Equine Fluid Physiology

C. Langdon Fielding

Physiologic fluid compartments consist of total body water (TBW), extracellular fluid volume (ECFV), and intracellular fluid volume (ICFV). TBW is the most clearly defined compartment because it represents the total amount of water comprising an individual. Values for TBW in adult horses have been reported to range from 0.623 to 0.677 L/kg.[1-4] Values in foals are larger than adult horses and have been reported as 0.74 L/kg.[5] Acute changes in TBW in clinical patients can be detected with serial body weight measurements, but this becomes less accurate over longer periods of time.

ECFV represents the component of TBW that is not contained within the cells. This includes plasma volume, interstitial volume, and transcellular compartments (gastrointestinal tract, joint fluid, cerebrospinal fluid [CSF], body cavities, etc.). The ECFV has been measured using a number of techniques in horses; reported values in adult horses range from 0.214 ± 0.01 to 0.253 ± 0.01 L/kg.[1,6] Estimations of ECFV in foals are significantly larger, including 0.38 to 0.40 L/kg in newborn foals and 0.290 L/kg in foals 24 weeks of age.[5,7] Plasma volume has been determined to be 0.050 L/kg in healthy adult horses and 0.090 in foals at 2 days of age.[5,7]

ICFV is the volume of fluid contained within cells. It has been estimated as the difference between TBW and ECFV. Bioimpedance technology has also been used to estimate the volume of intracellular space in horses, whereas standard indicator dilution techniques cannot be easily applied to the ICFV.[1,2] Reported values for ICFV in adult horses range between 0.356 ± 0.01 and 0.458 ± 0.06 L/kg.[1,2] The ICFV of newborn foals is estimated to be 0.38 L/kg.[5]

Rapid changes in fluid balance and compartment volumes can occur during disease states, especially critical illness. The next section discusses the physiologic relationships between these fluid volumes.

Plasma and Interstitial Balance

Although both the plasma volume and interstitial volume are components of the ECFV, the plasma volume is separated from the interstitial space by blood vessel walls, with constant flow of fluid and proteins into the interstitial space. The plasma and interstitial volume, therefore, are in constant flux, and a single equation (the Starling hypothesis) describes the flow between these two spaces:

$$\text{Net capillary filtration } K_f([P_{cap} - P_{if}] - \sigma[\pi_P - \pi_{if}])$$

where K_f is the capillary filtration coefficient, being dependent on capillary surface area and hydraulic conductivity. The other five terms in the equation represent the primary determinants of fluid balance between plasma and the interstitium:

1. π_p is the colloid osmotic pressure (COP) within the capillary (capillary oncotic pressure).

   COP is determined by the concentration of plasma proteins, primarily albumin, and their ability to attract ions. Normal COP in adult horses is approximately 20 mm Hg (19 to 26 mm Hg) and in neonatal foals is 18.8 ± 1.9 (15 to 22.6) mm Hg.[8,9] Hypoproteinemia with resultant decreased oncotic pressure can occur during a variety of diseases in horses but is most often a result of loss or decreased production. Losses most commonly occur through the diseased gastrointestinal tract in large animal species (protein-losing enteropathies); losses may also occur as a result of glomerular diseases or large accumulations of protein-rich effusions within body cavities or the interstitial space. Decreased production of protein (specifically albumin) occurs in response to systemic inflammation because albumin is a negative acute-phase protein.[10] Hypoproteinemia also occurs uncommonly because of liver disease.[11] Decreases in COP are also commonly observed during intravenous fluid therapy in horses undergoing general anesthesia.[12]
2. π_{if} is the COP within the interstitium.

   Interstitial COP is more difficult to measure than plasma COP, but estimates of this number include 12 to 15 mm Hg in other species under experimental conditions.[13] Changes in total plasma protein concentration are likely to also affect the interstitial protein concentration and therefore alter both oncotic pressure components in Starling's equation. This may explain why some horses with significant hypoproteinemia do not show clinical signs of interstitial fluid accumulation (i.e., edema). That is to say, the gradient between capillary and interstitial oncotic pressure is only minimally affected when both have decreased proportionally, especially with time. It has been speculated that acute changes in plasma total protein concentration, however, may lead to edema formation more often than chronic hypoproteinemia; this is because of a relatively larger decrease in plasma protein concentration as compared with that in the interstitium with acute disease. Conversely, administration of hyperoncotic intravenous fluids (fluids with a COP greater than 20 cm H_2O) can potentially shift the balance of oncotic pressure back to the vascular space by raising plasma COP. However, the colloid molecules from these fluids must remain within the vascular space to have this effect, which may be negated by significant alterations in capillary permeability.
3. P_{cap} is the hydrostatic pressure within the capillary.

   Vascular hydrostatic pressure represents the pressure of plasma within the vessels pushing out toward the interstitium. A number of factors influence this pressure, including blood volume, vascular tone, and central venous pressure (CVP). This outward pressure on the vessel walls serves as the driving pressure for the continuous flux of fluid and protein out of the vessels into the interstitium. Pathologic increases in hydrostatic pressure can be caused by right-sided heart failure or other obstructive processes, such as venous thromboses, which can lead to edema formation. Pulmonary capillary hydrostatic pressure increases with left-sided heart failure and significant pulmonary vasoconstriction. Administration of intravenous fluids can also increase capillary hydrostatic pressure. Fluid losses resulting from diuretic administration

VetBooks.ir

and acute blood loss are examples of changes that result in decreased capillary hydrostatic pressure.

4. P_{if} is the hydrostatic pressure within the interstitium.

   The hydrostatic pressure of the interstitium varies in different tissues but often is overlooked as a significant contributor to fluid balance between the vascular and interstitial spaces. The importance of the interstitial hydrostatic pressure as it pertains to fluid balance has been reviewed by Reed and Rubin.[13,14] Degeneration of the interstitial collagen network may cause a decrease in interstitial hydrostatic pressure, resulting in a shift of fluid into the interstitium. Inflammatory cytokines have been implicated as a cause for these changes in interstitial hydrostatic pressure. Severe burn injury can also result in marked negative pressures within the interstitium, causing a draw of fluid into the interstitial space and subsequent edema formation. In the future there may be practical therapeutic options to manipulate interstitial hydrostatic pressure and alter fluid balance.

5. σ is the capillary reflection coefficient for proteins.

   Changes in capillary permeability can dramatically increase the flux of fluid and protein from the intravascular space into the interstitium.[15] If this increase in flow cannot be balanced by a corresponding increase in lymphatic return, edema results. Increased vascular permeability has been regarded as a major mechanism of edema formation; however, it may be only one component of the significant fluid shift that results from a systemic inflammatory response syndrome (SIRS). Adult horses and neonatal foals may have significant differences in interstitial composition and vascular permeability. It has also been proposed that foals have an increased capillary filtration coefficient as compared with adults.[16] These hypotheses may explain the propensity of neonatal foals to form edema relatively easily in response to overzealous fluid administration. Because of this increased risk, careful monitoring and serial assessment of the balance between plasma volume and the interstitium are warranted when treating neonatal foals with fluid therapy.

Extracellular to Intracellular Fluid Volume Relationship

There are three main determinants of net movement of fluid between the ECFV and ICFV: tonicity of the ECFV, tonicity of the ICFV, and cellular membrane permeability.

TONICITY OF THE ECFV. The tonicity (or effective osmolality) of the ECFV is estimated by the following equation[17]:

$$\text{Effective extracellular fluid osmolality} = (2 \times \text{Na}) + \frac{\text{Glucose}}{18}$$

Under normal circumstances, sodium and chloride are the primary determinants of ECFV tonicity; the equation doubles the sodium concentration rather than including the concentration of specific anions, some of which may not be easily measured. It should be noted that BUN is not included in the tonicity formula, because BUN is an ineffective osmole. Other effective osmoles can be added to the ECFV, thereby increasing tonicity and inducing a shift of water from the ICFV to the ECFV. The tonicity of the ECFV is primarily regulated by vasopressin (ADH). Administration of fluids with a tonicity greater or less than ECFV tonicity is a means to manipulate the balance of fluid between the ECFV and ICFV. This explains why hypertonic saline causes a shift of water from the ICFV to the ECFV. Recent mathematic models have been used to predict the influence of tonicity on the absolute volumes of these fluid compartments.[18] Similarly, fluid loss that has a tonicity different from the ECFV will also alter the ratio of fluid between the ECFV and the ICFV.

TONICITY OF THE ICFV. The tonicity of the ICFV is primarily determined by the intracellular concentration of potassium and its related anions. The tonicity of the ICFV and ECFV are the same at any given time point, a homeostatic mechanism meant as a safeguard to prevent acute changes in cell volume. Any imbalance in tonicity between the two fluid spaces will result in a rapid shift of fluid in order to maintain osmolar equality. The tonicity of the ICFV can be altered over time by the cells in response to changes in ECFV tonicity; an example of such a response is the production of idiogenic osmoles during hypernatremia.[19] Significant changes to ICFV tonicity during disease (resulting from damaged cell membranes) can result in accumulation of intracellular potassium, calcium, or cellular debris.

CELLULAR MEMBRANE PERMEABILITY. Cell membranes are selectively permeable to water and ions. Changes in this permeability usually do not cause large alterations in global fluid balance during healthy states. However, cell membrane damage during disease states can result in significant fluid shifts. In fact, a shift of fluid from the ECFV to the ICFV is an indicator of cellular membrane damage.

Effects of Fluid Physiology on Clinical Fluid Therapy

Specific disease states dictate individualized fluid plans. However, with intravenous therapy the administered fluid enters the vascular space. From there, the characteristics of the administered fluid will determine its movement from the vascular space into the interstitium and from the ECFV to the ICFV. Hyperoncotic or hypertonic fluids result in the greatest relative expansion of plasma volume, with a corresponding reduction in ICFV. Hypotonic fluids result in the smallest increase in ECFV but add volume to the ICFV, owing to a decrease in the tonicity of the ECFV. Estimates of the volumes of the different fluid spaces (whether based on clinical or laboratory values) before and during fluid therapy will allow for evaluation of the physiologic response in the clinical setting. The standard and universal administration of isotonic and hypo-oncotic fluids (such as lactated Ringer solution [LRS] or physiologic saline) to all patients regardless of disease condition ignores the available research and clinical insight to suggest otherwise.

General Principles for Fluid Therapy in Critical Care

K. Gary Magdesian

Current guidelines for replacement fluid therapy in human critical care emphasize the "fluid challenge" method, believed to be more effective and safer than traditional estimates of percent dehydration.[1] The author's (KGM) protocol of fluid administration in horses follows this same algorithm. Considerations for the fluid challenge technique incorporate four primary decision phases: (1) type of fluid, (2) rate and volume, (3) goals or endpoints of fluid therapy, and (4) safety limits to fluid therapy.

1. Types of fluids include crystalloids (isotonic, hypotonic, and hypertonic) and natural and synthetic colloids. There is much controversy and no consensus as to whether crystalloids or colloids are more effective or advantageous in human critical care.[1] The advantages of both fluid types are capitalized on by using them together in the treatment of some cases of hypovolemia. Otherwise, because of cost differences and lack of demonstrated benefit of colloids as compared with crystalloids in terms of mortality for fluid resuscitation in critically ill human patients, the use of colloids cannot be recommended over crystalloids.[2] Recent publications have suggested increased mortality and complication rates in humans receiving hetastarch as compared to crystalloids. See page 1374, Fluid Therapy for Diarrhea and Colitis in Horses. Table 44-1 lists the composition of several commercially available crystalloids that are used in equine practice.
2. The rate of fluid therapy for replacement (i.e., treatment of hypovolemia) is based on the "fluid challenge" principles, whereby a 30-minute bolus of 10 to 20 mL of isotonic crystalloid per kilogram is administered with subsequent reassessment of perfusion parameters.[1] This challenge method assumes that uncontrolled

5% dextrose	0	0	0	0	0	252-253	0

hemorrhage is not present, because that would warrant hypotensive resuscitation instead. Perfusion parameters include mentation, heart rate, mucous membrane color, capillary refill time, jugular fill, extremity temperature (limbs, ears), and pulse quality. Blood or plasma lactate concentration, arterial blood pressure, urine output, and urine specific gravity are additional monitoring tools that aid in assessment for need of further fluid challenges. After the initial bolus, additional boluses—over 30 to 60 minutes depending on the degree of hypovolemia present—would be administered if perfusion parameters dictate. These are repeated until signs of shock abate, or a lack of improvement is noted with subsequent boluses, or fluid limits are reached (see later). Most animals require one to three of these boluses, and rarely are four required. Alternatively, or in addition to isotonic crystalloids, hypertonic saline (7% to 7.5%) can be administered at a rate of 4 to 5 mL/kg IV once. Plasma sodium concentration should be monitored. Colloids, because of their distribution that is limited to the central compartment, are bolused at lower volumes than isotonic crystalloids, such as 3 to 5 mL/kg for hetastarch. Up to 10 mL of hetastarch per kilogram may be administered per day, being limited by development of dose-dependent coagulopathies. If after reassessment of the perfusion parameters, additional resuscitative fluids are deemed necessary, another similar bolus is given, although each subsequent bolus is usually provided at a slightly slower rate unless the patient is markedly hypovolemic. This is repeated until signs of hypoperfusion resolve (endpoints are achieved) or safety limits are reached, at which point inotrope and/or vasopressor therapy is indicated if hypoperfusion persists.

3. The goals or endpoints of fluid therapy include both replacement and maintenance of fluid balance. *Replacement* refers to the replenishment of fluid deficits, primarily referring to those in the extracellular fluid compartment. *Maintenance fluid therapy* refers to the provision of maintenance fluid requirements to account for metabolism, insensible losses, growth, and ongoing losses. In general terms, *replacement* refers to replenishment of circulating volume and secondarily of interstitial fluid deficits; *maintenance* refers to provision of fluids after hypovolemia and dehydration have been corrected. Maintenance fluid therapy maintains both circulating volume and hydration status, including that of the intracellular compartment. In this section, replacement fluid is emphasized; the goals of replacement fluid therapy include rapid correction of hypovolemia by reversal of the signs of shock, including seven perfusion parameters: tachycardia (except in some neonatal foals), pale mucous membranes, prolonged capillary refill time, cold extremities, poor pulse quality, depressed mentation, and, in horses, reduced jugular fill. Urine production is another positive sign indicating correction of fluid deficits. Dehydration is corrected more slowly and is marked by reduced skin turgor (increased skin tent), dry mucous membranes, and dry corneal surface (reduced tear production). Additional goals of volume replacement include correction of hypotension, tachycardia, oliguria, and blood lactate.[1] A decrease in urine specific gravity (in the absence of renal failure), an increase in arterial blood pressure and CVP, and improvement in venous oxygen saturation are specific endpoints. The goals of maintenance fluid therapy are different; they are to maintain a normal degree of hydration by providing for ongoing losses, including insensible losses (respiratory, cutaneous evaporative losses) and any abnormal ongoing losses such as diarrhea. Maintenance fluid rates for horses vary with ambient temperature, use, diet, and metabolic status. In general, a reasonable starting point for maintenance fluid requirements includes 2 to 3 mL/kg/h for adult horses (possibly slightly lower if off feed) and 4 to 6 mL/kg/h for neonatal foals.[3,4]
4. The safety limits to fluid therapy are indicators of intravascular volume overload, including supranormal CVP, a decrease in arterial oxygen saturation (Pa_{O_2}), and clinical indicators of volume overload and overhydration. Once maximal CVP is achieved (10 to 12 cm H_2O in neonatal foals and 15 cm H_2O in adult horses), replacement bolus fluid therapy must stop; if continued, edema will form as systemic and capillary hydrostatic pressures increase in response to test boluses. A decrease in oxygen saturation in serial arterial blood samples, or in Sp_{O_2} measured with pulse oximetry, in a horse receiving fluid boluses may be consistent with development of pulmonary edema; this may precede development of tachypnea or frank edema in large airways/nostrils. Although no published reports address fluid overload in clinical equine patients, one experimental study evaluating hyperhydration before moderate-intensity exercise in horses suggested the development of arterial hypoxemia during exercise.[5] These animals were administered oral fluids equivalent to 6% of body weight (approximately 26 L of isotonic fluid by nasogastric tube). Hyperhydration resulted in arterial hypoxemia, suspected to be caused by pulmonary edema associated with hyperhydration, during moderate-intensity exercise.[5] Clinical indicators serving as limits to fluid therapy include visible subcutaneous edema and tachypnea; with optimal monitoring, fluid therapy will not be allowed to continue to this point. Another endpoint or limitation to fluid therapy is a lack of further improvement in perfusion parameters despite repeated fluid boluses. This would indicate that hypoperfusion is not solely due to hypovolemia and would require inotropes and/or pressor agents (e.g., dobutamine and norepinephrine, respectively). If safety limits are reached before

the goals of fluid therapy are achieved, the next step is also to turn to inotrope and vasopressor therapy.

See page 1374, Fluid Therapy for Diarrhea and Colitis in Horses.

VetBooks.ir

Critical Care and Fluid Therapy Monitoring Techniques

K. Gary Magdesian

Monitoring tools provide for advanced critical care in the large animal intensive care unit. Several of these tools are pertinent to fluid therapy and provide guidance, endpoints, and safety limits. Many of these allow for direct monitoring of fluid during administration of therapy, whereas others provide indirect information through hemodynamic data. Both of these are important to overall case management of the critically ill equine patient.

Central Venous Pressure

Central venous pressure (CVP) is the pressure within the vena cava; the term most commonly refers to that within the cranial vena cava. It is determined by blood volume as well as venous tone and cardiac contractility. With serial measurements CVP provides a limit to the administered volume of fluid. Normal CVP is approximately 2 to 12 cm H_2O (1.5 to 8.8 mm Hg) in foals and 5 to 15 cm H_2O (3.7 to 11 mm Hg) in adults.[1-4] Subnormal to negative CVP values signify hypovolemia; however, normal values do not necessarily imply euvolemia. This is because CVP is affected by compensatory responses such as venoconstriction, and is affected by cardiac contractility and intrapleural pressures among others.

CVP is easily measured in neonatal foals through the use of 20-cm central venous catheters, such as long-term single- to triple-lumen polyurethane catheters. Measurements can be obtained in adult horses with the use of 55-cm commercial CVP catheters. CVP can also be measured by passing a smaller gauge polyurethane catheter or polyethylene tubing through a 14-gauge, 5¼-inch standard intravenous catheter. CVP can be measured with a disposable water manometer (for spot readings) or using a pressure transducer for continuous waveforms. Interpretation of CVP waveforms requires knowledge of component waves and descents, including the a, c, and v waves and x and y descents. The a wave represents atrial contraction. The mean of the a wave is the appropriate point at which to measure CVP (at expiration). The c wave is associated with tricuspid valve closure and a bulging of the valve into the right atrium, and the v wave is caused by atrial filling from venous return. The x descent occurs after the a wave and represents the fall in pressure associated with atrial relaxation. The y descent occurs after the v wave, representing a drop in CVP caused by ventricular relaxation and reopening of the atrioventricular valves.

High CVP readings also occur with pericardial tamponade, pleural effusion, or pneumothorax, as well as false increases from catheter occlusion and air within the lines. For accurate and consistent serial results, a zero reference point should be selected and used for each measurement. The top of the sternal manubrium is a good reference point for the level of the pressure transducer or water manometer. The pressure transducer or water manometer can be taped to a fluid pole, providing a fixed zero point for repeated measurements in standing horses.

It should be noted that adequacy of intravascular volume cannot be guided by any one CVP level. Precision and reliability are limited by variable zero reference points, the effects of afterload and ventricular compliance, and alterations in intrathoracic pressure.[5] There is no linear relationship between intravascular volume and filling pressures, and CVP should be regarded as only an indirect estimate of volume. Serial measurements and trends over time are more useful than single numbers. CVP can be used on a clinical level for monitoring fluid therapy as follows: If the patient responds to fluid boluses without increases or with only minor increases (2 to 3 cm H_2O) in CVP, it is appropriate to continue infusions until signs of hypoperfusion are reversed.[5] Additional guidelines used in human patients are as follows: If the CVP increases to 3 to 7 cm H_2O (2 to 5 mm Hg), the infusion should be paused and perfusion reevaluated after a 10-minute wait. If the change in CVP was an increase of 7 cm H_2O (5 mm Hg) or greater after the fluid bolus, the infusion is stopped.[5] In this regard CVP is a better "upper limit" to fluid therapy rather than an actual goal to strive for, other than normalization in horses with low CVP values.

Arterial Blood Pressure

Arterial blood pressure measurements provide some insight into perfusion status, particularly when used in conjunction with clinical signs and lab work, such as blood lactate concentration. It can be measured either directly through the use of arterial catheters or indirectly with a blood pressure cuff on the tailhead. Arterial lines can be placed in the great metatarsal artery of recumbent foals and the transverse facial artery in standing adult animals for direct measurements. Indirect measurements are best performed with oscillometric blood pressure monitors that provide systolic, diastolic, and mean arterial pressure (MAP). Cuffs are provided by the manufacturer and vary in width and length with size of the patient.

Arterial blood pressure in healthy neonatal foals is highly variable and depends on breed, gestational age, and size of foal. In general, normal mean arterial blood pressure (direct) is 84.4 ± 3.7 mm Hg at 1 day of age and up to 101.3 ± 4.4 mm Hg at 14 days of age.[2] Indirect blood pressure readings in Thoroughbred foals has been reported as 144 ± 15, 74 ± 9, and 95 ± 13 mm Hg for systolic, diastolic, and mean pressures, respectively.[6] Direct blood pressure has been reported for adult horses: 126 to 168 (systolic)/85 to 116 (diastolic) with a range for the mean arterial pressure of 110 to 133 mm Hg.[7-10] Indirect blood pressure in adult horses is 111.8 ± 13.3 mm Hg for systolic pressure and 67.7 ± 13.8 mm Hg for diastolic pressure.[11]

Blood pressure values should not be regarded as the sole criteria for intervention. Rather, they should be used in conjunction with perfusion parameters, blood lactate concentration, and urine output in deciding whether there is need for further fluid administration or inotrope and vasopressor support. The exact blood pressure value that should trigger intervention in horses and foals is unknown and likely varies with the individual patient; however, end organ perfusion requires a mean arterial pressure of 60 mm Hg, thereby making that a reasonable general target.

Blood or Plasma Lactate Concentration

Blood or plasma lactate concentrations are very useful in monitoring fluid support as well as perfusion and metabolic status. Increased blood lactate concentration may be a result of hypoperfusion and reduced oxygen delivery (hypovolemia, hypotension, anemia, hypoxemia, heart failure). Other considerations for hyperlactatemia should include SIRS, sepsis, catecholamine surges, liver or renal failure, thiamine deficiency, alkalosis, hyperglycemia, exercise, seizure activity, and the action of drugs such as salicylates and theophylline.[12-15] SIRS may increase circulating lactate concentrations independent of perfusion status; inflammatory mediators and cytokines activate pyruvate dehydrogenase kinase, an inactivator of pyruvate dehydrogenase, resulting in reduced activity of the citric acid cycle. Normal lactate concentrations in horses are less than 2 mmol/L, with most horses having concentrations less than 1 mmol/L.[16-18] Neonatal foals have decremental values after birth, with reported concentrations of 4.9 ± 1.02, 2.25 ± 0.6, and 0.89 mmol/L at birth, 12 hours of age, and 24 hours of age, respectively.[18-20] In a study performed by the author, foals had values of 2.4 ± 1.0, 1.2 ± 0.3, and 1.1 ± 0.3 mmol/L at 0 to 2, 24, and 48 hours of age, respectively, compared with 0.6 ± 0.2 mmol/L in adult horses.[21]

Cardiac Output

Advanced monitoring in equine critical care includes cardiac output measurement. A number of methods of cardiac output monitoring have been described in horses, including the Fick principle, indicator dilution methods (such as lithium dilution), Doppler and volumetric

VetBooks.ir

echocardiography, pulse contour analysis, and partial carbon dioxide rebreathing. The most practical of these include lithium dilution and echocardiographic techniques.[22-26]

Lithium dilution precludes the need for placement of cardiac catheters. A small bolus of lithium chloride is injected into a peripheral vein or the cranial vena cava (via central line). Arterial blood is sampled using an arterial catheter at a constant rate and passes through a lithium electrode to generate a lithium concentration-time curve. Cardiac output is calculated from the area under the curve for lithium over time. Advantages of lithium dilution include only moderate invasiveness, good accuracy, and requirements for only small volumes of injectate. Disadvantages include the need for continuous arterial blood and limitations on repetitive measurements owing to lithium accumulation.[25-27]

Noninvasive cardiac output measurements can be made using the Bullet method through volumetric echocardiography.[24] McConachie and colleagues[24] reported that the Bullet method provided an accurate estimate of cardiac output in anesthetized foals. The Bullet method, as well as the four-chamber area-length, Simpson, and right ventricular outflow Doppler methods, had reasonable agreement with lithium dilution in adult horses.[28] For the Bullet method, cardiac output is calculated using heart rate and stroke volume (SV) as follows:

$$SV = \left(\frac{5}{6} \times LVAd \times LVLd\right) - \left(\frac{5}{6} \times LVAs \times LVLs\right)$$

where LVAd = left ventricular area in diastole (short-axis view); LVLd = left ventricular length in diastole (long-axis view); LVAs = left ventricular area in systole (short-axis view); and LVLs = left ventricular length in systole (long-axis view).

Cardiac output in healthy adult horses (400 to 500 kg) is 32 to 40 L/min.[22] Normal cardiac index, which is cardiac output expressed per unit of body weight, is 72 to 88 mL/kg/min. In the neonatal foal, cardiac output has been reported to be 7.1 ± 0.4 L/min (cardiac index = 155.3 ± 8.1 mL/kg/min) in 2-hour-old foals.[2] At 24 hours of age cardiac output was determined to be 9.0 ± 0.5 L/min (cardiac index = 197.3 ± 12.0 mL/kg/min). This increased to 15.7 ± 1.5 L/min (cardiac index = 222.1 ± 21.6 mL/kg/min) at 14 days of age.[2] A general guideline for normal cardiac index is 100 to 300 mL/kg/min in foals.[24]

Blood Glucose

Blood glucose concentration has been the focus of much study in human critical care in recent years. A number of initial studies have demonstrated improved survival and reduced complications with tight glucose control using intensive insulin therapy in critically ill humans.[29,30] Maintenance of euglycemia (80 to 110 mg/dL) resulted in reduced mortality in surgical intensive care unit patients as compared with hyperglycemia (180 to 200 mg/dL). Hyperglycemia may be associated with detrimental effects in pediatric intensive care patients as well.[31] However, after these initial studies, additional studies, including meta-analyses, did not document similar benefits and revealed some adverse events with tight glycemic control, including severe hypoglycemia.[32,33] Current guidelines therefore recommend using a glucose concentration of 180 mg/dL or less as a goal.[34] How these findings relate to critically ill horses is unknown, but prevention of hyperglycemia is likely warranted, and its effects in the equine intensive care unit require further study.

Monitoring Urine Analytes

Urine indices are useful for monitoring responses to fluid therapy. Successful production of urine output is a primary goal of fluid therapy, and measurement of urine production allows determination of "fluid balance" (input–output). Another important means of assessing the response to fluid loading is measurement of urine specific gravity and/or osmolarity. In the absence of renal failure, progressively dilute urine is a positive response to fluid administration. Horses on feed and water should be making 0.4 to 2.0 mL/kg/h urine, whereas those off feed and water will produce far less (0.13 to 0.5, up to 1 mL/kg/h depending on duration).[35,36] Horses on fluids should therefore be producing a minimum of 0.5, but optimally 1 to 2 mL/kg/h of urine.

Urinalysis should be performed, and fractional excretion of electrolytes, particularly sodium, provides information regarding tubular function and can aid in differentiation of prerenal from renal azotemia. Normal fractional excretion is less than 1% in adult horses and 0.31% ± 0.18% in neonatal foals.[37-40]

Fluid Therapy for Specific Diseases and Disorders in Horses

Fluid Therapy for Liver Dysfunction and Failure in Horses (Box 44-1)

K. Gary Magdesian

Acute liver disease may result in hypovolemia owing to lack of water intake, third space losses into the gut and peritoneal cavity, and possibly pooling of blood in the portal circulation. Portal hypertension may result in gut edema with subsequent fluid loss. Considerations of fluid therapy in cases with hepatic dysfunction include reduced metabolic capacity as well as compromised synthetic ability of the liver. Because lactate clearance primarily occurs in the liver, fluids containing lactate should be avoided. Isotonic replacement fluids, such as Normosol-R (Abbott Laboratories, North Chicago, Ill.) and Plasma-Lyte A or 148 (Baxter Healthcare Corporation, Deerfield, Ill.), and acetated Ringer solution are preferred over LRS. One millimole of acetate yields 1 mmol of bicarbonate during metabolism and is therefore alkalinizing.[1] These balanced, polyionic fluids are optimal as compared with physiologic saline (0.9% sodium chloride) because of the propensity of the latter to produce a mild hyperchloremic metabolic acidosis (HCMA), and many horses with liver dysfunction have a propensity toward acidemia anyway.[2] Hyperchloremic acidosis has potentially adverse effects, including renal afferent arterial constriction, and has negative effects on organ function, including gastrointestinal, central nervous system, and coagulation.[3,4]

Provision of dextrose, even in the face of normoglycemia, should be considered unless enteral nutrition is adequate. The addition of dextrose to fluids will minimize gluconeogenesis demands on the liver, as well as catabolism of endogenous tissues with subsequent increases in nitrogen turnover (and increased ammoniagenesis). Risk of hypoglycemia from liver dysfunction is also minimized, since patients may have insufficient liver and muscle glycogen reserves and impaired hepatic gluconeogenesis in order to maintain normal blood glucose concentrations. A dextrose supplementation rate for adult horses is 1 to 2 mg/kg/min. This equates to 3% to 6% dextrose in fluids if 1 L/h of crystalloid is administered to a 500-kg horse. The author often begins with 0.5 mg/kg/min of dextrose and gradually advances the rate of administration as the horse tolerates the dextrose (<180 mg/dL). The addition of B vitamins can be helpful for anorectic horses because they are required cofactors for oxidative metabolism. In addition many of the B vitamins are stored in the liver. Horses

BOX 44-1

Fluid Considerations for Liver Failure

1. A combination of balanced, polyionic crystalloids and colloids is optimal.
2. Acetated fluids, rather than lactated Ringer solution, should be used.
3. Colloids, particularly plasma, can be beneficial if hypoalbuminemia is present and to minimize third space accumulation of fluids.
4. Potassium supplementation (20 to 80 mEq/L) may aid in reducing hyperammonemia (<0.5 mEq/kg/h total).
5. Dextrose supplementation (1 to 2 mg/kg/min) should be provided for energy support.

VetBooks.ir

that remain anorectic for longer than 24 to 72 hours should be considered candidates for parenteral nutrition.

Horses with liver dysfunction should be monitored closely for hyperammonemia as a marker of hepatic encephalopathy. Fluids can be tailored to minimize the risks of hyperammonemia. Provision of potassium, even in the presence of normokalemia, provides for an electrolyte draw of hydrogen atoms from intracellular stores, thereby lowering pH and promoting ionization of ammonia to its less diffusible form, ammonium ion, which is not able to cross the blood-brain barrier.[5] Hypokalemia also promotes metabolic alkalosis and may compound hepatoencephalopathy owing to increased urinary losses of hydrogen ion (H^+) and increased tubular absorption of ammonia. For similar reasons, sodium bicarbonate should be used judiciously and with caution in horses with a propensity toward hepatic encephalopathy. Increases in the pH of plasma will result in conversion of ammonium ion to ammonia; this facilitates the brain uptake of ammonia with subsequent intracerebral trapping of ammonium ion.

The rate of fluid administration for horses with liver dysfunction will vary with the volume and hydration status of the individual. In general, rates should exceed maintenance requirements to account for hypoperfusion and produce diuresis of ammonium and other toxins such as conjugated (direct) bilirubin that would otherwise have been metabolized or eliminated by the liver. Volume of fluid administration should be monitored closely in horses with ascites or portal hypertension resulting from severe liver disease because of the propensity of these patients for third space fluid accumulation. Other considerations for horses with liver disease include hypoalbuminemia, hyponatremia, hypokalemia, coagulopathies, and hyperlactatemia. Monitoring CVP will aid in preventing rises in hydrostatic pressure that would contribute to transudates or ascites.

Fluid support, for "maintenance fluid therapy," can be modified in horses with preexisting ascites or edema to reduce the administered sodium load. These are hypotonic and should never be administered as a rapid bolus. Commercially available solutions with restricted sodium concentrations (maintenance crystalloids), such as Plasma-Lyte 56 or Normosol-M, can be used in foals. Because of their availability in only small volumes (1-L bags), combinations of isotonic crystalloids and sterile water or 5% dextrose in water can be used as maintenance fluids in larger patients (half isotonic fluid and half water or D_5W). If sterile water is selected, it should be allowed to mix with the isotonic fluid before entering the patient; administered alone, water could cause osmotic hemolysis. Another option in such horses is to restrict the volume of crystalloid administered through concurrent administration with colloids. Colloids expand the intravascular volume, limit the requirement for crystalloids, and may reduce the propensity of edema formation by raising oncotic pressure. However, consumptive coagulopathies would be contraindications to the administration of synthetic colloids.

Colloids are indicated in horses with significant hypoalbuminemia (<1.5 g/dL). Hetastarch can be used at a dose of up to 10 mL/kg/day unless coagulopathies are present. Liver failure may result in decreased production of clotting factors or antithrombin and can initiate disseminated intravascular coagulation (DIC). Because hetastarch can induce decreased activity of von Willebrand factor and factor VIII, as well as interfere with platelet function, it is contraindicated in horses with bleeding tendencies (after consumption of factors).[6] Plasma is an alternative colloid that has additional benefits for horses with hepatic failure. Coagulopathies associated with liver disease can be addressed through provision of exogenous antithrombin and clotting factors in plasma products. Plasma should probably not be administered to horses with serum hepatitis (Theiler disease), since this disease is poorly understood and associated with prior administration of equine-origin biologics. Recently, a flavivirus has been associated with Theiler disease.[7] Replacement of albumin is beneficial not only for oncotic pressure support, but also for drug and toxin binding and as an endogenous buffer. If hypoalbuminemia is a result of hepatic dysfunction, and not urinary or gastrointestinal losses, colloids will have a longer retention time in the circulation.

Fluid Therapy for Diarrhea and Colitis in Horses (Box 44-2)

K. Gary Magdesian

Horses with acute colitis are often presented in a state of severe SIRS with endotoxemia, hypovolemia, and malperfusion of tissues. Fluid therapy is the cornerstone of hemodynamic and therapeutic support for these horses. Not only is low circulating volume an indication for fluids, but acid-base and electrolyte derangements also warrant their use in these cases. Specifically, horses with colitis often exhibit hypovolemia, both organic and inorganic acidoses, and hyponatremia. Organic acidosis primarily is a result of hyperlactatemia, whereas inorganic acidosis is often a result of relative hyperchloremia (or hyponatremia).

Because of the poor sensitivity of physical examination in detecting hypovolemia, estimates of percent dehydration and water deficit are not very accurate.[1] A more objective means of providing fluids is through the "fluid challenge method" described in the previous sections.[1] In this protocol a bolus dose of 10 to 20 mL/kg of isotonic crystalloid is administered over approximately 30 minutes to horses with hypovolemia, with subsequent reassessment of perfusion parameters. Perfusion parameters consist of mentation, peripheral pulse quality, heart rate, mucous membrane color, capillary refill time, and extremity temperature. Lactate, arterial blood pressure, and central venous oxygen saturation are perfusion monitoring tools that should be evaluated serially in patients undergoing fluid administration and can provide endpoints to fluid therapy. Urine output is another clinical indicator of improvement in perfusion in response to fluid loading. Fluid challenge should continue as repeat boluses, albeit at progressively slower rates for each subsequent bolus, until perfusion parameters normalize or plateau in terms of improvement. No further improvement of perfusion parameters in response to boluses of fluids, with persistence of clinical indicators of hypoperfusion, suggests that inotrope or vasopressor support may be required and that further fluid therapy will not be of aid. A safety limit to fluid loading includes measurement of a high normal CVP value.

Crystalloid fluid choices for horses with colitis include replacement fluids, such as Normosol-R, LRS, and Plasma-Lyte 148 or A. Normosol-R and Plasma-Lyte 148/A are slightly advantageous over LRS from the standpoint of providing a wider strong ion difference (sodium-chloride difference). In contrast, LRS has a chloride concentration greater than that of equine plasma (109 mEq/L vs. approximately 100 mEq/L) and can compound an inorganic acidosis. Physiologic saline (0.9%) is even greater in its chloride concentration and produces a mild strong ion acidosis on administration of large volumes.[2] In addition, Normosol-R and Plasma-Lyte 148 or A contain acetate (and gluconate) rather than lactate as the alkalinizing salt. This is a significant advantage in horses with hepatic dysfunction, because the liver is the primary site of lactate metabolism whereas acetate and gluconate are metabolized by many tissues.

Colloids may be adjunctive to crystalloid therapy, particularly for horses with hypoproteinemia such as those with acute colitis. In human critical care medicine there is no consensus as to whether crystalloids or colloids provide more successful fluid resuscitation.[1]

BOX 44-2

Fluid Considerations for Horses with Diarrhea or Colitis

1. A combination of crystalloids and colloids has many benefits in horses with colitis.
2. Colloids are indicated when concurrent hypoproteinemia and hypovolemia are present.
3. Potassium, calcium, and magnesium should be supplemented as necessary.
4. Hypertonic saline has several potential benefits for horses with acute colitis, including volume expansion, immunomodulation, antiinflammatory effects, antiedema effects, and positive inotropic effects.

