specimen is obtained, the procedure can be repeated. After sufficient biopsy specimens have been obtained and the biopsy instrument withdrawn, a single skin suture can be placed at the incision site, but no additional aftercare is needed. The specimen should be placed directly in 10% formalin or glutaraldehyde for fixation. If additional samples may be safely obtained, they should be submitted for bacterial and fungal culture, and potentially for more advanced molecular diagnostic

VetBooks.ir

techniques, and handled appropriately for the desired testing technique. Complications of lung biopsy have been reported to range from transient epistaxis or hemoptysis, which is to be expected, to more severe pleural and parenchymal hemorrhage. Lung biopsy is not indicated for pleuropneumonia cases but is generally required to differentiate between equine multinodular pulmonary fibrosis, discrete fungal lesions, and potential neoplasia, when accurate diagnosis is required for therapeutic and prognostic purposes.

Molecular Techniques

Infectious pulmonary disease represents a diagnostic challenge for the equine practitioner. A presumptive diagnosis can often be made based on the history, physical examination, clinical impression, complete blood cell count, radiography, and endoscopy. Definitive identification of the causative agent(s) is necessary to ensure that the appropriate therapeutic and prophylactic protocols are instituted.

Culture of infectious pathogens (viral or microbial) is an indispensable diagnostic technique and should be attempted in all cases of pulmonary disease. However, cultivating infectious pulmonary pathogens from clinical specimens is time-consuming and may require from days to months before an organism is identified, potentially delaying appropriate management. Molecular recognition systems that can be used for rapid identification can improve response time and reduce the number of susceptible animals exposed to the infectious pathogen.

Several technologic innovations have improved the rapidity and sensitivity with which microorganisms are identified.[40] Immunologic assays and nucleic acid–based methods for the identification of bacterial, viral, and fungal pathogens have found clinical application in the diagnosis of pulmonary disease. In addition, these techniques are widely used in research to characterize immunologic response (e.g., cytokine expression) to a variety of infectious and inflammatory respiratory diseases.

IMMUNOLOGIC TECHNIQUES. Immunologic techniques for detection of bacterial, viral, and fungal pulmonary pathogens have been developed. Immunoassays rely on interactions among the bacterial, viral, and fungal antigens and radioisotope-, enzyme-, or fluorescent-labeled antibodies. The use of polyclonal antibodies tends to increase the sensitivity of the assay as the preparation may contain antibodies to multiple epitopes on the target antigen, thus increasing the chance of antigen detection, but at the same time the use of polyclonal antibodies tends to decrease assay specificity due to their heterogeneous nature. Test specificity can be improved by the use of monoclonal antibodies as these antibodies interact with only a single well-defined epitope or very similar epitopes. Immunofluorescence, although labor intensive and time-consuming, is considered highly sensitive and specific, particularly for virus-infected cells. The enzyme-linked immunosorbent assay (ELISA) is available for the diagnosis of a wide range of infectious respiratory diseases. For certain pathogens the ELISA has the advantage of rapid turnaround of results and minimal labor; however, these tests may be subject to false-negative and false-positive results. Virus neutralization (VN) assays are also widely used and are considered highly accurate and sensitive. Unfortunately, VN is more expensive, labor intensive, and time-consuming compared with other diagnostics.

Immunohistochemistry is rapidly becoming a standard diagnostic tool for the identification of viral, bacterial, and protozoal pathogens in tissue sections. This technique depends on polyclonal or monoclonal antibodies binding to a target antigen and the demonstration of this interaction by colored histochemical reactions visible by light microscopy or by emittance of fluorescence detectable after ultraviolet light illumination. Immunohistochemistry is highly versatile, and assays have been developed to detect a variety of equine pulmonary pathogens including, but not limited to, equine herpesviruses, equine viral arteritis virus, Hendra virus, *Rhodococcus equi,* and *Pneumocystis carinii* (renamed *P. jiroveci* in humans) in tissue sections. Recent advancements in methodology have increased the ability to detect antigens in formalin-fixed tissues.

NUCLEIC ACID–BASED TECHNIQUES. Nucleic acid–based techniques for the diagnosis of equine pulmonary disease are becoming widely accepted because of the sensitivity, specificity, and speed with which results can be obtained. These assays can detect nucleic acid of both live and dead pathogens at very low concentrations, often less than 100 copies per microliter, and in a wide variety of specimens. Polymerase chain reaction (PCR) may also be advantageous compared with conventional microbiology in that it enables identification of organisms that are difficult to culture. Bacterial, viral, and fungal pulmonary pathogens can be discriminated based on nucleic acid sequences unique to that particular organism. PCR is the most widely used molecular diagnostic technique in both research and clinical laboratories. PCR involves the enzymatic replication of a target region of deoxyribonucleic acid (DNA) as defined by a set of oligonucleotide primers. DNA polymerase synthesizes each complementary strand of the target region in the 5′ to 3′ direction, and the amount of DNA that is synthesized increases exponentially.

Modifications to standard PCR, such as reverse transcriptase PCR and real-time PCR (RT-PCR), have greatly expanded its diagnostic utility. Reverse transcriptase PCR enables identification of viruses whose genome is composed of ribonucleic acid (RNA). Viral RNA is reverse transcribed into complementary DNA (cDNA) through an initial reverse transcriptase step, and the cDNA is then amplified with DNA polymerase. Commercially available single-step kits have increased the diagnostic utility of this technique.

Real-time PCR (qPCR) combines PCR amplification with simultaneous detection of the amplified products, allowing quantification of PCR products. Compared with traditional PCR, real-time PCR reduces the risk of contamination and increases sensitivity and speed of detection. DNA is detected with either nonspecific fluorescent dyes (e.g., SYBR Green I, Life Technologies Corp., Grand Island, N.Y.) that intercalate into double-stranded DNA or sequence-specific hydrolysis DNA probes (TaqMan, Applied Biosystems, Foster City, Calif.). The PCR reaction is carried out in a reaction tube to which an optical device is attached to read the fluorescent signal generated during each cycle of PCR reaction. Increases in the reported fluorescence are proportional to the increase in PCR product. By monitoring the changes in degree of fluorescence, the time in which a transition is made from exponential to log phase amplification can be determined and compared with that of a standard control to determine the initial template concentration. Real-time PCR may be combined with reverse transcriptase PCR (qRT-PCR) for the quantification of messenger RNA.

Intercalating dyes such as SYBR Green I bind to all double-stranded DNA undergoing amplification. Increases in DNA product yield proportional increases in the intensity of measured fluorescence, and thus the DNA concentration can be quantified. The use of intercalating dyes precludes the need to develop probes specific for each unique target sequence. The potential for nonspecific binding of the dye is the primary disadvantage with this technique. Hydrolysis probes, such as TaqMan, are short dual fluorophore-labeled oligonucleotides with a 5′-terminal reporter dye and 3′-terminal quencher dye. These probes can be tailored to detect specific pathogens. In the TaqMan assay, the probe binds to a nucleic acid sequence within the target region. During amplification, the *Thermus aquaticus (Taq)* polymerase hydrolyzes the probe that separates the reporter from the quenching dye and allows the emission of fluorescence. The amount of fluorescence emitted is proportional to the accumulation of specific PCR product. As these probes target only DNA containing the probe sequence, amplification of nonspecific PCR products should not result in emission of fluorescence. Because of its specificity a different probe must be provided for each unique target sequence. With the increased use of PCR as diagnostic tests, there is increased demand for standardized techniques and internal control measures. PCR is a highly sensitive test and may produce false-positive results, commonly attributed to contamination. False-negative results may occur as a result of the presence of enzyme inhibitors in the sample that suppress DNA amplification. Control

VetBooks.ir

plasmids—containing a DNA sequence that would be amplified at the same time as the target DNA but sufficiently mutated so that it could be distinguished from the target DNA sequence after PCR—are increasingly used to identify the presence of inhibitory molecules within the assay due to tissue or sample handling problems or associated with collected tissues.

Flow cytometry is a laser-based technology used to detect and quantify light scatter and fluorescence emitted by fluorescent-labeled cells suspended in liquid as they pass through a laser beam. Combinations of scattered and fluorescent light are identified by specific detectors and analyzed to derive information about the physical and chemical properties of a large number of cells at one time. Immunophenotyping of cells isolated from peripheral blood, tissues, or respiratory secretions is an important application of flow cytometry and may help to better characterize the immunologic response associated with select pulmonary diseases. Flow cytometry is currently used primarily as a research tool.

These assays do not substitute for careful clinical evaluation but can shorten the time to confirmed, accurate diagnosis and thus allow for early initiation of therapeutic strategies and prevention protocols. The continued refinement of available molecular assays, along with the development of newer technologies such as flow cytometry, will not only further our understanding of the molecular biology and immunology of pulmonary disease, but will also improve diagnosis and management.

Pulmonary Function Testing

Daniela Bedenice

Pulmonary function testing (PFT) has emerged as an essential tool in equine referral practice and is largely aimed at describing the severity, anatomic pattern, stability (reactivity), and reversibility of bronchoconstriction caused by noninfectious airway obstruction and inflammation, such as is seen in heaves and inflammatory airway disease (IAD).[1] Clinical indications for noninvasive PFT include assessment of horses with intermittent cough, exercise intolerance, abnormal breathing pattern, and excess mucus, as well as early detection of subclinical disease, evaluation of treatment response, intensive care monitoring, and prediction of outcome. PFT is generally divided into the assessment of respiratory mechanics (mechanical properties of the respiratory system) and gas exchange. Analysis of gas exchange investigates ventilation-perfusion matching, shunt, diffusion capacity, and dead space to tidal volume ratio (V_D/V_T). Lung mechanics, on the other hand, determine the static and dynamic properties of the lung, including resistance, compliance, functional residual capacity (FRC), and ventilatory parameters.[1]

Mechanics of Breathing

The mechanical function of the lung is essentially defined by static and dynamic properties. Tests that are performed with the respiratory system at equilibrium and zero flow are referred to as *static tests*. Examples include measurement of lung volume subdivisions (e.g., FRC) and compliance of the lung and chest wall.[1]

FRC is a measure of the amount of gas that remains in the lungs at end-expiration (end-expiratory volume). FRC is lower in patients with increased "lung stiffness" (reduced elastic recoil of the lung) as well as airway inflammation, whereas FRC increases in patients with expiratory airway obstruction and gas trapping.[2] This test can be easily performed in awake clinical patients via a helium dilution technique.[3] In short, the patient is connected to a reservoir bag at end-expiration to rebreathe a standard, commercial breathable gas mixture of 10% helium (He), 20% oxygen, and the remainder nitrogen for 90 seconds. The dilution of He (a nonexchangeable gas) gives a measure of end-expiratory lung volume.[3]

Measurements of static compliance or "elastic recoil of the lung" require breath holds and have applications only to the anesthetized patient. So-called pressure-volume curves are generated in the relaxed patient during lung deflation from total lung capacity (TLC), using an esophageal balloon technique. Compliance is defined as the lung volume change per unit of pressure change[2]:

$$\text{Compliance} = \frac{\Delta V}{\Delta P}$$

Reduced lung compliance (i.e., increased lung stiffness) may be associated with increased fibrous tissue (pulmonary fibrosis), atelectasis (e.g., underventilated lung), or an increased pulmonary venous pressure, in which the lung becomes engorged with blood. Emphysema and normal aging of the lung, which leads to alteration in elastic tissue, are causes of increased lung compliance.[2]

In contrast to static tests, tests that are performed with the respiratory system in motion (e.g., during quiet breathing) are referred to as *dynamic*. An example of a dynamic measurement is resistance, a measurement that requires flow. Resistance arises from friction of air molecules against airway walls[1]:

$$\text{Resistance} = \frac{\text{Change in pressure } (\Delta P)}{\text{Change in flow } (\Delta V)}$$

The measurement of pulmonary resistance (R_L) using a flow meter attached to a face mask and an esophageal balloon catheter to measure transpulmonary pressure changes is conventional in the horse but is rarely used in the clinical setting.[1] This technique allows computation of both R_L and dynamic compliance (C_{dyn}) at spontaneous breathing frequencies. Maximal transpulmonary pressure change (ΔPPL_{max}) and R_L both increase in cases of obstructive airway disease, whereas C_{dyn} decreases. However, this classic technique is fairly insensitive in detecting subclinical disease[4,5] and has greater utility in the diagnosis of IAD if coupled with a challenge test (i.e., histamine bronchoprovocation [see later]).[6,7]

Forced Oscillation Techniques

In contrast to the conventional methods, noninvasive measurements of total respiratory system resistance via forced oscillation techniques (FOT) are used in the diagnosis of IAD in horses. In short, oscillometry is the study of lung mechanical function via the application of external forces to the respiratory system.[8] Either a loudspeaker (e.g., impulse oscillometry system [IOS]) or air pressure (e.g., monofrequency forced oscillatory mechanics [FOM]) is used to superimpose pulses of flow (4 to 5 L/sec peak) through a face mask on the horse's respiratory system during spontaneous breathing. The generated reciprocal pressure waves are subsequently recorded at the airway opening (i.e., face mask). The magnitude and phase relationship between the input of flow and output of pressure are then used to perform the calculations of impedance (total opposition to airflow) and its components, resistance and reactance, at a variety of oscillatory frequencies (generally 1 to 7 Hz).[1] In most horses with IAD there is a frequency dependence of resistance, with higher values for resistance recorded at the lower oscillatory frequencies (1 to 2 Hz), indicative of bronchoconstriction.[9-11] Horses with moderate to severe lower airway obstruction commonly show high initial baseline values for respiratory resistance at 1 Hz (e.g., >1.0 cm H_2O/L/sec).[1] Higher frequencies (≥2 Hz) provide information concerning central airway resistance (R_{aw}). Baseline respiratory resistance measurements using FOT are often combined with bronchoprovocation tests for the early diagnosis of IAD. Additionally, the use of impulse oscillometry (IOS) has been advocated for separate analysis of inspiratory and expiratory impedance parameters, to allow the evaluation of both phases of the respiratory cycle in horses.[12]

Histamine Bronchoprovocation

Bronchoprovocation is a challenge test that assesses the response of the respiratory system to a bronchoconstrictor agonist (e.g., inhaled histamine).[1] The provocatory concentration necessary to cause a 100% increase in baseline respiratory system resistance is commonly termed *$PC100_{RRS}$*. Horses with a low $PC100_{RRS}$ (e.g., <6 mg/mL of histamine) are designated as having hyperreactive airways. Airway hyperreactivity is an exaggerated narrowing response to a bronchoconstrictive stimulus, which was first found in horses with heaves,[13]

VetBooks.ir

and is considered a hallmark of IAD. There is a correlation between airway reactivity and mast cell percentage in BAL fluid in horses with a history of exercise intolerance.[14] The clinical symptoms associated with airway hyperreactivity are thought to include coughing (increased sensitivity) and exercise intolerance, whereas bronchoconstriction causes uneven ventilation and hypoxemia.[1]

Respiratory Inductive Plethysmography

The objective assessment of respiratory function and breathing pattern may also be obtained through the concurrent application of respiratory inductive plethysmography and pneumotachography, which has been validated for use in humans,[15,16] horses,[17] and sheep.[18] In summary, two elastic bands, each containing a single sinusoidal conducting wire, are temporarily placed around the animal's thorax and abdomen (Fig. 31-4). Stretch and contraction of the bands resulting from normal respiratory movements are measured as voltage changes, which are proportional to the change in circumference and volume of the thorax and abdomen. Simultaneous measurements of nasal flow are obtained at the airway opening (face mask). This technique rapidly assesses the synchronicity of breathing pattern (e.g., thoracoabdominal asynchrony due to diaphragmatic paralysis)[19] and the individual contribution of the thorax and abdomen to respiration. It further quantifies changes in flow resulting from airway obstruction. Recently, the use of a novel respiratory ultrasonic plethysmography system was proposed to detect circumference changes of rib cage and abdominal compartments in large and small animals.[20]

Forced Maneuvers

Forced expiratory maneuvers are commonly performed in humans with suspected asthma. Simplistically, the patient is asked to blow out hard from TLC until the lung is empty. The volume of air expelled in 1 sec (FEV_1) corrected for vital capacity (FVC) is used as a measure of lower airway obstruction.[1] Couëtil and colleagues adapted the method of forced maneuvers for routine clinical application in heavily sedated, nasotracheally intubated horses.[21] They further demonstrated flow limitation in horses with early signs of obstructive airway disease (IAD) that was worse in animals with heaves. Remission from heaves showed improvement in flow limitation.[1]

FIG. 31-4 Inductance plethysmography being performed in a horse. *(Courtesy Dr. Andrew Van Eps, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

PFT is considered instrumental in the understanding of the pathogenesis, pathophysiology, epidemiology, diagnosis, and treatment of lung disease in horses.[1] The described tests are aimed at quantifying airway obstruction, airway reactivity, and lung stiffness in the clinical setting. PFT will thus facilitate the diagnosis of subclinical disease and improve the clinician's assessment with regard to aggressive management of lung disease, decisions for ventilation, intensity of monitoring, and assessment of treatment response and prognosis.

Equine Respiratory System

Disorders of the Lung

Bacterial Pneumonia and Pleuropneumonia in Adult Horses

Steeve Giguère

Bacterial infections of the lower respiratory tract are common in adult horses. Lower respiratory tract infections may be localized to the lumen of the airways (termed *bacterial bronchitis* or *septic inflammatory airway disease*) or may involve the pulmonary parenchyma (termed *pneumonia*). In equine medicine, the term *bronchopneumonia* is often used to refer to lower respiratory tract infection regardless of whether the infection is localized to the bronchi or whether the infection involves both the bronchi and the lung parenchyma. When there is subsequent extension of the infection from the pulmonary parenchyma to the visceral pleura and pleural space, the disease is referred to as *pleuropneumonia.* The spectrum of clinical signs shown by horses with bronchopneumonia is broad and reflects the severity of the disease process. Early identification of affected animals and immediate initiation of appropriate therapy are essential to prevent mortality and functional impairment of the respiratory system. Expenses incurred by owners of affected horses include cost of medical care, loss of income during the illness and the recovery period, cost of training after a prolonged period of inactivity, and financial loss due to death of some animals or diminished performance of others following recovery.

Infectious Agents Involved

Adult horses most commonly acquire bacterial pneumonia by aspiration of microorganisms that normally inhabit their nasopharynx or oral cavity.[1,2] β-Hemolytic streptococci, particularly *Streptococcus equi* subsp. *zooepidemicus,* are by far the most common bacterial pathogens isolated from adult horses with bronchopneumonia.[3] Non-enteric gram-negative bacteria such as *Pasteurella* spp. and *Actinobacillus* spp. are also frequently isolated, either alone or in combination with *S. zooepidemicus*. Enteric gram-negative bacteria such as *Klebsiella* spp., *Escherichia coli, Enterobacter* spp., and *Salmonella enterica* may also be isolated. Other aerobic gram-positive bacteria such as *Staphylococcus* spp. and *Rhodococcus equi* or gram-negative bacteria such as *Pseudomonas* spp. and *Bordetella bronchiseptica* are occasionally isolated. *Pseudomonas* spp. are rarely a primary cause of pneumonia in horses, and their presence often reflects contamination

VetBooks.ir

of equipment used for taking airway samples (such as endoscopes). *Streptococcus pneumoniae,* a common pathogen of humans, has been positively correlated with lower airway inflammation in young Thoroughbred racehorses in the United Kingdom.[4] The microorganism can also induce pneumonia in ponies following heavy intrabronchial challenge.[5] However, *S. pneumoniae* is rarely isolated from pneumonic horses in the United States.

Anaerobic bacteria are isolated from approximately one third of adult horses with severe bronchopneumonia, pleuropneumonia, or pulmonary abscessation. The most common anaerobes isolated are *Bacteroides* spp., particularly *B. fragilis, Clostridium* spp., and *Peptostreptococcus* spp.; *Fusobacterium* spp. and *Eubacterium* spp. may also be isolated.[3,6] Isolation of anaerobes from horses with pneumonia or pleuropneumonia has been associated with a less favorable prognosis in some studies. In one study, the survival rate for 221 pneumonic horses with strictly aerobic isolates from tracheobronchial aspirates was 81.4% compared with 38.3% for the 81 horses in which anaerobes were cultured.[3] Mixed bacterial infections are very common and may represent synergy between aerobic or facultative aerobic and anaerobic bacteria.

The importance of *Mycoplasma* spp. in the development of equine bronchopneumonia and pleuropneumonia is controversial. Several *Mycoplasma* species have been isolated from the respiratory tract of both diseased and healthy horses, with *M. felis* and *M. equirhinis* being the most common isolates. In one study, isolation of *M. equirhinis* was positively correlated with lower airway inflammation in a group of young Thoroughbred racehorses in the United Kingdom,[7] whereas isolation of *Mycoplasma* spp. was not significantly associated with disease in a similar population in Australia.[8] An outbreak of lower respiratory tract disease caused by *M. felis* infection has been described.[9] *M. felis* has also been isolated from horses with pleuropneumonia and, at least in one instance, experimental infection with *M. felis* has resulted in pleuropneumonia.[10,11]

Epidemiology

Bacterial bronchopneumonia may affect horses of any age or breed. In one retrospective study of 327 horses with pneumonia or pleuropneumonia, there was no sex predilection, but 82% of the horses were less than 5 years of age.[3] In a retrospective case-control study of risk factors for development of pleuropneumonia, Thoroughbred horses were at greater risk while Standardbred horses were at lower risk of developing the disease.[12] In the same study, the most significant risk factor for development of pleuropneumonia was long-distance transport within the week prior to the onset of clinical signs.[12] In another study, 24.4% of 90 horses with pleuropneumonia had recently been transported over long distances, and 12.2% had recently undergone general anesthesia.[13] Five of the postsurgical cases had undergone upper airway surgery.[13] Whether these horses had preexisting lung disease or whether they developed aspiration pneumonia as a result of surgery and general anesthesia could not be ascertained.

Other factors significantly associated with increased risk of developing pleuropneumonia include recent viral respiratory tract infection or exposure to horses with viral infections and racing within 48 hours prior to developing clinical signs.[12] One study in the United Kingdom identified a higher incidence of pneumonia and pleuropneumonia in show jumpers, presumably reflecting the greater distance over which these horses are transported compared with racehorses in that country.[14]

Pathophysiology

Colonization of the lungs by opportunistic bacteria occurs when the pulmonary defense mechanisms are compromised or are overwhelmed by massive numbers of bacteria. Several factors can contribute to causing increased numbers of bacteria in the lower airways. Dysphagia or esophageal obstruction will lead to aspiration of large numbers of pharyngeal bacteria and these disease processes often result in pneumonia. However, the vast majority of horses with bacterial pneumonia or pleuropneumonia do not have a history of dysphagia or esophageal obstruction. Other factors that have been shown to significantly increase bacterial contamination of the lower respiratory tract include confinement with the head elevated, transportation, and high-intensity exercise.[15-17] In one study, confinement of horses with the head elevated resulted in a significant increase in bacterial numbers as well as neutrophilic inflammation in the lower respiratory tract as early as 6 hours after initiating confinement.[16] *Actinobacillus* spp., *Pasteurella* spp., and β-hemolytic streptococci were the predominant bacterial isolates. Lowering the head for 30 minutes every 6 hours to facilitate postural drainage during a 24-hour confinement did not prevent multiplication of bacteria.[16] Clearance of accumulated secretions and bacteria occurred within 8 to 12 hours after release from confinement.[16] In similar confinement experiments, pretreatment with penicillin considerably reduced the number of β-hemolytic streptococci but did not reliably reduce total bacterial numbers.[18] Cilia of many other species such as dogs and humans can transport mucus effectively against gravity, and posture has no effect on tracheal mucociliary transport in these species.[19,20] In contrast, periods of lowered head posture are absolutely essential for normal mucociliary clearance in horses.[21]

In one study, long-distance transport by road over 12 hours resulted in increased bacterial contamination and neutrophilic inflammation in tracheal aspirate fluid when the horses' heads were restrained in an elevated position.[22] This is in contrast to another study in which there was no significant cytologic or bacteriologic changes in bronchoalveolar lavage fluid from mares whose heads were not restrained in an elevated position during transportation for 12 hours.[23] Collectively, these findings suggest that duration of time with a raised head position is more important than the stress of transport alone in development of airway colonization. Finally, the last factor shown to increase bacterial contamination of the large airways of horses is exercise. In one study, a single bout of high-intensity exercise resulted in a 10-fold increase in aerobic and 100-fold increase in anaerobic bacterial counts in tracheal aspirate samples compared with preexercise values.[15]

Pulmonary defense mechanisms can be compromised by numerous factors. These include stress (e.g., transport and intense exercise), viral infections, malnutrition, exposure to dust or noxious gases, immunosuppressive therapy, immunodeficiency disorders, and general anesthesia. Infections with influenza virus and EHV-4 have been shown to significantly decrease mucociliary clearance for up to approximately 30 days postinfection in horses.[24] In one study, long-distance transportation resulted in a significant reduction in phagocytosis by peripheral blood neutrophils for approximately 36 hours after transportation.[22] The effects of long-distance transport on number, viability, and function of cells in bronchoalveolar lavage fluid have given conflicting results with no clear pattern emerging.[23,25-27] Similarly, the effects of exercise on the immune system are complex and depend on a multitude of factors, including the intensity or duration of exercise, the specific immune function being analyzed, and the timing of the measurement in relation to exercise. In general, moderate exercise enhances immune function, whereas strenuous exercise tends to be detrimental to immune function.[28] High-intensity exercise in horses leads to a significant decrease in blood neutrophil and bronchoalveolar macrophage phagocytic activity, which may lead to decreased bacterial clearance from the lungs.[29-31] Exercise also affects the adaptive immune system, as lymphocyte proliferation responses and IFN-γ production are decreased following high-intensity exercise.[32-34] Strenuous exercise has also been shown to increase susceptibility to experimental influenza virus infection in ponies compared with rested animals, indicating that alterations of the immune function following exercise are a real phenomenon and not just an in vitro artifact.[32]

Regardless of the exact mechanism predisposing to bacterial colonization, the inflammatory response induced by bacterial invasion results in infiltration with neutrophils and other inflammatory cells into the airways and pulmonary parenchyma. Inflammatory cells and their mediators cause damage to the airway epithelium and capillary endothelium, leading to flooding of the terminal airways with inflammatory cells, serum cellular debris, and fibrin. This process is

VetBooks.ir

generally more severe in the ventral portions of the lung. In early stages the lungs may be simply edematous, reflecting inflammation and early exudation, whereas in chronic severe cases the airways may be filled with purulent material and necrotic debris. Affected areas may show various degrees of consolidation, although in some cases focal abscesses may develop. These lesions interfere with gas exchange and, if severe enough, the resulting ventilation-perfusion mismatch leads to hypoxemia and clinical signs of respiratory disease.

In severely affected animals, inflammation will extend to the pleural space. The first stage of bacterial pleuropneumonia is an exudative stage, which is characterized by rapid outpouring of sterile pleural fluid into the pleural space in response to inflammation of the pleura. The associated pneumonic process is usually contiguous with the visceral pleura and results in increased permeability of the capillaries in the visceral pleura. If appropriate antimicrobial therapy is initiated at this stage, the pleural effusion may not become septic and may resolve. With progression the bacteria invade the pleural fluid from the contiguous pneumonic process and the second, fibropurulent, stage evolves. This stage is characterized by the accumulation of large amounts of pleural fluid with many degenerate neutrophils, bacteria, and cellular debris. Fibrin is deposited in a continuous sheet, covering both the visceral and the parietal pleura adjacent to affected areas. As this stage progresses, there is often loculation and formation of limiting membranes. These loculations prevent dissemination of the infection but make drainage of the pleural space with chest tubes increasingly difficult. The last stage is the organization stage, in which fibroblasts grow into the exudate from both the visceral and the parietal pleura surfaces and produce a membrane called the *pleural peel.* This inelastic pleural peel encases the lung and renders it virtually functionless. At this stage the exudate is generally thick.

Clinical Signs and Physical Examination

The spectrum of clinical signs shown by horses with bacterial lung infection is broad and usually reflects the severity of the disease process. Horses with septic inflammatory airway disease and no or minimal involvement of the lung parenchyma may be completely normal at rest. Clinical signs may be limited to exercise intolerance and/or poor performance, or affected horses may cough or have bilateral nasal discharge during or immediately following exercise. Even in early cases of bronchopneumonia, clinical signs may not be obvious. As the disease progresses, clinical signs may include any combination of fever, anorexia, depression, bilateral nasal discharge, cough, weight loss, tachypnea, and respiratory distress. Nasal discharge is usually mucopurulent but may be hemorrhagic in some cases with pulmonary infarction and necrotizing pneumonia.[35] Halitosis and a foul-smelling nasal discharge may be present and has been associated with infection by anaerobic bacteria. However, the absence of a putrid odor does not rule out infection with anaerobic bacteria.

Because the parietal pleura is highly innervated and painful when inflamed, horses with acute pleuropneumonia often exhibit pleurodynia (pleural pain). Pleurodynia can often be detected by applying digital pressure to the intercostal space, resulting in grunts, intercostal muscle spasm, or even escape maneuvers by the patient when pain is present. Pleurodynia may also be manifested as pawing, stiff forelimb gait, abducted elbows, and reluctance to move. The condition may easily be mistaken for colic, exertional rhabdomyolysis, or laminitis. As more fluid accumulates in the pleural space and the disease becomes chronic, pain is less evident. A plaque of sternal edema is a common clinical finding in horses with pleuropneumonia. This is not a specific finding, as it can occur with many other disease processes.

Careful auscultation after application of a rebreathing bag (if not precluded by respiratory distress) is extremely valuable in defining the presence, and sometimes extent, of lung involvement. Horses with a large amount of secretions in the trachea often have an audible tracheal rattle. Most horses with bronchopneumonia will cough when the rebreathing bag is applied, whereas horses without bronchopneumonia will not. Occasional inspiratory or expiratory crackles and/or wheezes may be heard over affected areas, which are more commonly located ventrally. Because consolidated lung parenchyma is a good acoustic medium, mild consolidation sometimes results in only increased bronchial sounds. In contrast, the lung sounds may be diminished in areas of severe consolidation, extensive abscess formation, or pleural effusion.

Auscultation of horses with pleuropneumonia reveals normal lung sounds in the dorsal lung fields with no sound or considerably decreased lung sounds ventrally. Pleural friction rubs are often not heard because they are present only in the acute stage of the disease. If they are heard, friction rubs are present predominantly at the end of inspiration and the early part of expiration. They disappear as inflammation decreases or as pleural fluids accumulate. Cardiac sounds are often heard over a wider area of the chest than normal, probably as a result of enhanced conduction of sound through the pleural fluid. Thoracic percussion is useful to detect and delineate pleural effusion with resonant sounds dorsal and dull sounds ventral to the horizontal line of effusion.

Differential Diagnosis When physical examination and auscultation indicate pulmonary disease, the major clinical task is differentiating infectious from noninfectious causes. Among infectious causes, bacterial pneumonia is most common. Most viral infections are confined to the upper respiratory tract. The clinical presentation of equine multinodular pulmonary fibrosis may resemble that of horses with bacterial bronchopneumonia. Pulmonary aspergillosis most often follows severe gastrointestinal (GI) disease that had resulted in mucosal compromise.[36] Severe respiratory disease unresponsive to antimicrobial therapy might suggest fungal pneumonia or equine multinodular pulmonary fibrosis. Parasitic pneumonitis is rare in adult horses but may be seen in horses pastured with donkeys or mules. The two major noninfectious causes of pulmonary disease that may be confused with bacterial pneumonia are heaves and nonseptic inflammatory airway disease. Other uncommon causes of noninfectious pulmonary disease that may result in similar clinical signs are pneumothorax, pulmonary edema, smoke inhalation, neoplasia, and idiopathic interstitial pneumonia. The diagnostic tests described below aid in the differentiation between infectious and noninfectious causes of lower respiratory tract disease.

When pleural effusion is present, several differentials should be considered. Bacterial pleuropneumonia is by far the most common cause of pleural effusion in horses. In one study, 90 of 122 horses (73.8%) with pleural effusion had pleuritis secondary to bacterial pneumonia or lung abscessation.[13] Other less common causes of pleural effusion in horses include hemothorax, penetrating chest wounds, esophageal ulceration or rupture, neoplasia, fungal pneumonia, pericarditis, congestive heart failure, diaphragmatic hernia, hypoproteinemia, and chylothorax.

Diagnostic Approach Presumptive diagnosis of lower respiratory tract infection is generally based on clinical signs and careful auscultation of the lungs with a rebreathing bag. The need for additional diagnostic procedures is determined by the severity and duration of clinical signs, the number of affected animals, the value of the affected animal(s), as well as prior treatment used and response to such therapy. Bacterial pneumonia or pleuropneumonia most commonly affects an individual horse on a given farm. In horses suspected of having bacterial pneumonia, the goal of diagnostic evaluation is to rule out diseases of the upper respiratory tract and to determine the cause and severity of lung involvement.

HEMATOLOGY AND BIOCHEMISTRY. Horses with bacterial bronchopneumonia commonly have an inflammatory hematologic profile. Leukocytosis and absolute neutrophilia with or without a left shift are supportive of bacterial infection. Neutropenia with a toxic left shift may also be evident in the acute stages in severely affected animals. Increased fibrinogen concentrations, hyperglobulinemia, and mild hypoalbuminemia are common. Anemia of chronic

VetBooks.ir

inflammation may develop in chronically affected animals. There does not seem to be a good correlation between the severity of clinical signs and the presence or the magnitude of hematologic changes. When plasma fibrinogen concentrations are increased, their sequential measurement provides a useful means of monitoring response to treatment. It must be remembered that a normal hematologic profile does not rule out bacterial bronchopneumonia.

ENDOSCOPY. Endoscopy may be useful to rule out upper airway infection in situations when physical examination and auscultation of the lungs are not conclusive. Presence of mucopurulent secretions in the trachea and bronchi confirms lower respiratory tract disease. However, the presence of mucopurulent secretions does not necessarily indicate a bacterial infection, as this is also a common finding in horses with heaves and horses with nonseptic inflammatory airway disease. Bronchoscopy may also be useful in locating the affected lung segment in horses with focal pneumonia or draining pulmonary abscesses. It should be noted that exploration of the trachea and lower airways via bronchoscopy may contaminate subsequent samples taken for culture.

TRACHEOBRONCHIAL ASPIRATE FOR CYTOLOGY AND CULTURE. Tracheobronchial aspirate (TBA) for cytologic examination and bacterial culture is one of the most helpful diagnostic procedures available when bronchopneumonia is suspected. BAL is not as useful as TBA in cases of bronchopneumonia because with BAL only a small portion of a lung is sampled. In contrast to BAL, TBA samples contain a pooled sample of secretions from all portions of the lung, thus increasing chances of culturing the pathogen of interest. In one study involving 22 horses diagnosed with pneumonia or pleuropneumonia based on thoracic radiographs or ultrasonography, BAL cytology was abnormal in only 10 horses despite attempts at selectively sampling the affected area.[37] In contrast, all horses had evidence of septic inflammation based on TBA cytology.[37] Whenever possible, antimicrobial therapy should be discontinued at least 24 hours before performing TBA. TBA is preferably obtained by sterile percutaneous transtracheal aspiration to avoid contamination from the upper airway. Alternatively, the sample can be collected with a sterile guarded aspiration catheter passed through the biopsy channel of a flexible endoscope.[38,39] Endoscopy has the advantage of allowing selective aspiration of exudate when it is present, which may enhance recovery of bacteria. However, bacterial contamination of nasal or pharyngeal origin more commonly occurs in TBA samples collected via endoscopy. Airway fluid specimens should be submitted for cytology, Gram stain, and aerobic and anaerobic bacterial cultures. The fluid used for anaerobic cultures should be transferred to the laboratory immediately after collection in a manner that prevents or minimizes exposure to air. Anaerobic transport media are commercially available and should be routinely used. Specimens submitted for isolation of anaerobes should not be refrigerated, because many anaerobes are intolerant to cold. In horses with pleural effusion, a TBA should be obtained even if pleural fluid is available for bacterial culture. In one study, culture of the pleural fluid was negative in 43% of 111 horses with pleuropneumonia, whereas tracheobronchial fluid yielded growth in all cases.[3] Only approximately 5% of cases had growth from the pleural fluid but not from TBA.[3]

Macrophages and columnar ciliated epithelial cells predominate in TBA from healthy horses. The percentage of neutrophils in TBAs from apparently healthy horses can be quite variable. In one study, approximately 75% of apparently healthy Thoroughbred racehorses in training had less than 20% well-preserved neutrophils.[40] Occasional plant spores and fungal hyphae may be present, either free or in large mononuclear cells. Their presence does not necessarily indicate fungal infection and probably reflects the horse's environment. Degenerated neutrophils displaying karyolysis and cytoplasmic vacuolization are the predominant cell type in horses with bacterial lower respiratory tract infections. Bacteria may be found intracellularly or extracellularly. Presence of squamous epithelial cells indicates contamination with the upper respiratory tract or pharynx and is more common in samples obtained via the endoscope. The trachea is not a perfectly sterile site, and potentially pathogenic bacteria can be isolated from the trachea of normal horses.[38] Therefore culture results should always be interpreted in the context of clinical signs and cytologic examination. If small numbers of bacteria are cultured in the absence of cytologic evidence of sepsis, it is unlikely that they are the cause of the respiratory problem. Similarly, growth of various molds is common in TBA cultures, and the clinical signs and cytologic findings should be considered prior to initiating treatment with antifungal agents.

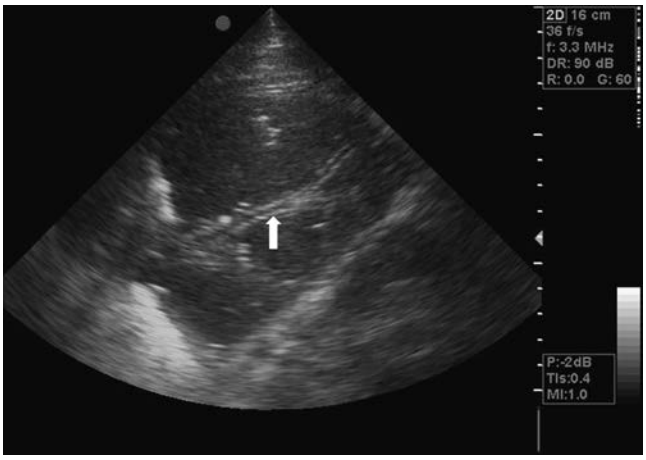

FIG. 31-5 Sonogram of the left thorax obtained from a 3-year-old Thoroughbred gelding. The ventral aspect of the lung is completely consolidated. Notice the liver-like appearance of the wedge-shaped area of the lung. Fluid bronchograms are indicated by a white arrow.

THORACIC ULTRASONOGRAPHY. Thoracic ultrasonography can be performed using a range of transducers and machine types. The normal aerated lung parenchyma is not penetrated by the ultrasound beam, rendering only the pleural space and superficial lung surface available for study. Ultrasonography is a helpful diagnostic tool when lung involvement includes peripheral areas, but it may not be as useful as radiography to evaluate the full extent of lung lesions since lesions with overlying aerated lung will not be detected. However, in most horses with bronchopneumonia, the periphery of the lung is affected, enabling the clinician to successfully image some of the lesions. Early ultrasonographic lesions are nonspecific and may only include irregularities of the pleural surface. These lesions may progress to form focal areas of consolidation of various sizes. Consolidated lung varies in appearance from dimples of the pleural surface to large wedge-shaped areas of sonolucent lungs (Fig. 31-5).

Ultrasonography offers a considerable advantage over radiographs in the study of the pleural surfaces and space. A small amount of pleural effusion that would otherwise be missed clinically or by radiography can be detected easily by ultrasonography. Ultrasonography can also be used to assess the nature and approximate volume of fluid, select the optimal site and depth for thoracocentesis, and detect sequelae such as fibrin deposition, pleural adhesions, abscess formation, and pneumothorax. Pleural effusion appears as hypoechoic to anechoic fluid between the parietal pleural surface and the lungs (Fig. 31-6). The echogenicity of the fluid typically reflects the degree of cellularity. Fibrin appears as filamentous strands floating in the effusion (see Fig. 31-6). The presence of small (<1 mm) bright echoes (gas echoes) often indicates anaerobic infections (Fig. 31-7).[41] Gas echoes may also be seen with gangrenous pneumonia or bronchopleural fistulas, or they may result from leakage of air during thoracocentesis.

RADIOGRAPHY. In horses with mild septic inflammatory airway disease, thoracic radiographs may be normal or may reveal only mild bronchial or bronchointerstitial patterns. In more severely affected

VetBooks.ir

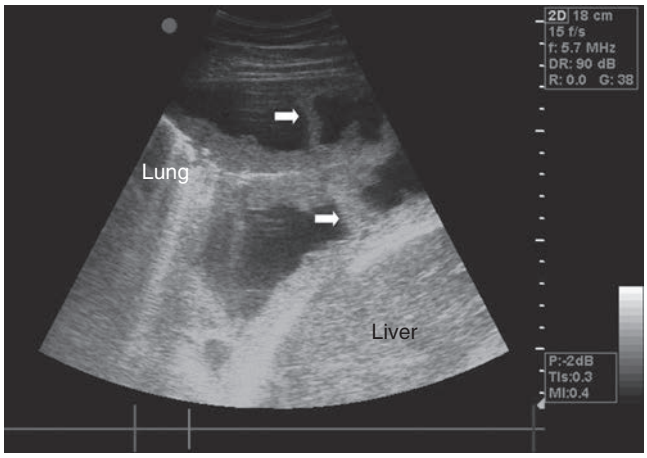

FIG. 31-6 Sonogram of the thorax obtained from a 4-year-old horse with pleuropneumonia. The ventral tip of the lung is atelectatic and covered with fibrin. There are adhesions between the tip of the lung and the diaphragm and chest wall *(white arrows)*.

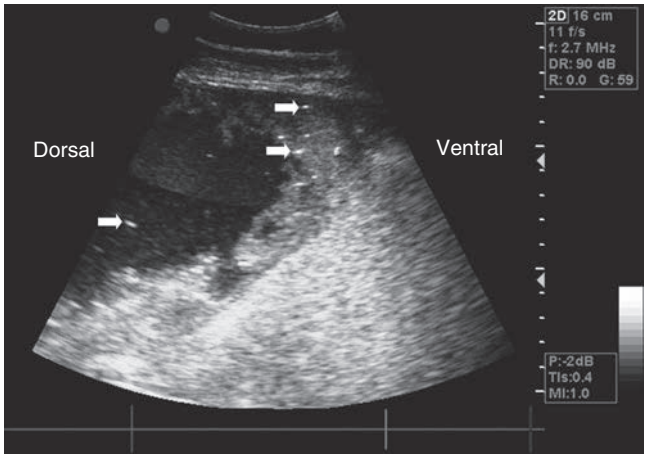

FIG. 31-7 Sonogram of the ventral thorax obtained from a horse being treated for pleuropneumonia. The sonogram shows a pleural abscess filled with fluid dorsally and with hyperechoic material ventrally. There are multiple gas echoes (some indicated by *arrows*). Multiple anaerobes were obtained on culture of an aspirate.

FIG. 31-8 Lateral thoracic radiograph of the caudoventral lung field from a 4-year-old Thoroughbred mare showing a pronounced alveolar pattern with air bronchograms. The caudal silhouette of the heart is almost completely obscured.

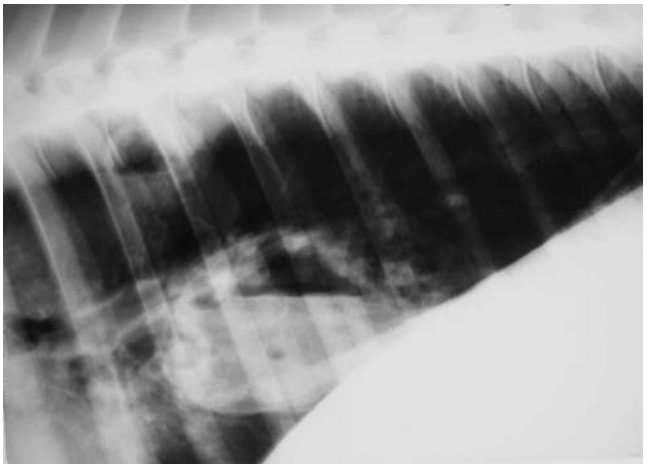

FIG. 31-9 Lateral thoracic radiograph of the caudodorsal lung field from a 3-year-old Thoroughbred filly showing two cavitary abscesses with distinct horizontal lines representing fluid-gas interface.

animals, radiographs demonstrate irregular opacities in the ventral thorax that may obscure the normal vasculature and cardiac silhouette (Fig. 31-8). Air bronchograms are sometimes visible. Abscesses are often present as circular soft-tissue opacities of varying sizes. In some cases they may be cavitated with thick walls and a distinct horizontal line representing fluid-gas interface (Fig. 31-9). Pleural effusion appears as a horizontal line demarcating a ventral soft-tissue opacity that obscures the heart and ventral lung fields (Fig. 31-10). When severe pleural effusion is present, it is most efficient to perform thoracic radiographs after the pleural fluid has been drained. Although ultrasonography is superior to radiographs in horses with pleuropneumonia, radiography should still be performed, when possible, to detect and monitor resolution of deep pulmonary abscesses that may be missed during ultrasonography.

THORACOCENTESIS FOR CYTOLOGY AND CULTURE. Thoracocentesis should be considered in horses with pleural effusion. The procedure can be of diagnostic value by allowing differentiation of septic pleuritis from effusion caused by other disease processes. It can also be of therapeutic value via removal of excessive chest fluid, which allows pulmonary reexpansion and a reduction in respiratory distress. Thoracocentesis is best performed using ultrasound guidance to determine the most appropriate site. A blunt teat cannula is typically used if a small volume of effusion is being sampled strictly for diagnostic purposes. Depending on the volume of effusion, a 16-, 24-, or 32-French chest tube is used when pleural drainage is also indicated (see below). An aliquot of pleural fluid is placed into tubes containing anticoagulant solution (ethylenediaminetetraacetic acid [EDTA]) so that cytologic evaluation may be performed. Part of the fluid should be saved in sterile containers with appropriate transport media for subsequent Gram stain and aerobic as well as anaerobic bacterial cultures.

Normal equine pleural fluid is clear to light yellow and odorless. Protein concentration is less than 3.4 g/dL (range 0.2 to 4.7 g/dL) and the nucleated cell count (NCC) is less than 8000/μL (range 800 to 12,100/μL) in approximately 95% of apparently healthy horses.[42] In horses with bacterial pleuropneumonia, the effusion is typically

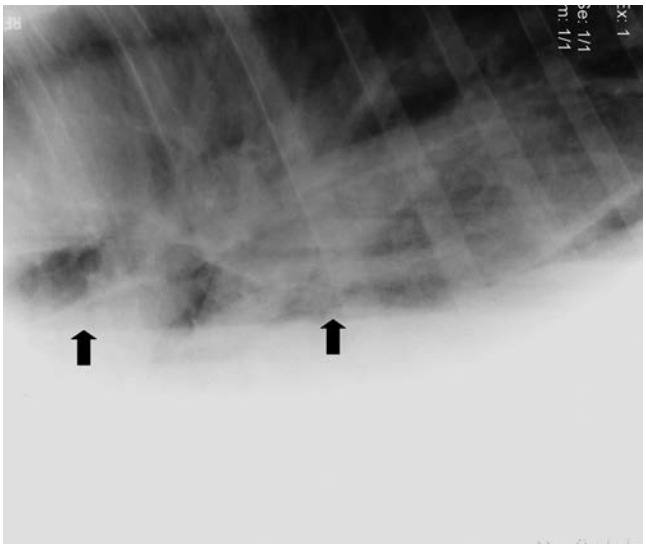

FIG. 31-10 Lateral thoracic radiographs from a 4-year-old Thoroughbred gelding with pleuropneumonia. A large amount of pleural effusion obscures the ventral lung fields. The dorsal aspect of the fluid line is indicated by black arrows. An interstitial pattern is noted in the caudodorsal lung fields.

exudative, cloudy, and yellow to red with increased NCC and protein concentration. Such effusion usually contains greater than 90% neutrophils, most of which exhibit degenerative changes. Putrid-smelling pleural fluid is a hallmark of anaerobic infection; however, the absence of odor does not exclude anaerobic infection. There is no association between the NCC count or protein concentration in pleural fluid and survival.

Biochemical analysis of the pleural fluid may also provide a rapid assessment of the likelihood of sepsis, hence the need for pleural drainage. Values for pH, P_{O_2}, P_{CO_2}, bicarbonate, lactate, and glucose in pleural fluid from horses with nonseptic pleural effusion are similar to those of concurrent venous blood samples.[43] Horses with septic pleural effusion have significantly lower pH, bicarbonate, and glucose in their pleural fluid compared with paired venous blood samples. In contrast, their pleural fluid has significantly higher P_{CO_2} and lactate concentration.[43] Pleural fluid pH less than 7.1 and glucose concentration less than 40 mg/dL are suggestive of septic effusion in horses.[44]

THORACOSCOPY. Thoracoscopy is rarely necessary in the initial evaluation of horses with pleuropneumonia. However, the technique may be of diagnostic and therapeutic value in more chronic cases in which pleural abscesses or pleural adhesions develop (see section on treatment).[45]

Treatment

SYSTEMIC ANTIMICROBIAL THERAPY. Administration of appropriate antimicrobial agents is the most important part of the therapeutic plan. The choice of the antimicrobial agent depends on the severity of the clinical signs, cost, ease of administration, and, when available, results of bacteriologic culture and susceptibility testing of TBA or pleural fluid. Dosages for commonly used antimicrobial agents are presented in Table 31-2. In early cases of mild bronchopneumonia, the practitioner is justified in suspecting *S. zooepidemicus* as the likely causative microorganism and in treating accordingly. *S. zooepidemicus* is almost invariably susceptible to penicillin, ampicillin, and cephalosporins such as ceftiofur (Table 31-3). The possibility of a mixed infection involving *S. zooepidemicus* and gram-negative microorganisms must be kept in mind when such empirical therapy is unsuccessful. Ceftiofur offers the advantage of having a good spectrum of activity against common non-enteric gram-negative pathogens (e.g., *Pasteurella* spp. and *Actinobacillus* spp.) and against many enteric gram-negative pathogens (see Table 31-3). Ceftiofur is available as a sodium salt that requires daily intramuscular administration or as ceftiofur crystalline free acid. Two intramuscular doses of ceftiofur crystalline administered 4 days apart provide therapeutic concentrations of ceftiofur- and desfuroylceftiofur-related metabolites in plasma and pulmonary epithelial lining fluid for approximately 10 days from the beginning of treatment.[46,47]

Therapy of horses with mild lower respiratory tract infections should be continued for a minimum of 10 days or until clinical signs resolve. In some cases, the duration of therapy needed may preclude continuous intramuscular therapy because of muscle soreness. Trimethoprim-sulfonamide (TMS) combinations offer the advantage of oral administration. Unfortunately, the usefulness of TMS combinations for the treatment of bacterial respiratory tract infections in horses is limited by their lack of in vivo activity against *S. zooepidemicus*. In contrast to penicillin, TMS is ineffective in eradicating *S. equi* subsp. *zooepidemicus* in a tissue chamber model of infection in horses.[48,49] This failure of in vivo response was observed despite in vitro susceptibility of the isolate and high concentrations of TMS in the tissue chamber fluid.[48,49]

In more severe cases of bronchopneumonia and in all cases of pleuropneumonia, antimicrobial therapy should ultimately be selected based on results of culture and in vitro susceptibility testing. Before obtaining these results, selection should be based on knowledge of the prevalence and susceptibility pattern of bacteria commonly isolated from affected horses (see Table 31-3). Polymicrobial and mixed aerobic/anaerobic infections are common; thus broad-spectrum antimicrobial therapy is initially required. A combination of gentamicin for gram-negative coverage and penicillin for gram-positive and anaerobic coverage is commonly used as initial broad-spectrum therapy for moderate to severe bronchopneumonia. Enrofloxacin can be used as a substitute to gentamicin for gram-negative coverage in adult horses. Advantages of enrofloxacin over gentamicin include greater activity against Enterobacteriaceae, better penetration in phagocytic cells and tissues, and better activity in purulent material. However, enrofloxacin should never be used as stand-alone initial therapy in horses with bronchopneumonia because of its lack of activity against anaerobes and variable activity against streptococci such as *S. zooepidemicus*. Ampicillin or cefazolin can replace penicillin for gram-positive coverage and offer the supplementary advantage of providing additional gram-negative coverage.

Treatment of anaerobic pleuropneumonia is usually empirical, as antimicrobial susceptibility testing of anaerobes is difficult because of their fastidious nutritive and atmospheric requirements. Thus familiarity with antimicrobial susceptibility patterns is helpful in formulating the treatment regimen when an anaerobe is suspected. The majority of anaerobic isolates is susceptible to relatively low concentrations of penicillin. However, *Bacteroides fragilis,* a frequently encountered anaerobe in horses with pleuropneumonia, is routinely resistant to penicillin. Other members of the *Bacteroides* family are known to produce β-lactamases and are potentially penicillin resistant. Metronidazole has excellent in vitro activity against a variety of obligate anaerobes, including *B. fragilis.* Oral administration rapidly results in adequate serum levels and thus is an acceptable route of administration for horses with pleuropneumonia. Therefore, if anaerobic infection is suspected, oral metronidazole is usually added to the combinations mentioned previously. Malodorous nasal discharge, halitosis, or the presence of gas echoes in pleural effusion seen on ultrasonographic examination suggests the presence of an anaerobic infection. However, the absence of these findings does not rule out anaerobic bacterial infection. Horses with extensive lung consolidation and horses with pleuropneumonia may benefit from having metronidazole added to the treatment regimen. Metronidazole is not effective against aerobes and therefore should always be used in combination therapy. Chloramphenicol is active against most aerobes and anaerobes cultured from horses with bronchopneumonia or pleuropneumonia. However, because of human health concerns, its use should be limited to the treatment of horses with severe anaerobic bacterial infections refractory to metronidazole therapy in countries

TABLE 31-2

Antimicrobial Agents Commonly Used to Treat Bacterial Bronchopneumonia in Adult Horses

Antimicrobial*	Dose	Frequency (h)	Route
β-Lactams			
Benzyl Penicillins			
Penicillin G (Na, K)	25,000 IU/kg	6	IV
Penicillin G (procaine)	25,000 IU/kg	12	IM
Aminobenzyl Penicillins			
Ampicillin sodium	20 mg/kg	8	IV
Ampicillin trihydrate	20 mg/kg	12-24	IM
Cephalosporins			
Cefazolin	10-20 mg/kg	6	IV
Ceftiofur sodium	2.2-4.4 mg/kg	24	IM
Ceftiofur crystalline free acid	6.6 mg/kg	See note†	IM
Aminoglycosides			
Amikacin	10 mg/kg	24	IV or IM
Gentamicin	6.6 mg/kg	24	IV or IM
Fluoroquinolones			
Enrofloxacin‡	5.5 mg/kg	24	IV
	7.5 mg/kg	24	PO
Tetracyclines			
Oxytetracycline§	6.6 mg/kg	12	IV§
Doxycycline¶	10 mg/kg	12	PO¶
Minocycline	4	12	PO
	2.2	12	IV
Others			
Chloramphenicol	50 mg/kg	6	PO
Metronidazole	25 mg/kg	12	PO
	35 mg/kg	12	Per rectum
Rifampin	5 mg/kg	12	PO
Trimethoprim-sulfonamide	30 mg/kg (combined)	12	PO

*Pharmacokinetics data are available for horses, but in most cases safety studies have not been performed in the equine species.

†Two doses 4 days apart will provide 10 days of coverage. If a longer treatment period is necessary, weekly (q7days) administration is sufficient after the initial two doses.

‡Should not be used in young growing horses because of the risk of arthropathy.

§Dilute and give by slow IV infusion.

¶Administer orally only. Intravenous doxycycline has resulted in severe cardiovascular effects, including collapse and death in some horses.

where its use is allowed. Rifampin is bactericidal and active against streptococci and some species of anaerobes. It penetrates well into abscesses and may be helpful in the treatment of infections with walled-off abscesses. Rifampin should always be used in combination with another antimicrobial agent to decrease the likelihood of emergence of resistant mutants.

In cases of severe bronchopneumonia, lung abscesses or pleuropneumonia long-term antimicrobial therapy ranging from 3 weeks to sometimes several months may be required. In the initial stages of therapy, intravenous antimicrobials are preferred to achieve higher serum concentrations. Oral antimicrobial agents can be used later in the course of the disease if appropriate based on in vitro susceptibility testing. Clinical signs, lung auscultation, fibrinogen concentrations, and repeated ultrasonographic and radiographic examination are useful in assessing response to therapy and deciding when to discontinue antimicrobial therapy. Stall rest must be enforced during therapy of pneumonia, and return to exercise should be gradual and permitted only after the horse is clinically normal and antibiotic therapy has been completed.

AEROSOLIZED ANTIMICROBIAL AGENTS. Aerosolized antimicrobial agents may be a useful adjunct to oral or systemic antimicrobial agents, particularly in horses with chronic septic inflammatory airway disease and no or minimal involvement of the lung parenchyma. The rate and extent of penetration of a drug into most sites outside the vascular space such as lung tissue are determined by the drug's concentration in plasma, molecular charge and size, extent of plasma protein binding, and blood flow.[50] In other tissues such as the central nervous system, and the eye, a lipid membrane provides a barrier to drug diffusion.[50] There is a similar barrier between blood and the bronchial epithelium, restricting penetration of some drugs into bronchial secretions and epithelial lining fluid of the lower airways.[51] Aerosol administration of antimicrobial agents can result in high drug concentrations in the respiratory tract while minimizing systemic concentrations and their resulting toxicity.

Antimicrobial delivery by inhalation is greatly influenced by the product formulation and type of nebulizer. Aerosol use of intravenous formulations can lead to exposure to potentially irritant or toxic additives and inappropriate pH or osmolality ranges. In one study, the particle size distribution and particle density of gentamicin sulfate and ceftiofur sodium aerosols were affected by the antimicrobial concentration of the solution.[52] Gentamicin concentrations of 50 mg/mL or ceftiofur concentrations of 25 mg/mL produced the optimal combinations of particle size and aerosol density when a medical ultrasonic nebulizer was used.[52] Development of a silent battery-operated nebulizer for horses (Flexineb, Nortev Ltd., Galway, Ireland) has greatly facilitated delivery of antimicrobial drugs by inhalation in horses.

*Data from the clinical microbiology laboratory, University of Florida (2003-2005). Isolates were obtained from multiple equine clinical specimens including, but not restricted to, tracheobronchial aspirates and pleural fluid.

†Percentage of susceptible isolates (number of susceptible isolates/number of isolates tested × 100).

‡In vivo, ceftiofur is rapidly metabolized to desfuroylceftiofur. Desfuroylceftiofur is as effective as ceftiofur against most bacterial pathogens, but most coagulase-positive *Staphylococcus* spp. are resistant. Therefore, despite in vitro susceptibility, ceftiofur is not the ideal choice for the treatment of staphylococcal infections.

— Not tested or testing not warranted.

AM, Ampicillin; *AMI,* amikacin; *CFT,* cefotaxime; *CFZ,* cefazolin; *CHL,* chloramphenicol; *CIP,* ciprofloxacin; *CPE,* cefepime; *ENR,* enrofloxacin; *GM,* gentamicin; *P,* penicillin; *RIF,* rifampin; *TE,* tetracycline; *TIM,* ticarcillin-clavulanic acid (Timentin); *TMS,* trimethoprim-sulfonamide; *XNL,* ceftiofur.

In healthy horses, aerosolization of 20 mL of the commercially available IV gentamicin sulfate solution (diluted to 50 mg/mL) with the use of an ultrasonic nebulizer resulted in bronchial lavage fluid concentrations approximately 12 times higher than concentrations achieved by IV administration at a dose of 6.6 mg/kg.[53] In the same study, serum concentrations following aerosol administration were below 1 µg/mL at all times.[53] Once-daily aerosol administration of gentamicin to healthy horses for 7 consecutive days did not result in pulmonary inflammation or drug accumulation in the respiratory tract.[54] The major limitation to the use of aerosolized gentamicin in horses is its lack of activity against *S. zooepidemicus,* the most common bacterial pathogen of the equine respiratory tract. Additional studies are required to assess the efficacy of aerosolized antimicrobial agents for the treatment of bacterial respiratory tract infections in horses.

ANCILLARY TREATMENTS. The need for ancillary treatments depends on the severity of the disease and is most often necessary in horses with pleuropneumonia. Nonsteroidal antiinflammatory agents such as flunixin meglumine (1 mg/kg IV or by mouth [PO] once or twice daily) or phenylbutazone (2.2 mg/kg IV or PO once or twice daily) may be beneficial to minimize inflammation, provide analgesia, and control high fevers. Additional analgesia may be necessary in horses with severe pleurodynia. Adequate hydration should be maintained in patients receiving these agents for extended periods, especially if aminoglycosides are used concurrently. Intravenous fluid therapy may be necessary to correct hypovolemia in acute stages, but it is rarely required for chronic cases. Intrapharyngeal insufflation of oxygen is indicated in horses that remain severely hypoxemic despite adequate drainage of the pleural cavity. Adequate parenteral or preferably enteral nutritional support via a nasogastric tube is beneficial in horses that remain anorectic for several days. In horses with severe systemic illness, additional therapies aimed at treating endotoxemia may be beneficial (see the section on endotoxemia in Chapter 32). In horses with severe systemic illness, distal limb cryotherapy is indicated in an attempt to prevent development of laminitis.

PLEURAL DRAINAGE. Small amounts of pleural effusion may resorb quite readily with appropriate antimicrobial therapy. Therefore, although a small sample of pleural fluid is useful diagnostically, pleural drainage is not necessarily indicated in all cases of pleuropneumonia. Drainage of pleural effusion results in removal of exudate and debris and allows for reexpansion of the lungs. Indications for drainage include a poor response to conservative therapy or the presence of pleural fluid with at least one of the following characteristics: (1) sufficient volume to cause respiratory distress, (2) emphysematous character, (3) fetid odor, or (4) cytologic or biochemical evidence of sepsis. If indicated, the procedure should be attempted as early as possible before deposition of fibrin results in loculations and impairs drainage. The ventral mediastinum is perforated in normal horses such that the left and right pleural spaces communicate. During severe inflammation, the small perforations in the ventral mediastinum may become obstructed by fibrin. Therefore, depending on the severity of the inflammatory response, draining one side of the thorax may or may not be sufficient to resolve bilateral pleural effusion. Repeat ultrasonography of the opposite hemithorax should always be performed before the placement of a chest tube to determine if draining one side has actually emptied both sides of the thorax. Pleural drainage is best performed using ultrasound guidance to determine the most appropriate site. Pleural drainage can be accomplished with either intermittent thoracocentesis or indwelling chest tubes. Thoracocentesis is easily accomplished in the field and may not need to be repeated unless considerable pleural effusion reaccumulates. Indwelling chest tubes are indicated when continued pleural fluid accumulation makes intermittent thoracocentesis impractical. If properly placed and managed, indwelling tubes provide a method for frequent fluid removal and do not exacerbate the underlying pleuropneumonia or increase the production of pleural effusion. A one-way valve must be attached to allow for continuous drainage without aspiration of air into the thorax. A Heimlich valve or an unlubricated condom with the tip cut off may be used for that purpose. As an alternative to continuous drainage, the tube can be temporarily occluded and periodically attached to a one-way valve for intermittent drainage. Heparinization of tubing after drainage may help maintain patency. The chest entry site and end of the drainage tube must be maintained aseptically. If a chest tube is placed aseptically and managed correctly, it can be maintained for several days. Local cellulitis may occur at the site of entry into the

VetBooks.ir

chest, but it is considered a minor complication. Pneumothorax is another potential complication of indwelling chest tubes. Tubes should be removed when they are no longer functional. A purse-string suture must be preplaced and tied as the tube is removed to prevent pneumothorax.

PLEURAL LAVAGE. Pleural lavage may be helpful to dilute thick viscous pleural fluid and remove fibrin, debris, and necrotic tissue. Pleural lavage is most helpful in subacute stages before loculated pockets of pleural fluid develop. However, pleural lavage may help break down fibrous adhesions and establish communication between loculae. Pleural lavage is typically performed by using the same chest tube for infusion and drainage of lavage fluid. Alternatively, lavage can be performed by infusing fluid through a dorsally positioned tube and draining it through a ventrally positioned tube. Approximately 5 L of sterile, warm isotonic fluid solution is infused by gravity flow. After infusion, the chest tube is reconnected to the unidirectional valve for drainage. Allowing the horse to walk once the continuous flow has stopped will often result in drainage of additional fluid. Pleural lavage is probably contraindicated in horses with bronchopleural communications because it may result in spread of septic debris up the airways and into normal areas of the lungs.[55] Coughing and drainage of lavage fluid from the nose during infusion suggest the presence of a bronchopleural fistula (see discussion of complications).

USE OF FIBRINOLYTIC AGENTS. The use of intrapleural fibrinolytics in the treatment of loculated pleural effusion remains controversial in human medicine.[56] Various fibrinolytic agents such as streptokinase, urokinase, and recombinant tissue plasminogen activators (rtPAs; such as alteplase and tenecteplase) have been used.[56] Numerous case series in people have shown that such therapy is fairly safe and may facilitate drainage. However, controlled trials are scarce and have given contradictory results regarding the ultimate benefit of intrapleural fibrinolytic therapy. In one study, intrapleural administration of streptokinase did not improve survival, the rate of surgery, or the length of the hospital stay among patients with pleural infection when compared with patients who had received a placebo.[57] In contrast, another study demonstrated a significant decrease in the need for surgical intervention and in the length of hospital stay with intrapleural streptokinase prior to drainage when compared with pleural drainage alone.[58]

In recent years, rtPA has largely replaced streptokinase as an adjunct therapy for selected human patients with loculated pleural effusion. Several case series indicate a potential benefit for rtPA,[59,60] but large randomized placebo-controlled clinical trials are lacking.[56,59] Fibrinolytic drugs have negligible effects on decreasing the viscosity of purulent material because the viscosity of pus is attributable mainly to its DNA content. Intrapleural recombinant human deoxyribonuclease I (rhDNase I; dornase alfa) has been used with apparent success in a single human patient who did not respond to fibrinolytic therapy.[61]

There are isolated reports of the use of rtPA in horses with fibrinous pleuropneumonia. In one report, 12 mg of alteplase was infused in volumes of 0.9% saline ranging between 250 mL and 2 L.[62] In another report, tenecteplase (12 to 30 mg in 500 mL of 0.9% saline) was administered alone or in combination with 25 mg of rhDNase I.[63] In both reports, there was a subjective decrease in the amount of fibrin in the thoracic cavity as assessed by ultrasonography. Additional studies evaluating the safety and efficacy of rtPA and rhDNase I are required before the widespread use of these agents can be recommended in the management of fibrinous pleuritis in horses.

THORACOSCOPY. Thoracoscopy allows direct evaluation of the lungs and pleural cavity. In selected cases, thoracoscopy may be a useful tool to facilitate placement of thoracic drains in abscesses, transect pleural adhesions, and disrupt loculations.[45] The technique can also be used to biopsy or aspirate specific lesions affecting the periphery of the lungs. The procedure can be performed in the standing sedated horse with local anesthesia and is usually very well tolerated.[64]

Adhesions between the lung and the diaphragm or body wall may prevent complete collapse of the lung, making insertion of the instruments more difficult and sometimes limiting the view of the pleural cavity. Adhesions are easier to disrupt during the first week after formation when the tissue is fibrinous rather than fibrous. Transection of mature adhesions is more difficult and can result in severe hemorrhage. Creation of a pneumothorax is a necessary feature of thoracoscopy, and horses should be monitored carefully throughout the procedure. Transient exacerbation in clinical signs of pulmonary disease due to pneumothorax can be alleviated by reinflation of the lungs.

THORACOTOMY. Surgical intervention in horses with pleuropneumonia is not a substitute for adequate medical management, but in carefully selected cases, it can save the lives of horses that would have to be euthanized otherwise. The criteria for surgical interventions include (1) failure to respond to antimicrobial therapy, pleural drainage, and pleural lavage; (2) stable systemic medical condition; (3) presence of a large amount of fibrin, debris, or pus in the pleural space; and (4) either a walled-off lesion or presence of a complete mediastinum to avoid creation of a bilateral pneumothorax. Surgical intervention is most beneficial in chronic cases with large unilateral localized pockets of thick debris, especially if there is resolution or at least a significant improvement of the disease in the opposite hemithorax. Before surgical exploration, the nature and location of the lesion must be thoroughly characterized by ultrasonography or thoracoscopy to determine the ideal surgical site. When there is bilateral disease, thoracotomy is performed on the most severely affected side. If necessary, a second thoracotomy can be performed on the opposite side at a later time. Thoracotomy is typically performed with the horse standing. It is common practice to place a large chest tube into the targeted cavity and leave it open to atmospheric air for at least 2 hours before thoracotomy.[55] The onset of respiratory distress indicates development of bilateral pneumothorax, in which case standing thoracotomy is contraindicated and pneumothorax must be corrected. Unilateral pneumothorax is usually well tolerated.

The standing surgical procedures most commonly performed include thoracotomy via an intercostal approach or thoracotomy and rib resection. For the intercostal approach, the surgical site is prepared and infiltrated with local anesthetic. The lateral thoracic vein must be identified to avoid inadvertent incision. A vertical incision is made through the skin, intercostal musculature, and pleura. The length of the incision is dictated by the size of the pleural abscess and consistency of its content. When necessary, partial excision of the intercostal muscles will facilitate manual exploration of the cavity and removal of fibrin and necrotic debris (Fig. 31-11). The major advantage of the intercostal approach over rib resection is preservation of thoracic wall integrity and compliance. Thoracotomy with rib resection is elected when the cavity is very large and it is anticipated that extensive manual débridement of fibrin and necrotic debris will be necessary. The advantage of the thoracotomy with rib resection over the intercostal approach is improved access to the thorax, allowing manual removal of large fibrin clumps and necrotic debris (Fig. 31-12). With both rib resection and intercostal approaches, the incision is left open and irrigated once or twice daily with a sterile isotonic fluid solution. The cavity is periodically débrided via gentle massage, taking care not to disrupt mature adhesions. After adequate formation of granulation tissue, tap water may be used. Depending on the size of the incision, it may take a few weeks to 2 to 3 months for complete closure by second intention. Complications during thoracotomy may include bilateral pneumothorax (if the cavity is not walled off and the mediastinum is not complete) and cardiac dysrhythmias (if the lesion is in close proximity to the heart). The most common long-term complication is the formation of a chronic draining fistula, but by itself, this complication does not prevent the horse from returning to its usual occupation. In a retrospective study of 16 horses that had a standing lateral thoracotomy for pleural disease,

VetBooks.ir

FIG. 31-11 Intercostal thoracotomy with partial excision of the intercostal muscles in a 7-year-old horse with a large pleural abscess. The image was obtained 3 weeks after surgery.

FIG. 31-12 Thoracotomy and rib resection in a Thoroughbred filly with a large pleural abscess in the right hemithorax communicating with another abscess cranial to the heart. In this case, a rib resection was done to facilitate manual removal of purulent material and necrotic debris from both abscesses.

14 horses (88%) survived to discharge and 46% of horses that survived returned to their previous level of athletic activity.[65]

Complications of Pleuropneumonia Several complications may occur during medical therapy of severe pneumonia and pleuropneumonia. These complications include jugular vein phlebitis or thrombosis from catheter placement, diarrhea resulting from antimicrobial therapy, pneumothorax or cellulitis secondary to thoracocentesis, endotoxemia, coagulopathy, and laminitis. In a retrospective study of 153 horses with pleuropneumonia presented to a referral hospital, complications included pleural abscesses (21.6%), cranial thoracic masses (7.2%), bronchopleural fistulas (6.5%), pericarditis (2.6%), and laminitis (1.3%).

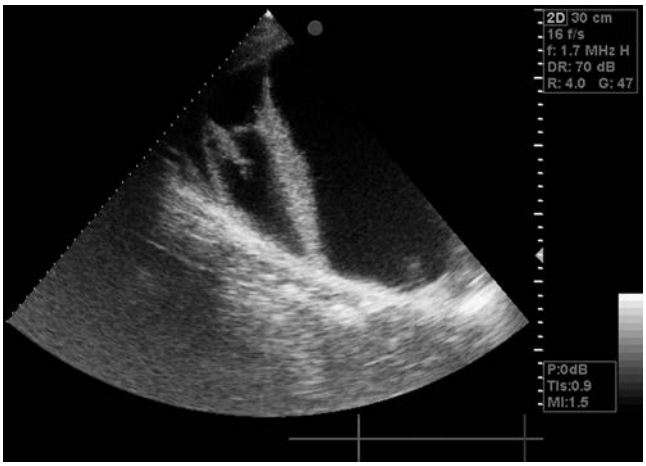

FIG. 31-13 Sonogram of the cranial thorax obtained from the third intercostal space of a 2-year-old Thoroughbred filly with distended jugular veins and pitting edema of the ventral thorax. A large fluid-filled loculated abscess was imaged.

Pleural abscesses refractory to antimicrobial therapy are treated by thoracocentesis or thoracotomy (see earlier sections). In some cases of pleuropneumonia, the heart may act as a valve to trap effusion and inflammatory debris in the cranial thorax. Small cranial thoracic masses may result in nonspecific clinical signs such as fever, tachycardia, and sternal edema. Larger abscesses may result in jugular vein distention, forelimb extension (pointing), and caudal displacement of the heart. Diagnosis is made by ultrasonography (Fig. 31-13). It is necessary to pull a forelimb forward to successfully image the cranial thorax. Most horses with cranial thoracic masses will respond to conservative therapy with antimicrobial agents.[66] Drainage of the abscess should be performed in cases refractory to medical therapy or when the mass interferes with normal cardiac function. Cranial thoracic abscesses may be sampled in the standing horse with a front limb pulled forward. However, when drainage and lavage are required, the procedure is best performed under short-term general anesthesia to avoid damage to the heart and major blood vessels present in the cranial thorax. It is not recommended to leave an indwelling tube because the triceps musculature often causes the tube to kink. Repeated drainage and lavage may be necessary in some cases.

Bronchopleural fistulas develop when necrosis of lung tissue leads to direct communication between the airways and the pleural cavity. Diagnosis may be confirmed by thoracoscopy or by injecting sterile fluorescein dye into the pleural fluid and looking for presence of dye at the nostrils or within the trachea by endoscopy. Horses with bronchopleural fistulas will often cough during pleural lavage, and lavage fluid may be noted at the nostrils. Most bronchopleural fistulas seal spontaneously as a result of adhesions to the chest wall or fibrin deposition on the visceral pleura. Sealing may take several weeks to months. In one case, partial pneumonectomy was successful at resolving a chronic bronchopleural fistula and pulmonary abscess.[67]

Prognosis The prognosis for survival and return to normal athletic function depends on the severity and duration of clinical signs prior to therapy. Horses with septic inflammatory airway disease or mild to moderate bronchopneumonia have a very good prognosis for a return to previous athletic performance. The prognosis for horses with pulmonary abscesses and without concurrent pleuritis is also good. In one study, 45 of 50 (90%) adult horses with pulmonary abscesses survived.[68] In the same study, 92% of Standardbreds and 52% of Thoroughbreds raced after treatment of pulmonary abscesses.[68] For horses that returned to racing, performance after successful treatment of lung abscesses was not significantly different from that before the illness.[68]

In a retrospective study of 327 horses with pneumonia or pleuropneumonia, the overall survival rate was 75%.[3] In the same study,

VetBooks.ir

the survival rate for 81 horses from which anaerobic bacteria were cultured was only 38.3%.[3] However, another study failed to identify an association between the presence of anaerobic bacteria and decreased survival.[69] In cases of pleuropneumonia, retrospective studies have shown survival rates ranging from 43.3% to 87.6%.[13,69,70] Differences in survival rates among studies may reflect differences in referral populations as well as advances in therapy in more recent years. Many horses that would have been euthanized because of chronicity and lack of response to medical therapy several years ago are now successfully treated with the surgical approaches described previously. This is evidenced by a retrospective of 153 horses with pleuropneumonia in which the survival rate was 95.7% when horses electively euthanized were excluded.[70]

The effect of pleuropneumonia on subsequent racing performance has not been examined extensively. In one retrospective study, 43 of 70 (61%) horses that had recovered from pleuropneumonia returned to racing, and 24 of the 43 (56%) won at least one race.[71] In the same study, horses that required placement of an indwelling thoracic drain did not have a worse prognosis for return to performance compared with horses that did require placement of a drain.[71] In contrast, horses that developed complications such as pulmonary abscesses, cranial thoracic masses, or bronchopleural fistulas were significantly less likely to return to racing.[71]

Rhodococcus equi Infections

Steeve Giguère

Rhodococcus equi, a gram-positive facultative intracellular bacterium, is one of the most common causes of pneumonia in foals between 3 weeks and 5 months of age. *R. equi* has also emerged as a significant opportunistic pathogen in immunosuppressed people, especially those infected with the human immunodeficiency virus.[1,2] Although *R. equi* can be cultured from the environment of virtually all horse farms, the clinical disease in foals is endemic and devastating on some farms, sporadic on others, and unrecognized on some farms. On farms where the disease is endemic, costs associated with veterinary care, long-term therapy, and mortality of some foals may be very high. This text reviews the clinical manifestations, pathogenesis, epidemiology, diagnosis, treatment, and control of *R. equi* infections in foals.

Clinical Manifestations

PULMONARY DISEASE. The most common clinical manifestation of disease caused by *R. equi* infections in foals is a chronic suppurative bronchopneumonia with extensive abscessation (Fig. 31-14). The slow spread of the lung infection combined with the remarkable ability of foals to compensate for the progressive loss of functional lung makes early clinical diagnosis difficult. Early clinical signs often consist of only a mild fever, occasional cough, or a slight increase in respiratory rate that may not be apparent unless foals are exercised or stressed by handling. If pneumonia progresses, clinical signs may include decreased appetite, lethargy, fever, cough, tachypnea, and labored breathing characterized by nostril flaring and increased abdominal effort. Bilateral nasal discharge is an inconsistent finding. In a recent report of 161 foals affected with *R. equi* pneumonia, the most common clinical signs were cough (71%), fever (68%), lethargy (53%), and increased respiratory effort (43%).[3] A smaller percentage of affected foals present with a more devastating subacute form. These foals may be found dead or more commonly are presented in acute respiratory distress with a high fever and no previous history of clinical respiratory disease. Foals with the subacute form of the disease have a poor prognosis despite appropriate therapy.

Because ultrasonographic screening for early detection has become routine practice at many farms endemic for pneumonia caused by *R. equi,* the most frequently recognized form of *R. equi* infection on those farms is a subclinical form in which foals develop ultrasonographic evidence of peripheral pulmonary consolidation or abscessation without manifesting clinical signs.[4,5] On those farms, the cumulative frequency of ultrasonographically visible areas of focal pulmonary consolidation or abscessation considerably exceeds the historical frequency of clinical pneumonia attributed to *R. equi,* indicating that many subclinically affected foals might spontaneously recover without therapy. In two independent studies at breeding farms endemic for *R. equi* infections, 80% to 90% of foals with ultrasonographically visible lesions recovered without antimicrobial therapy.[6,7] The proportion of such subclinically affected foals that progress to clinically apparent disease might vary by farm, geographic region, and age at which foals are examined.

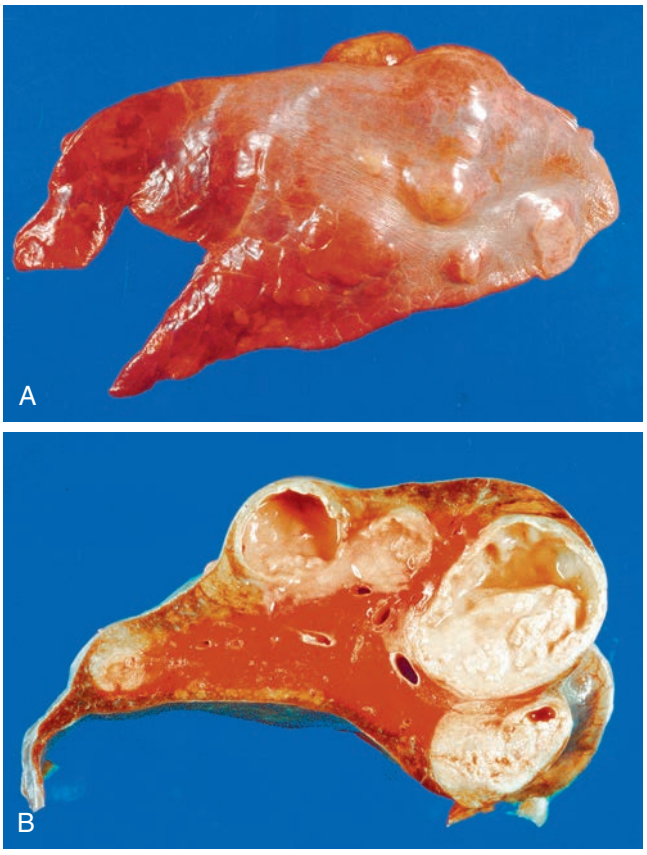

FIG. 31-14 **A,** Left lung from a foal with severe pneumonia caused by *R. equi*. There is marked consolidation of the cranial portion of the lung, and multiple abscesses are present caudodorsally. **B,** Cross-section of the same lung, showing multiple abscesses filled with caseous material. *(Courtesy Dr. William Castleman, University of Florida, College of Veterinary Medicine.)*

EXTRAPULMONARY DISORDERS. Extrapulmonary manifestations of rhodococcal infections are common.[8] In a study of 150 foals with *R. equi* infections admitted to a teaching hospital, at least 1 of 39 different extrapulmonary disorders (EPDs) were recognized in 74% of foals, although some EPDs, particularly abdominal lesions, can be difficult to recognize antemortem and were recognized only during necropsy.[8] Survival was significantly lower among foals with EPDs (43%; 48/111) than among foals without EPDs (82%; 32/39).[8] Some EPDs (e.g., polysynovitis, uveitis) might be the first clinical manifestation of *R. equi*–associated disease, detected prior to signs of pneumonia.

Intestinal lesions are present in approximately 50% of foals with *R. equi* pneumonia presented for necropsy.[9] However, the majority of foals with *R. equi* pneumonia do not show clinical signs of intestinal disease. In the same study, only 4% of the foals had intestinal lesions without pneumonia.[9] The intestinal form of *R. equi* infection is characterized by a multifocal ulcerative enterocolitis and typhlitis over the area of the Peyer patches with granulomatous or suppurative inflammation of the mesenteric and/or colonic lymph nodes.[9] In some cases, the only abdominal lesion noted may be a single large abscess (usually in a mesenteric lymph node) that often adheres to

VetBooks.ir

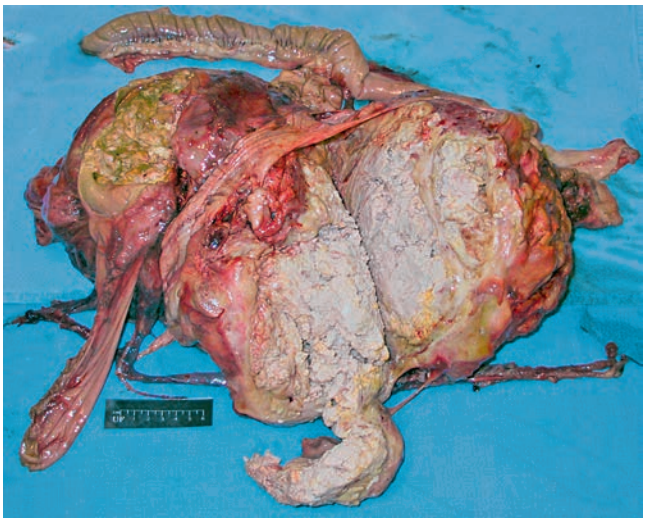

FIG. 31-15 Large abdominal abscess from a 4-month-old foal with a history of weight loss, fever, and mild intermittent episodes of colic. A portion of the small intestine and a portion of the small colon are adhered to the abscess. Culture yielded pure growth of *R. equi*.

the large or small bowel (Fig. 31-15). Foals with abdominal abscesses have a poor prognosis.[8]

Clinical signs associated with the abdominal form of the disease may include fever, depression, anorexia, weight loss, colic, and diarrhea.[8,10] Diarrhea might occur in foals infected with *R. equi* either as an EPD caused by pyogranulomatous typhlocolitis or as a result of antimicrobial treatment. Of 31 foals with ulcerative enterotyphlocolitis identified at necropsy, only 12 foals had diarrhea, whereas 9 foals had diminished growth.[8] Marked gastrointestinal lymphatic obstruction associated with increased protein concentration in the peritoneal fluid and systemic hypoproteinemia may lead to ascites, giving affected foals a pot-bellied appearance. Such foals have a poor prognosis because of the extensive granulomatous inflammation of the colonic mucosa and submucosa and mesenteric lymph nodes.

Polysynovitis is present in approximately one third to one fourth of cases with *R. equi* infections; in some cases, effusion of multiple joints may even be the presenting complaint.[11,12] The tibiotarsal and stifle joints are most commonly affected. Occasionally all joints are affected. The degree of joint effusion is variable and, in most cases, lameness is not apparent or limited to a stiff gait. Cytologic examination of the synovial fluid usually reveals a nonseptic mononuclear pleocytosis, and bacteriologic culture of the synovial fluid is negative.[12] Histologic examination of the synovial membrane of a few affected foals revealed lymphoplasmacytic synovitis.[11,13] Fluorescein-labeled antiequine immunoglobulin G (IgG) staining of the synovial membrane of three affected foals revealed evidence of immunoglobulin within the synovial membrane, and rheumatoid factors (i.e., antibodies directed against autologous or heterologous Fc portion of immunoglobulin) were identified in the synovial fluid of a foal with nonseptic joint effusion and *R. equi* pneumonia.[11,13] These findings are suggestive of an immune-mediated process. However, experimental infection with a heavy intrabronchial inoculum of virulent *R. equi* consistently results in polysynovitis without associated lameness, and culture of the synovial fluid within a few days of the onset of synovial effusion in these foals is often positive for *R. equi*.[14] Histologic examination of the synovial membrane reveals suppurative inflammation.[14] Therefore an alternative and more likely explanation is that septic polysynovitis results from bacteremia, but the infection is rapidly cleared from the synovial structures, resulting in chronic nonseptic inflammation at the time of diagnosis. Regardless of the inciting cause, local therapy of the affected joints in clinical cases of *R. equi*–associated polysynovitis is usually not indicated because the effusion resolves without any apparent consequences as the primary infection responds to appropriate antimicrobial therapy. The presence of a nonseptic polysynovitis in a foal between 3 weeks and 6 months of age is highly suggestive of *R. equi* infection and deserves further investigation (see section on diagnosis).

Intermittent or persistent bacteremia with *R. equi* might be more common than recognized and might result in metastatic spread of infection. The proportion of foals that are blood culture–positive and the stages of disease during which bacteremia is most likely to occur are poorly defined. In a retrospective study, *R. equi* was isolated from the blood of 11 of 19 foals, and foals with positive blood culture results were less likely to survive than foals that were culture-negative.[8]

Bacteremic spread of the organism from the lungs or gastrointestinal tract may occasionally result in septic arthritis and, more commonly, osteomyelitis. However, foals can occasionally develop *R. equi* septic arthritis or osteomyelitis without apparent lung involvement or other source of infection. The degree of lameness of foals with septic arthritis distinguishes them from foals with nonseptic polysynovitis. In equivocal cases, bacterial culture and cytologic examination of the synovial fluid should be performed. In addition to appropriate antimicrobial therapy (see treatment), foals with *R. equi* septic arthritis and osteomyelitis often require aggressive local therapy. *R. equi* vertebral osteomyelitis or diskospondylitis resulting in spinal cord compression has also been reported.[15-17] Clinical signs of vertebral osteomyelitis or diskospondylitis might include stiff gait, reluctance to move, palpable pain, and sometimes soft-tissue swelling associated with paravertebral abscessation.[8] If the infection or associated swelling extends to the epidural space, neurologic signs of spinal cord disease or nerve root compression might be apparent.[8] Specific neurologic signs vary according to the specific region of the spinal cord that is affected. Foals with vertebral osteomyelitis generally have a poor prognosis. However, there are reports of successful treatment with prolonged antimicrobial therapy alone or with antimicrobial therapy in conjunction with surgical débridement of infected bone.[15]

Some foals with *R. equi* infections develop ocular lesions, including uveitis, keratouveitis, and panophthalmitis.[8] Affected foals might display epiphora, photophobia, aqueous flare, hypopyon, iris discoloration, miosis, and other ophthalmic abnormalities. The pathogenesis of uveitis is often unknown but might include dissemination of bacteria to the eye or immune-mediated mechanisms. In one study, foals with uveitis were less likely to survive than foals without uveitis.[8]

Other less common EPDs associated with metastatic spread of *R. equi* include pericarditis, endocarditis, cellulitis, dermatitis, subcutaneous abscesses, peripheral lymphadenopathy, guttural pouch empyema, pleuritis, sinusitis, ulcerative lymphangitis, myositis, stomatitis, pyometra, and omphalitis.[8,18] Other immune-mediated EPDs include immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, and telogen effluvium.[8,19]

ADULT HORSES. Disease caused by *R. equi* in adult horses is rare, but there are sporadic reports of infection involving primarily the lungs or abdominal lymph nodes (similar to infection observed in foals) and, less common, of wound infection. In one adult horse, acquired combined immunodeficiency of unknown origin led to *R. equi* septicemia and lung abscessation.[20] Occasionally, the microorganism has also been isolated from infertile mares and aborted fetuses.[9,21,22]

OTHER DOMESTIC ANIMAL SPECIES. *R. equi* has been isolated from many species other than people and horses. *R. equi* is frequently cultured from the submaxillary lymph nodes of pigs with granulomatous lymphadenitis. However, *R. equi* can also be isolated from the submaxillary lymph nodes of 3% to 5% of apparently healthy pigs, and experimental infection studies in pigs have failed to reproduce granulomatous lymphadenitis.[23,23,24] The causative role of *R. equi* in granulomatous lymphadenitis in pigs thus remains unproven. Isolation of *R. equi* from other domestic animal species is rare. *R. equi* can be isolated from lymph node granulomas in 0.008% of cattle at abattoir postmortem inspection.[25] *R. equi* has also been cultured from

VetBooks.ir

rare cases of bronchopneumonia, mastitis, metritis, ulcerative lymphangitis, and septic arthritis in cattle. In goats, *R. equi* has a tendency to cause liver abscesses with concurrent bronchopneumonia or pulmonary abscessation.[26] In dogs and cats, *R. equi* has been isolated from cases of pneumonia as well as from wound infections, subcutaneous abscesses, vaginitis, hepatitis, osteomyelitis, myositis, and joint infections.[27]

Virulence

The ability of *R. equi* to induce disease in foals likely depends on both host and microbial factors. *R. equi* is a facultative intracellular pathogen and its ability of *R. equi* to persist in, and eventually destroy, alveolar macrophages seems to be the basis of its pathogenicity. Knowledge of the virulence mechanisms of *R. equi* was largely speculative until the discovery of a virulence plasmid in the early 1990s.[28,29] Unlike most environmental *R. equi,* isolates from pneumonic foals typically contain an 80- to 90-kb plasmid. Plasmid-cured derivatives of virulent *R. equi* strains lose their ability to replicate and survive in macrophages.[14] Plasmid-cured derivatives also fail to induce pneumonia and are completely cleared from the lungs of foals within 2 weeks following heavy intrabronchial challenge, confirming the absolute necessity of the large plasmid for the virulence of *R. equi*.[14,30]

Sequencing and annotation of the virulence plasmid revealed 73 coding sequences[31,32] and that it was divisible into four discrete areas based on open reading frame (ORF) amino acid sequence similarity and predicted protein function. The "backbone" sequence of the plasmid is highly similar to that of a plasmid found in the environmental microorganism *Rhodococcus erythropolis* and consists of regions for replication and partitioning, conjugation, and unknown functions.[31] The fourth plasmid region is a 21-kb pathogenicity island (PAI) that is crucial for virulence.[31,32] The 26 coding sequences of the PAI include the unique and *Rhodococcus equi*–specific virulence-associated protein (Vap) family.[32] There are six full-length *vap* genes *(vapA, vapC, vapD, vapE, vapG,* and *vapH)* and three truncated *vap* pseudogenes *(vapF, vapI,* and *vapX).*[31] To date, *vapA,* which encodes an immunodominant, temperature-inducible, and surface-expressed lipoprotein,[33,34] is the only *vap* gene with a demonstrated role in virulence,[35] whereas Vaps C, D, E, F, G, I, and X are dispensable.[35,36] VapA is required for intracellular growth in macrophages,[35] where it aids in preventing maturation of the phagosome to the stage of fusion of *R. equi*–containing vacuoles with lysosomes.[37] The functions of the other Vap proteins are unknown.