VetBooks.ir

A combination of both is likely optimal.[1] Colloids are particularly important for horses with hypoproteinemia, such as those with colitis. Concurrent hypovolemia and hypoproteinemia warrant administration of colloids in the resuscitative period, because the use of crystalloids alone could result in dilutional hypoproteinemia.[3]

Hypertonic saline (7% to 7.5%) is a rapid plasma volume expander that can be used in the early volume replacement period of volume resuscitation of the horse with liver failure. Hypertonic saline increases plasma volume by three to four times the volume administered. In comparison, crystalloids increase plasma volume by only 0.25 to 0.33 mL for each milliliter administered. Hypertonic saline has additional advantages beyond volume expansion, particularly for the horse with endotoxemia. These include immunomodulatory, antiinflammatory, antiedema (particularly of the endothelium and erythrocytes), and inotropic effects.[4-6] Microvasculature effects enhance microcirculatory perfusion, which is often disturbed during sepsis and endotoxemia. Reduction of endothelial and erythrocyte edema, two processes that contribute to multiple organ dysfunction during sepsis, results in reduced vascular resistance and blood viscosity.[5,6] The hypertonicity created by hypertonic saline evokes vasodilation, which also contributes to microperfusion when coupled with an increase in cardiac output caused by contractility-enhancing effects of hypertonic saline. The antiinflammatory and immunomodulatory effects include antiapoptosis, free-radical scavenging properties, inhibition of leukoactivation, and prevention of immunosuppression after sepsis.[4-6] In an experimental model of hemorrhagic shock in horses, hypertonic saline resulted in improved cardiac output, stroke volume, cardiac contractility and blood pressure as compared with isotonic saline.[7] Hypertonic saline has demonstrated attenuation of cardiovascular derangements in equine endotoxemia models as compared with isotonic saline.[8]

The dose for hypertonic saline is 4 mL/kg once, and it should be followed with isotonic crystalloids or water to replace the "borrowed" water from the intracellular space. Hypertonic saline is generally safe but should be avoided in horses with uncontrolled hemorrhage when hypotensive resuscitation is indicated. In addition, horses with marked sodium derangements should not be administered hypertonic saline. It should also be used with caution in neonatal foals.

Fluid Therapy for Sepsis (Peritonitis, Pleuritis, Pneumonia, Internal Abscess) in Horses (Box 44-3)

K. Gary Magdesian

The optimal fluid for resuscitation of patients with sepsis is unknown.[1-3] Despite this controversy, a rational approach to fluid therapy in patients with sepsis is to optimize hemodynamics (increase oxygen delivery, blood pressure, and urine output) while attempting to limit edema formation.[1,4,5] There is no evidence to support the use of either colloids or crystalloids over the other. Meta-analysis of clinical studies comparing crystalloids and colloids in human patient populations showed no outcome difference.[2,3,5-7] Regardless of the lack of consensus recommendations for fluid choices, fluid therapy is a keystone in the management of severe sepsis and septic shock. This is because septic shock is associated with both absolute and relative hypovolemia. Relative hypovolemia is the result of vasodilation and peripheral blood pooling in the face of cytokinemia. Volume repletion allows for increases in cardiac output and subsequently in systemic oxygen delivery.[6]

Fluid therapy in horses with sepsis is similar to that recommended for horses with acute enterocolitis; both conditions are examples of a state of SIRS. In fact, enterocolitis can be thought of as a form of sepsis. Sepsis incites a host of hemodynamic derangements that challenge fluid therapy. It causes myriad microperfusion abnormalities; these include hypovolemia, myocardial depression, vascular permeability derangements, vasodilation, DIC, and cellular changes resulting in abnormal membrane potential and membrane pump or channel function.[8] These pathophysiologic processes must be considered when a fluid plan for horses with sepsis is designed.

Sepsis is defined as concurrent SIRS and documented or suspected infection.[9] Many equine cases fall into this category, including horses with peritonitis, pneumonia, pleuritis, enterocolitis, meningitis, and metritis. Sepsis and SIRS are states of cytokine milieu, in which cytokines and inflammatory mediators predominate. Aside from antimicrobials, the fundamental therapy is hemodynamic support, consisting of fluid and vasopressor therapy.

Initial fluid resuscitation is centered on isotonic (or near isotonic) replacement type fluids, colloids, and hypertonic saline. Horses with sepsis often are presented with negative fluid balance resulting from both hypovolemia and dehydration. Fluid choices are the same as for horses with enterocolitis, and a combination of crystalloids and colloids may have advantages in sepsis.[4] Such a combination would address both blood volume and interstitial deficits, with colloids expanding the vascular space and crystalloids addressing both fluid spaces. Hypertonic saline may have some additional advantages during sepsis, including immunomodulatory, antiinflammatory, antiedema, vascular, and inotropic effects.[10-12] A dose of 2 to 4 mL/kg of hypertonic saline may be added to the combination of isotonic crystalloids and colloids.

Colloids are intriguing fluids for horses with sepsis. Colloids may attenuate capillary leak associated with sepsis and SIRS.[13] The exact physiology behind this colloid effect is not exactly worked out; however, theories include reduction in endotoxin-induced leukocyte-endothelial cell interactions.[14] Interactions with endothelial glycocalyx are also hypothesized in the ability of both synthetic colloids and albumin to reduce capillary leakiness.[15] However, recent meta-analyses have failed to demonstrate a benefit of colloids over crystalloids in volume replacement of the critically ill human patient.[16] Hetastarch exhibits antiinflammatory properties by reducing neutrophil adhesion and accumulation in tissues.[17] In addition, hetastarch has been suggested to be beneficial for tempering DIC in that it exerts dose-dependent effects on coagulation; however, this remains to be further studied.[18] Hetastarch lowers concentrations of von Willebrand factor and factor VIII:C and reduces platelet aggregability, which may aid during hypercoagulable states such as DIC.[18-23] Both of these properties warrant further investigation in horses with sepsis because vascular derangements and coagulopathies are quite common. It should be kept in mind, however, that bleeding may be potentiated by the administration of hetastarch to the hemorrhaging patient and hetastarch should not be administered to hypocoagulable patients.[24] It should be noted that recent research in human critical care has suggested an increase in mortality rate in patients receiving hetastarch as compared to crystalloids. In a trial comparing concentrated albumin with crystalloids in human patients, there was a trend toward improved survival with albumin in patients with sepsis.[25] Concentrated equine albumin is not currently available; however, one study showed that a human albumin product could be used safely in horses.[26]

Care should be taken to avoid overexpansion of the extracellular fluid compartment with excessive fluid administration. Horses with sepsis have a predilection for edema because of the presence of concurrent hypoalbuminemia and increased vascular permeability. Therefore, careful monitoring of fluid balance is warranted. *Fluid balance* refers to input and output of fluids, and it can be monitored

BOX 44-3

Fluid Considerations for Horses with Sepsis

1. Crystalloids are the mainstay of fluid therapy in sepsis.
2. A combination of crystalloids and colloids may have advantages in patients with sepsis when hypoproteinemia is present.
3. Fluid challenge, consisting of 10- to 20-mL/kg boluses with reassessment of perfusion parameters and monitoring tools, is a safe and effective means of determining volume to be administered.
4. Monitoring of fluid therapy increases safety, especially in patients prone to edema. Monitoring should consist of measurement of central venous pressure, arterial blood pressure, and urine output.
5. Metabolic acidosis is very common among patients with sepsis.

VetBooks.ir

with urinary collection systems. Under normal circumstances urine output should represent 50% or greater of input, with the remaining output caused by fecal and evaporative losses (skin and pulmonary). CVP is also useful in monitoring for safety limits in this group of patients; maximal normal CVP (10 cm H_2O [8.8 mm Hg] in foals; 15 cm H_2O [11 mm Hg] in adults) should not be exceeded. Serial ultrasonography and arterial blood gas analysis can be used to detect pulmonary edema from relative or absolute fluid overload, before the development of gross signs (froth, crackles, tachypnea) of edema.

Because of thrombotic risks associated with sepsis-induced coagulopathies, these patients should be instrumented with minimally thrombogenic catheters, such as long-term polyurethane catheters. Attention to asepsis and cleanliness is paramount.

In human critical care, "early goal-directed therapy" has been advocated by some clinical trials.[27] These studies have used goal-oriented therapeutic adjustments of preload, afterload, and contractility to achieve a balance between oxygen delivery and demand. Endpoints have included normalization of central venous oxygen saturation (70%), blood lactate, CVP (8 to 12 mm Hg in humans), urine output (0.5 mL/kg/h or greater), and MAP (65 mm Hg or greater in humans).[28] The therapy consisted of crystalloids and colloids for correction of CVP, vasopressors and vasodilators for MAP, and dobutamine and red blood cell transfusions for central venous oxygen saturation. Patients receiving this early goal-directed therapy received a greater volume of fluids early (first 6 hours of treatment) and less later, as compared with patients in the conventional group. The treatment group had a lower mortality rate and less severe organ dysfunction, highlighting the importance of early identification of patients with insidious or occult malperfusion, consisting of patients with global hypoxia yet stable vital signs.[27]

There has been considerable debate over what the optimal fluid choices are for human patients with sepsis: crystalloids or colloids. The ideal fluid for volume replacement remains equivocal because concrete evidence implicating one over the other is lacking.[2,29] Because of cost differences, and lack of clear benefit of one over another, crystalloids are usually favored. A current philosophy is to recognize the advantages of both fluids, with concurrent or sequential administration of both in certain types of cases. Because crystalloids distribute approximately 75% of administered volume to the interstitium, they allow for greater interstitial expansion compared with colloids. This property is advantageous when dehydration is also present, but a disadvantage when edema is a risk. In fact, crystalloid administration further dilutes total protein and albumin concentrations, thereby lowering COP and predisposing to edema. Colloids, on the other hand, are restricted to the intravascular space and therefore may be indicated in hypovolemic shock; they replace intravascular losses more rapidly than do crystalloids.[30] Colloids are associated with a plasma volume expansion between 100% and 200% of the infused volume.[31-33] In humans and anesthetized horses with colic, cardiac output is better maintained with lower volumes of fluid administration when colloids are used rather than crystalloids.[34]

Marked alterations of the reflection coefficient, as are associated with severe capillary leak and acute respiratory distress syndromes (ARDS), warrant careful consideration and monitoring of patient status when colloids are administered; because of a theoretical potential for extravascular leakage of colloids with marked endothelial alterations, patients with ARDS should be monitored closely for clinical deterioration. Despite these theoretical concerns, a more recent form of hydroxyethyl starch (130/0.4) has demonstrated protective effects in a model of acute lung injury (ALI).[35] The numbers after the colloid just mentioned (130/0.4) refer to the average molecular weight and degree of substitution of starch molecules with a hydroxyethyl group, respectively. This hydroxyethyl starch resulted in the best oxygenation and a reduced inflammatory response as compared with a modified gelatin colloid or Ringer acetate crystalloid in a rabbit model of ALI.[35] Standard hetastarch has an average molecular weight of 450 kDa and a degree of substitution of 0.7; the newer hydroxyethyl starch (Voluven; 130/0.4) has been modified to have more complete renal elimination and less tissue storage than the standard product, with fewer side effects such as coagulopathies. Recently, the FDA has approved a veterinary hydroxyethylstarch colloid for use in dogs and cats (VetStarch, Abbott Animal Health, Abbott Park, Ill.). This product also has 6% hydroxyethyl starch in a 130/0.4 formula, thereby allowing it to have lower potential complications compared with hetastarch, including coagulopathy, allergic reactions, and renal injury. It is indicated to treat and prevent hypovolemia. It would be particularly useful in the presence of concurrent hypoalbuminemia. The use of different colloids in patients with ARDS needs further study. Except for situations that may call into question the use of colloids, the concurrent use of crystalloids and colloids obviates the need for large volumes of crystalloids; this approach minimizes the risk of interstitial edema and may restore blood volume more rapidly than crystalloids alone. A "blending" of crystalloids and colloids should therefore be considered for patients with sepsis whenever colloids are not contraindicated and particularly when hypoproteinemia is present. Contraindications to synthetic colloids include known hypersensitivity, fluid overload, pulmonary edema, and renal failure (oliguric/anuric), severe hypernatremia/hyperchloremia (resulting from dilution in 0.9% saline), and intracranial bleeding.

See the previous section for glucose regulation in critically ill patients. The current goal in human patients is to maintain a blood glucose of 180 mg/dL or less.

Fluid Therapy for Renal Failure in Horses (Box 44-4)

C. Langdon Fielding • K. Gary Magdesian

Fluid therapy is the major component of treatment for renal failure in horses, regardless of cause. Renal replacement therapies have been reported in horses; however, they are not widely available, further highlighting the importance of fluid diuresis.[1-3] Peritoneal dialysis is an option to complement fluid therapy, particularly if unresponsive anuria is present.[2] Development of a fluid plan for horses with renal failure begins with classification of the disease into polyuric, anuric, or oliguric renal failure. Polyuria and anuria are self-explanatory; oliguric renal failure in this section refers to a normally hydrated animal with concurrent azotemia and urine production less than 0.5 mL/kg/h.

BOX 44-4

Fluid Considerations for Horses with Acute Renal Failure

1. Horses with acute renal failure can be polyuric, oliguric, anuric.
2. Polyuric horses should be treated with isotonic crystalloids with the goal of diuresis. A rate of administration equal to two times a maintenance rate is a reasonable starting point, but fluid balance (input and output) should be monitored. This would equate to 4 to 6 mL/kg/h as an initial starting rate, which should be tailored (increased or decreased) to perfusion parameters, urine output, patient clinical status, and monitoring tools. Balanced, polyionic commercial electrolyte solutions, such as Normosol-R or lactated Ringer solution, can be used in most cases.
3. Frequent reassessment of patient's fluid status should be done to adjust rate accordingly.
4. Physiologic (0.9%) saline is mildly acidifying because of hyperchloremia and should be avoided in patients with renal failure because hyperchloremic metabolic acidosis may reduce renal blood flow.
5. Anuric or oliguric horses should be treated promptly. Adequacy of circulating volume and blood pressure must be ensured initially. If fluid loading with isotonic replacement crystalloids and correction of hypotension does not correct the lack of urine production, then furosemide, mannitol, and dopamine can be tried. Dialysis (hemodialysis or peritoneal) can be performed if there is potential for reversible renal injury.
6. Synthetic colloids (hetastarch, dextrans) should be avoided in horses with acute renal failure.

VetBooks.ir

For both oliguric or anuric and polyuric renal failure, there are two primary considerations when beginning fluid therapy: fluid type and rate. The total amount of fluid administered is usually determined by the response to treatment and does not necessarily need to be identified at initiation of therapy.

POLYURIC RENAL FAILURE. The goal of fluid therapy in these patients is to induce diuresis, with removal of uremic toxins and maintenance of fluid, acid-base, and electrolyte balance.[4,5] The degree of renal failure that is reversible is often unknown at the onset; this is evaluated over time, particularly with response to fluid therapy. It should be noted that azotemia may not improve for up to 72 hours after initiation of fluid therapy when acute renal failure is severe. A lack of initial improvement in plasma creatinine or BUN during the first day or two of therapy should not necessarily prompt a poor prognosis or discontinuation of therapy.

The rate of fluid administration should facilitate diuresis.[5] A rate of two times maintenance fluid rate (4 to 6 mL/kg/h, where maintenance rate is 2 to 3 mL/kg/h) is a reasonable starting point; however, there is a paucity of literature to recommend evidence-based rates of fluid administration for treatment of acute renal failure or other disorders. Similar fluid rates have been suggested in small animal patients with renal failure.[5] It is unknown whether increases in the fluid rate beyond this point are beneficial. Certainly, if urine output is greater than this rate, it should be matched with fluid input.

Fluid overload is a problem in renal failure and has been reported in people.[6,7] Excessive fluid administration may result in edema and associated morbidity and mortality. Measurement of CVP can be used to monitor excessive fluid administration and has become more practical in equine patients.[8-10] Reference ranges of less than 15 cm H_2O have been reported for adult horses; values exceeding 20 cm H_2O indicate a need to decrease the rate of fluid administration to avoid development of edema.[9] The value of CVP monitoring continues to be controversial and CVP measurement should not be used as the sole means for monitoring fluid overload.[11]

A balanced isotonic crystalloid is suitable for diuresis while preventing significant electrolyte alterations.[5] Horses should be allowed free access to water whenever possible while intravenous fluids are administered. This allows for some degree of self-regulation of water balance and can provide free water for renal excretion of the large sodium load provided by isotonic crystalloids.

Hyperkalemia is a relatively common feature of acute renal failure.[12,13] This is often corrected when renal perfusion is optimized and diuresis is instituted. When hyperkalemia is present, anuria should be ruled out. Cardiac dysrhythmias can develop during hyperkalemia; potassium-free fluids (0.9% saline or isotonic sodium bicarbonate) should be administered to patients with dangerous hyperkalemia (>6 mmol/L), along with calcium, dextrose, and possibly insulin.

LRS has the benefit of containing a minor amount of free water (osmolarity 273 mOsm/L) and slightly less sodium than other fluids (130 mEq/L). A potential disadvantage, however, is that it contains more chloride (109 mEq/L) than equine plasma. Horses with renal insufficiency may be unable to excrete excess chloride provided by LRS diuresis. Mild hyperchloremia may result, causing a minor strong ion acidosis. LRS also contains potassium (4 mEq/L), which is a consideration in the hyperkalemic patient. However, studies in human renal transplant patients failed to demonstrate development of hyperkalemia as a result of LRS administration.[14]

Isotonic saline (0.9%) solution has an even higher chloride content (154 mEq/L) than LRS. In fact, neither the sodium nor the chloride concentration in this fluid is similar to those of equine plasma. Isotonic saline solution has been shown to cause hyperchloremia and a mild acidosis during prolonged administration.[15-17] This hyperchloremia may make isotonic saline a less ideal fluid for long-term management of acute renal failure. Saline does not contain potassium and therefore may be warranted in horses with hyperkalemia. However, creation of a metabolic acidosis because of hyperchloremia may also pose a risk for hyperkalemia by causing an extracellular shift of potassium; this shift occurs as a result of acute changes in blood hydrogen concentration, which occur in association with hyperchloremic metabolic acidosis.[14] The effects of saline on potassium balance in horses warrant further study. Metabolic alkalosis, caused by hypochloremia or relative hypernatremia, is an indication for saline administration.

Normosol-R and Plasma-Lyte 148 have a sodium and chloride concentration most similar to equine plasma among the commercial isotonic or nearly isotonic fluids and are excellent fluids for diuresis of acute renal failure cases. It should be noted that these contain the highest potassium concentration (5 mEq/L) of all of the commercial fluids described; however, this potassium content is unlikely to contribute to clinically significant hyperkalemia in polyuric animals because of urinary excretion of excessive potassium (possible exceptions are uroperitoneum and anuria).

Isotonic sodium bicarbonate solution can be made by mixing sterile water and sodium bicarbonate to create a solution with a sodium concentration of approximately 150 mmol/L. Isotonic sodium bicarbonate does not contain potassium or chloride and can be modified to contain an increased amount of free water as needed by lowering the sodium concentration. It exerts an alkalinizing effect by increasing strong cation (Na^+) concentrations without a corresponding increase in strong anions (i.e., strong ion alkalosis).

Blending of fluids with different compositions is also an option in order to correct or maintain electrolyte and free water balance. Over time, horses often develop a plasma electrolyte profile similar to that of the administered fluid, especially when large volumes are administered for prolonged periods; therefore, combining or changing fluids may be necessary if derangements develop. It is also clear that monitoring of electrolytes (one to four times per day) is particularly important in renal patients.

Synthetic colloids should be avoided in horses with acute kidney disease because renal injury is a known complication of administration of synthetic colloids in humans.

ANURIC OR OLIGURIC RENAL FAILURE. Anuria and oliguria should be considered emergency medical conditions; the longer the duration of little to no urine production, the lower the chances of correcting it. Urine output in healthy horses is approximately 1 mL/kg/h, but this may decrease by 80% (to 0.2 mL/kg/h) in horses deprived of water.[18,19] In humans without significant fluid deficits, a urine flow below 0.5 mL/kg/h is one criterion used to define acute renal *injury,* whereas acute renal *failure* is associated with a urine flow below 0.3 mL/kg/h.[20] Oliguric renal failure should be suspected in azotemic horses with urine production below 0.5 mL/kg/h despite the administration of intravenous fluids. Once anuria or oliguria is suspected, a methodic approach to fluid administration and monitoring should be instituted immediately because of the associated high mortality rate. A delay in instituting treatment makes reversal of anuria less likely.

Treatment of Anuria or Oliguria

1. Obtain baseline laboratory and hemodynamic parameters. These should include serum or plasma electrolyte levels, total plasma protein and blood lactate concentrations, packed cell volume, and clinical perfusion parameters. When possible, CVP, arterial blood pressure, and central venous oxygen tension should be measured as well. If possible, a body weight measurement should be obtained and recorded.
2. If CVP is not already significantly increased and there are no clinical signs of fluid overload (increased respiratory rate, peripheral edema, etc.), a fluid challenge should be initiated using 10 to 20 mL of an isotonic crystalloid per kilogram. CVP, clinical pathology, urine output, and physical examination status should be reevaluated for improvement after completion of the bolus.
3. If urine output has not significantly increased, additional fluid challenges should be given and the patient reevaluated until urine production begins or until CVP limitations are reached. A CVP

VetBooks.ir

value greater than 15 to 20 cm H_2O (>10 to 12 cm H_2O in foals) signifies an endpoint to fluid administration.

4. Arterial blood pressure should be monitored. If hypotension is present despite fluid loading, inotrope and vasopressor therapy should be considered. Dobutamine can be used as an inotrope (5 to 10 mcg/kg/min). See page 1374, Fluid Therapy for Diarrhea and Colitis in Horses.
5. Once urine flow has increased, fluids should be continued as described previously for polyuria; careful monitoring of CVP and fluid balance (measurement of serial body weight and urine output) should be done.
6. If urine flow does not begin over the next 30 to 60 minutes with fluid challenge, furosemide should be started with an initial bolus of 0.12 mg/kg intravenously (IV) followed by a constant rate infusion (CRI) of 0.12 mg/kg/h.[21] If CRIs are not possible, a bolus dose of 1 mg/kg IV can be administered instead. Furosemide may improve urine production, but there is no definitive evidence that it improves creatinine clearance or positively affects outcome in people.[22]
7. If urine production does not begin within 30 to 60 minutes of instituting furosemide therapy, a dose of mannitol should be administered (0.25 to 0.5 g/kg bolus as a 20% solution). If there is still no urine produced after an additional 30 minutes, another dose of mannitol can be administered; a total dose of 1 g/kg should not be exceeded in the anuric patient to prevent hypervolemia and edema formation. Alternatively, a CRI of mannitol (1 to 2 mg/kg/min) can be used, with a maximum dose of 1 g/kg. Plasma osmolarity should be monitored.
8. If urine output has not improved after furosemide and mannitol, the prognosis is grave without peritoneal dialysis or hemodialysis. Treatment with low-dose dopamine has been controversial in human medicine, and several large studies have failed to demonstrate a benefit.[23,24] In fact, furosemide, mannitol, and dopamine may increase urine flow but have not been shown to unequivocally improve outcome in humans with acute renal failure.[25] When dialysis is not an option for horses with anuric renal failure, dopamine can be tried in an attempt to produce urine flow (2 to 3 mcg/kg/min); its proposed action is through increasing renal perfusion with renal afferent arteriolar vasodilation.[26] Without urine flow, there is no opportunity to provide the patient with time to heal if the acute renal injury is reversible. If dopamine is successful at reversing anuria, this time can be provided.

Hyperkalemia and metabolic acid-base disorders are common in horses with anuric or oliguric renal failure.[12] As noted earlier, hyperkalemia can be associated with life-threatening dysrhythmias. Rapid initiation of diuresis and administration of sodium bicarbonate, dextrose, and insulin are therapeutic interventions for hyperkalemia. If dysrhythmias are present, calcium should be administered to raise membrane threshold potential, thereby reducing the likelihood of abnormal rhythms.

As mentioned previously, hemodialysis has been reported infrequently in horses for clinical cases of renal failure.[1] Peritoneal dialysis has been described as a cost-effective and practical approach for horses with acute renal failure.[2] More recently, continuous venovenous hemodiafiltration was performed in experimental horses for short periods (6 hours). These therapeutic options may become more commonly used in horses that do not respond to conventional fluid therapy and medical treatments of anuria described earlier.

Fluid Therapy for Horses with Vasculitis

K. Gary Magdesian

Horses with vasculitis present a unique challenge to fluid therapy in that they have increased vascular permeability and are therefore at increased risk for developing edema. Examples of such patients that may require restoration of fluid volume include horses with purpura hemorrhagica, type I hypersensitivity reactions (such as anaphylaxis or anaphylactoid reactions), and *Anaplasma phagocytophilum* infections. Often horses with systemic vasculitis have edema, particularly in the distal limbs and ventrum, in the face of concurrent hypovolemia.

Correction of hypovolemia in these horses is challenging, since increasing the extracellular fluid compartment with crystalloid fluids may compound edema and lose efficiency in terms of blood volume expansion. Such cases may benefit from colloid administration. However, depending on the degree of vasculitis and the molecular weight of the colloid, a portion of the administered colloid may also extravasate into the interstitium or third space area, thus compounding edema. Therefore, horses receiving colloid fluids should be monitored for progression of their overall status, including increasing edema in response to fluid administration.

Colloids with a molecular weight of 100 to 300 kDa and those with narrower ranges, such as pentastarch (average molecular weight of 268 kDa) and the newer (third-generation) hydroxyethyl starches (molecular weight of 130 kDa), may have reduced extravasation compared with those with smaller molecular weights and wider molecular weight ranges. One of these with a molecular weight of 130 kDa (VetStarch, Abbott Animal Health, Abbott Park, Ill.) is now available diluted in 0.9% saline for use in dogs and cats. Colloids with this size molecule may reduce endothelial-leukocyte responses and are thought to interact with the endothelial glycocalyx in reducing capillary leakiness.[1,2] Previously available commercial hetastarch solutions (such as 6% hetastarch in 0.9% saline [Teva Parental Medicines Inc., Irvine, Calif.] or 6% hetastarch in lactated electrolyte [Hextend, Hespira, Inc., Lake Forest, Ill.]) are heterogeneous in terms of particle size (range, 15 to 3400 kDa), and those molecules below 100 kDa could extravasate more readily. Hextend has an average molecular weight of 670 kDa and a molar substitution of 0.75.

The total amount of colloid administered needs to be considered, since doses above 10 mL/kg/day of hetastarch may lead to coagulopathies.[3] The safe total cumulative dose of hetastarch over time (i.e., over days) is unknown. It should be noted that recent research in human critical care has suggested an increase in mortality rate in patients receiving hetastarch as compared to crystalloids. Plasma can be administered instead; however, albumin is relatively small (68 kDa), and much of it can redistribute extravascularly because of the altered reflection coefficient.

Fluid Therapy for Horses with Hypoproteinemia

K. Gary Magdesian

Similar to horses with systemic vasculitis, those with hypoproteinemia are at increased risk for edema formation with fluid therapy, making them among the most challenging to manage. The presence of concurrent hypovolemia and hypoproteinemia is a potential indication for colloids rather than crystalloids. Administration of crystalloids alone may result in compounding of the hypoproteinemia through hemodilution.[1] With altered Starling's forces, crystalloids distribute to the extracellular fluid to a relatively greater extent than they would otherwise, because of a lack of plasma oncotic force for retention. However, colloids can also extravasate due to increased vascular permeability, and therefore colloids should not be considered the definitive fluid in such cases because they too may exacerbate edema. Currently available colloids include hetastarch, dextrans, plasma, and concentrated human albumin.[2] Because of the increased potential for side effects associated with dextrans, there is no clear indication to use them over hetastarch. Side effects of dextrans reported in horses include muscle fasciculations, swaying of the hindquarters, tachycardia, and collapse in 8 of 64 horses.[3] Potential side effects of hetastarch products include coagulopathies. Other possible side effects in humans include allergic reactions and acute kidney injury.

Numerous commercial equine plasma products are also currently available. Many include antibodies to salmonella, endotoxin, and clostridial organisms; these are unlabeled claims and are largely unstudied in terms of efficacy. Another advantage of plasma,

VetBooks.ir

especially for the hypoproteinemic horse, includes provision of albumin, antithrombin, and additional clotting factors. Because albumin has multiple functions, including as a carrier protein (drugs, toxins) and physiologic buffer, plasma cannot be entirely replaced with synthetic colloids. Concentrated albumin has been used in neonatal foals, but its use in adult horses may be limited by cost.[2] The potential side effects of human plasma products in horses are largely unknown and require further study.

In one study evaluating the response of hypoproteinemic horses with gastrointestinal disease to hetastarch, it was determined that the oncotic benefit lasted 24 hours; in contrast, hetastarch raised the oncotic pressure of healthy horses for up to 5 days.[1,4] Nevertheless, in some cases even a short-term benefit in oncotic pressure may be preferable to the further dilutional effects of crystalloids.

Fluid Therapy for Hemorrhagic Shock (Box 44-5)

K. Gary Magdesian

With the exception of prompt hemorrhage control, the key component to early trauma care is adequate fluid resuscitation. Traditionally, replacement with isotonic crystalloids of three times the volume of shed blood has been the approach in human trauma patients. Up to eight times the blood loss volume has been administered in severe shock states because isotonic crystalloids distribute throughout the extracellular fluid compartment by volume, such that only 25% of the administered volume will remain within the circulating plasma volume.

Despite its importance, high-volume resuscitation is not innocuous; ARDS has been described in patients that received massive crystalloid resuscitation after trauma.[1] Severe trauma patients enter a phase of SIRS, with some patients developing multiple organ failure and others entering a compensatory antiinflammatory response syndrome (CARS). This latter syndrome causes immune suppression and increased susceptibility to infections. Commercial LRS brands used to contain a racemic mixture of L- and D-lactate. Those solutions, along with artificial colloids, namely dextrans and some hydroxyethyl starches, had proinflammatory effects.[2] Nonracemic LRS only contains the L-lactate form and does not share in the proinflammatory effect. It appears that the D-lactate (nonmammalian form) is largely responsible for the inflammatory reaction to racemic LRS, because removing it from the solution eliminates this effect.[3] These fluids, both artificial crystalloids and colloids, can also cause neutrophil activation and upregulation of adhesion molecules.[4] Most currently available forms of LRS contain only the L-isomer form of lactate. Hypertonic saline, on the other hand, has been shown to be immunomodulatory and causes suppression of neutrophil oxidative burst activity and neutrophil-endothelial adhesions.[5-8] Hypertonic saline counteracts the inflammatory effects of dextrans when used in combination.[9] Therefore, hypertonic saline has potential advantages for early fluid resuscitation of patients with significant blood loss, after the source of hemorrhage has been controlled. This should be followed with isotonic crystalloids, perhaps acetate-containing fluids, such as Normosol-R, or physiologic saline rather than racemic LRS. Hypertonic saline should not be used in cases of uncontrolled hemorrhage. Plasma similarly does not result in inflammatory cell activation. If hetastarch is used in acute blood loss patients, hemorrhage must be controlled before its administration because of rapid volume expansion as well as dose-dependent induction of coagulopathies.[10-15]

Aggressive fluid resuscitation in the face of uncontrolled hemorrhage cannot be justified. Such fluid protocols can exacerbate bleeding as a result of increases in blood pressure, disruption of clots, and hemodilution of clotting factors. Instead, a protocol of hypotensive resuscitation should be followed when bleeding cannot be stopped directly.[16] With hypotensive resuscitation, low volumes of crystalloids or whole blood should be administered to maintain organ vitality without normalizing pressures. A goal of maintaining a MAP of 60 mm Hg will still allow end-organ perfusion while allowing for hemostasis.

BOX 44-5

Fluid Considerations for Horses with Acute Hemorrhage

1. For horses with controlled hemorrhage, a combination of hypertonic saline, colloids, and acetated isotonic crystalloids or physiologic saline can be used.
2. Because of experimental evidence of proinflammatory effects of racemic lactated Ringer solution (LRS) in severe trauma, use of this solution should be questioned in cases of severe trauma until further studies are available. Non-racemic LRS (with L-lactate) should be used when LRS is desired.
3. Hypertonic saline exhibits antiinflammatory effects and may have benefits for horses with severe trauma, especially when LRS or synthetic colloids are used for resuscitation, and after hemorrhage has been controlled.
4. For controlled hemorrhage, a volume three to four times the estimated blood loss should be administered in isotonic crystalloids.
5. For uncontrolled hemorrhage, hypotensive resuscitation should be used; small volumes of fluids are administered to maintain organ perfusion and a mean arterial pressure of 60 mm Hg until the hemorrhage can be controlled.

Fluid Therapy in Acute Neurologic Injury (Box 44-6)

Darien J. Feary

The approach to fluid therapy in horses and ruminants with acute brain or spinal cord injury is aimed at maintaining oxygen delivery and energy supply to meet the metabolic demands of the neuronal tissue, and fluid therapy is a fundamental part of preventing or minimizing secondary neuronal injury, ischemia, and irreversible damage.

The primary goals of fluid therapy for both brain and spinal cord injury follow similar principles and include prevention and/or prompt recognition and treatment of hypovolemia and hypotension, intracranial hypertension (or cerebral edema), and glucose and electrolyte abnormalities.

Although both brain and spinal cord injuries are potentially life threatening in large animals, acute brain injury is likely to be the most influenced, either negatively or positively, by the particular fluid therapy plan that is instituted. This is mainly because the cranial vault is a closed space, composed of brain (approximately 80%), blood (approximately 10%), and CSF (approximately 10%). An increase in one component has to result in a compensatory decrease in another. The presence of the blood-brain barrier, intact or not, is another important factor in the selection of the most appropriate fluid for management of acute brain injury.

The most important consideration in the management of cerebral injury is the maintenance of cerebral blood flow (CBF), which is

BOX 44-6

Fluid Guidelines for Horses with Acute Neurologic Injury

1. The clinical outcome of large animal patients with brain and spinal cord injury may be improved by the prompt recognition and treatment of systemic and central nervous system hypoperfusion.
2. Isotonic crystalloid solutions appear to be the most appropriate fluids for resuscitation in acute neurologic injury, followed by careful administration of hyperosmolar therapy with mannitol or hypertonic saline if evidence of cerebral edema is present.
3. Diligent monitoring of clinical and laboratory measures of perfusion, osmolarity, and electrolyte concentrations is important for optimizing patient care and the likelihood of recovery in these patients.

VetBooks.ir

often reduced post injury. The major determinant of CBF is cerebral perfusion pressure (CPP), which is the difference between MAP and intracranial pressure (ICP) as defined by the following equation: CPP = MAP − ICP. In the normal brain, cerebral autoregulation maintains a relatively constant CBF despite wide variations in perfusion pressure, within the range of 50 to 150 mm Hg (in humans). In the injured brain autoregulation may be impaired, often with concurrent traumatic shock and hypotension, and CBF becomes directly dependent on CPP. Therefore, it becomes critical to prevent hypotension by maintaining MAP above 80 mm Hg and to avoid increases in ICP that result from cerebral edema or hemorrhage. ICP is not routinely measured in large animal patients, limiting its use in guiding fluid therapy. However, neurologic signs suggestive of elevated ICP (e.g., obtunded mentation, mydriasis) indicate the need for specific treatment to reduce ICP, with frequent reassessment of neurologic status being important in determining response to treatment.

Fluid management in large animal patients with acute neurologic injury is essentially based on the principles and guidelines established in human medicine from extensive laboratory and clinical studies. The ideal fluid for these human patients remains controversial and is a topic of ongoing research. When presented with a large animal patient with central nervous system injury, the clinician should formulate a fluid therapy plan tailored to the individual animal, based on findings of thorough physical and neurologic examinations and assessment of laboratory data. The author (DJF) suggests the following goal-directed approach:

- Goal 1: Treat hypovolemia and hypotension with adequate fluid replacement therapy to attain a normovolemic and normotensive state.
- Goal 2: Treat signs of cerebral edema or intracranial hypertension with hyperosmolar therapy.
- Goal 3: Use fluid additives to normalize glucose and electrolyte values, and provide thiamine supplementation.

REPLACEMENT FLUID THERAPY FOR NEUROLOGIC TRAUMA CASES. Although fluid restriction historically has been advocated for patients with traumatic brain injury (TBI) under the premise that intravenous fluids increase cerebral edema formation, this practice is no longer recommended, in humans or horses, for two main reasons. First, inadequate data support the theory that fluid restriction decreases cerebral edema formation, and second, systemic hypotension has been associated with increased mortality and poor neurologic outcome in human patients with TBI.[1-3]

Therefore, prompt restoration of adequate intravascular volume with the goal of achieving and maintaining euvolemia, normal blood pressure, and tissue oxygenation should be the primary goal of fluid management in patients with neurologic injury. This is best achieved and controlled via the intravenous route in injured horses. Overhydration should be avoided, particularly in neonates, which are more susceptible to volume overload than adult horses.