Although *vapA* is necessary for virulence, it is not sufficient.[14] Additional virulence determinants reside within the PAI.[36] Two of these, *virR* and *orf8,* each encode a regulatory protein.[38,39] Loss of either regulator results in decreased *vapA* transcription and also in attenuation of the organism.[38,39] All the *vap* genes, as well as five other ORFs within the PAI, are upregulated when *R. equi* is grown in macrophage monolayers.[40] Regulation of expression of the genes in the PAI is complex and depends on at least five environmental signals, including temperature, pH, oxidative stress, magnesium, and iron.[40-42] The precise role of each of these genes in the pathogenesis of *R. equi* infections remains to be determined. The entire virulence plasmid can be transferred by conjugation from plasmid-containing strains of *R. equi* to plasmid-free *R. equi* strains at a high frequency, and plasmid transmission restores the capacity for intracellular growth in macrophages.[43] Deletion of a putative relaxase-encoding gene *(traA)* located in the proposed conjugative region of the plasmid prevents plasmid transfer.[43]

A second major advance in the understanding of *R. equi* virulence was the recent sequencing and annotation of the genome of *R. equi*.[44] The 5.04-Mb *R. equi* genome is most similar to that of the environmental bacterium *Rhodococcus jostii* and then to *Nocardia farcinica* and *Mycobacterium tuberculosis.*[44] As with these other actinomycetes, a large number of the 4598 genes of *R. equi* appear to be involved in lipid metabolism. Like *M. tuberculosis,* lipids are a key component of the outer cell envelope of *R. equi.*[45] This mycolic acid–containing glycolipid barrier might serve to protect the peptidoglycan and plasma membrane from the damaging effects of host-generated enzymes and immune-mediated reactive intermediates. Cell envelope mycolic acid carbon chain length varies among *R. equi* isolates, and, notably, it was observed that strains with longer mycolic acids were more lethal to mice.[46] This might be explained by the fact that mycolic acid chain length plays a key role in diversion of macrophage phagosome trafficking by *R. equi*.[47]

Some of the most exciting recent data in the *R. equi* field involve the recognition of molecular "cross talk" between the virulence plasmid and the *R. equi* chromosome. Microarray analysis has shown that a gene or genes on the plasmid directly or indirectly regulate chromosomal gene expression patterns and that the two regulators in the PAI region could be involved. Although it has been firmly established that the virulence plasmid is essential for infection of foals, several chromosomally encoded genes have also been proven to play essential roles in intracellular survival and virulence, notably those involved in various metabolic functions such as fatty acid metabolism, anaerobic metabolism, aromatic amino acid biosynthesis, regulation of secreted proteins, iron acquisition, hydrogen peroxide resistance, and cholesterol catabolic pathways.[44,48-56]

R. equi isolates are often classified as virulent, avirulent, or intermediately virulent based on their ability to induce disease or death in mice. Virulent *R. equi* isolates contain the large plasmid described earlier and express VapA. Intermediately virulent *R. equi* isolates contain one of four distinct large plasmids encoding a 20-kDa antigen (VapB) that is related to, but distinct from, VapA. In contrast, avirulent *R. equi* isolates do not express Vap antigens. All three categories of *R. equi* have the ability to cause disease in immunosuppressed humans. Analysis of *R. equi* isolates from immunocompromised human patients with or without AIDS reveals that only approximately 20% of isolates contain an 80- to 90-kb plasmid and express VapA.[57,58] Therefore the pathogenesis of *R. equi* infection in immunocompromised human patients appears to be different from the pathogenesis in foals, in which the virulence plasmid is always found. Intermediately virulent isolates (expressing VapB) have never been isolated from foals with naturally acquired *R. equi* infections. Experimentally, heavy intrabronchial challenge of foals with intermediately virulent *R. equi* results in pneumonia but at a dose much higher than that required for induction of pneumonia with VapA-expressing strains.[59] Almost all isolates from the submaxillary lymph nodes of pigs produce VapB and are intermediately virulent to mice, suggesting that pigs or their environment may be the source of infection for some human cases.[60] Most isolates from cattle, goats, and dogs are avirulent and do not contain plasmids encoding *vapA* or *vapB*.[25-27] In contrast, most isolates from cats contain the virulence plasmid and express VapA.[27]

Pathogenesis Inhalation of virulent *R. equi* is the major route of pulmonary infection in foals. The incubation period following experimental intrabronchial challenge varies from approximately 9 days after administration of a heavy inoculum to approximately 2 to 4 weeks when a lower inoculum is administered.[14,61] Lung consolidation can be detected as early as 3 days following heavy intrabronchial challenge.[14] However, the incubation period under field conditions is unknown and likely varies depending on several factors, including the number of virulent bacteria in air samples in the environment, the age of the foal, and host defense mechanisms. Ingestion of the organism is an important route of exposure, and likely also of immunization, but rarely leads to hematogenously acquired pneumonia unless a foal has multiple exposures to large numbers of bacteria.[62] Indeed, intragastric administration of live virulent *R. equi* to foals on day 2 and day 7 of life is highly effective in preventing development of pneumonia following subsequent heavy intrabronchial challenge.[63] Despite conferring protection, oral vaccination with live virulent *R. equi* would not be an acceptable strategy to immunize foals since it would lead to progressive contamination of the environment with virulent bacteria. However, it undoubtedly shows that newborn foals have the ability to mount protective immune responses against *R. equi* (see section on immunity).

VetBooks.ir

Epidemiologic evidence suggests that most foals on endemic farms become infected early in life.[64] The median age at the time of diagnosis is approximately 35 to 50 days on most endemic farms.[3,65] Given the fairly long incubation period of the disease, this finding would also support the fact that many foals become infected early in life. In one study, foals aged between 3 and 13 days (mean 6.4 days) were more susceptible to experimentally induced *R. equi* pneumonia than foals aged between 14 and 36 days (mean 25 days).[66] In a recent study, foals between 3 and 42 days of age were experimentally infected with various doses of virulent *R. equi* 10^3 to 10^7.[67] Whereas the youngest foals were highly susceptible to infection, the oldest foals were resistant to 1000-fold higher challenge.[67] Collectively, these findings indicate that many foals on endemic farms become infected at a young age and that younger foals are more susceptible than older foals to infection caused by *R. equi*. However, these findings do not necessarily indicate that foals are only susceptible to *R. equi* during the neonatal period. Older foals are also susceptible to experimental infection with *R. equi,* but they require a higher inoculum. In one study, intratracheal administration of *R. equi* to 10 foals between 27 and 67 days (mean 49 days) of age resulted in disease in all foals.[30] The relative resistance of older foals to infection caused by *R. equi* compared with younger foals is likely the result of immunologic priming after natural exposure to the pathogen.

Epidemiology

Although *R. equi* can be cultured from the environment of virtually all horse farms, the clinical disease in foals is endemic and devastating on some farms, sporadic on others, and unrecognized on some farms. This probably reflects differences in environmental and management conditions, as well as differences in the virulence of isolates, but the exact basis for the difference in the prevalence of the disease among farms remain unknown. Breeding farms with a large acreage, a large number of mares and foals, a high foal density, and a large population of transient mares and foals have greater odds of being affected by *R. equi* pneumonia.[68,69] In contrast, *R. equi* pneumonia does not appear to be associated with lack of attention to routine preventive health practices.[70]

R. equi is a soil microorganism with simple growth requirements. The highest numbers of *R. equi* are found in surface soil, whereas the organism cannot be found at depths exceeding 30 cm.[71] *R. equi* can be cultured not only from the soil of all horse farms but also from the soil of areas not inhabited by horses. In one study, *R. equi* was isolated from approximately 74% of soil samples collected from 115 parks and 49 household yards in Japan. The number of *R. equi* in those samples ranged from 10 to 10^5 colony-forming units (CFUs) per gram of soil. None of the 1294 isolates from those samples expressed VapA or VapB, suggesting that the environment of people is not a significant route of exposure to virulent or intermediately virulent *R. equi*.[24]

R. equi can be isolated from the feces of most adult horses at concentrations ranging between 10 and 10^3 CFUs per gram of feces. The number of *R. equi* in the feces of mares on endemic farms does not increase in the weeks before or following foaling.[72] In one study, virulent *R. equi* could be isolated from the feces of all mares sampled; this demonstrates that mares can be an important source of virulent *R. equi* for their surrounding environment.[73] However, dams of affected foals did not shed more *R. equi* in feces than did dams of unaffected foals, indicating that heavier shedding by particular mares does not explain infection in their foals.[73] In another study, *R. equi* could be isolated from the feces of only 19% of the foals at 1 week of age and from all foals by 4 weeks of age.[72] Foals can shed high concentrations of *R. equi* in their feces, reaching numbers up to 10^5 CFUs per gram of feces.[74] Virulent *R. equi* present in the sputum of pneumonic foals will be swallowed and, as a result, the manure of *R. equi*–affected foals is likely a major source of progressive contamination of the environment with virulent organisms. Under suitable conditions of high summer temperatures, *R. equi* can multiply in the environment by 10,000-fold in only 2 weeks.[75] A single gram of soil contaminated with foal manure may therefore, under favorable conditions, contain millions of virulent *R. equi*.[76]

In a survey of the prevalence of *R. equi* at horse breeding farms in Japan, the organism was isolated from almost all soil samples, at numbers of 10^2 to 10^5 CFUs per gram of soil.[77] Although virulent *R. equi* isolates containing 80- to 90-kb plasmids and expressing VapA were cultured from 24 of the 31 farms examined, the vast majority of these isolates did not contain plasmids and were avirulent. On those farms, virulent *R. equi* represented 1.7% to 23.3% of all isolates.[77] However, neither the presence nor the concentration of virulent *R. equi* in soil is positively associated with increased cumulative incidence of *R. equi* pneumonia at breeding farms in North America or Australia.[78-80] In addition, soil geochemistry does not appear to be associated with occurrence of *R. equi* pneumonia at farms.[81]

In contrast, airborne concentration of virulent *R. equi* is correlated with disease incidence at Thoroughbred breeding farms in Australia.[80] Factors associated with increased air concentration of *R. equi* at these farms included site (holding pens and lanes relative to paddocks), warmer ambient temperature, less soil moisture, reduced grass height, and later date during the foaling season.[80] In Kentucky, concentrations of airborne *R. equi* were lower between midnight and 6 AM than later times, and the presence of horses at the sampling site appeared to increase the airborne concentrations of virulent *R. equi*.[82] These findings suggest that airborne concentrations may be increased by greater activity and density of horses at sites where foals are housed. Also in Kentucky, foals were more likely to be exposed to airborne virulent *R. equi* when housed in stalls versus paddocks and earlier (January and February) versus later (May and June) during the foaling season.[83] Similarly, the odds of detecting airborne virulent *R. equi* at three breeding farms in Ireland were approximately 17 times greater in stables (stalls) than in paddocks of a given farm, and concentrations of virulent *R. equi* were also significantly higher in stables than in paddocks.[84] In a recent study at a breeding farm in Texas, exposure of foals to airborne virulent *R. equi* during the first 2 weeks after birth was significantly associated with subsequent development of *R. equi* pneumonia.[85] The fact that exposure preceded development of *R. equi* pneumonia suggests that the higher concentration of airborne virulent *R. equi* is likely the cause of pneumonia rather than an effect.

In one study, air samples from the breathing zone of pneumonic foals had higher concentrations of virulent *R. equi* than environmental air samples collected from lanes and pens at the same farms.[86] However, concentrations of virulent *R. equi* from air samples collected from the breathing zones were not significantly different between pneumonic foals and healthy controls, indicating that affected foals do not represent a greater risk than other foals for aerosol transmission. In addition, there was no association between virulent *R. equi* in the breathing zone of foals and the subsequent diagnosis of rhodococcal pneumonia.[87] Thus, to date, there is no compelling evidence that *R. equi* infection is contagious among foals and that affected foals should be isolated from other foals.

Considerable genotypic variability has been found among isolates of *R. equi* obtained from the same farm and among isolates from various countries or continents.[88-90] Interestingly, multiple different *R. equi* strains were isolated in five of the six cases in which more than one isolate from a single foal was examined.[89] Similarly, six distinct genotypes were identified among nine *R. equi* isolates from one foal with pneumonia and concurrent abdominal lesions.[91] None of the four pulmonary isolates was identical; however, a pulmonary isolate was found to be identical to an isolate recovered from a small intestinal lymph node, and a second pulmonary isolate was identical to an isolate from a mesenteric lymph node.[91] Therefore foals can be infected with multiple strains of virulent *R. equi* and, with current techniques, it is not possible to link infections to a given geographic site or region on the basis of analysis of isolate genotyping.

Rhodococcus equi–Phagocytic Cell Interactions

Once inhaled, *R. equi* is taken up by alveolar macrophages through a process of receptor-mediated phagocytosis. One of the receptors used by macrophages to engulf complement opsonized *R. equi* is

VetBooks.ir

complement receptor 3 (CR3 or Mac-1).[92] In addition, *R. equi* might utilize the macrophage mannose receptor for entry, which might recognize lipoarabinomannan (LAM), an outer surface component of the bacterium, either directly or via mannose-binding protein or surfactant molecules adhered to LAM.[93] Once engulfed by resident macrophages, virulent *R. equi* are able to modify the phagocytic vacuole to prevent acidification and subsequent fusion with lysosomes.[37,94-96] Bacterial gene expression patterns are altered to accommodate survival in the intracellular environment and allow acquisition of essential nutrients such as iron, as well as to promote resistance to host-derived reactive oxygen intermediates.[40,41,56] Uncontrolled intracellular replication of *R. equi* leads to necrosis of the macrophage.[97] If bacteria are opsonized with *R. equi*–specific antibody, presumably promoting bacterial entry via the macrophage Fc receptor, the fate of the *R. equi*–containing phagosome is altered and lysosome fusion occurs.[98] This might explain how the presence of *R. equi* antibody might aid in the prevention of infection. Killing of *R. equi* by mouse macrophages is dependent on the presence of interferon (IFN)-γ, which activates macrophages to produce both reactive oxygen and reactive nitrogen intermediates. These two radicals combine to form peroxynitrite, which efficiently kills *R. equi*.[99] Neither reactive oxygen nor reactive nitrogen intermediates alone are sufficient to mediate killing of *R. equi*.[99] Macrophage activation and nitric oxide synthesis act, at least in part, by increasing the ability of macrophages to store iron in a way that it cannot readily be accessed by *R. equi*.[100] Additional cytokines such as tumor necrosis factor α (TNF-α) might have similar effects on restricting intracellular growth of *R. equi* in macrophages, because both IFN-γ and TNF-α are required for clearance of virulent *R. equi* in mice.[101] Neutrophils also play an important role in early host defense against virulent *R. equi*.[102] As opposed to macrophages, neutrophils from foals and adult horses are fully able to kill *R equi*.[103-105] As seen with macrophages, killing of *R. equi* by neutrophils is considerably enhanced by specific opsonizing antibody.[106,107]

Immunity

ANTIBODY-MEDIATED IMMUNITY. Immunity to *R. equi* pneumonia in foals likely depends on both the antibody and cell-mediated components of the immune system, but its exact basis remains to be determined. The strongest evidence for a role of antibody in protection against *R. equi* is the partially protective effect of passively transferred anti–*R. equi* hyperimmune equine plasma (HIP; see section on prevention). Opsonization of *R. equi* with specific antibody has been shown to promote phagocytosis and killing of *R. equi* by alveolar macrophages, identifying antibody as a critical component of HIP.[98,108] In most studies evaluating the protective effect of HIP, donors were immunized with whole cell vaccines or a mixture of several soluble antigens, making it impossible to determine the role of antibody against defined antigens of *R. equi*.

A number of studies have focused more specifically against the role of antibody against plasmid-encoded virulence-associated proteins (Vap). First, monoclonal antibody to VapA and serum from horses immunized with partially purified VapA have opsonizing activity.[109] Moreover, purified immunoglobulins obtained from horses vaccinated with partially purified VapA protected mice against intraperitoneal challenge with virulent *R. equi* compared with mice administered immunoglobulins from nonimmunized horses.[110] Finally, intravenous administration of purified immunoglobulins obtained from horses immunized with recombinant VapA and VapC to foals was found to reduce the severity of pneumonia following heavy experimental challenge with *R. equi*.[111] In the same study, the degree of protection conferred by purified anti-VapA and anti-VapC immunoglobulins was similar to that provided by commercially available HIP.[111]

In adult horses, the concentrations of *R. equi*–specific and VapA-specific IgGa and IgGb antibodies (the IgG isotypes that preferentially opsonize and fix complement in horses) are dramatically enhanced following intrabronchial challenge with virulent *R. equi*. This occurs in conjunction with clearance of the bacteria from the lungs.[112] In foals, production of antibody to VapA and VapC, but not that to other Vap proteins, increases following natural exposure to *R. equi*.[111] Characterization of the subisotype response in naturally infected foals revealed mainly an increase in IgGa, IgGb, and IgG(T).[111,113] Experimental infection of young foals with a low inoculum of virulent *R. equi* that resulted in subclinical pulmonary lesions caused a marked increase in serum IgGa and IgGb levels, resulting in concentrations that were significantly higher than those of adult horses undergoing the same challenge.[114] It is interesting to note that infection of foals of the same age with a higher inoculum leading to severe respiratory disease resulted in a switch from a predominant IgGa response to a striking IgG(T) response, indicating that the size of the *R. equi* inoculum can modulate immune responses.[115]

CELL-MEDIATED IMMUNITY. Because of the facultative intracellular nature of *R. equi,* cell-mediated immune mechanisms are thought to be of major importance in resistance to infection. A large part of the knowledge of cell-mediated immunity to *R. equi* infections comes from infection of mice. Deficiencies in the complement component C5 and in natural killer (NK) cells in mice do not impair the pulmonary clearance of virulent *R. equi*.[116] In contrast, functional T lymphocytes are absolutely required for the clearance of virulent (plasmid and VapA positive) *R. equi* in mice.[117-119] However, athymic nude mice (lacking functional T lymphocytes) clear plasmid-cured derivatives from their lungs within 1 week of infection, suggesting that, as opposed to virulent organisms, clearance of avirulent plasmid-negative strains in mice does not require functional T lymphocytes and depends mainly on innate defense mechanisms.[118]

The two major mechanisms by which T lymphocytes mediate clearance of intracellular pathogens are secretion of cytokines and direct cytotoxicity. Although both $CD4^+$ (helper) and $CD8^+$ (cytotoxic) T cells contribute to host defense against *R. equi* in mice, $CD4^+$ T lymphocytes play the major role and are absolutely required for complete pulmonary clearance.[119-121] Studies in mice have clearly shown that a type I response, characterized by IFN-γ production by T-helper lymphocytes, is sufficient to effect pulmonary clearance of *R. equi,* whereas a type II response, characterized by IL-4 production, is detrimental.[117,122]

As opposed to foals, adult horses are typically resistant to *R. equi* infections. Thus immune adult horses have been used as a relevant model to better understand what responses are necessary for immunologic protection. Clearance of virulent *R. equi* in adult horses is associated with a significant increase in bronchoalveolar (BAL) fluid $CD4^+$ and $CD8^+$ lymphocytes, lymphoproliferative responses to *R. equi* antigens, development of *R. equi*–specific cytotoxic $CD8^+$ lymphocytes (CTL), and IFN-γ induction by $CD4^+$ and $CD8^+$ lymphocytes.[112,123,124] *R. equi*–specific CTL, which are apparently present in all immune adults, are major histocompatibility complex (MHC) class I unrestricted and appear to recognize unique bacterial lipids from the cell wall.[124,125] The current thought is that these lipid antigens might be presented to T lymphocytes via the CD1 system, as has been well described in *Mycobacterium tuberculosis*.[126] How these findings in mice and adult horses relate to the foal is an area of active research.

IMMUNITY TO *R. EQUI* IN FOALS. Virtually all newborn mammals are immunologically immature and have an assortment of immunologic deficits compared with older animals. In general neonates and perinates have diminished innate immune responses and decreased antigen-presenting cell function and are less able to mount type I immune responses.[127] As a result, neonates of various species demonstrate an increased susceptibility to certain infections.

A number of relative immunologic deficits have been demonstrated in foals. In conjunction with the lack of immunologic memory in newborns, these deficits are postulated to account for the unique age-associated susceptibility of foals to rhodococcal pneumonia. Age-related deficiencies in *R. equi*–specific cytotoxic T lymphocyte (CTL) activity has been documented in 3-week-old foals.[124] Activity of CTLs is improved by 6 weeks of age and is similar to that of adult

VetBooks.ir

horses by 8 weeks.[124] Antigen-presenting cells from foals have significantly lower CD1 and MHC class II expression compared with adult horses.[126,128] In addition, several studies have demonstrated that the ability of equine lymphocytes and neutrophils to produce and/or upregulate various cytokines is strongly influenced by age.[127-132] In particular, the finding that young foals are deficient in their ability to produce IFN-γ in response to mitogens has led to the hypothesis that an IFN-γ deficiency and T-helper type 2 (Th2) bias might be at the basis of their peculiar susceptibility to *R. equi* infections.[129,130] However, recent data demonstrate that foals are also deficient in their ability to produce IL-4 in response to stimulation with mitogens, stimulation with *R. equi,* and after vaccination with a killed adjuvanted vaccine, suggesting that a clear polarization toward a Th2 response is unlikely in neonatal foals.[133-136] Consistent with these findings, experimental infection of young foals with virulent *R. equi* results in IFN-γ induction and antibody responses similar to, or greater than, those of adult horses undergoing the same experimental challenge.[114]

Recent studies have investigated various immunostimulants that might enhance host defense mechanisms during the relatively narrow period of susceptibility to *R. equi*. Inactivated *Parapoxvirus ovis*, *Propionibacterium acnes,* and unmethylated CpGs all enhance ex vivo or in vitro phagocytic cell function or cytokine induction in foals.[137-140] However, despite successfully enhancing IFN-γ production in foals, inactivated *Parapoxvirus ovis* failed to decrease the cumulative incidence of pneumonia at an *R. equi*–endemic farm. In the same study, IFN-γ and IL-4 secretion at birth was not associated with subsequent development of pneumonia.[141]

Spontaneous resolution of *R. equi* pneumonia after experimental challenge has been recognized.[66,142,143] Many foals on farms where the disease is endemic do not develop disease or develop subclinical disease that resolves without intervention. In addition, intragastric administration of live, virulent *R. equi* to newborn foals confers complete protection against subsequent heavy intrabronchial challenge.[63,144] Oral inoculation with virulent *R. equi* results in accelerated development of *R. equi*–specific CTLs,[145] providing a potential mechanism for the protection conferred by oral inoculation. Collectively, these findings unequivocally demonstrate that most foals have the ability to mount protective immune responses to *R. equi*. The basis for the peculiar susceptibility of foals to infection with *R. equi* is likely complex and multifactorial rather than involving a simple and single explanation.

Diagnosis

The distinction between lower respiratory tract infections caused by *R. equi* and those caused by other pathogens is problematic, especially at farms without previous history of *R. equi* infections. Diagnostic tests, including white blood cell (WBC) concentration, measurement of fibrinogen concentrations, ultrasonography, and radiography, may help raise the degree of suspicion that pneumonia in a given foal may be caused by *R. equi* rather than by another microorganism. However, the definitive diagnosis of bronchopneumonia caused by *R. equi* should be based on bacteriologic culture or amplification of the *vapA* gene by polymerase chain reaction (PCR) from a *tracheobronchial aspirate* (TBA) obtained from a foal with (1) clinical signs of lower respiratory tract disease, (2) cytologic evidence of septic airway inflammation, and/or (3) radiographic or ultrasonographic evidence of bronchopneumonia. Amplification of *vapA* by PCR is done preferably in conjunction with bacterial culture because it does not permit identification of other bacterial pathogens and in vitro antimicrobial susceptibility testing of *R. equi* isolates.[146] The definitive diagnosis of extrapulmonary infections (e.g., abdominal abscess, osteomyelitis) caused by *R. equi* must rely on bacteriologic culture or PCR amplification of *vapA* from samples from the site of infection. The diagnosis of extrapulmonary disorders from sites at which *R. equi* cannot be detected (e.g., uveitis or polysynovitis) should be based on isolation of *R. equi* from a TBA or other primary sites of infection. The diagnosis of enterocolitis caused by *R. equi* is problematic because isolation of *R. equi* from feces cannot be taken as evidence of enterocolitis caused by *R. equi*.[146]

CLINICAL LABORATORY TESTS. Hyperfibrinogenemia is the most consistent laboratory finding in foals with *R. equi* pneumonia, although rare cases may have normal fibrinogen concentrations. Neutrophilic leukocytosis with or without monocytosis is also common. One study showed significantly higher fibrinogen concentrations and WBC counts in nonsurvivors than in survivors,[147] whereas other studies showed no difference between the two groups.[12,148] In one study, a WBC count higher than 20,000 cells/μL, a fibrinogen concentration higher than 700 mg/dL, and evidence of pulmonary abscessation were more likely to be found in foals with pneumonia caused by *R. equi* than in foals with pneumonia caused by other bacteria.[149] However, there is a considerable overlap in distributions, which precludes the use of fibrinogen concentrations and WBC counts for diagnosis or prognosis for an individual foal.[149]

IMAGING TECHNIQUES. Thoracic radiography is useful in evaluating the severity of pneumonia and in assessing response to therapy. A prominent alveolar pattern characterized by ill-defined regional consolidation is the most common radiographic abnormality.[147] The consolidated lesions are often seen as more discrete nodular and cavitary lesions consistent with pulmonary abscessation (Fig. 31-16). Severity of alveolar pattern and number of cavitary lesions are the radiographic findings significantly associated with a poor outcome in foals with *R. equi* pneumonia.[150] Although nonsurvivors tend to have more severe radiographic lesions than survivors, many survivors have very severe radiographic lesions; thus radiographs should not be used as the sole criterion for prognostication and euthanasia.[12,148-150] Ultrasonography is a helpful diagnostic tool when lung involvement includes peripheral areas, but it may not be as useful as radiography to evaluate the full extent of lung lesions because abscesses with overlying aerated lung will not be detected. However, in most horses and foals with pulmonary abscessation, the periphery of the lung is affected, enabling the ultrasonographer to successfully image some of the abscesses.[151] Early ultrasonographic lesions are nonspecific and may include only irregularities of the pleural surface. These lesions may progress to form focal areas of consolidation of various sizes (Fig. 31-17, *A*). In more chronic cases, well-circumscribed, encapsulated abscesses can be detected (see Fig. 31-17, *B*). Ultrasonography is very useful in evaluating the severity of pneumonia and in assessing response to therapy, especially for equine practitioners who do not have access to thoracic radiography. Ultrasonography is also a useful tool for detection of some abdominal abscesses (Fig. 31-18) and for screening for *R. equi*–infected foals on farms where the disease is endemic (see section on control). Ultrasonographic or radiographic detection of lung abscesses raises the

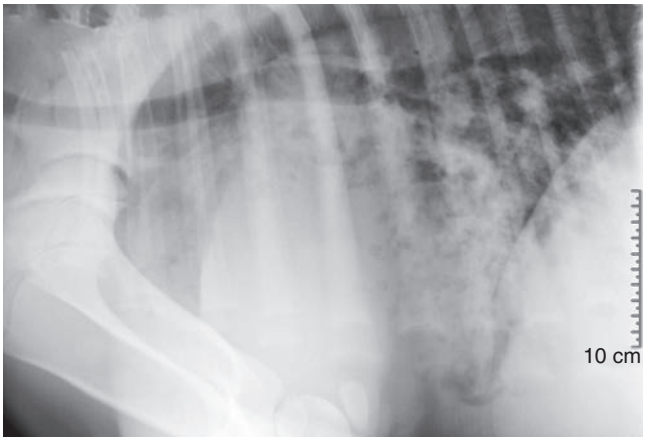

FIG. 31-16 Thoracic radiograph from a 2-month-old foal with pneumonia caused by *R. equi*. The study shows a combination of alveolar and nodular interstitial patterns as well as cavitary nodular infiltrates, primarily in the cranioventral and caudoventral thorax. A mild interstitial infiltrate is present in the caudodorsal lung. The trachea is displaced dorsally, suggesting tracheobronchial lymphadenopathy. There is slight narrowing of the tracheal lumen at the thoracic inlet, likely indicating the presence of tracheal secretions.

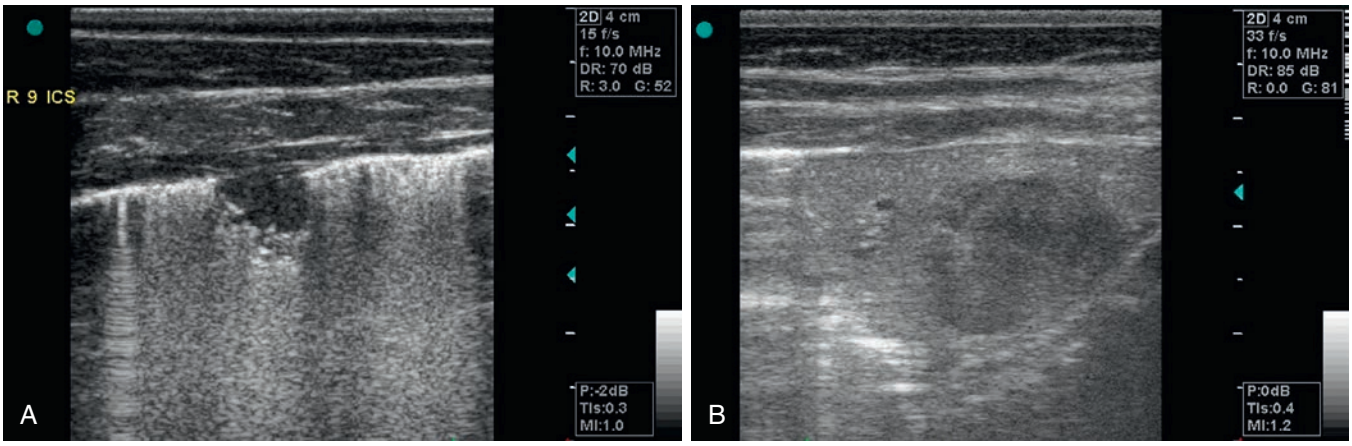

FIG. 31-17 **A,** Sonogram of the right thorax in a foal with mild pneumonia caused by *R. equi*. There is an approximately 1 cm^2 area of focal consolidation. **B,** Sonogram of the left thorax in a foal with severe pneumonia caused by *R. equi*. There is consolidation of the ventral aspect of the lung surrounding a large encapsulated abscess.

FIG. 31-18 Sonogram of the abdomen obtained from a 3-month-old Thoroughbred foal with severe pneumonia caused by *R. equi* and multiple abdominal abscesses. The sonogram shows an abdominal abscess *(arrow)*. The pneumonia resolved with therapy, but the abdominal abscesses persisted. The foal was eventually euthanized because of weight loss and intermittent episodes of colic. Postmortem examination confirmed resolution of pneumonia and the presence of abdominal abscesses caused by *R. equi*.

degree of suspicion that pneumonia in a given foal is caused by *R. equi*. However, detection of pulmonary abscesses, while commonly used as a screening test (see later), is not a definitive diagnostic test.

SEROLOGY. The current state of knowledge precludes the use of serologic tests to determine a diagnosis for *R. equi* pneumonia. Independent studies evaluating the performance of serologic tests available for diagnosis of infection caused by *R. equi* at endemic farms have demonstrated these tests have either low sensitivity, low specificity, or both.[152-155] Improving either sensitivity or specificity of enzyme-linked immunosorbent assays (ELISAs) by changing the cutoff value corresponding to a positive or negative test result could only be done to the detriment of the other. The presence of antibodies indicates exposure, subclinical infection, or maternal transfer of antibodies, but it does not necessarily indicate infection leading to clinical disease.

CYTOLOGY, CULTURE, AND POLYMERASE CHAIN REACTION AMPLIFICATION. Bacteriologic culture or PCR amplification of *vapA* from a TBA are therefore the only acceptable ways of establishing a diagnosis of *R. equi* pneumonia. In one study, only 7 (64%) of the 11 foals with positive *R. equi* culture at necropsy and 57 (64%) of the 89 foals with radiographic evidence of lung abscessation yielded *R. equi* from culture of a TBA.[156] However, in two other studies, all 17 foals in which *R. equi* was isolated from lung parenchyma at necropsy yielded the organism from culture of TBAs obtained antemortem; this suggests that culture of a TBA is a valid method for diagnosing *R. equi* pneumonia.[157,158] Larger case series are required to more accurately estimate the sensitivity of TBA culture for diagnosis of *R. equi* pneumonia in foals. Specificity of the test must also be considered. Foals without clinical disease may have *R. equi* in their trachea as a result of subclinical disease or, incidentally, from inhaling *R. equi* in contaminated environments. At a farm with endemic *R. equi* pneumonia, 77 of 216 (35%) foals sampled had positive TBA cultures but remained free of clinical signs of respiratory disease throughout the season.[159] For this reason, culture or PCR amplification of *R. equi* from a TBA should always be interpreted in the context of cytologic and clinical findings. Detection of *R. equi* from a foal without clinical signs of respiratory disease, cytologic evidence of septic airway inflammation, or ultrasonographic or radiographic evidence of pulmonary lesions is likely an incidental finding, due to the ubiquitous nature of the organism on horse farms. Amplification of *vapA* by PCR has been shown to be more sensitive than bacterial culture in most but not all studies.[160-162] However, increased sensitivity may also result in a higher incidence of false-positive results due to the detection of very small numbers of *R. equi* present as environmental contaminants. Moreover, culture offers the advantage of detecting other bacterial pathogens present and permits in vitro susceptibility testing of recovered pathogens. As a result, PCR amplification of *vapA* may be done in conjunction with, but should not replace, bacterial culture. The use of PCR assays based on genes other than *vapA* is not recommended, as these assays would also detect environmental isolates lacking the virulence plasmid, which are not known to cause disease in foals.

Isolation or detection of *R. equi* from nasal or fecal swabs cannot be taken as evidence of disease due to infection with *R. equi*. *R. equi* can be cultured from the feces of healthy horses even if they live at farms without history of *R. equi* pneumonia.[74,76,163] Quantitative culture of the feces of foals at weekly intervals has been advocated to aid in early diagnosis of *R. equi* infections because the fecal concentration of *R. equi* increased at the same time as clinical signs of respiratory disease appeared in a few foals.[76] However, a single fecal sample from a foal has no diagnostic value because of individual and farm-to-farm variation in the number of *R. equi* in feces.[74,76,163] Furthermore, a negative fecal culture may not be helpful in excluding *R. equi* infection because only 5 (17%) of 30 foals with confirmed *R. equi* pneumonia had positive fecal cultures.[159] Similarly, bacterial culture and PCR amplification of nasal swabs are insensitive for diagnosis of *R. equi* pneumonia.[160,161,164]

VetBooks.ir

VetBooks.ir

Treatment A wide variety of antimicrobial agents are active against *R. equi* in vitro. However, many of these drugs are reported to be ineffective in vivo, likely because of poor cellular uptake and resulting low intracellular concentrations. For example, in a retrospective study, all 17 foals with *R. equi* pneumonia treated with the combination of penicillin and gentamicin died despite the fact that all isolates were sensitive to gentamicin.[12] The combination of rifampin and erythromycin became the treatment of choice in the 1980s and has apparently reduced foal mortality relative to historical data.[12,156] However, there are no controlled studies directly comparing the efficacy of erythromycin and rifampin to that of other antimicrobial agents. In recent years, clarithromycin or azithromycin, two newer generation macrolides, often replace erythromycin in the combination with rifampin.[165] Macrolides and rifampin are highly active against *R. equi* in vitro but only exert bacteriostatic activity.[166,167] As a result, macrolides and rifampin exert time-dependent activity against *R. equi* in vitro.[167] Of the three macrolides listed previously, clarithromycin is the most active against *R. equi* in vitro and against intracellular *R. equi* in cell culture.[167,168] The minimum inhibitory concentration at which 90% of *R. equi* isolates are inhibited (MIC_{90}) is 0.12, 0.25, and 1.0 μg/mL, for clarithromycin, erythromycin, and azithromycin, respectively.[169] The combination of a macrolide and rifampin is synergistic both in vitro and in vivo, and the use of the two classes of drugs in combination reduces the likelihood of *R. equi* resistance to either drug.[166,167,170] Rifampin and macrolides are lipid soluble, allowing them to penetrate cell membranes and caseous material.

The recommended dosages are listed in Table 31-4. Several formulations of erythromycin are commercially available. Although they all show slight differences in bioavailability and elimination, they all result in therapeutic concentrations at recommended dosages. However, the bioavailability of erythromycin in foals is considerably lower when foals are not fasted (mean ± SD: 26 ± 15% when fasted and 8 ± 7% when fed).[171] Advantages of azithromycin and clarithromycin over erythromycin in foals include enhanced oral bioavailabilities (especially in the absence of fasting), prolonged half-lives, and much higher concentrations in BAL cells and pulmonary epithelial lining fluid (PELF).[172-174] These properties of the newer generation macrolides contribute to their lower dosages and longer dosing intervals.

In general, plasma concentrations of macrolides in people and cattle are considerably lower than the MIC of the pathogens against which these drugs have been proven to be effective. Thus, plasma concentrations of macrolides are considered poor predictors of in vivo efficacy against respiratory pathogens, whereas concentrations at the site of infection provide more clinically relevant information.[175] Measurement of drug concentration in PELF and cells collected by bronchoalveolar lavage is a widely used method to estimate antimicrobial concentrations at the site of infection for antimicrobials intended to treat lower respiratory tract infections in people.[175,176] After equivalent doses, concentrations of clarithromycin in PELF and BAL cells of foals are considerably higher than concentrations reported after administration of azithromycin or erythromycin to foals.[173,174,177] However, clarithromycin concentrations at these sites decrease rapidly, whereas the release of azithromycin from cells is much slower, resulting in sustained concentrations of azithromycin in tissues for days following discontinuation of therapy.[172-174,177] There are no data from randomized prospective studies comparing the relative efficacy of erythromycin, clarithromycin, and azithromycin in pneumonic foals. In a retrospective study, the combination clarithromycin-rifampin was significantly more effective than erythromycin-rifampin or azithromycin-rifampin, especially in foals with severe radiographic lesions.[165] However, these results must be interpreted with caution because foals were not randomly distributed to treatment groups and because of biases inherent to retrospective data. Nevertheless, these data are the best available evidence to guide macrolide selection in foals with *R. equi* pneumonia. Recent studies demonstrate that concurrent therapy with rifampin considerably decreases plasma, PELF, and BAL cell concentrations of clarithromycin and potentially other macrolides.[178,179] However, there are no studies in foals comparing the clinical efficacy of the combination of a macrolide with rifampin to a macrolide alone. Until it is documented that a macrolide alone is as effective as the combination with rifampin, the combination of a macrolide (erythromycin, azithromycin, or clarithromycin) with rifampin remains the recommended treatment.[146]

Various bacteria and fungi are often isolated from TBA along with *R. equi*. The most common concurrent bacterial isolates are β-hemolytic streptococci and *Escherichia coli*.[180] However, isolation of multiple types of bacteria or fungi from a TBA does not negatively impact survival, and mixed infections are significantly more likely to be encountered in TBA than in lung tissue, suggesting that many bacteria isolated from a TBA colonize the trachea without necessarily contributing to pulmonary pathology.[180] It is common practice to add a third antimicrobial agent if heavy growth of a gram-negative pathogen resistant to macrolides and rifampin is isolated along with *R. equi*. However, recent data indicate that this practice may not be beneficial.[180] The combination of an aminoglycoside (gentamicin or amikacin) with macrolides or rifampin in vitro is antagonistic against *R. equi* compared with either drug alone.[166,167,170] However, the clinical significance of this in vitro finding has not been established.

Resolution of clinical signs, normalization of plasma fibrinogen concentrations, and radiographic or ultrasonographic resolution of lung lesions are commonly used to guide the duration of therapy, which generally ranges between 3 and 12 weeks, depending on the severity of the initial lesions and response to therapy. Foals treated based on subclinical lesions identified during ultrasonographic screening typically do not require as long a treatment period as foals

TABLE 31-4

Recommended Dosages, Oral Bioavailability, and Serum Half-Lives of Antimicrobial Agents Commonly Used for the Treatment of *R. equi* Infections in Foals

Class	Drug	Dose (mg/kg)	Route	Frequency (h)	Oral Bioavailability (%)	Serum $t_{1/2}$ (h)	References
Macrolides	Erythromycin*	25	PO	6-8	8[†]-25[‡]	1	171, 227
		5	IV	6	NA	1	226
	Clarithromycin	7.5	PO	12	57[†]	5.4	225
	Azithromycin	10	PO	24-48[§]	56[†]	18	172, 173
		5	IV	24-48[§]	NA	16	172, 173
Rifamycins	Rifampin	5	PO	12	49[‡]	15	228, 229, 230

*Erythromycin base, stearate, phosphate, estolate, or ethylsuccinate.

[†]Mean (± SD) bioavailability with ad libitum access to milk and hay.

[‡]Mean (± SD) oral bioavailability after fasting.

[§]Administration q24h for 5 days and q48h thereafter.

VetBooks.ir

in respiratory distress with severe pulmonary lesions. In fact, as addressed later, many foals with subclinical ultrasonographic lesions clear the infection without therapy.[6,181] Currently, there are no validated criteria to differentiate foals with subclinical ultrasonographic lesions that will clear the infection from those that will progress to clinical disease.

Although well tolerated by most foals, macrolides commonly cause diarrhea. The diarrhea is often self-limiting and does not necessitate cessation of therapy. However, affected foals should be monitored carefully because some may develop severe diarrhea, leading to dehydration and electrolyte losses that necessitate intensive fluid therapy and cessation of oral macrolides. The incidence of diarrhea in foals treated with erythromycin-rifampin has ranged between 17% and 36%.[165,182] In one study, foals treated with clarithromycin had a higher incidence of diarrhea (28%) than those treated with azithromycin (8%) although in most cases, diarrhea was mild and self-limiting.[165] In the same study, the incidence of severe diarrhea necessitating administration of IV fluids was not significantly different between groups of foals treated with azithromycin-rifampin, clarithromycin-rifampin, or erythromycin-rifampin.[165] During periods of very hot or humid weather, an idiosyncratic reaction characterized by severe hyperthermia and tachypnea has been described in foals treated with erythromycin.[182] Anecdotal reports suggest that these reactions may occasionally occur with newer macrolides as well. Administration of antipyretic drugs and placing the foal in a cool environment will treat this problem. Severe enterocolitis also has been reported in mares whose foals are treated with erythromycin, presumably by disrupting the mare's normal colonic microflora following ingestion of small amounts of active drug during coprophagia or by contamination of feeders or water buckets with drug present on the foal's muzzle. This complication seems to be rare. Enterocolitis in mares has been reproduced experimentally by administration of subtherapeutic doses of erythromycin.[183] In some cases, the severe enterocolitis in the mares of treated foals is associated with *Clostridium difficile*.[184]

Availability of a long-acting macrolide antimicrobial agent providing sustained therapeutic concentrations at the site of infection would result in less frequent administration, which in turn might improve compliance. Tulathromycin, a semi-synthetic macrolide approved for use in swine and cattle, has been shown to concentrate in the BAL cells of foals after intramuscular administration.[185] Tulathromycin was recently compared with azithromycin-rifampin for the treatment of foals with subclinical pneumonia as identified by ultrasonographic screening on a farm with a high cumulative incidence of *R. equi* infections. Although differences in survival were not statistically significant, pulmonary abscesses 1 week after initiation of treatment with tulathromycin were significantly larger and duration of therapy was significantly longer, indicating that tulathromycin is not as effective as standard therapy with azithromycin-rifampin.[5] These results might be explained by the fact that tulathromycin is poorly active against *R. equi* in vitro with a MIC_{90} higher than 64 μg/mL.[186] This concentration is more than 100-fold higher than achievable tulathromycin concentrations in BAL cells after intramuscular administration at the recommended dose of 2.5 mg/kg.[185] Tilmicosin, another long-acting macrolide approved for use in swine and cattle, is also poorly active against *R. equi* (MIC_{90} of 32 μg/mL) and administration to foals sometimes results in swelling at the site of injection.[174] Similarly, tildipirosin is also poorly active against *R. equi* in vitro with a MIC_{90} of 32 μg/mL. As a result, tulathromycin, tilmicosin, and tildipirosin are not recommended for use in foals with pneumonia caused by *R. equi*. In contrast, gamithromycin, another long-acting macrolide approved for the treatment and prevention of respiratory disease in nonlactating cattle is active against *R. equi* in vitro (MIC_{90} = 1.0 μg/mL).[168] A single intramuscular administration of gamithromycin at a dosage of 6 mg/kg maintains BAL cell concentrations above the MIC_{90} for *R. equi* for approximately 7 days.[168] However, treatment with gamithromycin is not recommended until the clinical efficacy and the safety of the drug have been established.

TREATMENT OF FOALS INFECTED WITH MACROLIDE- AND RIFAMPIN-RESISTANT ISOLATES OR TREATMENT OF FOALS WITH ADVERSE REACTIONS TO THE COMBINATION MACROLIDE-RIFAMPIN. Although the vast majority of *R. equi* isolates from foals are highly susceptible to macrolides and rifampin, strains resistant to either drug class have been encountered. Rifampin should not be used alone because this increases the chance of resistance developing,[166,187] as a result of mutations in the RNA polymerase β subunit encoded by the *rpoB* gene.[188,189] Apparent progressive development of resistance to both erythromycin and rifampin during treatment is extremely rare but has been reported.[13] In a recent study, the overall prevalence of resistant isolates in Texas and Florida over a 10-year period was 4%.[190] In the same study, the odds of death were 7 times higher in foals infected with resistant isolates.[190] In addition, the study demonstrated that isolates of *R. equi* susceptible to macrolides were sometimes misclassified as resistant; therefore it is reasonable to request retesting and/or validation of resistance by the testing laboratory. The molecular mechanisms of macrolide resistance of *R. equi* isolates have not been determined, but *R. equi* isolates resistant to erythromycin, clarithromycin, or azithromycin are almost invariably resistant to the other macrolides.

Therapy of foals that develop severe diarrhea during macrolide therapy or therapy of foals infected with resistant isolates is problematic because of the limited range of effective alternatives. Macrolide- and rifampin-resistant isolates of *R. equi* are susceptible in vitro to fluoroquinolones, aminoglycosides, oxazolidinones, and glycopeptide antimicrobials.[186,190] In one study, 18 of 24 isolates were also susceptible to chloramphenicol, tetracycline, and trimethoprim-sulfamethoxazole.[190] Currently, there are no data to indicate the preferred antimicrobial agent(s) for the treatment of foals infected with isolates resistant to macrolides and rifampin.

Although objective data regarding efficacy are lacking, several other classes of antimicrobial agents have been used to treat *R. equi* in foals. Oral doxycycline in combination with rifampin has been used with anecdotal success to treat foals with pneumonia caused by *R. equi*. Doxycycline and rifampin are highly synergistic against *R. equi* in vitro.[167] The recommended dosage for doxycycline in foals is 10 mg/kg PO q12h.[191] This dosage results in serum, PELF, and BAL cell concentrations above the MIC_{90} of *R. equi* isolates (1.0 μg/mL) for the entire dosing interval. Chloramphenicol can be administered orally and achieves high concentrations within phagocytic cells in other species. The recommended dosage regimen is 50 mg/kg PO q6h. However, the fact that only 70% of *R. equi* isolates are susceptible to this drug and the potential human health risk make this drug a less attractive alternative. High doses of a trimethoprim-sulfonamide combination (30 mg/kg of combination q8h or q12h, orally) have been used alone or in combination with rifampin in foals with mild or early *R. equi* pneumonia and for continued therapy in foals responding well to other antimicrobials.[12] Currently, there are insufficient data to recommend the use of these antimicrobial agents for treating infections caused by *R. equi*.

In an experimental model of *R. equi* infection in immunosuppressed mice, the most effective drugs in monotherapy were found to be, in order of effectiveness, vancomycin, imipenem, and rifampin.[192] Amikacin, erythromycin, ciprofloxacin, or minocycline in monotherapy did not lead to a significant decrease in bacterial counts. The most active drugs in combination were those including vancomycin or rifampin, but efficacy of these combinations was not significantly different from that of vancomycin monotherapy.[192] Vancomycin and imipenem in foals should be used only for the treatment of life-threatening *R. equi* infections caused by isolates confirmed to be resistant to all other possible alternatives.

ANCILLARY THERAPIES. Nursing care, provision of adequate nutrition and hydration, and maintaining the foal in a cool and well-ventilated environment are important. Humidified oxygen delivered by pharyngeal insufflation in moderately hypoxemic foals, or by percutaneous transtracheal oxygenation in severely hypoxemic patients, is indicated.[193] Judicious use of nonsteroidal antiinflammatory drugs

VetBooks.ir

might reduce fever and improve attitude and appetite in febrile, lethargic, anorectic foals. Nebulization with saline, antimicrobial agents, or bronchodilators has been advocated, but there are no data to either support or refute these therapeutic practices. Immune-mediated extrapulmonary disorders, such as polysynovitis, generally resolve with successful treatment of the accompanying pneumonia. Exercise should be limited but not eliminated in foals with polysynovitis. In addition to appropriate systemic antimicrobial therapy, foals with *R. equi* septic arthritis or osteomyelitis often require aggressive local therapy such as joint lavage, surgical débridement, and IV or intraosseous regional limb perfusion with antimicrobial agents. The prognosis for foals with abdominal abscesses is poor, although rare cases will respond to long-term antimicrobial therapy.[8,194] Surgical removal or marsupialization has been attempted in some foals, but abdominal adhesions usually result in inability to resect the abscess.

Prognosis Prior to the introduction of the combination of erythromycin and rifampin as the treatment of choice in the early 1980s, the prognosis of *R. equi*–infected foals was poor, with survival rates as low as 20%.[195] Using erythromycin and rifampin, Hillidge reported a successful outcome (as assessed by survival) in 50 (88%) of 57 foals with confirmed *R. equi* pneumonia.[156] Studies from referral centers, where severely affected cases are likely more prevalent, have revealed survival proportions ranging between 59% and 72%.[148,165,196] In contrast, the survival rate at farms that use a screening program to identify and treat foals with subclinical lesions has resulted in survival proportions of nearly 100%.[4,197] However, recent evidence indicates that many of these foals would have recovered without therapy. Controlled studies have shown that approximately 88% of foals with ultrasonographic lesion scores (sum of the diameter of each abscess) up to 10 cm recover without antimicrobial therapy.[6,181] In the same studies, treatment of affected foals with antimicrobial agents did not provide a clear benefit over administration of a placebo.[6,181]

The impact of *R. equi* infections on future athletic performance has been examined. No significant differences in total earnings, average earning index, or age at first race were observed when comparing 30 horses that previously had *R. equi* pneumonia with either their dams' other progeny or the North American averages.[198] In another study, 54% of 83 foals that survived *R. equi* pneumonia had at least one racing start as compared with 65% of their birth cohort, suggesting that horses contracting *R. equi* pneumonia as foals may be somewhat less likely to race as adults. However, consistent with a previous report,[198] the racing performance of those foals was not different from that of the U.S. racing population.[148] In summary, prognosis for performance after successful treatment of uncomplicated *R. equi* pneumonia should be regarded as very good.

Control and Prevention of *R. equi* Infections on Farms Where the Disease Is Endemic

Methods for control and prevention include using screening tests for early detection of *R. equi* pneumonia, environmental management, chemoprophylaxis, and prevention through use of either passive or active immunization. Currently, there is inadequate evidence to recommend environmental interventions to control or prevent *R. equi* pneumonia.[199] Further evaluation of certain practices, such as foaling at pasture and reducing either airborne concentrations of virulent *R. equi* or density of mares and foals, is merited.

SCREENING FOR EARLIER DETECTION OF AFFECTED FOALS. *R. equi* pneumonia is often not recognized until it is well advanced, and thus it is difficult to treat. Even severely affected foals may appear, to a casual observer, to suckle and behave normally. The rationale for screening is the assumption that detecting foals in the early stages of disease and implementing appropriate treatment of affected foals will improve outcomes. It is important to emphasize that screening methods are not diagnostic tests. A useful screening test is one in which the probability of disease is high with a positive test result (high positive predictive value) and very low with a negative test result (high negative predictive value). The higher the prevalence of disease is at a given farm, the higher the positive predictive value of a given test will be. Therefore, depending on the prevalence of *R. equi* infections at a given farm, a positive result of a screening test could be a basis from which to perform a diagnostic test (low to moderate prevalence) or to initiate therapy (high prevalence). Uncontrolled studies suggest that screening may reduce the mortality attributable to *R. equi* pneumonia.[4,200] Thus, in the absence of a vaccine or other effective methods for preventing this devastating disease, screening is a reasonable approach to control *R. equi* at endemic farms. Implementing screening testing at farms that are only sporadically affected by *R. equi* pneumonia may not be warranted.

A variety of screening techniques performed serially have been described, including visual inspection of foals for clinical signs of pneumonia, rectal temperature monitoring, hematologic parameters, serologic tests, and thoracic imaging using either radiography or ultrasonography, with an empirical recommendation that screening begin around 3 weeks of age.[201] Systematic comparisons of these tests have not been performed. Thus, a specific recommendation for any particular screening test cannot be made, and it is likely that the optimal approach for screening may vary among farms on the basis of cumulative incidence of disease, resources available for control and prevention, and preferences of the attending veterinarian(s) and farm management.

Studies have shown that serum concentrations of either antibodies against *R. equi,* serum amyloid A, or plasma fibrinogen are not useful screening tests.[153,155,202] WBC concentrations performed at monthly intervals had clinically acceptable sensitivity and specificity for early detection of *R. equi* pneumonia at one farm (sensitivity of 79% and specificity of 91% at a cutoff value of 15,000 cells/μL).[152] However, serial measurement of WBC or neutrophil concentrations resulted in limited performance for prediction of subsequent development of clinically apparent *R. equi* pneumonia at another farm.[203] In addition to conflicting data regarding the benefit of this approach, additional limitations of using WBC concentration for screening are the time and effort required to collect blood samples from foals, the lag from time of submission to availability of results, and the potential for false-positive results attributable to stress-associated leukocytosis or other infectious or inflammatory conditions that may be common among foals.

Over the past decade, control of *R. equi* infections at many farms where the disease is endemic has relied on early detection of subclinical pulmonary disease using thoracic ultrasonography and initiation of treatment with antimicrobial agents prior to development of clinical signs.[4,5,204] Ultrasonography of the chest offers several advantages over other screening tests: (1) results are specific for the presence of pulmonary pathology; (2) the procedure can be performed relatively quickly for an individual foal; (3) results are available immediately; and (4) the procedure may be more sensitive than radiography for detecting lesions in their early stages of development or in certain regions where soft-tissue structures are superimposed over regions of the lung.[151] Although controlled studies are lacking, periodic ultrasonography of the chest appears to result in decreased mortality due to *R. equi* pneumonia at some farms.[4,5,204]

The cumulative incidence of clinical signs of pneumonia attributed to *R. equi* on endemic farms that do not use ultrasonographic screening typically ranges between 5% and 20%,[68] whereas the cumulative incidence of foals with ultrasonographic evidence of pulmonary abscessation on *R. equi*–endemic farms is generally between 30% and 70%,[4,197,204] suggesting that many subclinically affected foals recover without therapy. Indeed, recent double-blinded randomized placebo-controlled studies documented that approximately 88% of foals with small pulmonary lesions (sum of lesion diameters [or abscess score] of 1 to 10 cm) recover without antimicrobial therapy.[6,181] In addition, antimicrobial treatment of foals with small lesions detected by ultrasonographic examination did not significantly hasten lesion resolution compared with administration of a placebo.[6,181] The use of ultrasonography for screening to detect *R. equi*

VetBooks.ir

pneumonia was recently evaluated at an endemic farm, with personnel and veterinarians blinded to screening results.[7] Of 270 foals enrolled in the study, 216 (80%) developed sonographically visible pulmonary lesions, whereas only 17% of foals developed clinically apparent *R. equi* pneumonia.[7] Resolution without clinically apparent illness or antimicrobial therapy occurred in 79% of foals with ultrasonographic pulmonary lesions.[7] In the aforementioned study, the cumulative sensitivity of ultrasonography was very good (89%) but cumulative specificity was low (62%).[7]

Because it is impossible to know which specific foal might recover spontaneously from subclinical disease, and because *R. equi* infections can cause severe disease, many breeding farms elect to treat all foals with ultrasonographic lesions. This approach has resulted in an increased number of foals treated for presumptive *R. equi* pneumonia in the absence of clinical disease. The temporal association between this widespread use of macrolides and rifampin as a result of ultrasonographic screening and a perceived increase in the frequency of detection of resistant isolates in the past decade[190] suggest that this practice may not be innocuous. Emergence of macrolide and rifampin resistance at a farm after widespread use of these drugs was instituted as part of an ultrasonographic screening program has been documented.[90] On that particular farm, 20% to 40% of *R. equi* isolates from pneumonic foals were resistant to macrolides and rifampin.[90] Currently, it is unknown if macrolide and rifampin resistance is widespread on many horse farms relying on mass antimicrobial therapy of foals with ultrasonographic lesions or if it is an isolated problem. In addition to the cost and risk for selection for resistant bacteria, unnecessary mass antimicrobial therapy of foals with pulmonary lesions might lead to development of life-threatening adverse reactions (e.g., diarrhea or hyperthermia) in some foals.

The spontaneous resolution of ultrasonographic lesions in a large proportion of foals,[6,7,181] combined with the apparent increase in macrolide and rifampin resistance at some farms,[90] support the need to stop the practice of mass macrolide treatment of all subclinically affected foals with ultrasonographic lesions. The goal should be to more accurately identify, of the many subclinically infected foals, which few are likely to go on to develop disease and hence require treatment. The degree of severity and the number of ultrasonographic lesions in a given foal that warrant therapy are unknown and may vary by farm, geographic region, and age at which lesions are detected. Additional studies are needed to establish better criteria to determine the need for therapy in subclinically affected foals and to better quantify the risks versus benefits of treating foals with subclinical ultrasonographic lesions.

PASSIVE IMMUNIZATION. Intravenous administration of HIP obtained from horses vaccinated against *R. equi* using various antigens has generally proved effective in significantly reducing the severity of *R. equi* pneumonia in foals following experimental challenge.[63,109,205] However, studies evaluating the efficacy of various HIP preparations under field conditions have given equivocal results. Although the data are conflicting and not all trials have shown a statistically significant reduction in the cumulative incidence of *R. equi* pneumonia, five of seven studies have demonstrated reduction of relative risk, suggesting some benefit of HIP.[3,65,158,206-209]

Intravenous administration of purified immunoglobulins obtained from horses immunized with recombinant VapA and VapC to foals reduced the severity of pneumonia following high-dose experimental challenge with *R. equi* to a degree similar to that provided by commercially available HIP.[111] This demonstrates that immunoglobulins, predominantly against VapA and VapC, are responsible for the protection conferred by HIP. Therefore administration of plasma obtained from horses that are not hyperimmunized against *R. equi* is not recommended for protection against *R. equi*. Because endemicity of *R. equi* at farms does not appear to be explained by farm-specific isolates and because foals may be infected with multiple strains at once,[88] there is no need to administer plasma that is produced from immunizing horses with isolates of *R. equi* obtained from a given farm; transfusion of plasma from horses that have been immunized against any virulent (i.e., VapA-positive) strain of *R. equi* should suffice.[199] Use of HIP licensed as an aid in the control of *R. equi* pneumonia is recommended (rather than plasma simply obtained from horses hyperimmunized against *R. equi*) because licensure ensures standards of potency, purity, and safety. Currently, there is insufficient information to recommend one brand of licensed antibody product over another.

The optimal amount of plasma to be transfused and the optimal age at which transfusion should occur remain to be determined. Administration of HIP 9 days after aerosol infection of foals with *R. equi* did not confer protection,[210] suggesting that administration of HIP prior to infection is important. Because of evidence that many foals become infected early in life,[64] it is commonly recommended that foals receive transfusion of at least 1 L of HIP no later than the second day of life. Because early administration may result in the decline of passively transferred antibody to a nonprotective level at a time when foals are still susceptible to *R. equi* and when environmental challenge is high, it is common practice to administer a second liter of HIP at 2 to 4 weeks of age.

Transfusion of HIP is not completely effective and therefore does not eliminate the need for careful monitoring of foals at risk. In addition to being incompletely effective, transfusion of HIP carries some risk to foals, such as trauma that may occur during handling and adverse reactions to transfusions. The process is also time intensive, labor intensive, and expensive. Thus the cost-effectiveness of transfusion depends on the value of the foals and the prevalence of disease at a given farm.

ACTIVE IMMUNIZATION. It would be convenient to control *R. equi* pneumonia on endemic farms by active immunization of mares or foals with a protective antigen. To date, however, this approach has been largely unrewarding. The role of antibody in partial protection against *R. equi* infection would suggest that vaccination of mares could confer at least some degree of protection. However, in both a field study and an experimental challenge, vaccination of mares did not provide protection against *R. equi* pneumonia despite a significant increase in colostral *R. equi*–specific antibody and transfer of these antibodies to foals.[208,211] More recently, vaccination of a small number of mares with VapA associated with a water-based nanoparticle adjuvant led to high anti-VapA IgG concentrations in mares and foals and might have conferred protection against natural challenge compared with nonvaccinated controls.[212] Large-scale studies at endemic farms will be necessary to confirm these preliminary findings before widespread vaccination of mares can be recommended.

Because cell-mediated immunity is of paramount importance for protection against *R. equi,* active immunization of foals likely will be required for complete protection. Oral immunization with *Salmonella enterica* Typhimurium expressing the VapA antigen protects mice against *R. equi* infection.[213] Preliminary studies indicate that the aforementioned vaccine also confers protection in foals.[214] Recent studies in mice indicate that DNA immunization with *vapA* protects against *R. equi* infection and that the IgG subisotype response is consistent with a Th1-based immune response.[215] A similar DNA vaccine containing the *vapA* gene has been shown to induce strong cell-mediated immune responses in adult horses, but responses were poor in foals.[216] Intrabronchial immunization of neonatal foals with a live, fully attenuated, riboflavin auxotrophic strain of *R. equi* stimulated immune responses but did not confer protection against subsequent intrabronchial challenge with live *R. equi*.[217] The fact that live, avirulent plasmid-cured *R. equi* does not elicit adaptive immunity and is cleared rapidly indicates that bacterial replication is needed for induction of strong cell-mediated immune responses.[218] Intrabronchial immunization with a deletion mutant of *R. equi* lacking the chromosomal genes isocitrate lyase *(icl)* and cholesterol oxidase *(choE)* conferred protection against subsequent challenge in three foals.[219] However, two foals developed pneumonia caused by the mutant strain.[219] More recently, oral vaccination of foals with a live attenuated *R. equi* strain lacking genes involved in the steroid

VetBooks.ir

catabolic pathway elicited substantial protection against subsequent intrabronchial challenge with live virulent *R. equi*.[53] Collectively, the aforementioned studies indicate that there is a fine line between sufficient replication of *R. equi* for induction of strong cell-mediated immune responses and development of disease from the vaccine strain. Additional challenges are that immunization in foals will need to be initiated very early in life, and an effective vaccine will have to overcome the relative immaturity of the naive neonatal immune system. Currently, there is inadequate evidence to recommend active immunization of mares or foals to control or prevent *R. equi* pneumonia, but there are promising vaccine candidates under development.

CHEMOPROPHYLAXIS. Because an effective vaccine is lacking, prophylactic administration of antimicrobial agents to all the foals during the time period when they are most susceptible to infection has been suggested as another approach for the prevention of *R. equi* infections on endemic farms. Azithromycin is an attractive choice for chemoprophylaxis because of good oral bioavailability, long half-life, and high and sustained concentrations in PELF, BAL cells, and neutrophils. Two studies have evaluated the use of azithromycin for chemoprophylaxis. In a randomized, controlled trial conducted in the United States among 338 foals at 10 farms, the cumulative incidence of *R. equi* pneumonia was reduced from 21% among untreated foals to 5% among foals that received azithromycin (10 mg/kg PO q48h for the first 14 days of life beginning on the first day of life).[220] By contrast, in a study conducted among 70 foals at a large breeding farm in Germany, the incidence of abscessing pneumonia was not significantly different between foals that received azithromycin (10 mg/kg PO q24h for the first 28 days of life) for prevention of abscessing pneumonia (cumulative incidence = 60%) and foals that did not receive azithromycin for chemoprophylaxis (cumulative incidence = 69%); however, the age at onset of abscessing pneumonia was delayed in treated foals.[197] The reason for the discrepancy between studies is unknown. Regardless, use of azithromycin is not considered an acceptable approach for chemoprophylaxis because widespread use of this drug would create greater pressure for emergence of macrolide resistance among bacteria.[146]

Gallium maltolate is a metal-based compound with antimicrobial properties that has been demonstrated to reduce replication of *R. equi* in pure culture[221] and within macrophages,[222] to reduce tissue concentrations of *R. equi* in mice following experimental infection,[221] and to be bioavailable[223] and safe in foals.[224] Unfortunately, chemoprophylaxis with gallium maltolate (30 mg/kg PO q24h for the first 14 days of life) failed to reduce the incidence of *R. equi* pneumonia in a placebo-controlled trial of 438 foals at 12 farms in the United States.[3]

Pneumonia in Foals

Daniela Bedenice

Equine pneumonia is a significant cause of morbidity and mortality in both the newborn and the older foal.[1-4] Although the causative agents and the mode of lung infection are generally different for each age group, foal pneumonia is commonly associated with a compromise in the immunologic protection of the host. The exact immunologic basis of the foal's inherent susceptibility to opportunistic respiratory pathogens needs to be further elucidated.

Failure of passive transfer of immunity (FPT) is a well-known risk factor of neonatal infection, including respiratory disease,[4] because not only are affected foals deprived of specific maternal antibody protection but their neutrophil function is also seriously impaired.[5] Although foals can respond immunologically in utero to bacterial or viral infections, their ability to do so is less than that of adults. Reduced complement values and defective chemotaxis (directed migration of neutrophils or macrophages) and killing capacity of the neonatal neutrophils contribute to a relatively decreased defense against invading bacteria. Furthermore, an immature ciliary apparatus and the presence of fewer alveolar macrophages in neonates, in comparison with adult horses, lead to decreased bacterial clearance from the lungs.[6] The number and distribution of the bronchoalveolar cells approach adult levels at approximately 3 to 6 weeks of age.[7]

It has been suggested that a natural cellular immunodeficiency may also occur in foals at 2 to 4 months of age.[8] Although the exact association between age-related cellular immunodeficiency and the defense against intracellular pathogens such as *Pneumocystis carinii* (renamed *P. jiroveci* in humans) and *R. equi* of foals still needs to be clarified, $CD4^+$ and $CD8^+$ T lymphocytopenia was documented in a filly with *P. carinii* pneumonia.[9]

Etiology

NEONATAL PNEUMONIA (<1 MONTH OF AGE). In contrast to the older foal, infectious lung disease in the neonate is usually part of a multiple-organ, systemic infection or sepsis, which may be acquired via the placenta in utero or perinatally through environmental bacteria leading to hematogenous (ascending) infection (e.g., omphalophlebitis). *E. coli, Klebsiella* spp., *Actinobacillus equuli, Salmonella* spp., and *Streptococcus* spp. are some of the more common bacteria involved in neonatal foal pneumonia.[10]

Descending lung infections may be caused by inhalation of viral, bacterial, or opportunistic fungal agents. Furthermore, iatrogenic aspiration (oil, medication, oral supplements) or aspiration of gastric reflux, milk, meconium, and contaminated amniotic fluid after placental infection may seed the foal's lung. Meconium aspiration occurs in utero in foals that experience fetal distress (perinatal asphyxia). Although meconium is commonly sterile at this time, it creates mechanical airway obstruction, surfactant inactivation, and pulmonary inflammation (caused by vasoactive mediators and chemotactic and inflammatory cytokines, including TNF-α, interleukin [IL]-1β, and IL-8).[11] The resulting edema and vasoconstriction may lead to hypoperfusion of the pulmonary parenchyma, with damage to type II pneumocytes and decreased production of surfactant.[12] This type of "secondary surfactant deficiency" may also be induced by other forms of generalized pulmonary inflammation, including diffuse bacterial and viral pneumonia. Neurologic dysfunction, severe inflammation, or structural abnormalities of the upper airways (congenital cysts, dorsal displacement of the soft palate, laryngeal paralysis, pharyngeal weakness, etc.) may predispose to aspiration pneumonia postpartum. The prognosis of foals with dysphagia due to pharyngeal dysfunction is considered favorable for life and fair for athleticism, based on a recent study by Holcombe and colleagues.[13] In the latter study, 8 of 16 (50%) affected foals were premature, diagnosed with neonatal encephalopathy, or both, and 12 of 16 (75%) had aspiration pneumonia.

Equine viral arteritis (EVA) and herpes viral infections (EHV-1 and EHV-4) have been implicated in in utero viral infections leading to lung disease.[14] Although involvement of adenovirus in the pathogenesis of pneumonia has also been reported in a Thoroughbred foal, fatal adenoviral pneumonia is primarily related to severe combined immunodeficiency (SCID) in Arabian foals.[15,16] Additionally, equine influenza virus (EIV) infection has been associated with fatal bronchointerstitial pneumonia in young foals that do not have maternal immunity.[17]

PNEUMONIA IN OLDER FOALS (1 TO 6 MONTHS OF AGE). *S. equi* subsp. *zooepidemicus* and *R. equi* are the most important pathogens associated with pneumonia in older foals, although plurimicrobial infections *(Actinobacillus* spp., *B. bronchiseptica, E. coli, Klebsiella pneumoniae, Pasteurella* spp., *Pseudomonas* spp., *Salmonella* spp., and *Staphylococcus* spp.) are not uncommon.[18,19] *S. equi* subsp. *zooepidemicus* was isolated from 87% of uncomplicated lower respiratory tract infections in foals (1 to 8 months old) on selected farms[20] and was documented as the most common cause of pulmonary abscesses in a second study.[21] In contrast, anaerobes appear to be infrequently involved in primary pneumonia of foals.[20] *Corynebacterium pneumonia* due to aerosol infection is a rare cause of

VetBooks.ir

diffusely increased interstitial and peribronchial radiographic densities, indicative of pulmonary abscesses in foals.[22] More recently, acute respiratory failure was associated with *Leptospira* spp. infection in five foals (3 weeks to 5 months of age). Pulmonary hemorrhage and interstitial pneumonia with infiltration of red blood cells, hemosiderophages, and inflammatory cells were observed at necropsy, similar to observations in people.[23]

Although respiratory viruses are often believed to be the primary offending agents that lead to secondary bacterial lung invasion, they have limited importance in nursing foals.[20,24] Equine adenoviruses (EAdVs) and EHV-2 are ubiquitous in the general equine population, with little apparent pathogenicity in immunocompetent foals. Although adenoviruses are the most common respiratory pathogens in Arabian foals with SCID, the role of EHV-2 in the respiratory disease complex of foals remains unclear. It has been suggested that EHV-2 exerts its effects on the host indirectly, through predisposition to secondary infections, such as *R. equi* pneumonia. Dunowska and colleagues recently evaluated serial blood samples from 43 foals on a single farm over a period of 10 months, where all but two foals were positive for EHV-2 on at least one occasion. The majority (88%) of foals became infected with EHV-2 within the first 2 months of life.[25]

Because of the complexity of the disease, in-depth discussions of *Rhodococcus* pneumonia and acute respiratory distress syndrome (ARDS) and acute lung injury (ALI) are presented elsewhere in this chapter.

INTERSTITIAL PNEUMONIA. Acute, severe interstitial or bronchointerstitial pneumonia is a sporadic, rapidly progressive disease in foals from 1 to 6 months of age that is characterized by a sudden onset of respiratory distress, tachypnea, fever, high mortality, and histopathologic evidence of severe, diffuse, necrotizing bronchiolitis; alveolar septal necrosis; and neutrophilic alveolitis on necropsy.[26-28] Although no definitive causative agent(s) or factor(s) of this disease have yet been identified, suspected causes include viruses, *P. carinii,* heat stroke, environmental toxins, and bacteria.[26-29] Enteric gram-negative organisms, *R. equi, Pseudomonas aeruginosa,* and *P. carinii* have all been cultured from the lungs of affected foals. The acute severe onset suggests that this disease process is a form of ALI and/or ARDS.

The reported cases are usually sporadic, affecting a single foal within a herd,[26] although rare clusters of cases have also been described.[28] The disease is generally rapidly progressive and may lead to sudden death as a result of fulminant respiratory failure. Severe respiratory distress, hypoxemia, hypercapnia, and respiratory acidosis are the most striking clinicopathologic signs. The hypoxemia of bronchointerstitial pneumonia is relatively resistant to supplemental oxygen therapy, indicating a pulmonary shunt. Thoracic radiographs commonly demonstrate caudodorsally distributed interstitial and bronchointerstitial pulmonary opacities. With advanced disease, the radiographic pattern progresses to include patches of a coalescing alveolar nodular pattern with air bronchograms.[30] As with bacterial pneumonia, many foals demonstrate hyperfibrinogenemia and neutrophilic leukocytosis on hematology.

Therapy is symptomatic, including antiinflammatory therapy, broad-spectrum antibiotics, thermoregulatory control, bronchodilation, and supplemental oxygen. In one report of this disease, survival was associated with corticosteroid treatment.[27] Surviving foals may develop a proliferative epithelial and interstitial response, including bronchiolar and alveolar epithelial hyperplasia, type II cell hyperplasia, and hyaline membrane formation.[30]

Chronic pulmonary disease (1 to 3 months' duration) with marked radiographic interstitial opacities was reported in 12 foals, age 3 to 9 months, that were examined at a veterinary teaching hospital.[31] Evaluation failed to yield a consistent pathogen from tracheobronchial aspirates. The authors proposed that chronic interstitial pneumonia occurring in foals is associated with a good prognosis and, similar to a report of acute disease, considered corticosteroid therapy as a potentially useful treatment.[27]

***PNEUMOCYSTIS JIROVECI (CARINII)* INFECTION.** Rare opportunistic fungal pathogens of the lung may include *P. carinii* (renamed *P. jiroveci* in humans), *Aspergillus, Candida,* and *Mucor* spp. *P. carinii* is a unicellular eukaryote that has been classified as a fungus after DNA studies.[32] It is most commonly seen in humans and animals that suffer from a concurrent immunodeficiency. It was first recovered in Arabian foals with SCID.[33] It has since been recovered from foals of other breeds with no specific history of immunodeficiency, although for the most part no direct testing for immunocompetence was performed in the reported cases. However, one more recently documented case demonstrated a low number of circulating $CD4^+$ and $CD8^+$ lymphocytes in a filly with *P. carinii*.[33]

In several reports the onset of clinical signs in affected foals ranged from a 3-week history of weakness, weight loss, and nasal discharge to acute dyspnea. Half of the reported non-Arabian cases had concurrent infections with *R. equi, Enterobacter cloaca, E. coli,* or *S. equi* subsp. *zooepidemicus.* A severe interstitial, sometimes miliary and alveolar pattern was seen on radiographs of the lungs. The majority of the reported foals died, and the diagnosis of *P. carinii* was obtained at necropsy.[29,33-36] On postmortem examination the lungs were uniformly heavy and consolidated, and a diffuse interstitial pneumonia was found. Trophozoites and cysts were observed in the alveolar epithelial cells and macrophages within the alveoli. Silver staining and streptavidin-biotin immunolabeling of histologic sections provide a better visualization of the organisms in the pulmonary tissue.[34] A few foals were diagnosed by visualization of the organism on a BAL sample. Two surviving foals responded to trimethoprim-sulfamethoxazole (TMS) therapy.

Clinical Presentation and Diagnosis of Foal Pneumonia

The clinical manifestation of pneumonia in the newborn foal can be variable and depends on the disease severity and underlying or associated problems. Early in life, localizing clinical signs of respiratory infection may be absent even in the presence of extensive disease. Dyspnea may be seen in severely affected foals and may manifest as an increase in respiratory rate, effort, or thoracoabdominal asynchrony (paradoxical breathing). However, signs of respiratory distress and hypoxemia are frequently vague. Some severely hypoxemic foals may show only restlessness, considerable resistance, and struggling when being handled or restrained. Abnormal respiratory sounds (crackles or wheezes) may be heard on auscultation of ill foals. However, even normal foals may show crackles on the down lung after having remained in lateral recumbency for a prolonged period of time. Furthermore, foals with no auscultable abnormalities may still have extensive pulmonary disease.[37,38] Similar to other species, cyanosis is a sign of severe hypoxemia in foals. The arterial partial pressure of oxygen (PaO_2), however, must reach very low levels (35 to 45 mm Hg) before clinical cyanosis is observed. At a minimum, 5 g/dL of unoxygenated hemoglobin needs to be present in the capillaries to generate the dark-blue color that is appreciated as cyanosis in humans. Therefore severely anemic foals may never appear cyanotic even in the face of profound hypoxemia. Weakness, depression, anorexia, weak or absent suckle reflex, dehydration, and fever may also be noted in newborn foals with respiratory disease. Cough and nasal discharge are usually absent in the early stages of neonatal pulmonary disorders.[10] The older foal, on the other hand, will generally exhibit clinical signs that focus on the respiratory tract, such as abnormal auscultation of the lungs, nasal discharge, cough, fever, tachypnea, and increased respiratory effort.

Thoracic radiographs and arterial blood gas analysis are important in confirming the presence and evaluating the extent and distribution of foal pneumonia. Because radiographic findings may precede or lag behind alteration of respiratory function, repeated diagnostic imaging is recommended. A recent study documented that radiographic abnormalities involving the caudodorsal lung region were most common in neonatal foals admitted to a referral center.[39] The presence of dyspnea, tachypnea, fibrinogen concentration greater than 400 mg/dL, systemic inflammatory response syndrome (SIRS), hypoxemia, or FPT in neonatal foals may be a predictor

VetBooks.ir

of underlying respiratory disease and should prompt an early radiographic evaluation of the thorax, even in the absence of other localizing clinical signs.[4,39] Thoracic ultrasonography has become a popular diagnostic tool for the assessment of equine lung and pleural disease and is particularly useful in determining the side(s) of the thorax affected, as well as the precise location of the lesion in most cases.[4]

Diagnostic sampling of the respiratory tract is less commonly performed in neonatal foals compared with older foals and adult horses. However, transtracheal aspirate, bronchoalveolar lavage, protected catheter brush (PCB), or protected aspiration catheter sampling (PAC) is important in stabilized patients, irrespective of age, to direct antimicrobial therapy and evaluate therapeutic efficacy. Lung biopsies are rarely performed and are limited to patients with chronic disease or suspected fungal pneumonia.[38]

Treatment The treatment goals in dealing with bacterial pneumonia in either age group are similar and directed at maintaining adequate gas exchange to ensure patient survival, limit progressive pulmonary damage, and ultimately eradicate infection. Long-term goals should aim to maintain optimal pulmonary function and conserve adult athletic performance. Specific treatment strategies for septic pneumonia may include goal-directed antimicrobial therapy, treatment of inflammation independent of antimicrobial therapy, respiratory therapy (oxygen therapy, ventilation, bronchodilation), and cardiovascular support.[37]

Broad-spectrum antimicrobial treatment, with consideration of the drugs' anticipated sensitivity and lung penetration, should be initiated before culture results are available. Third- or fourth-generation cephalosporins (ceftiofur and cefepime, respectively) show good penetration into lung tissues.[40] Ceftiofur administered intramuscularly at 6.6 mg/kg in weanling foals provided plasma and pulmonary epithelial lining fluid concentrations above the therapeutic target of 0.2 µg/mL for at least 4 days and would thus be expected to be an effective treatment for pneumonia caused by susceptible pathogens such as *S. equi* subsp. *zooepidemicus*.[41] Alveolar delivery of antimicrobials typically occurs via diffusion of a free, nonprotein-bound drug and is usually satisfactory if plasma concentrations and alveolar perfusion are adequate.[42] Aminoglycosides penetrate lung tissue at 10% to 45% of serum levels. However, the acidic environment of infected airways may reduce the drug's activity below levels sufficient to eradicate the offending bacteria in some cases.[43,44] Antimicrobial therapy should not be discontinued prematurely in neonatal foals, because pulmonary infection is commonly well established before its diagnosis.[45]

Outcome The survival of neonatal foals with septic pneumonia is contingent on the underlying disease conditions, a prompt diagnosis, and the cause and severity of lung dysfunction. Few studies have objectively evaluated the outcome of foal pneumonia.[38] One report documented that 65% of foals with radiographic evidence of pulmonary disease were discharged alive from the hospital, in contrast to 86% survival of foals without respiratory illness. The presence of diffuse radiographic infiltrates (caudodorsal, caudoventral, and cranioventral lung involvement) or concurrent alveolar patterns within the caudodorsal and caudoventral lung indicated lower survival rates.[38] Pneumonia is also considered one of the greatest causes of morbidity and mortality in foals greater than 1 month of age.[2]

The long-term effect on athletic performance has thus far been evaluated only in older foals that survived rhodococcal pneumonia. *R. equi* infection in foals was associated with a decreased chance of racing as adults. However, the performance of foals that went on to race was not significantly different from that of the general U.S. racing population.[46] It remains speculative whether severe equine neonatal pneumonia will most likely limit future peak athletic performance. Human studies have shown that many hosts develop long-lasting or permanent lung changes after recovery from neonatal pneumonia, which may significantly affect the quality of life and susceptibility to later infections. Case-based evaluations in horses have demonstrated that functional and structural pulmonary abnormalities may occur in survivors of severe neonatal pneumonia. However, the clinical significance of this finding currently remains unclear.

Fungal Infections of the Equine Respiratory Tract

Allison Jean Stewart

Definition and Etiology Fungi are eukaryotic organisms with a definitive cell wall made up of chitins, glucans, and mannans. Within the fungal cell wall, the plasma membrane contains ergosterol, a cell membrane sterol that is frequently targeted by antifungal agents. There are more than 70,000 species of fungi, but only 50 species are known to cause disease in people or animals. Pathogenic fungi can be divided into three groups: multinucleate septate filamentous fungi, nonseptate filamentous fungi, and yeasts. Dimorphic fungi are able to interchange between forms depending on environmental conditions. Examples of dimorphic organisms include *Blastomyces dermatitidis, Histoplasma capsulatum,* and *Coccidioides immitis,* which exist in yeast form in vertebrate host tissue and in hyphal or mycelial form in vitro. In soil and decaying matter, the mycelial form usually is present and is composed of a collection of hyphae. The mycelia produce infective spores that are capable of inoculating vertebrate tissue.

Fungal infections in horses are relatively uncommon, although geographic prevalence is highly variable. Fungi are ubiquitous, and their constant aerosol exposure to respiratory tissue is inevitable. Upper respiratory and pulmonary disease caused by fungi is frequently acquired by the inhalation route, with the sporular diameter small enough to allow penetration into the distal airways and alveoli. In most samples of stable air, more than 90% of particles visible under a light microscope are spores of fungi or actinomycetes.[1] One study found that if a horse stood quietly in its stable without access to hay, the mean concentration of dust was very low (approximately 12 particles per cubic centimeter [of particles less than 5 mm in diameter]). When the bedding was disturbed during the normal "bedding down" operation, the concentration of respirable dust increased sixfold.[2] Systemic fungal infections and some cases of fungal pneumonia are thought to arise through a compromised gastrointestinal tract, by inhalation or via open wounds.

Tissue invasion of pulmonary tissue usually occurs in the immunocompromised host, although on occasion the normal individual may be affected. Important predisposing factors for fungal pneumonia include (1) qualitative and especially quantitative granulocyte abnormalities and (2) the presence of devitalized tissue. In most cases of upper respiratory tract fungal granuloma, there are no obvious predisposing causes.

Primary pathogenic fungi such as *Blastomyces dermatitidis, Histoplasma capsulatum, Coccidioides immitis, Cryptococcus neoformans,* and *Conidiobolus coronatus* usually infect immunologically normal horses. However, in a report of cryptococcosis in seven horses, five had a history of illness that may have predisposed them to cryptococcosis.[3] A separate group of fungal pathogens tend to infect only those equine patients with abnormal host defenses. Opportunistic fungi, including *Aspergillus* spp., *Candida* spp., *Fusarium* spp., *Emmonsia crescens,* and *Pneumocystis carinii* (renamed *P. jiroveci* in humans), have caused fungal disease in horses that are immunocompromised or neutropenic; have neoplasia, colitis, enteritis, or bacterial pneumonia; or have been treated with corticosteroids.[4-15] In vitro studies support the critical role of phagocytic cells in host defense against opportunistic fungi.

Clinical Signs Mycotic granulomas have been found in nasal passages, paranasal sinuses, nasopharynx, guttural pouch, trachea, bronchioles, lungs, and mediastinum of infected horses. The most common clinical signs of upper respiratory tract fungal infection

include unilateral or bilateral serosanguineous or mucopurulent nasal discharge, as well as inspiratory or expiratory noise. Other clinical signs include coughing, facial deformation, and dyspnea caused by partial blockage of nasal passages by granulomatous masses. Differentials for fungal granulomas of the respiratory tract include ethmoidal hematoma, squamous cell carcinoma, amyloidosis, and exuberant granulation tissue.

Fungal plaques in the guttural pouch often are located over the arterial blood supply. Horses with guttural pouch mycosis usually present with episodic serosanguineous nasal discharge that may progress to potentially fatal epistaxis if there is erosion into an artery. The duration of clinical signs can vary from days to many months. Guttural pouch mycosis is discussed in detail elsewhere.

Pulmonary fungal infections causing granulomas, diffuse pneumonia, or pleuropneumonia can present with signs similar to those of bacterial infection. There may be cough, nasal discharge, tachypnea, respiratory distress, hemoptysis, and, if chronic, weight loss. Radiographic appearance of fungal pneumonia may reveal virtually any infiltrative pattern. Although miliary patterns are occasionally seen, the most common initial finding is a patchy bronchopneumonia. Multiple focal sites are common, and lesions tend to be peripheral in distribution. Differentials include bacterial pneumonia, recurrent airway obstructive disease, silicosis, granulomatous disease complex, and neoplasia.

Systemic infections can have variable clinical signs depending on the location and extent of the infection. Fungal infections can affect multiple organ systems and body cavities. Weight loss, colic, or diarrhea can often occur with infection within the abdominal cavity.

Diagnostic Sampling Lesions in the nasal passages, nasopharynx, guttural pouch, trachea, and bronchioles usually can be observed directly during endoscopic examination. Masses in paranasal sinuses and lungs may be observed radiographically. Computed tomography or magnetic resonance imaging provide detailed imaging of the equine skull and can be used to determine the extent of lesions and bony invasion. An 8- to 20-mm trephine (Michelle 8-mm trephine or 14- to 20-mm Galt trephine, Jorgensen Laboratories, Inc., Loveland, Colo.) can be drilled into the nasal or maxillary sinus through which a sterile rigid arthroscope or flexible endoscope can then be passed to directly view some lesions within the paranasal sinuses.

For nasal and nasopharyngeal lesions, specimens for cytology, histopathology, and culture can be obtained by use of endoscopically guided biopsy instrument; however, these samples tend to be small, superficial, and often nondiagnostic. Mucosal contaminants may overgrow the organism of interest. Larger biopsy samples from the nasal passages or nasopharynx often can be obtained by use of a uterine biopsy instrument (Jorgensen Laboratories, Inc., Loveland, Colo.) passed nasally with visual guidance from a flexible endoscope. Excisional biopsy or surgical debulking may be performed through a sinus flap or via laryngotomy.

Fungal pneumonia may be diagnosed from samples obtained by tracheal wash or bronchoalveolar lavage fluid, or via a lung biopsy (Fig. 31-19). Lung biopsy is associated with significant risk if a large pulmonary vessel is accidentally punctured. The biopsy should be performed ideally after radiographic evaluation or with concurrent ultrasound guidance and should be obtained from the periphery of the lung; however, some horses have experienced fatal hemorrhage associated with puncture of a vessel only 2 cm from the periphery. The lung is rich in plasminogen, so bleeding complications may be severe. Spring-loaded biopsy needles (4-gauge × 20-cm biopsy needle, Temno Products Group International, Lyons, Colo., or Magnum biopsy needle) are safer for lung biopsy compared with Tru-Cut biopsy instruments (Cardinal Health, Dublin, Ohio).[16] Ultrasound evaluation can be used to monitor for bleeding after the procedure.

CYTOLOGY. Fungal hyphae may be identified in airway fluid or in impression smears obtained from biopsied masses. Clinicians must be careful in attributing significance to presence of fungal elements in a transtracheal aspirate. Fungal hyphae are often present either free or in large mononuclear cells in tracheal aspirates from healthy horses.[17] A study of healthy Thoroughbred racehorses showed 70% had fungal elements detected in their tracheal aspirates.[18] None of the horses from either study had other evidence of fungal pneumonia. Barn fungus such as *Alternaria* spp. are nonpathogenic and rarely incite an inflammatory response in the host. The organisms often have a block-like appearance and may be colored (Fig. 31-20). A normal predominance of macrophages, lymphocytes, and nondegenerate neutrophils (<5% to 10%) would be expected.

FIG. 31-19 Percutaneous lung biopsy from caudal periphery of lung of a weanling foal.

To be significant cytologically, large numbers of fungi should be involved in the inflammatory process within the lung. With fungal pneumonia, aspirates may contain predominantly neutrophils that often are degenerate and may contain intracellular fungal hyphae. If processing of the sample is delayed, extracellular fungi may be phagocytized, and this makes interpretation more difficult. Some fungi have characteristic morphologic features that can give an early presumptive identification (Table 31-5).

HISTOPATHOLOGY. Hyphae of certain fungi may be poorly visualized using routine hematoxylin and eosin (H&E) stains; therefore special stains such as periodic acid Schiff (PAS), Gridley fungus, and Grocott-Gomori methenamine–silver nitrate (GMS) can be useful to stain histopathologic specimens. With chronicity, there is often evidence of extensive fibrosis.

MICROBIOLOGICAL CULTURE. Fungi can be found in tracheal aspirates from healthy horses. Sixteen percent of healthy horses are reported to have fungal growth on the tracheal aspirate bacterial culture plates; therefore results of fungal culture must be interpreted with caution.[19] Some fungi have fastidious growth requirements. They may be outcompeted by contaminant bacteria and may take up to several weeks to grow on culture media. For transport of tissue for microbiological culture, the sample should be placed in a prepared culture medium (BBL Port-A-Cul Vial, Becton, Dickinson and Company, Sparks, Md.) and transported at room temperature. Specific culture media such as Sabouraud dextrose agar (Remel, Inc., Lenexa, Kans.), inhibitory mold agar, or Mycobiotic (Neogen, Lansing, Mich.) containing cycloheximide and chloramphenicol are useful.

MOLECULAR TECHNIQUES. Serologic tests that use immunodiffusion, radioimmunoassays, complement fixation, and enzyme-linked immunosorbent assays (ELISAs) are available to detect circulating antibodies against several fungal organisms (see Table 31-5). These titers often decrease with resolution of disease; therefore repeated measurements can be used to help monitor response to

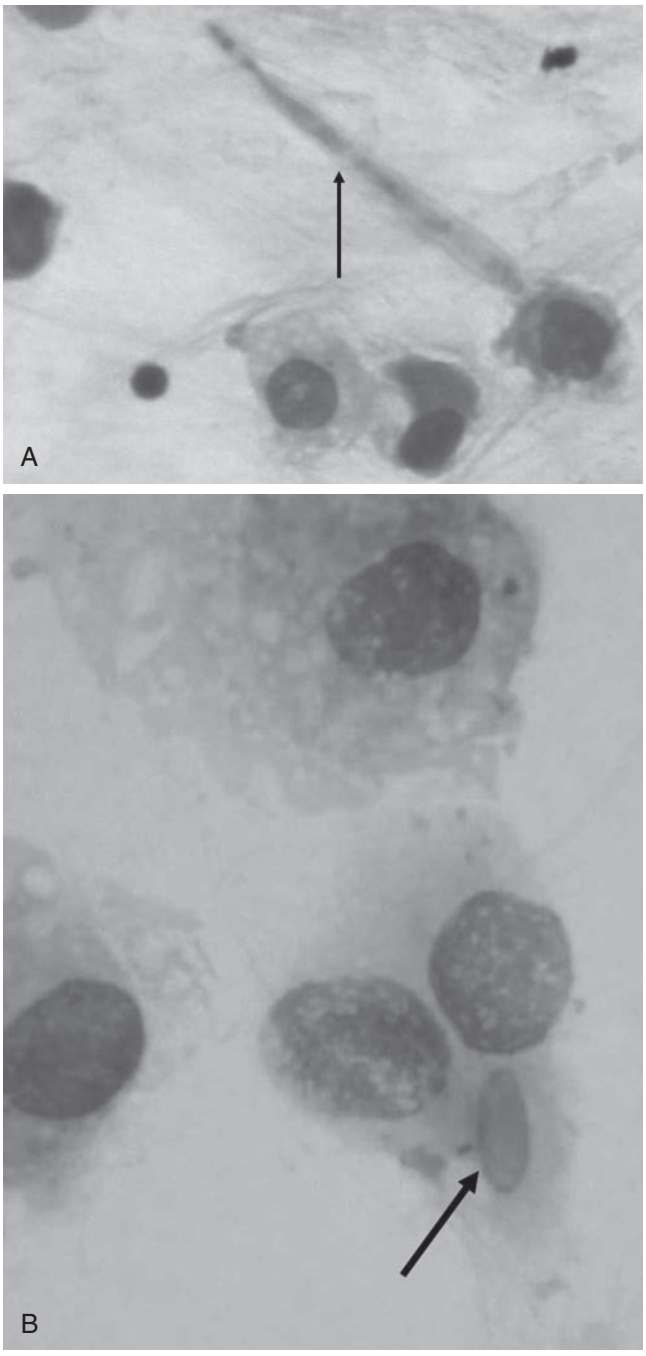

FIG. 31-20 *Alternaria* spp. from transtracheal wash specimens obtained from healthy horses. **A,** An extracellular spore *(arrow)* with several macrophages, squamous cell (indicative of pharyngeal contamination). **B,** Intracellular spores *(arrow)* within binucleated macrophage. *(Courtesy Elizabeth Welles, Auburn University, Auburn, Ala.)*

treatment. Immunohistochemistry,[10,20-22] fluorescent in situ hybridization,[21] and DNA probes[23] can be used to positively diagnose fungal organisms in histopathology sections. A panfungal real-time PCR assay (University of California, Davis, Calif.) can be used to detect a variety of fungal organisms in body fluids and fungal isolates, followed by species-specific real-time PCR to positively identify the organism.[5]

IMMUNE FUNCTION TESTING. Several fungal infections have been associated with host immune suppression caused by severe malnutrition, congenital immunodeficiency, or acquired immunodeficiency.[13-15] Blood can be tested for immunoglobulin quantification by radial immunodiffusion (Cornell University, Ithaca, N.Y.) and lymphocyte subpopulation phenotyping via flow cytometry (Kansas State University, Manhattan, Kans.).[15,24]

Treatment Treatment of fungal granulomas of the upper respiratory tract may involve surgical options (debulking, laser therapy, or cryotherapy) and/or medical therapy (systemic, topical, or intralesional). Treatment of *Aspergillus* spp. pneumonia is usually frustrating, as diagnosis is often late in the course of disease and the horse frequently has severe underlying illness. Successful therapy has been reported for other causes of fungal pneumonia.[5,25-28] Several pharmacokinetic studies on antifungal drugs have been recently performed,[29-34] and as these medications become more affordable, the success rate of therapy is likely to increase. The drug of choice depends on the site of infection, the fungus involved, and the financial resources of the owner. Specific antifungal agents used in horses have been reviewed.[35] Therapy may not be attempted because of the severity of the primary disease, the expense, or the poor prognosis.