Selection of the appropriate fluid for replacement therapy requires an understanding of the role of the blood-brain barrier. Because of its unique properties, the development of cerebral edema is fundamentally different from edema formation in other organs or tissues.[4] Briefly, the normal blood-brain barrier functions as a semipermeable membrane, separating the brain from the intravascular space. In the normal animal the blood-brain barrier is impermeable to large molecules (plasma proteins) but is only minimally permeable to most ions. It is freely permeable to water, however. The tonicity of the intravascular fluid, determined by its sodium concentration, influences the movement of free water across the blood-brain barrier by creating an osmotic pressure gradient between the brain interstitium and the intravascular space. In TBI the blood-brain barrier may be damaged, often producing heterogeneous regions of varying degrees of blood-brain barrier integrity and permeability. Unfortunately, demonstrating and predicting the extent of such injury in clinical patients is very difficult; the clinician often likely has to assume the presence of normal brain and functional blood-brain barrier regions for certain principles of fluid management, such as osmotherapy, to be effective.[5]

Hypotonic crystalloids, such as 5% dextrose in water or 0.45% saline solutions, are contraindicated in TBI patients. They lower plasma osmolarity and result in excess free water diffusion into the brain, with subsequent cerebral edema formation. Hypotonic fluids should be avoided for rapid volume replacement in patients with brain injury.

Isotonic crystalloids, such as 0.9% saline, LRS, and Normosol-R, create a minimal to no osmotic gradient across the blood-brain barrier, are readily available and inexpensive, and are therefore the current fluids of choice for replacement and maintenance therapy in brain and spinal cord injury patients.

Hypertonic crystalloids, such as 7.5% saline, create an osmotic gradient across the blood-brain barrier in favor of free water movement out of the brain, thereby reducing ICP. Hypertonic fluids are indicated *only after adequate provision of intravascular fluid volume* in horses with signs of elevated ICP or deteriorating neurologic status and are discussed in more detail in the following section on hyperosmolar therapy.

Colloids—such as plasma, human albumin, and the synthetic agents hetastarch, pentastarch, and dextran—exert variable oncotic pressures and are very effective for intravascular volume expansion and maintenance. The use of colloid solutions in neurologic injury is debatable, mainly because the major determinant of fluid flux across the blood-brain barrier is plasma osmolarity; because colloids contribute only a small number of particles in plasma, even large changes in plasma colloid oncotic pressure only minimally influence water movement across the normal blood-brain barrier. This is in contrast to the effectiveness of even small changes in plasma osmolarity.[6] In addition, the relatively higher cost of colloid solutions and the greater risk of development of hemostatic abnormalities and allergic reactions suggest little benefit of colloid solutions over crystalloids in cases of TBI. The exception is when they are used in combination with crystalloids for fluid volume expansion, provided that hydrostatic pressures are not increased excessively as a result of the colloid infusion.[4]

HYPEROSMOLAR THERAPY IN BRAIN AND SPINAL CORD INJURY. Hyperosmolar therapy is the pharmacologic induction of supraphysiologic serum osmolality with either hypertonic saline or mannitol and is the mainstay of medical management of patients with intracranial hypertension (ICP > 20 mm Hg) associated with TBI and intracranial haemorrhage.[7] If clinical evaluation of the equine patient with TBI suggests the patient has, or is at risk for developing, intracranial hypertension, then osmotherapy may be indicated. Clinical signs such as obtunded mentation, progressive mydriasis, or any deterioration of neurologic status may indicate increased intracranial hypertension. Hyperosmolar solutions exert their effect of reducing ICP by creating an osmotic gradient across the blood-brain barrier of at least 10 mOsm/L. It is advisable to measure plasma osmolarity in large animal patients, at least before administration of hyperosmolar solutions, to avoid excessive increases in plasma osmotic pressure. Osmotherapy should be instituted only after restoration of adequate intravascular volume and blood pressure if CPP is to be optimized.

The two most commonly used and available hyperosmolar solutions for use in large animals are mannitol (20%) and hypertonic (3% to 7.5%) saline. Both agents have been shown to be effective in lowering ICP in human TBI patients, although more recent meta-analysis of the literature suggests greater efficacy and fewer side effects with the use of hypertonic saline.[7,8]

Mannitol (20%) is a six-carbon sugar with an osmolarity of 1098 mOsm/L. The recommended dose is a 0.5- to 1.5-g/kg IV bolus administered over 20 to 30 minutes, every 6 to 8 hours. It is important to avoid rapid mannitol infusion (<5 minutes) since this can lead to transient hypotension. The ICP-reducing effects of hyperosmolar solutions are believed to be biphasic in nature. After bolus dose administration, an initial plasma-expanding effect reduces blood

VetBooks.ir

viscosity and hematocrit and improves rheologic properties of red blood cells, resulting in reduced ICP and improved CBF. After this immediate hemodynamic effect is a delayed osmotic diuretic effect resulting from the decreased reabsorption of sodium and water by the renal tubules, which also contributes to ICP reduction. Onset of effect of mannitol therapy is 15 to 30 minutes after bolus administration. Mannitol should not be administered as a continuous infusion for the purpose of treating cerebral edema, since it loses its plasma-expanding effects and increases the likelihood of development of side effects.[9]

The detrimental effects of mannitol are more likely to develop and become clinically significant with excessive or prolonged use (>2 to 3 days). Side effects include hypovolemia and hypotension caused by excessive diuresis, electrolyte disturbances (e.g., hyponatremia, hypochloremia, hypokalemia, hypocalcemia), acidosis, acute renal failure, and a rebound increase in ICP associated with reversal of the osmotic gradient, a phenomenon most likely explained by accumulation of the osmotic agent in brain tissue after movement across regions of damaged blood-brain barrier.[9] A threshold level of serum osmolarity of 320 mOsm is often used as an indicator for decrease or withdrawal of mannitol therapy. However, serum osmolarity is not a sensitive indicator of mannitol-induced renal failure, and the osmolar gap (the difference between calculated and measured serum osmolarity) is more reflective of serum mannitol accumulation. Based on this, an osmolar gap threshold of 55 mOsm/kg has been suggested for monitoring mannitol therapy in TBI.[7] There is insufficient evidence to support the dogma that mannitol is contraindicated in the presence of intracranial hemorrhage.

Hypertonic (7.5%) saline has an osmolarity of 2400 mOsm/L and, similarly to mannitol, effectively reduces ICP primarily through an immediate hemodynamic effect, followed by a delayed osmotic effect. Hypertonic saline can be administered as an intravenous bolus dose (4 mL/kg) or as a CRI. There are no clear guidelines as to the optimal concentration (3% to 23.4%) or dose of hypertonic saline in human patients with TBI. However, effective CRI dosing has been achieved in human patients using 3% hypertonic saline at 0.1 to 2.0 mL/kg/h, titrating to serum sodium concentrations of 145 to 155 mmol/L, and not exceeding serum osmolarity of 360 mOsm/L.[7] Hypertonic saline may have additional beneficial effects over mannitol in TBI because of rapid augmentation of cardiac output, contractility, and MAP with administration of smaller volumes. In addition, hypertonic saline is theoretically less likely to cross the blood-brain barrier than mannitol because the reflection coefficient of NaCl is 1 (not permeable), compared with 0.9 for mannitol (more permeable). Additional benefits of hypertonic saline on the injured brain include Na-related stabilization of cell membrane electrochemical gradients and modulation of the inflammatory response.[10]

Laboratory studies investigating the effect of hypertonic saline in resuscitation after spinal cord injury have also shown promising results, with increased spinal cord blood flow, downregulation of the inflammatory response, and attenuation of spinal cord injury.[11] Further clinical studies are needed.

Complications of hypertonic saline are uncommon and include hypernatremia and theoretical development of central pontine myelinolysis.[7] Hypokalemia can occur because of kaliuresis in response to reabsorption of large amounts of Na in the distal tubule, as well as hyperchloremic acidosis, emphasizing the importance of regular assessment of hemodynamic and plasma electrolyte and acid-base status. Coagulopathy and bleeding complications could occur as a result of dilutional effects but are of more concern in the actively bleeding patient. Risk of hypovolemia and acute renal failure are not reported for hypertonic saline in TBI, although renal insufficiency is a relative contraindication to all hyperosmolar therapy. Rebound elevations in ICP can occur with withdrawal of therapy; therefore, slow, gradual weaning of hypertonic saline infusions is recommended.[7]

Osmotherapy is likely to be most effective if initiated early (after isotonic fluid replacement) following TBI and with duration determined by response to therapy, with close observation and monitoring of neurologic status, serum electrolytes, acid-base, osmolarity, and renal function, to minimize development of side effects. Because measurement of intracranial pressure is not practical to perform routinely in equine patients with TBI at this time (it has been measured in a research setting), the efficacy of, and optimal recommendations for, hyperosmolar therapy in equine patients with TBI are unknown and based on the human medical literature.

FLUID ADDITIVES IN NEUROLOGIC INJURY

Glucose. It has been widely recognized that hyperglycemia is a common occurrence in acute brain injury in humans.[12] Hyperglycemia is believed to worsen neuronal injury and is associated with increased mortality and neurologic outcomes after TBI.[12,13] Consequently, glucose supplementation during large-volume fluid replacement should be avoided, unless the patient is hypoglycemic.

It has not been determined whether hyperglycemia after TBI is a physiologic reflection of the response and severity of injury, or if it contributes to the progression of secondary brain injury. Nevertheless, in ischemic brain tissue aerobic metabolism is impaired and excess glucose leads to lactate accumulation and intracellular acidosis via anaerobic metabolism; this can contribute to a proinflammatory and prooxidant state, thereby potentially worsening neurologic injury and increasing cell death.[7] Tight glycemic control (80 to 110 mg/dL) with the use of insulin had become commonplace for critically ill human patients worldwide. A beneficial effect of reducing blood glucose with insulin therapy in human patients with TBI has been suggested.[14] However, patients with traumatic brain injury present a more unique situation, since the brain is dependent on a constant supply of glucose for continued aerobic energy production. An increase in energy demand by the brain, such as during seizure activity, may result in metabolic crisis that contributes to secondary brain injury. Therefore, it is also crucial to avoid hypoglycemia in TBI patients. Although there are no studies in horses with TBI to enable recommendations regarding the best management of glucose to be made, recent human medical studies have shown that tight glycemic control after TBI is potentially detrimental due to increased regional glucose metabolism in the brain, leading to enhanced metabolic crisis.[15] It is currently suggested that delivery of more glucose through mild hyperglycemia (120 to 150 mg/dL) may be necessary following TBI.[15] This is more in line with the revised glucose control guidelines of maintenance of blood glucose concentrations 180 mg/dL or less in critically ill patients (not just brain injured) rather than 80 to 110 mg/dL, in order to avoid hypoglycemia.[16]

These factors should be considered in the monitoring and fluid therapy plan for any large animal with neurologic injury, particularly neonates, since they are more susceptible to hypoglycemia.

Thiamine. Thiamine (vitamin B_1) is a water-soluble B vitamin synthesized only by plants and microorganisms. Most animals have a nutritional requirement for this vitamin, although adult ruminants and horses normally can obtain adequate quantities produced by bacteria in the rumen or cecum.

Thiamine, in its active form (thiamine pyrophosphate), plays a very important role in glucose metabolism and energy production, where it functions as a required cofactor for certain enzymes (pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, branched-chain ketoacid dehydrogenase, transketolase) involved in glycolysis, the citric acid cycle, and the pentose phosphate pathway. Thiamine is also important in nerve and muscle function, where it plays a role in neurotransmission and excitation.

Thiamine deficiency is known to be associated with neurologic disease in humans and in ruminants (polioencephalomalacia). Determination of thiamine status of an animal requires measurement of red blood cell transketolase activity; therefore, measurement and documentation of thiamine deficiency in clinical cases is not routinely reported. Whether or not supplementation of thiamine in acute traumatic neurologic injury is indicated is not currently supported by published evidence. However, given the increased susceptibility of damaged neuronal tissue to inadequate energy production and supply, the practice of thiamine supplementation in

VetBooks.ir

neurologic injury in large animals appears justified. In addition, recent experimental investigation suggests a potential neuroprotective role of thiamine in reactive oxygen species–induced neuronal injury.[17] The author (DJF) has used a dose of 5 to 10 mg of thiamine per kilogram diluted in crystalloids. Thiamine should be protected from light.

Electrolytes. Sodium disturbances can have serious consequences in brain injury and should be corrected promptly if they are acute (<24 hours' duration). Isotonic fluid administration is appropriate in the majority of cases. Glucose and mannitol cause translocation of water into the extracellular fluid, and excessive amounts can lead to a clinically significant reduction in sodium concentration, as can free water administration with hypotonic fluids. If hyponatremia ($Na^+ < 125$ mEq/L) is believed to have been present for longer than 24 hours, slower correction (0.5 mEq/L/h) is needed to avoid development of central pontine myelinolysis.

Calcium is essential in maintaining cell membrane potentials and promoting neurotransmitter release. Excessive intracellular calcium accumulation is also well recognized as one of the most important pathways of secondary neuronal damage. During conditions of cerebral or spinal cord ischemia, inadequate energy supply in the form of adenosine triphosphate (ATP) leads to widespread neuronal depolarization and alterations in ion channel permeability, ultimately resulting in excessive intracellular calcium concentrations and cell death.

Serum total and ionized calcium concentrations are measures of extracellular calcium, and so the goal of targeting intracellular calcium homeostasis is limited to maintaining normal extracellular fluid concentrations at this time. Because of the known toxic effects of excessive calcium in neuronal injury, a conservative approach to calcium supplementation may be justified in the acute fluid management of large animal patients. In order to prevent the detrimental effects of hypocalcemia, one approach may be to avoid the addition of calcium to the intravenous fluids over the initial 24 to 48 hours unless the ionized calcium concentration is less than 1.0 mmol/L or clinical signs of hypocalcemia are present.

Magnesium is an important cofactor in many enzymatic reactions and for the regulation of sodium and potassium transport across cell membranes through activation of the Na-K ATPase pump. Magnesium is essential for central nervous system cellular energy metabolism, modulation of excitatory amino acid transmission, and calcium channel antagonism. After neurologic injury, disruptions in the blood-brain barrier may impair regulation of CSF magnesium concentrations, and hypomagnesemia is commonly recognized in human patients with brain injury.[18] Experimental and clinical evidence suggests that a depletion of CSF magnesium concentrations is associated with the risk of secondary neurologic injury.[19] Animal studies also suggest a neuroprotective effect of intravenous magnesium administration after traumatic brain injury.[20] However, studies in human patients with TBI have failed to show a consistent therapeutic effect of magnesium supplementation.[19] Although magnesium supplementation for the treatment of TBI in equine patients cannot be recommended at this time, it would seem important to monitor serum total and ionized magnesium concentrations to prevent and treat hypomagnesemia after neurologic injury. Selection of intravenous fluids containing magnesium, such as Normosol-R ($Mg^{2+} = 3$ mEq/L) may be beneficial.

Other electrolyte disturbances identified commonly in patients with neurologic injury include hypokalemia and hypophosphatemia. A combination of decreased dietary intake and increased renal loss as a result of diuretic therapy is a likely explanation. Because of the important role of potassium in establishing normal resting membrane potential and nerve conduction, among other functions, regular monitoring and intravenous fluid supplementation if serum potassium concentration decreases to less than 3.0 to 3.2 mEq/L is indicated in large animal patients with neurologic injury.

Serum phosphate concentrations are not as routinely monitored as other electrolytes in large animal patients, and so deficiency is rarely reported. Clinical signs of hypophosphatemia usually do not manifest until serum concentrations fall below 1 mg/dL in humans and animals. It is important to recognize phosphate deficiency in patients with recent neurologic injury because it can cause or contribute to altered mental status, muscle weakness, seizures, respiratory insufficiency, and ventricular dysrhythmias. Because clinical manifestations of hypophosphatemia have not been reported in horses, it is difficult to make recommendations for supplementation. I have used a dose of 0.01 mmol/kg/h of sodium phosphate when marked hypophosphatemia has been present in horses.

Fluid Therapy for Horses with Rhabdomyolysis (Box 44-7)

K. Gary Magdesian

Horses with severe rhabdomyolysis are at risk for renal failure from myoglobinuria and hypovolemia. Myoglobin causes formation of tubular casts (with resultant tubular obstruction) by precipitation with secretory proteins from the tubular cells. It is also directly toxic through release of iron and formation of free radicals. Finally, myoglobin leads to release of platelet activating factor and endothelins that lead to renal arteriolar vasoconstriction. In addition, horses and foals with severe rhabdomyolysis may develop marked electrolyte derangements from cell lysis, including hyponatremia, hypochloremia, hyperkalemia, and hyperphosphatemia.[1,2] In one study evaluating the electrolyte changes in horses with acute rhabdomyolysis, the most consistent abnormality was hypochloremia.[1] These changes have been reported in foals with rhabdomyolysis as a consequence of selenium deficiency with or without vitamin E deficiency, possibly combined with increased oxidant stress resulting from sepsis or hypoxia and reperfusion injury after parturition.[2] Three of four foals developed cardiac arrhythmias characterized by spiked T wave and decreased P wave amplitude on electrocardiographic analysis. Destruction of the major intracellular fluid compartment through extensive myonecrosis, combined with myoglobinuric renal insufficiency, produces major fluid shifts and electrolyte derangements. In this report, foals with hyperkalemia caused by rhabdomyolysis were effectively treated with mineralocorticoids, loop diuretics, and ion exchange resins to enhance elimination of potassium. Intravenous calcium, glucose, insulin, and sodium bicarbonate were also administered to help redistribute potassium back to the intracellular fluid.[2]

Metabolic acidosis is not common in horses with acute rhabdomyolysis, and alkalosis associated with hypochloremia may be more of a concern.[1] In fact, fluids with relatively higher chloride concentration as compared with horse plasma may be optimal when hypochloremia is present. These include LRS (chloride, 109 mEq/L). If LRS is used, attention should be paid to serum or plasma potassium concentrations, because LRS contains potassium chloride in the amount of 4 mEq/L of potassium (see Table 44-1). LRS might be preferable over acetate-containing fluids such as Normosol-R or Plasma-Lyte 148 in acute rhabdomyolysis cases because the liver is the primary organ of lactate metabolism, whereas the muscle tissue plays a larger

BOX 44-7

Fluid Considerations for Horses with Rhabdomyolysis

1. Horses with acute myopathies often exhibit hypochloremia and may have concurrent hyponatremia, hyperkalemia, and hyperphosphatemia, especially when the rhabdomyolysis is severe.
2. Lactated Ringer solution is a fluid with a physiologic basis for use with rhabdomyolysis.
3. Horses with acute myopathies should be administered fluids at a rate greater than maintenance requirements in order to provide for dilution and diuresis of myoglobin.

VetBooks.ir

role in metabolism of acetate. In addition, the chloride concentration of these acetated fluids is lower than that of LRS, which may be a slight disadvantage if horses have metabolic alkalosis resulting from hypochloremia. Lactate in LRS does not preclude its use in hyperlactatemic horses with muscle disorders, because hepatic metabolism of lactate occurs rapidly once plasma volume is expanded. In addition, lactate is not necessarily markedly increased in horses with rhabdomyolysis.[3]

LRS is preferred over normal saline for treatment of humans with rhabdomyolysis.[4] In a randomized blinded study of humans with rhabdomyolysis, urine and plasma pH was higher in the LRS group, whereas serum sodium and chloride concentrations were higher in the saline group.[4] Unlike the saline group, the LRS group needed little supplemental sodium bicarbonate and did not develop metabolic acidosis. Acidic urine favors formation of myoglobin-induced tubular casts and tubular obstruction. Therefore, LRS is considered by many to be the fluid of choice to maintain adequate urine flow in patients with rhabdomyolysis. One potential disadvantage of LRS in treatment of rhabdomyolysis is the presence of a low concentration (3 mEq/L) of calcium. Calcium influx plays a role in cell lysis after lipoperoxidation of muscle cells. How these data apply to adult horses, which generally have alkaline urine, requires further study. Because 0.9% saline is mildly acidifying in horses as well, it likely is not the optimal fluid choice for horses with rhabdomyolysis either. As foals often have acidic urine, LRS may be a good fluid choice for foals with rhabdomyolysis as well.

In addition to crystalloid support, sodium bicarbonate is recommended for human rhabdomyolysis only if necessary to correct a systemic metabolic acidosis.[5] Mannitol is administered to maintain urine output (300 mL/h or greater urine output in adult humans).[5]

Hereditary causes of rhabdomyolysis in horses include polysaccharide storage myopathy, glycogen branching enzyme deficiency, and recurrent exertional rhabdomyolysis (RER).[6-8] Because an alteration in muscle cell calcium regulation is a primary feature in the pathophysiology of RER, calcium supplementation of fluids administered to affected horses should be avoided.[9] Serum potassium concentrations should be monitored frequently in horses with rhabdomyolysis because of risks associated with hyperkalemia.

Because horses with acute rhabdomyolysis are at risk for renal failure, rates of fluid administration should exceed maintenance requirements to provide diuresis and dilution of urine myoglobin concentration. In adult human patients with rhabdomyolysis, the goal of urine production is greater than 300 mL/h.[5] Myoglobin is nephrotoxic directly to renal tubular epithelium, as well as indirectly causing renal arteriolar vasoconstriction and secondary hypoperfusion. Rates of fluid administration vary with individual fluid balance and renal function, but 1.5 to 2 times maintenance requirement is a reasonable starting point. The rate can be adjusted based on the rate of creatine kinase (CK) decline and resolution of myoglobinuria.

Fluid Therapy for Hyperkalemic Periodic Paralysis (Box 44-8)

K. Gary Magdesian

Hyperkalemic periodic paralysis (HYPP) is caused by a genetic defect in the sodium channel on the sarcolemma, resulting in intermittent signs of sweating, muscle fasciculations, stridor, and weakness.[1] Stressors such as anorexia, anesthesia, concurrent illness, trailering, and cold environmental temperatures can precipitate hyperkalemia and onset of clinical signs. Fluid therapy for horses with hyperkalemia should be low or free of potassium. Physiologic (0.9%) saline and isotonic sodium bicarbonate (1.3%) are both potassium-free options. Note that these two fluid types have potential effects on acid-base physiology, with saline producing a mild strong ion acidosis and sodium bicarbonate a metabolic alkalosis. Another option for horses without acid-base disturbances is to combine commercial balanced polyionic fluids, such as LRS or Normosol-R, with one of these fluids (i.e., hanging one bag of each), as long as the horse is not experiencing hyperkalemia at the time. This would dilute the potassium administered from the LRS (4 mEq/L) or Normosol (5 mEq/L) and would minimize the effects of saline or sodium bicarbonate on acid-base balance.

Horses experiencing stressors such as forced withholding of feed before surgery or being off feed because of concurrent illness should be administered fluids with dextrose and/or calcium supplementation prophylactically at a maintenance rate. These dextrose supplementations (2.5%) may minimize the development of hyperkalemia and subsequent HYPP episodes. Calcium does not decrease serum potassium concentrations but rather protects the heart from its adverse effects by raising threshold potential. Horses experiencing an active episode of hyperkalemia or showing clinical signs of HYPP should be administered 0.9% saline as the fluid choice, with the additives of calcium (0.2 to 0.5 mEq/kg of 23% calcium gluconate diluted as 50 mL 23% calcium gluconate/L or less of fluid) and dextrose (2.5% to 5% for provision of 0.5 to 2 mg of dextrose per kilogram per minute. If signs persist, a second bag with sodium bicarbonate (1 mEq/kg of bicarbonate empirically) and dextrose should be added. Calcium and sodium bicarbonate should not be administered concurrently in the same fluid administration set because of a potential for precipitation. LRS also contains calcium, and therefore sodium bicarbonate should not be added directly to it. Administration of two 5-L bags of saline to a 500-kg horse, with 2.5% to 5% dextrose, with the first bag containing calcium (250 mL of 23% calcium gluconate total) and the second containing sodium bicarbonate (1 mEq/kg of bicarbonate) given sequentially, is a reasonable approach to treating an acute episode. Some horses may not require this volume of crystalloid and can be treated with less; if less volume is desired, 4 to 6 mL of saline per kilogram can be administered. Dextrose, calcium, and sodium bicarbonate can be added to 1-L bags; the sodium bicarbonate and calcium must be kept separate from one another. In this case 5% dextrose, 0.2 mL/kg of 23% calcium gluconate (in first 1-L bag), and 5% dextrose, 0.5 mEq/kg of bicarbonate can be used (in second 1-L bag).[1]

Long-term management of horses with HYPP consists of a low-potassium diet, regular exercise, attempts to minimize stressors, and medications such as acetazolamide and phenytoin.[2] Horses undergoing chronic acetazolamide therapy could theoretically develop hyperchloremia and a tendency toward metabolic acidosis because of the effects of long-term inhibition of carbonic anhydrase. Administration of large volumes of 0.9% saline can compound hyperchloremia[3]; to minimize acidemia, it can be coadministered with isotonic sodium bicarbonate or other alkalinizing crystalloid when such horses require large volume or long-term fluid therapy devoid of or low in potassium. Phenytoin can mask the clinical signs of HYPP, even when hyperkalemia is present; it must be emphasized that phenytoin should not be the sole prophylactic medication in these horses, because hyperkalemia may be left unchecked.[2]

BOX 44-8

Fluid Guidelines for an Acute Hyperkalemic Periodic Paralysis Episode

1. 4 to 20 mL of 0.9% saline per kilogram, depending on severity and duration.
2. 2.5% to 5% dextrose.
3. 0.2 to 0.5 mEq of calcium per kilogram (0.2 to 0.5 mL of 23% calcium gluconate per kilogram total); calcium should be administered early (along with dextrose) since it is protective against arrhythmias.
4. 1 mEq of bicarbonate per kilogram in second bag along with dextrose. Note sodium bicarbonate and calcium should not be mixed in same bag.
5. For refractory cases: insulin can be added to dextrose supplementation (regular insulin, 0.005 to 0.1 unit/kg/h).

Fluid Therapy for Competitive Endurance Horses

C. Langdon Fielding

Approximately 4% to 9% of endurance horses are eliminated from competition for metabolic reasons that include colic, rhabdomyolysis, synchronous diaphragmatic flutter, and exhaustion.[1,2] Veterinarians are responsible for the emergency treatment of horses with metabolic derangements, and fluid therapy is an essential component of the therapeutic management of critically ill endurance horses.

GENERAL APPROACH TO FLUID MANAGEMENT OF ENDURANCE HORSES. Endurance horses experience significant fluid losses during competition; even horses successfully completing rides lose approximately 5% of body weight in water.[3,4] Horses presented for treatment of metabolic problems often exhibit clinical signs of hypoperfusion. In evaluating sick endurance horses, the seven clinical perfusion parameters should be evaluated:

1. Mentation
2. Heart rate
3. Pulse quality
4. Mucous membrane color
5. Capillary refill time
6. Extremity temperature
7. Jugular fill

Urine production, when apparent, can be used as an additional perfusion parameter. In the absence of polyuric renal failure, urine output signifies renal perfusion, which is one means of assessing organ perfusion. Horses with altered mentation, persistent tachycardia (>60 bpm), poor peripheral pulse quality, pale mucous membranes, capillary refill time greater than 2 seconds, cool extremities, or lack of urine production should be considered candidates for fluid therapy. Laboratory parameters consistent with dehydration such as increased PCV, increased total protein, and increased serum creatinine have been identified in endurance horses at risk for metabolic failure.[5]

The rapid administration of large volumes of crystalloids is the basis of treatment at many ride events. Volume loading increases preload, thereby enhancing stroke volume, cardiac output, and subsequent oxygen delivery. One suggested protocol for fluid resuscitation of hypovolemic endurance horses is the fluid challenge method described earlier; this consists of a bolus dose of 20 mL of isotonic crystalloid per kilogram (10 L for an average, 500-kg horse) followed by reassessment of the seven perfusion parameters. If the parameters have not improved in response to the initial bolus, another 20-mL/kg bolus should be administered and followed by clinical reassessment. Approximately 1 hour is required to administer a 10-L bolus through a 14-gauge intravenous catheter and standard administration set; multiple catheters or those with large bores (10 gauge) can be used for more rapid administration. The majority of endurance horses requiring emergency intravenous fluid administration during competition typically require 20 to 30 L of fluids.[6,7] However, more severely affected horses may require up to 40 to 60 L of crystalloids to address hypovolemia.

Several types of intravenous crystalloids are available for administration to endurance horses. LRS and Normosol-R are balanced polyionic crystalloids commonly administered to treat hypovolemia in these horses. Specific electrolyte abnormalities may dictate the use of isotonic saline (when hypochloremic alkalosis is present) or fluid additives (potassium chloride or calcium gluconate when hypokalemia or hypocalcemia is identified, respectively). However, in one study, 0.9% sodium chloride resulted in hyperchloremia when administered to eliminated endurance horses.[6] The electrolyte and serum biochemistry profiles of endurance horses that fail to finish a race are not necessarily markedly abnormal and allow the use of commercial fluids such as LRS and Normosol R.[4] A range of electrolyte abnormalities have been identified in competing endurance horses and include hypokalemia and an increased strong ion difference (SID).[8,9] Calcium supplementation is common during fluid therapy of eliminated endurance horses. However, results of studies examining the concentration of total and ionized serum calcium in horses during endurance rides have been equivocal as to calcium status.[3,4,10] If calcium is used, it can be added to fluids through the use of calcium gluconate (1 mL of 23% calcium gluconate per kilogram at a rate of 50 mL of crystalloid per liter). Calcium supplementation is required in horses with synchronous diaphragmatic flutter and should be administered until clinical signs resolve.[11] Excessive use of calcium in endurance horses may not be warranted, since it plays a role in cell death and apoptosis, particularly with reperfusion injury; supplementation of calcium in humans with rhabdomyolysis is controversial.[12]

Endurance horses with prolonged ileus or anorexia may benefit from dextrose supplementation of fluids. A dose of 1 mg/kg/min of dextrose is well tolerated by most adult horses and is equivalent to 3% dextrose in fluids administered at a rate of 1 L/h for a 500-kg horse. Ideally, blood glucose concentrations should be monitored in horses administered dextrose to avoid hyperglycemia.

Medications commonly used in the treatment of endurance horses with metabolic derangements may affect fluid balance and should be considered in horses receiving fluid therapy. Sedatives and tranquilizers such as α_2-agonists (xylazine, detomidine, romifidine) and phenothiazines (acepromazine) have deleterious effects on cardiac output and/or blood pressure.[13,14] Drugs such as dimethyl sulfoxide (DMSO) and α_2-agonist sedatives also affect urine output and can therefore alter fluid balance.[15,16]

The following metabolic conditions are common metabolic disorders of endurance horses.

EXERTIONAL MYOPATHY. Intravenous fluid therapy is the most important feature of treatment for rhabdomyolysis. The reader is referred to the Fluid Therapy for Horses with Rhabdomyolysis section. Fluids should be administered in 10-L (20-mL/kg) boluses until urine output is achieved and the urine is grossly clear. Low doses of flunixin meglumine (0.5 mg/kg IV) are indicated for inflammation once hypovolemia is resolved and diuresis is achieved. Adequate fluid resuscitation is indicated before release of affected horses because exertional rhabdomyolysis has been associated with severe renal failure in both humans and horses.[17,18] Horses with myopathies should be monitored closely and reevaluated within 48 hours for azotemia and progress of increased muscle enzymes.

FAILURE TO RECOVERY. Horses that are eliminated from ride events because of persistent tachycardia warrant close monitoring. Such horses often require treatment at a later time. The seven clinical perfusion parameters should be evaluated thoroughly, and any animal with equivocal circulatory or hydration status should be reevaluated frequently to make sure that it is improving through voluntary eating and drinking, rather than deteriorating further. Those with clear hypovolemia or failure to improve with rest should be administered intravenous fluids as described earlier.

SYNCHRONOUS DIAPHRAGMATIC FLUTTER (THUMPS). Synchronous diaphragmatic flutter is typically associated with hypocalcemia, and concurrent metabolic alkalosis, hypochloremia, and hypokalemia are often also present and have been implicated in its development.[19] Many affected horses are otherwise stable hemodynamically and meet all the criteria for adequacy of perfusion. Despite these findings, horses with thumps often require treatment with intravenous fluids supplemented with calcium for resolution of hypocalcemia and clinical signs. Calcium gluconate can be added to 5-L bags of crystalloid (0.5 mL of 23% calcium gluconate per kilogram per 5-L bag), and fluids with dilute calcium can be administered as a bolus. Adverse effects of rapid calcium administration include bradycardia and warrant slow administration. Many mildly affected horses would likely resolve synchronous diaphragmatic flutter with oral electrolytes and/or the consumption of feed (particularly alfalfa).

VetBooks.ir

COLIC. Colic is a common problem identified in eliminated endurance horses and can result in significant mortality.[20] All horses exhibiting signs of colic should have a nasogastric tube passed as nasogastric reflux (likely resulting from ileus) is a common finding in these horses.[20] Intravenous fluids should be administered as outlined previously until the horse is no longer producing gastric reflux and the horse is passing manure regularly. Flunixin meglumine (0.5 to 1 mg/kg) can be administered intravenously once hydration is restored. Calcium gluconate can be added to 5-L bags of crystalloid (0.5 mL of 23% calcium gluconate per kilogram per 5-L bag), and fluids with dilute calcium can be administered as a bolus. Managing endurance horses with colic can be challenging because many show significant levels of pain. It is important to remember that endurance horses with colic rarely have a surgical lesion and typically respond to aggressive medical therapy.[9,20]

Fluid Therapy for Burn (Thermal) Injury in Horses (Box 44-9)

K. Gary Magdesian

Horses with severe burn injuries develop hypovolemic shock and require large volumes of balanced electrolyte replacement fluids.[1] Hypertonic saline and colloids may also be used but should be followed with isotonic crystalloids. In humans with burn injuries, the guidelines for rate of administration of isotonic fluids is 2 to 4 mL/kg for each percentage of surface area burned (Parkland formula).[2] A retrospective study found that significantly larger volumes of fluid (i.e., 5.58 mL/kg per percent total body surface area affected) were administered to patients during the first 24 hours of hospitalization than was predicted by the Parkland formula.[3] If smoke inhalation has occurred, the affected horse is at risk for pulmonary edema. In this case, fluid deficits should be corrected but not exceeded. Administration of excess crystalloids or high rates of fluids after resolution of hypovolemic shock will result in edema, which is detrimental to healing of burned tissues and potentially smoke-injured lungs. Once hydration is adequate, fluid therapy should be discontinued (if drinking) or administered at a rate necessary only to maintain hydration status. If maintenance rates of fluids are required, patients with severe burns may require more sodium than provided for by commercial maintenance fluids owing to the tremendous sodium losses through wounds.[4] In these cases, isotonic to slightly hypertonic (1.8%) crystalloids may be required.[5] Excess free water should be avoided in these patients, since it can promote intracellular tissue edema.[5]

An important component of fluid therapy of the thermal injury patient is the administration of plasma. Significant amounts of plasma proteins are lost through cutaneous burns.[4] In addition, burn patients are at risk for coagulopathies, although this has been reported to be rare.[6] Plasma transfusions are an effective source of albumin, as well as antithrombin for coagulopathies. Horses with significant burns can require large volumes of plasma in the first 2 to 3 days. A CRI of plasma can be provided when ongoing losses are present.

BOX 44-9

Fluid Guidelines for Burn Injury Patients

1. Hypertonic saline can be used in the resuscitative phase of burn patients but should be followed with isotonic crystalloids.
2. Colloids can be used in conjunction with or in place of hypertonic saline during fluid resuscitation.
3. Isotonic to slightly hypertonic (1.8%) crystalloids are often necessary because of tremendous sodium losses through burn wounds.
4. Plasma is an important component of fluid therapy in the severely burned patient because of the potential for protein loss.
5. Administration of excessive volumes of fluids should be avoided because edema is a common complication of burn injuries.

Fluid Therapy for Acute Respiratory Distress Syndrome in Horses (Box 44-10)

K. Gary Magdesian

ARDS presents a therapeutic challenge; because of altered Starling's forces (increased vascular permeability) in the pulmonary capillaries, affected horses and foals often have significant pulmonary edema, with protein-rich fluid.[1] Pulmonary capillary hydrostatic pressure becomes the main determinant of edema in these patients owing to the increased permeability of pulmonary capillaries.[2] Despite this propensity toward edema formation, horses and foals with ARDS should not be allowed to develop dehydration. Maintenance of normal blood volume and hydration status is critical to tissue oxygenation, including the diseased pulmonary tissue. The goal in therapy of ARDS patients is to reduce extravascular lung water while still maintaining hemodynamic stability and perfusion. In a human clinical trial, conservative fluid management in patients with ALI improved lung function and shortened duration of mechanical ventilation and intensive care as compared with patients managed with a liberal fluid strategy, although there was no difference in mortality.[3] The conservative management did not increase nonpulmonary organ failures.[3] It should be noted that the patients in this study were volume replete and relatively stable hemodynamically. Conservative fluid therapy therefore applies to the post-resuscitation phase of these patients, when administration in excess of physiologic needs can be detrimental.

Large swings in pulmonary vascular pressures should be avoided to minimize increases in pulmonary hydrostatic pressure. To avoid these wide fluctuations, intravenous fluids should be provided as a continuous infusion rather than as intermittent boluses.[4] The ideal type of fluid for volume replacement at the time of initial therapy of ARDS patients is unknown; however, colloids should be used judiciously owing to the theoretical risk of potentiating pulmonary edema through extravasation of colloids across the leaky pulmonary vasculature. This concern warrants further study; one study demonstrated no increase in transmicrovascular flux of radiolabeled colloids when COP was raised with albumin administration in human patients with pulmonary edema.[5] Isotonic crystalloids, administered at a modest rate and only to effect in normoproteinemic patients, and replacement of plasma proteins in hypoproteinemic patients are probably the safest fluid guidelines for these patients with the current level of understanding.