Prevention of invasive fungal pneumonia is difficult. It is impossible for the horse to avoid large inhaled inocula, given its environmental conditions. Improving ventilation and minimizing exposure to inspired spores are most beneficial in immunocompromised patients. At present the most important methods of disease prevention are treating predisposing illnesses promptly and effectively and judiciously avoiding overuse of corticosteroids and broad-spectrum antibiotics.

ANTIFUNGAL THERAPEUTICS (Table 31-6)

Amphotericin B. Amphotericin B deoxycholate is a polyene antibiotic that combines with ergosterol in the fungal cell membrane, resulting in an increase in cell permeability. Intravenous amphotericin B can cause nephrotoxicity and phlebitis. Other possible side effects include anorexia, anemia, cardiac arrhythmias, hepatic and renal dysfunction, and hypersensitivity reactions.[36] Amphotericin B also has been used successfully to treat histoplasmosis and pulmonary aspergillosis and cryptococcosis.[25,26,37] A high dose of oral amphotericin B successfully treated mucormycosis caused by *Absidia corymbifera*.[38] Topical amphotericin B has been successful in treatment of nasopharyngeal *C. coronatus*.[39-42]

Azoles. Benzimidazole derivatives in the class *azoles,* such as miconazole, enilconazole, ketaconazole, itraconazole, fluconazole, and voriconazole, destroy fungi by inhibition of ergosterol biosynthesis in the fungal cell membrane. Azole antifungals inhibit cytochrome P450–dependent 14α–sterol demethylase, which is essential for the formation of ergosterol. Topical 2% miconazole was used in the resolution of four cases of guttural pouch mycosis[43] and as part of successful multimodal therapy against nasopharyngeal *P. boydii*.[44] Enilconazole is not commercially available in the United States but has been used topically in the successful treatment of guttural pouch mycosis.[45-47] Aerosolization of 1.2 mg/kg enilconazole q12h in 125 mL of saline resolved *Scopulariopsis* pneumonia.[28] Ketoconazole is absorbed poorly in the nonacidified form[29] but can be acidified for better absorption (30 mg/kg via nasogastric tube [NGT] q12h mixed with 0.2 N HCl).[28]

Itraconazole (Sporanox solution [Janssen, Titusville, N.J.]) is absorbed well orally (bioavailability 60%). A dose of 5 mg/kg PO q24h maintains concentrations above mean inhibitory concentration (MIC) for susceptible yeasts (*Histoplasma* spp. and *Blastomyces* spp.) and *Aspergillus* spp., with no detectable side effects.[31] The use of compounded itraconazole is not recommended. It is very unstable (requires low pH), and owing to its lipophilic nature it is difficult to formulate in aqueous solution.

Oral fluconazole at a loading dose of 14 mg/kg, followed by 5 mg/kg q24h, yields concentrations in plasma, CSF, synovial fluid, aqueous humor, and urine above the MIC reported for several equine fungal pathogens.[30] Fluconazole, however, reportedly has minimal activity against filamentous fungi (*Aspergillus* spp. and *Fusarium* spp.). Low-dose oral fluconazole (1 mg/kg PO q24h) for at least 10 to 15 days anecdotally has been successful in treatment of fungal keratitis.

VetBooks.ir

TABLE 31-5

Characteristic Morphologic Features and Availability of Serologic Tests for Fungal Organisms Reported to Cause Fungal Granulomas in Horses (January 2013)

	Cytologic Appearance	Serologic Test	
Agent	Tissue Form	Method	Veterinary Laboratory
Cryptococcus neoformans	Round, thin-walled, yeast-like fungus (5-10 µm) with a large heteropolysaccharide capsule (1-30 µm in diameter) that does not take up common cytologic stains. Capsule is best stained using the Mayer mucicarmine stain. Organisms show narrow-based budding and lack of endospores.	Capsular antigen, ELISA (antigen), or latex agglutination (antigen)[26]	$33.00 UT $21.50 CU $21.00 CSU $16.00 UGA $18.00 NMDA
Conidiobolus coronatus	Broad, thin-walled highly septate, irregularly branched hyphae (5-13 µm in diameter).[53] Often surrounded by acidophilic staining glycoprotein antigen-antibody complex known as Splendore-Hoeppli material.	Immunodiffusion is highly sensitive and specific. Decreasing titer correlated to disease resolution in horses.[51,55]	Serologic testing not widely available.
Pseudallescheria boydii	Hyaline, nonpigmented, septate, randomly branched hyphae (2-5 µm in diameter) with regular hyphal contours. Asexual form has nonbranching conidiophores with terminal conidia. Sexual form in culture has cleistothecium (large round body) and ascospores.[44]		
Coccidioides immitis	Spherules have a double-contoured wall, are variable in size, but can be large (20-80 µm, up to 200 µm). The mature spherules (sporangia) contain endospores (sporangiospores) 2-5 µm in diameter. In the environment, mycelium are thick-walled with barrel-shaped arthroconidia.	AGID (antibody) for IgM and IgG[27,76,79,81]	$30.00 UT $16.00 CSU $16.00 CU $14.00 NMDA
		MVista Quantitative EIA (antigen)	$50.00 MDL
Aspergillosis spp.	Broad (2-4 µm in diameter) septate hyphae with parallel sides and acute right-angled branching.	Platelia *Aspergillus* galactomannan EIA (sandwich immunoassay) Some reactivity to *Penicillium, Alternaria,* and *Paecilomyces*	$50.00 MDL
		AGID (antibody) *Aspergillus fumigatus* only	$20.00 UT $16.00 CSU $16.00 CU $14.00 NMDA
		Aspergillus spp. panel	$70.00 UT (send out)
Blastomyces dermatitidis	Yeasts are spherical (15-17 µm in diameter) with basophilic protoplasm and unstained, uniformly shaped refractile walls. Unilateral, broad-based budding is characteristic. Yeasts are often located within multinucleated giant cells.	AGID (antibody)[23]	$20.00 = UT $16.00 = CSU $16.00 CU $14.00 NMDA
		MVista quantitative EIA (antigen)	$50.00 MDL
Histoplasma capsulatum	Yeasts (2-4 µm in diameter) have a thin clear halo surrounding a round or crescent-shaped basophilic cytoplasm.	AGID (antibody)[75]	$20.00 UT $16.00 CSU $16.00 CU $14.00 NMDA
		MVista quantitative EIA (antigen)	$50.00 MDL
Acremonium strictum	Mononuclear cells contain single, spherical, intracytoplasmic encapsulated spores 3-5 µm in diameter.[5]		
Candida spp.	Ovoid budding yeast cells (2-4 µm in diameter) with thin walls, or they can occur in chains that produce septate pseudohyphae when blastospores remain attached after budding division. Filamentous, regular, true hyphae also may be visible.		
Pneumocystis carinii (renamed *P. jiroveci* in humans)	Trophozoite (yeast form) is a 2-5 µm in diameter ameboid with filopodia that attach to the surface of type I pneumocytes. Sporangia (cystic form) are encapsulated spores (4-6 µm in diameter) containing eight uninucleate spores (intracystic bodies).[85,14,15,20]		
Fungal serology panel	Antibody to *Histoplasma, Blastomyces, Coccidioides, Aspergillus* (AGID) The CU panel also includes *Cryptococcus* antigen.		$62.75 CU $39.00 NMDA

AGID, Agar gel immunodiffusion; *CF,* complement fixation; *EIA,* enzyme immunoassay; *ELISA,* enzyme-linked immunosorbent assay.

TABLE 31-6

Pharmacokinetic Studies of Antifungal Drugs Performed in Horses

Drug and Relative Cost	Dosage	Source	Susceptible Organisms, Equine Reports, Comments
Ketoconazole $ = Moderate	30 mg/kg q12h mixed with 0.2 N HCl via nasogastric intubation[29]	LH Tablets (200 mg) (Nizoral [Janssen, Titusville, N.J.])	*Scopulariopsis,*[28] *Coccidioides, Cryptococcus, Candida, Malassezia, Histoplasma, Sporothrix, Microsporum, Trichophyton.*
Itraconazole $ = Very expensive	5-mg/kg/day solution PO[31] (bioavailability 60%, compared to 12% for capsules)	Sporanox solution (10 mg/mL oral or injectable solution) Sporanox capsules (100 mg) (Janssen)	*Aspergillus,*[45,69] *Histoplasma, Blastomyces, Coccidioides,*[80] *Cryptococcus, Candida, Paracoccidia, Paecilomyces, Scopulariopsis, Sporothrix, Alternaria, Sporotrichum, Prototheca.* Not active against *Fusarium, Mucor, Rhizopus.* Very unstable and lipophilic; therefore compounded substances are not recommended.
Fluconazole $ = Inexpensive	14 mg/kg PO loading followed by 5 mg/kg/day PO[30]	LH Diflucan (Zoetis, Florham Park, N.J.; Bedford Labs, Bedford, Ohio) Injectable solution (2 mg/mL) (Zoetis, Bedford Labs) Tablets (200 mg) (Zoetis) Generic available Powder (100 g) (Spectrum Chemicals, Mumbai, India)	*Histoplasma, Blastomyces, Coccidioides,*[27] *Cryptococcus,*[60,61] *Mucor, Rhizopus, Candida,*[12] *Conidiobolomycosis,*[54] *Paracoccidia, Paecilomyces, Scopulariopsis, Sporothrix, Alternaria, Sporotrichum, Prototheca.* Minimal activity against *Aspergillus* and *Fusarium.*
Voriconazole $ = Very expensive	4 mg/kg/day PO[32-34]	Vfend (Zoetis, Bedford Labs) Tablets (200 mg)	Drug of choice for invasive *Aspergillus,*[68] *Candida, Cryptococcus, Scedosporium apiospermum,* and *Fusarium* spp. in human patients who are unable to tolerate or are refractory to other therapeutic agents.

HCl, Hydrochloride; *LH,* local wholesaler; *PO,* by mouth.

Compounded fluconazole formulations are very stable. The cost of fluconazole has been markedly reduced since the availability of generic products.

Voriconazole, a broad-spectrum triazole antifungal agent, was approved for use in human medicine in 2002. It is now considered the drug of choice for initial treatment of invasive aspergillosis, candidiasis, cryptococcosis, and serious fungal infections caused by *Scedosporium apiospermum* and *Fusarium* spp. in patients that are unable to tolerate or are refractory to other therapeutic agents.[46-49] An initial single-dose pharmacokinetic study in horses recommended a dose of 4 mg/kg PO q24h.[32] Voriconazole distributes widely into body fluids and reached therapeutic concentrations in peritoneal, synovial, and cerebrospinal fluids; aqueous humor; periocular tear film; epithelial lining fluid; and urine.[33-34]

SYSTEMIC IODIDE THERAPY. The exact mode of action of iodides is unknown; however, they seem to have a beneficial effect on the granulomatous inflammatory process. Iodides have very little, if any, direct in vitro antibiotic effect.[50] Although several successful cases are reported in which iodides were used as primary or adjunctive therapy, overall efficacy is considered limited at best. Treatment is inexpensive, but toxicity and resistance can occur. Iodide toxicity is characterized by excessive lacrimation, nonproductive cough, increased respiratory secretions, and dermatitis.[50] The recommended dose of 20% sodium iodide is 20 to 40 mg/kg/day IV for 7 to 10 days.[39,42,51,52] Orally administered iodine is available in two forms. Inorganic potassium iodide (10 to 40 mg/kg/day) is available only as a chemical grade and is unstable in the presence of light, heat, and excessive humidity.[42,52] Organic ethylenediamine dihydriodide (EDDI) (0.86 to 1.72 mg/kg of EDDI is equivalent to 20 to 40 mg/kg/day of the 4.57% dextrose powdered form [Butler Co., Columbus, Ohio]) is commercially available.[52] Administration of iodine in the diet of pregnant mares may cause congenital hypothyroidism in foals and thus should be avoided.

ETIOLOGIC AGENTS

Conidiobolomycosis. *Conidiobolus coronatus* is a saprophytic fungus that causes granulomatous lesions of the upper respiratory tract in horses. Single to multiple granulomatous lesions in the nasal passages, trachea, or soft palate can be observed endoscopically (Fig. 31-21). Histologic appearance of conidiobolomycosis is similar to that of pythiosis and of basidiobolomycosis. Hyphae of *C. coronatus* are thin-walled, highly septate, and irregularly branched (see Table 31-5).[53] The lesions typically have large numbers of eosinophils and fewer macrophages, neutrophils, plasma cells, and lymphocytes surrounding hyphae. Definitive diagnosis is based on microbiological culture, immunodiffusion, or PCR.[54] Detection of serum antibodies by immunodiffusion is considered highly sensitive and specific[51,55] and can be used to monitor response to treatment.[55]

FIG. 31-21 Endoscopic image of mycotic granulomas caused by *Conidiobolus coronatus* in the nasopharynx of a horse.

Conidiobolomycosis lesions can be treated with surgical excision, laser therapy, cryotherapy, or long-term administration of iodides or antifungals.[54,39,51] Amphotericin B has been administered intralesionally or topically in combination with DMSO to treat *C. coronatus*.[39-42] It is important to remember that long-term therapy and reevaluation

VetBooks.ir

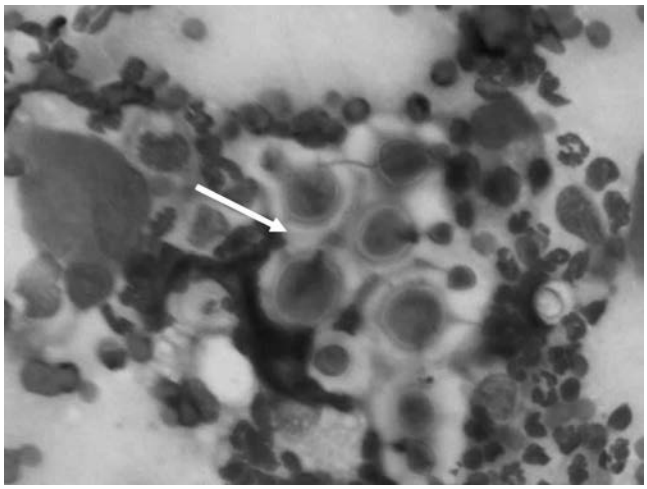

FIG. 31-22 Photomicrographs of an impression smear from a biopsy of a mass in the nasal passage of a horse. The smear is extremely cellular with abundant neutrophils and macrophages. Round yeast cells with large nonstaining capsules and occasional narrow-based budding consistent with cryptococcal organisms *(arrow)* are shown. (Modified Wright stain, ×100.) *(Courtesy Elizabeth Welles, Auburn University, Auburn, Ala.)*

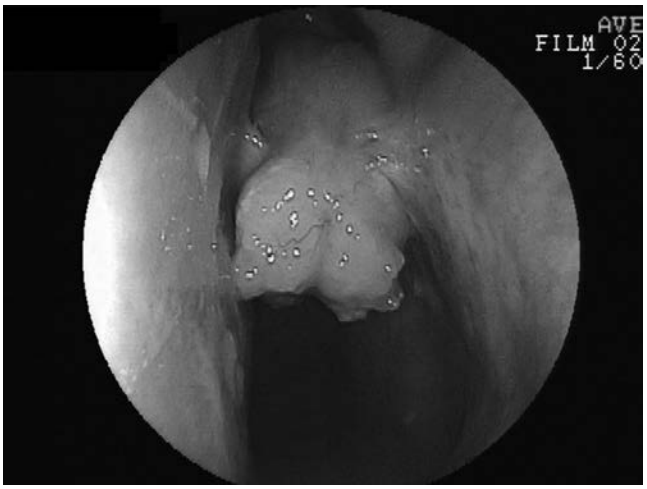

FIG. 31-23 Endoscopic image of a *Cryptococcus* granuloma in the nasal passages of a horse.

are essential, as recurrence can occur.[42] Oral fluconazole was successful in treating two pregnant mares with nasal conidiobolomycosis.[56] Fluconazole would be considered the drug of choice for the treatment of conidiobolomycosis, with treatment length varying between 4 and 16 weeks based on endoscopic reevaluation. A vaccine using *C. coronatus* antigen from broth cultures was unsuccessful in treating seven horses with conidiobolomycosis.[54]

Cryptococcosis. Cryptococcosis is caused by *Cryptococcus neoformans* (var. *neoformans* and var. *gattii*) and is a ubiquitous, saprophytic, round, basidiomycetous yeast-like fungus with a large heteropolysaccharide capsule that does not take up common cytologic stains (see Table 31-5, Fig. 31-22). The capsule forms a clear halo when stained with India ink. The capsule is immunosuppressive and antiphagocytic. A relatively high frequency of equine cryptococcosis occurs in Western Australia.[3,57] There is an epidemiologic relationship between *C. neoformans* var. *gattii* and the Australian river redgum tree *(Eucalyptus camaldulensis)*, while *C. neoformans* var. *neoformans* has historically been associated with bird (particularly pigeon) excreta.[3] Cytologic or histopathologic identification is very reliable for diagnosis because of the characteristic morphology.[58] Serologic testing with latex agglutination to identify cryptococcal capsular antigen is useful with resolution of lesions correlated with declining serum titers.[26]

Cryptococcosis in horses is associated primarily with pneumonia, rhinitis (Fig. 31-23), meningitis, and abortion. Successful medical treatment, however, has been reported rarely until the recent availability of financially viable and effective antifungal medications. Surgical removal of a localized jejunal lesion was successful in one horse.[59] A pony with multiple pulmonary cryptococcomas, from which *Cryptococcus gattii* was cultured from both transtracheal washings and lung mass aspirates, was treated successfully with daily infusions of amphotericin B over 1 month. One year after cessation of treatment, clinical signs had resolved and the cryptococcal antigen titer decreased from 4096 to 256.[26] Sinonasal cryptococcosis was successfully treated in two horses after extensive surgical débridement and long-term treatment with oral fluconazole.[60-61]

Cryptococcosis should be treated with amphotericin B, fluconazole, or voriconazole (Table 31-7).

Pseudallescheriosis. *Pseudallescheria boydii* is a saprophytic ascomycete. Infection most commonly involves the extremities, and in human patients it is known as Madura foot. Hyphae within tissue cannot be differentiated from *Fusarium* spp. or *Aspergillus* spp. unless cultured. *P. boydii* cultured from the nasal cavity and sinus of a horse with chronic, malodorous nasal discharge was susceptible in vitro to miconazole, ketaconazole, natamycin, and clotrimazole. After débriding and flushing the plaque, miconazole cream was infused twice daily for 4 weeks through lavage tubing that had been passed into the nasal passage through a hole drilled in the frontal bone and sinuses. Adjunctive iodide therapy was also administered and the lesions resolved (Fig. 31-24).[44]

Nasal mycosis caused by *P. boydii* has been reported in two other horses, both of which were euthanized.[62,63] *P. boydii* has also been isolated from the pharynx of 2 of 60 normal donkeys and from horses with chronic uterine infection.[64,65]

Aspergillosis. *Aspergillus* spp. have broad septate hyphae with parallel sides and acute right-angled branching (see Table 31-5). They have a propensity for vascular invasion. Definitive diagnosis is by culture or staining by immunohistochemistry or immunofluorescence. *Aspergillus* spp. are very common in the environment, especially in moldy feed and bedding.[37] They are opportunistic pathogens and often cause disease in horses that are immunosuppressed from debilitating disease such as enterocolitis, septicemia, neoplasia, Cushing disease, and equine protozoal myeloencephalitis (EPM), that have undergone surgery, or that have been treated with immunosuppressive drugs[4,6,8-10] (Fig. 31-25).

Infection is by inhalation of an overwhelming number of spores resulting in fungal proliferation and invasion of the small airways, or by translocation of organisms across an inflamed gastrointestinal tract leading to lesions centered around large blood vessels as a result of hematogenous spread. In two retrospective studies of invasive pulmonary aspergillosis, 41 of 49 cases were associated with enterocolitis.[4,6] *Aspergillus* spp. pneumonia is almost uniformly fatal, often with no or mild respiratory signs. Antemortem diagnosis of pulmonary aspergillosis is made rarely. In a retrospective study of 30 cases of *Aspergillus* spp. pneumonia, only 2 cases were diagnosed or suspected antemortem.[6] Transtracheal aspirates or bronchoalveolar lavages may not be helpful because hyphae and spores are often present extracellularly or within macrophages in aspirates and lavages from healthy animals.[4] False-negative results also can occur. Cytologic examination of a transtracheal wash specimen obtained from the foal shown in Fig. 31-25, *A*, 2 days prior to euthanasia failed to identify *Aspergillus* spp. hyphae. Serologic diagnosis occasionally has been useful,[66] but it is often unreliable because many horses have titers to *Aspergillus* spp. Development of a commercially available ELISA is promising.[8,37]

In human medicine, 50% to 90% of patients with invasive aspergillosis die despite treatment. Amphotericin B has been the mainstay of treatment for invasive aspergillus for decades, but it is associated with nephrotoxicity in about 50% of human patients. Nephrotoxicity is reduced with the use of liposomal amphotericin B. Voriconazole, an azole antifungal, is now considered the drug of choice against human aspergillosis, and caspofungin (in the new class

VetBooks.ir

TABLE 31-7

Treatment of Common Fungal Infections in Humans and Horses

Fungal Infection	Recommended Treatment in Humans[87]	Treatments Tried in Horses	Comments
Cryptococcosis	Induction with amphotericin B 0.7-1 mg/kg, plus 5-fluorocytosine 100 mg/kg/day for 2 weeks, then consolidation with fluconazole 400 mg/day for > 10 weeks	Daily infusions of amphotericin B (initially 0.35 mg/kg, increasing over 8 days to 0.5 mg/kg in 1 L 5% dextrose in water over 1 h IV for 1 month) successfully used to treat pulmonary cryptococcosis. Flunixin meglumine (0.25 mg/kg IV) was administered before each treatment.[26,61]	Reported dosages range from 0.3 to 0.9 mg/kg in saline IV over 1 h.
		Successful treatment with long-term fluconazole (14 mg/kg loading, then 5 mg/kg PO q24h) for sinonasal cryptococcosis after surgical débridement.[60,61]	Long-term oral fluconazole is recommended as sole treatment or after 2 weeks of IV amphotericin B.
Histoplasmosis	Amphotericin B 0.7-1 mg/kg/day for 2 weeks, then itraconazole 200-400 mg/day for 4-18 months	Successful treatment of histoplasmosis in a filly using amphotericin B (0.3-0.6 mg/kg eod IV infused over 1 h) with a total cumulative dose of 6.75 mg/kg administered over a 1-month period. After each treatment the filly became lethargic for 18-24 h. Polyuria and polydipsia occurred during week 4, but urine concentrating ability was maintained and azotemia did not occur.[25]	In vitro susceptibility to fluconazole is poor.
Blastomycosis	Amphotericin B 0.7-1 mg/kg/day to 1.5-2.5 g total or to 0.5 g total, then itraconazole 200-400 mg/day		
Aspergillosis (invasive pulmonary)	1. Voriconazole 200-400 mg PO q12h, 3-6 mg/kg IV q12h 2. Amphotericin B 1-1.5 mg/kg/day until desired response, then itraconazole 400 mg/day when disease progression slows	Voriconazole 4 mg/kg PO q24h. Successful treatment of a neonatal foal with pulmonary aspergillosis after lung lobe resection.[68]	Fluconazole has limited efficacy. Oral itraconazole or voriconazole would be the drugs of choice, possibly after 2 weeks of IV amphotericin B.
Candidiasis	1. Amphotericin B 0.7-1 mg/kg/day for 2 weeks 2. Fluconazole 6 mg/kg for 2 weeks 3. Caspofungin 70 mg × 1, then 50 mg/day for 2 weeks 4. Voriconazole	Two foals were treated with intravenous amphotericin B for 8 days (total dose, 2.6 mg/kg) and 29 days (total dose, 10.3 mg/kg), respectively. Fluconazole (5.5 mg/kg PO, q24h) for 6 weeks and (4 mg/kg PO, q24h) for 28 days was used to treat two other foals.[12]	Fluconazole is generally considered the drug of choice against *Candida* spp., although *C. krusei* is resistant to fluconazole.
Pneumocystosis	1. Trimethoprim-sulfamethoxazole 2. Pentamidine isethionate 3. Trimetrexate	Trimethoprim-sulfamethoxazole (25-30 mg/kg PO q12h) is the treatment of choice.[86] Dapsone (Jacobus, Princeton, N.J.) (3 mg/kg PO daily for 2 months) was used to successfully treat a foal with *P. carinii* that developed *Salmonella* enterocolitis after treatment with TMS.[24]	Lacks ergosterol; therefore antifungals are not effective.

eod, Every other day; *IV,* intravenous; *PO,* by mouth; *TMS,* trimethoprim-sulfamethoxazole.

of echinocandin antifungals) shows promising results in patients with refractory infections.[67] Oral voriconazole and itraconazole are currently the treatments of choice for aspergillosis in horses. In human medicine, itraconazole has shown comparable response rates to those of amphotericin B.[67] *Aspergillus* spp. are usually resistant to fluconazole. There are limited reports of horses surviving pulmonary aspergillosis.[37] A neonatal foal with pulmonary aspergillosis was successfully treated by lung lobe resection followed by treatment with systemic voriconazole.[68]

Treatment of mycotic aspergillus rhinitis and sinusitis in horses has been more successful. It is important, however, to rule out concomitant invasive pulmonary aspergillosis. Oral itraconazole,[69] topical natamycin (flushed via an endoscope or indwelling catheter placed into the sinus), nystatin powder (insufflated up the nostril), and topical enilconazole have been curative.[70,71]

Blastomycosis. Blastomycosis is caused by inhalation of conidiae of the thermally dimorphic saprophytic fungus *Blastomyces dermatitidis*. *Blastomyces* yeasts can be identified on cytologic examination, often within multinucleated giant cells. They are spherical, with basophilic protoplasm and unstained, uniformly shaped refractile walls. Unilateral, broad-based budding is characteristic (see Table 31-5).

Blastomycosis was reported to cause pyogranulomatous pleuropneumonia, pulmonary abscessation, peritonitis, and abscesses in a 5-year-old horse.[23] *B. dermatitidis* was positively identified from transtracheal wash fluid by use of a DNA probe, and serologic testing was strongly positive. The horse was euthanized without treatment.[23] Disseminated blastomycosis was diagnosed in a miniature horse with subcutaneous infections associated with a chronic pectoral wound. The pony had pulmonary consolidation and pleural effusion. Yeasts

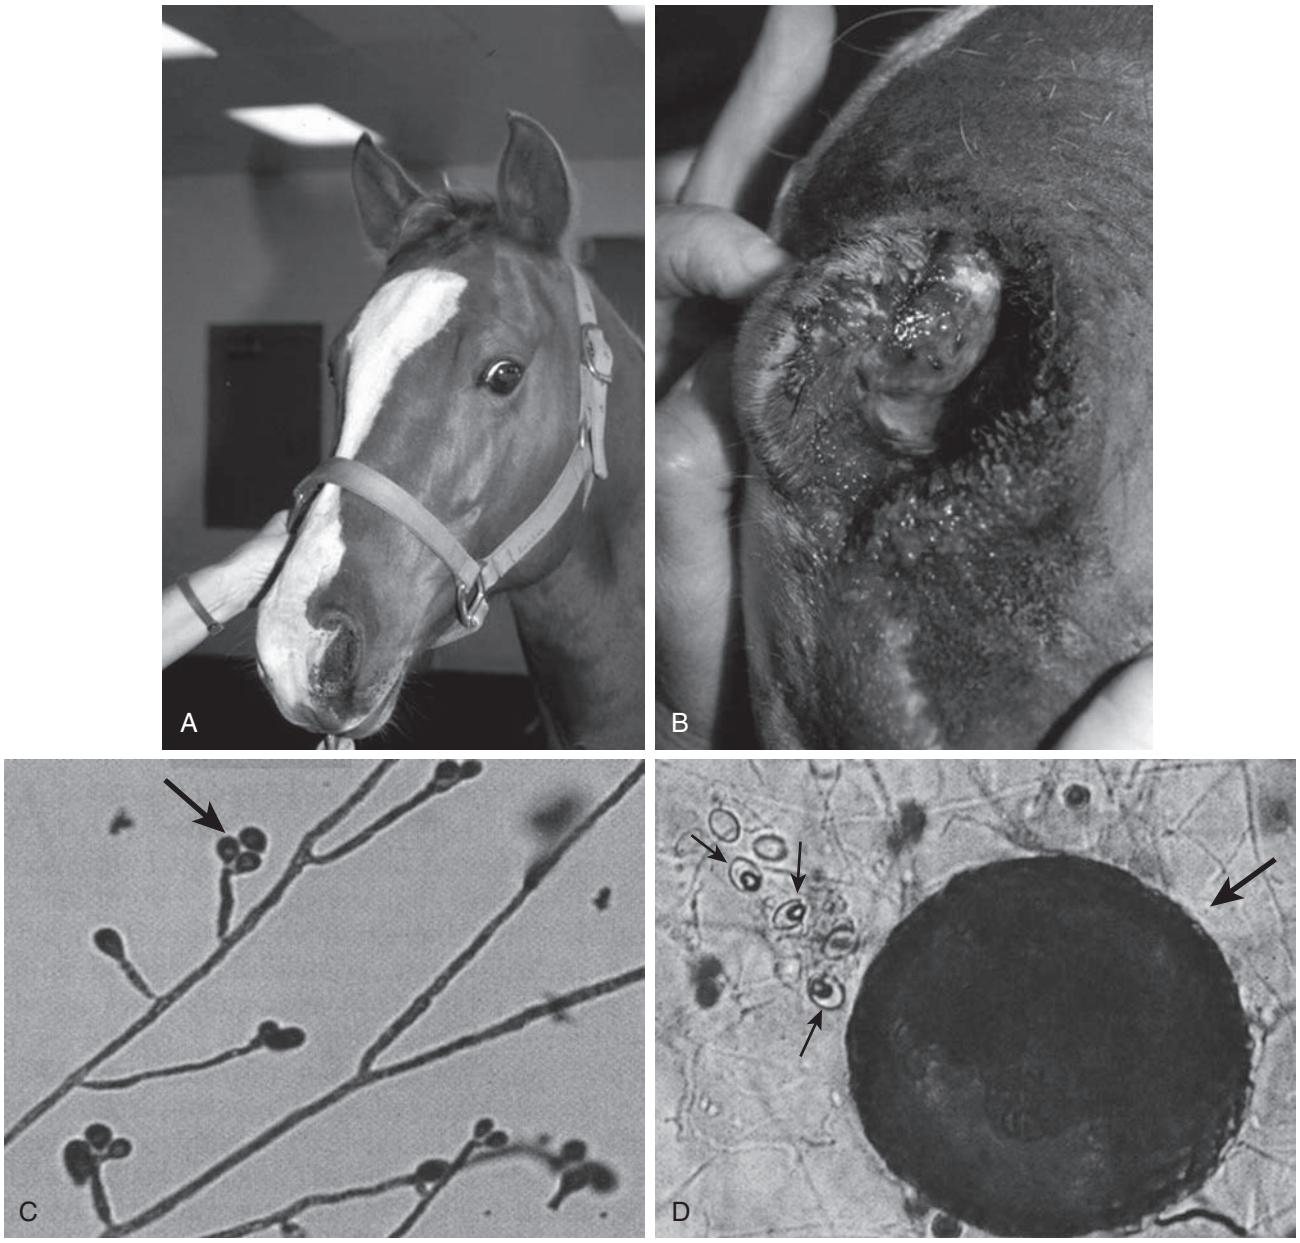

FIG. 31-24 Nasal and nasopharyngeal masses caused by *Pseudallescheria boydii* in a Quarter Horse gelding with chronic, malodorous nasal discharge. **A,** Mucosanguineous nasal discharge. **B,** Mass visible within the external nares. **C,** Asexual form of *P. boydii* in culture showing nonbranching conidiophores with terminal conidia *(arrow).* **D,** Sexual form of *P. boydii* in culture with the cleistothecium *(thick arrow)* and ascospores *(thin arrow). (Courtesy R. Reid Hanson, Auburn University, Auburn, Ala.)*

were observed histologically in many tissues, and *B. dermatitidis* was cultured after 6 weeks.[72] Disseminated blastomycosis was diagnosed in a mare with unresponsive mastitis that progressed to subcutaneous lesions on the ventrum.[73]

Treatment with amphotericin B, itraconazole, or fluconazole is recommended (see Table 31-7).

Histoplasmosis. Histoplasmosis is caused by the saprophytic, dimorphic fungus *Histoplasma capsulatum* and is most prevalent in moist soil containing bird or bat waste. Yeast organisms are 2 to 4 µm in diameter, with a thin clear halo surrounding a round or crescent-shaped basophilic cytoplasm (Fig. 31-26). Histoplasmosis has been reported in fewer than 10 equine cases,[25] and thus horses are considered to be relatively resistant to disease. *H. capsulatum* may occur in an enteric, pulmonary, or disseminated form.[25] *H. capsulatum* was identified in pulmonary granulomas in a horse dying of chronic *Yersinia* colitis.[74] It has also been associated with abortions and severe granulomatous pneumonia in neonatal foals (Fig. 31-27) and a yearling.[75] Successful treatment with amphotericin B was reported in a filly with pulmonary histoplasmosis diagnosed by cytologic identification of the organism on a tracheal wash smear and from a lung aspirate.[25] Treatment with amphotericin B or itraconazole is recommended (see Table 31-7).

Epizootic lymphangitis is caused by *Histoplasma capsulatum* var. *farciminosum* and is considered an economically important disease in the Middle East, India, the Far East, and parts of Africa. Control of the disease is gained usually by destroying infected horses and through application of strict hygiene practices to prevent spread of the organism.

Coccidiomycosis. *Coccidioides immitis* is a soil saprophyte that grows in semiarid areas with sandy, alkaline soils.[76] Inhaled arthroconidia enlarge to form nonbudding spherules, which incite an inflammatory reaction in the lungs and lymph nodes.[77] Horses infected with this fungus have weight loss, fever, abdominal pain, and signs of respiratory disease (Fig. 31-28). Localized, recurring nasal

VetBooks.ir

FIG. 31-25 One-month-old foal with *Escherichia coli* septicemia and secondary *Aspergillus* pneumonia. **A,** Dyspneic foal being supported with intranasal oxygen. The foal had eight septic joints and severe pneumonia and was subsequently euthanized because of the guarded prognosis. **B,** Photomicrograph of the pleural surface of the lung *(black arrows)* with extensive superficial and deep fungal growth. *Aspergillus* spp. characteristically have parallel-sided, regular septate hyphae with acute-angled dichotomous branching. They are seen reasonably well with hematoxylin and eosin stain. **C,** *Aspergillus* spp. hyphae within pulmonary parenchyma stained metachromatic with specific fungal stain (Gridley stain). *(Courtesy Calvin Johnson, Auburn University, Auburn, Ala.)*

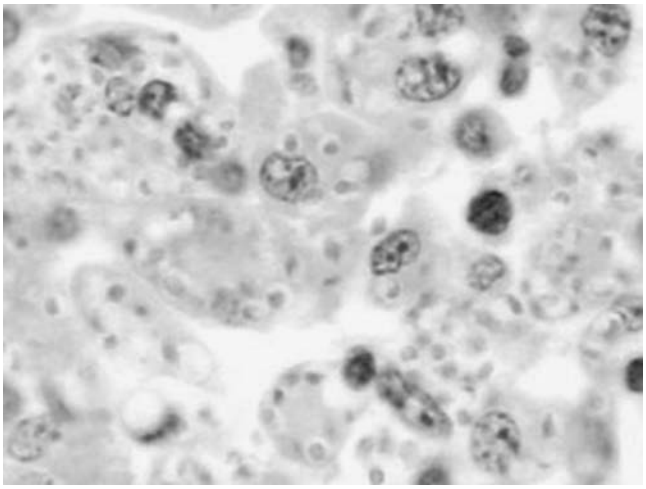

FIG. 31-26 Photomicrograph of tissue infiltrated by activated macrophages containing usually multiple yeasts of *Histoplasma* spp. These yeasts characteristically measure about 2 to 4 µm and appear as structures with a basophilic center and clear halo. (Hematoxylin and eosin stain, ×40.) *(Courtesy Arno Wünschmann, University of Minnesota, St. Paul, Minn.)*

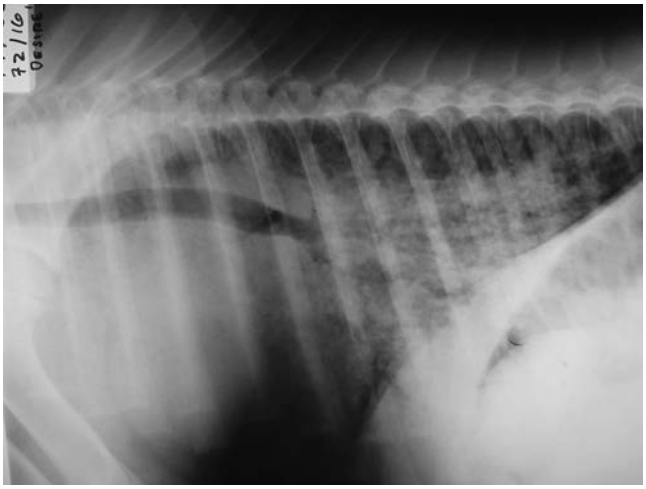

FIG. 31-27 Lateral thoracic radiographs from a foal with *Histoplasma pneumonia. (Courtesy Carol Clark, Peterson and Smith Equine Hospital, Ocala, Fla.)*

granulomas also have been reported.[77] Diffuse infections, with granulomas in the lungs, liver, kidney or spleen have a grave prognosis.[77] Przewalskii horses may be more susceptible.[78]

Coccidioides immitis is difficult to culture, and spherules may not be observed histologically from antemortem lung biopsies. However, serology is very useful for diagnosing infection, and decreasing titers are associated with clinical improvement.[27,76] Serum antibodies are detected rarely in healthy horses.[79] Higher serologic antibody titers are associated with a poorer prognosis for survival.[81] Horses with disseminated disease and pneumonia with thoracic effusion usually have severe clinical disease and frequently die (19 of 21 cases).[81] Antifungal agents successful in treatment of infected horses include itraconazole and fluconazole.[80,27]

Scopulariopsis. *Scopulariopsis* pneumonia was diagnosed by culture of bronchoalveolar lavage fluid in a 2-year-old Quarter Horse filly with pleuropneumonia. The infection resolved following

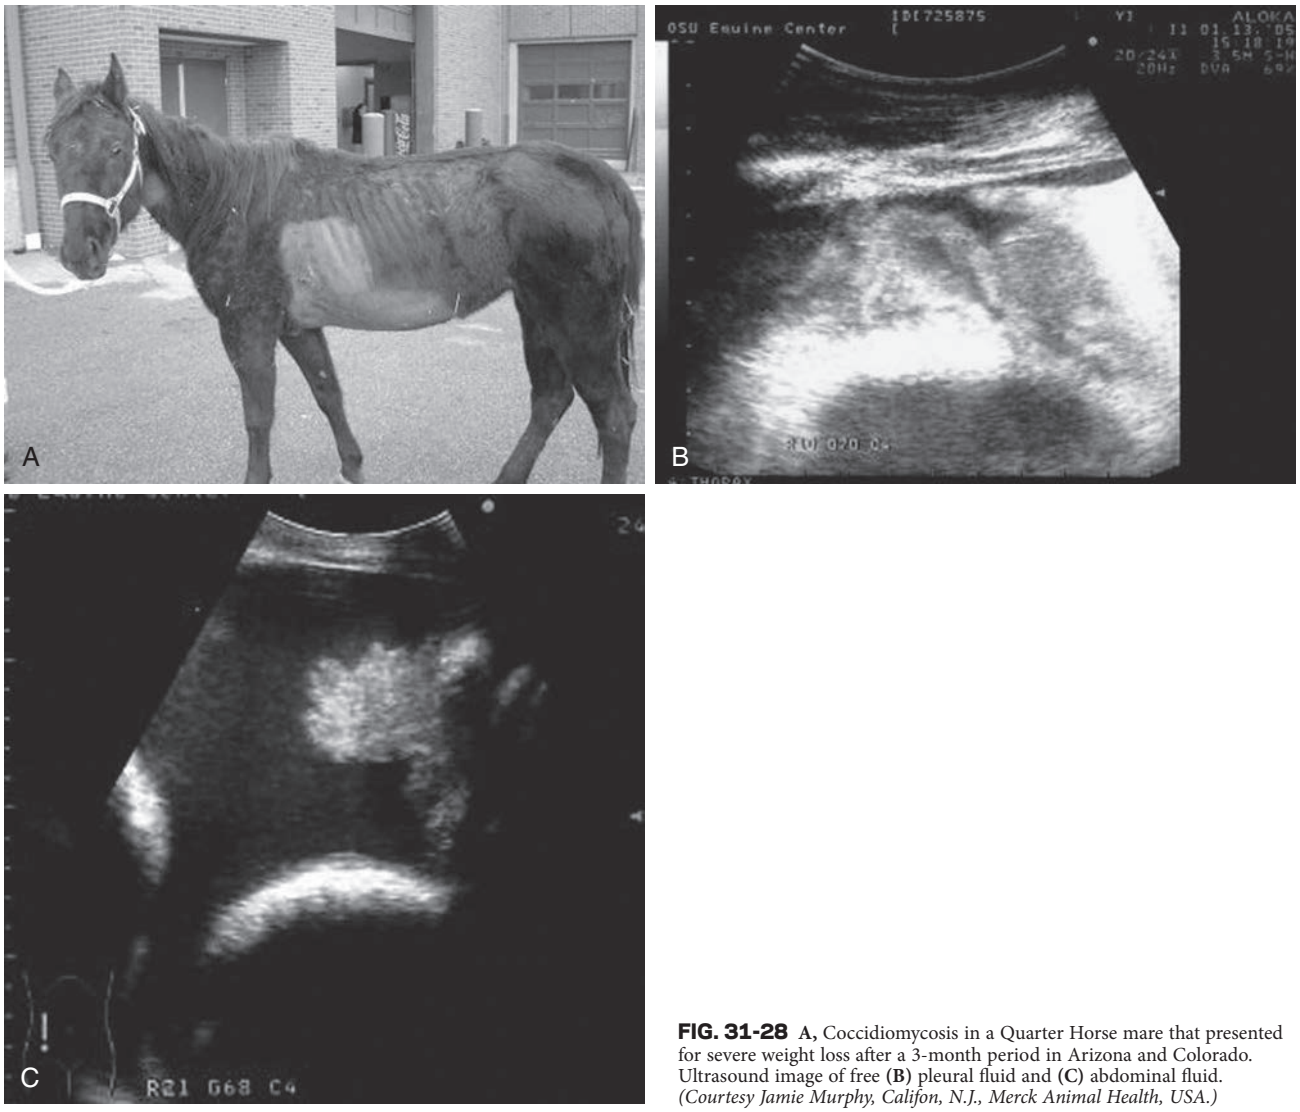

FIG. 31-28 **A,** Coccidiomycosis in a Quarter Horse mare that presented for severe weight loss after a 3-month period in Arizona and Colorado. Ultrasound image of free **(B)** pleural fluid and **(C)** abdominal fluid. *(Courtesy Jamie Murphy, Califon, N.J., Merck Animal Health, USA.)*

multimodal therapy with ketaconazole and aerosolization of enilconazole.[28]

Adiaspiromycosis. Adiaspiromycotic miliary fungal pneumonia caused by the saprophytic soil mold *Emmonsia crescens* was diagnosed in a horse by percutaneous lung biopsy. Euthanasia was performed without treatment.[11]

Acremonium strictum. A diagnosis of interstitial fungal pneumonia caused by *Acremonium strictum* was made based on cytologic evaluation, culture, and PCR testing of bronchoalveolar lavage fluid in a 10-year-old horse. The horse made an uneventful recovery with supportive treatment that included 1 month of fluconazole.[5] In general, fluconazole has been shown to have poor activity against *A. strictum* in vitro.[82] The isolate cultured from the horse was found to be resistant to fluconazole based on in vitro sensitivity testing that was performed after the course of treatment. It is therefore uncertain if the fluconazole assisted in disease resolution.[5]

Candidiasis. In human medicine, candidemia is the most common fungal infection in burn patients, neutropenic patients with malignancies, patients undergoing complex abdominal surgery, and patients receiving total parenteral nutrition and long-term corticosteroid therapy.[67] In humans, *Candida* spp. account for 8% to 10% of all blood culture isolates and rank fourth in the list of most frequently isolated pathogens from blood cultures.[67] The mortality rate in patients with candidemia is 40% to 75%.[67] Over 60% of isolates are *Candida albicans*.[67] Fluconazole is generally considered the drug of choice against *Candida* spp., although *C. krusei* is resistant to fluconazole. Itraconazole, amphotericin B, caspofungin, and voriconazole are alternative antifungal agents (see Table 31-7).[67]

Systemic candidiasis was diagnosed and successfully treated in four neonatal foals. Each foal had prior sepsis attributable to gram-negative bacteria that had been aggressively treated with numerous antibiotics and parenteral nutrition. *Candida albicans* was cultured from a transtracheal wash from one of the foals. Three of the foals had *Candida* glossitis, and one had panophthalmitis and fungal keratitis. Two of the foals were treated with intravenous amphotericin B, and oral fluconazole was used on the other two foals.[12]

Superficial *Candida* spp. infections of the mucous membranes (thrush)[83] can occur in isolation or as part of a systemic infection, and further microbiological culturing of the blood, tracheal wash, urine, or joint fluid may be indicated to rule out systemic infection.[12] *Candida* spp. glossitis can be treated by rinsing the mouth either with potassium permanganate (0.025% q24h) or nystatin (0.3 g in 10 mL of water q8h).