Patients with ALI or ARDS should be monitored closely for hypoproteinemia. Correction of hypoproteinemia in human patients with ALI benefits from concurrent administration of albumin.[6] Hypoproteinemic patients receiving both furosemide (as a CRI) and albumin had improved oxygenation, increased net fluid loss, and better maintenance of hemodynamic stability compared with those receiving only furosemide.[6] In addition, 50% of patients in the treatment group

BOX 44-10

Fluid Guidelines for Acute Respiratory Distress Syndrome

1. The ideal initial resuscitative fluid choice for acute respiratory distress syndrome (ARDS) patients is unknown, but crystalloids should probably be used rather than colloids because of the risk for compounding pulmonary edema as colloids leak into lungs. The exception would be the hypoproteinemic patient, in which plasma should be used to correct albumin deficits.
2. Hypovolemia and dehydration should be corrected, but excessive fluid volume should be avoided to minimize worsening of edema. A conservative long-term fluid plan is warranted.
3. Fluid balance in patients with ARDS should be assessed frequently; central venous pressure is a useful means of monitoring fluid balance to prevent large increases in capillary hydrostatic pressure.

VetBooks.ir

achieved resolution of the ALI or respiratory distress syndrome, compared with only 11% of controls. Consideration should be given to correction of hypoproteinemia in foals and horses with ARDS or ALI. An additional benefit of albumin is its antioxidant properties. Albumin can also reduce microvascular permeability and endothelial cell apoptosis.[7-9]

Monitoring of fluid therapy in these patients is especially important in order to avoid marked increases in pulmonary hydrostatic pressure. This can be accomplished through measurement of pulmonary capillary wedge pressure; however, this requires placement of an intracardiac catheter. Alternatively, CVP can be measured. This is easily performed through central lines—those placed in the cranial vena cava. In a study comparing the use of pulmonary artery catheters with that of central venous catheters in guiding treatment of ALI in humans, it was found that pulmonary catheter–guided therapy did not improve survival or organ function and was associated with more complications than central venous catheter–guided therapy.[10] The predominant catheter-related complication was development of arrhythmia. It was concluded that pulmonary catheters should not be routinely used for the management of ALI.[10]

Fluid Therapy for Horses with Metabolic Acidosis (Box 44-11)

K. Gary Magdesian

Both organic and inorganic acidoses are found in horses with critical illness. A common cause of organic acidosis in horses is lactate (lactic acidosis). Hyperlactatemia occurs with hypovolemia, sepsis, and SIRSs such as endotoxemia, marked hypoxemia, heart failure, cytopathic hypoxia, and liver failure.[1-4] Volume resuscitation can be performed with a combination of crystalloids and colloids, and possibly hypertonic saline. Acetated crystalloids (such as Normosol-R or Plasma-Lyte 148) do not contain lactate; however, even LRS (which contains sodium lactate) will correct hyperlactatemia when it is caused by hypoperfusion. Providing for hepatic perfusion will allow for clearance of the lactate previously accumulated. The exception is in liver failure, where fluids devoid of lactate should be administered because metabolism will be reduced. Other less common causes of organic (high anion gap) acidosis include ethylene glycol, salicylate toxicity, and uremic acidosis. The treatment of lactic acidosis is correction of the underlying pathogenesis. If the cause is hypoperfusion, reversal of that state should be the goal of therapy; this is accomplished through restoring blood volume, cardiac output, and finally systemic vascular resistance through the administration of fluids, dobutamine, and vasopressors, respectively. Sodium bicarbonate is therefore not a part of the routine treatment of lactic acidosis; its use in lactic acidosis is in fact controversial.[5,6] In a canine model of lactic acidosis, the administration of sodium bicarbonate actually caused a decrease in pH and bicarbonate concentration and an increase in lactate.[7] Similarly, in a model of endotoxemia in ponies, administration of sodium bicarbonate resulted in an increased blood lactate concentration.[8] Despite these controversies with sodium bicarbonate and lactic acidosis, when the pH of the patient's blood is below 7.2, administration of sodium bicarbonate until the pH reaches 7.2 is justified to prevent the detrimental effects of severe acidemia, even when the acidosis is a result of lactate. Severe acidosis can lead to life-threatening cardiovascular complications such as impaired contractility, sensitization to ventricular arrhythmias, and impaired responses to pressors.[9] Small doses of sodium bicarbonate should be administered slowly to increase the pH to 7.2, at which point increasing perfusion should be the goal.

Inorganic acidoses occur because of strong ion acidosis associated with electrolyte derangements. In horses these commonly result from hyperchloremia or hyponatremia, both of which decrease the strong ion difference. Common diseases associated with these metabolic abnormalities include enteritis, colitis, renal failure, and renal tubular acidosis (RTA). In these cases the acidosis is often caused by renal or gastrointestinal dysfunction of electrolyte homeostasis, whereas perfusion may be normal (i.e., normal plasma lactate). Chronic administration of carbonic anhydrase inhibitors, such as acetazolamide, is another cause of hyperchloremia. The fluid of choice for patients with hyperchloremic metabolic acidosis is one containing only strong cations without strong ions. Because sodium bicarbonate contains only strong cations (sodium), it is an ideal choice for patients with normal anion gap (hyperchloremic) acidosis. Sodium bicarbonate should be administered slowly to allow time for distribution and evaluation of its effects. As a fluid choice, rather than as a supplement, isotonic (1.3%) sodium bicarbonate can be used; this formulation contains 150 mEq each of sodium and bicarbonate ion per liter. Potential side effects of rapid or large-volume sodium bicarbonate therapy include hypernatremia, hypokalemia, ionized hypocalcemia, vasodilation, metabolic alkalosis (if in excess), and an increased affinity of hemoglobin for oxygen (left shift of the oxygen dissociation curve).[8]

BOX 44-11

Fluid Guidelines for Metabolic Acidosis

1. The two primary forms of metabolic acidosis in horses are organic acidosis, most often resulting from hyperlactatemia, and inorganic acidosis, often resulting from relative or absolute hyperchloremia.
2. Treatment of hyperlactatemia consists of addressing the underlying cause. In many cases, lactic acidosis is caused by hypovolemia.
3. Commercial acetated fluids, such as Normosol-R or Plasma-Lyte 148, and lactated Ringer solution are good fluid choices for hypovolemia, although volume rather than type of fluid is the most important component of treatment.
4. The use of sodium bicarbonate is controversial in lactic acidosis and may be contraindicated.
5. Sodium bicarbonate is the treatment of choice for inorganic acidosis (hyperchloremia).
6. Sodium bicarbonate can be administered as a fluid in the form of an isotonic solution.

Fluid Therapy for Heart Failure (Box 44-12)

K. Gary Magdesian

The cardiac patient represents a unique challenge to fluid therapy. Volume expansion poses significant risk to the horse with heart failure by raising venous pressures (edema risk) and potentiating sodium retention. Administration of sodium-containing fluids can lead to or compound edema and body cavity effusions. Despite these risks, patients with heart failure sometimes require fluid therapy, such as when they develop anorexia, renal failure, or diarrhea. Monitoring of CVP should be performed in these patients to aid in prevention of edema. Initial fluid therapy should consist of conservative rates, with frequent reassessment of the effects of fluids on the patient. Continuous, slow administration of fluids, rather than boluses, should be used to avoid rapid swings in CVP. Any rise in CVP should be avoided in horses with heart failure.

BOX 44-12

Fluid Guidelines for Heart Failure

1. Horses with heart failure are intolerant of significant changes in central venous pressure.
2. Fluid boluses should be avoided, and fluids should be administered at a slow, continuous rate.
3. Consideration of the amount of sodium administered should be a priority.
4. Conservative fluid rates are warranted.
5. Concurrent and careful use of diuretics may be indicated.
6. Central venous pressure should be monitored.

VetBooks.ir

The choice of fluid depends largely on concerns over sodium retention in the heart failure patient. Fluids with lower sodium content may be preferable for maintenance fluid therapy, such as maintenance fluids (0.45% NaCl/2.5% dextrose, Plasma-Lyte 56, or combinations of replacement fluids mixed with sterile water).[1] As soon as the patient is able to drink water, the intravenous fluids should be discontinued.

Because of sodium retention in heart failure, these horses are often treated with diuretics such as furosemide, which aid in minimizing edema formation.[1] A fine balance between fluid therapy and diuretics is required.

Fluid Therapy in Ruminants

Marie-Eve Fecteau

General Principles

In addition to its obvious use for correction of dehydration, fluid therapy in ruminants can be instrumental in the treatment of a variety of disorders, including sepsis, electrolyte and acid-base disturbances, gastrointestinal disease, liver disease, and renal disease. Although enteral fluid therapy is commonly used in adult cattle, parenteral fluid therapy is often regarded as impossible in field situations because of practical and/or economic reasons. In many cases of severely debilitated ruminants, targeted fluid therapy is the key treatment aiding in the recovery from a disease process. This section addresses some key principles of fluid therapy in ruminants, for both field situations and hospital setting, focusing on a variety of commonly encountered disease processes.

In adult ruminants, estimation of dehydration can be based on several factors including eyeball recession, upper eyelid skin tent, heart rate, and mucous membrane moistness (Table 44-2). Once the degree of dehydration is determined, maintenance fluid requirements, as well as ongoing losses, also need to be considered. The amount of water an adult dairy cow needs just to cover for her lactation is often underestimated. The daily water requirements of a 600-kg cow eating a corn silage–based diet in a thermoneutral environment, and milking 45 kg of milk per day, are at least 140 L of water/day.[1] Although laboratory measurements are necessary to confirm and quantify electrolyte and acid-base derangements, those derangements can be predicted on the basis of the suspected disease process. For example, cattle with abomasal volvulus typically suffer from a hypochloremic, hypokalemic, metabolic alkalosis, whereas ruminants with acute grain overload are typically acidotic and often hypocalcemic.[2] Patient-side biochemistry analyzers can be very useful during the initial evaluation of the patient and for monitoring of fluid therapy in field situations. An attempt should be made at matching fluid composition (either oral or parenteral) to the (suspected or confirmed) electrolyte and acid-base deficits of the animal. However, one should remember that the restoration of kidney function alone (by providing fluid volume) might represent the most effective step in addressing the metabolic derangements of the patient.

Oral fluids are practical and economical and can be useful in correcting mild to moderate dehydration and metabolic disturbances in ruminants. In the adult ruminant, the rumen should be viewed as a large reservoir capable of absorbing large volumes of water and electrolytes.[3] The main force for water movement across the rumen wall is the gradient of osmolality between ruminal fluid (normally isoosmotic) and blood perfusing the ruminal epithelium.[4] Studies in adult cattle have shown that net flow of water from rumen to plasma occurs whenever plasma osmolality exceeds rumen osmolality by at least 20 mOsm/kg,[5] which means that to optimize free-water absorption, rumen osmolality should be hypo-osmotic. The opposite situation is best represented during an episode of acute grain overload when the rumen osmolality quickly becomes hyperosmotic and that water is drawn to the rumen from the extravascular space, which leads to severe dehydration in those animals.[6] Therefore, the practitioner should take advantage of the ruminal capacity for water and electrolyte absorption by administrating hypo-osmotic oral electrolyte solutions to mildly to moderately dehydrated ruminants that do not suffer from preexisting abdominal distention or ileus. Enteral fluids should contain Na^+, K^+, and Ca^{2+}. Because most dehydrated adult ruminants are alkalotic, nonalkalinizing fluid formulations should be preferred.[2]

Intravenous fluids should be preferred in patients that are severely dehydrated and/or that suffer from severe metabolic disturbances or sepsis. An intravenous catheter is typically placed in a jugular vein, although the use of an auricular vein has also proved useful in adult cattle.[7] The animal should be restrained in a tie-stall or box-stall and given enough length of fluid administration set to allow him or her to lie down. Large-bore coiled intravenous fluid administration sets are useful for this purpose because they have a lesser tendency to become entangled when the animals moves around the stall. Commercially available crystalloid solutions such as LRS or 0.9% NaCl may be used, although homemade solutions can also be prepared cheaply on the farm or in a hospital setting. For example, a 0.9% NaCl solution can be prepared by adding 180 g of table salt to 20 L of filtered water using large plastic carboys. Additional recipes for homemade electrolyte solutions for cattle may be found in Table 44-3. If tap (unfiltered) water is used in the mixing of the fluids, the author recommends that the animal not be kept on those fluids for extended periods (less than 48 hours) and that parenteral antimicrobials be

used concurrently to minimize the risks of bacteremia and sepsis in the patient.

Response to fluid therapy should be closely monitored and adjusted as needed. Correction of electrolyte and acid-base imbalances should be based on laboratory results when available. For additional fluid therapy monitoring techniques, the reader should refer to the Critical Care and Fluid Therapy Monitoring Techniques section of this chapter.

Fluid Therapy for Specific Ruminant Diseases and Disorders

Fluid Therapy for Abomasal Disorders and Upper Gastrointestinal Obstructions

Ruminants with simple abomasal displacements that are managed promptly usually do not necessitate aggressive fluid therapy. Because simple displacements (left or right) of the abomasum do not constitute a complete gastrointestinal obstruction, they rarely cause severe electrolyte and acid-base derangements in the adult cow. In cows that appear mildly dehydrated, enteral fluids (10 to 20 L) consisting of water and electrolytes usually suffice. Older, high-producing dairy cows often have some degree of subclinical hypocalcemia, especially in the early postpartum period, and should therefore be supplemented with calcium. If present, ketosis should be treated with intravenous infusion of dextrose or oral administration of propylene glycol.

Ruminants with abomasal volvulus, abomasal impaction, or other forms of upper gastrointestinal (GI) obstructions such as intestinal volvulus or intussusception typically have more severe metabolic derangements as a result of the trapping of fluid and electrolytes within the GI compartments proximal to the obstruction. Those animals are typically moderately to severely dehydrated; and necessitate a more aggressive approach to fluid and electrolyte therapy, usually intravenously. The acid-base and electrolyte abnormalities of ruminants with upper GI obstructions typically include hypokalemia, hypochloremia, metabolic alkalosis (although reduced perfusion of peripheral tissues may lead to metabolic acidosis terminally), hypocalcemia, and prerenal azotemia.[8-9] To replenish fluid losses and improve the circulating blood volume, an initial fluid bolus of 15 to 20 L (20 to 25 mL/kg) of isotonic crystalloid solution should be administered prior to or during surgery. It is the author's opinion that the best crystalloid fluid choice for cattle with hypochloremic metabolic alkalosis is 0.9% NaCl, although other balanced crystalloid solutions such as LRS, Normosol-R, and Plasma-Lyte may also be appropriate. Following the initial bolus, fluid therapy should be continued with an additional 30 to 40 L (3 to 5 mL/kg/h) of 0.9% NaCl or another balanced crystalloid solution, supplemented with at least 20 to 40 mEq/L of potassium chloride. In metabolic alkalosis, hypokalemia may result from redistribution of potassium from the extracellular to the intracellular compartment.[10] Ruminants with severe hypokalemia may also have to be supplemented orally (10 g KCl per 100 kg BW, bid)[11] through stomach tube or in gelatin caps, especially if the intravenous fluids are supplemented with dextrose, which may cause a shift of potassium intracellularly.[12] When potassium chloride is supplemented, 1.0 g yields approximately 14 mEq. Care must be taken to never exceed 0.5 mEq/kg/h in order to avoid cardiotoxicity.[11] Multiparous cows in the postpartum period may also benefit from calcium supplementation at a rate of 25 mL/L of 23% calcium borogluconate.

Hypertonic solutions (7.2% to 7.5% NaCl), at a rate of 2 to 4 mL/kg, can also be used to rapidly expand the intravascular volume in severely dehydrated cattle.[11] Ideally, the infusion of hypertonic solution should be followed by intravenous infusion of an isosmotic crystalloid solution as stated previously. Cattle should also have access to a supply of fresh water and electrolytes, or be administered oral fluids through stomach tube if intravenous fluid administration is not possible. Oral fluid administration should be used only following surgical correction of the abomasal volvulus because a large volume of orally administered fluids may worsen abdominal distention before surgery.

Fluid Therapy for Metabolic Acidosis (Acute Rumen Acidosis and Diarrhea)

In ruminants, severe metabolic acidosis may be encountered in a variety of cases including acute grain overload (rumen acidosis) and severe enteritis with profuse diarrhea. Severe ketosis, pregnancy toxemia, and sepsis can also lead to the development of a metabolic acidosis in the affected ruminants. Fluid therapy for ruminants with severe ketosis and sepsis is discussed later in this chapter.

Animals with acute rumen acidosis are typically severely debilitated and need aggressive medical and surgical therapy. Acute ruminal acidosis is discussed in detail in Chapter 32. The rapid accumulation of lactic acid in the rumen osmotically draws water into the rumen, resulting in marked dehydration.[6] In addition, the chemical damage to the rumen mucosa allows bacterial transposition into the peritoneal cavity and portal circulation, resulting in the development of endotoxemia.[13-14] Finally, third spacing of proteins in the rumen as well as in the abdominal cavity can result in profound hypoproteinemia in the affected animals, which further compounds their precarious hemodynamic state by its negative impact on the animal's oncotic pressure. Moderate to severe hypocalcemia is also common in those cases.

Fluid therapy in calves with diarrhea is discussed in length in Chapter 20. Adult ruminants with severe enteritis and diarrhea such as those with salmonellosis may necessitate intravenous fluid therapy if they are completely anorectic, depressed, and significantly dehydrated. Oral fluids and electrolytes may be helpful in ruminants that are mildly to moderately dehydrated, but the effectiveness of those fluids may be compromised by malabsorption and ileus resulting from the enteritis. Similar to ruminants with acute rumen acidosis, cattle with acute diarrhea will suffer from varying degrees of metabolic acidosis, which is a result of the loss of bicarbonates in the diarrhea and possibly from the enteric production of D-lactate. The poor perfusion of the peripheral tissues that is sometimes seen in severe cases of hypovolemia may lead to the development of a lactic acidosis that may also contribute the overall acidosis in those patients. Also similar to ruminants with acute grain overload, ruminants with severe enteritis and diarrhea will develop a hypoproteinemia from GI losses and third spacing within the abdominal cavity. Finally, although a lesser concern in adult ruminants, sepsis caused by severe enteritis may pose an additional problem that should be addressed by the use of intravenous fluids. Intravenous fluid therapy in the face of sepsis is discussed further later in this chapter.

The goals of fluid therapy in ruminants with severe acute rumen acidosis and acute enteritis with profuse diarrhea should be (1) volume repletion, (2) correction of acid-base and electrolyte disturbances, (3) addressing the endotoxemia/sepsis, and (4) providing colloidal support. Fluids should be provided in the intravenous form, especially in the case of rumen acidosis, to avoid exacerbating the abdominal distention and because most animals suffer from severe ileus. The choice of crystalloid solution should be based on the suspected metabolic disturbances. Therefore, nonacidifying solutions such as LRS, Normosol-R, and Plasma-Lyte should be preferred over 0.9% NaCl solutions. In cases of severe acidemia (blood pH < 7.20), a sodium bicarbonate solution (1.3% to 5%) may be preferred until the blood pH is closer to normal range. The amount of sodium bicarbonate required to correct metabolic acidosis can be calculated by the following formula: $NaHCO_3$ (mmol) = BW (kg) × base deficit × 0.3. If laboratory data are not available, a clinician may choose to alternate between fluid solutions (e.g., between LRS and bicarbonate solution) in order to avoid overcorrection of the metabolic acidosis. An initial bolus of 20 to 25 mL/kg should be followed by a CRI of crystalloid fluids containing potassium (20 to 40 mEq/L) and calcium (25 mL/L of 23% solution). Fluids containing potassium and/or calcium should not be bolused in order to avoid cardiotoxicity. Care should also be taken not to fluid-overload the patient, especially small ruminants and young cattle, as excessive fluid administration

VetBooks.ir

may result in edema, including pulmonary edema. To address the hypoproteinemia and the poor oncotic pressure, colloids should be considered if finances allow. Colloids (whole blood, plasma, or hetastarch) may attenuate capillary leak associated with sepsis and will help expand the vascular space.[11] Details for collecting, harvesting, storing, and administrating whole blood and plasma are available elsewhere.[15] Hetastarch, a high-molecular-weight glucose synthetic polymer, is supplied as a 6% concentration in 0.9% NaCl, and can be administered at a rate of 5 to 20 mL/kg/h.[11] This may be more feasible in small ruminants or young cattle because the use of colloids may be cost prohibitive in a full-size cow.

Fluid Therapy for Sepsis (Toxic Mastitis, Metritis, Peritonitis)

Endotoxemic shock, which often accompanies disease processes like coliform mastitis, toxic metritis, and septic peritonitis, can lead to a marked hypovolemia necessitating aggressive fluid therapy in the affected animals. For the septic patient, expanding the effective circulatory blood volume in order to improve tissue perfusion and counteract the decreased cardiac output and hypotension is crucial. Fluid therapy in ruminants with sepsis is similar to that recommended for ruminants with severe enteritis or acute rumen acidosis (see previous section).

Oral fluids can be useful in ruminants that are mildly to moderately dehydrated; however, in animals that are severely dehydrated and that have signs of endotoxemia, intravenous fluids are preferred. If intravenous fluid therapy cannot be achieved because of practicality or costs, the combination of intravenous hypertonic saline (7.2% to 7.5%) and oral water and electrolytes should be considered. The increase in plasma osmolality results in a movement of water from the extravascular space to the intravascular space.[11] In adult ruminants, the rumen represents the major reservoir from which the animal can draw water. For this reason, the administration of intravenous hypertonic solution alone, without continuing with oral or isotonic intravenous fluids, is insufficient in addressing the hypovolemia. For a typical adult cow, 1 to 2 L of hypertonic saline (2 to 4 mL/kg)[11] intravenously is followed by the administration of approximately 20 L (5 gallons) of water orally. If intravenous fluid administration is an option, isotonic fluids should be continued at a rate of 4 to 5 mL/kg/h for a total of at least 40 to 60 L (for a typical adult cow) during the first 24 hours. Care should also be taken not to overload the patient with fluids, especially small ruminants and young cattle as excessive fluid administration may result in edema, including pulmonary edema. As discussed earlier in the metabolic acidosis section, a combination of crystalloids and colloids may also have advantages in treating patients with sepsis because colloids may attenuate capillary leak associated with sepsis.[16] In addition, some animals with severe sepsis may suffer from coagulation disorders such as DIC, and may benefit from hetastarch's dose-dependent effects on coagulation.[17]

Whether fluid resuscitation is performed orally or intravenously, calcium supplementation (25 mL/L of a 23% solution) should also be considered because hypocalcemia is often encountered in toxic cattle.[18,19] The reason for the decrease in calcium concentrations in endotoxemic cattle is not fully understood.[18,19] Ruminants that are anorectic should also be supplemented with potassium chloride (20 to 40 mEq/L). Although septic adult ruminants rarely become hypoglycemic (as opposed to neonates), dextrose supplementation (2.5% to 5%) may be beneficial in anorectic patients with concomitant ketosis and/or hepatic lipidosis. The animal's blood glucose should be monitored and kept between 80 to 110 mg/dL to avoid a hyperglycemic state.

Fluid Therapy for Negative Energy Balance Disorders (Hepatic Lipidosis/Ketosis/ Pregnancy Toxemia)

The vast majority of cattle and small ruminants with type I (primary) ketosis respond quickly to simple treatments that usually involve the administration of glucose precursors (such as propylene glycol) and/or a single administration of intravenous dextrose. However, cattle and small ruminants with severe ketosis, hepatic lipidosis, or advanced pregnancy toxemia may need a more aggressive approach of treatment to their condition, which usually involves the use of a continuous rate infusion of intravenous fluids containing dextrose. Ruminants with liver dysfunction/failure have a decreased ability to perform normal metabolic functions such as gluconeogenesis, to synthetize proteins, and to clear a variety of metabolites, including lactate.

The main goal of treatment of hepatic lipidosis, severe ketosis, and pregnancy toxemia is to limit the mobilization of fat by increasing the availability of glucose or glucose precursors and promoting uptake of glucose by the cells. It is important to note that the provision of dextrose is primordial, even in the face of normoglycemia, since it will minimize gluconeogenesis demands on the liver and prevent further production of ketone bodies. A CRI of isotonic fluids such as Normosol-R or Plasma-Lyte, containing 2.5% to 5% dextrose, is preferred over the use of 5% dextrose solutions (D_5W) because the latter contain too much free water. Because lactate clearance primarily occurs in the liver, and may be impaired in those animals, LRS should be avoided. In ruminants with suspected or confirmed metabolic acidosis, saline solutions (0.9% NaCl) should also be avoided, since they will compound the acidemia. Small ruminants with severe pregnancy toxemia may have to receive an initial bolus of fluids containing 10% to 50% dextrose to break the vicious cycle of negative energy balance. The rate of glucose administration should be around 1 to 2 mg/kg/min, which for a typical adult cow equates to about 1 L/h of a fluid solution containing 5% dextrose. The animal's blood glucose should ideally be monitored and kept between 80 to 110 mg/dL to avoid a hyperglycemic state. Insulin (total dose of 200 IU zinc protamine available from compounding pharmacies) can be used subcutaneously every 24 to 36 hours to promote glucose uptake by the peripheral tissues and inhibit lipolysis. The addition of B vitamins to the fluids may also be useful in anorectic ruminants.

Fluids should also contain potassium chloride (20 to 40 mEq/L) since most ruminants are completely anorectic and may also experience a shift of potassium intracellularly in response to dextrose administration.[12] Special caution should be taken at monitoring plasma potassium levels in cows receiving mixed glucocorticoid/mineralocorticoid drugs to aide in the treatment of hepatic lipidosis since their chronic use has been associated with the development of severe hypokalemia in cows.[20] As discussed earlier, cows with marked hypokalemia should receive oral and intravenous supplementation with potassium chloride. Calcium supplementation (25 mL/L of a 23% solution) is also important since most cows with hepatic lipidosis are in the peripartum period and may also suffer from subclinical hypocalcemia, and since clinical signs of pregnancy toxemia may resemble those of preeclampsia in small ruminants. Plasma or serum phosphorus levels should also be monitored in ruminants receiving repeated infusions of intravenous dextrose since it can cause significant drops in plasma phosphorus levels.[21,22]

Fluid Therapy for Obstructive Urolithiasis

Most ruminants with obstructive urolithiasis present with azotemia, which is usually postrenal, although prerenal azotemia from dehydration, and renal azotemia from renal damage, are possible. Metabolic disturbances typically include metabolic alkalosis, hyperkalemia, hyponatremia, and hypochloremia.[23] Hypophosphatemia is another common biochemical finding in goats presenting with acute urolithiasis.[23] If a rupture in the urinary tract is present on admission, the degree of hyperkalemia may be severe. Ruminants with urinary tract obstruction, particularly those with severe electrolyte disturbances, often need to be stabilized before surgery.

Although it may not be advised to administer large volumes of intravenous fluids prior to relieving the obstruction, most patients' hemodynamic state will benefit from a fluid bolus prior to surgery. In the very unstable patients with severe electrolyte disturbances (K^+ > 6 mmol/L), a clinician may choose to drain the urinary bladder (or the uroabdomen) prior to surgery by performing a cystocenthesis or

VetBooks.ir

by placing a self-retaining suprapubic cystic catheter (Bonnano catheter, BD, Franklin Lakes, N.J.), which can stay in place for up to 24 hours in most small ruminants and allow for urine egress from the bladder while the patient is receiving intravenous fluid therapy. It should be emphasized that the ultimate goals of preoperative fluid therapy are to improve the patient's hemodynamic state and to address its most severe electrolyte abnormalities (usually hyperkalemia) so that the patient can more safely undergo anesthesia. Also, surgery should not be delayed until the animal's azotemia is completely resolved as azotemia may persist for several days following surgery in some animals.

Much has been written about the best fluid composition to use in hyperkalemic animals. The most common recommendation is to favor fluids that do not contain potassium, such as physiologic saline, D_5W, or isotonic sodium bicarbonate solution. However, others may argue that any other type of balanced isotonic solutions such as LRS may also represent a valid option, even in the face of hyperkalemia.[24] Insulin may also be used to help correct the hyperkalemia, especially preoperatively. If insulin is used preoperatively or postoperatively, blood glucose should be monitored closely postoperatively, especially in young ruminants, since they may become hypoglycemic. Potassium plasma concentration should also be monitored closely following the combination of insulin and diuresis, since many ruminants will become hypokalemic postoperatively, especially if they remain anorexic for some time.

The fluid rate should be tailored to the patient's hydration needs, level of azotemia, and urine production. Although overhydration is rarely a concern in adult cattle with normal kidney function, small ruminants with acute renal failure should be monitored closely to avoid pulmonary edema. An initial rate of administration of 1.5 to 2 times maintenance is usually used until the azotemia is resolved.

• CHAPTER 45

Rational Antimicrobial Therapy

BARBARA A. BYRNE, *Consulting Editor*

VetBooks.ir

Antimicrobial Stewardship

Antimicrobial stewardship is defined as "an activity that includes appropriate selection, dosing, route, and duration of antimicrobial therapy" in order that a positive clinical outcome can be achieved with a minimum of unintentional consequences.[1,2] The dearth of new antimicrobial drug development with the advent of increasingly resistant bacteria necessitates that we use these drugs in a judicious manner that prolongs their effectiveness. Not only does inappropriate use of antimicrobial drugs result in the emergence of resistance to these drugs, they also can have such an impact on the normal microbiota that severe and sometimes fatal gastrointestinal disease can develop. Hence, veterinarians have an obligation to use these drugs in a responsible manner.

Antimicrobial therapy is the cornerstone for treatment of infectious diseases. Therapy depends on appropriate identification of the infectious agent, determination of antimicrobial susceptibility of the causative organism, and application of pharmacokinetic/pharmacodynamic principles to achieve therapeutic levels of drug at the site of infection. Additional factors such as route of administration, toxicity, cost, compliance with administration, penetration of the drug of interest to the site of infection, host factors, and development of resistance must be considered when choosing an antimicrobial drug regimen (Box 45-1). Avoiding development of resistant pathogens or commensal flora is also desirable. This chapter focuses on use of antimicrobial drugs directed toward bacterial pathogens; however, similar principles apply when choosing antifungal, antiparasitic, or antiviral therapies. The ultimate goals of antimicrobial therapy are to provide effective treatment, with the fewest adverse reactions and at the lowest cost, and to prevent development of resistance in the target organism and host microbiota. Indiscriminant or inappropriate use of antimicrobial agents leads to development of resistance in the targeted pathogen as well as the host microbiota. The consequences of resistance are many-fold, including the inability to treat certain infections, superinfections, and transfer of resistant organisms to humans.[3] As veterinarians, we have an ethical obligation to protect both animal and human health and well-being through judicious use of antimicrobial drugs. A consensus statement published by the American College of Veterinary Internal Medicine[3] provides guidance for use of antimicrobial drugs and raises important considerations for the veterinarian regarding their use.

One recommendation of this consensus statement is that the veterinarian develops standardized antimicrobial drug use guidelines for different types of cases (e.g., wounds, respiratory infections) that are appropriate for their hospital or clinical practice.[3] These authors also indicate that antimicrobial therapeutics be categorized into primary-, secondary-, and tertiary-use drugs. Primary-use drugs are older antimicrobials that have a narrower spectrum of activity (e.g., penicillin, older tetracyclines, and sulfonamides) and are used for most infections. Secondary-use drugs generally have a broader spectrum than primary-use drugs and are reserved for more serious infections or when susceptibility data indicate resistance to primary drugs. Tertiary-use drugs are those with an even further extended spectrum of activity, are effective against resistant bacteria, and are also important drugs used for human patients. These tertiary drugs should be reserved for serious infections with confirmed resistance to all primary and secondary drugs. Thus, use of higher-level drugs should be directed by antimicrobial susceptibility testing.

In addition to establishing tiers of drugs for antimicrobial use, it is important to follow a logical approach when deciding on the type of antimicrobial drug to use. This starts with establishing whether an infection is present, identification of the organism(s), determination of antimicrobial susceptibilities, and consideration of host factors. Once therapy has been initiated, assessment of the patient is essential to decisions regarding length of treatment and whether antimicrobial therapy should be altered. In addition, adjunctive therapies, such as surgical interventions should be considered.

Is There an Infection?

This is a frequently overlooked step for consideration when determining what type of antimicrobial therapy should be instituted. Too often, antibacterial drugs are used "just in case" there is an infection without proper examination for the signs of infection. A number of clinical signs and clinical laboratory findings can be evaluated that may point to the presence of an etiologic agent. The old saying that redness, swelling, and heat are cardinal signs of infection and inflammation still holds true. Certainly one frequently encountered finding is elevation of body temperature. However, inflammation for reasons other than the presence of an infectious agent may result in fever. Swelling and redness are indications of a localized infection. Development and appearance of purulent material is further evidence of infection.

Clinicopathological findings are also important supportive evidence for an infectious disease. Elevated or depressed peripheral white blood cell counts frequently accompany significant infections. In large animal species, fibrinogen elevations are observed in bacterial infections. Serum biochemistry values may also inform the decision to use antimicrobial therapy. For example, elevations in globulin may indicate production of excess immunoglobulin as seen in subacute to chronic infectious, primarily bacterial, processes. Decreases in serum albumin may develop as a negative acute phase protein in response to inflammation accompanying an invasive pathogen.[4] If possible, cytologic examination of material from the site of suspected infection should be performed. The presence of neutrophils, particularly with features of degeneration, is indicative of a septic process. Observation of infectious agents, ideally intracellularly, confirms the presence of an infection.

What Organism Is Present?

Once the presence of an infection is determined, the next step is to decide what organism might be present. Ideally, samples should be collected prior to initiating therapy so that an etiologic diagnosis can

Agent factors
Cost
Withdrawal time
Extralabel use

be made and susceptibility testing performed. In the case of a serious or life-threatening infection, therapy must be initiated prior to receipt of culture and susceptibility results. Empirical therapy often relies on clinical judgment and knowledge regarding the likely organisms present depending on the body system affected and their likely susceptibility pattern. Additional findings such as results from cytologic examination help to inform the antimicrobial choice.

Sample Selection and Transport to the Laboratory

Appropriate collection and transport of samples to the microbiological laboratory are essential to detection of the causative agent. The site of the infection should be sampled. This may seem obvious; however, a surprisingly large number of inappropriate samples are submitted to the microbiology laboratory. For example, sampling of nasal discharge is almost never the appropriate choice when faced with purulent nasal discharge. Identification of the large number of normal bacteria and interpretation of the findings are difficult when normally colonized sites are sampled. The actual source of the discharge, such as the sinus, guttural pouch, or lung should be determined and sampled directly. An exception to this rule is in the case of equine *Streptococcus equi* subsp. *equi* infections. In general, sterile sites are the best regions to sample. Lesions such as a draining tract are problematic. Frequently, they have superficial contamination of the opening of the tract that is inadvertently sampled. When possible, underlying soft tissue or bone should be collected rather than inserting a swab into the tract.

If anaerobic culture is deemed necessary, it is important that adequate volume of tissue or fluid be collected to preserve the anaerobic environment. If possible, at least a milliliter of fluid or a square centimeter of tissue should be collected. Swabs are inappropriate for anaerobic culture because air can be trapped between the fibers, leading to death of non-aerotolerant obligate anaerobes. If the sample is smaller and not taken immediately to the laboratory, it should be placed in some sort of transport media that will maintain an anaerobic environment. These anaerobic systems will maintain the presence of aerobic and facultative anaerobes as well.

Samples for microbiological culture should be transported to the laboratory as soon after collection as possible. The sample should be refrigerated if it cannot be delivered quickly, and it should be kept cool or cold but not frozen for transport to the laboratory. An exception to this rule is when anaerobic transport media (e.g., Anaerobe Systems, Morgan Hill, Calif.) is used. These vials should be maintained at room temperature.

It is best if samples are collected prior to initiation of therapy. However, if antimicrobial treatment has already been instituted, the clinician should consider withdrawing therapy for a short period of time before sampling. Between 24 and 36 hours after the last administration of drugs is advisable, and 99% of the drug should be eliminated after 7 half-lives. In seriously ill animals such as the septic foal, delaying antibiotic therapy for any amount of time to collect samples may be detrimental. In such cases, samples should be collected just prior to the next administration of drug. Some blood culture systems contain resins that bind or inactivate antimicrobial drugs and have proven to increase the ability to detect bacteria within the sample.[5]

Fusobacterium spp. (obligate anaerobe)

Microscopic Examination of Sample

Initial examination of a sample provides important clues to the type of organism present. A Wright-Giemsa–type stain is frequently used to examine cytologic preparations made from samples. This staining technique can provide much information regarding the bacterial or fungal organism present. Identification of coccoid or rod-shaped bacteria along with the site of infection will often result in a differential diagnosis list of organisms to consider. An examiner with a practiced eye may be able to make an educated guess about the genera of the organism observed. A Gram stain provides additional information. Although many veterinarians do not use this stain in their clinical practice, this technique is rapid and, with a little practice, easy to perform. Identification of an organism as gram negative or positive further informs the practitioner of the likely organisms present and helps to guide empirical antimicrobial choice (Table 45-1).

What Is the Severity of the Infection?

One of the first decisions to be made when considering antimicrobial therapy is the severity of the infection. The clinician needs to decide if therapy must be initiated immediately or whether the patient can wait for results of culture and susceptibility testing before initiating therapy. Obviously, life-threatening infections require immediate and aggressive antimicrobial therapy. Infections of sites such as an equine joint may necessitate empirical therapy while awaiting the results of microbiological testing. In this case, samples should be taken for identification and susceptibility testing before initiating therapy. On the other hand, an animal with a chronic, mild, or moderate infection may wait to receive antimicrobial drugs until testing has been completed.