Pneumocystosis. *Pneumocystis carinii* (renamed *P. jiroveci* in humans) has been reclassified from a protozoan to a saprophytic fungus based on the DNA sequence of its 16S-like RNA subunit, but some researchers consider it to be a plant because it lacks ergosterol, the major fungal sterol.[84] It exists as an ameboid yeast or as a cystic sporangia. *P. carinii* cannot be cultured, and diagnosis is based on the cytologic identification of characteristic morphologic features using

VetBooks.ir

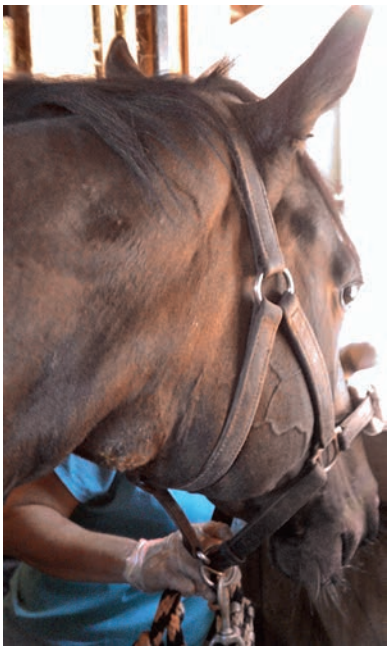

FIG. 31-29 Horse with retropharyngeal lymphadenopathy resulting in head and neck extension characteristic of *S. equi* infection.

specimens obtained by bronchoalveolar lavage rather than tracheal wash. A fluorescent in situ hybridization method with an oligonucleotide probe that targets the 18S ribosomal RNA has been developed recently to detect *P. carinii* in histologic sections.[21] Immunohistochemistry also can be used.[20]

P. jiroveci is the most common organism to cause opportunistic infection in people with HIV, and people undergoing immunosuppressive therapy after organ transplantation are predisposed. *P. carinii* causes diffuse interstitial pneumonia, especially in immunocompromised patients such as Arabian foals with severe combined immunodeficiency (SCID).[13] It also has been diagnosed in immunocompromised adult horses,[14,15] as well as an immunocompetent foal.[20] Trimethoprim-sulfamethoxazole (TMS) (25 to 30 mg/kg PO q12h) is the treatment of choice (see Table 31-7).[85,86] Dapsone (3 mg/kg PO daily for 2 months; Jacobus Pharmaceutical, Princeton, N.J.) was used to successfully treat a foal that developed *Salmonella* enterocolitis after treatment with TMS.[24]

Streptococcus equi Infection (Strangles)

Ashley G. Boyle*

The highly contagious *S. equi* subsp. *equi* infections in horses, commonly referred to as *strangles,* were first described in early veterinary science literature by Jordanus Ruffus in 1251.[1] Strangles is currently a reportable disease in at least seven U.S. states.

Clinical Signs Strangles is characterized by sudden onset of fever followed by upper respiratory tract catarrh, as evidenced by mucopurulent nasal discharge and acute swelling with subsequent abscess formation in submandibular and retropharyngeal lymph nodes (Fig. 31-29). The name *strangles* was coined because affected horses sometimes suffocated as the lymph nodes became enlarged and obstructed the airway.

Fever is the first clinical sign and remains as lymphadenopathy develops and abscesses mature. Pharyngitis makes swallowing painful, and affected animals may become anorectic or reluctant to eat and stand with the neck extended.

*Previous contributions by Corinne Sweeney are acknowledged.

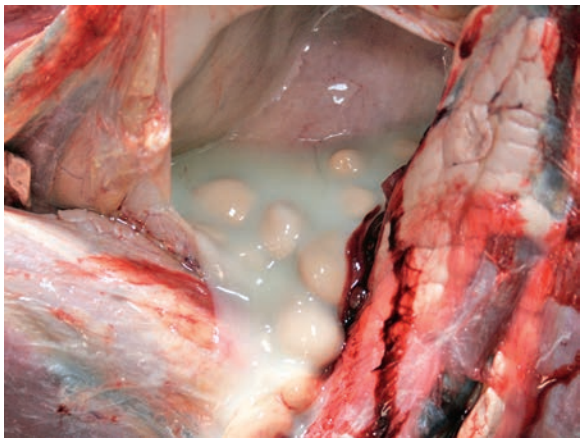

FIG. 31-30 Guttural pouch *S. equi* empyema with chondroids at postmortem. *(Courtesy Dr. Julie Engiles, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

FIG. 31-31 Horse with the unique presentation of periorbital abscessation with concurrent ocular discharge that cultured positive for *S. equi. (Courtesy Dr. Erica Koch, Atlantic Veterinary College, University of Prince Edward Island, Canada.)*

Lymphadenopathy is a major clinical sign. The submandibular and retropharyngeal lymph nodes are about equally involved in *S. equi* infections. They usually become swollen and painful approximately 1 week after infection. Other lymph nodes of the head region (parotid, cranial, and cervical) are also frequently involved and may abscess. Retropharyngeal lymph nodes may drain into and cause empyema of the guttural pouch (Fig. 31-30). Periorbital abscesses can cause marked swelling of the eyelids and result in ocular discharge that will culture positive for *S. equi* if sampled (Fig. 31-31). Abscesses of the lymph nodes at the thoracic inlet can cause severe tracheal compression, asphyxia, and death. Clinical severity and progression varies greatly depending on the immune status of the animal.

Pathogenesis *S. equi* is of the Lancefield group C streptococcal diseases and enters via the mouth or nose and attaches to cells in the crypt of the lingual and palatine tonsils and to the follicular-associated epithelium of the pharyngeal and tubal tonsils. There is no evidence of colonization before penetration. After a few hours the organism is difficult to detect on the mucosal surface but is visible within cells of the epithelium and subepithelial follicles. Translocation occurs in a few hours to the mandibular and suprapharyngeal lymph nodes that drain the pharyngeal and tonsillar region.[2]

Complement-derived chemotactic factors attract large numbers of polymorphonuclear neutrophils (PMNs), although gross evidence of abscessation is not visible for 3 to 5 days after *S. equi* enters the

VetBooks.ir

lymph node. Failure of neutrophils to phagocytose and kill the streptococci appears to be a result of a combination of the hyaluronic acid capsule, antiphagocytic SeM protein, Mac protein, and other undetermined antiphagocytic factors released by the organism. Depending on the immune status of the patient and the degree of exposure to *S. equi* bacterial load, clinical signs may develop 3 to 14 days after exposure.[1]

Although strangles involves predominantly the upper airways, including the guttural pouches and associated lymph nodes, metastasis to other locations occasionally occurs. Spread may be hematogenous or via lymphatic channels, which results in abscesses in lymph nodes and other organs of the thorax and abdomen. This form of the disease is known as *bastard strangles.*

Nasal shedding of *S. equi* usually begins 2 to 3 days after onset of fever and persists for 2 to 3 weeks in most animals. Some animals never shed. In others, shedding may last much longer if infection persists in the guttural pouch.[3,4] Systemic and mucosal immune responses are evident 2 to 3 weeks after infection and coincide with mucosal clearance.

As long as they were not treated with antibiotics, approximately 75% of horses develop a solid enduring immunity to strangles that lasts about 5 years after recovery from the disease. A small percentage of these horses become susceptible to a second attack of the disease within months, which probably represents a failure to produce or maintain an adequate level of the appropriate mucosal and systemic antibodies. Older horses with residual immunity have limited susceptibility and develop a mild form of strangles often termed *catarrhal strangles.* These animals shed virulent *S. equi* that will produce severe disease in more susceptible, often younger horses. Colostral antibodies ingested during the first 24 hours of life have also been shown to recirculate to the nasopharyngeal mucosa, thus providing an additional source of protection to the foal during its first weeks. Foals that suckle immune mares are usually resistant to *S. equi* infection until weaning.[1]

Epidemiology

TRANSMISSION. Outwardly healthy horses that still shed organisms are a source of infection when introduced into a new population of horses. Definitive determination of carrier status requires endoscopic examination of the guttural pouches as well as culture and PCR testing of guttural pouch lavage fluid.[5,6] *S. equi* may originate from outwardly healthy horses such as the following:

- Horses that are incubating the disease and go on to develop signs themselves
- Horses that are recovering from recent disease but that continue to harbor the organism after full clinical recovery for some weeks (carriers)
- Horses that are fully recovered from the disease but continue to be potentially infectious for prolonged periods through periodic shedding of *S. equi* (carriers)

ENVIRONMENTAL PERSISTENCE OF *STREPTOCOCCUS EQUI*. Currently there is a lack of definitive field-based proof for prolonged environmental persistence of *S. equi. S. equi* is known to be sensitive to bacteriocins from environmental bacteria and does not readily survive in the presence of other soil-borne flora. Modeled environmental field conditions revealed that the organism was found to persist for less than 4 days, but moist environments (e.g., water buckets) may allow the organism to persist for extended periods.[7]

Diagnosis

Early definitive diagnosis is essential for containing this highly infectious disease. Sampling may be unsuccessful during the incubation and early clinical phases. *S. equi* is normally not present on the mucosa until 24 to 48 hours after the onset of fever, so infection in horses monitored by daily measuring of rectal temperatures during an outbreak may be recognized early and isolated to limit transmission of *S. equi*. Cytologic evaluation reveals gram-positive extracellular cocci in long chains, supporting a general diagnosis of a β-hemolytic streptococcus organism. Common hematologic findings of horses with *S. equi* are hyperfibrinogenemia, neutrophilic leukocytosis, and mild anemia.

FIG. 31-32 Infusing 50 mL of 0.9% saline for a nasopharyngeal wash on a sedated horse with a uterine pipette. The pipette is punctured through one side of the rectal sleeve.

CULTURE. Historically, the gold standard for diagnosis has been bacterial culture of abscess aspirates, nasopharyngeal swabs, and nasopharyngeal and guttural pouch washes revealing *S. equi.* Culture is the preferred method on aspirates of mature abscesses, but it takes a minimum of 24 hours to obtain results.

POLYMERASE CHAIN REACTION. The polymerase chain reaction (PCR) is designed to detect DNA sequence of *SeM,* the gene for the antiphagocytic M protein of *S. equi.* PCR can also be performed on nasopharyngeal swab, nasopharyngeal wash, and guttural pouch wash samples. Nasopharyngeal washes (Fig. 31-32) are preferable to nasopharyngeal swabs due to a larger sampling area,[1] but guttural pouch sampling is the most reliable, although most expensive, requiring aspirating the sample via polyethylene tubing through the instrument channel of a 1-meter endoscope.[5,6] The endoscope should be sterilized following and between sampling of suspect horses. PCR testing is more sensitive than bacterial culture[8] and should always be used in combination.[1]

SEROLOGY. Serologic testing involves the use of ELISA to detect the SeM protein. Serology is useful for detecting recent, but not current, infection; assessing the need for vaccination; identifying horses that may be predisposed to purpura hemorrhagica; and diagnosing *S. equi*–associated purpura hemorrhagica and metastatic abscessation (SeM titers often are =1:12,800 but have been seen as low as 1:3200 and 1:6400 in confirmed cases).[1,9] It has been suggested that horses with high serum SeM-specific antibody titers may be predisposed to developing purpura hemorrhagica when vaccinated against *S. equi*.[1] A 2009 study identified older horses, non-Thoroughbreds and non-warmbloods, and horses that had been recently vaccinated (last 1 to 3 years) with an attenuated live intranasal *S. equi* vaccine as having an increased likelihood of SeM-specific antibody titers 1:1600 or greater. Of 35 horses that had been vaccinated with intranasal strangles vaccine when SeM titer was equal to 1:1600, 26 (74%) did not have any complications associated with purpura.[10] Therefore the recommendation is to not vaccinate when the titer is 1:3200 or greater.

VetBooks.ir

The Animal Health Trust in the United Kingdom recently developed a serologic test that detects different surface antigens. This test is currently being used to identify horses with recent strangles exposure for the purposes of isolation and further examination via endoscopic guttural pouch examination.[11]

VACCINATION. Most horses develop a solid immunity during recovery from strangles, which persists in over 75% of animals for 5 years or longer. This indicates that stimulation of a high level of immunity is biologically feasible given appropriate presentation of protective immunogen(s). There is evidence that immunity in horses resistant to reinfection is mediated at the mucosal level and functions to block entry of *S. equi*. However, systemic immunity after parenteral inoculation of avirulent live *S. equi* is also protective. Together, these findings indicate that optimum immunity may require both systemic and mucosal responses.

Vaccine should be administered only to healthy nonfebrile animals free of nasal discharge. Although controversial, vaccination should be considered only in horses with no known contact with animals with strangles during an outbreak.[1] The American Association of Equine Practitioners (AAEP) Infectious Disease Committee does not recommend vaccination during an outbreak. It is suggested that horses recovering from infection should not be vaccinated for 1 year.

USE OF EXTRACT VACCINES. Extract vaccines (Strepvax II [Boehringer Ingelheim Vetmedica, Inc., St. Joseph, Mo.]) are given intramuscularly and elicit serum antibody responses 7 to 10 days later. Naive horses and foals require a schedule of two or three doses at an interval of 2 weeks. Booster doses are given once annually. Pregnant mares may be boostered a month before expected date of foaling. Extract vaccines have been associated with cases of purpura hemorrhagica.[12]

USE OF ATTENUATED LIVE INTRANASAL VACCINE. Attenuated live vaccine (Pinnacle I.N. [Zoetis, Florham Park, N.J.]) is given in a schedule of two doses at 2- to 3-week intervals. Annual booster doses are recommended. The mode of application should be such that an adequate amount of vaccine reaches the pharyngeal and lingual tonsils but does not enter the trachea. Careful handling of live vaccine is recommended to prevent inadvertent injection intramuscularly either via the vaccine directly or contamination of other vaccines given at the same time. It is not recommended in horses less than 1 year of age because of the possibility of development of vaccine-associated clinical disease.[13]

FUTURE VACCINES. It is likely that more effective and safer vaccines will eventually be developed based on genomic sequence information from *S. equi* and *S. zooepidemicus*. In Europe, clinical studies are under way evaluating a recombinant multicomponent subunit vaccine.[14]

CONTROL OF OUTBREAKS. Most outbreaks are thought to originate from introduction of an infected horse to a naive population. All new horses should be isolated for 3 weeks and monitored for any signs of disease, including fever. If cost is not prohibitive, horses should be screened for *S. equi* infection using nasopharyngeal washes. Many farms with repeated infections have resorted to screening for infection via endoscopic evaluation and PCR testing of guttural pouch lavages, a procedure considered by many as the "gold standard" for carrier detection.[5,6] A series of three nasopharyngeal swabs, collected 1 week apart, will result in detection by a positive culture on at least one of the swabs in approximately 60% of carrier animals. Concurrent testing of these swabs by PCR increases the likelihood of detection to over 90% of carrier animals.[11]

A practical disease-control strategy should then be agreed on and implemented. The general aims and measures for such a strategy are outlined in Table 31-8.[1]

Treatment

The goal of treating strangles is to control transmission and eliminate infection while providing future immunity to the disease. Appropriate treatment of horses with strangles usually depends on the stage and severity of the disease, and veterinary opinion as to whether or not to use antibiotic treatment remains markedly divided.[15]

HORSES WITH EARLY CLINICAL SIGNS. During an outbreak, immediate antibiotic therapy for new cases in the early acute phase with fever and depression may be curative and may prevent focal abscessation and shedding. Because abscesses have not developed at this early stage, the antibiotics have adequate access to the bacteria. Immediate treatment of horses that show the earliest clinical sign, fever, could be an effective way of controlling strangles outbreaks in racing stables or riding barns, although the disadvantages of treatment should be weighed.

HORSES WITH LYMPH NODE ABSCESSATION. Uncomplicated cases of strangles are often left to run their course with supportive care, providing lasting immunity. Affected horses should be isolated in a clean, dry stall and fed moist, palatable food. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be used judiciously to decrease swelling and promote eating. Hot compresses or topical 20% ichthammol can be used to accelerate maturation of abscessation. Mature external abscesses should be lanced to allow drainage, followed by daily lavage of open abscesses using dilute povidone iodine solution. This speeds resolution of abscessation as well as alleviation of compression of the pharynx.

Although the use of antimicrobials for treating strangles is controversial, if the horse is febrile, depressed, anorectic, and particularly if manifesting dyspnea, antibiotic therapy is indicated to decrease abscess size and prevent complete airway obstruction. In rare cases, affected horses may require intensive supportive therapy, including IV fluids, feeding by nasogastric tube, and tracheostomy. An animal requiring a tracheostomy should be given systemic antimicrobial drugs to prevent secondary bacterial infections of the lower respiratory tract.

DRUGS OF CHOICE FOR THERAPY. Penicillin G (procaine penicillin [22,000 to 44,000 IU/kg IM q12h] or aqueous potassium penicillin [22,000 to 44,000 IU/kg IV q6h]) is generally considered the drug of choice for the treatment of nonpneumococcal streptococcal disease, with alternative drugs used depending on ease of administration or the site of infection. Other agents for therapy include cephalosporins and macrolides. Although there is evidence that trimethoprim-sulfadiazine did not eliminate *S. zooepidemicus* infection in tissue chambers implanted subcutaneously in ponies, the study did not determine its effectiveness against *S. equi*.[16] Anecdotally, trimethoprim-sulfadiazine treatment failure has been seen. Use of antibiotics during any phase of the disease may prevent the development of lasting immunity.

Complications

GUTTURAL POUCH EMPYEMA AND CARRIER STATUS. The percentage of carriers per outbreak could be as high as 10%. Endoscopic examination is required for identification of guttural pouch empyema. The SeM ELISA does not detect empyema or carrier status.[5] Elimination of guttural pouch empyema requires repeated lavage with a solution of 20% acetylcysteine in buffered saline via polyethylene tubing through an endoscope or via a chambers catheter. Chondroids are particularly difficult to remove, possibly requiring manual removal with endoscopic equipment such as a memory helical polyp retrieval basket, repeated lavage via indwelling catheters, or surgical removal. Successful elimination of *S. equi* in these carriers requires local treatment of the guttural pouch with a penicillin gel after removal of the material within the guttural pouch in addition to systemic treatment with procaine penicillin or potassium penicillin for 7 to 10 days. Eradication of this disease will not be possible until the subpopulation of carriers is eliminated.[17]

VetBooks.ir

TABLE 31-8

Aims and Measures Used to Control Transmission of *S. equi* on Affected Premises

Aim	Measure
1. To prevent the spread of *S. equi* infection to horses on other premises and to new arrivals on the affected premises	Stop all movement of horses on and off the affected premises immediately and until further notice. Horses with strangles and their contacts should be maintained in well-demarcated "dirty" (i.e., *S. equi*–positive) quarantine areas. Clustering of cases in groups should allow parts of the premises to be easily allocated as "dirty," "recovering," and "clean" areas. Perform twice-daily monitoring of rectal temperatures to identify temperature increases in horses early and move them to the "dirty" area prior to the start of shedding.
2. To establish whether convalescing horses are infectious at least 2 to 3 weeks *after* clinical recovery	*S. equi* PCR assay and culture testing of at least three nasopharyngeal lavages are performed at approximately weekly intervals in all recovered horses and their contacts, or preferably of one guttural pouch lavage with endoscopic examination. Horses that test consistently negative are returned to the "clean" area.
3. To investigate all outwardly healthy horses in which *S. equi* is detected by either culture or PCR assay	Perform endoscopy of the upper respiratory tract and guttural pouches.
4. To eliminate *S. equi* infection from the guttural pouches	Remove pathology through a combination of flushing and aspiration with saline, and remove chondroids using endoscopically guided instruments. Perform topical and systemic administration of antimicrobials to eliminate *S. equi* infection. A minimum of 3 weeks should pass before retesting a treated, previously positive guttural pouch via PCR.
5. To prevent indirect cross-infection by *S. equi* from horses in the "dirty" area to those in the "clean" area of the premises	Personnel should use dedicated protective clothing when dealing with infectious animals and should not deal simultaneously with susceptible animals. If this is unavoidable, infectious horses should be dealt with *after* susceptible animals. Strict hygiene measures are introduced, including provision of dedicated clothing and equipment for each area and disinfection facilities for personnel and use of thorough stable cleaning and disinfection methods. When cost is not a factor, consideration should be given to destruction of the dedicated equipment after eradication of the infection. After removal of organic material from stables, all surfaces should cleaned first with detergent and then be thoroughly soaked in an appropriate liquid disinfectant (phenols, quaternary ammonium compounds) and allowed to dry. Manure and waste feed from infectious animals should be composted (disinfected by heat) in an isolated location. Pastures used to hold infectious animals should be rested for 4 weeks. Care should be taken to clean and disinfect water troughs at least once daily during an outbreak. Horse vans should be cleaned with detergent and then disinfected after each use.

PCR, Polymerase chain reaction.

COMPLICATIONS ASSOCIATED WITH METASTATIC SPREAD OF INFECTION. In as many as 20% of cases, *S. equi* spreads hematogenously or lymphatically. This results in metastatic abscessation, which can affect any organ system. Aspiration of mucopurulent discharge or hematogenous or lymphatic spread to the lungs can cause pneumonia. Abscessation in the mesentery, liver, spleen, and kidneys is common, leading to peritonitis and clinical signs of colic. Abscessation of the cranial mediastinal lymph nodes can cause tracheal compression and respiratory distress. Neurologic signs are present when abscessation occurs in the brain.[1] The mortality rate of horses with strangles is less than 2%, but the presence of bastard strangles can increase the mortality rate to as high as 62%.[18,19] Attempted culture and sensitivity from the affected body cavity provides direction for the appropriate antibiotic treatment, which has included penicillin, ceftiofur, chloramphenicol, and doxycycline. An average of 2.5 months of antibiotic treatment was needed for resolution.[18] Some horses have been treated via surgical drainage along with systemic antibiotics.[19]

PURPURA HEMORRHAGICA. Purpura hemorrhagica is an aseptic necrotizing vasculitis that can occur in mature horses after repeated natural exposure to infection or after vaccination of horses that have had strangles. The actual incidence of this type III hypersensitivity response secondary to strangles or vaccination is unknown. Clinical signs range from mild to life-threatening, including pitting edema of the head, trunk, and distal limbs, as well as petechiae and ecchymoses. In some cases, antigen-antibody complexes affect other sites, including the gastrointestinal tract, muscles, lungs, myocardium, and kidneys. In addition to prolonged treatment with penicillin, cases of purpura hemorrhagica also require the use of systemic corticosteroids (dexamethasone, 0.1 to 0.2 mg/kg IV or IM q12-24h; prednisolone, 0.5 to 1 mg/kg PO q24h) for an average of 3 weeks to reduce systemic vasculitis.[12] Significant rhabdomyolysis with progressive atrophy has been identified in some Quarter Horses, after exposure to *S. equi,* without other signs of purpura.

Acute Respiratory Distress Syndrome and Acute Lung Injury (Acute Bronchointerstitial Pneumonia)

Bettina Dunkel

Definition and Pathophysiology Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) comprise a syndrome of severe pulmonary dysfunction and respiratory failure caused by physical or chemical injury or an exaggerated pulmonary immune response. In human medicine, ALI and ARDS are defined by an acute onset, bilateral pulmonary infiltrates, a ratio of partial arterial oxygen pressure (PaO_2) to fraction of inspired oxygen (FiO_2) of less than 300 mm Hg for ALI (the less severe form) and less than 200 mm Hg for ARDS, and no clinical evidence of left atrial hypertension or a pulmonary arterial occlusion pressure of less than 18 mm Hg.[1] Recently, a further stratification based on the PaO_2/FiO_2 ratio into mild (201 to 300 mm Hg), moderate (101 to 200 mm Hg), and severe (up to 100 mm Hg) disease has been introduced.[2] During

VetBooks.ir

a consensus meeting, definitions for veterinary ALI and veterinary ARDS were developed (Box 31-1).[3] Because of lack of available data, no species-specific definitions were established, but the physiologic differences in arterial oxygenation in foals less than 1 week of age were addressed by introducing different inclusion criteria for this age group (Table 31-9). The consensus definition also acknowledged the disease presentation in neonatal foals with presumed pulmonary surfactant deficiency (termed *neonatal equine respiratory distress syndrome; NERDS*) secondary to very early gestational age, induction of parturition, or caesarean section as a distinct entity different from VetALI/VetARDS.[3]

ALI or ARDS arises as a complication after major infectious or noninfectious bodily injury. During injury or infections, the body mounts a protective response that involves controlled activation of the inflammatory and coagulation system.[4,5] In ALI and ARDS an imbalance of proinflammatory and antiinflammatory factors, combined with activation of the pulmonary endothelium and derangement of the coagulation cascade, favors the development of a fulminant, uncontrolled pulmonary inflammatory response and a widespread procoagulant environment in alveoli and the pulmonary microcirculation.[5,6] The triggering event can be an intrapulmonary insult (viral or bacterial pneumonia, smoke inhalation, near drowning, or food aspiration) or an extrapulmonary insult (trauma, multiple transfusions, systemic inflammatory response, or sepsis). In people, variants of several genes regulating inflammation, coagulation, and endothelial cell function, as well as genetic polymorphism predisposing individuals to the pathogenic effects of specific bacteria and viruses, are thought to influence the development of ALI and ARDS and also the outcome.[5]

The pathophysiology of ALI and ARDS is centered around dysregulation of pulmonary inflammation and coagulation, leading to accumulation and activation of leukocytes and platelets, altered permeability of the endothelial and epithelial barrier, and ultimately accumulation of extravascular protein-rich edema fluid.[5,7] Although not temporally distinct and largely overlapping, the pathophysiologic events can be divided into an initial exudative phase, a fibroproliferative phase, and, if the patient survives, a recovery phase.[8] The exudative phase is characterized by uncontrolled release of inflammatory mediators and influx of inflammatory cells into the pulmonary tissue. Activated platelets, neutrophils, and alveolar macrophages marginate in the microcirculation and extravasate into the pulmonary tissue, where they release oxidants, reactive oxygen species, proteases, and cytokines, amplifying and perpetuating inflammation and coagulation.[9] A variety of mediators, pathways, and molecular systems ultimately contribute to the breakdown of the alveolar endothelial and epithelial barrier, causing flooding of the alveoli once the edema safety factors have been exhausted. The barrier tends to collapse suddenly, resulting in rapid filling of the alveoli with proteinaceous exudate, leukocytes, and red blood cells, and destruction of the surfactant layer.[6] The fast onset of pulmonary edema may correspond with the clinically observed acute onset of respiratory distress in foals. The prothrombotic and antifibrinolytic environment favors formation of thrombi in the pulmonary microvasculature and deposition of intraalveolar fibrin-rich hyaline membranes.[10] The fibroproliferative response, which can begin within 24 hours of the onset of ALI and ARDS, is characterized by type I pneumocyte necrosis and proliferation of the more resistant type II pneumocytes in an attempt to restore the epithelial surface.[6,11] Fibroblasts invade the

BOX 31-1

Veterinary Acute Lung Injury (VetALI) and Acute Respiratory Distress Syndrome (VetARDS)

At least one each of the first four criteria must be met; criterion 5 is recommended but optional (Wilkins et al, 2007).

1. Acute onset (<72 hours) of tachypnea and labored breathing at rest
2. Exposure to a known risk factor
3. Evidence of pulmonary capillary leak without increased pulmonary capillary pressure* (any one or more of the following):
   a. Bilateral/diffuse infiltrates on thoracic radiographs (>1 quadrant/lobe)
   b. Bilateral dependent density gradient on computed tomography
   c. Proteinaceous fluid within the conducting airways
   d. Increased extravascular lung water
4. Evidence of inefficient gas exchange (any one or more of the following):
   a. Hypoxemia without PEEP or CPAP and known FiO_2
      i. PaO_2/FiO_2 ratio
         1. <300 mm Hg VetALI ($PaO_2 \leq 63$ mm Hg at room air†)
         2. <200 mm Hg VetARDS ($PaO_2 \leq 42$ mm Hg at room air†)
      ii. Increased arterial-alveolar (A-a) gradient
      iii. Venous admixture (noncardiac shunt)
   b. Increased "dead-space" ventilation
5. Evidence of diffuse pulmonary inflammation
   a. Transtracheal wash/bronchoalveolar lavage cytologic neutrophilia
   b. Transtracheal wash/bronchoalveolar lavage biomarkers of inflammation
   c. Molecular imaging (positron emission tomography)

VetBooks.ir

pulmonary interstitium and alveolar walls and deposited collagen, which can result in fibrosis and significant impairment of pulmonary mechanics and gas exchange. The extensive pulmonary pathology leads to severe hypoxemia with hypocapnia or hypercapnia caused by ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch and decreased pulmonary compliance. Alveolar edema creates areas of a low $\dot{V}/\dot{Q}$ ratio (adequate perfusion but no ventilation), causing hypoxemia, whereas areas with deceased perfusion generate hypoxemia and eventually hypercapnia by increasing dead space ventilation (high $\dot{V}/\dot{Q}$ ratio; adequate ventilation with minimal perfusion).[6] The coexistence of areas with high and low $\dot{V}/\dot{Q}$ ratios adjacent to normal lung tissue makes mechanical ventilation of patients with ALI and ARDS extremely challenging and predisposes the patient to ventilator-induced lung injury.

The resolution of ALI and ARDS requires repair of endothelial and epithelial barriers, reabsorption of alveolar edema, and removal of inflammatory exudate and cellular debris.[5] Sodium and chloride ions are actively transported via ion channels on the apical surface and Na+/K+-ATPase on the basolateral membrane of alveolar epithelial cells while water follows the created osmotic gradient through aquaporin-5 channels located on type I epithelial cells. If damage to the pulmonary epithelium is minor, pulmonary edema can be cleared swiftly, pulmonary function improves rapidly, and chances of survival increase. If large areas of alveolar epithelium are destroyed, gradual reepithelialization by proliferation of type II cells, and potentially also by recruitment of progenitor cells, must occur first.[5,12] Severe damage to the epithelium corresponds with prolonged respiratory failure, slow recovery, and high mortality.[13] Recovering patients may have complete resolution of pulmonary compromise or may suffer from residual functional impairment, such as muscle weakness, decreased pulmonary function, restrictive or obstructive changes, and low diffusion capacities.

VetALI/VetARDS, in earlier reports also referred to as *acute interstitial* or *bronchointerstitial pneumonia,* has been described in foals and weanlings up to 7 months of age.[14-20] Extensive searches for a common pathogen were conducted until, with increasing understanding of the pathophysiology, it became evident that multiple infectious and noninfectious agents are capable of initiating the inflammatory response.[14-17] In foals the most common risk factor appears to be intrapulmonary injury, namely bacterial or, in rare cases, viral pneumonia.[14-17,19-21] There are no clinical reports of VetALI or VetARDS in adult horses, although descriptions in case reports and small studies suggest its occurrence. Buergelt and colleagues[14] reported respiratory distress in six adult horses; however, the description they give better fits the heterogeneous group of interstitial pneumonias than it does VetALI and VetARDS. Two adult horses with respiratory distress after near drowning met the criteria for ALI,[22,23] and two horses affected by smoke inhalation experienced fulminant pulmonary inflammation and, most likely, VetALI.[24] Experimentally, VetARDS has been induced by intravenous (IV) injection of perilla mint ketones[25,26] and was observed after experimental gram-negative sepsis.[27] However, most of the animals in the latter study were in an agonal state, making interpretation of the observed pulmonary changes difficult.[27] Further risk factors recognized in other species that might also occur in the horse include systemic inflammation, severe trauma, multiple transfusions, aspiration of stomach contents, drugs, and toxins.[3] The discovery of genetic predispositions to dysregulation of inflammation and coagulation in people is intriguing, as a similar predisposition in equids could potentially explain why, of many foals affected by infectious pneumonia, very few develop VetALI and VetARDS.

Clinical, Diagnostic, and Postmortem Findings

It is almost impossible to clinically differentiate foals with VetALI and VetARDS from foals with severe bacterial, chiefly advanced *Rhodococcus equi,* pneumonia, particularly as the syndrome can be triggered by an underlying bacterial infection. Clinical signs include profound depression, fever, and respiratory distress with tachycardia, tachypnea, nostril flare, and cyanotic mucous membranes. Auscultation of the lungs can reveal a variety of abnormal sounds or complete silence over nonventilated areas. Laboratory findings include severe hypoxemia with hypocapnia or hypercapnia and, depending on the underlying disease process, leukocytosis or leukopenia and hyperfibrinogenemia. Signs of disseminated intravascular coagulation were present in two foals with VetALI and VetARDS in one report,[16] and abnormal coagulation parameters may be observed. Transtracheal lavage fluid demonstrates neutrophilic inflammation with or without signs of infection, depending on the underlying cause. Thoracic radiographs show a diffuse, dense bronchointerstitial pattern often coalescing to a focal or diffuse alveolar pattern with prominent air bronchograms. The initial radiographic appearance of the lungs may worsen dramatically within hours as a result of rapid progression of pulmonary edema. On the other hand, absorption of the alveolar fluid may result in impressive improvement of the radiographic appearance within days.[16,17] A thoracic sonogram is useful in foals that cannot be safely transported to a radiography unit and reveals multiple coalescing comet-tail artifacts, predominantly in the caudodorsal lung field.

On gross pathologic examination, the affected lungs are wet and firm and fail to collapse; airways contain variable amounts of pink, foamy liquid. Histologically, necrosis of alveolar and terminal bronchial epithelium is observed, with extensive filling of the alveolar spaces with neutrophils, macrophages, hemorrhage, protein-rich edema fluid, or hyaline membranes. Occasionally, microthrombi can be detected in interstitial capillaries. In more chronic cases, diffuse proliferation of cuboidal pneumocytes and fibroblasts and beginning fibrosis may be present.[14-17]

Diagnosis

The diagnosis can be established if the criteria outlined in Box 31-1 and, depending on the age, Table 31-9 are met; cardiac disease is absent; and the extent of the respiratory distress cannot solely be attributed to a primary disease process (e.g., almost complete destruction of the pulmonary parenchyma by a primary disease process). Presence of bacterial or viral pneumonia does not rule out concurrent VetALI or VetARDS.

Treatment and Prognosis

A recent reduction in mortality rates in human ALI and ARDS has largely been attributed to more widespread use of lung-protective ventilation with lower tidal volumes (6 mL/kg) and airway pressures and conservative fluid therapy.[28] Antiinflammatory, antioxidant, anticoagulant, and surfactant therapy and treatment to enhance alveolar edema removal (aerosolized or intravenous β-adrenergic agonists such as salmeterol, terbutaline, or epinephrine to stimulate active transepithelial ion transport) have largely failed to improve survival.[5] However, considering that, in contrast to human medicine, most equine patients die as a direct result of respiratory failure, some of those therapeutic options may still benefit equine patients. As mechanical ventilation is, with few exceptions,[29] feasible only in neonates, the most important treatment remains intranasal insufflation of humidified oxygen via unilateral or bilateral intranasal cannulas. Large-bore tubing systems minimize the resistance to airflow, and Fi_{O_2} as high as 70% and 75% has been measured at the carina in adult horses and foals, respectively, using bilateral flow rates of 15 L/min (10 L/min in foals; combined 30 L/min in adults or 20 L/min in foals).[30,31] Alternatively, use of intratracheal oxygen insufflation has been described, achieving results similar to high bilateral intranasal flow rates.[32] Although controversial, administration of methylprednisolone at 1 to 2 mg/kg/day is still occasionally recommended in acute cases of human ALI and ARDS for up to 2 weeks, followed by a gradual decrease of the dose.[33] Considering that ventilation is rarely an option and that in two reports all but two foals surviving ALI and ARDS received corticosteroids, anecdotal evidence is in favor of steroid administration (IV prednisolone sodium succinate or methylprednisolone at 1 to 2 mg/kg/day divided in 2 to 4 doses). Antimicrobial treatment, if required, should be directed against the underlying disease process. Bronchoconstriction is not a prominent feature of ALI and ARDS, and bronchodilators are therefore most likely of limited use. Care should be

VetBooks.ir

taken when administering bronchodilators as they can induce sudden worsening of $\dot{V}/\dot{Q}$ mismatch and can lead to acute decompensation of the severely hypoxic patient. Judicious IV fluid therapy may be necessary in dehydrated patients, but overhydration or rapid changes in circulating blood volume should be avoided as capillary hydrostatic pressure is the main determinant of pulmonary edema formation when endothelial and epithelial permeability is increased. On the other hand, a suboptimal hydration status decreases cardiac output and worsens oxygen delivery to the peripheral tissue. Measurement of central venous pressure may aid in determination of the patient's hydration status. If foals are too depressed to nurse or eat, nutritional support is essential.

Based on the limited information available, the prognosis for survival and future athletic performance is guarded, with survival rates ranging from 60% to 69% in two clinical reports.[16,17] It is difficult to extrapolate long-term outcomes of pulmonary function from human patients because of the extensive use of mechanical ventilation with associated injury and frequent presence of preexisting comorbidities such as smoking.[34] Experimental induction of ARDS in horses did not result in any lasting histologic changes or fibrosis despite severe clinical signs.[25] The few long-term reports of equine survivors have so far suggested little noticeable lasting respiratory compromise, and successful careers as racehorses have been reported even in severely affected animals.[17] More information is clearly needed to determine the long-term effects of severe pulmonary injury in horses.

Interstitial Pneumonia

Pamela A. Wilkins • Kurt Williams • Fabio Del Piero

Interstitial pneumonia is an uncommon cause of acute or chronic lower respiratory tract disease in horses.[1-7] Because of the potential severity of the process, it becomes important to recognize and definitively diagnose interstitial pneumonia as early as possible in its clinical course. Unfortunately, its onset is often insidious and subclinical. By the time it clinically manifests itself, there is often considerable involvement of the lungs, with chronic remodeling of the gas exchange regions with extensive fibrosis, resulting in altered mechanical properties of the lung typical of restrictive lung disease.

Etiology A variety of agents have been implicated in the genesis of interstitial pneumonia in animals, although fewer than 20 have been confirmed in horses (Box 31-2). Chief among these are infectious agents and ingested and inhaled toxins. Because of the frequently insidious onset of interstitial pneumonia, the causative agent(s) is(are) often not identified, leading to a diagnosis of idiopathic interstitial pneumonia. Because the lung response to injury, especially in long-standing cases of interstitial pneumonia, is often nonspecific relative to the initial insult, and the cause may no longer be present, it is often difficult to identify the inciting cause. Therefore all efforts should be made to identify a causative agent early in the course of the disease, if possible, but the practitioner needs to be aware that treatment frequently will be nonspecific and supportive.

INFECTIOUS AGENTS. Infectious causes of interstitial pneumonia in horses and foals include viral, bacterial, parasitic, protozoal, and fungal agents. Typically the pneumonia is acute and severe, characterized by severe damage to the lung parenchyma (alveolar region).

Viral agents are frequently implicated or suspected but rarely identified by the usual serologic, histopathologic, and virus isolation methods. The advent of more sensitive and specific techniques, such as in situ PCR and monoclonal antibody immunohistochemistry, may partially resolve the current diagnostic challenge.

Since 2008 the equine gammaherpesvirus EHV-5 has been associated with a nodular form of interstitial pneumonia of horses characterized by pulmonary interstitial fibrosis, suggesting that these rather unusual cases may have an underlying infectious cause.[8] This disease has been termed *equine multinodular pulmonary fibrosis* (EMPF) by the authors describing the pathology of the disease. Horses affected by the disease generally have a history of fever, cough, and weight loss, accompanied by exercise intolerance and, finally, respiratory distress. They can be acutely affected or have a more chronic progressive disease. Typical radiographs reveal multiple discreet to coalescing nodular densities overlying a diffuse interstitial pattern (Figs. 31-33 and 31-34). Histologic appearance is diagnostic of this disease (Fig. 31-35). EHV-5 has been identified in both BALF and lung biopsy samples from affected patients by both PCR assay and immunohistochemistry. Preliminary efforts to reproduce the disease through lung inoculation of horses with isolates of EHV-5 obtained from animals with EMPF have shown that similar nodular pulmonary fibrosis can be induced in such infected animals, providing strong evidence that the virus is the cause of the disease.

BOX 31-2

Causes of Interstitial Pneumonia in Horses

Acute

Infections (systemic viral, bacterial, parasitic)
Inhaled chemicals
  Oxygen (Fio_2 > 50%)
  Smoke
Ingested toxins or precursors
  Perilla mint (*Perilla frutescens*), Crofton weed (*Eupatorium adenophorum*), *Crotalaria* spp., *Senecio* spp.
Adverse drug reactions
  Uncertain
Hypersensitivity
  Acute hypersensitivity pneumonitis
Endogenous metabolic or toxic conditions
  Shock—particularly endotoxic (ARDS)
  Disseminated intravascular coagulation (DIC)
  Uremia
Idiopathic or cryptogenic

Chronic

Infections (systemic viral, bacterial, parasitic)
Inhaled inorganic dust (pneumonoconioses)
  Silicosis
Hypersensitivity
  Hypersensitivity pneumonitis
Ingested toxins or precursors
  Perilla mint (*Perilla frutescens*), Crofton weed (*Eupatorium adenophorum*), *Crotalaria* spp., *Senecio* spp.
Collagen-vascular disorders
  Uncertain
Idiopathic or cryptogenic

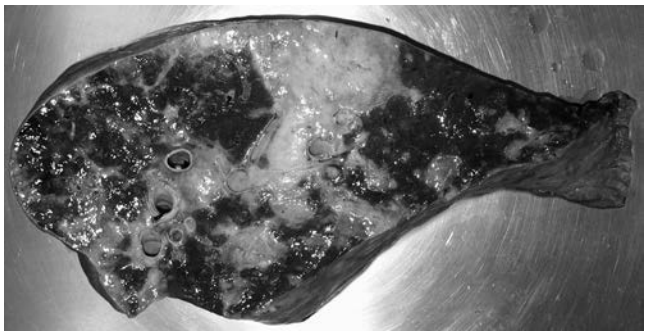

FIG. 31-34 Cut section of lung from horse with equine multinodular pulmonary fibrosis. Note large areas of fibrosis within the pulmonary parenchyma. *(Courtesy Dr. Perry Habecker, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

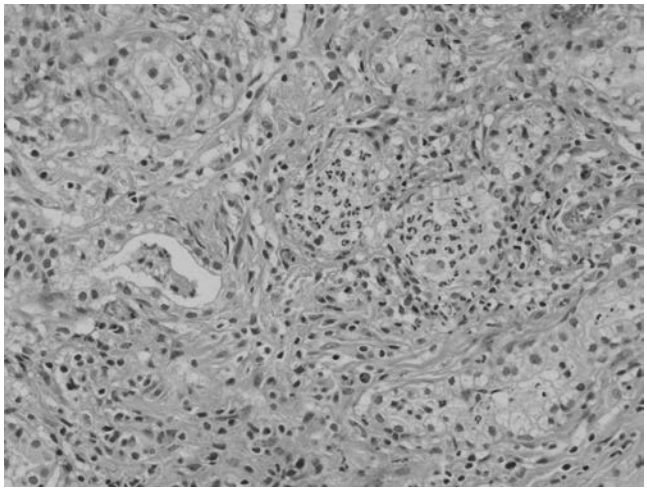

FIG. 31-35 Lung histopathology from a horse with equine multinodular pulmonary fibrosis. Note the cuboidal epithelial cells lining the remodeled airspaces in the regions of fibrosis. Within the airspace lumen there is a mix of neutrophils and macrophages. An intranuclear viral inclusion body is visible within one of the cells. *(Courtesy Dr. Fabio Del Piero, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.)*

In some horses with bronchointerstitial pneumonia of unknown cause, bacterial agents have been isolated from the lung. The usual distribution of bacterial bronchopneumonia in the horse is cranioventral, whereas the distribution in interstitial pneumonia is often nearly diffuse. In the latter cases the bacteria most likely represent contaminants or possibly opportunistic agents and do not represent the primary cause. An exception is *R. equi* pneumonia of foals, which has been associated with ARDS-like disease in older foals. *R. equi* has been cultured from foals with severe, acute bronchointerstitial pneumonia with a diffuse pulmonary distribution.[4] Interstitial pneumonia associated with *P. carinii* has been described in the foal, and *Mycoplasma* spp. have been isolated from the respiratory tract of adult horses.[9] *Mycoplasma* isolates in horses should usually be considered incidental to the disease, as their significance in equine respiratory disease is unproven. *P. carinii* pneumonia is thought to occur primarily in immunocompromised foals as a complication of some other serious disease, such as infectious pneumonia *(R. equi)* or SCID. It is characterized by a severe plasmacytic lymphocytic interstitial pneumonia with flooding of alveoli with foamy acidophilic material.

Parasitic pneumonia, an uncommon cause of chronic bronchointerstitial pneumonia, usually occurs in young foals secondary to migration of *Parascaris equorum* larvae through the pulmonary parenchyma.

INGESTED CHEMICALS. Ingested chemicals rank second only to infectious agents as potential causes of interstitial pneumonia in horses. Ingestion of pyrrolizidine alkaloids from a variety of plants (mostly genera *Crotalaria, Trichodesma,* and *Senecio*) can cause interstitial pneumonia in horses.[10] This toxicity is associated with production of a toxic metabolite that is activated in the liver and then circulates to the lung. The toxic alkylating agents damage capillary endothelial cells, although the amount of alkaloid required to damage the lung is generally less than that required for hepatotoxicity. Crofton weed *(Eupatorium adenophorum),* a poisonous plant found primarily in Australia and Hawaii, produces interstitial pneumonia in horses. Toxicity is associated with ingestion of the flowering plant, but the nature of the toxin is not known. Perilla ketone, derived from the plant *Perilla fructans,* experimentally produced acute respiratory distress with a week of ingestion in ponies. The lesions include diffuse alveolitis and type II pneumocyte proliferation with sparing of the bronchioles. Toxicity depends on additional metabolism of the 3-substituted furan by the mixed function oxidase system, which occurs directly in the lung of the horse.