What Is the Likely or Confirmed Antimicrobial Susceptibility of the Organism?

In a perfect world, the clinician should have laboratory-generated antimicrobial susceptibility results to guide therapy. However, frequently therapy has to be initiated prior to receipt of culture

VetBooks.ir

and susceptibility results. Empirical therapy should be based on knowledge of the inherent resistance of suspected agents and the antimicrobial susceptibility patterns observed in the practice region. Regular generation of susceptibility data should be compiled by the microbiology laboratory and used by the practitioner in the hospital setting.

The microbiology laboratory should be proficient in antimicrobial susceptibility testing and follow guidelines established by the Clinical Laboratories Standards Institute (CLSI).[6] Quality assessment testing should be performed regularly. A number of methodologies are used to examine susceptibility to different antimicrobials. Two frequently used methods for antimicrobial susceptibility testing are disk diffusion, also known as Kirby-Bauer, and broth dilution or broth microdilution, which uses a 96-well plate.

Disk diffusion is a relatively straightforward testing methodology that can be performed with little specialized equipment. It involves creating a lawn of bacteria using a standardized amount, placing disks containing a set amount of antimicrobial drug on top of the bacterial lawn, incubating, and measuring the zone of inhibition around the disk. This zone diameter determines whether the bacterium should be considered susceptible, intermediately susceptible, or resistant to the particular drug. The advantages of this method are that it is rapid and easy to perform provided strict protocols are followed. The disadvantages are that it cannot be used for slow-growing bacteria and that it provides only an interpretation rather than information about the specific concentrations of drug that inhibits growth. Consequently, knowledge about the pharmacokinetics and pharmacodynamics of a particular drug cannot be fully used to develop a treatment regimen to deliver optimal dose of drug to the site of infection.

The broth dilution or microdilution method involves inoculation of a standard amount of bacteria into tubes or wells containing an antimicrobial drug. Most clinical laboratories utilize twofold dilutions of drug centered on the amount of drug found systemically. The plate is subsequently incubated and then the wells are examined for visible growth. The lowest concentration of drug that inhibits visible growth is called the minimum inhibitory concentration (MIC). Sometimes the wells are subcultured to a nonselective agar and then incubated, and this agar is examined for growth. The lowest concentration of drug that results in no growth is the minimum bactericidal concentration (MBC). Because of cost reasons, most clinical laboratories do not determine the MBC for each organism.

The MIC is unique for each bacterium : drug combination. The resulting MIC guides interpretation of the bacterium as susceptible, intermediately susceptible, or resistant to the particular drug. The concentration of drug at which the interpretation of testing changes from susceptible to intermediate or resistant is termed the *breakpoint*. For example, bacteria are considered susceptible to amikacin if the MIC is less than or equal to 16 μg/mL; they are deemed resistant if the MIC is greater than or equal to 64 μg/mL. If the MIC is 32 μg/mL, the isolate is considered intermediately susceptible.[6] Frequently, the clinician only needs to use the interpretation when deciding which drug to choose for therapy. However, the MIC can be used to refine therapy, through increasing the dose of drug or frequency, to optimize treatment.

Interpretation breakpoints for susceptibility testing of a bacterium as susceptible or resistant are set by the CLSI. This body bases the interpretation on three major factors: the epidemiologic breakpoint of a population of bacteria, pharmacokinetic data, and, when available, clinical outcome from treatment of animal or human patients.[7] A graph showing MICs of a population of a single species of bacteria frequently has a bimodal distribution. The trough between the two peaks is the epidemiologic breakpoint; those bacteria with higher breakpoints have acquired some sort of resistance determinant. The pharmacokinetic information used to assist with determination of the breakpoint includes the peak concentration of drug, the area under the pharmacokinetic curve, and time the drug is above a particular MIC. A simplified way to think of how these data are used is to look at a bacterium with a high MIC. It would be considered resistant because the amount of drug administered in order to exceed the MIC would be considered toxic to the animal host. Generally, the highest concentration of drug tested is near or a bit above the highest concentration of drug that can be achieved with recommended dosages.

Antimicrobial therapy should be directed to achieve levels that are above the MIC for the particular isolate. Ideally, the "best" antimicrobial drug to use depends on many factors other than the susceptibility result. Obviously, the organism should be susceptible to the drug chosen but other considerations should be included such as route of administration, penetration to the site of infection, toxicity, cost, and convenience. All of these factors being equal, the optimal choice of a drug is one in which the organism's MIC is several dilutions below the breakpoint. However, further refinement is possible when one understands the pharmacodynamic properties of the drug and bacterium.

Bactericidal and Bacteriostatic Antimicrobial Drugs

The terms *bactericidal* and *bacteriostatic* refer to the in vitro observation that a drug kills or merely inhibits growth of a particular bacterium, respectively. If one examines the relationship between the MIC and MBC, these two values are close or nearly identical for bactericidal drugs. In contrast, the MBC is several twofold concentrations above the MIC for bacteriostatic drugs. To be clear, it takes a higher drug concentration to kill bacteria with a static drug. The in vivo consequence of this relationship means that more drug must be delivered to the site of infection in order to kill the bacteria with a bacteriostatic drug. Often this is not achievable given the toxicity and pharmacokinetics of the drug. In the case of bacteriostatic drugs, the clinician must rely on the host immune responses to clear the inhibited organisms. Consequently, bactericidal drugs should be used in an immunocompromised patient. Some drugs are concentrated in areas of infection. For example, drugs undergoing renal clearance are found in high concentrations in urine. Thus, drugs that show in vitro bacteriostatic activity may achieve concentrations high enough to kill bacteria in the bladder. The converse is also true; use of a bactericidal drug at inadequate dosages or that have poor penetration to the site of infection may not achieve high enough concentrations to kill the offending organism.

Concentration and Time-Dependent Antimicrobial Drugs

Pharmacokinetic (PK) and pharmacodynamic principles can also be used to guide antimicrobial therapy. The relationship between the MIC and PK parameters such as the peak drug concentration may also determine the outcome of therapy. There are two categories of antimicrobial drugs: concentration-dependent and time-dependent drugs. This categorization is also primarily based on in vitro work but is supported by clinical data in animals and humans.[8]

Concentration-dependent drugs are those whose antimicrobial activity is best predicted by the relationship between peak drug concentration and the MIC of the organism. Drug classes that are considered concentration-dependent drugs include aminoglycosides and fluoroquinolones. The ratio between the peak drug concentration and the MIC should equal at least 8 to 10.[9] Using the example of amikacin given earlier, if the bacterium had an MIC of 2 μg/mL, the drug should be dosed to reach a peak concentration of 20 μg/mL. The time that the drug concentration is above the MIC appears to be less important for concentration-dependent drugs. Accordingly, many concentration-dependent drugs can be administered infrequently (e.g., once daily). This dosing strategy can be advantageous with certain drugs with toxicity. For example, nephrotoxicity of the aminoglycosides is best determined by trough concentrations of drug. These antimicrobials may be administered at high dosages once daily to achieve the high peak concentration, well above the MIC, while having prolonged low trough levels. Many concentration-dependent drugs have prolonged post-antibiotic effect, meaning that the effect of the drug to inhibit growth of the organism is apparent for some time after the drug is removed.

TABLE 45-2

Antimicrobial Drugs, Classifications, Activities, Post-antibiotic Effect, and Pharmacodynamic Parameter

Drug	Activity	Bacterial Effect	Post-antibiotic Effect*	PD Parameter†
Aminoglycosides	Bactericidal	Concentration-dependent	Yes	T > MIC
β-Lactams	Bactericidal	Time-dependent	No, gram negative; yes, gram positive	T > MIC
Fluoroquinolones	Bactericidal	Concentration-dependent	Yes	AUC_{24}/MIC, Cmax/MIC
Glycopeptides (Vancomycin)	Bactericidal	Time-dependent	Yes	AUC_{24}/MIC
Macrolides	Bacteriostatic	Time-dependent	No	T > MIC
Sulfonamides	Bacteriostatic	Time-dependent	No	
Tetracyclines	Bacteriostatic	Time-dependent	Yes	AUC_{24}/MIC
Trimethoprim	Bacteriostatic (unless combined with sulfonamide)	Time-dependent	No	

Adapted from Martinez M, Toutain PL, Walker RD. 2006. The pharmacokinetic-pharmacodynamic [PK/PD] relationship of antimicrobial agents, pp 81-106. In Giguere S, Prescott JF, Baggot JD, et al (eds), Antimicrobial therapy in veterinary medicine, ed 4. Blackwell Publishing, Ames, IA.

*Yes = prolonged effect longer than 6 hours; no = less than 1 hour.

†T > MIC, time drug concentration is greater than the MIC; AUC_{24}/MIC, area under the concentration curve over 24 hours/Minimum inhibitory concentration; Cmax/MIC, Maximum concentration/Minimum inhibitory concentration.

Fluoroquinolone efficacy is best predicted by the area under the concentration curve (AUC) in relationship to the bacterial MIC. The AUC:MIC ratio should be equal to or greater than 125 for gram-negative organisms.[8-11] This ratio should be 60 or greater for gram-positive bacteria.[8] Some studies indicate that ratios that approach 250 or more be used to avoid development of resistance.[8]

Time-dependent drugs are those whose antimicrobial activity is best predicted by time that the drug concentrations are above the MIC. Many drug classes are considered time dependent, including the beta-lactam drugs and tetracyclines. These drugs should remain above the MIC for at least 50% of the time. These antimicrobial drugs generally are dosed more frequently or via continuous rate infusion for those with short half-lives.

Knowledge of the pharmacodynamic principles such as the peak drug concentration:MIC ratio or time above the MIC can guide the practitioner in appropriate dosages and frequencies for an individual drug. Monitoring of drug levels can further aid development of the therapeutic plan. Table 45-2 summarizes the pharmacodynamic parameters and activities of some example antimicrobial drugs.[12]

Where Is the Infection?

Too often the question of where the infection is located is not considered when choosing an antimicrobial drug. Penetration of the drug to the site of infection is essential for successful therapy. Remember that the MIC and interpretation of the MIC are focused on systemic (plasma) levels of drugs and rarely include the subtleties of drug penetration to various sites. Some anatomic locations are particularly difficult to enter, such as the central nervous system, ocular fluid, and bone. Abscesses are another structure that is difficult for antimicrobial drugs to penetrate; they are surrounded by a thick capsule with poor blood supply and lack of oxygen, which can limit penetration into the abscess and offer poor entry into the bacteria. The pH is generally low, which may inactivate some agents, and there is abundant protein present to bind antimicrobial drugs. A further complication is the presence of purulent debris, which can provide metabolic precursors for bacteria to bypass inhibitors of metabolism, such as trimethoprim-sulfa combination drugs. In general, lipophilic drugs will be better able to penetrate these difficult-to-reach anatomic locations. Highly polar or charged molecules have difficulty reaching these sites.

If the causative organism is found intracellularly as seen with rhodococcal pneumonia or as with *Corynebacterium pseudotuberculosis* infections, the cell membrane is an additional impediment to drug penetration. Fortunately, some drugs penetrate cells well, such as macrolides, rifampin, chloramphenicol, fluoroquinolones, and trimethoprim-sulfa combinations.

Empirical versus Definitive Therapy

Empirical therapy is used for severe infections prior to obtaining culture and susceptibility results. The choice of antimicrobial drug depends on the clinician's knowledge of the likely agents present at the site of infection and their predicted susceptibilities. Knowledge of the Gram-staining results can further guide therapy. Generally, empirical therapy is broad spectrum to cover multiple possible etiologies. Eventually, once the etiologic agent and its susceptibility have been identified, definitive therapy, using a drug(s) with a narrower spectrum, can be initiated. Definitive therapy should be directed to best result in a cure, using the narrowest spectrum of drug therapy, and have limited toxicity for the patient. The goal is to de-escalate the spectrum of activity of the drug as much as possible with definitive therapy in order to minimize the impact on commensal bacteria and development of resistance.

Combination Therapy

Many infections can be effectively treated with a single antimicrobial drug; however, in some instances, combination therapy may be chosen. Some drug combinations have been demonstrated to be synergistic based on both in vivo and in vitro studies. Synergy is seen when the ability of the combination to kill bacterial growth is greater than the mere additive effect of each drug. Drug combinations can also be indifferent, where each drug's effects are merely additive. Finally, a drug combination may be antagonistic where the drug combination effectiveness is less than the sum of the independent activities. Synergistic antimicrobial drug combinations are best used to treat resistant organisms. A common synergistic pair of antimicrobial drugs can be seen in the combination of trimethoprim with a sulfonamide. Either agent alone would be considered bacteriostatic, but since each of these drugs inhibits sequential steps in folic acid metabolism, they are considered bactericidal.

A combination of antimicrobial drugs might be chosen for empirical therapy before the agents and their susceptibilities are known in order to provide broad-spectrum therapy. The combination of a β-lactam drug with an aminoglycoside is frequently chosen as empirical therapy in equine patients. This combination is synergistic as well as broad spectrum. It is important to remember that in these cases, therapy should be reduced to a single agent or a less broad spectrum of activity as soon as testing results become available.

The presence of a polymicrobial infection is another reason why combination therapy may be used because a single agent will not be able to treat all bacteria present. For example, intraperitoneal infections are frequently caused by more than one agent. It is difficult to find a single antimicrobial drug to treat all the possible bacteria

VetBooks.ir

present such as enterics, gram-positives, and anaerobes. Individual drugs are available for use in humans that are sufficiently broad spectrum; however, many of these would be cost prohibitive in large animal patients. The clinician should be cautious, however, of isolation of multiple agents from a single site such as a wound. Superficial samples taken from these sites may have contaminating bacteria, often with highly resistant antimicrobial patterns, that are not truly part of the infectious process.

Combined antimicrobial drug therapy can be used to prevent emergence of resistant bacteria. Certainly for serious or difficult-to-treat infections such as those caused by *Pseudomonas* spp., avoiding development of resistance is important not only to the patient receiving treatment, but also to others who come in contact with it. Interestingly, the ability of combination therapy to prevent resistance seems to be important only when it results from chromosomal mutations.[13] The best illustration of this principle is in the treatment of human patients for *Mycobacterium tuberculosis,* in which combination therapy is always used to prevent development of resistance.[13]

There are some drawbacks to using combination therapy. One is the possibility of antagonism between antimicrobial drugs. Most instances of antagonism have been demonstrated in vitro, although in vivo reports have appeared.[13,14] This phenomenon has been seen between gentamicin and chloramphenicol to treat *Proteus mirabilis* infections in immunocompromised mice.[15] Use of antimicrobial drug combinations is also an increased cost to the client. Finally, there is an increased possibility of toxicity of and/or hypersensitivity reactions to the drugs when used together. Antimicrobial drug combinations that may be detrimental include penicillin with tetracyclines and chloramphenicol with erythromycin. Combination therapy should not be chosen merely to provide comfort to the clinician but rather clinicians should have specific reasons for their choice.

Drug Incompatibility

Drug incompatibility can be the result of direct incompatibility, meaning that they should not be mixed together for administration or that they should not be used together therapeutically. Table 45-3 provides information about antimicrobial drug incompatibilities.

Host Factors That Influence Antimicrobial Choice or Dosage

Age

The age of the animal may influence many aspects of antimicrobial therapy. Bioavailability of certain drugs varies with age where some drugs can be used orally in neonatal or young animals but are poorly absorbed in mature animals.[16] The drug distribution may also vary with age because young animals generally have a larger volume of distribution than adults because of their larger percentage of total body water.[17] Drug biotransformation in neonates may vary from that in adults as well.[17] Therefore, drug dosages and/or frequencies may have to be adjusted in young animals to provide adequate levels of drug at the site of infection and to minimize toxicity.

Fluoroquinolone use in young and adult animals should be considered carefully. This class of antimicrobial drug has been documented to cause cartilage damage in several species of young animals, and ciprofloxacin has been associated with tendinopathies in humans.[18-20] Of interest is the observation that fluoroquinolones are capable of having chondrotoxic effects on equine and canine chondrocytes in vitro,[21] whereas a lamb model failed to demonstrate chondrotoxicity.[22] Unfortunately, specific guidelines for safe use of fluoroquinolones in young animals are lacking. If fluoroquinolone use is necessary in young animals, it is important to limit the duration of therapy in order to minimize the chances of damage to developing cartilage. Along the same line, tetracyclines should also be avoided in young patients to avoid discoloration of enamel of developing permanent teeth.

Reproductive Status

Antimicrobial drugs may have deleterious effects on reproduction and the developing fetus. Depending on the drug, the type of placentation, and stage of gestation, some drugs are able to reach the fetus. For example, use of potentiated sulfonamides in pregnant mares has been associated with anemia, fever, and abortion.[23] Administration of pyrimethamine and trimethoprim-sulfamethoxazole to stallions has been associated with weakness and abnormal copulatory form and function.[24]

TABLE 45-3

Specific Drugs and Additives That Are Incompatible When Comixed before Administration[38,39]

Drug	pH	General Comments	Incompatibilities
Aminophylline	8-9	Not stable if pH < 8	Cephalothin Na, tetracyclines, polyionic fluid solutions, penicillin G, morphine sulfate, erythromycin gluceptate, methylprednisolone Na succinate, multiple vitamin solutions, thiamine
Ammonium chloride	4.5-6		Chlortetracycline, sulfadiazine, sulfisoxazole
Ampicillin sodium	8.5-10	Do not mix with other medication because of pH changes	
Calcium chloride	6-8.2		Cephalothin Na, chlorpheniramine, hydrocortisone or prednisolone phosphate, kanamycin sulfate, tetracyclines, sodium bicarbonate (concentration dependent)
Calcium disodium EDTA	6.5-8		Dextrose solutions, tetracyclines
Calcium gluconate	6-8.2		Cephalothin Na, tetracyclines, prednisolone phosphate, sodium bicarbonate, phenylbutazone, sulfonamides
Carbenicillin disodium	6-7		Tetracyclines, aminoglycosides
Cephalothin sodium	5.2	pH <4 or >7 Not advised; do not mix with other medication	
Cyanocobalamin (vitamin B_{12})	4-5.5		Alkaline solutions, ascorbic acid, vitamin B complex with C, vitamin K, warfarin
Dexamethasone phosphate	6.5-7		Chlorpromazine

TABLE 45-3

Specific Drugs and Additives That Are Incompatible When Comixed before Administration[38,39]—cont'd

Drug	pH	General Comments	Incompatibilities
Ergonovine maleate	2.7-3.5		Do not mix with other medications
Erythromycin lactobionate	6.5-7.5	Do not combine with mixtures having a final pH < 5	Aminophylline, multiple vitamins, cephalothin Na, pentobarbital, sodium iodide, heparin Na, penicillin G, tetracyclines
Furosemide	8.8-9.3		Acid solutions
Gentamicin sulfate		Do not mix with other medications	
Heparin sodium	5-7.5		Sodium bicarbonate, multiple vitamins, tetracyclines, chlorpromazine or promazine, erythromycin lactobionate or gluceptate, gentamicin SO_4, hydrocortisone sodium succinate, methylprednisolone Na succinate, kanamycin SO_4, meperidine HCl, morphine SO_4, penicillin G (K^+), protamine
Hydrocortisone sodium succinate	7-8		Cephalothin Na, tetracyclines, heparin Na, kanamycin SO_4, multiple vitamins, pentobarbital Na, promazine, erythromycin, tylosin
Kanamycin sulfate	4.5	Cephalothin Na, dextrose, heparin Na, hydrocortisone Na succinate, penicillins, sulfadiazine	
Levamisole	Neomycin, phenylbutazone, sulfonamides, tetracyclines		
Lidocaine	6-7		Alkaline solutions
Magnesium sulfate	5.5-7		$NaHCO_3$, calcium-containing solutions, tetracyclines
Mannitol	4.5-7		Strongly acidic or alkaline solutions, whole blood, penicillin G
Methylprednisolone sodium succinate	7-8		Aminophylline, heparin Na, tetracyclines, vitamin B
Multiple vitamins			Aminophylline, cyanocobalamin, erythromycin lactobionate, heparin Na, hydrocortisone Na succinate, penicillin G, sodium bicarbonate, tetracyclines
Nitrofurantoin sodium	7.7-9.8		Calcium chloride, insulin, phenol, procaine
Oxytocin	2.5-4.5	Do not mix with other medications	
Penicillin G (K^+ or Na^+)	6-7	Significant inactivation if pH <5.5 or >8	Tetracyclines, acetylcysteine, multiple vitamins, vitamin B with C, lincomycin, aminophylline, pentobarbital, thiopental, cephalothin Na, erythromycin, sodium bicarbonate, sulfonamides, heparin Na, gentamicin
Pentobarbital sodium	10-10.5		Acidic solutions, cephalothin Na, erythromycin, tetracyclines, sodium bicarbonate, succinylcholine chloride
Ringer lactate solution	6-7.5		Epinephrine HCl, tetracyclines, sodium bicarbonate, sulfadiazine Na
Sodium bicarbonate	7-8		Calcium-containing solutions, magnesium sulfate, vitamin B with C, tetracyclines, penicillin G (Na or K), thiopental sodium, pentobarbital Na, streptomycin
Sodium iodide	7.5-9		Vitamin B with C
Succinylcholine chloride	3-4.5		Alkaline solutions, pentobarbital Na, thiopental Na
Sulfonamides	Basic		Acidic solutions, ammonium chloride, gentamicin SO_4, kanamycin SO_4, lincomycin HCl, methicillin, penicillin G, tetracyclines, vitamin B with C, calcium gluconate, dextrose, tylosin, procaine
Tetracyclines	1.8-2.8		Aminophylline, penicillins, magnesium or calcium salts, cephalothin Na, erythromycin, lactobionate, heparin Na, hydrocortisone Na succinate, methylprednisolone Na succinate, multiple vitamins, nitrofurantoin, novobiocin, polymyxin B, lactated Ringer or Ringer solution, sodium bicarbonate, sulfonamides, barbiturates
Thiamine (vitamin B_1)	3-4	Neutral or alkaline pH causes decomposition	Iron salts
Thiopental sodium	10-11		Acidic solutions, promazine HCl, sodium bicarbonate, succinylcholine Cl, atropine SO_4, penicillins, cephalosporins, tetracyclines, hydrocortisone Na succinate
Ticarcillin disodium	6-8		Aminoglycosides
Tylosin			Hydrocortisone, tetracycline, streptomycin, sulfonamides
Vitamin B complex	10-11		Alkaline solutions, cephalothin Na, cyanocobalamin, erythromycin lactobionate, hydrocortisone Na succinate, tetracyclines
Vitamin B complex with C	3-6.5		Aminophylline, cephalothin Na, erythromycin lactobionate

VetBooks.ir

The lactating large animal must also be considered. Many antimicrobial drugs can be found in milk and may be transferred to the lactating animal or human who consumes the milk. Some drugs reach the milk in high concentrations whereas others are found in low amounts relative to plasma. Regardless, almost all antimicrobial drugs may be found in milk. Such adulteration may make the milk unsuitable for human consumption, and appropriate withdrawal times should be adhered to before milk enters the human food chain.

Treatment of bacterial mastitis provides several challenges and is covered in more detail elsewhere in this book. Treatment should be initiated early and based on susceptibility of the particular causative agent. If individual milk culture and susceptibility testing is not feasible, then treatment should be based on historical information from the affected herd. Penetration into milk is also an important consideration when using systemic drugs to treat mastitis. Many drugs are found in much lower concentrations in milk, such as the β-lactams and sulfonamides. Others can be concentrated into milk, such as the macrolides. Because of the low concentrations found in milk for many of the drugs used in food production animals, intramammary administration is preferred, although systemic administration can also be used and is probably indicated in the systemically ill animal or when abscesses preclude delivery of the drug via the intramammary route. As for systemic administration, withdrawal times should be closely followed with intramammary infusions.

Renal and Hepatic Function

As for all drugs, metabolism of antimicrobial drugs takes place in the liver and/or kidneys and excretion follows these routes. Therefore, compromised renal or hepatic function should be considered when choosing an antimicrobial drug. Aminoglycosides are well known for their nephrotoxicity and should be avoided in cases with elevations in serum blood urea nitrogen or creatinine. If their use is still warranted despite renal dysfunction, the frequency of administration or in some cases the dose should be altered. Therapeutic monitoring of aminoglycoside levels should be performed to guide therapy. Macrolides and rifampin are metabolized and excreted via the hepatic route, and liver enzymes should be monitored for elevation during use. Knowledge of the route of excretion of active drug can be used to concentrate drugs at the site of infection. In the case of bacterial pyelonephritis or cystitis, renal excretion of many antimicrobial drugs can be used to the clinician's advantage during treatment.

Immune Status

The effectiveness of the immune response is important for successful antimicrobial therapy. Many drugs only reach bacteriostatic levels at the site of infection and thus may only inhibit growth of the offending agent. In these cases, the immune response is essential for clearing the infection. Bactericidal concentrations of drugs at the site of infection should be used in cases of immunocompromise. Immunodeficiency, whether primary or secondary, may be an indication for use of combination therapy.

Duration of Therapy

Unfortunately, there are few guidelines in veterinary medicine that direct duration of therapy. Certainly serious or deep-seated infections such as endocarditis, pyelonephritis, and osteomyelitis warrant prolonged antimicrobial administration. In human patients, such infections would be treated for 6 weeks or longer. In veterinary medicine we must frequently rely on response to therapy. Resolution of pyrexia, decreases in white blood cell count or fibrinogen, or resolution of abnormal radiographic and ultrasonographic findings are important parameters to monitor when deciding to cease therapy. In some cases, re-sampling and culture of the previously infected site may be warranted. For simple infections, treatment for a few days past resolution of clinical abnormalities and clinicopathologic findings may be adequate. For complicated infectious processes, treatment may be needed for weeks or longer after apparent cure.

Route of Administration

The route of administration will vary depending on the patient species, age, severity of the infection, bioavailability of orally administered drugs, and site of the infection. Intravenous delivery of antimicrobials is indicated for serious life-threatening infections in which high levels of drug at the site of infection are indicated. Many drugs with good oral bioavailability in small animals, such as β-lactams, cannot be administered orally in large animal patients, necessitating parenteral administration. Oral administration of antimicrobials should be used cautiously in large animal species to minimize disruption of ruminal or colonic microflora in ruminants and horses, respectively. The route of administration may also be influenced by client or patient compliance. Intramuscular administration may be difficult for some clients and patients, resulting in inadequate duration of therapy and possible development of resistance by microorganisms. Therapeutic administration of antimicrobial drugs in feed is an alternative that is easy for the client but is ineffective if the animal refuses to consume it. Guidelines for therapeutic use of antimicrobial drugs in feed can be found later in this chapter.

Monitoring of Therapy

The response to treatment should always be monitored throughout antimicrobial drug administration. It helps to guide decision making regarding duration of therapy and effectiveness of the chosen antimicrobial regimen. As mentioned previously, clinical and clinicopathological findings are useful guides to judge therapeutic success. Failure to respond to therapy could indicate that the organisms present in the infection are resistant to the chosen drug, particularly if the drug was chosen empirically. It may also indicate development of resistance during therapy or that there is poor penetration of drug to the site of the infection. Monitoring of drug levels may be indicated to determine if dosage and/or frequency is adequate in cases of treatment failure. A positive response to therapy can be an indication that antimicrobial treatment can be de-escalated in the case of broad-spectrum administration or that the patient can be switched from parenteral to oral administration.

Prophylactic and Metaphylactic Use of Antimicrobial Drugs

Antimicrobial drugs for prophylactic or metaphylactic use should be used only for cases or situations that are deemed high risk for infection and in which clinical data have demonstrated that this use is effective for preventing infection or decreasing morbidity or mortality.[3] Prophylactic use of antimicrobial drugs is therapy directed toward preventing infection in which the risks or consequences of development of an infection are great and outweigh the risks of adverse outcome from the drug used. Its most frequent application is in the surgical setting to prevent surgical site infections. The decision to use prophylactic antimicrobials depends on the type of surgery and possibility of entering nonsterile sites such as the gastrointestinal or genitourinary tract, the length of the surgical procedure, the use of surgical implants (metal or nonmetal), and the degree of tissue damage. It is important that the antimicrobial drug be present at therapeutic levels at the time of contamination in order to be effective in prevention of surgical site infections.[25] The therapy should be directed toward the pathogens likely to cause the infection. In the case of surgical site infections of large animals, these include Enterobacteriaceae, *Staphylococcus,* and *Streptococcus*.[26,27] Generally, the drug should be administered 30 to 60 minutes before the actual surgery begins.[28] If the surgery is prolonged, repeated administration of the antimicrobial drug should be performed. Perioperative administration is what is important to prevent surgical

VetBooks.ir

site infections and continued use after completion of surgery is unnecessary.[29] Therapy beyond this point will not appreciably reduce the incidence of surgical site infections and may predispose to development of resistance or superinfections and increase the likelihood of adverse reactions.[25]

Prophylactic antimicrobials should be drugs other than those used therapeutically so that treatment options remain available should an infection develop. It has been recommended that older drugs be used so that newer drugs may be used therapeutically.[30] Prophylaxis should never be used in the place of good aseptic technique and is not indicated for use to prevent infection of intravenous catheters or other similar indwelling devices. Antimicrobial use in these instances only increases the likelihood that if infection develops, it will be more likely to be resistant.

Metaphylaxis is use of antimicrobial drugs after exposure to an infectious agent but before development of clinical signs. Examination of parenteral treatment of calves at high risk for infection in the bovine respiratory disease complex prior to or upon entry into the feedlot has shown decreased morbidity and mortality.[31,32] It is important to note that metaphylactic use of antimicrobial drugs will not eliminate all infections and may have a greater impact on the severity or duration of the illness. Metaphylactic administration may not always be practical for large groups of animals, and labeling may preclude antimicrobial use in this manner.

Biosecurity and Infection Control

Establishment of effective means of infection control can help to reduce nosocomial infections and decrease the need for antimicrobial therapy. Simple measures such as frequent hand washing, isolation or segregation of animals with contagious or highly resistant organisms, and control of movement of animals can go a long way to decreasing infection rates. Infection control and hygiene plans are important for any premises where animals are managed, not just for veterinary hospitals or clinics.[3]

Microbial Factors Impacting Therapy

Resistance

A number of microbial factors may influence the success of therapy. Resistance of the agent to the chosen therapeutic is a common occurrence in therapeutic failure. Resistance can result from the inherent properties of the microbe. For example, mycoplasmas lack a cell wall and are impervious to the effects of cell wall–targeting drugs like the β-lactams. Other drugs may not be able to penetrate the bacteria as is seen in the inability of anaerobes to take up aminoglycosides. A major contribution to resistance is acquisition of resistance determinants. Resistance may result from alteration of the antimicrobial target, gaining of genes capable of degrading the drug (e.g., β-lactamases), or acquisition of genes encoding efflux pumps (tetracyclines, aminoglycosides) that pump antimicrobials out of the bacterial cell. Bacteria can develop resistance through mutation of the gene encoding the protein target of the drug (e.g., fluoroquinolones and DNA gyrase). These events are not frequent, occurring once every 10^{10} to 10^{14} cell divisions. However, the rapid multiplication rate of a large number of bacteria makes this a real possibility. These events are random and their appearance is not affected by the presence of a particular antimicrobial drug. However, if a drug is present, bacteria with the mutation will have a selective advantage and will rapidly out-compete non-resistant ones.

Alternatively, bacteria can acquire genes encoding a resistance determinant. Bacteria can obtain resistance genes through several mechanisms. Movement of plasmids, a type of extrachromosomal DNA, through conjugation between bacteria of the same or different species is a major means by which resistance develops. Other mobile DNA elements can move resistance genes between bacteria. Resistance genes are frequently associated with transposons, DNA capable of excision from host genomic DNA to plasmids and subsequent transport to other bacteria. Bacteriophages (bacterial viruses) may also move resistance genes between bacteria through a process called *transduction*. Finally, resistance genes can be taken up as naked DNA in the bacterial environment through a process known as *transformation*.

The simple act of using antimicrobial drugs will result in selection of bacteria that are resistant. Survey of gastrointestinal microbes *(Escherichia coli)* after initiation of antibiotic therapy has shown that resistance will develop in normal flora.[33-35] The most effective way to avoid resistance is to minimize use of antimicrobial drugs and, when they are used, to be sure that they are delivered to the site of infection at adequate levels to kill the bacteria.

Biofilms

Bacteria can move from existing as individual cells, also known as planktonic growth, to develop into a population that functions more as a multicellular organism known as a biofilm. The definition of a *biofilm* is "aggregated microbial cells surrounded by a polymeric self-produced matrix, which may contain host components."[36] Biofilms are notoriously difficult to treat with simple antimicrobial therapy and are known to form on a variety of surfaces including catheters, orthopedic implants, and bone. Biofilm bacteria are different from planktonic organisms in several ways. First, they are less susceptible to antimicrobial agents. Second, they persist in the animal despite a vigorous immune response. Unfortunately, often the most effective way to treat the biofilm-associated infection is to remove the infected implant or bone.

Adverse Reactions

Adverse reactions to antimicrobial drugs certainly occur although hundreds or thousands of doses may have to be given before they are observed. A recent report from Switzerland indicated that 20% of adverse reactions to drugs were to antimicrobial agents.[37] Adverse events associated with antimicrobial use can range from a hypersensitivity reaction to direct toxicity to disruptions of normal microbiota. Fortunately, antimicrobial agents are directed toward the prokaryotic structures of bacteria that generally differ to some degree from the eukaryotic equivalent of the host. Consequently they are less likely to result in direct toxicity in the patient. Some drug toxicities are predictable based on their mechanism of action or accumulation in certain cells of the host. Hypersensitivity reactions are the result of immunologic stimulation by the drug or carriers in the drug formulation. One frequently observed adverse event associated with antimicrobial use is development of severe gastrointestinal disturbances. These may be the result of changes in the gut microbiota and/or proliferation of pathogenic bacteria such as *Clostridium difficile* or *Salmonella*. Adverse reactions to antimicrobial drugs should be reported to the manufacturer and to the Food and Drug Administration Center for Veterinary Medicine. Another source of adverse reactions is drug incompatibility. Table 45-3 lists some antimicrobial drug incompatibilities.[38,39]

Adjunctive Therapy

In some infections, antimicrobial drugs alone are unable to clear the infection. In these cases, adjunctive therapy should not be overlooked. Surgical débridement of necrotic material and reestablishment of an adequate blood supply helps to remove bacteria and allow better antimicrobial penetration. Sometimes simple drainage of an abscess is all that is necessary to treat certain infections, obviating the use of antimicrobial drugs.

Topical treatment may be possible in some instances. Superficial skin infections may be treated with either topical antimicrobial drugs or antiseptics. Deep or severe infections may need both systemic and topical treatment. Most ocular infections are successfully treated topically where high drug concentrations can be delivered.

Local treatment of severe internal infections can also be used as an adjunct to systemic therapy. Intraarticular administration of antimicrobials and/or regional perfusion are frequently used to treat

VetBooks.ir

joint and bone infections. These routes deliver high levels directly to the site of the infection. Although efficacious, adjunctive therapy including débridement and lavage are important to remove the bacterial burden and inflammatory substances that may be detrimental to joint structures. In these instances, systemic administration is indicated.

Medicating animals that are used to produce food for human consumption is a worldwide phenomenon. Medications can be used to increase production, treat illnesses, produce healthier animals, or prophylactically and/or metaphylactically prevent or reduce morbidity and/or mortality caused by diseases. In recent years, the potential impacts of drug residues are of increasing concern for consumers, regulators, and legislators. In order to maintain public safety, it is important for veterinarians to educate themselves and work closely with their clients to help minimize drug residues in the human food chain.

Definition of Food-Producing Animal Species

For the purposes of this chapter, a food animal is any animal for which its tissues or products from that animal have the potential to enter the human food chain. In the United States, food animals are further categorized as major or minor food animal species. The Food, Drug, and Cosmetics Act defines the major food-producing species of animals to include cattle, swine, chickens, and turkeys. The U.S. Center of Veterinary Medicine (CVM), a branch of the Food and Drug Administration (FDA), has a list of definitions for bovine, swine, and poultry species and classes, which can be found in Table 45-4.[1] Furthermore, in addition to these definitions, the Code of Federal Regulations (CFR) has defined dairy cattle to include all

TABLE 45-4

U.S. Food and Drug Administration's Definitions of Species and Classes of Major Food Animals[1]

Species	Class		Definition
Cattle	Beef Cattle (cattle intended for meat production)	Suckling Calves	Immature, pre-ruminant cattle (including *dairy breeds* intended for meat production), maintained with and dependent upon their dam for nourishment. Veal calves are not considered suckling calves.
		Pasture Cattle (stocker, feeder, slaughter, and sometimes replacement beef heifers)	Weaned cattle (including dairy breeds) maintained on pasture and receiving the majority of their diet from grazing. The term *pasture cattle* is intended to refer to cattle considered to be stockers, feeders, and/or slaughter cattle. Therefore, parenthetical reference to *stocker, feeder,* or *slaughter cattle* is typically included in labeling. *Stockers* refers to weaned calves grazing pasture to enhance growth prior to finishing and slaughter; they are usually younger, weigh less, and are of lower condition (finish) than "feeders." *Feeders* refers to weaned calves grazing pasture and of sufficient weight and maturity to be placed on high-energy rations for finishing; they are generally older, weigh more, and carry more condition (finish) than stockers. *Slaughter* refers to cattle grazing pasture and suitable for slaughter. Sex differentiation (e.g., heifers, steers, and/or bulls) should be indicated on product labeling. *Replacement beef heifers* may be added to the Pasture Cattle class if the drug has been shown to have no negative impact on reproduction in female cattle during the period from weaning until first calving, and the female cattle are intended for reproduction to produce calves intended for meat production.