INHALED CHEMICALS. Direct pulmonary injury by inhaled chemicals is an uncommon cause of interstitial pneumonia in horses. In people this type of pneumonia is primarily related to occupational exposure. Smoke inhalation causes acute, diffuse interstitial pneumonia in horses, frequently followed within a few days by opportunistic bacterial pneumonia. Oxygen toxicity can theoretically produce interstitial pneumonia and alveolar type II cell proliferation. This problem is more likely to be seen in neonatal foals mechanically ventilated with increased levels of oxygen ($Fi_{O_2} > 50\%$) for several days, although this may in fact be a form of ventilator-associated lung injury (VALI) associated with mechanical stretch of the airspaces. Damage is thought to be due to production of reactive oxygen metabolites, which attack a lung that may already have been injured by barotrauma resulting from a ventilator-driven increase in airway pressure. Agrichemicals or herbicides, such as paraquat, may cause acute interstitial pneumonia (AIP) in horses and should be considered in horses with a history of possible exposure. Silicate pneumoconiosis is a specific chronic granulomatous pneumonia of horses associated with inhalation of silicates. This syndrome has been described in horses originating from the Carmel Valley region of California. The inhaled particles are ingested by alveolar macrophages and result in lysis of the macrophage, chronic alveolitis, and fibrosis. Multiple granulomas are present, and intracytoplasmic crystalline particles can be identified in macrophages.

HYPERSENSITIVITY REACTIONS. In the most specific sense, *hypersensitivity pneumonitis* refers to pulmonary disease caused by inhalation of organic antigens. Lymphocytic, plasmacytic bronchitis and bronchiolitis, combined with lymphocytic interstitial pneumonia, characterize the disease in horse lung. Granuloma formation and fibrosis can be observed. Chicken dust and fungi have been implicated as causes of severe, chronic bronchointerstitial pneumonia, but the syndrome itself is quite rare.

Endogenous Metabolic and Toxic Conditions

Various conditions cause acute pulmonary injury with inflammatory edema or severe alveolar wall damage and serofibrinous exudation similar to that described for AIP. Acute uremia, shock, burns, and trauma can produce an acute pulmonary injury termed *acute lung injury* (ALI) or *acute respiratory distress syndrome* (ARDS), depending on severity. Although endotoxin does not directly injure the lung, endotoxemia in the horse initiates inflammatory and metabolic cascades that can lead to pulmonary injury. Activation of these pathways produces vasoactive and chemoattractant molecules that increase vascular permeability, activate complement, produce proinflammatory cytokines, and release neutrophil enzymes that can adversely affect the lungs of horses. Horses as a species are quite sensitive to the negative effects of endotoxemia, and their lungs are particularly sensitive, perhaps because of the presence of intravascular macrophages, which further amplify the inflammatory cascade. Both ALI and ARDS have recently been defined for veterinary patients.

VetBooks.ir

Pathophysiology Interstitial pneumonia progresses through four phases. During the first, the initial insult causes parenchymal injury and alveolitis. This is followed by a proliferative phase characterized by cellular and parenchymal alterations in tissues of the lung. Chronic cases progress to the development of interstitial fibrosis, and the final stage results in end-stage irreparable fibrosis of the lung.

The structural changes that occur in the lung reduce the number of functional alveoli, adversely affecting ventilatory function of the lung and altering ventilation-perfusion relationships. Reduced lung compliance is associated with the loss of distensible alveoli, the presence of pulmonary edema, and fibrosis. Total and vital lung capacities are decreased in association with the loss of functional gas exchange units and reduced lung compliance. The work of breathing is increased, resulting in exercise intolerance and difficulty in breathing. Pulmonary hypertension and cor pulmonale may be complications of severe chronic interstitial pneumonia and fibrosis. Although the origin of pulmonary hypertension is unclear, hypoxic vasoconstriction and generation of vasoactive compounds (such as endothelin-1) that alter pulmonary vascular resistance acutely, and vessel anatomy chronically, may play a role.

Clinical Signs Horses affected with interstitial pneumonia frequently have fever, cough, weight loss, nasal discharge, exercise intolerance, severe dyspnea, cyanosis, and a restrictive breathing pattern. A "heave line" is frequently present; nostril flare and an anxious expression are usual. The history can be acute or chronic. Although affected foals are frequently depressed and anorectic, adults may be bright and alert with a variable appetite. The disease proceeds toward death in many cases, with progressive respiratory compromise, although some patients may also slowly improve with time. More than one foal at a farm may be affected.

Diagnosis In older horses the primary differential diagnosis of heaves may be excluded by the leukocytosis and hyperfibrinogenemia that commonly occur in horses with interstitial pneumonia and fibrosis but do not occur in horses with heaves. However, these abnormal features are common in horses with infectious bronchopneumonia, and thoracic radiography is of paramount importance in the establishment of a definitive diagnosis. Typically, thoracic radiographs reveal extensive interstitial and bronchointerstitial pulmonary patterns.[11] Nodular infiltrates may be present, either large or miliary, but always diffusely distributed.

Culture of transtracheal or BAL aspirates often yields no significant growth of bacterial or fungal pathogens. Cytologic evaluation of tracheal or BALF shows increased numbers of neutrophils and macrophages. If *P. carinii* is involved, BALF may reveal trophozoites or intracystic bodies with special stains, such as toluidine blue or methenamine silver. Using PCR, EHV-5 has been found in BALF from horses with EMPF.

Histologic examination of a transthoracic lung tissue biopsy specimen is the definitive diagnostic test for chronic interstitial pneumonia and fibrosis and for EMPF. Care must be taken to ensure the tissue biopsy is obtained from a representative area, and ultrasound guidance can be useful. Clinically important complications from this technique are uncommon but can occur. Biopsy can both define the causative agent and confirm the clinical diagnosis in EMPF when the sample is evaluated for EHV-5.

Additional diagnostic procedures could include arterial blood gas analysis, abdominocentesis and thoracocentesis to rule out metastatic neoplastic disease, PFT, viral isolation, serologic testing for antibody to fungi and chicken serum if hypersensitivity pneumonitis is suspected, and immunohistochemical evaluation of lung tissue for suspected infectious agents. A complete cardiac evaluation should also be conducted, as pulmonary hypertension and cor pulmonale are not uncommon sequelae.

Treatment Treatment of these cases is often unrewarding. Therapeutic goals are treatment of any underlying or secondary infection; suppression of inflammation; maintenance of tissue oxygen delivery within appropriate limits; relief of any associated bronchoconstriction; and prevention or treatment of complications. Environmental control, with appropriate temperature and humidity control and good ventilation, is beneficial.

Parenteral corticosteroid therapy is the mainstay of treatment, with early and aggressive therapy providing the best long-term outcome, particularly in foals. In one report of 23 foals affected with acute bronchointerstitial pneumonia, 9 of 10 treated with corticosteroids survived, but none of those not receiving steroid treatment lived.

Broad-spectrum antimicrobial treatment should be instituted initially, particularly in foals, as described for the treatment of infectious bronchopneumonia. The choice of antimicrobial agent and duration of therapy should be dictated by the culture and sensitivity results from the transtracheal aspirate (TTA) and by the patient's clinical course. Anecdotally, horses with EMPF have responded to treatment with acyclovir and corticosteroids. The course of therapy is generally prolonged (6 to 12 weeks); clinical and radiographic improvement has been noted in a few cases to date.

Foals, in particular, and adults with severe respiratory distress may benefit from nasal insufflation of humidified oxygen, with flow rates of 10 L/min for foals and 15 L/min in adults. If necessary, as determined by persistent hypoxemia in the face of intranasal insufflation at the rates given, a second nasal cannula can be placed in the opposite nostril to increase the FiO_2. Care must be taken to avoid obstruction of the nasal passages. Alternatively, intratracheal or transtracheal insufflation can be considered to further increase FiO_2 and improve oxygenation.

Systemic bronchodilator therapy may or may not be indicated in these cases. If used, bronchodilators may worsen ventilation-perfusion inequalities. Therefore bronchodilator therapy should be accompanied by supplemental oxygen, and the effects should be monitored with serial blood gas measurements and discontinued if hypoxemia worsens. Nebulized or aerosolized bronchodilator therapy may be more judicious, and beneficial effects are evident in some foals with respiratory distress. Aminophylline and theophylline should not be used, owing to their narrow therapeutic range. Furosemide may be appropriate for its bronchodilator effect and its effect on reducing pulmonary artery pressure, particularly if cor pulmonale develops.

Prognosis The prognosis for horses with interstitial pneumonia is uniformly poor to guarded. Affected foals, treated early and aggressively with corticosteroid and antimicrobial therapy, have the best outlook for life. The disease is usually progressive in adults and eventually results in the demise of the horse, although the occasional horse recovers sufficiently to return to previous performance levels. A fair number of adult horses, with continuous intense management, will live for a period of time but will be severely compromised, which limits their usefulness. Exceptions to the poor prognosis may be seen in cases of *P. carinii* pneumonia in foals if they are treated early and aggressively and possibly also in cases of idiopathic interstitial pneumonia or EMPF in adult horses that are treated early with corticosteroids and antiviral drugs. A trial of treatment for peracute interstitial disease for 48 hours is warranted, and patients with chronic interstitial pneumonia should be treated for a minimum of 6 weeks before the possibility of recovery is discarded.

Equine Respiratory Viruses

Gabriele A. Landolt

Viral respiratory infections in horses are major causes of respiratory disease resulting in impaired pulmonary function and reduced performance. Although vaccines are available for many of the causative agents, the respiratory viruses have remained a major concern in the horse industry. Infection with equine respiratory viruses can lead to serious respiratory illness with potentially fatal consequences. The incidence and severity of viral respiratory disease varies from year

VetBooks.ir

to year and is dependent on the attack rate, virulence of the circulating virus, infectious dose, management and environmental conditions, and the degree of immunity of individual animals in the population.

With the exception of Hendra virus infection, in a group of susceptible horses, equine viral respiratory infection generally is characterized by the rapid spread of an acute, febrile respiratory disease accompanied by a dry cough and nasal discharge. Therefore a presumptive diagnosis of viral respiratory disease can often be made based on history and clinical signs. However, to confirm and differentiate among the potential causative agents, laboratory diagnosis is required.

Diagnosis of Equine Respiratory Viruses

The basic approaches for the laboratory diagnosis of equine viral respiratory disease are the isolation of the causative agent (virus isolation), demonstration of the virus or viral product in clinical specimens (detection of virus particles by electron microscopy; detection of viral antigens by immunofluorescence, enzyme-linked immunosorbent assay [ELISA], or immunoperoxidase; detection of the viral genome), and the detection of virus-specific antibodies (serology). Because each of these methods has its merits as well as disadvantages (e.g., lack of sensitivity, long turnaround time, high costs), it may be necessary to combine several of them to identify the causative agent accurately and rapidly. The World Organization for Animal Health (OIE, http://www.oie.int) publishes the *Manual of Diagnostic Tests and Vaccines for Terrestrial Animals,* which provides an in-depth review of current diagnostic testing strategies.

VIRUS ISOLATION. Virus isolation from clinical samples is crucial for epidemiologic investigation and for vaccine production and generally is carried out in cell culture. The notable exception is equine influenza virus for which embryonated chicken eggs have remained the culture system of choice. As virus shedding in secretions of the respiratory tract is greatest within the first few days after infection, the best results for virus isolation are often achieved by culturing nasal or nasopharyngeal swab samples collected in the first 24 to 48 hours after onset of clinical disease. As the duration of nasal virus shedding is often brief in partially immune animals, it may prove useful to sample immunologically less protected individuals in a group (e.g., younger horses, poorly vaccinated or unvaccinated animals) to increase the likelihood of demonstrating infectious virus. Nasopharyngeal or nasal swab samples are best collected using polyester-tipped swabs instead of cotton swabs because certain viruses (e.g., influenza A virus) have been found to adhere to the cotton fibers. The swabs should be placed in a sterile viral transport medium and kept on ice until further analysis.

ANTIGEN DETECTION. The most important advantages of diagnostic tests aimed at the detection of viral antigen over traditional virus isolation are the faster turnaround time as well as the ability to detect virions that have lost their infectivity. Immunofluorescence (fluorescent antibody [FA] test) is based on the detection of virus-infected cells employing virus-specific fluorochrome-labeled antibodies. The technique is used to detect viral antigen in a broad range of clinical samples (e.g., frozen sections of tissues, tissue imprints, cells obtained from nasal scrapings or tracheal washes) and has been shown to be highly sensitive. A number of antigen-capture ELISA-based assays have been developed for the detection of equine respiratory viruses.[1-5] Frequently, a solid-phase system is used for virus detection. Specific antibody is first adsorbed to the surface of a microtiter plate, and the sample containing the suspected virus is then added. If the virus is present, it binds to the adsorbed antibody. After washing, specific enzyme-labeled antibodies are added. Detection of virus in the sample is achieved by addition of the enzyme substrate, which results in a color reaction. Commercially available ELISA-based test kits (e.g., Flu OIA assay [Biostar, Boulder, Colo.]; Directigen Flu-A assay [Becton Dickinson Microbiology Systems, Cockeysville, Md.]) have been validated for the rapid, stall-side detection of equine influenza virus. Many investigators found these commercial diagnostic kits to be highly specific and rapid, and their sensitivity approaches that of egg isolation.[6-10] Since the discovery of the polymerase chain reaction (PCR), the technique has found wide application in diagnostic laboratories. By choosing appropriate oligonucleotide primers, a selected region of the viral genome can be amplified. PCR-based assays are extremely sensitive and theoretically can detect a single copy of the target nucleic acid in a sample.[11-13] Because of the assay's high sensitivity, the greatest challenge facing the diagnostic application of PCR is the production of false-positive results. Nevertheless, PCR-based techniques offer a more sensitive tool for the diagnosis of equine respiratory viruses than conventional techniques such as culture or immunoassays. To increase the diagnostic capacity of PCR, multiplex PCR assays have been developed. By including more than one pair of primers in the reaction mixture, these assays are designed to simultaneously detect a panel of respiratory pathogens. For example, multiplex PCR assays designed to detect nucleic acid of influenza A and B viruses, respiratory syncytial virus, adenovirus, and parainfluenza virus have been developed for screening of human clinical samples.[14-17] In equine diagnostics, assays capable of simultaneously detecting and differentiating EHV-1 and EHV-4[18-20] as well as EHV-2 and EHV-5[21] have been published. More recently, real-time PCR-based assays have been used for the detection and quantification of equine respiratory pathogens.[22-24] By employing a target-specific fluorescent probe, real-time PCR-based assays eliminate the need to distinguish the target by PCR fragment size on electrophoresis or hybridization with probes post-PCR. The advantages of real-time PCR include high specificity, sensitivity, and a rapid turnaround time.

ANTIBODY DETECTION. Detection of virus-specific antibodies has been, and continues to be, a key tool in the diagnosis of equine viral respiratory disease. Detection of specific antibody can provide support that an animal has been exposed to a given antigen. Although this is often used as circumstantial evidence of infectious disease, a diagnosis of active infection requires the demonstration of at least a fourfold increase in antibody titers (seroconversion) in samples collected during acute infection and during convalescence. Therefore serology typically provides only retrospective information. Yet, as most serologic assays are fairly easy to perform, are cost-effective, and large numbers of samples can be collected and tested simultaneously, serologic testing is particularly useful for large-scale herd surveillance. Commonly used techniques for antibody detection include ELISA-based assays, virus neutralization tests, single radial hemolysis, complement fixation tests, and hemagglutination inhibition assays. Because of the inherent variability of immunoassays, paired samples always should be run by the same laboratory. Lastly, it is important to recognize that antibody is not always detected in the presence of active infection. The most common reason for a negative result despite infection is that insufficient time has passed between infection and measurement of an antibody response. Alternatively, immunocompromised horses may fail to produce a detectable antibody response despite active infection.

Treatment

The treatment of horses suffering from viral respiratory disease is primarily symptomatic. It is important to ensure that sick animals are kept in a clean, well-ventilated, and stress-free environment. Morbidity caused by pyrexia and myalgia may be reduced by administering NSAIDs. It is important to monitor affected horses for development of complications such as pneumonia and myocarditis, and animals exhibiting signs of respiratory disease beyond 10 days should be reevaluated to rule out secondary bacterial infections.

Antiviral drugs, such as amantadine, rimantadine, oseltamivir, and the chain-terminating nucleoside analogs (e.g., acyclovir, valacyclovir, valganciclovir) have been evaluated for prophylaxis and treatment of horses during outbreaks of equine influenza and EHV-1, respectively. Clinical trials with the influenza virus M2 ion channel blockers amantadine and rimantadine have shown that both drugs

VetBooks.ir

appear to be equally effective in reducing the severity and duration of clinical illness.[25,26] In addition, oral administration of rimantadine (30 mg/kg, q12h) was shown to reduce the virus load in nasal secretion, although the duration of nasal virus shedding was similar to that in the untreated controls.[25] However, the therapeutic and prophylactic benefits of M2 ion blocker antiviral therapy during outbreaks of equine influenza may be limited because of the potential for the rapid development of drug resistance. In vivo and in vitro studies have demonstrated that drug-resistant influenza virus mutants can develop as early as 1 day after start of treatment.[27] Subsequent isolation of the drug-resistant virus from susceptible contacts showing signs of clinical disease indicates that acquisition of drug resistance is not associated with attenuation of the virus.[28,29] Lastly, treatment of horses with amantadine has also been associated with adverse effects and poor oral bioavailability.[30] Oseltamivir, a neuraminidase inhibitor with demonstrated antiviral activity against equine influenza in vitro, was also found to reduce the magnitude of nasal virus shedding and severity of clinical signs in horses following experimental inoculation.[31] In addition, oseltamivir administration reduced the counts of *Streptococcus equi* subsp. *zooepidemicus* in bronchoalveolar fluid samples collected 7 days after influenza infection compared with the untreated controls.[31] Despite these findings, the use of antivirals during an equine influenza outbreak should be carefully deliberated, as their use can result in the development of antiviral resistance among influenza A viruses.[32-34] Hence, the indiscriminate use of these drugs can possibly reduce the effectiveness of treatment during an outbreak.

Acyclovir, valacyclovir, ganciclovir, valganciclovir, and other chain-terminating nucleoside analogs have been shown to be efficacious against various strains of abortigenic and neuropathogenic EHV-1 viruses in vitro.[35-38] Although there are no controlled studies reporting on the efficacy of acyclovir in the treatment and prevention of EHV-1 infection in horses, anecdotal reports suggest a potential benefit of acyclovir administration (10 mg/kg PO 5 times daily; 20 to 30 mg/kg PO 2 or 3 times daily) in horses with clinical signs of EHV-1 infection (e.g., EHM, neonatal infection).[39-41] Two studies evaluating the pharmacokinetics of a single oral dose of acyclovir in adult horses revealed that intragastric administration of the drug was associated with high variability in serum drug concentrations as well as poor oral bioavailability.[42] Studies examining the effectiveness of oral valacyclovir, a prodrug of acyclovir, in the treatment of horses infected with EHV-1 have demonstrated controversial results. While administration of valacyclovir (27 mg/kg q8h followed by 18 mg/kg q12h), either prior to experimental EHV-1 inoculation or at the onset of fever, reduced the severity of clinical signs in one study,[43] another study found no effect on clinical signs, nasal virus shedding, or viremia in ponies treated (40 mg/kg q8h) compared with the untreated control ponies.[44]

Equine Influenza Virus

Equine influenza is the most frequently diagnosed cause of viral respiratory disease in horses.[45,46] It is a highly infectious disease that affects horses, donkeys, mules, and zebras. Outbreaks of a disease resembling influenza have been reported as early as 1751; however, the causative agent was not isolated until 1956.[47,48]

Etiology Equine influenza viruses are members of the family Orthomyxoviridae, which contains enveloped viruses with segmented, single-stranded, negative-sense RNA genomes.[49] The Orthomyxoviridae comprise five genera; influenza A, B, and C viruses; thogotoviruses; and isaviruses.[49] Equine influenza viruses are influenza A viruses. In contrast to influenza B and C viruses, which appear to have a fairly narrow host range, influenza A viruses can infect a wide variety of species (e.g., horses, humans, wild and domestic birds, pigs, sea mammals, dogs, and cats). It has long been recognized that influenza A viruses exhibit partial restriction of their host range,[48] indicating that viruses from one host species occasionally can transmit to infect another host. Although horses have often been regarded as isolated or "dead-end" hosts for influenza,[48] events of recent years clearly indicate that the species barrier for viruses jumping either to or from horses is not absolute. For example, the severe influenza epidemic in horses occurring in 1989 in the Jilin and Heilongjiang provinces in the northeast region of the People's Republic of China was caused by a virus with avian-like genetic features, suggesting that the virus had spread directly to horses from birds.[50] Another, more recent example is the transmission of an equine-lineage H3N8 virus to dogs in the United States.[51]

Although the viral and host factors that determine the host range of influenza viruses, and the mechanisms by which species barriers are overcome, are not completely understood, a large body of research highlights the importance of the viral hemagglutinin (HA) glycoprotein in determining host specificity.[48,52,53] The HA serves as the viral receptor-binding protein and is embedded, along with the neuraminidase (NA) and the ion channel M2 protein, in a host cell–derived lipid envelope. Mediated by binding of the HA to sialic acid residues on the host cells, the virion envelope and the host cell membrane fuse. This interaction subsequently promotes the release of the viral genome into the cytoplasm of the host cell. The NA is responsible for the cleavage of the α-ketosidic linkage between a sialic acid molecule and an adjacent sugar D-galactose or D-galactosamine. Biologically, the NA facilitates the mobility of the influenza virus virion by assisting in the release of the budding virus particle from the host cells.[54,55] Both HA and NA are major surface antigens of the influenza virus virion. Partly because of the host immune pressure, these proteins can undergo substantial antigenic variation (antigenic drift), which allows the mutant viruses to escape neutralizing antibodies.

Based on antigenic properties of the HA and NA, influenza A viruses are divided into subtypes. To date, 17 HA subtypes (H1 to H17) and 10 NA subtypes (N1 to N10) have been described.[56] With the exception of one HA and one NA subtype, all other subtypes have been isolated from wild waterfowl.[56-59] In contrast, only a limited number of subtypes have been associated with infection of mammals. For example, in humans, only viruses of H1, H2, H3, N1, and N2 subtypes have circulated widely in the population,[48,60] and only H1, H3, N1, and N2 subtypes have been consistently isolated from pigs.[61-63] In horses, influenza infections have been caused mostly by viruses of H7N7 (A/equine/1) and H3N8 (A/equine/2) subtypes.[47,64,65] Although serologic evidence suggests that H7N7 viruses may still be circulating at low levels in the equine population of Central Asia[48] and Eastern Europe,[47,66] these viruses have not been isolated from horses since the late 1970s.[10,57,67] In contrast, despite intensive vaccination programs, equine H3N8 viruses continue to circulate in large parts of the world. Since the 1980s, a number of severe, widespread influenza outbreaks in horses have occurred in South Africa,[68] in India,[69] in the People's Republic of China,[50,70] and in the United Kingdom.[71] The causative agent of the South African outbreak was identified as an H3N8 virus, which was most likely introduced by importation of infected horses from the United States or Europe.[10,72] In 2007, an equine influenza outbreak occurred for the first time in Australia, a country previously considered to be free of the disease.[73] The outbreak was caused by an equine-lineage H3N8 virus that was thought to have been introduced by importation of influenza-infected horses from Japan.[73,74] Stringent control measures, consisting of movement restrictions and vaccinations, allowed for the eradication of the virus from the Australian horse population, and Australia regained its equine influenza–free status in December 2008.[75,76]

Since the early to mid 1980s, the equine H3N8 viruses have diverged into two distinct evolutionary lineages, Eurasian and American. Although the circulation of both lineages initially centered largely on their geographic origin,[77] introduction and apparent maintenance of American-lineage viruses in horses in Europe initially resulted in the co-circulation of both lineages in Europe. In contrast, only a few reports support sporadic infection of horses in North America with viruses originating in Europe.[78-80] Continued genetic divergence of the American-lineage viruses resulted in the formation of three antigenically distinct American-like sublineages (a South American lineage, a Kentucky lineage, and a Florida lineage)[80] with

VetBooks.ir

further evolution of the Florida sublineage into two antigenically distinct groups, referred to as Florida sublineage clades 1 and 2. Whereas clade 1 viruses circulate in North America and parts of Europe, clade 2 viruses have only been identified in Europe and parts of Asia. Despite the fact that the rate of genetic diversion of equine viruses is small compared with human and swine influenza viruses, this sustained genetic and antigenic evolution continues to have an impact in terms of immunization.

Epidemiology Experimentally, horses of all age groups are susceptible to infection.[81] However, whereas sporadic infection in foals has been described, there exists only one published report of a widespread influenza outbreak in foals less than 6 months of age.[82] The lower incidence of disease in young foals is most likely due to the presence of maternally derived antibodies. Influenza-specific serum antibody concentration is an accurate correlate to protection against infection and disease, and animals with high concentrations of homologous antibody are by and large protected against experimental challenge.[83,84] After natural infection, ponies were reported to be protected from infection for 8 months, with partial protection persisting for more than 1 year.[85] Although vaccination does not always provide full protection against clinical disease, immunization has reduced the frequency of influenza outbreaks and the frequency and severity of clinical signs when influenza occurs among vaccinated animals.[81,86,87]

Equine influenza outbreaks occur most often when susceptible animals are congregated and housed in close contact with each other (e.g., horse shows, racetracks, sale barns). Virus transmission is thought to occur through direct contact with infected animals, contact with virus-contaminated fomites (e.g., feed buckets, tack), or airborne droplets of respiratory tract secretions.[88] Depending on the prevailing environmental conditions (humidity, temperature, exposure to sunlight, etc.), the virus can remain infectious for days on contaminated surfaces.[89] Once the virus has been introduced into a group of immunologically naive animals, disease can spread rapidly (in a matter of hours to days). Such effective spread is enhanced by a short (≈2 days) incubation period, high concentrations of virus shed in nasal secretions, an explosive cough, as well as the practice of housing horses in confined spaces.[89] In partially immune animals, the spread of disease is often considerably slower and outbreaks may last as long as 3 to 4 weeks.[90] Following experimental infection, horses typically shed virus for 6 to 7 days.[91-94]

Pathogenesis Influenza A viruses replicate and induce pathologic changes throughout the entire respiratory tract with the most significant lesions typically occurring in the lower airways. After inhalation of the virus, the virion attaches to sialic acid receptors on the surface of the respiratory epithelial cell and enters the cell by receptor-mediated endocytosis. Following replication and release from the host cell, the virus spreads quickly throughout the respiratory tract. Largely through apoptosis,[95-97] influenza virus replication leads to cell death. The loss of the ciliated respiratory epithelium in the trachea and bronchial tree[98] results in the impairment of tracheal mucociliary clearance.[64,99,100] In addition, the disruption of the superficial layers of the respiratory epithelium allows opportunistic bacteria to invade the deeper tissues of both the upper and the lower respiratory tract. The combination of reduced airway clearance and erosion of the respiratory epithelium predisposed affected horses to the development of secondary bacterial complications such as bacterial bronchopneumonia.[98,101] In uncomplicated cases, regeneration of the respiratory epithelium begins about 3 to 5 days after onset of illness,[101] but resolution of the epithelial damage takes a minimum of 3 weeks.[100,102]

Clinical Presentation Clinical signs of influenza virus infection in horses are often seen 48 hours after exposure to the virus. In vaccinated animals, the disease is rarely fatal, but deaths have been reported during some epidemics, particularly in donkeys and, rarely, in neonatal foals.[47,103] The typical clinical presentation of equine influenza consists of pyrexia, anorexia, lethargy, nasal discharge, and cough. Pyrexia is often the first symptom present, with body temperatures peaking somewhere between 48 and 96 hours after infection. In some cases, a second peak of pyrexia may occur around 7 days after infection. Nasal discharge is typically serous in the first few days of illness but may become mucopurulent 72 to 96 hours after infection. Concurrently, a dry, hacking cough develops. Coughing tends to persist long after pyrexia and nasal discharge have resolved and may still be present 3 weeks postinfection. The majority of affected animals are anorexic during the initial pyrexia. Whereas uncomplicated cases of equine influenza can resolve within 7 to 14 days postinfection, complications of equine influenza can be severe and include secondary bacterial pneumonia, myositis, myocarditis, and limb edema.[65,99,100] It has also been speculated that influenza infection may predispose horses to the development of inflammatory airway disease (IAD), recurrent airway obstruction (RAO), and exercise-induced pulmonary hemorrhage (EIPH).[65,98,99] Furthermore, the effects of influenza virus infection can be significantly exacerbated by even moderate exercise.[104]

Hemogram abnormalities associated with equine influenza infection can include a moderate normocytic, normochromic anemia and a leukopenia, which may result from both neutropenia and lymphopenia. Monocytosis during early convalescence is a variable finding.

Control Vaccination against equine influenza virus infection remains the foundation of equine influenza control. Although a wide variety of vaccine formulations, including modified live and recombinant vaccines, are commercially available, inactivated vaccines remain the most common type of vaccine used. Many challenge studies have demonstrated the ability of inactivated vaccines to protect against homologous virus challenge.[83,84,105,106] However, the value of inactivated vaccines is critically dependent on the type of adjuvant, quality, quantity, and strain of virus used for vaccine preparation.[107]

Based on the finding that the H7N7 viruses have not been isolated from horses since the late 1970s,[67] the inclusion of A/equine/1 virus is no longer thought to be necessary for equine influenza vaccines. In the recent past, vaccine manufacturers were encouraged to include strains representative of both American and Eurasian H3N8 lineages. However, because there has been an absence of any isolation of Eurasian viruses in recent years, the 2010 OIE Expert Surveillance Panel on equine influenza vaccine composition recommended that there is no longer a need to include these viruses in vaccines. In contrast, with the divergence of the Florida sublineage viruses into two antigenically distinct clades, the 2010 OIE panel recommends that killed vaccines should include strains representative of Florida clades 1 and 2. As the sustained genetic evolution of the equine H3N8 viruses will likely continue to result in failure of killed vaccines in the future, inclusion of viral antigens representative of contemporary circulating viruses has to remain a priority.

Studies have demonstrated that an intranasal, cold-adapted, modified live virus vaccine (FluAvert I.N., Intervet, Millsboro, Del.) was able to confer protection for up to 12 months after a single administration. Despite this, only a 6-month claim is made on the product data sheet.[94,108] Although the vaccine contains only one modified life virus strain, which is based on the H3N8 A/Eq/KY/91 isolate, the vaccine appears to protect against both European and American lineage isolates.[109] Lastly, the recombinant canary pox vector-based vaccine (Proteq-Flu, Merial, Duluth, Ga.) has also shown excellent performance against recent influenza virus strains.[110]

Because of the presence of maternal antibodies, recommendations for vaccination generally state not to vaccinate foals less than 6 months of age.[111-113] For inactivated vaccines, initial vaccination should include three doses (even when the data sheet only recommends two initial doses). The timing of the first three doses is critical. As such, the recommended interval between the first and second dose is 3 to 4 weeks. The third dose should be administered when the antibody response to the second dose has waned, which is thought to occur at 3 to 4 months after the administration of the second dose.

VetBooks.ir

Regardless of the recommendations provided by the manufacturer, this vaccination regimen is preferred, and contemporary inactivated vaccines are likely to perform well if this approach is taken. Following the initial vaccination series, subsequent booster vaccinations should be given at 6-month intervals in high-risk populations. The modified live cold-adapted intranasal vaccine requires only a single initial dose, followed by booster doses at 6-month intervals. If a higher risk of infection is anticipated (e.g., horse show), booster doses may be administered, even to well-vaccinated horses, 1 to 2 weeks prior to potential exposure.

Equine Herpesviruses

Equine herpesvirus (EHV) infection is a common infection of equids throughout the world, with at least nine herpesviruses identified to date.[114,115] The most important equine herpesviruses are the Alphaherpesvirinae EHV-1 and EHV-4, which cause respiratory disease. EHV-1 commonly infects horses, donkeys, other equids, and occasionally infects domestic cattle, captive camelids, cervids, and zebras; EHV-4 is restricted to horses.[114] EHV-3, also a member of the subfamily Alphaherpesvirinae, is the cause of equine coital exanthema, a venereally transmitted disease characterized by superficial lesions on the epithelium of the external genitalia of mares and stallions. Both EHV-2 and EHV-5, which are members of the subfamily Gammaherpesvirinae, can be associated with respiratory disease, although their pathogenicity is still under investigation.[116] Recently, potential associations between EHV-5 infection and equine multinodular pulmonary fibrosis (EMPF), as well as equine lymphoma, have been suggested.[117-119] EHV-2 is distributed throughout the world and is a ubiquitous infection of the horse, which increasingly appears to be the case for EHV-5.[120-122]

Etiology

Both EHV-1 and EHV-4 are members of the Alphaherpesvirinae subfamily of herpesviruses, in the genus Varicellovirus. These two viruses have very similar antigenic, genetic, and pathogenetic characteristics, although they are quite distinct from the gammaherpesviruses EHV-2 and EHV-5.[114] Both viruses are easily inactivated by solvents, detergents, disinfectants, and other common veterinary means of decontamination, but in favorable environmental conditions they can persist for as long as a month and in refrigerated liquids for much longer.

EHV-1 and EHV-4 have a linear double-stranded DNA genome of 145 and 150 kbp encoding 79 and 80 open reading frames (ORFs), respectively,[123-124] which can code for 77 proteins. Amino acid homology of EHV-1 and EHV-4 is 55% to 96%.[123] The gene products of EHV-1 and EHV-4 are classified as immediate early, early, or late (which include the major glycoproteins).[125-129] In recent years, a single nucleotide polymorphism (N752/D752) in the EHV-1 ORF 30, encoding the catalytic subunit of the viral DNA polymerase, was suggested to be significantly associated with the neuropathogenic potential of EHV-1 strains.[130,131] The link between the substitution of asparagine (N) and aspartic acid (D) at position 752 and its neuropathogenic potential may be due to the higher magnitude and duration of viremia that was found after experimental infection of horses with virus carrying this mutation.[132] The discovery of this mutation and its association with neuropathogenic potential led to the development of PCR-based diagnostic assays that are able to detect strains carrying the N752D mutation. Despite this, it should be taken into consideration that infection with an EHV-1 strain encoding D at position 752 does not inevitably result in neurologic disease. Likewise, although D752 is present in the large majority of EHV-1 viruses causing neurologic disease, EHM has also been caused by strains with N at position 752.

Epidemiology

EHV-1 infection causes significant suffering in horses and extensive economic losses through frequent outbreaks of respiratory disease, abortion, neonatal foal death, equine herpesvirus myeloencephalopathy (EHM), and chorioretinopathy.[114] EHV-4 can cause respiratory disease outbreak but only sporadic cases of abortion rather than abortion storms. Infections caused by EHV-1 and EHV-4 are particularly common in young performance horses and frequently result in establishment of latent infection within the first weeks or months of life.[133] Establishment of latency with subsequent viral reactivation resulting in clinical disease and viral shedding during periods of stress is a characteristic of herpesviruses in general, including EHV-1 and EHV-4,[114] and makes elimination of these pathogens from the equine population a difficult if not impossible endeavor. Latency and reactivation are critical features of the epidemiology of EHV-1 and EHV-4 infections, allowing the virus to persist for lengthy periods and in all likelihood as a lifelong infection in the majority of previously infected horses before reactivating. Reactivation and subsequent nasal virus shedding can result in infection of newly susceptible horses and possibly in disease in the latently infected horse itself. Although the true prevalence of latent equine herpesvirus infection is unknown, as more sophisticated methods of detecting latent infection with EHV-1 and EHV-4 are developed,[134] the detectable prevalence of infection continues to rise with the implication that EHV-free horses are a very rare occurrence.

Pathogenesis

The pathogenesis of EHV-1 infection has been comprehensively reviewed.[114,135,136] Primary EHV-1 infection occurs at the respiratory epithelium, resulting in erosion of the upper respiratory mucosal surface and viral shedding for 4 to 7 days postinfection; shedding can occur for longer at lower levels, and possibly beyond 14 days. Cell-to-cell spread results in the presence of virus in respiratory tract lymph nodes within 12 to 24 hours postinfection. In contrast to EHV-4 infection, which is mostly limited to the respiratory tract, EHV-1 establishes a lymphocyte-associated viremia, which is responsible for the delivery of virus to the pregnant uterus and other tissues. Spread of virus from leukocytes to endothelial cells at these secondary sites results in vascular injury (vasculitis) with potential hemorrhage, thrombosis, and ischemic necrosis. Viremia can persist for up to 21 days and is a prerequisite for abortion, chorioretinopathy, and EHM. Moreover, there appears to be a positive correlation between the development of EHM and the magnitude as well as the duration of viremia.[137] Despite this, only a small percentage of horses with viremia develop EHM, indicating that the clinical outcome of infection in the individual animal is influenced by other factors (e.g., age, sex, breed, and virus strain).[131] In pregnant mares, EHV-1 infection can result in abortion subsequent to vasculitis of the small arteriolar branches of the glandular layer of the endometrium with subsequent thrombosis, microcotyledonary infarction, perivascular cuffing, and transplacental spread of virus.[114] Abortion typically occurs in the last 4 months of pregnancy but has been reported to occur as early as the second trimester. There are usually no signs of impending abortion, and the foal is typically expelled in the amniotic membrane having just died from asphyxia caused by placental separation. Some fetuses survive initially but then die as a result of respiratory failure due to infection of the lungs. EHV-1 myeloencephalopathy results from widespread vascular injury after damage to the vascular endothelium of the blood-brain barrier and thromboischemic necrosis in the spinal cord and the brain. It is possible that the immunopathologic response to EHV-1 infection of the vascular endothelium of the CNS may play a part in the etiology of the thromboischemic necrosis. EHV-1 chorioretinopathy is also caused by a vascular endotheliopathy with subsequent ischemic injury to the chorioretina, and it is characterized clinically by focal or multifocal "shotgun" lesions.[138] Although the incidence of ocular lesions has been reported to be over 50% following EHV-1 infection, most ocular infections remain subclinical.[138] Moreover, these lesions are typically not detectable in acute disease and take weeks following infection to become visible. Latency is established in the lymphoreticular system and/or in the trigeminal ganglion, and it remains unclear which tissue is more commonly the home of latent EHV-1 virus.[114,139,140] Reactivation of latent virus frequently results in reinfection of the upper respiratory tract and shedding of virus in nasal secretions.

Immunity to EHV-1 and EHV-4 has been extensively reviewed.[141] The protective immune response following infection is short lived

VetBooks.ir

(3 to 6 months), although this may increase with age and repeated exposure. High titers of virus-neutralizing (VN) antibody before infection can reduce the amount and duration of virus shed from the nasopharynx[142] but fail to prevent infection or the development of EHM or abortion.[141] The reason for this failure is likely to be related to the rapid intracellular translocation of the virus,[143,144] thereby escaping the effects of VN antibody. However, intracellular virus is susceptible to cytotoxic T lymphocytes (CTLs), which can lyse virus-infected cells. This CTL activity is MHC class I restricted and mediated by CD8+ lymphocytes.[145] Ponies with high frequencies of CD8+ CTLs show a reduction in the clinical and virologic outcome of infection[146] and are protected against abortion.[147] Control of EHV-1 infection requires an immune response that not only limits primary infection but also controls reactivation of latent infections.[141] While circulating and mucosal antibodies each play some role in protection,[142,148] the most important component of a protective immune response to EHV-1 is the CTL response.[147,149,150]

Another important aspect of EHV-1 pathogenesis and immunity is the capacity of the virus to evade the immune response.[151] Strategies of immunoevasion employed by EHV-1 virus include modulation of cytokine responses with subsequent effects on T- and B-cell responses, interference with antigen presentation by downregulation of MHC-1 expression, alteration of NK-cell lysis, and loss of efficient chemoattraction of professional antigen-presenting cells.[152-155]

Clinical Presentation Clinical diseases associated with EHV-1 and, to a lesser extent, EHV-4 infection include respiratory disease, abortion, EHM, chorioretinopathy, and neonatal foal death. Infection with both EHV-1 and EHV-4 causes respiratory signs, but clinical signs are likely more severe for EHV-1, as is the likelihood of viremia. Clinical signs of EHV-1 and EHV-4 respiratory tract infection include pyrexia, which may be biphasic, with a first peak at 24 to 48 hours associated with upper respiratory tract infection and a second peak occurring at 4 to 8 days if viremia develops. Lethargy and anorexia are often mild, and nasal discharge, serous at first, becomes mucopurulent by days 5 to 7. Conjunctivitis, lymphoadenopathy of the submandibular lymph nodes, and edema or vasculitis of the distal limbs are variable findings. Respiratory disease, particularly affecting a large number of animals, is uncommon in horses over 2 years of age, presumably because of recurrent exposure to the virus and development of sufficient immunity to suppress clinical signs of airway disease.

Neonatal foals infected with EHV-1 in utero may be normal at birth, but they quickly become weak and lethargic and develop profound respiratory distress. Prognosis is poor for survival. The abortion and EHM forms of EHV-1 are discussed elsewhere under the appropriate system.

The clinical signs resulting from infection with EHV-2 and EHV-5 remain poorly described and established, although these viruses may be a cause of acute respiratory tract disease with clinical signs of nasal discharge, reactive submandibular lymph nodes, and coughing.[116,156] There is mounting support of a potential association between EHV-5 infection and equine multinodular pulmonary fibrosis (EMPF). However, despite findings of EHV-5 in pulmonary macrophages within the fibrotic portions of the lungs of horses suffering from EMPF, the exact nature of the relationship between the virus and the disease has not yet been elucidated.[117,118,157-159]

Prevention Because of the ability of the equine herpesviruses to establish latency within their host, the elimination of these pathogens from the equine population is not a feasible approach to infection control. Therefore strategies must be used that prevent dissemination of the virus from horses with active infection. Vaccines are an attractive tool for this, but currently there are no products that can provide comprehensive protection against equine herpesvirus infection and its potential sequelae. Inactivated EHV-1 vaccines are capable of eliciting circulating VN antibody responses, which can limit respiratory disease and nasal viral shedding, and the use of some of these vaccines has been associated with a reduction in the incidence of abortion storms.[141,142,160] Vaccines containing higher antigen loads, and typically those licensed for control of abortion, can generate high-titered VN antibody responses and even EHV-1–specific IFN-γ responses.[160] Such vaccines are likely to outperform other inactivated products with lower antigen loads. The one commercially available modified live EHV-1 vaccine (MLV) generates limited EHV-specific cellular immunity[161] and has been demonstrated to reduce respiratory disease and viral shedding.[162] The use of current commercial vaccines of proven efficacy is recommended at 6-month intervals for control of respiratory disease and shedding of EHV-1 and EHV-4. Generally, vaccines effective against EHV-1 will cross-protect against EHV-4. There is no evidence that any commercial or experimental vaccine can prevent the occurrence of EHM.

No attempts are made to control infection caused by EHV-2 or EHV-5 with vaccination. However, the proposal that concurrent EHV-2 infection may play a role in the etiology of *Rhodococcus equi* pneumonia has led some clinicians to attempt vaccination of foals with killed EHV-2 vaccines.[163]

Biosecurity measures following detection of outbreaks of EHV-1 and EHV-4 infection should include the use of strict hygiene and barrier precautions as well as isolation of affected and in-contact horses for periods of up to 28 days. The virus is thought to spread primarily through contact, with limited airborne droplet spread compared with equine influenza virus. Extensive codes of practice have been described for control of the spread of EHV-1 in facilities, both in publications[114] and in online resources (http://www.hblb.org.uk; http://www.aaep.org).

Equine Arteritis Virus

Equine viral arteritis (EVA), named after the characteristic inflammatory changes found in the walls of small arteries, is a contagious disease of horses caused by equine arteritis virus (EAV).[164] Although EVA is a disease with worldwide distribution, the seroprevalence varies substantially between countries and equine populations. Despite the fact that the vast majority of EAV infections are subclinical, occasional outbreaks occur that result in respiratory disease in adult horses, abortion, and fatal pneumonia in foals. These disease outbreaks have significant costs in terms of animal suffering and economic loss. Recent examples of larger scale outbreaks with substantial impacts on animal health and economic losses include a multistate EAV outbreak in 2006/07 in the United States as well as a 2007 disease outbreak in the Normandy region of France.[165-167]

Etiology EAV is an enveloped positive-strand RNA virus and is a member of the family Arteriviridae, order Nidovirales.[168] The Arteriviridae currently comprise four members: EAV, porcine reproductive and respiratory syndrome virus (PRRSV), lactate dehydrogenase-elevating virus (LDV) of mice, and simian hemorrhagic fever virus (SHFV). The polycistronic genome of EAV is approximately 12.7 kb and contains 10 known functional ORFs.[169-171] ORF1a and ORF1b encode two replicase polyproteins that are post-translationally processed by three proteinases to produce at least 13 nonstructural proteins. The remaining eight ORFs encode eight structural proteins, two (M and GP5) of which serve as the major viral envelope proteins. The GP5 envelope glycoprotein carries the major neutralization determinants of the virus and four neutralization sites (A through D) have been identified.[172] Based on phylogenetic analyses of the EAV-ORF5, the viruses are divided into two distinct clades: a North American clade and a European clade that share approximately 85% nucleotide identity.[173,174] Only one serotype has been identified, which is the Bucyrus strain isolated during the 1953 disease outbreak of abortion and respiratory disease in Standardbreds that first led to the definition of EVA as a clinical viral disease of horses and the identification of EAV as the causative agent.[164] Despite the fact that there is only one serotype, there are extensive variations in virulence of different isolates of the virus. Although the molecular determinants of EAV virulence have not been fully elucidated, recent data suggest that amino acid

VetBooks.ir

substitutions in the replicase and/or the structural proteins (GP2, GP4, GP5, and M) result in attenuation of a virulent strain of EAV.[175] The virus is readily inactivated by lipid solvents and disinfectants, although it can survive for years at subfreezing temperatures.