TABLE 45-4

U.S. Food and Drug Administration's Definitions of Species and Classes of Major Food Animals[1]—cont'd

Species	Class			Definition
		Cattle Fed in Confinement for Slaughter		Cattle (including dairy breeds) confined in group pens and fed a high-energy diet ad libitum until slaughter. Sex differentiation (heifers, steers, and/or bulls intended for slaughter) should be indicated on product labeling.
		Growing Cattle on Pasture or in Dry Lot (stocker and feeder)		Weaned cattle (including dairy breeds) maintained on pasture or in a dry lot, receiving the majority of their diet from forage.
		Lactating Beef Cows		Lactating beef breed female cattle nursing calves intended for meat production; their milk is not intended for human consumption.
		Non-Lactating Beef Cows		Female beef breed cattle that had previously nursed calves intended for meat production, but which are not currently producing milk.
		Replacement Beef Bulls		Intact male beef breed cattle intended for reproductive purposes.
	Veal Calves			Immature cattle (including dairy breeds) lacking a functional rumen and intended for meat production. They are recognized as a separate class from suckling calves because of their handling, housing, and proximity to slaughter.
	Dairy Cattle (cattle intended for production of milk for human food)	Lactating Dairy Cows		Female dairy breed cattle that are producing milk.
		Dry Dairy Cows		Female dairy breed cattle that had previously lactated, but which are not currently producing milk (cows between two lactations).
		Non-Lactating Dairy Cattle	Replacement Dairy Heifers	Female dairy breed cattle from weaning until first calving.
			Replacement Dairy Bulls	Intact male dairy breed cattle intended for reproductive purposes.
			Dairy Calves	Female or male dairy breed cattle being fed a ration that includes milk or liquid milk replacer and which are not intended for veal production.
Swine	Boars			Intact, sexually mature, male pigs intended for breeding purposes; generally not intended for slaughter in the United States.
	Barrows			Castrated male pigs intended for slaughter.
	Gilts			Female pigs intended for slaughter or breeding purposes; have not yet farrowed a litter.
	Replacement Gilts			Breeding female pigs that have not yet farrowed a litter; usually weigh 220 to 300 lb (100 to 135 kg).
	Sows			Female pigs that have had at least one litter.
	Nursing Pigs			Pigs from birth until weaning and still nursing.
	Starter or Nursery Pigs			Boars, barrows, and gilts from approximately 2 to 4 weeks of age and approximately 50 to 60 lb (23 to 27 kg).
	Growing Pigs			Barrows and gilts from approximately 50 to 60 lb (23 to 27 kg) to 120 to 150 lb (55 to 68 kg).
	Finishing Pigs			Barrows and gilts from approximately 120 to 150 lb (55 to 68 kg) to market weight for slaughter.
Chickens	Egg			From in ovo until hatching.
	Laying Hens (or layers)			Hens that produce eggs for human consumption.
	Chicks			Chickens from day of hatch until they are able to survive in ambient temperature (no longer brooded).
	Broiler Chickens (or fryers or frying chickens)			Meat-type chickens normally grown to a market age of 35 to 49 days and market weights between approximately 4 and 7 lb (1.80 and 3.2 kg).
	Roasters (or roasting chickens)			Meat-type chickens grown to market weights between approximately 6 and 9 lb (2.7 and 4.1 kg).
	Replacement Chickens			Chickens intended to become laying hens or breeding chickens.
	Breeding Chickens			Sexually mature male and female chickens of any type intended for the production of fertile eggs; the eggs are not intended for human consumption.
Turkeys	Egg			From in ovo until hatching.
	Laying Hens (or layers)			Hens that produce eggs for human consumption.
	Poults			Turkeys from day of hatch until they are able to survive in ambient temperature (no longer brooded).
	Growing Turkeys			Turkeys grown for meat purposes to a market age of approximately 17 (female) or 22 (male) weeks; may be further divided into heavy or light turkey strains.
	Finishing Turkeys			Turkeys intended for meat production during the last 2 to 4 weeks of growth.
	Replacement Turkeys			Turkeys intended to become laying hens or breeding turkeys.
	Breeding Turkeys			Sexually mature male or female turkeys intended to produce fertile eggs; their eggs are not intended for human food use.

female cattle of a recognized dairy breed over 20 months of age.[2] Both dry and lactating dairy cattle would fall under this category. "Minor" food animal species are defined by exclusion, meaning that the "major" animal species have been identified and all others are considered "minor." Examples of "minor" food animal species would include goats, sheep, and cervids.

On-Label Drug Use

In food animal medicine, medications can be administered to an individual animal or a herd or flock depending on numbers of animals needing treatment, disease, and/or overall management practices. Practitioners treating food-producing animals in the United States can use FDA-approved veterinary products according to the label. Using medications according to the label directions is termed *on-label drug use,* where all of the drug label specifications (animal species and class, administration route, dose, dosing frequency/interval, indication, limitations, and withdrawal time) are fulfilled and the FDA-approved withdrawal time is observed. The FDA-approved withdrawal time (WDT) is the amount of time that must be observed after the last dose is administered and before the food product intended for human consumption can enter the human food chain. There are multiple databases where label information for FDA-approved veterinary medications is accessible and can be consulted. Table 45-5 lists a few resources.

Extralabel Drug Use and the Animal Medicinal Drug Use Clarification Act (AMDUCA) of 1994

Prior to the enactment of the Animal Medicinal Drug Use Clarification Act (AMDUCA) in 1994, veterinarians could legally treat food animals with on-label medications only. Passage of AMDUCA legalized most instances of extralabel drug use (ELDU) in food animals by or on the order of veterinarians.[3] Extralabel drug uses include prescribing or administering a human or veterinary drug at a higher dose, frequency, or duration, by a different route of administration, in a different species, or for a different indication than as described on the product's label. For food animal practitioners, with this privilege comes the weighty responsibility of protecting the health of consumers of animal products. Veterinarians must meet very specific conditions before they may legally use or prescribe drugs in an extralabel fashion. Under AMDUCA, ELDU is limited to cases in which the health of the animal is threatened or when suffering or death may result from a lack of treatment. ELDU may not be used to enhance production or for non-therapeutic reproductive cycle manipulation in healthy animals and can only occur on the order of a veterinarian within the context of a veterinarian-client-patient relationship (VCPR) as described in Box 45-2. ELDU may be considered in food-producing animals only when no approved drug is available that contains the same active ingredient in the required dose, form, and concentration or when the veterinarian finds that there is no approved drug that is clinically effective for the intended use. Extralabel drug use in or on animal feed is also expressly prohibited.

AMDUCA stipulates that ELDU only applies to FDA-approved human and veterinary medications. It does not legalize the extralabel use of EPA-regulated pesticides or USDA-regulated biologics. New animal drug application (NADA) or abbreviated new animal drug application (ANADA) numbers are a good indication of whether a drug is FDA approved. The presence of a NADA or ANADA number on the product label is an indication that the veterinary drug has FDA approval. Similarly for human drugs, every approval has a unique new drug application (NDA) number for pioneer drugs or abbreviated new drug application (ANDA) number for generic drugs. Approval status of both animal and human drugs can be found on the FDA-CVM (http://www.fda.gov/AnimalVeterinary/) and FDA (http://www.fda.gov) websites, respectively.

BOX 45-2

Conditions Necessary for Extralabel Drug Use

1. Extralabel drug use (ELDU) is permitted only by or on the order of a veterinarian.
2. The veterinarian judges on-label treatments to be unavailable or ineffective.
3. ELDU uses only U.S. Food and Drug Administration (FDA)–approved animal and human drugs, not drugs imported from foreign countries or compounded from bulk sources. When treating food animals, approved food animal drugs should be used before approved animal drugs which should be used before approved human drugs.
4. A valid veterinarian-client-patient relationship (VCPR) exists in which the veterinarian:
   - oversees medical treatment decisions on the farm
   - is familiar with animal care through appropriate and timely visits
   - has sufficient knowledge to initiate a diagnosis
   - is available for follow-up care as needed
5. ELDU is for therapeutic or humane purposes only, not to increase production or manipulate reproductive cycles in normal animals.
6. ELDU applies only to administration to individual animals and in water, not in feed.
7. Animal identification and treatment records are sufficient to identify treated animals and their treatment history and are maintained for 2 years.
8. The veterinarian establishes an extended drug withdrawal period protective of human health supported by scientific evidence. ELDU resulting in violative or dangerous food residues is not permitted.
9. Drug labels list the name and address of the prescribing veterinarian, animals to be treated, and the drug name, disease indication, dose, frequency, duration, cautions, and withdrawal periods associated with treatment.
10. Certain extralabel uses specifically prohibited by the FDA are not used (see Box 45-4).

BOX 45-3

Conditions Necessary for Extralabel Use of Medicated Feed in Minor Species

1. Extralabel use of medicated feed is only for treatment of minor species, defined by exclusion as animals other than cattle, horses, swine, chickens, turkeys, dogs, and cats.
2. Extralabel use of medicated feed is limited to farmed or confined minor species but not unconfined wildlife.
3. Extralabel use of medicated feed is limited to situations in which the health of an animal is threatened and suffering or death may result from failure to treat.
4. There is no alternative therapeutic dosage form (besides feed) that can be practically used under legal extralabel use.
5. Only feeds formulated and labeled for use in a major species animal are used.
6. Extralabel use of medicated feed in aquaculture is limited to medicated feed products approved for use in aquatic species.
7. The medicated feed is used within 3 months of a veterinarian's written recommendation. Recommendations, feed labels, and invoices are kept for at least 1 year. Adverse reactions are reported to the U.S. Food and Drug Administration within 10 days.
8. All other Animal Medicinal Drug Use Clarification Act requirements are complied with, including a valid veterinarian-client-patient relationship, lack of label alternatives, treatment records, animal identification, and extended withdrawal times (see Box 45-2).
9. The medicated feed is used in accordance with federal, state, and local environmental regulations and approval. This is particularly important for aquaculture uses.
10. The producer has followed worker safety provisions in the approved product labeling.

When veterinary products are used in an extralabel manner, a withdrawal "interval" must be estimated based on scientific evidence and must be extended beyond the FDA-approved WDT regardless of the dose, route, or indication. This ensures that there are no illegal residues, another stipulation in AMDUCA. A residue is considered to be either the parent compound or metabolite of that parent compound that may accumulate, deposit, or otherwise be stored within the cells, tissues, organs, or edible products (e.g., milk, eggs) of an animal following its use to prevent, control, or treat animal disease or to enhance production.[4]

As stipulated by AMDUCA, veterinarians' obligations regarding extralabel drug use are listed in Box 45-2. The American Veterinary Medical Association (AVMA) has developed an algorithm that helps veterinarians determine whether the intended ELDU is legal according to AMDUCA.[5]

Veterinarians violating state or federal laws regulating the transport, sale, or use of drugs may face a variety of sanctions, including warning letters, fines, temporary or permanent revocation of license, and incarceration.

Extralabel Drug Use of Medicated Feeds in Minor Species

Even though AMDUCA prohibits the extralabel use of medications in feed, a compliance Policy Guide (CPG) 615.115 for extralabel use of medicated feeds for minor animal species does exist.[6] The AMDUCA prohibition of extralabel use of medications in feed was generated because of concerns of antibiotic resistance. AMDUCA's Section 530.11 specifically prohibits the "extralabel use of an approved new animal drug or human drug in or on an animal feed." As a matter of enforcement discretion, CVM generally has not objected to mixing a drug with an individual animal's feed, but extralabel mass medication in feed is prohibited "without limitation or exception." Veterinarians may, however, be called on to treat minor food animal species such as farmed exotic ruminants, fish, or game birds. CVM has found that for many of these species, very few approved drugs exist. In addition, CVM recognizes that some minor food animal species (such as fish and game birds) cannot be practically medicated in any way other than through the use of medicated feeds. In such situations, a veterinarian may determine that extralabel use of medicated feeds (approved for use in other species) can prevent suffering and death in these minor species.

Although AMDUCA prohibits ELDU in feed, in the previously described circumstances CVM "ordinarily will not consider regulatory action" against the veterinarian or animal producer provided that certain criteria listed in Box 45-3 are met.[6] The CVM policy being implemented in these cases is akin to that of extralabel drug use by veterinarians before the 1994 passing of AMDUCA. The drug use is still illegal, but CVM will apply regulatory discretion relative to taking enforcement action. A critical aspect of CVM's regulatory discretion in this practice is that labeled treatment alternatives are not available. The best resource to aid practitioners in determining what treatments are approved for minor food animal species is the Minor Species Drug Approval site (http://www.nrsp-7.org).

Prohibited Drugs/Drug Classes Prohibited from Extralabel Drug Use in Food Animals

Certain drugs may not be prescribed or used even under the auspices of AMDUCA.[7] Under statutory authority provided in AMDUCA, the FDA's Center for Veterinary Medicine (CVM) has prohibited approximately a dozen drugs or drug classes, making their extralabel use in food animals illegal. Other compounds not specifically listed in AMDUCA are prohibited by virtue of the fact that no approved animal or human products are commercially available. Last, extralabel use of treatments is also regulated by the Pasteurized Milk Ordinance (PMO). The extralabel use in food animals of the

VetBooks.ir

BOX 45-4

Drugs or Drug Classes Prohibited from Extralabel Drug Use*

Diethylstilbestrol (DES)
Chloramphenicol
Nitroimidazoles (including dimetridazole, metronidazole, and ipronidazole)
Sulfonamide (other than sulfadimethoxine) in adult dairy cattle†
Clenbuterol
Fluoroquinolones (e.g., enrofloxacin and danofloxacin)
Glycopeptides (e.g., vancomycin)
Nitrofurans (including nitrofurazone, furazolidone; topical use prohibited as well)
Phenylbutazone in adult dairy cattle†
Adamantane and neuraminidase inhibitors in poultry
Cephalosporins (not including cephapirin) in cattle, swine, chickens, or turkeys:
(i) For disease prevention purposes;
(ii) At unapproved doses, frequencies, durations, or routes of administration; or
(iii) If the drug is not approved for that species and production class.

*Extralabel use of some drugs or drug classes (not specifically addressed in the Animal Medicinal Drug Use Clarification Act) are prohibited because these drugs are not available as approved animal or human products, by U.S. Food and Drug Administration (FDA) policy or in the Pasteurized Milk Ordinance (see chapter text).
†Defined by FDA as dairy cattle (lactating or dry) older than 20 months of age.

compounds listed in Box 45-4 represents one of the FDA's highest priorities for regulatory attention. It is advised that the FDA-prohibited drug list be checked on a regular basis for updates as it is subject to change. FARAD and AVMA websites both list prohibited drugs.[8,9] Alternatively, 21CFR530, the section of the CFR pertaining to ELDU, may be accessed directly.[10]

If any of these prohibited drugs are mistakenly used in a food-producing animal, that animal and its by-products should never be allowed to enter the human food chain and ideally that animal should be isolated from other food animals.

Drugs Prohibited from Use in Food Animals:

1. Diethylstilbestrol: From the 1940s to the 1970s, U.S. physicians prescribed diethylstilbestrol (DES, a potent nonsteroidal synthetic estrogen) to pregnant women to prevent miscarriage and other reproductive diseases. In 1971 a link between in utero exposure to DES and a rare vaginal cancer (clear cell adenocarcinoma) was established. In the same year the FDA published an alert advising doctors against the use of DES during pregnancy. The U.S. Department of Agriculture (USDA) banned the use of DES in food animals in 1979.
2. Chloramphenicol: An estimated 1 in 10,000 to 50,000 people exposed to chloramphenicol will develop a non-dose-related aplastic anemia. Because of concerns that this idiosyncratic and frequently fatal complication could be triggered by residues, chloramphenicol use in food animals was prohibited in 1984. The prohibition extends to all formulations of chloramphenicol including ophthalmic ointments. Florfenicol, a synthetic member of the chloramphenicol family, lacks the p-NO2 group thought to be responsible for inducing the aplastic anemia. Florfenicol may be used extralabel in food-producing species. However, veterinarians should be aware that extralabel use of florfenicol in dairy cattle greater than 20 months of age requires extended withdrawals to allow depletion of drug residues in the liver to a level below detection by the Food Safety Inspection Service (FSIS).
3. Nitroimidazoles: Historically, dimetridazole and ipronidazole have been approved for the treatment of histomoniasis (infectious enterohepatitis, blackhead) in turkeys. Ipronidazole and the human drug metronidazole have been used off-label to eliminate the carrier state of trichomoniasis in bulls. Laboratory studies of members of this drug class demonstrated mutagenicity and carcinogenicity, leading to the prohibition of their use in food animals. Because there are no approved veterinary nitroimidazole labels, the use of any member of this drug class in food animals is illegal.
4. Nitrofurans: In the past, nitrofurazone and furazolidone were approved for a variety of protozoal and bacterial infections in poultry and swine. Topical formulations (sprays and "puffer" products) have also historically been marketed for wounds and ocular infections in livestock ("pinkeye"). Based on laboratory evidence of carcinogenicity and the absence of a reliable detection method, the FDA withdrew approval for systemic animal nitrofuran products in 1991 and prohibited all extralabel treatment (including topical use) in 2002. Because nitrofurans have no approved food animal uses, the use of any member of this drug class in food animals is illegal.
5. Clenbuterol: Marketed in the United States as an equine bronchodilator, this synthetic sympathomimetic has been used illicitly to increase weight gain and lean body mass in food animals, particularly show animals. Because muscle depletion and fat re-deposition commences after drug withdrawal, producers may be tempted to market animals with little or no withdrawal interval. Cooking temperature only minimally denatures the compound, and toxicity from residues has resulted in hundreds of emergency hospitalizations in consumers of tainted beef in Spain and Italy.[11,12]
6. Glycopeptides: Vancomycin, the only glycopeptide antibiotic available in the United States, is often the therapy of last resort for methicillin-resistant *Staphylococcus aureus* (MRSA) infections in humans. Demonstration of vancomycin-resistant *Enterococcus* in the feces of poultry and swine fed the glycopeptide avoparcin led CVM in 1997 to prohibit extralabel use of glycopeptides in food animals.
7. Phenylbutazone in Adult Dairy Cattle: The use of phenylbutazone, a nonsteroidal antiinflammatory agent, in humans has been associated with a variety of adverse drug reactions including fatal blood dyscrasias. After USDA reports of a high incidence of phenylbutazone tissue residues in cull dairy cows, CVM prohibited its use in female dairy cattle older than 20 months of age. Antiinflammatory therapy for lactating dairy cattle is available as flunixin meglumine. Flunixin should be used only on-label (intravenously) because intramuscular or intravenous administration can greatly extend withdrawal times.[13]
8. Antiviral Drugs in Poultry: Concern exists that use of antiviral drugs in poultry could promote drug resistance in zoonotic pathogens, particularly avian influenza H5N1 ("bird flu"). These concerns led CVM in 2006 to prohibit extralabel use of two drug classes used in treating human influenza. Adamantanes and neuraminidase inhibitors may not be used in chickens, turkeys, and ducks. Aside from compounds specifically prohibited through AMDUCA, there are several compounds that CVM has reminded veterinarians cannot be legally obtained as finished animal or human products and therefore have no legal extralabel uses.
9. Dipyrone: At one time, approved for humans and animals, dipyrone was withdrawn from the market because of concerns of adverse events in humans associated with its use, including teratogenicity, prolonged bleeding times, and agranulocytosis.
10. Estradiol Cypionate: Before 2003, estradiol cypionate (ECP, a synthetic estrogen) was commercially marketed as reproductive therapy in food animals. ECP had not undergone a formal approval process, however, and discretionary marketing was discontinued for lack of food safety and efficacy data. Use in or compounding of ECP for food animals remains illegal.
11. Gentian Violet: Gentian violet was originally used as an additive to poultry feed as a mold inhibitor. However, the FDA has never approved the use of this product as a feed additive or as an

VetBooks.ir

animal drug, and the impact of any residues on human health is unknown. Therefore, any use in feeds constitutes extralabel use of a medicated feed and unapproved animal drug. In addition to medicated feeds, topical formulations containing gentian violet are currently being marketed. However, in 2007, the FDA issued a warning advising veterinarians of the illegal nature of using topical products containing gentian violet in food-producing animals.

12. Hormone Implants in Veal Calves: Although growth-promoting hormone implants have been marketed for ruminating cattle, these products never underwent regulatory approval for non-ruminating veal calves. Concern existed in CVM that non-ruminating calves may eliminate the hormone contained in the implants differently than ruminants. In 2005 a new warning statement was added to the label of all growth-promoting hormone implants, reminding producers and veterinarians that their use in veal calves is illegal.
13. Dimethyl Sulfoxide and Colloidal Silver: Besides AMDUCA, the Grade A PMO also directs how drugs will be used and stored on dairy farms. Dimethyl sulfoxide (DMSO) and colloidal silver may not be used in or on dairy animals and, if found during a dairy inspection, can result in "debits."

Drug Classes Prohibited from ELDU in Food Animal Species

In addition to the aforementioned specific drugs that the FDA has prohibited, there are drug classes for which some drugs may have FDA approval for use in food-producing animals, but these drug classes are prohibited any extralabel drug use. These drug classes with an ELDU prohibition include the following:

1. Cephalosporin-class antibiotics

   On April 5, 2012, in hopes of preserving their effectiveness for human populations and decreasing the likelihood of the emergence of cephalosporin-resistant strains of foodborne bacterial pathogens, the extralabel use of cephalosporins in cattle, swine, chickens, and turkeys was prohibited. This prohibition does not include (1) the extralabel use of cephapirin in food-producing animals, (2) use of a cephalosporin to treat an extralabel indication, provided that all other label directions are followed, including species, dose, route, duration, and frequency, and (3) extralabel use in minor food-producing animal species (i.e., species that do not include cattle, swine, chickens, or turkeys).
2. Sulfonamides in Adult Dairy Cattle

   The observed carcinogenicity of sulfonamides in laboratory animals, coupled with frequent finding of sulfonamide residues in milk, led to the prohibition of extralabel use of these compounds in adult dairy cattle. The FDA defines a lactating cow as any dairy cow (milking or dry) older than 20 months of age. The use of any sulfonamide in adult dairy cattle other than approved uses of sulfadimethoxine (SDM), sulfabromethazine, and sulfamethoxypyridazine is illegal. This would include use of a higher dose of SDM or using slow-release formulation SDM boluses.
3. Fluoroquinolones

   Uncertainty exists related to the magnitude and significance of human pathogen resistance resulting from antibiotic use in animals. Fluoroquinolones are mainstay treatments of antibiotic-resistant *Salmonella* and anthrax infections in humans. Concern that fluoroquinolone use in food animals was promoting human pathogen resistance prompted CVM in 1997 to prohibit extralabel use of these compounds. Any deviation from a fluoroquinolone product label (altering species use, dosage, route of administration, or disease indication) is illegal. In the case of the approved beef cattle formulation of danofloxacin, this prohibition extends to use in all non-beef-production animals, including lactating and nonlactating dairy cows, heifer replacements, bulls, and veal calves. The same applies to enrofloxacin with the exception of nonlactating dairy cattle, defined by the FDA as dairy cows less than 20 months of age, for which there is a label indication.

Considerations for Treatment of Companion Food Animal or Pack Animal Species with Prohibited Substances

The previously detailed FDA-prohibited drug and drug class list pertains to food-producing animals only and not companion species such as dogs and cats. Veterinarians occasionally treat companion animals belonging to a food-producing species (horses, llamas, pygmy goats, pot-bellied pigs). As long as these animals can be guaranteed to never enter the human food chain, CVM does not normally consider these to be food animals. However, even if they are not to be slaughtered, consideration for why the prohibition exists should be carefully examined and prudent pharmacovigilance used. Practitioners who have used a prohibited substance in a companion or pack animal that subsequently enters the food supply are subject to enforcement actions under the Food Drug and Cosmetic Act. In choosing to use a prohibited drug in a companion or pack animal, the practitioner is accepting a certain amount of liability because the ultimate fate of such treated animals is often beyond their control. Practitioners may choose to have owners sign an agreement (entered into the medical record) not to introduce the animal into the human food chain.

Compounding of Medications for Food Animals

Compounding is defined as a manipulation to produce a dosage form of a drug other than that provided for in the labeling, such as reconstitution. CVM recognizes the need for compounding within certain areas of veterinary practice, such as mixing or dilution. Because of the absence of safety, efficacy, and food safety data for compounded drugs, the potential exists for adverse reactions in treated animals or consumers of their products. In addition, if there are not sufficient scientific data upon which to estimate a withdrawal for a compounded medication, it is the responsibility of the veterinarian to ensure that the animal and any food products that result from that animal do not enter the human food chain. Under AMDUCA, it is legal for veterinarians (or pharmacists on the order of a veterinarian) to compound from U.S.-approved animal and human drugs if the conditions listed in Box 45-5 are met.[3,14]

Overall, when treating a food-producing animal, the use of compounded medications should be only a last resort because safety of the food chain should be the first priority of the veterinarian.

Antidotes Compounded from Bulk Drug

Despite the prohibition, several chemicals commonly recommended as food animal antidotes are available only through compounding from bulk drug. As described in the previous section, compounding veterinary medications from bulk drugs is illegal. However, analogous to its policy concerning ELUD in feed for minor species, CVM

BOX 45-5

Requirements for Compounding in Veterinary Practice

1. No approved animal or human drug can be used in its available dosage form and concentration.
2. Only approved animal or human drugs are used in the compounding, specifically not foreign or bulk drugs.
3. Compounding is performed by a licensed pharmacist or veterinarian in compliance with state pharmacy laws.
4. Adequate procedures are in place to ensure the safety and effectiveness of the product.
5. Withdrawal intervals are set by the veterinarian and not the pharmacist.
6. The scale of the compounding operation is commensurate with the established practice needs.
7. All other Animal Medicinal Drug Use Clarification Act requirements are met (see Box 45-2).

VetBooks.ir

will not normally consider regulatory action against veterinarians compounding certain antidotes from bulk sources if certain conditions are met, essentially the same as those listed in Boxes 45-2 and 45-5. CVM has listed chemical antidotes against which the FDA and CVM would presently not ordinarily object. These include ammonium molybdate, ammonium, tetrathiomolybdate, ferric ferrocyanide, methylene blue, picrotoxin, pilocarpine, sodium nitrite, sodium thiosulfate, and tannic acid.[6,14] This list should not be construed as containing the only drugs for which the FDA would extend regulatory discretion for compounding, and inquiries about additional compounds can directed to the FDA/CVM, Division of Compliance, at 301-827-1168. It is critical that veterinarians recognize that in toxicity cases, withdrawal periods will need to be established not only for the antidotes but also the toxicants. Some antidotes require substantially extended withdrawals, which may affect the decision to treat.[15] As a practical matter, toxicity cases are frequently resolved based on testing in state or federal laboratories. Because of these complexities, practitioners are advised to consult the diagnostic laboratories and/or FARAD when dealing with such cases in food animals.

FARAD: The Food Animal Residue Avoidance and Depletion Program

One of the regulatory requirements for legal ELDU is that the attending veterinarian recommends a scientifically based withdrawal interval recommendation before the producer can market the milk, meat, eggs, or other edible products. Commonly, the most efficient way for a food animal practitioner to meet these requirements is to consult FARAD. Veterinarians, producers, students, or regulatory personnel may obtain free consultation with specialists by contacting 1-888-US-FARAD or accessing the FARAD website at http://www.farad.org and submitting a request. Recommendations are made on a case-by-case basis depending on the individual variables of each exposure, changing tolerances or FDA withdrawal times and new information in the literature. FARAD also advises on pesticide exposure and accidental contaminations (biotoxins, heavy metals, radionuclides, unintended feeding of medicated feed).

FARAD maintains a database of all food animal products approved in the United States and more than 9000 pharmacokinetic citations describing depletion of more than 2000 chemicals in various species. FARAD collects, analyzes, and evaluates scientific data to provide withdrawal intervals when drugs are used in an extralabel manner. The FARAD website (http://www.farad.org) contains a database of approved food animal drugs searchable by drug, trade name, and species, known as Vetgram. A mobile version of Vetgram is also available on the FARAD website. Veterinarians may also find downloadable copies of published summary recommendations as well as a quick review of past recommendations there.

Published techniques for estimating a withdrawal interval (WDI) after ELDU in food animals are available.[16-18] Information that FARAD considers when estimating a WDI include:

1. General factors impacting pharmacokinetic parameters and drug residues such as conditions affecting drug absorption and elimination as well as dose, duration of treatment, and administration route.
2. Existence of an FDA-established withdrawal time. AMDUCA stipulates that a substantially extended withdrawal should be applied for any ELDU. Therefore, doses that are less than the labeled dose will still require a withdrawal that is longer than the labeled WDT.
3. Physiologic factors/compromised health conditions impacting pharmacokinetic parameters and drug elimination (e.g., dehydration, renal dysfunction, gastrointestinal disease).
4. Published pharmacokinetic parameters (i.e., time vs. concentration data, including drug residue serum, tissue, or milk data).
5. The existence of an established tolerance or maximum residue limit (MRL).
6. Analytical testing method and limits of detection.
7. Foreign drug approval data.

Testing for Drug Residues

If a practitioner or producer/owner wants to confirm that edible products (i.e., meat or milk) are at or below the tolerance, they can consider testing for drug residues. A number of commercial rapid tests exist for drug residue testing using a milk, serum, or urine matrix. Examples of some manufacturers of these tests include IDEXX Laboratories, Inc.; Charm Sciences; DSM Food Specialties; Neogen Corporation; and Silver Lake Research Corporation. Care should be taken to ensure that the test used detects residues to a level at or below the FDA-established tolerance to be certain that the food product is safe to enter the human food chain. Alternatively, samples or carcasses can be submitted to a commercial laboratory or state veterinary diagnostic laboratory for residue testing. For milk, processing plants may be willing to test.

Regulatory Monitoring of Drug Residues in Animal Products

Once products begin the process of entering the human food chain, they may undergo residue testing as part of the National Residue Program (NRP). The FSIS, the Environmental Protection Agency (EPA), and FDA cooperate to regulate animal drug residues, pesticides, environmental contaminants, and any other chemical hazards in meat or egg products. Every year, the sampling plan, known as the "Blue book," is released, which includes such details as the number of tissue or egg samples that will be tested and which chemical or drug residue it will be tested for. Results of the testing are also made publicly available on an annual basis in the "Red book."

Unchanged for many years, in July 2012, FSIS announced that scheduling of the NRP sampling plan will be changing.[19] Sample numbers per production class will be reduced because of the adoption of new analytical methods. Analysis for more chemical residues per sample will be possible, requiring fewer overall samples than in the past.

Biosecurity and Infection Control for Large Animal Practices

PAUL S. MORLEY and J. SCOTT WEESE, *Consulting Editors*

Infection control, biosecurity, biocontainment, and biosafety are essential functions at all health care operations, including veterinary practices.* All veterinarians, at some level, recognize and act to prevent adverse outcomes in patients. However, as major outbreaks of health care–associated infections (HCAI) at veterinary hospitals have become increasingly publicized,[1-12] it has become increasingly obvious that coordinated infection control practices are a critical component of delivering high-quality care at veterinary facilities, especially those with large caseloads and those that specialize in intensive care of patients. This threat is relevant to all veterinarians and all hospitals. A survey of veterinary referral hospitals at American Veterinary Medical Association (AVMA)–accredited institutions reported that 81% had recognized outbreaks of HCAI in patients within 5 years, and at least 45% had recognized more than one outbreak.[13] The two agents most commonly associated with these outbreaks were *Salmonella enterica* and methicillin-resistant *Staphylococcus aureus* (MRSA), but 12 other agents were also implicated. Fifty-eight percent of the 38 participating hospitals had to restrict admissions to protect patients and allow mitigation, and 12 of these hospitals (all were equine hospitals) were temporarily closed. Even with very limited surveillance, 51% of these same hospitals recognized significant HCAI and illness within 3 years of interviews. The agent most commonly implicated in human illnesses was *Cryptosporidium parvum*.

The standard of veterinary care is changing such that sporadic occurrences and outbreaks of HCAI may no longer be interpreted as unavoidable accidents if coordinated measures are not routinely used to minimize their likelihood. Our understanding about infection control issues in veterinary medicine has also advanced significantly during the past decade. As such, what may have passed as sufficient for infection control in veterinary practices 10 or 20 years ago may often not be sufficient today. It is also important to realize the important part that infection control and biosecurity must play in ambulatory practices and on our clients' premises. Inherently, healthy animals with lower contagious disease risks represent a smaller proportion of hospital populations than they do among populations in their home environments. However, veterinarians are obviously called upon to contact those animals most likely to be shedding contagious pathogens regardless of whether this is in hospitals or in the field. In addition, there are several examples in which patients discharged from hospitals were the likely source of viral and bacterial infections for animals in their home environments.[6,9] The magnitude of this potential hazard is perhaps best illustrated by the equine herpesvirus type 1 (EHV-1) outbreak, which occurred in association with the National Cutting Horse Association Western National Championship in Ogden, Utah, in May, 2011.[14,15] It is likely that exposure to a single horse that was shedding EHV-1 at this event resulted in over 165 horses developing clinical disease that was known or suspected to be caused by EHV-1, and at least 13 of these horses were euthanized. The outbreak spanned at least 10 western U.S. states and two Canadian provinces. Clearly the need to apply sound biosecurity and infection control practices extends well beyond the walls of veterinary hospitals.

However, it is also clear that these dramatic outbreaks are not the only circumstances in which HCAI affect patients. Lessons learned in human health care settings clearly show that endemic occurrence of HCAI typically creates a much greater overall burden in exacerbated morbidity and mortality than does the occurrence of epidemics. Unfortunately, there is insufficient information available from veterinary care settings to clearly say whether the same is true for animal patients, but there is no reason to believe that it would be different. Still, when studied systematically, the burden of disease associated with sporadic or endemic HCAI is substantial in veterinary patients. A recent publication of a multicenter study performed in five academic referral hospitals reported that nosocomial events monitored as seven different clinical syndromes were recognized during hospitalization in 19.7% (95% CI = 14.5% to 26.7%) of equine patients admitted for gastrointestinal disease at a rate of 3.9 events per 100 days of hospitalization (95% CI = 2.9 to 4.3 events per 100 hospitalization days).[16] Other studies reported in equine patients have principally focused on HCAI related to surgical site infections.[17,18] These rates are not dissimilar from rates reported for HCAI among humans in critical care settings. Thus, these notable outbreaks of HCAI and the emerging awareness of the importance of endemic occurrences should create an acute awareness that dramatically sharpens our focus on preventing all types of HCAI, including those that seem sporadic. Although the discussions in this chapter are mostly framed in the context of hospital settings, the concepts and issues apply much more broadly to ambulatory practices and animals' home premises.

*Throughout this chapter, the terms *infection control* and *biosecurity* are used interchangeably to encompass all practices related to the prevention of introduction and spread of infectious diseases in populations of animals or their human caregivers. Some authors differentiate activities by using the term *biosecurity* to specifically refer to issues related to disease introduction and differentiate this from *biocontainment,* which may focus more on control of the spread of agents after introduction. In addition, the term *biosafety* is sometimes used to specifically relate to matters pertaining to human health.

VetBooks.ir

How Much Is Enough? How Much Is Too Little?

Exposures to contagious disease threats, HCAI in patients, and zoonotic infections in care providers are undeniable risks in every veterinary practice. Because veterinarians have ethical and legal obligations to take reasonable protective actions to prevent their patients and employees from foreseeable harm associated with their actions (and inactions), it is clearly possible to not pay enough attention to infection control. The consensus opinion of veterinary infection control experts is that there is a recognizable standard of practice for infection control in veterinary medicine and appropriate effort must be given to the control and prevention of infectious disease transmission in all animal populations.[19] The implication that should be recognized is that it is possible to commit malpractice by not paying enough attention to infection control while caring for patients. There are key areas that must be addressed in all comprehensive infection control programs, including patient contact, hygiene, surveillance, communication, and education.[20] However, we cannot determine whether we are meeting an acceptable standard of care for infection control by listing the specific prevention strategies that are used, but rather we must evaluate the occurrence of HCAI in a veterinary practice along with how we respond to the identification of these HCAI. Few prevention practices for HCAI are universally considered applicable and efficacious for preventing HCAI in all settings. Rigorous attention to hand hygiene would meet these criteria, but many other common control methods such as the use of disinfectant footbaths or coveralls do not. Thus, it is not possible to judge whether a control program is sufficiently rigorous solely by evaluating procedures, protocols, and policies.

Recognition of the risks for legal liability undoubtedly give reason for pause, but a better motivation for emphasizing infection control practices should be to provide the best care possible within the scope of a practice's specialization. In order to create an environment where patient care can be optimized, it is incumbent upon veterinarians to actively manage the risk of HCAI in their patients. Achieving excellence in patient care and helping clients are undoubtedly among the highest priorities for all veterinary practices. However, the occurrence of HCAI in our patients is an ever-present hazard that interferes with our ability to deliver optimal patient care. Good infection control practices are not the only feature defining excellence in veterinary care, but it is impossible to achieve excellent patient care without appropriately controlling HCAI. The implications of suboptimal infection control may not always be readily apparent, but both sporadic/endemic infections and outbreaks can have a significant effect on patient morbidity, patient mortality, hospital economics, personnel health, personnel morale, and facility reputation. There are also liability implications for HCAI that occur in the absence of an appropriate infection control program.

Although HCAI are an undeniable hazard associated with caring for patients, and although it is possible to reduce the risk of infections through a variety of prevention strategies, it is important to note that not all HCAI are preventable using practical and cost-effective control programs. In reality, even impractical and cost-prohibitive programs would not eliminate HCAI, since there is an undefined but undeniably significant "nonpreventable" fraction of infections that will occur despite any infection control practices. To be most successful, it is important that over time administrators and personnel responsible for infection control programs strive to better understand and target prevention efforts at this preventable fraction of all HCAI.

Principles of Infection Control

In general, all comprehensive infection control programs center on four major goals:

- Decreasing the likelihood of exposure to infectious agents among patients and personnel
- Decreasing the intrinsic risks for HCAI
- Maximizing participation of personnel in infection control activities
- Optimizing the efficiency of infection control procedures and policies

These goals are achieved through five general areas of action:

- Decreasing direct and indirect patient contact
- Optimizing hygiene
- Using proven directed actions that decrease risks or are protective against HCAI, as well as actions that have a reasonable likelihood of efficacy based on biology, principles of pathogen transmission, and data from other species
- Recognizing high-risk patients and HCAI through efficient surveillance strategies
- Maximizing communication and education among all personnel

When initiating an infection control plan, it is important to take a global assessment of the contagious disease hazards in a practice, the level of risk aversion, and the resources that can be expended on infection control efforts. If a veterinary practice predominantly works in preventive health care under extensive field conditions, the contagious disease hazards may be less common and less severe than those encountered if a practice concentrates on intensive care of patients in a hospital. The specific disease hazards will also vary with the types of patients being managed (i.e., sick neonates vs. patients with acute GI disorders vs. reproduction cases, equine vs. bovine vs. camelid, etc.). Risk aversion is a concept that relates to how much a person or business is unwilling to accept or allow a negative event to occur. The inverse of risk aversion can be thought of as risk tolerance. The more risk averse a person is, the more it may be reasonable for him or her to initiate and maintain a rigorous infection control program. In contrast, a more risk-tolerant veterinarian may recognize the potential for contagious disease hazards in his or her practice but may not believe it is necessary to engage in preventive strategies that are seen as extreme. However, the risk tolerance of an individual or facility cannot be the sole deciding factor, since management decisions have impacts on patients and their owners, hospital personnel, and even animals and humans in the broader population. Thus, there is a baseline level of risk aversion that must be present. As our understanding of risks for HCAI methods for infection control advance, the bar is being raised, resulting in professional and legal risks should veterinarians fail to ensure that they are adequately pursuing infection control in their daily practices. The third component of this internal inventory is to assess the resources that will be available for infection control activities. The term *resources* in this context is intended to broadly encompass monetary resources, personnel time, and effort.

Keeping in mind this assessment of mindset and resources, the next step in developing an infection control program is to elaborate what the specific goals will be. For example, specified goals for an infection control program might include protection of hospital personnel and clients from exposure to zoonotic disease agents, creating an environment where patient care can be optimized by minimizing the risk of HCAI, optimizing education of personnel and clients regarding important infectious disease hazards, and protecting the operational capabilities of the practice. Using a comprehensive, systematic process for evaluation of disease hazards and design of control systems will then allow design of a logical control system that triages efforts to optimize efficiency. One systematic approach that the authors have used successfully is Hazard Analysis and Critical Control Points (HACCP) methodology.[21] After identifying which specific hazards (infections) are most likely to occur, as well as when and where in the systems these events might occur or be prevented, the next step is to define specific control measures. As mentioned previously, the majority of these prevention efforts are effective because they decrease the likelihood of exposing patients to infectious agents (i.e., by optimizing hygiene in the environment, personnel, or patients or by decreasing direct and indirect contact among patients). A few other prevention practices are effective because they reduce the inherent susceptibility to infection. To understand which control measures are of greatest importance and where efforts should be targeted, it is critical to consider the lifecycle and methods of

VetBooks.ir

transmission for the specific agents of concern. Among the questions that should be asked: Is the agent most likely transmitted through direct contact, or are respiratory aerosols or contaminated surfaces and fomites also important sources of exposure? Is there a subclinical carrier state associated with agent shedding or is shedding mostly restricted to clinically affected patients? Does the agent persist well in the environment and can common disinfection procedures readily inactivate organisms?

Each infectious disease may be considered individually in this evaluation process, but it is useful to remember that control measures that are effective against one agent are usually effective against others, particularly if they share common routes of transmission or have common risk factors in patients. Design of infection control programs should focus on practical actions for known problems, but it is important not to ignore the potential for newly recognized and re-emerging diseases. Infectious diseases continue to emerge internationally and many are of relevance to large animal veterinary medicine. The general strategy used in infection control protocols should be sufficiently rigorous to protect against most emerging issues, at least at a basic level. However, infection control programs should also be adequately fluid so that they can be modified to address new issues.

Another critical aspect in the practice of infection control is effective targeting of efforts. Taken to hypothetical extreme, the most rigorous infection control methods would prescribe that *every* patient be handled in complete isolation using barrier precautions verging on those used by "hazmat" personnel. Clearly this is not practical or needed in most situations, and yet, in a few rare circumstances this level of precaution can be warranted. In many more situations, some lesser level of precaution is warranted beyond that used in casual encounters with animals in their home environments. By their very nature, these extra control measures will inevitably inconvenience caregivers and clients in addition to increasing costs associated with care. These measures could also affect the quality of patient care and result in a corresponding *increase* in morbidity when taken to the extreme. The challenge is to target prevention efforts to just those patients that warrant increased concern and to use the most appropriate, albeit inconvenient, methods for controlling risks to personnel and other patients.

Another side effect of the inconvenience created by infection control efforts is that people by their very nature gravitate to the most convenient methods for daily activities. As such, the more personnel are inconvenienced through infection control efforts, the less likely they are to follow prescribed policies unless they understand and believe that procedures are needed and have value. Thus, a critical component of any effective infection control program is maximizing awareness of personnel and educating them about potential hazards and the value of established control measures. Presenting nightmarish worst-case scenarios without other objective information may be initially effective in getting people's attention, but continually using this approach as justification for infection control inevitably fails to truly motivate all or even most personnel. Establishing interactive communication regarding risks and concerns coupled with logical, objective, evidence-based presentations is clearly a better approach for convincing personnel of the need to fully participate in infection control efforts. However, this is also dependent upon engaging sufficiently in surveillance and investigation so that useful objective information will be available regarding the significance of specific disease risks in a practice.

Informed Consent and Implications for Infection Control

The principle of informed consent, as it applies to veterinarians caring for animals, implies that owners have the right to be provided with adequate information prior to treatment so that they can make appropriate decisions for their animals and themselves.[22,23] As professionals with specialized training, veterinarians can be assumed to have knowledge about the health and care of animals that goes beyond that which someone without this training will have. As such, one of the components that experts generally agree is part of the informed consent process is the disclosure of potential risks that may be associated with a veterinarian's management of his or her animals, particularly in situations in which there is greater than average risk for a particular adverse consequence.[24] As such, it is reasonable and prudent for veterinarians to routinely disclose the potential for HCAI as part of the informed consent process for all patients. This is especially true for patients with an enhanced risk of acquiring HCAI (e.g., because of required invasive procedures or because patients are immunocompromised). However, this same principle can be applied in consideration of the general risk to all patients. For example, if it is known or suspected that there is an increased risk of nosocomial infections for patients at a facility, then there is likely an ethical and legal obligation to disclose how this risk pertains to new patients *prior* to their admission. It is extremely prudent to document the informed consent process in writing with clients. Often, there is reluctance to do so based on concerns that it may deter clients, particularly when other facilities do not address the issue. However, the informed consent process can be an opportunity to educate clientele about risks (and thereby increase their overall understanding) and highlight measures taken by the facility to mitigate those risks.

Paying for Infection Control Activities

As mentioned previously, procedures used to decrease risks of HCAI inherently increase labor and material costs related to patient care. If these infection control activities are an essential part of delivering veterinary care, it is reasonable that these costs should be passed on to clients. It should not be expected that these costs should reduce profits or that they be paid by veterinarians or hospitals. Remembering that only a portion of HCAI is preventable, if veterinarians have met the expected standard of care for infection control, then it is also reasonable to assume that extra costs incurred for treating complications associated with HCAI are paid by the client. In addition, if HCAI are an expected risk related to care of any patient, veterinarians and hospitals should develop plans for management of financial issues related to these risks. It is also important to differentiate consideration for how charges might be presented to the client from how costs for infection control activities are assessed. These costs might be passed on to clients by directly accounting for each item, which is most reasonable when there are specific charges that can be attributed to a specific patient (e.g., increased nursing or materials costs associated with care of a specific patient in isolation). However, this is less applicable when costs relate to care and protection of more than one patient (e.g., costs related to cleaning and disinfection of the hospital environment). In these cases it may make more sense to compensate for costs by aggregating expenses into a general fee category related to infection control (such as a daily surcharge) or to include these costs in overhead costs that are compensated by general admission or hospitalization fees. In special circumstances, such as when it is necessary to investigate or mitigate against suspected outbreaks of infections, it is useful to have a contingency fund that has been accrued and earmarked to pay for unforeseen expenses such as mass testing or additional labor related to cleaning and disinfection. Administrators should ensure that the potential for infection control emergencies is considered and that fee schedules will allow for development of this type of reserve fund.

Environmental Hygiene

Much attention is paid to the possible role of the inanimate environment in HCAI of large animals. Contamination of the hospital environment by microorganisms is inevitable and entirely expected, and detection of microorganisms in a hospital environment does not, by itself, indicate anything of clinical relevance. A variety of factors are likely involved in the potential clinical relevance of contaminants, including the organism, numbers present, likelihood of contact with susceptible hosts, degree of susceptibility of potential hosts, environmental effects (temperature, ultraviolet exposure, humidity) and routine infection control protocols. Many microorganisms grow well on environmental surfaces, provided there is adequate moisture and

VetBooks.ir

organic debris, and may survive for very long periods. Even with relatively inhospitable conditions, many organisms persist for extended periods. If environmental pathogens are able to contact the appropriate body site of a susceptible individual in adequate numbers, disease could result. Environments where patients are housed or veterinary care is delivered can be expected to have greater numbers of environmental microorganisms than corresponding areas with lesser animal and human traffic.[25]

The relevance of environmental contamination is often difficult to determine. Even recovery of genetically indistinguishable organisms from the environment and from a patient does not confirm that exposure to an environmental reservoir was the source of infection since it can be difficult to distinguish cause versus effect. However, environmental contamination is of concern for both direct (e.g., oral inoculation from a reservoir of microorganisms in a stall) and indirect (e.g., transmission of an organism from an environmental reservoir to the hands of a care provider and then to an animal) transmission. Measures should be in used in all veterinary care environments to reduce the environmental pathogen load. This involves cleaning and disinfection of environmental sites.

Cleaning

Cleaning is defined as the removal of all visible debris[26] and is arguably the most important step in decontamination of animal environments. Even the best disinfectants will be minimally effective when used in the presence of moderate volumes of dirt and organic debris such as feces and bedding material. Dirt and debris hamper disinfection by inactivation of many chemicals, acting as a physical barrier between disinfectants and microorganisms and by providing a nutritional source for microorganisms. Not only does cleaning enhance efficacy of the disinfection process by providing optimal conditions for desired biochemical reactions, but cleaning can actually remove a majority of microorganisms so that fewer need to be killed by disinfectants. Therefore, removal of as much organic debris as possible is required for optimal disinfection. This involves manual labor, consisting of removal of all bedding and feces, and scrubbing of surfaces to remove adherent debris and biofilms. Detergents should be used to loosen organic debris, emulsify oils and fats, and remove biofilm. The disinfectant to be used must be considered when choosing a detergent because there can be interaction between chemicals in detergents and disinfectants.

Because of the effort required to clean and scrub stalls and other large areas, less labor-intensive methods are often sought. For example, cleaning with high-pressure (>120 psi) power washers is frequently used in barns and hospitals. There are theoretical advantages that seemingly justify use of high-pressure washers, especially when they are designed to dispense high-temperature water and steam. Although power washing can be quite helpful in removing organic debris, this process can also exacerbate infection control problems by aerosolizing and widely dispersing infectious agents. Further, used indiscriminately, they can even damage surfaces, which then impairs subsequent cleaning and facilitates survival of pathogens. The true risk related to the use of high-pressure washers is unclear. However, the convenience of using high-pressure systems must obviously be balanced with more intensive manual cleaning methods in order to minimize untoward consequences. Using high-pressure systems on surfaces with large amounts of gross contamination should clearly be avoided.[27] In areas likely to be contaminated with important contagious pathogens (e.g., isolation facilities), it is logical to use them minimally or at least only as a secondary cleaning process on surfaces that have been previously manually cleaned and disinfected.

Disinfection

Disinfection is the process of substantially reducing the burden of microbial contaminants on inanimate objects in order to reduce the likelihood of transmission of infectious agents. This should be contrasted with sterilization, which is the inactivation of all microbial agents on an object, and is typically only performed on materials used in invasive procedures. Disinfectants are biocidal chemicals that must be used at appropriate concentrations, allowing for adequate contact time in order to achieve the intended effect. Even with proper cleaning and selection of an appropriate disinfectant, disinfection errors can occur. It is also important to remember that microbial responses to disinfectant exposures are not uniform. There is tremendous variation in the ability of microorganisms to tolerate cleaning and disinfection. Most enveloped viruses are easy to eliminate whereas protozoal oocysts, nonenveloped viruses, and bacterial spores may be difficult or impossible to kill with surface disinfectants.[28]

For disinfection to be effective, a few key factors must be considered: the presence of organic debris, disinfectant concentration, temperature, and contact time. Organic debris inactivates disinfectants to varying degrees, emphasizing the need for careful cleaning. Most disinfectants are available as concentrates and must be diluted prior to use. Excessively dilute disinfectant solutions may have little or no effect, whereas excessively concentrated solutions can be dangerous to use in addition to being wasteful of resources. Dilution of disinfectants is an important process and must be performed by measurement, not estimation. One method to easily ensure that disinfectants are appropriately diluted is to use metered dispensing units that can be either wall mounted or attached to the end of a hose. For some disinfectants, different concentrations may be recommended for different situations. Test strips that can commonly be purchased from a variety of vendors can also be used to verify appropriate dilution and activity disinfectant solutions. This is especially important when stock solutions are prepared for use over time. Cleaning personnel must be informed of the importance of disinfectant dilution and trained in proper methods. Contact time is critical, particularly for certain disinfectants and difficult-to-kill microorganisms. If disinfectants are applied and immediately rinsed away, there is little chance that they can be effective. Most disinfectants require 10 to 30 minutes of contact time to provide maximal microbial reduction. Chemical reactions that produce disinfection are slowed in cold temperatures, which should be considered when determining the amount of contact time that is required. Disinfectants should never be combined because of the potential for inactivation and production of noxious or toxic gases.

Disinfectants

It is critical to be aware that all disinfectants do not have the same effectiveness. As with antimicrobial drugs, disinfectants have a spectrum of activity that can be highly variable between disinfectant classes (Table 46-1). Choosing the most appropriate disinfectant can be complex, involving a variety of factors including spectrum of activity, relative efficacy in the presence of organic debris, toxicity to animals and humans, potential damaging effects on certain surfaces, cost, and potential environmental effects. There is no standard disinfectant to be used in all situations in large animal facilities, although oxidizing agents such as accelerated hydrogen peroxide and peroxymonosulfate are increasing in popularity because of their broad spectrum of activity, acceptable performance in moderate amounts of organic material, relatively rapid action at room temperature, relative safety for personnel, and environmental friendliness. Other options may be appropriate in certain situations. When disinfectants with a narrower spectrum of activity are used as the primary disinfectant, protocols should be in place to use alternative products should certain situations be encountered that require a higher level of activity.

Effect of Surface Material on Cleaning and Disinfection

The material to be cleaned and disinfected can also have a tremendous impact on efficacy. Many surfaces found in large animal clinics and farms are not amenable to thorough cleaning and disinfection. These include unsealed wood surfaces, unsealed block, dirt flooring, and areas that are difficult to clean. For stalls, solid walls with a sealed surface are optimal for disinfection. This may be difficult to achieve; however, certain procedures can be performed to facilitate

VetBooks.ir

TABLE 46-1

Disinfectants Commonly Used in Veterinary Medicine*

Disinfectant	Activity in Organic Debris	Spectrum	Comments
Bleach (sodium hypochlorite)	Rapidly inactivated	Broad, including nonenveloped viruses and bacterial spores. No activity against *Cryptosporidium*.	• Used to disinfect clean environmental surfaces. • Sporicidal activity is particularly useful. • Efficacy decreases with increasing pH, with decreasing temperature, and in the presence of ammonia and nitrogen. • Varying concentrations can be used. 1:64 dilution of standard commercial (4% hypochlorite) bleach is most commonly used. Higher concentrations, up to 1:10, can be used but should be reserved for infrequent use in special situations. • Inactivated by cationic soaps/detergents and sunlight. • Chlorine gas can be produced when mixed with other chemicals. • Bleaches fabrics and is corrosive to concrete.
Quaternary ammonium	Moderate	Variable. In general, effective against gram-negative bacteria and enveloped viruses, variably effective against gram-positive bacteria, limited activity against enveloped viruses, and no activity against bacterial spores or *Cryptosporidium*.	• There are differences among different types of quaternary ammonium compounds. • Commonly used primary environmental disinfectant, although the spectrum is not necessarily optimal. • In general, low toxicity. • Inactivated by anionic detergents. • Some residual activity after drying. • Less effective in cold temperatures and low pH. • Stable in storage.
Phenols	Very good	Relatively broad spectrum, with limited activity against nonenveloped viruses and no activity against bacterial spores or *Cryptosporidium*.	• Main advantage is better activity in organic debris. • Can be irritating to skin and mucous membrane surfaces. • Reportedly toxic to cats and pigs. • Some residual activity after drying. • Noncorrosive.
Peroxygen/ accelerated hydrogen peroxide	Very good	Broad spectrum, including bacterial spores and nonenveloped viruses. Some activity against *Cryptosporidium*.	• Excellent choice for routine environmental disinfection, footbaths, and environmental fogging. • Rapid action makes them a good choice for footbaths. • Low toxicity except at high concentrations. • Environmentally friendly. • Can be corrosive to plain steel, iron, copper, brass bronze, vinyl, rubber, and concrete. • More expensive than most other disinfectant options.
Alcohols	Rapidly inactivated	Moderate to no activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*.	• Not appropriate for environmental disinfection. Can be used to disinfect certain medical and patient care items, but better options are available. • Flammable. • Minimally toxic. • Fast acting.
Chlorhexidine	Rapidly inactivated	Moderate. Limited activity against enveloped viruses. No activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*.	• Not appropriate for environmental disinfection. • Appropriately diluted solutions are suitable for use on tissues or on materials that contact skin or mucous membranes. • Minimally toxic. • Bactericidal activity on skin is more rapid than many other compounds, including iodophors. Residual effect on skin diminishes regrowth.
Povidone iodine	Rapidly inactivated	Moderate. Limited activity against enveloped viruses. No activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*.	• Not appropriate for environmental disinfection. • Appropriately diluted solutions are suitable for use on tissues or on materials that contact skin or mucous membranes. • Minimally toxic but some people can become sensitized to skin contact. • Appropriate dilution is important to maximize activity.

*It is critical to handle disinfectants and other chemicals using appropriate safety precautions. Refer to MSDS sheets for each product to obtain recommendations regarding appropriate handling and personal protective equipment that is recommended.

disinfection.[27] Cement block walls can be reasonably well sealed with at least two coats of good-quality enamel. Wood walls can be sealed using two or more coats of marine epoxy. Regular maintenance of stalls is required to seal defects that occur from kicks or chewing.

The optimal floor surface, in terms of cleaning and disinfection, is a smooth, solid, completely sealed surface. However, surfaces meeting these criteria are not all amenable to animal housing, so a compromise may be required. Finding the right balance of floor cushion, traction, durability, ease of cleaning, and cost is difficult. Regardless, certain key factors should be considered. The floor should be completely sealed so that water (and pathogens) cannot seep underneath, since this creates an obvious environmental reservoir and prevents adequate contact with disinfectants. Damaged stall matting has been cited as the likely environmental reservoir associated with serious outbreaks of HCAI.[1] If obtaining a seamless, water-impervious floor surface is not possible, floor coverings should be completely removable (i.e., rubber mats over sealed concrete floor) and must be removed regularly for disinfection. Dirt, sand, and other organic materials cannot be disinfected and are therefore unsuitable for permanent flooring in hospital stalls or other veterinary care

VetBooks.ir

facilities. If sand is required for care of orthopedic patients, plans should be made to completely remove and discard this material between every patient.

Animal Contact Items

For items that are used in patient care, disinfection processes are sometimes divided into three categories: high-, intermediate-, and low-level. High-level disinfection involves elimination of all viruses and vegetative bacteria but is not expected to inactivate bacterial spores, fungal spores, or protozoal oocysts. High-level disinfection is, in reality, difficult to attain and is uncommonly used. Intermediate disinfection involves eliminating all vegetative bacteria but not necessarily all viruses (especially nonenveloped viruses), spores, or oocysts. Low-level disinfection results in elimination of most but not all potentially pathogenic bacteria and enveloped viruses. Items requiring disinfection should be classified as to the level of disinfection required; Table 46-2 shows examples of these.

After use, all items in a patient's stall should be considered to be potentially contaminated with pathogens that the animal might be shedding. Thus, for patients suspected or known to have contagious diseases, every item in the stall should be treated as a source of infectious material and must be appropriately decontaminated or discarded. Many stall items may be difficult to disinfect, or it may not be possible to be confident in the ability to fully decontaminate them. If it is cost effective, disposal of these items is ideal. Otherwise, standard principles of cleaning and disinfection apply. It must be recognized that rough, damaged, and permeable surfaces may be very difficult to adequately disinfect. Particular attention should be paid to disinfection of surfaces that patients contact orally such as feeders and water bowls as well as surfaces likely to be contacted by hands of personnel. Appropriate decontamination of water bowls can be problematic. Ideally, the water supply should be turned off, and the bowl should be drained, cleaned, and applied with disinfectant for an appropriate time before the bowl is rinsed and the water is turned on again. Nets used to hold hay have a high likelihood of contamination and are difficult to disinfect without use of gas or plasma sterilization techniques. As such, their use should be avoided if possible.

Certain items may be at particular risk for contamination. For example, thermometers used on animals with salmonellosis are almost assuredly contaminated, and complete disinfection of digital thermometers is very difficult. It is reasonable to dedicate thermometers to individual patients and discard them when they are no longer required. An alternative is the use of disposable temperature strips, which are sometimes used in human medicine. These have not been specifically validated but are routinely used in some large animal hospitals.[29]

Twitches and muzzles have a high potential for contamination with pathogens such as *Streptococcus equi* and MRSA. Rope used for twitches is extremely difficult to disinfect, apart from removing the rope for autoclaving. Chain twitches are easier to disinfect, but many find them less desirable to use. The ideal twitch material is easy to disinfect, is atraumatic, and provides good grip on the nose. It is debatable whether the ideal material is available at this time. Twitches should be routinely disinfected, to the best of the ability considering the material. Consideration should be given to regularly changing or autoclaving rope used for twitches, and routinely decontaminating twitches with the understanding that complete disinfection may not be possible. Twitches used on animals that are known to harbor or are likely harboring nasal or upper respiratory tract pathogens should be considered contaminated and the material discarded or disinfected.

Few areas show a greater difference in approach to infection control between human and veterinary medicine than the handling of hypodermic needles after use. In human medicine, recapping of needles is strictly forbidden because of the potential for needlestick injuries and subsequent exposure to life-threatening bloodborne pathogens. In veterinary medicine, recapping of needles is very common and needlestick injuries are often not perceived to be a significant health threat to veterinary personnel. Currently, there are minimal risks to veterinary personnel in almost all situations regarding bloodborne transmission of infectious agents from large animals. However, infectious disease hazards clearly are continuing to emerge, and it is prudent to develop safe practices that minimize the potential for exposure to bloodborne pathogens that might be transmitted from domestic large animals. In addition, physical trauma from the needle and accidental inoculation of some vaccines (e.g., RB51 modified-live *Brucella abortus* vaccine), medications (e.g., hormones, cancer chemotherapeutic drugs), or bacteria can lead to serious outcomes.

TABLE 46-2

Examples of Items Requiring Different Levels of Disinfection

Level of Disinfection	Example Items
High level	Endotracheal tubes
	Tonometer tips
	Cystoscope
Intermediate level	Dental equipment
	Endoscopes
	Thermometers used on multiple patients
	Vaginal specula
Low level	Thermometers used on individual patients
	Feeding instruments
	Muzzles
	Nasogastric tubes
	Oral specula
	Stethoscopes

Hand Hygiene

Rigorous use of hand-hygiene procedures is one of the oldest recognized infection control measures, and it is perhaps the single most important infection control practice. Unfortunately, extremely poor compliance with best practices in human and veterinary hospitals as well as in the community negates much of the potential benefit. CDC guidelines suggest that health care workers in human hospitals should wash hands or use hand-sanitizing products before and after every contact with patients, as well as prior to eating, and after using the restroom. It is hard to argue that less stringent procedures are warranted in veterinary hospitals.

There are numerous indications for hand-hygiene procedures in health care settings that have been identified as part of guidelines for human medicine. As evidenced by Box 46-1, hand hygiene is needed frequently in a clinical situation, something that may be problematic in typical settings where veterinary care is provided to large animals. Maintaining optimal hand hygiene can be especially important for ambulatory clinicians and yet can also be particularly difficult to achieve because of logistical difficulties. A variety of options exist for decontaminating hands. The most common practices are hand-washing and use of waterless hand-sanitizing solutions. Both are acceptable methods in most situations, and each has individual benefits and drawbacks.

Hand-Washing

Washing with antibacterial soap has been standard method of decontaminating hands of health care workers for over a century. However, the potential benefits of this practice generally are never realized because of failure to use appropriate methods or failure to wash hands at all.[30,31] Common errors in hand-washing include inadequate duration of hand-washing, failure to use soap, use of contaminated items to dry hands, and contamination of hands immediately following hand-washing (i.e., through contact with contaminated faucets, door handles, etc.). An appropriate technique for hand-washing is outlined in Box 46-2.

The importance of the type of soap used in hand-washing is also often overlooked. Plain soaps, those without antibacterial agents,

VetBooks.ir

BOX 46-1

Indications for Hand Hygiene in Medical Practice

- When hands are visibly dirty or contaminated with proteinaceous material, blood, or other body fluids.
- Before direct contact with patients.
- Before donning sterile gloves for invasive procedures (e.g., suturing wounds).
- Before inserting an indwelling urinary catheter, peripheral vascular catheter, or other invasive device that does not require a surgical procedure.
- After contact with a patient's intact skin.
- After contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings.
- After contact with an inanimate object in the immediate vicinity of a patient.
- After removing gloves.
- Before eating and after using a restroom.

Adapted from Centers for Disease Control and Prevention. 2002. Guideline for Hand Hygiene in Health-Care Settings: Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. MMWR 51(No. RR-16). [WWW page]. http://www.cdc.gov/mmwr/PDF/rr/rr5116.pdf, accessed Apr 25, 2013.

BOX 46-2

A Recommended Technique for Hand-Washing

- Wet hands first with water and then apply an appropriate amount of disinfectant soap (as recommended by the manufacturer).
- Vigorously rub hands together for *at least* 15 seconds, covering all surfaces of the hands and fingers. Make sure to scrub fingertips and clean under fingernails.
- Rinse hands with water and dry thoroughly with a disposable paper towel. Multiple-use towels of any type are not recommended.
- Use towel to turn off the faucet (and open doors when exiting a restroom).
- Avoid using hot water because repeated exposure to hot water may increase the risk of dermatitis.

Adapted from Centers for Disease Control and Prevention. 2002. Guideline for Hand Hygiene in Health-Care Settings: Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. MMWR 51(No. RR-16). [WWW page]. http://www.cdc.gov/mmwr/PDF/rr/rr5116.pdf, accessed Apr 25, 2013.

have minimal direct antibacterial activity. The main benefit of these is assistance with removal of dirt and organic debris, although efficacy data are conflicting. The use of plain soap can slightly decrease bacterial numbers on hands, but studies in human medicine have failed to demonstrate effective removal of significant pathogens from the hands of hospital personnel.[32] Also, the routine use of plain soap can at times be associated with *increases* in numbers of bacteria carried on hands if use of these products results in skin damage and irritation through drying.[33] Plain soaps are therefore not an optimal choice for routine use in medical settings, but use is certainly preferable to not washing hands in the absence of suitable alternatives (such as in field settings).

Most soaps used in hospital settings contain biocides such as triclosan or chlorhexidine. Both of these can produce greater decreases in skin contamination compared with plain soap, and both compounds have antibacterial effects that may persist after application, although the duration of activity is shorter against gram-negative organisms (especially *Pseudomonas* spp.).[31] Iodine and iodophors have been used as skin disinfectants and have a broader antibacterial spectrum. However, both (particularly iodine) can be irritating to skin and are less commonly used for routine hand-washing and skin disinfection in medical personnel. In addition, some people become sensitized to skin contact with these products.

Compliance with hand-washing protocols is often poor for a variety of reasons. The time required is a major factor, particularly in situations in which contact with a large number of patients is likely. Although hand-washing requires less than a minute to complete, if it is indicated 100 times in a day, this represents a significant amount of time cumulatively committed to this activity. Lack of convenient access to proper hand-washing facilities is also frequently a problem. If access to sinks with running water, soap, and disposable towels is not convenient (i.e., not adjacent to where animal contacts occur), it is less likely that hand-washing protocols will be rigorously followed. Regardless of the type of soap used, frequent hand-washing leads to skin irritation and damage, which compounds compliance problems by making people reluctant to wash their hands, and skin damage associated with hand-washing increases potential for colonization or transient carriage of potential pathogens.[33-36]

Nail care and jewelry can also be significant impediments to achieving optimal levels of hand hygiene.[37] Colonization with higher bacterial numbers, colonization with bacterial pathogens, and outbreaks of infectious disease have been reported in human hospitals in association with effects related to long fingernails and artificial nails.[38] Studies have shown that these hamper effective hand disinfection, and many health care facilities, particularly intensive care units, prohibit their staff from having long (¼ inch or longer) or artificial nails. The role of these factors in risks to patients in veterinary settings is unclear, but some veterinary facilities have developed similar protocols and restrictions.

Waterless Hand Sanitizers

For many years, waterless hand sanitizers have been described as an alternative to hand-washing, but in the past decade, expert opinion and evidence supporting use has evolved to where use of these products is often the primary method for hand-sanitizing in health care settings. These products are effective, inexpensive, easy to use, and easier to make widely available throughout health care settings than are hand-washing stations. Most waterless hand sanitizers use varying concentrations of alcohol (isopropanol, ethanol, n-propanol, or a combination), although a few products contain alcohol plus biocides, or biocides (e.g., triclosan and benzalkonium chloride) alone. Alcohol products are most commonly available, with concentrations ranging from 60% to 95%. Most products are available as gels or liquids, but newer products are dispensed as foams, which may increase acceptability of products. Products with alcohol concentrations greater than 95% are less effective because the presence of water is important for the bactericidal activity. Alcohols have excellent effect against gram-positive and gram-negative bacteria, but not bacterial spores or protozoal oocysts.[30,31] Antiviral effects are variable, with less reliable effects against nonenveloped viruses. Alcohol-based products have been shown to have good effect on reduction of hand contamination of health care workers and have been shown to be more effective than standard hand-washing.[39] Frequent contact with alcohol can lead to significant drying of skin, so most commercial products contain emollients, humectants, or similar skin-conditioning agents. Alcohol-impregnated towelettes are also commercially available but contain a small volume of alcohol and are no more effective for hand decontamination than washing with plain soap.[40]

One concern that is sometimes expressed about waterless hand sanitizers is their activity in the presence of organic debris. This is a particular concern in large animal practice, where the likelihood of gross contamination is high and access to hand-washing facilities is sometimes limited. However, a study of the efficacy of hand sanitizers on hand disinfection after performing physical examinations in horses reported that both alcohol and alcohol/chlorhexidine hand sanitizers were more effective for decreasing bacterial contamination than washing hands for 15 seconds with antibacterial soap.[41] This level of disinfection was noted even though the culture fluid collected off the hands was visibly dirty, indicating that there was a reasonable amount of gross contamination. Thus, waterless hand sanitizers are likely to be effective under normal large animal practice situations. When there is readily apparent contamination of the skin, however, debulking of the hands is probably required for optimal effect. It is important to remember that alcohol-containing products are

VetBooks.ir

flammable. Although very rare, fires have been associated with exposure to open flame. Common sense and ensuring that hands are rubbed together until all the alcohol has evaporated should greatly minimize any risks.

While most available products contain only alcohol as a sanitizing agent (in addition to humectants or emollients), some commercial products contain alcohol plus other biocides such as chlorhexidine. Some of these products have sufficient efficacy such that they are widely used for presurgical hand disinfection. The main advantage of using this combination of products is the residual antibacterial effect that the chlorhexidine confers. Some users complain of a sticky feel to the skin, which is one of the reasons that this combination is less commonly used for routine situations.

One of the main advantages of waterless hand sanitizers is their portability. Although it is difficult to make the water sources needed for hand-washing portable or always accessible, these products can be easily placed in ambulatory vehicles, can be carried by individual staff, and can easily be placed throughout hospitals. As such, there is a greater likelihood of obtaining compliance by facilitating access. Unfortunately, regardless of the types of products used, compliance with hand hygiene is often a major problem.[42,43] Infection control programs need to address hand-hygiene compliance through a variety of means to increase use of this critical infection control tool.

Surgical Hand Antisepsis

Scrubbing of the hands and forearms with disinfectant solutions has been a standard practice prior to surgery, but in the past decade use of scrubless or brushless protocols for hand antisepsis has become increasingly common. Recommended techniques for presurgical scrubbing vary somewhat but typically involve a systematic 2- or 3-minute scrub of all hand and forearm surfaces.[44] Other studies have demonstrated that a two-step approach, using a 1- to 2-minute surgical scrub followed by application of an alcohol-based hand sanitizer is as effective as a 5-minute surgical scrub.[45] One concern with repeated surgical scrubbing is the potential for skin irritation and subsequent increases in bacterial contamination. This has led to increasing use of brushless techniques, especially with the use of waterless hand sanitizer containing 1% chlorhexidine gluconate and 61% ethanol, which has been shown to be equal or superior to brush application of 4% chlorhexidine soap.[46] There may be some concern about the sole use of brushless techniques in situations in which there may be moderate debris contamination as could be encountered in veterinary applications. A variety of hybrid techniques have been recommended, including performing a thorough hand wash with soap or full surgical scrub at the beginning of the day followed by application of a waterless hand sanitizer product as the sole hand antisepsis technique for subsequent procedures. The main advantage of these may be elimination of alcohol-resistant bacterial spores.[47] One factor to consider, however, is that alcohol products may work better on dry hands, so hands should be allowed to thoroughly dry if hands are washed prior to application of an alcohol hand sanitizer.[47]

Barrier Protocols and Protective Attire

Barrier nursing techniques are an important infection control tool. The basic premise for their use is that placing some type of barrier between caregivers and patients prevents skin or clothing from being contaminated, whereas the contaminated outer barrier item can be discarded or left in the contaminated environment. Prevention of contamination of personnel's skin, regular clothing, personal items, and medical instruments can substantially reduce the risk of transmission of pathogens between animals, contamination of the general environment, and zoonotic transmission.

Use of Barrier Precautions

Basic barrier techniques should be used in all veterinary hospitals. Standardized, clean protective outwear should be worn over hospital-dedicated attire for any patient contact, regardless of the anticipated nature of contact or the assumed infectious disease status of the patient. The need for other barrier items varies with circumstances and is often dictated by the type of disease syndrome being managed (e.g., diarrhea or gastrointestinal disease, respiratory disease, wound infection, fever of unknown origin) as opposed to documentation of specific infections or diseases. Other factors that might indicate a need for additional barriers include farm of origin (e.g., farms with endemic *S. equi* or rotavirus infections) or a patient that is considered to have an increased risk of infection (e.g., compromised neonates). Gloves, gowns, and overboots are the most commonly used items for additional barrier protection, but masks, caps, and eye protection may also be required at times. In some facilities, overboots are not used in all areas, but personnel are required to wear footwear that can be readily disinfected. Disinfection of this footwear is required after exiting potentially contaminated areas.

Limitations to Barrier Precautions

The greatest limiting factors associated with use of barrier precautions in infection control are poor compliance and improper use. Written protocols should be developed that document practical use protocols for barrier precautions. These should specifically state when additional barriers are required; it is not possible to achieve consistent results if protocols are ambiguous or suggest too much discretionary interpretation. In addition, it is critical to educate personnel regarding the need for barrier nursing precautions and on proper application. Many human hospitals require physicians and nursing staff to undergo practical training in proper use of barrier precautions to avoid inadvertent spread of contaminants, and this type of active training may help to ensure uniform understanding and application of protocols. It is also important to regularly monitor compliance with protocols.

Protective Outerwear

Standard protective outerwear for large animal veterinary personnel should include clean coveralls, lab coats, scrubs, or other dedicated clothing (hospital uniforms). Protective outerwear should be worn for every animal contact and should be changed regularly. This includes any time outerwear becomes visibly soiled or otherwise contaminated with body fluids perceived or known to be contaminated with potential pathogens (e.g., feces, blood, nasal exudates, urine, or uterine fluid). In addition, outerwear should be changed frequently (at least daily) because gross contamination does not need to be present for pathogen contamination to have occurred. Hospital personnel should change their hospital outerwear before leaving the building to decrease the risk of transfer of infectious agents from the hospital to the community. In order to facilitate this control measure, it is optimal from an infection control perspective for veterinary practices to provide laundry services or laundry facilities. Clothing that is potentially contaminated with biohazardous material should be handled appropriately so that personnel handling laundry are aware of the hazards and how to reduce risks for exposure.