Epidemiology EAV is spread by the respiratory and venereal routes, and the persistently infected carrier stallion is central to the persistence of the virus in the horse population.[164] As a consequence, disease outbreaks frequently follow the importation of carrier stallions or their semen. With the increasing internationalization of the horse industry, this has been become an important factor in the spread of the virus throughout the world in recent years and highlights the fact that identification of the carrier stallion is a key component of EVA control programs.[165,176]

Following infection, a variable percentage (30% to 70%) of stallions infected can become carriers and shed the virus for months to years in their semen. The virus persists primarily in the ampulla of the vas deferens, and the carrier state has been shown to be testosterone dependent, as castration resolves infection.[176] In addition, some carrier stallions may also spontaneously eliminate the virus from their reproductive tract. During replication of the virus in the carrier stallion, genetically and phenotypically distinct variants of the virus can emerge and these variants can be found subsequently in the semen of these stallions.[166,177,178] When one of these variants is transmitted to a mare through breeding, or occasionally through contaminated fomites, a new outbreak can occur.[164] Transmission by the venereal route is associated with infection rates in mares as high as 85% to100%, and disease outbreaks often result from breeding a seronegative mare with EAV-containing semen.[168] Subsequent spread of the virus to other horses on the premises is by respiratory droplets and the airway route.[168] During these outbreaks the EAV strain remains stable with minimal genetic change.[164] Seroprevalence varies among breeds and between countries and geographic regions, with a reported seroprevalence of up to 85% of Standardbreds but less than 5% of Thoroughbreds in the United States.[179] Because there is no variation in breed susceptibility to EVA, this difference is probably a consequence of the number of actively shedding carrier stallions in different breeds. The virulence of strains in specific breeds can vary, however, and the strains shed by Standardbreds are typically highly attenuated, causing minimal disease.[164] Recent research suggests a correlation between the host's genotype (i.e., CD3(+) T-cell susceptibility to EAV infection) and the clinical outcome of infection, including the potential to become a carrier of the virus.[180-182]

The immune response to infection is strong, leading to protective immunity with a duration of several years.[168] Foals born to immunized mares are protected by colostral antibodies for 2 to 6 months.

Pathogenesis Virus transmission occurs by both venereal and respiratory routes. After respiratory infection the virus invades the respiratory epithelium and infects bronchial and alveolar macrophages, reaching bronchial and other regional lymph nodes by 48 hours postinfection.[168] The establishment of viremia then leads to dissemination of the virus throughout the body and further replication of the virus in the adrenals, thyroid, liver, and testes. Following infection, virus can be detected in the buffy coat for 2 to 21 days and in the plasma and serum for 7 to 9 days. The virus infects and replicates in endothelial cells, causing direct injury to the vascular endothelium and adjacent muscularis media, and subsequently gains access to the media of affected vessels. Vasculitis is characterized by fibrinoid necrosis of small muscular arteries, leukocyte infiltration, and perivascular hemorrhage and edema. With the exception of the carrier stallion, virus is eliminated by 28 days postinfection, although reports have been made of the virus being recovered for up to 180 days postinfection from the accessory sex glands of prepubertal colts.[168,183,184]

Clinical Presentation The great majority of infected horses are asymptomatic. When disease does occur, the clinical signs of EVA infection can vary from fever and leukopenia to severe disease and death. In general, the severity of EVA tends to be greater in very young and old horses. The incubation period is 2 to 14 days (6 to 8 days following venereal exposure). Horses may show some of the following signs. Typically the affected animals are pyrexic, with temperatures reaching 40.5° C (105° F) for 1 to 5 days. Anorexia, lethargy, serous nasal and ocular discharge, and coughing may occur. Conjunctivitis ("pinkeye") with ocular discharge and periorbital as well as supraorbital edema; dependent edema of the limbs, prepuce, scrotum, and mammary glands; and urticaria, localized to the sides of the neck and face or generalized, have also been reported.[168]

In stallions, acute infection can cause short-term subfertility characterized by reduced libido, decreased sperm motility, decreased sperm concentration, and abnormal sperm morphology. These changes in semen quality are transient but can persist for up to 16 weeks.[165] In contrast, persistent infection does not appear to have an effect on sperm quality in carrier stallions.[165]

Abortions in pregnant mares occur in the acute or early convalescent phases of infection and are often not preceded by premonitory signs. Abortion can occur from 2 to 10 months of gestation, with abortion rates from 10% to 70%. Comingling of pregnant mares with mares recently bred by an infected stallion is a common scenario leading to abortion.

Neonatal foals infected with EVA show severe respiratory signs and a high mortality rate. In foals that survive more than 24 hours, fever and leukopenia or thrombocytopenia are present. Interstitial pneumonia, lymphocytic arteritis or periarteritis, renal tubular necrosis, and fibrinoid necrosis of the tunica media are seen on pathologic examination.[164]

Prevention EVA control programs should be directed at eliminating the risk of abortion and neonatal foal death and establishing carrier status in stallions. The prevention of the development of carrier status in future stallions can be accomplished through vaccination of all colts with breeding potential in the first year of life and annual revaccination thereafter.[168] If carrier status has been identified, these stallions should be managed separately and under strict hygiene protocols to prevent spread of virus to naive in-contact animals.[165,176] Mares being bred to carrier stallions should be vaccinated against EVA. Fresh and frozen semen from carrier stallions is also infective, and EVA-negative mares receiving this semen should be vaccinated. Extensive codes of practice have been produced by both the U.S. Department of Agriculture (USDA; http://www.aphis.usda.gov) and the Horserace Betting Levy Board (http://www.hblb.org.uk) to assist in control of EVA. Moreover, guidelines for vaccination of horses against EAV have been established by the American Association of Equine Practitioners (AAEP; http://www.aaep.org).

Both a modified live and a killed vaccine against EVA have been developed.[164,168] In the United States, the modified live virus (MLV) vaccine has been available since the mid-1980s. The vaccine was derived from an experimental vaccine that had been created by serial passage of the virulent Bucyrus strain in primary horse kidney and primary RK cells. The MLV vaccine provides complete or partial protection against the clinical signs of EVA, but viral replication still occurs after challenge. The duration of vaccinal protection appears to be as long as 2 years, although annual revaccination of breeding stallions is recommended before the start of the breeding season. The MLV vaccine has been used successfully to limit outbreaks of infection in racehorses after initial diagnosis.[168] The manufacturer does not recommend the use of this vaccine in pregnant mares, and vaccination of pregnant mares during the last 2 months of gestation has been associated with the risk of abortion.[185]

Equine Rhinitis Virus

Etiology Equine rhinitis viruses (formerly equine rhinoviruses) are a known cause of clinical and subclinical respiratory infections in horses worldwide. The viruses are classified as members of

VetBooks.ir

the family Picornaviridae, which includes small ("pico"), nonenveloped, single-stranded RNA viruses. Among the equine rhinitis viruses, at least two serotypes have been isolated from horses: equine rhinitis A virus (ERAV; formerly equine rhinovirus 1 [ERV-1]) and equine rhinitis B virus (ERBV; formerly equine rhinovirus 2 [ERV-2]).[186,187]

Considerable uncertainty has surrounded the classification of the equine rhinitis viruses. As the illness caused by these viruses resembles the common cold brought about by rhinoviruses in humans, they initially were included in the genus *Rhinovirus*. However, subsequent studies demonstrated that ERAV differed from other members of the *Rhinovirus* genus as well as from ERBV.[187-190] For example, whereas rhinoviruses generally demonstrate a narrow host-cell range in vitro and in vivo, ERAV can infect and replicate in a broad range of cell types and host species. For instance, intranasal inoculation of a human volunteer with ERAV resulted in pharyngitis, lymphadenitis, fever, and viremia.[191] Furthermore, the presence of systemic signs and viremia during ERAV infection, the occurrence of persistent infections, and the physical properties of the virus are all more reminiscent of foot-and-mouth-disease virus (FMDV). Based on these characteristics, along with similarities in protein sequences, ERAV was placed alongside FMDV in the *Aphthovirus* genus of the Picornavirus family. Subsequently, ERBV has been reclassified as the sole member of the new genus *Erbovirus*. To date there are three known serotypes of ERBV: ERBV1, ERBV2, and ERBV3 (acid-stable equine picornavirus).

Epidemiology First isolated from horses in the United Kingdom,[192] ERAV infection occurs worldwide and is a recognized cause of acute respiratory disease.[186,193-195] The incidence of neutralizing antibody to ERAV varies according to the age of the horse, and most horses appear to become infected during their second year of life. In a study by Studdert and Gleeson, only 16% of horses between the age of 6 and 12 months were seropositive.[189] However, studies conducted in older horses found that a high percentage (50% to 90%) of horses 5 years of age have antibodies to equine rhinitis virus.[193,196-198] As is the case with many other respiratory pathogens, young horses entering a large population in frequent contact with other horses are most susceptible to infection.[194] In addition, there appears to be a seasonal distribution with most of the ERAV infections occurring in late winter and spring.[199,200] Stress (e.g., transportation and training) and concurrent disease resulting in immunosuppression may predispose to infection.[201] The virus is fairly resistant to inactivation and is thought to survive in the environment for a considerable amount of time. The spread of human rhinoviruses occurs most likely through direct and indirect contact (fomites).[202]

The clinical significance of ERBV-1, ERBV-2, and ERBV-3 is not well defined. Several recent surveillance studies indicate that the prevalence of ERBV-1 and ERBV-2 neutralizing antibodies is between 24% and 80% of horses.[156,197,198,203] However, the consequence of infection with ERBV-1 and ERBV-2 are unclear, as these viruses have been isolated from horses with and without signs of acute respiratory illness.[197,204,205]

Clinical Presentation Although ERAV is generally considered a respiratory pathogen, the clinical signs associated with infection may be quite variable. Following experimental infection with ERAV, horses may develop pyrexia, anorexia, nasal discharge, pharyngitis, and lymphadenitis involving at least the submandibular and pharyngeal lymph nodes.[206] On rare occasions, laryngitis or mild bronchitis can develop.[196] Based on serologic studies, subclinical ERAV infection may also occur and may be important in the dissemination of the disease.[189,199,202,206,207]

An important distinction of ERAV, compared with other members of the genus *Rhinovirus* (e.g., human or bovine rhinoviruses), is the finding that horses infected with ERAV may develop viremia. On average, viremia lasts 4 to 5 days, and the disappearance of virus from the blood coincides with the appearance of neutralizing antibodies.[206] Although the relationship between antibody levels and protection against disease has not been established, immunity is thought to be solid and antibodies persist for a long time.[202]

Infection with ERAV may be accompanied by long-term urinary and fecal shedding as well as virus persistence.[206,208] The recognition of the potential for ERAV persistence has important implications for disease diagnosis. Highly sensitive diagnostic methods (e.g., immunofluorescent antibody [IFA] or RT-PCR) may be able to detect persistent ERAV in horses suffering from respiratory disease, which may not be associated with the observed illness. This notion is underlined by the recent finding that the ERAV genome was detected by RT-PCR in nasopharyngeal swab samples obtained from two clinically healthy horses 1 year after acute ERAV infection.[187]

Control There is currently no vaccine available to control ERAV infection. As the capsid protein VP1 participates directly in viral receptor binding[209] and is a major surface antigen, it could serve as a potential target for vaccines.

Equine Adenovirus

Etiology Adenoviruses (family Adenoviridae) comprise a group of nonenveloped, icosahedral DNA viruses. Whereas most vertebrate species harbor an adenovirus, the viruses are highly species specific. In humans, adenoviruses are extremely prevalent and represent a significant cause of acute respiratory, ocular, and gastrointestinal disease. Infections of immunocompetent individuals usually stay localized and often take a mild or subclinical course.[210] Similarly, equine adenoviruses have been isolated from clinically healthy adult horses[211] and foals.[212,213] Equine adenovirus 1 (EAdV-1) has been implicated as the cause of acute respiratory tract disease[214,215] and conjunctivitis, as well as a progressive, fatal pneumonia in Arabian foals with severe combined immunodeficiency (SCID).[216-218] A second serotype, equine adenovirus 2 (EAdV-2) has been incriminated as a cause of intestinal infection[219,220] and diarrhea in immunocompetent foals.[221,222]

Epidemiology First isolated in 1969 from a foal with respiratory disease,[223] equine adenoviruses have a worldwide distribution.[224,225] Although serologic evidence from Australia, the United Kingdom, the United States, the Netherlands, and Nigeria indicates that adenovirus infection occurs at a high frequency in the general horse population,[225-228] the role of equine adenovirus in respiratory disease in adult horses remains unclear. In this regard it is interesting that a number of studies found no apparent association between clinically apparent respiratory disease in young adult horses and infection with adenovirus, as diagnosed by subsequent seroconverison.[205,207,229]

In contrast, fatal and nonfatal adenovirus pneumonia has been well documented in foals, particularly of the Arabian breed. Fatal respiratory disease is seen predominantly in foals with SCID. Other foals may develop respiratory disease but usually do not succumb to disease.

In general, adenovirus transmission is thought to occur via direct contact with secretions from infected animals or indirect contact via fomites or infected premises. In adult horses, the virus can persist in the upper respiratory tract, and these animals can act as a reservoir host for the virus. Adenoviruses are highly stable and have been found to remain infectious at 4° C for up to 1 year.

Clinical Presentation The clinical signs recorded after experimental intranasal infection of a Thoroughbred yearling were confined to a serous nasal discharge that lasted from 4 to 12 days postinoculation. Peak levels of serum antibodies were found at 13 days after inoculation and dropped by approximately 2 months after experimental infection.[230]

In foals, clinical signs generally occur between 10 and 35 days of age.[231] After experimental inoculation at 24 hours of age, clinical signs appeared 3 to 5 days after infection and consisted of intermittent pyrexia, nasal and ocular discharge, tachypnea, and cough. All

VetBooks.ir

foals recovered by day 10 postinoculation. The majority of foals developed a mild and transient lymphopenia that was followed by lymphocytosis. Typically, about 25% of infected foals also develop diarrhea.[231] Gross pulmonary lesions found in animals euthanized at 14 to 21 days postinoculation included atelectasis, involving up to 25% of the pulmonary parenchyma, and suppurative bronchopneumonia. Histologically, swelling and hyperplasia of the airway epithelium, as well as intranuclear inclusion bodies in the respiratory epithelial cells, were a consistent finding up to 11 days postinfection.[232]

Foals with SCID show a progressive decline in health despite intensive therapy. In necropsy, conjunctivitis, rhinitis, tracheitis, and bronchopneumonia are present. Intranuclear inclusion bodies are readily demonstrated in the respiratory epithelial cells. Areas of interstitial pneumonia surround affected bronchi. Acute pancreatitis characterized by inclusion bodies in acinus and ductal cells, as well as adenoviral sialoadenitis involving labial and parotid salivary gland, can often be demonstrated.[220,233]

Control No vaccine is available to control adenovirus infection in horses. However, except in immunocompromised animals, the virus appears to be of little clinical importance.

Hendra Virus

In August 1994, two horses died suddenly on a property in Mackay, Queensland, Australia. Ten days after the death of the second horse, the owner of the animals was admitted to the hospital with meningitis. One month after the incident in Mackay, 13 horses housed at a stable in Hendra, Queensland, died or were euthanized because of severe respiratory illness. Subsequently, the trainer and one of the stable workers developed an influenza-like illness, to which the trainer succumbed 6 days later. Although exotic to Australia, potential diagnoses included African horse sickness and equine influenza. Yet, during postmortem examination, a novel paramyxo-like virus was isolated from tissues of the affected horses and the trainer.[234] The virus, first referred to as *equine morbillivirus,* was subsequently named *Hendra virus* (HeV). Sporadic HeV infections of horses, and occasionally of humans, have since been reported in Queensland and northern New South Wales in Australia. Since 2006 there has been a marked increase in the frequency of equine HeV infections, with an unprecedented rise of equine cases occurring in 2011.[235,236]

Etiology HeV is a member of the genus *Henipavirus* (that also contains Nipah virus) within the Paramyxoviridae virus family. Paramyxoviruses, like orthomyxoviruses (see equine influenza), are enveloped viruses that contain a negative-sense, single-stranded RNA genome. HeV has unique morphologic characteristics that are useful for diagnostic purposes.[237] Electron microscopy reveals a pleomorphic enveloped particle, which contains a helical nucleocapsid that is characteristic for paramyxoviruses. The envelope is covered with spikes of 10 and 18 nm length, which gives the particle a unique "double-fringed" appearance.[238] Due to the fact that HeV contains a host-cell–derived lipid envelope, inactivation of the virus is possible using compounds that disrupt the lipid envelope (e.g., Lysol, sodium dodecyl sulfate [SDS], acetone, methanol).[239]

Epidemiology HeV can cause natural disease in humans and horses[234] and experimentally induced disease in cats, guinea pigs, and mice.[240,241] The virus infects pteropid bats (fruit bats or flying foxes). These bats are considered to be the reservoir host of HeV, and infection of these animals with virus does not seem to cause clinical disease.[242,243] However, experimental infection of flying foxes results in the appearance of virus in blood, saliva, urine, feces, as well as in fetal tissues and fetal membranes.[244] Transmission of virus between bats has been thought to occur within the roost by exposure of naive animals to virus-contaminated urine or feces.[245] The mode of transmission of HeV from bats to horses (the spillover host) is unknown. Whereas the virus transmits readily between bats, it does not appear to spread easily between horses or from horses to humans. Horse-to-horse transmission has been observed to occur during two disease outbreaks and was most likely due to direct contact with virus-contaminated urine, saliva, and blood or nasal secretions or contaminated fomites.[240] Despite these findings, horse-to-horse transmission in the experimental setting has not been documented to date.[246] Transmission of the virus from horses to humans has been recognized but appears to occur in only rare instances.[245] To date, seven human HeV infections have been reported, all of which were associated with close contact with infected horses.[234,247,248] In contrast, direct bat-to-human or human-to-human transmission of HeV has not been reported.[247]

Despite the fact that intermammalian transmission of HeV appears to be relatively rare, the virus has the potential to cause lethal zoonotic infection and poses a serious public health and occupational safety risk for veterinarians.[249]

Pathogenesis Experimentally, horses can be infected following parenteral and oronasal challenge.[234,246] Infection is characterized by the systemic distribution of the agent. After experimental infection of horses and cats, the virus was isolated from the buccal cavity, blood, brain, spleen, lungs, bronchial lymph nodes, kidneys, and urine.[240,241,246] Based on the finding that the virus is shed in the urine of experimentally infected animals, it has been speculated that consumption of food contaminated with the urine of infected horses may serve as a method of transmission under natural conditions. However, although the virus was present in the urine of horses that had died of natural HeV infection, investigators failed to recover HeV from the floor of the stalls where the animals had been housed.[246]

Clinical Presentation In horses, HeV infection is characterized by an acute, febrile respiratory illness that is sometimes accompanied by facial swelling, ataxia, head pressing, and recumbency.[250] Experimentally, the incubation period is 6 to 12 days. Frothy nasal discharge and tachycardia are considered to be indicators of imminent death. The course of disease in infected horses is short, with animals dying within 36 hours after onset of clinical signs. On necropsy, the most significant lesions are the severely congested, firm, and fluid-filled lungs. In some cases, fibrin tags are present on the pleural surface. Histologically, HeV infection is associated with vasculitis and fibrinoid degeneration and necrosis in major organs such as the lungs, brain, spleen, lymph nodes, and kidneys.[250] Pulmonary lesions identified at necropsy include necrotizing alveolitis, proteinaceous alveolar edema, and hemorrhage. Possibly the most remarkable histologic finding is the presence of syncytial giant cells in the endothelium of pulmonary blood vessels.[250] If examined under the electron microscope, these giant cells contain cytoplasmic inclusion bodies with the characteristic nucleocapsid structure of paramyxoviruses.[239]

As only seven cases of human HeV infection have been reported, the disease syndrome associated with infection is not well defined. In six patients, infection was initially characterized by an influenza-like illness. Whereas two of these patients recovered clinically, the other four patients succumbed after having developed more severe illness characterized by either encephalitis (three patients) or pneumonitis and multiorgan failure (one patient).[245,251,252] One patient developed fatal encephalitis without prior signs of influenza-like illness.[245]

Control Although a number of drugs (e.g., ribavirin, chloroquine) have been tested for their activities against HeV,[245,253] no approved antiviral drug is available to date. As horses appear to serve as an intermediate host in the transmission of HeV from bats to humans, an equine vaccine preventing virus replication and shedding would have the potential to protect horses and humans alike. Experimental testing of such a vaccine has been performed in mammals and has shown promising results.[254,255] To date, however, HeV control continues to be based on education, stringent infection-control measures, quarantine of infected premises, segregation of in-contact

horses, control of animal movement in defined zones, and serologic surveillance.

Equine Lungworm

Kara M. Lascola

The equine lungworm, the nematode *Dictyocaulus arnfieldi,* has a worldwide distribution particularly in temperate areas.[1] *D. arnfieldi* can infect all equid species with donkeys and mules considered to be the natural reservoir hosts.[1-3] Overt clinical disease associated with *D. arnfieldi* infection is typically not observed in reservoir species even in the face of prolonged patent infections or very high parasite burden.[1,2] In contrast, clinical signs of respiratory disease caused by *D. arnfieldi* infection are observed in horses and ponies.[1,4-6] The primary source of infection for horses is believed to be exposure to larvae that have developed from parasite eggs shed in feces by donkeys. Evidence for horse-to-horse transmission exists in cases of *D. arnfieldi* infection in horses with no known history of exposure to donkeys or other reservoir hosts.[1,4] Although less common than in donkeys, patent infections have also been identified in both adult and immature horses and ponies under natural and experimental conditions.[3-8] Under experimental conditions pony foals exposed to *D. arnfieldi* larvae shortly after birth more readily established patent infection compared with adults or foals exposed at an older age.[3] In addition, clinical signs of *D. arnfieldi* infection may be less common in pony foals infected when less than a year of age.[1,3,9]

Reported estimates of prevalence of *D. arnfieldi* from the 1980s and 1990s are 51% to 80%, 30%, and 2% to 11% for donkeys, mules, and horses, respectively.[1,3,4,6,10] In these studies considerable variability in prevalence was noted among horse farms surveyed and was attributed to differences in management or parasite control programs.[4,7] More recent estimates of prevalence have not been performed; however, it has been suggested that it has decreased, particularly in areas with effective anthelmintic administration.[11] The true prevalence of *D. arnfieldi* infection in horses and ponies is difficult to establish as infection is usually nonpatent.[6,8] A study of 488 Thoroughbred horses examined postmortem confirmed *D. arnfieldi* infection in 11% of horses with only 3% of horses demonstrating patent infection (documented via a modified Baermann technique).[7] These values are similar to estimates of prevalence based on patent infection in live horses from other studies[3,10] and are much lower than what has been observed in donkeys. A study of 5437 live equids revealed a prevalence of patent *D. arnfieldi* infection of 68% and 30% in donkeys and mules, respectively, compared with only 2% in horses and no infection in ponies.[4]

The direct life cycle of *D. arnfieldi* has been previously described and is thought to be similar to the life cycle of *Dictyocaulus viviparus,* the bovine lungworm.[8] L1 hatches almost immediately after eggs are passed in the feces, and the larvae undergo two molts before they enter a free-living, infective form (L3), which migrates to the surrounding vegetation. The development of L3 can occur in as little as 4 days. L3 has a limited survival time in the environment (49 days in warm soil) and cannot overwinter on pasture.[1] L3 that are ingested by the host penetrate the intestinal mucosa before passing to the mesenteric lymph nodes where they molt to L4. The L4 then travel via the lymph and blood to the lungs, where they migrate though the walls of the capillaries into the alveoli. The final molt from L4 to L5 occurs in the bronchioles, and maturation to the adult form occurs in the small bronchi.[1,6,8] Eggs are laid in the bronchi and then transported via mucociliary clearance to the pharynx where they are swallowed and eventually passed in the manure. The prepatent period of *D. arnfieldi* is 2 to 4 months.[1,8] In horses and ponies with nonpatent infection, larval development is arrested at the L5 stage.

Clinical disease has been documented as early as 12 days after infection in severe cases, but often it takes several weeks to develop.[1,6,12] Infected donkeys pass eggs throughout the year; however, fecal larval production increases through the spring and summer months and environmental conditions may favor larval development to the infective L3 stage during the summer in temperate climates.[1,5,12] As with *D. viviparus, Pilobolus* fungi may play a role in the dissemination of *D. arnfieldi* larvae from feces. L3 larvae travel to the fungal sporangia and are dispersed with the fungal spores when the sporangia rupture.[8,13]

The most common clinical signs attributed to *D. arnfieldi* infection in horses include cough, increased expiratory effort, tachypnea, audible wheezes and crackles on auscultation, and mucoid or mucopurulent nasal discharge.[3,5,6,10] Clinical signs described less frequently include dyspnea, paroxysmal cough, and abnormal tracheal auscultation.[5,10] Most reports of lungworm infection describe a chronic disease process of several weeks' duration[5,6,10]; however, acute onset of clinical signs is possible with severe infection or concomitant bacterial or viral respiratory disease. Although clinical disease is rare in donkeys, *D. arnfieldi* infection has been associated with increased susceptibility to respiratory viruses (e.g., influenza).[14]

A presumptive diagnosis of *D. arnfieldi* infection may be made in horses with clinical signs of nonpyrexic, chronic respiratory disease and a history of contact with donkeys once other causes of respiratory disease have been ruled out and if clinical signs resolve with appropriate anthelmintic treatment. In adult horses clinical signs of *D. arnfieldi* infection are similar to those observed in horses with recurrent airway obstruction. In young animals, similar clinical signs may be observed during transient migration of *Parascaris equorum*. Fecal examination using a modified Baermann technique frequently delivers false-negative results in horses but can be used to identify animals with patent infection and should be performed in suspect cases.

Endoscopic examination may reveal lymphoid hyperplasia and increased tracheal or bronchial exudate, but these signs are not specific for *D. arnfieldi* infection.[5,10] Examination of tracheobronchial fluid or bronchoalveolar lavage may reveal eosinophilia,[5,6,14] and *D. arnfieldi* larvae have been identified in respiratory secretions and in centrifuged tracheal mucus prior to fixing and staining.[5] Tracheobronchial aspirates and bronchoalveolar lavage fluid obtained from normal horses are expected to contain few (<3%) eosinophils[15,16]; however, eosinophilia has been identified in horses with no apparent respiratory disease[17] as well as in those with eosinophilic pulmonary disease,[14,18] inflammatory airway disease,[16,19] and during transient migration of *P. equorum*. Eosinophilia in respiratory secretions is therefore suggestive but not pathognomonic for *D. arnfieldi* infection. Repeat evaluation of respiratory secretions posttreatment should reveal a marked improvement in eosinophilia in lungworm cases.[5,20] Peripheral eosinophilia has not been definitively correlated with lungworm infection.[5,21] A definitive diagnosis can be made at necropsy by identifying larval or adult worms within the airways. A modified Baermann technique can be applied to diced lung tissue to aid in the identification of larvae.

Treatment for *D. arnfieldi* includes effective anthelmintic treatment, removal from contact with donkeys, and moving horses and ponies to a pasture not grazed by donkeys since the previous autumn. Moxidectin (0.4 mg/kg) and ivermectin (0.2 mg/kg) are active against larval and adult parasites and have been associated with 99.9% and 100% efficacy in donkeys and horses, respectively.[3,9,22] Mebendazole (15 to 20 mg/kg/day for 5 days) was effective in significantly reducing patent infection in donkeys.[23] Fenbendazole has been shown to improve clinical signs of presumed *D. arnfieldi* infection in horses; however, suppression of fecal shedding was maintained for less than 4 weeks with doses up to 30 mg/kg.[21] The pharmacokinetics and efficacy of pour-on eprinomectin against *D. arnfieldi* infection have recently been evaluated in donkeys.[24,25] Treatment of naturally infected donkeys with 0.5 mg/kg eprinomectin was found to be 100% effective in eliminating fecal larvae up to 28 days post administration.[24] Treatment of donkeys should be instituted to decrease transmission to horses and ponies and potentially to decrease the donkey's susceptibility to other respiratory diseases.[12]

Necropsy findings in donkeys and horses with *D. arnfieldi* infection are similar.[2,26] Gross findings include circumscribed areas of raised pulmonary tissue (3 to 5 cm), typically in the caudal lung

VetBooks.ir

VetBooks.ir

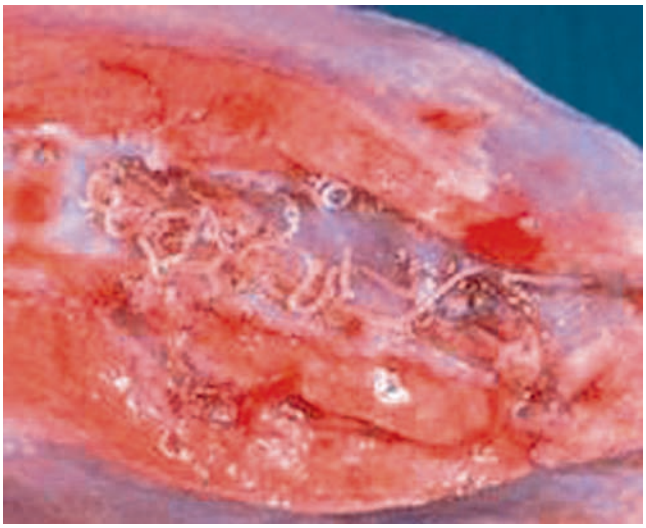

FIG. 31-36 Overinflated pulmonary tissue surrounding small bronchi that are packed with mature *Dictyocaulus arnfieldi*.

lobes. Section of these areas reveals overinflated pulmonary tissue surrounding small bronchi that are packed with mature *D. arnfieldi* nematodes (Fig. 31-36). Small airways in these areas tend to be occluded with exudate. Histologic examination of the pulmonary tissue reveals diffuse eosinophilia throughout the pulmonary tissues, especially around the airways. A marked inflammatory reaction is found around parasitized bronchi, with heavy lymphoid cell infiltration of the epithelium, lamina propria, and peribronchial tissue. The epithelium is often hyperplastic with an increase in size and number of mucus-secreting cells. Little cellular or mucoid reaction is seen in the bronchial lumen surrounding adult parasites; however, free larvae in the lumen result in an intense mucopurulent reaction. Bronchioles in affected areas of the lung usually show evidence of bronchiolitis with free mucus present in the lumen of bronchioles and hyperplastic, columnar epithelium. Bronchioles are most commonly surrounded by discrete lymphoid nodules. Pulmonary pathology in donkeys tends to be very localized, with much of the lung appearing normal on histologic examination.[2]

Prevention of *D. arnfieldi* infection in horses and ponies involves effective anthelmintic treatment and pasturing horses and ponies separately from donkeys, or treating donkeys with appropriate anthelmintic treatment to avoid patent infection. Anthelmintic treatment is especially important in the spring. Regular removal of manure from pasture can also help to decrease the parasite load in the environment.

Thoracic Trauma

Jane E. Axon • Pamela A. Wilkins

Thoracic trauma results from blunt or penetrating injuries to the chest wall, axillary, and pectoral regions. Trauma can result in thoracic wounds (penetrating and nonpenetrating), hemothorax, pneumothorax, pneumomediastinum, pleuritis, fistula of the sternum or ribs, fractured ribs, lameness, osteomyelitis, or diaphragmatic hernia, and a combination can occur in the same horse.[1-3] Prompt assessment and implementation of emergency procedures in injured horses presenting with respiratory distress is vital to optimize their chances of survival.

Clinical signs associated with injury to the thorax can vary from mild musculoskeletal pain and a stiff gait (lameness) to severe respiratory distress and hypovolemic shock (pneumothorax, hemothorax, diaphragmatic hernia). Signs of respiratory distress include anxiety, tachycardia, cyanotic mucous membranes, tachypnea, nostril flaring, and an altered respiratory pattern. Auscultation and percussion of the thorax may assist with locating and identifying the lesions. Percussion and palpation will need to be performed carefully in horses that are in pain and may reveal areas of tenderness, subcutaneous emphysema, and crepitus associated with fractures. Palpation of subcutaneous emphysema in the absence of an external wound may be associated with a lacerated lung or tracheal trauma and, in a dyspneic horse, should raise the suspicion of a concurrent pneumothorax.[2-4] Injured horses may also show signs of weak pulses, pale mucous membranes, and tachycardia due to acute hemorrhage from lacerated intercostal or pulmonary parenchymal vessels. Evaluation of the abdomen should also be undertaken. On expiration the cranial portion of the diaphragm extends to the sixth rib; thus an abdominocentesis should be performed on a horse with a wound caudal to the sixth rib or with a deep penetrating wound to assess abdominal involvement.[1] Further evaluation of the injured horse will include thoracic radiographs, ultrasonographic examination, thorough exploration of the wound and, in cases of lameness, nuclear scintigraphic examination. Arterial blood gas analysis will assist in determining the extent of hypoventilation and hypoxemia.

FIG. 31-37 Emergency stabilization of a horse with an open thoracic wound and subsequent pneumothorax. Plastic wrap has been wrapped around the chest to prevent air entering the thoracic cavity. Air has been removed from the thoracic cavity and a Heimlich chest drainage valve has been attached to the dorsally placed chest tube. The horse is on intravenous fluids and intranasal oxygen.

Emergency stabilization may be required prior to a full evaluation of the horse. The aim is to stabilize the cardiovascular system, providing respiratory support, preventing further air entering the thorax, and, whenever possible, controlling hemorrhage. Sedatives and tranquillizers should be used judiciously as most cause respiratory depression, but they may have to be used if the horse's anxiety precludes instituting treatment. Open thoracic wounds should be covered immediately to prevent further air entering the chest cavity.[2-4] Plastic food wrap can be placed over the wound and around the thorax, or a gauze roll or towel can be used (Fig. 31-37). A tension pneumothorax, which may occur with sucking thoracic or axillary wounds, can be alleviated by inserting a trocar into the dorsal pleural space so that pleural and atmospheric pressures can equilibrate and result in a less compromising pneumothorax.[1,2] Intranasal oxygen therapy and removal of air from the thorax may be necessary to improve alveolar ventilation and oxygenation in the horse. Circulatory support may be necessary until hemorrhage has stabilized.[1-3] Analgesics, antiinflammatory therapy, broad-spectrum antimicrobial therapy, and tetanus prophylaxis may also need to be instituted.

VetBooks.ir

Hemothorax

Thoracic trauma, by causing lacerations to pleural or pulmonary vessels or rupture of large thoracic vessels, may result in hemothorax. Other causes of hemothorax include rupture of lung parenchymal bullae, vessel erosion by severe lung abscessation or neoplasia, hemangiosarcoma, spontaneous hemorrhage at maximal excursion, and coagulopathy.[5,6] Iatrogenic causes include tube thoracostomy and lung biopsy. Hemothorax has recently been reported as a complication of phenylephrine administration for treatment of left dorsal displacement of the large colon (nephrosplenic ligament entrapment) and should be suspected if the history is appropriate.[7] Hemothorax can be unilateral or bilateral depending on the cause and whether the mediastinum is complete.

Diagnosis is based on clinical signs, radiographic and ultrasonographic findings, and laboratory evaluation of fluid obtained from thoracocentesis.[2-5] Dyspnea and tachycardia may be present, depending on the volume of blood loss into the pleural cavity. On auscultation there is a decrease in audible breath sounds ventrally and heart sounds are often muffled and radiate over a wider area.[2-5] Percussion reveals a change from normal resonance of aerated lung to dullness over the hemothorax.[5] Thoracic radiographs show opacity of ventral lung fields with an associated horizontal fluid line and a loss of diaphragmatic and cardiac silhouettes.[2,3,8] Ultrasonography shows fluid within the pleural cavity with a characteristic hypoechoic to echogenic smoke swirling pattern.[2,9] Fluid collected by thoracocentesis should be submitted for cell count, packed cell volume, and total protein. A cytologic evaluation should also be performed to determine whether there is evidence of infection or neoplasia, and the sample should be cultured if an infection is suspected. A clotting profile and platelet count should be performed if a coagulopathy is suspected. Hematology and biochemistry should also be performed as the horse may develop anemia and hypoproteinemia associated with the blood loss. Systemic antibiotics, tetanus prophylaxis, and NSAIDs are indicated in most cases.

Treatment is aimed at stabilizing the cardiopulmonary function and treating the underlying cause.[1-3] Horses with hemothorax from nonpenetrating thoracic trauma or noninfectious causes can be managed conservatively with intranasal oxygen insufflation, analgesics, intravenous fluids, or whole blood transfusion if the blood loss is severe. If the horse is not hypoxemic or in respiratory distress, rest alone and close monitoring may suffice. Even if respiratory distress is evident, a tube thoracostomy and drainage of blood may not be necessary.[2,6] Drainage of the thorax is not recommended in horses with a coagulopathy unless severe respiratory distress is present.[6] If there is a penetrating wound or evidence of infection, drainage should be attempted by ultrasound-guided ventral placement of chest drains. This, however, should not be undertaken until the hemorrhage has stopped and circulating blood volume has been restored.[2,10] All horses, even without evidence of infection, should have broad-spectrum antimicrobial coverage, as blood is an excellent medium for bacterial growth.[2,5]

The prognosis for horses with uncomplicated trauma and hemothorax is good. If the hemothorax is the result of a penetrating wound, the prognosis is poor.[2,3]

Pneumothorax

Traumatic causes of pneumothorax include puncture or laceration of the trachea, ruptured esophagus, penetration of foreign objects into the thoracic cavity, external wounds resulting in subcutaneous emphysema and pneumomediastinum, or direct penetrating or blunt trauma to the lung parenchyma.[2,3,12-14] Pleuropneumonia also causes pneumothorax; in one study, 17 of 40 horses had pneumothorax resulting from pleuropneumonia.[11] Air can escape into the pleural cavity through slow leaks from necrotic lung or through formation of bronchopleural fistulas. Additional causes of pneumothorax include ruptured emphysematous lung bullae, maximal exercise, and iatrogenic causes such as tube thoracostomy, lung biopsy, mechanical ventilation, and transtracheal aspiration.[5,6]

Pneumothorax can be described as closed, in which air from the lung is trapped in the pleural space, or open, in which there is free communication between the pleural space and external environment and air is sucked into the pleural space with inspiration.[14] Tension pneumothorax occurs when air accumulates in the thorax until intrapleural pressure exceeds atmospheric pressure. This is usually seen with a sucking pleurocutaneous wound as air moves into the chest cavity with inspiration and, because of a valve effect of the wound, cannot escape during expiration.[2-4] Intrapleural pressure may increase to an extent that the thorax becomes fixed in maximal extension. This leads to severe cardiopulmonary effects, thoracic tamponade, with decreased venous return to the heart from vena cava compression and consequent hypoxemia.[15] Pneumothorax is usually bilateral because of the incomplete mediastinum of horses; however, it may be unilateral if the fenestrations in the mediastinum are blocked as a result of inflammation or collapsed lung.

Diagnosis is based on clinical signs, aspiration of air from the pleural cavity, and radiographic and ultrasonographic findings.[2-4] Clinical signs that can be associated with pneumothorax are dyspnea, tachypnea, cyanosis, and evidence of trauma. Characteristic findings on auscultation are a decrease or lack of audible breath sounds dorsally and tympany and hyperresonance on percussion; however, these clinical signs can vary and are not reliable.[11] Concurrent subcutaneous emphysema may complicate interpretation. However, if a horse with subcutaneous emphysema is dyspneic or distressed, pneumothorax should be suspected, unless the emphysema is causing airway compression.[5] Thoracic radiographs show lack of pulmonary vasculature in the dorsal aspect of the caudal lung fields and ventral displacement of the dorsal lung margin (Fig. 31-38, *A*). On

ultrasonographic examination there are parallel horizontal lines of air artifact reverberation without the pattern of pleura and "comet tail" artifacts. The dorsal air image also moves ventrally with inspiration over underlying collapsed lung or pleural fluid, creating a "curtain" image.[9] Subcutaneous emphysema in tissue and fascial planes may prevent accurate sonographic imaging. Aspiration of air from the thorax is also diagnostic, as is the associated improvement in clinical signs (see Fig. 31-38, *B*).

Treatment is aimed at improving alveolar ventilation by correcting the pneumothorax, if the horse is showing signs of respiratory distress, and treating the underlying cause. Treatment of simple pneumothorax requires rest and close observation while gradual reabsorption of air occurs. If hypoxemia (Pa_{O_2} < 80 mm Hg, percentage oxygen saturation [$\%O_2$sat] < 90%) or dyspnea is present, nasal insufflation of oxygen (5 to 15 L/min) should be administered.[2,3,10] Open sucking wounds should be occluded. Air is removed from the pleural space by inserting a teat cannula or thoracostomy tube into the dorsal thoracic cavity in or near the twelfth intercostal space and attaching a suction device. If a suction machine is not available, repeated aspiration can be accomplished with a 60-mL syringe through a three-way stopcock valve and/or tubing attached to the teat cannula and run into a container of water.[2,4] The latter acts as a simple water trap allowing air to be expelled during inspiration while preventing air movement back into the chest with expiration. If the pneumothorax reoccurs or continues, tubes should be left in place to allow constant air removal. A Heimlich chest drainage valve (Bard Parker, Division of Becton-Dickinson, Rutherford, N.J.) provides continual drainage and, if correctly placed, is effective for long periods. In long-standing cases, gradual reexpansion of the lungs is recommended to avoid reexpansion pulmonary edema.[5] Prophylactic broad-spectrum antimicrobial therapy is recommended as long as the tube is in place. If the cause of pneumothorax requires correction under general anesthesia, ventilation should be improved prior to induction by removing air from the pleural cavity and correcting lung atelectasis.

The prognosis for horses with pneumothorax is good, providing infection can be successfully treated and air leaks are sealed. Pneumothorax associated with pleuropneumonia and parenchymal lesions resulting in air leakage carry a poor prognosis; esophageal rupture and penetrating thoracic trauma carry a poorer prognosis.[3,5,11]

Pneumomediastinum

Pneumomediastinum can result from physical trauma with direct penetration into the region from wounds to the axilla, caudal neck, or thorax. Extensive subcutaneous emphysema that often occurs with large wounds to the axilla region may also result in air tracking into the mediastinum, and potentially into the thoracic cavity. Pneumomediastinum has also been reported with tracheal rupture, perforation of the thoracic esophagus, and pulmonary bulla formation.[2] No clinical signs may be evident unless the horse develops complications such as pneumothorax or infection. Diagnosis is based on classic radiographic findings of visualization of the esophagus, greater vessels, and outer margin of the trachea.[2] Treatment is aimed at treating the primary cause and monitoring for complications.

Rib Fractures

Fractured ribs are most often a result of an accident, fall, or kick. In neonates fractured ribs are commonly associated with birth trauma.

ADULTS. Fractured ribs can be detected on physical examination either through exploration of the wound or eliciting pain on palpation over the affected area, although not all fractures will be discovered in this manner. Crepitus associated with a closed fracture is often not detected. Shallow breaths and guarded thoracic movements may be seen as a result of pain from the fracture; however, these signs may also be indicative of complications such as hemothorax, pneumothorax, or pleuropneumonia. Soft-tissue swelling and subcutaneous emphysema may also be present. Ultrasonographic examination of the cortical surface of the rib is a sensitive method of detecting fractures and enables evaluation of the pleural cavity, underlying lung parenchyma, and the surrounding soft tissue. Fractured ribs in adults usually heal without fixation; however, if there is pain and excessive movement of rib ends, surgical correction may be warranted. True flail chest (fractures at two points, dorsal and ventral of a rib or neighboring ribs, resulting in paradoxical movement of that section of ribs with breathing) requires some type of stabilization. Analgesic therapy (including opioids and nonsteroidal antiinflammatories), circumferential bandaging, and intercostal nerve blocks with a long-acting anesthetic along the caudal border of the rib provide some pain relief. Open fractures should be explored and débrided, and soft tissue should be repaired.[2-4] The horse should be closely monitored for respiratory distress or hemorrhage because a closed pneumothorax or hemothorax may result if a fractured rib end lacerates underlying lung parenchyma or vessels.[1] Lameness has been reported as the only consequence of rib injury in adult horses and thus thoracic trauma, particularly if there is an appropriate history, should be considered in some occult lameness cases.[16]

FOALS. Blunt thoracic trauma during parturition resulting in costochondral dislocation or rib fracture is more common in foals from primiparous mares and dystocias.[17] The majority of fractures are subclinical; however, sudden death, hemothorax, hemopericardium, lacerated myocardium, pneumothorax, diaphragmatic hernia, and severe respiratory distress can occur.[17,18] The incidence of fractured ribs in newborn foals on one farm was 21% (55 of 263) and none of the affected foals had clinical signs associated with the fracture after a 6-month period.[17] However, in other reports, rib fractures accounted for 13% of life-threatening fractures in foals less than 7 days of age, and 19 of 67 (28%) foals in a necropsy study with fractured ribs died as a direct result of rib fracture.[18,19] The most common site of injury is at the costochondral junction or adjacent dorsal area.[18] Clinical signs are variable and include pain on rib palpation; "clicking" or crepitation on auscultation; edema localized over, or ventral to, the fractured ribs; and signs of pain, including grunting or groaning when manipulated or lying on the affected side. Palpation of crepitus over the fractured site is not a consistent finding. If the foal is systemically stable, asymmetry of the thoracic cage can be evaluated if the foal is positioned in dorsal recumbency.[17] In severe cases involving multiple consecutive ribs, the foal can be in respiratory distress, particularly with true flail chest. Foals may also exhibit respiratory distress with pneumothorax, hemothorax, or diaphragmatic hernia. Pale mucous membranes can be indicative of internal hemorrhage and abdominal hemorrhage, and diaphragmatic hernia should be considered if the diaphragm has been lacerated. Radiographs for detection of fractured ribs in neonates is not reliable although visualization is improved if radiographs are taken using a horizontal beam with the foal in lateral recumbency, injured side up (author's experience).[18,20] Ultrasonographic examination is more reliable and also assists in evaluating the adjacent structures and presence of hemothorax, pneumothorax, or diaphragmatic hernia (Fig. 31-39). Conservative treatment with box rest and supportive care is successful in the majority of uncomplicated rib fractures; however, surgical repair has been performed in cases with multiple rib fractures or those with potential for severe internal injury and is considered lifesaving in many cases.[20-22] Specific treatments based on the internal injuries should also be implemented.

Diaphragmatic Hernia

Diaphragmatic hernias occur sporadically in horses. Occurrence is usually associated with a history of trauma or sudden increase in abdominal pressure and exertion, as may be experienced by stallions during breeding or mares during parturition.[23-25] In one study, 48% of 50 horses diagnosed with diaphragmatic hernia had a history of recent trauma.[23] In some cases no history of injury or predisposing cause can be identified.[24] Congenital diaphragmatic hernia can occur as a result of incomplete fusion of any of the four embryonic components of the diaphragm or as a result of abdominal compression

during parturition.[26] A congenital peritoneopericardial hernia has been reported.[27] Congenital hernias are typically located in the ventral-most portion of the diaphragm, whereas diaphragmatic defects from trauma are usually located at the junction of muscular and tendinous portions of the diaphragm.[26] The size and position of the defect are important in determining whether herniation of abdominal viscera occurs.[24,25,28] Any segment of intestine can be involved, although the small intestine is the most frequent.[26]