Gloves

Gloves are an important component of barrier precautions if used properly. The Centers for Disease Control and Prevention (CDC) recommends glove use by health care workers to reduce the risk of transmission of infections from patients to personnel, to prevent health care workers' skin flora from being transmitted to patients, and to reduce transient contamination of the skin on hands of personnel by microorganisms that can be transmitted from one patient to another.[48] The same concepts apply to veterinary medicine. In certain situations, glove use has been shown to be an effective means of reducing pathogen transmission in human medicine.[49] However, incorrect use can negate these effects or even be harmful. Common errors with glove use include failing to wear gloves when needed, not changing gloves after contact with infectious items, touching items (e.g., pagers, cell phones, pens, medical supplies) while wearing contaminated gloves, contamination of hands or clothing while

VetBooks.ir

removing gloves, and failing to wash hands after glove removal.[50] Although gloves are used to prevent contamination of hands, the potential for inadvertent contamination through micro-breaks in the glove surface or contamination during glove removal necessitates use of hand-washing or application of hand-sanitizing solutions in conjunction with their use.[48]

There are no widely accepted standards in veterinary medicine for when gloves must be used, apart from the use of sterile gloves during surgical procedures. Examination gloves that are clean but not sterile are often used when handling wounds or infected body sites, and for contact with animals known or suspected to be shedding contagious pathogens. Despite relatively widespread use of examination gloves in a variety of circumstances in veterinary medicine, it is quite unusual for practices to have formal protocols regarding how and when they should be used.

Gowns

Although protective gowns have traditionally been used during surgery, their use as a barrier garment when contacting high-risk patients is increasing in both human and veterinary medicine. The CDC has produced guidelines for human medicine stating that "gowns should be worn by personnel during the care of patients infected with epidemiologically important microorganisms to reduce the opportunity for transmission of pathogens from patients or items in their environment to other patients or environments."[48] In general, gowns should be worn whenever direct or indirect contact with patients or their environment may result in contamination of caregivers' clothing or skin that facilitates transmission of pathogens.

The ideal barrier gown would cover all areas of the body that might become contaminated, prevent penetration of liquids, would be of adequate strength to resist tearing and puncture under normal activities, would be comfortable to wear for long periods, would be available in appropriate sizes for all personnel, would be easy to put on and remove without contamination of regular attire, would be nonabrasive to skin, would be unlikely to startle patients, and would be of acceptable cost. Unfortunately, a product with all of these characteristics does not currently exist, and facilities must prioritize the relative importance of different gown properties. This is often difficult because neither the overall effectiveness of gowning nor the effectiveness of different gowns in veterinary situations has been adequately evaluated. The problem most likely to be encountered with barrier gowns in veterinary practice is poor resistance to liquids, especially under direct contact or pressure. In large animal practice, there is a greater likelihood of contact with relatively large volumes of fluids (e.g., with diarrheic animals) or direct contact with patient surfaces that would have moist secretions or excretions (e.g., animals with nasal discharge or large infected wounds). The types of anticipated activities may also have an impact on the required size of gown. Gowns that do not completely cover the legs and feet may be useful in some circumstances but ineffective in situations with prolonged direct contact such as with assisted neonatal nursing.

In human medicine, there are conflicting data regarding the efficacy of gowning for prevention of hospital-associated infections.[49,50] Gowns may be more effective for reducing infection of personnel. It is possible that the most significant advantage in some situations is not the protective effect of gowns or other protective outerwear, but rather the raised awareness of the potentially infectious nature of the patient, which may in turn encourage concurrent application of other important infection control practices.

Eye and Face Protection

The use of protective eyewear, including goggles and face shields, is common in human medicine during procedures that generate aerosols or airborne droplets of blood, body fluids, and secretions.[51] Use of these items is mandated in some instances by the health and safety regulations, but they are not widely used in clinical settings in veterinary medicine.[52] Face shields have the advantage that they decrease the potential for facial mucous membrane exposures in addition to ocular exposures. Inexpensive disposable face shields are commonly available and are generally quite comfortable for people with varying face shapes and sizes, and thus would seem to have great potential for use in all large animal practices. Despite the current low prevalence of bloodborne zoonotic pathogens in large animal species, it would be prudent to consider the use of some type of eye protection whenever generation of small particulates or aerosols of liquids or secretions is likely to occur, including when motorized equipment is being used for dental procedures, foot trimming, or orthopedic surgery. Situations in which eye protection should be seriously considered include examination of animals with suspected viral encephalitides. Although not studied, face protection may also help protect against zoonotic disease involving fecal-oral transmission, such as *Cryptosporidium parvum,* which has an extremely small infectious dose.

Respiratory Protection

Masks and respirators are often used to reduce the risk of respiratory and oral exposures to infectious agents, to reduce the risk of contamination of patient sites with organisms from personnel, and in some situations to prevent contamination of hands with nasal or oral microflora. Standard surgical masks may be effective against the spread of large particle droplets that are transmitted by close contact and travel only short distances (up to 3 ft) from infected patients.[53] However, the overall effectiveness of surgical masks in hospital situations has recently been questioned.[54]

Airborne transmission of zoonotic pathogens is commonly thought to be of minimal concern in most veterinary settings, and mask use is uncommon in veterinary hospitals apart from use during surgical procedures. The actual reduction in zoonotic disease risk that might be associated with the use of surgical masks during routine patient contact is unclear. However, increased awareness of risks of specific zoonotic diseases and infections in immunocompromised personnel and others with special disease risks has prompted reconsideration of recommendations regarding personal protective equipment in some circumstances. For example, although airborne transmission is not considered an important route of exposure for MRSA, the hospital personnel primarily become colonized in the nasal passages and hand-to-nose contact is frequent. Thus, mask use might prevent direct contact of hand and nose, thereby decreasing hand contamination or decreasing the risk of inoculation of the nose following contamination of the hands during animal contact. Mask use might be particularly important for prevention of MRSA exposure when working in barns containing many MRSA-positive animals and high dust burdens. This is most relevant for swine veterinarians but could include clinicians entering veal calf units in some regions. Masks capable of filtering non-oily particulate aerosols with 95% capability (N95 masks) are recommended in human medicine for dealing with airborne contagions such as the severe acute respiratory syndrome (SARS) coronavirus. Although there is currently little indication that these masks are routinely required in large animal practice, it may be reasonable to expect facilities to at least have a plan in place to implement N95 masks if required. A critical aspect of the use of N95 masks is fit-testing and training in their use, since improperly fitted or used masks may confer little or no benefit over surgical masks.

Animal Movement and Housing

Housing and movement can have a profound effect on the likelihood of exposure of patients to pathogens. Ideal facilities have no contact between inpatients and outpatients, allow for grouping and segregation of animals with different risks for contagious diseases, prevent direct contact with adjacent animals, reduce the potential for indirect exposures through contact with contaminated environments, and have adequate space so that there is time to properly disinfect all housing and handling environments between use with different animals. This, of course, is completely dependent upon early recognition and effective management of patients with higher risks of transmitting contagious diseases.

VetBooks.ir

One major problem frequently encountered in large animal facilities, particularly older facilities, is that construction and design factors often hinder infection control activities. Infection control issues were often not given high priority when designing many older facilities, so a variety of problems are often encountered. These include patient traffic flow problems, requisite mixing of inpatients and outpatients, inability to segregate different cohorts in the population, heavy traffic around important areas (e.g., surgery, isolation), inadequate stall numbers, inadequate isolation facilities, poor ventilation, improper drainage, use of materials that are difficult to clean and disinfect, design issues that hinder adequate cleaning and disinfection, etc. There are a variety of challenges with designing an optimal facility. Many measures used to enhance infection control are inherently inconvenient, and designs that optimize infection control often have a significant impact on building costs and efficient use of the facility. It can be difficult to reconcile ease of operation with the level of infectious disease risk that is desired. However, development and rigorous use of sound infection control protocols can overcome most deficits in design and construction to achieve an acceptable practice standard for minimizing HCAI.

Outpatient Areas

In general, outpatients tend to have a lower contagious disease risk, both in terms of likelihood of shedding infectious agents as well as in their susceptibility to infectious disease. However, "lower" risk does not mean "no" risk, and it is important to design holding areas that minimize contact with other animals while clinicians obtain histories and initial examinations to more clearly categorize patients relative to their contagious disease risk. Ideally, outpatients should have little or no contact with inpatient animals and minimal contact with areas visited by inpatients. However, this is often not entirely possible. For example, it is often impractical to build completely separate areas for diagnostic imaging of inpatients and outpatients. However, the general principle of separation of inpatients from outpatients should be adhered to as much as possible.

Holding stalls in admission and outpatient examination areas may need to house a large number of animals every day. As such, it is important that a sufficient number are available to allow appropriate cleaning between use, that there are established mechanisms to allow admitting clinicians to identify high-risk cases, and that this information is promptly conveyed to relevant personnel so extra precautions can be taken with that patient and the environment with which it has been in contact. Environmental precautions may range from routine cleaning and disinfection to restricting use pending high-level cleaning and disinfection, stall cultures, or patient cultures.

Inpatient Areas

Inpatients pose greater challenges than outpatients because they often have significant risk factors for infectious disease acquisition such as co-morbidity, dietary changes, antimicrobial treatment, disruption of natural defense mechanisms, surgery, and placement of invasive devices. Compromised inpatients, particularly certain patient groups (e.g., those with gastrointestinal disease), may be more likely to shed infectious agents such as *Salmonella enterica*. Thus, infection control protocols should emphasize the need to reduce the risk of transmission of infectious agents from inpatients to other hospitalized animals and hospital personnel, and to minimize risks related to contamination of the hospital environment. A variety of methods can be used to manage this risk, which needs to be balanced with levels of risk aversion and available resources to support infection control efforts.

One method of reducing the risk of disease transmission between individuals and groups (i.e., between animals in different wards or those assigned to different services) is to assign animals to different cohorts and then create physical and procedural separation among the different groups. It is important to group animals based upon known or suspected infectious disease status or infectious disease susceptibility, as well as group and separate animals with different disease syndromes (e.g., respiratory disease or gastrointestinal disease). It is also logical to group and segregate animals that are managed by different clinical services in order to decrease the probability of transmitting infectious agents through indirect contact and increase the ability to contain a cluster of infections related to one clinical service. Examples might include segregation of patients managed by surgery and medicine services to help reduce risks for transmission of different contagious agents, or managing cattle separately from other large animal patients (especially horses) to reduce risks for *Salmonella* transmission. In general, managing inpatients as smaller cohorts helps contain transmission risk, thereby decreasing the likelihood of a widespread outbreak in the entire patient population. Creating smaller cohorts of patients with different risks for contagious disease also facilitates the use of varying levels of infection control precautions for different groups.

The design of some facilities does not allow for the separation of different cohorts in different buildings or wards. When physical separation of inpatient groups (excluding isolation cases) is impossible or impractical, animals with different disease risks can still be managed differently in a common ward system. One approach is to designate areas within large wards for different cohorts. Another is to identify animals in different risk categories, applying different levels of infection control precautions, but to allow interspersing of animals from different risk categories in the same area. This is similar to the approach for patient isolation that is used in most human hospitals, but it is only effective for diseases that are not transmitted by aerosols (i.e., it is not generally effective for contagious respiratory diseases such as influenza or EHV) and where there is a reasonable ability to prevent direct (e.g., nose-to-nose contact over stall walls) or indirect (e.g., cross-contamination from stall cleaning supplies) transmission. Physical separation within a ward can be enhanced by use of chain or rope barricades to identify and minimize access to patients with elevated contagious disease risk status. A key for successful infection control using this type of system is the absolute need for prominent identification of different groups, having defined protocols for each group, and maintaining effective communication about disease status of these patients. One system that has been used is color labels to indicate infection control status. For example, colored adhesive dots can be placed on stalls or stall cards of all patients; red dots might indicate animals with a known highly contagious disease, yellow dots might indicate that animals are suspected of having an infectious disease or may have increased risk of acquiring infectious disease, and green dots might indicate that animals are considered to have an average or low risk of carrying or acquiring contagious disease agents. This type of system is easy to apply and easy to understand. In addition, more prominent signs can be used to more clearly indicate certain concerns (e.g., *Salmonella,* MRSA, rabies suspect) to all personnel. One consideration with these more specific labels, however, is whether visitors could obtain confidential and sometimes prejudicial information from visible notices.

Isolation of Highest Risk Patients

The most rigorous control of contagious disease hazards requires that transmission potential be absolutely minimized for patients suspected or known to be infected with highly contagious pathogens or pathogens associated with highly consequential diseases. In general, this means that these patients should have no direct or indirect contact with other animals or areas used in routine care of patients via personnel, fomites, aerosols, or other materials. It also means that human access to these patients and their care environment should be tightly controlled. In general, in order to achieve this level of isolation, these patients will require housing in a separate, specially designed unit.

Most isolation protocols in large animal medicine focus on a limited number of pathogens. Protocols for large animal facilities tend to focus heavily on animals clinically affected by *Salmonella enterica,* viral respiratory pathogens, and *S. equi,* and more recently on horses with neurologic disease because of the risks related to EHV-1. Whether these protocols are adequate, or excessive, for

VetBooks.ir

control of other pathogens is debatable and a broader scope is likely required in many facilities. That said, protocols that reduce the risk of transmission of one agent generally reduce the transmission potential of other agents, particularly if there are similarities regarding transmission routes or risk factors for exposure and infection.

Large animal isolation protocols need to consider a variety of issues, including indicators for isolation, cleaning and disinfection protocols, protocols regarding personnel movement and barrier precautions, protocols for patient contact and movement, manure disposal, and supply stocking. Defining methods for identifying animals that need to be isolated and establishing specific criteria for handling these animals are critical steps, and these methods must be properly communicated to all individuals associated with patient or facility care. Developing protocols for rapid identification of patients that represent a contagious disease hazard is critical to the success of any infection control program. The best isolation units are not effective if unoccupied. Specific disease and syndromic criteria for isolation should be developed to facilitate prompt isolation of appropriate individuals, typically in advance of confirmation of the presence of an infectious agent. Isolated animals should be physically separate from the rest of the hospital population at all times if at all possible. This means that isolation units should be designed so that animals will rarely if ever have to leave the unit except for those that need an emergency procedure such as surgery. Stocks, examination areas, and scales should be available. A major deficiency of many large animal isolation facilities that is recently being recognized because of concerns regarding herpesvirus myeloencephalitis resulting from EHV-1 infections is the inability to use mechanical hoists and slings to safely manage recumbent, profoundly ataxic patients. Ideally, there should be minimal contact of personnel with isolated animals and their stall environment. The ability to monitor patients in isolation using viewing windows or by remote electronic means (e.g., web cameras, closed circuit video) facilitates the ability to deliver excellent patient care while minimizing risks associated with direct contact.

These units must be strictly managed with specific predetermined protocols in order to reliably manage the risk of transmission. Isolation protocols should be comprehensive and clearly documented in writing. Proper training of all staff, particularly lay staff that may have no background in infectious diseases and infection control, is critical. Standardized protocols for management of isolation units in human health care settings have been published by the CDC.[53] However, similarly standardized guidelines have not been established for veterinary medicine, and protocols used at veterinary facilities are highly variable because they are tailored to specific operations and different facility and logistical resources. It is logical for veterinary facilities to consider guidelines that have been developed at other veterinary facilities and from human health care settings when developing their own isolation protocols.

In some situations, housing of potentially infectious animals in an isolation unit is not possible because of patient care issues or limitations in isolation space. As a result, consideration needs to be given to management of higher-risk patients within the general hospital environment. This can be done in a few different ways, including grouping of general risk groups and application of intermediate isolation techniques to cases that are considered at higher risk of being infectious but not deemed candidates for housing in an isolation unit. In-hospital isolation protocols allow for an increased level of protection but are not a replacement for a proper isolation unit and should not be used solely for clinician convenience. Protocols should be developed regarding the handling of animals, the stall, and the area around the stall. Animals that are isolated in the hospital should not leave stalls unless they are being moved for required procedures. If movement is necessary, feet should be cleaned and disinfected using appropriately diluted chlorhexidine solutions. The potential for environmental contamination can be reduced by having a person follow the animal with a bucket to collect any feces that may be passed during transit. Traffic areas should be promptly cleaned and disinfected. Protective barrier clothing such as full waterproof coveralls or full-length waterproof gown, gloves, and dedicated footwear or boot covers should be worn for any contact with the patient or its environment. The area around the stall entrance should be considered potentially contaminated and disinfected routinely (at least three to four times per day). Disinfectant footbaths or footmats used at stall doors can reduce bacterial contamination of footwear.[55,56] Attention should be paid to the pattern of water drainage from the stall and in the area. If water runs from the stall to the breezeway, or runs down the breezeway past the stall, then housing of potentially or known infectious animals in the stall may be inappropriate. Animals should not be allowed contact with neighboring animals. Barriers may be required if solid walls are not present on all sides. Specific protocols should be developed for cleaning in-hospital isolation stalls. These stalls should be cleaned last, personnel cleaning stalls must wear protective gear, and items used to clean the stall must be disinfected immediately after use.

Isolation guidelines for human medicine target the prevention of five different types of transmission: contact transmission, droplet transmission, airborne transmission, common vehicle transmission, and vectorborne transmission.[48-53]

- Contact transmission is typically the most important mode of transmission and involves transmission of infectious agents to patients by caregivers or directly between patients. In large animal medicine, this could include situations such as transfer of MRSA from a colonized person to an animal under their care, transmission of *S. equi* between horses by personnel, or direct transmission of viral respiratory pathogens between horses in adjacent stalls that can have nose-to-nose contact.
- Droplet transmission involves transmission of infectious agents in relatively large fluid droplets generated by coughing, snorting, or vocalizing. These large droplets do not remain suspended in the air for long periods nor are they transmitted long distances; therefore, special air handling is not required. An example of this is transmission of bacterial agents from a coughing horse to another horse stabled in relative proximity. An extrapolation to veterinary context might also include transmission of surface contaminants during environmental cleaning processes with water under high pressure.
- Airborne transmission involves agents that can be transmitted effectively in small particles (5 μm or smaller) that can remain suspended in air and travel greater distances. Special air handling is required to control this route of transmission. Equine influenza can be spread through a barn via the airborne route over extended distances.
- Common vehicle transmission involves infection caused by contact with contaminated items such as feed bins, muzzles, twitches, thermometers, and other medical equipment.
- Vectorborne transmission involves vectors such as mosquitoes, flies, and rodents. This may be of particular concern in some areas with reportable vectorborne diseases such as equine infectious anemia.

Surveillance

All comprehensive infection control programs should have a surveillance component because the information collected serves as sensory input to guide ongoing efforts so that they are focused and efficient. Without surveillance information, infection control programs will be guided more by emotions and opinions rather than data and evidence. Infection control programs will have much greater acceptance and utility if, in the long term, decisions are based on objective information about infection and disease occurrence at a specific hospital. Useful surveillance goals for infection control programs include developing a system to allow prompt identification of contagious disease threats, evaluating the effectiveness of infection control practices, measuring personnel compliance with infection control procedures, providing a basis for logical infection control decisions, and stimulating efficient and economical use of resources.

VetBooks.ir

Surveillance Options and Strategies

Theoretically, an optimal surveillance system would allow real-time detection of all HCAI. However, pursuing this goal would be unrealistic for reasons of practicality and would be an inefficient use of resources. Although all HCAI are important relative to patient well-being, some are more important than others. This is because the impact on patient health is much more significant for some diseases, as well as because highly contagious diseases are more likely to impact a larger number of patients. Further, regardless of whether there is a contagious etiology, HCAI that affect a large number of patients can have a tremendous impact on the cost of care and the overall burden of morbidity for patients. Focusing surveillance on these high-impact HCAI is logical as a greater proportion of these occurrences are also likely to be preventable in comparison to more sporadic problems. Further, experiences with infection control in human health care settings has shown that it is possible to be more efficient with infection control and just as effective if high-risk, high-frequency, and high-cost problems are targeted.

Determining which specific HCAI were likely preventable is a difficult and potentially contentious task. Rather than focus on individual infections, infection control efforts in human hospitals have benefited by focusing on comparing rates of infection and estimating the proportion that might be preventable by referencing some accepted standard. During the past 30 years, human hospitals have made great efforts to characterize rates of HCAI that can be expected even under the best of circumstances. By estimating rates for these "nonpreventable" infections, it has then been possible to identify hospitals with higher-than-average rates for HCAI. Because of the tremendous differences among different hospitals and among different patient populations, it has become standard to focus on more restricted, high-risk patient groups for which there is better comparability (e.g., neonatal or cardiac intensive care patients). It is also far more feasible to perform surveillance for HCAI in these high-risk patient subgroups than it is in the larger general population that has much lower risks of HCAI. Performing surveillance with standardized case definitions over time allows identification of specific risk factors, which could then be used to prospectively refine management of patients (i.e., a high-risk patient could be identified and be subjected to more aggressive control measures as a preventive strategy). Unfortunately, there is very limited information available regarding rates of disease related to HCAI that can be found at individual hospitals let alone estimation in multiple hospitals, which would be required in order to obtain inter-hospital comparisons that would be useful in identifying latent problems at specific facilities. Although making standardized comparisons between hospitals would require tremendous cooperative effort, individual facilities could make significant progress in identifying important changes in rates for HCAI if efforts were made to benchmark their infection rates over time.

When designing a formal surveillance effort to aid infection control programs, it is important to tailor efforts to a specific facility or practice. A wide variety of design possibilities are available for hospital surveillance systems, and the specific focus and methods should be carefully matched to the needs and resources of each establishment. Diseases that are the highest priority for surveillance must be specified along with standardized case definitions that will be used to identify these cases. Efforts may target disease caused by HCAI that are related to specific procedures or organ systems, or just as commonly they may target specific infectious agents of interest. For example, systems might be established to look for surgical or IV catheter site infections, methods may target surveillance for respiratory tract infections, or efforts may specifically target detection of infections with specific etiologic agents such as *Salmonella* or MRSA. It must also be determined whether clinical disease will be the outcome of interest or whether it is important to look for animals with subclinical infections. This will generally vary by disease and likely will be determined by the natural history or pathophysiology of the disease (i.e., Does shedding occur in the absence of clinical signs? Is there a chronic carrier state? What are the risk factors related to the likelihood of shedding?). Further, if clinical disease is the outcome of interest, it is important to consider whether the case definition will include some type of etiologic confirmation, or whether diagnoses will be syndromic in nature and based upon clinical signs (i.e., surgical site infections could be defined based upon recovery of a bacterial agent in the presence of clinical disease, or it could be defined solely upon the presence of a predetermined combination of clinical signs such as erythema and drainage). As discussed previously, another consideration is whether surveillance will target specific subgroups of the population or whether it will include all patients. The major benefit of targeted surveillance is that it decreases the cost and effort of data collection, but the trade-off is the inability to detect potential problems in the patients that are not being monitored. However, increasing awareness about infection control methods for common or more important diseases generally has the effect of increasing awareness and compliance with control measures that relate to other potential HCAI. It also must be determined whether surveillance will be active (i.e., patients with HCAI will be actively sought out) or whether passive surveillance (i.e., reporting is voluntary) is acceptable and appropriate. In general, active surveillance will only be used in targeted subpopulations and only to look for more common and more important diseases, and syndromic surveillance should be more heavily relied upon when the targeted population is larger or as a supplement to culture or etiologically based surveillance efforts.

Another important consideration is how data will be gathered for this effort. Significant personnel compliance is needed for active culture-based surveillance of large numbers of patients. Similarly, any type of chart review system for benchmarking expected rates of HCAI requires a significant time commitment. Surveillance efforts are greatly aided by computer-based search mechanisms, and it is strongly recommended that practices consider using electronic medical record systems to maximize the ability to perform surveillance and that medical record systems be designed to facilitate collection and recovery of infection control–related data. For example, something as simple as being able to monitor the number of febrile or leukopenic patients on a daily basis could be extremely powerful as an aid to infection control efforts. Even financial databases can be useful in surveillance efforts. For example, financial databases may be very useful for surveillance for benchmarking antimicrobial prescriptions or specific procedures, such as IV catheterization, surgeries, or submission of samples for diagnostic tests.

General, nontargeted surveillance to look for potentially pathogenic bacteria that can be found in health care environments is widely considered of no real benefit to infection control efforts. This includes sampling of surfaces in surgical theatres to catalog the different bacteria that can be found. However, there is utility in use of targeted environmental cultures where there is biological plausibility as to their relevance and when there is a plan to act on the results (and where the action differs if results are positive or negative). For example, monitoring for contamination of veterinary hospitals with *Salmonella* has been a useful adjunct to patient surveillance in comprehensive infection control programs at veterinary hospitals.[29,57,58] In addition, in some situations, such as when attempting to control ongoing outbreaks, there is no substitute for culturing the hospital environment to detect important environmental reservoirs.[1,59] Use of electrostatic household wipes has been extremely useful for sampling to detect *Salmonella* in routine surveillance as well as in the face of outbreaks.

The use of rapid and sensitive diagnostic tests is particularly important for the management of highly contagious diseases. As such, PCR and antigen detection tests, which can be much more rapid than traditional culture systems for bacteria and viruses, have become more widely used for both patient and environmental surveillance efforts. However, these tests cannot fully replace culture-based assays because analysis of microbes is essential to fully understand the epidemiologic implications for each recovery. For example, if on a single day three patients were found to be shedding

VetBooks.ir

Salmonella after use of PCR, it would not be possible to know whether these were unrelated events. In contrast, if shedding were detected using culture and the *Salmonella* isolates were then shown to be from different serogroups, this would make it unlikely that shedding was related to exposures from a single source. In some situations it may be logical to use both a rapid and culture-based assay to maximize both speed and ability to perform epidemiologic investigations. Availability of qualified laboratories, rapidity of testing, and costs will all have to be considered and balanced.

Monitoring Personnel Compliance

Success of an infection control program is absolutely dependent upon universal participation within a hospital or other animal care facility that is born from a well-developed sense of responsibility among individuals. Actively engaging all personnel in infection control programs becomes increasingly difficult as organizations become larger and more complex. Unfortunately, the most cautious actions of a majority of personnel can be for naught if even one individual neglects to take appropriate precautions under just the right (wrong) circumstances. Although it is very important for administrators to engage in surveillance to detect systematic noncompliance with policies, it is just as important to empower and expect all personnel to participate in monitoring for individual acts of noncompliance. Remembering that most noncompliance is born from a natural tendency for people to revert to the most convenient practices (that are not necessarily the most "safe" from the infection control perspective), it is important to couple surveillance efforts with education so that all personnel fully understand why they are being inconvenienced. In addition, providing useful feedback and communication about issues that arise in the hospital will help to reinforce the need for compliance. For example, monitoring and reporting of bacterial shedding or environmental contamination detected as a part of surveillance programs can help to keep hospital personnel aware of the potential hazards of reduced infection control efforts.

Measurements Related to Health and Disease

Although outcomes for individual animals may be the most important bottom line for many clinicians, it is important to remember that infection control by its very nature often has a larger population-based perspective. Thus, although diagnostic test results for an individual animal obviously have great relevance for that animal, for the population, a positive test result may not have great meaning unless it is interpreted contextually. It is therefore critical to remember that in addition to tracking numerators (e.g., numbers of infections or animals with disease caused by HCAI), some type of denominator information is needed to provide relevance over time or among different subpopulations. Some examples of relevant denominators include patient admission totals for a given period, patient-days of hospitalization, numbers of procedure events such as surgeries or catheter placements, and numbers of samples submitted for culture.

Developing a Comprehensive Surveillance Strategy

As mentioned, it is unrealistic to expect to detect all occurrences of HCAI or all animals shedding agents of interest through any hospital surveillance system. Rather, veterinarians should work toward developing strategic surveillance programs that will allow reliable estimation of rates for important events if they occur with any significant frequency, as well as rapid detection of unexpected important events. It is likely that a mix of strategies described previously will be used for the various agents and disease problems. For example, if *Salmonella enterica* shedding occurs at some low-level yet regular frequency in a hospital (e.g., 3% of all hospitalized equine patients) and is considered an important potential hazard for other patients, it is reasonable for an active surveillance program to be developed that allows detection of clinical and subclinical shedding of *Salmonella* as a patient management tool and allows detection of important trends over time so that outbreaks of HCAI could be rapidly identified and stopped. In contrast, *Clostridium difficile* or EHV-1 may not have been detected with any regularity in patients at a particular hospital or may be more difficult to actively monitor because of available testing methodologies, yet they may still be considered important because of their significance as pathogens and their potential for contagious spread. For these pathogens, it may be more reasonable to use a reliable passive surveillance strategy to call attention to patients when clinical signs or diagnostic testing indicates that these agents may be present. In addition, maintaining some level of surveillance for compliance with infection control procedures and policies is necessary to ensure that an infection control program is functioning properly.

Education and Awareness

Education of all personnel regarding infectious disease hazards to themselves, patients, and veterinary practices is essential to the long-term success of any infection control program. Successful programs are critically dependent upon all personnel knowing and following procedures and policies used for control of contagious disease transmission in a practice. Although this type of information can be acquired over time through personal experience, this is an inefficient and unreliable method for disseminating critical information.

Written Protocols

The first step to ensuring that necessary information is disseminated to all personnel is to document policies and protocols in writing. This effort is valuable for all veterinary practices but is especially critical in larger and more complex veterinary hospitals. This relatively simple step has many benefits. First, documenting procedures requires a thorough review, which by itself is beneficial. Second, documenting policies and protocols in writing imbues the infection control program with a sense of purpose and commitment. Third, documenting procedures helps to ensure consistency in application across all personnel as well as over time. As discussed, all infection control procedures are inherently inconvenient, and the natural tendency is for personnel to drift toward more convenient ways of performing activities that may not provide an adequate degree of protection against HCAI. Fourth, documenting policies demonstrates a degree of due diligence, which is useful from a legal liability standpoint relative to the occurrence of HCAI or zoonotic infections.

Once these protocols have been documented, it is important to require their use as a reference and to make a specific effort to educate personnel about the policies and procedures. A written document serves no purpose if it is not used. Veterinarians and other personnel are busy people, and the immediacy of caring for patients and clients can easily overwhelm seemingly mundane tasks such as studying written protocols. A valuable aid in this process is to have some type of training program. This does not necessarily mean formal presentations; it is valuable to organize a meeting of all personnel for the sole purpose of discussing infection control issues. Although this seems logical, training in infection control practices is not a universal occurrence even in teaching hospitals. In a survey of teaching hospitals from AVMA-accredited institutions, only 42% (16 of 38) of responding institutions reported that they required that personnel (students, technical staff, veterinarians) participate in some type of formal training program regarding infection control and biosecurity, and only 7 of these institutions provided more than a single training exposure.[13]

Training Programs

It is also important to consider the differences in training and experience among personnel. By their nature, infection control programs are dependent upon adherence to important protocols by all personnel regardless of their position description. Non-veterinarians are invaluable members of most veterinary practice teams and even personnel who might never touch patients but instead serve as receptionists or for the single specific task of cleaning are absolutely critical for the success of infection control programs. Veterinarians sometimes underappreciate how their specialized training has

VetBooks.ir

provided them a broad appreciation for basic principles of contagious disease transmission and control. Without the experiences of a veterinary education, many personnel simply do not have the same understanding of contagious diseases. Simply telling people to follow certain rules without understanding why they are necessary leads to inevitable compliance problems. Without a thorough understanding of why inconvenient infection control practices are needed, they will inevitably be discarded over time as seeming illogical. To help ensure uniformity of education among all personnel, some hospitals have developed training documents and require that new employees pass a written evaluation before they are permitted to begin work.

Another important aspect of education and awareness is to instill a need to lead by example and to empower all personnel to hold anyone else in the practice accountable for their actions. The hierarchy in authority that is often used in the delivery of patient care (e.g., veterinarians at the top of the hierarchy, personnel without formal training at the bottom) can interfere with optimal infection control. A common non sequitur related to infection control is that those with the most training can be the persons least likely to adhere to important policies. This is true in both human and veterinary medicine, as has been repeatedly shown relative to hand hygiene.[30,31] Physicians and residents have been shown, in numerous studies conducted in a variety of settings, to be significantly less likely than nurses to adhere to appropriate hand-hygiene protocols. Observations in the veterinary setting suggest that the same trends are true for hand hygiene as well as for appropriate use of barrier nursing precautions. All people pick up cues for behavioral expectations from their surroundings. If personnel who clearly understand the importance of preventive measures (physicians and veterinarians) such as hand-washing fail to routinely follow best infection control practices, there is little hope that trainees and laypersons will routinely trouble themselves to habitually use an important albeit inconvenient practice. Further, it seems that the more respected position a person holds in a practice, the more likely that individual acts of noncompliance will be influential on the actions of others. Students in teaching hospitals can watch classmates correctly follow infection control policies throughout the day and yet can be more influenced to be noncompliant by observing the single time that a senior clinician ignores a practice guideline.

One way to improve compliance and counter the influences noted previously is to use disseminated enforcement by actively encouraging all personnel to call attention to noncompliance. Once it has been determined which procedures are required for a particular situation and this has been documented, there is no reason that nontechnical staff should be any less capable than a veterinarian in determining whether a procedure has been followed correctly. It is important that this community enforcement be empowered by all in a spirit of friendly camaraderie and team building. Some hospitals have noted significant improvements in compliance using this method of enforcement and have even used competitions among "teams" with the incentive of agreeing that the loser must pay a reward to the other team (e.g., pizza lunch).

Zoonosis Awareness

One of the most important objectives for an infection control program is to protect personnel and clients from illness associated with zoonotic infections. This is another area in which veterinarians sometimes forget that not all personnel have an understanding of hazards or of how to take appropriate actions to protect themselves. Without this knowledge, personnel may take inappropriate risks or may overreact to perceived hazards in what is actually a low-risk situation. In addition to holding briefings or question-and-answer sessions, it is wise to provide a good resource text, written summaries, or URL addresses to reliable Internet resources so that personnel have tools available to help them research answers to their questions. Table 46-3 provides a brief summary of some zoonotic pathogens that might be transmitted from domestic large animals through occupational activities of veterinary personnel.

Personnel with Increased Risk of Infection

An important area without much published literature relates to risks for zoonotic infections in personnel that have an increased susceptibility to infectious diseases or those in which the consequences of clinical infection may be particularly severe. Obviously there is an overall increase in risk of infection for immunocompromised personnel, but there is very little specific information about which disease risks might be of greatest importance to this population and which personnel may be at particular risk. In addition, there are many agents that pose minimal risk to people with healthy immune systems but can pose significant infection risk to immunocompromised personnel. Individuals being treated orally with antimicrobial drugs are generally considered to have an increased risk for infections with enteropathogens, and so it is prudent that personnel being treated with antimicrobial drugs be especially attentive to protocols related to personal protection. Pregnant women have a special risk for infections that can result in fetal infections or abortion, and should therefore use practical precautions that reduce the likelihood of infection. In general, paying strict attention to good hand-hygiene protocols, routine use of gloves to reduce the likelihood of contact exposures, regular use of protective outer garments or hospital-dedicated attire, and avoiding eating and drinking around animals or in their environments should help to reduce the likelihood of exposure to potential zoonotic pathogens.

Intervention and Investigation of Outbreaks of Health Care–Associated Infections

An outbreak is defined as an increased occurrence of infections above the expected baseline (endemic) level. Outbreaks are an ever-present risk in all health care facilities, veterinary or otherwise, and outbreaks will occur, despite rigorous infection control protocols. The general principles of outbreak management are to contain the outbreak and reduce the overall impact on individual animals and the facility. It is critical to note that despite the stigma often attached to outbreaks, an outbreak of disease does not necessarily indicate poor management or malpractice. By their very nature, most veterinary hospitals will always have higher risks for the occurrence of outbreaks of infectious disease. However, making no attempt to identify HCAI, neglecting signs of a developing outbreak, or responding inappropriately to the spread of HCAI could all be construed as poor management or even malpractice. Thus, there are a number of reasons why plans for a logical, aggressive, organized, and cooperative response should be developed. Consultation with internal and external experts in epidemiology, infectious diseases, microbiology, and infection control can be useful. It is unlikely that the person involved in coordinating the outbreak response will be an expert in all areas. Consulting others does not indicate a lack of ability on the part of the response team; rather, it indicates a logical approach to a typically complex problem. It makes sense to consult with those who, through interactions at multiple facilities, have gained experience that usually cannot be obtained while concentrating on primary responsibilities as a clinician at a single institution. Ideally, these individuals are consulted early in the outbreak, and it may be prudent to develop contingency plans and contact consultants in anticipation of potential problems. The use of external consultants can be particularly useful because they can examine a situation and facility without the same degree of inherent bias that develops through experience and habit of regular daily practice in a facility.

One of the most important factors in outbreak intervention is early recognition of potential problems. Ideally, infection control programs should be designed to allow early identification of related clusters of infection or disease either through laboratory testing, clinical disease reporting, or syndromic surveillance. When an infectious animal is exposed to a susceptible population, transmission may occur. First-generation transmission—that is, transmission from the index case (directly or indirectly) to other animals—can be difficult

TABLE 46-3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible through Occupational Exposures to Veterinary Personnel*

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Bacillus anthracis (Anthrax) • Gram-positive, spore forming, anaerobic bacterium	All species	There are three clinical forms of anthrax in humans: cutaneous, pulmonary, and gastrointestinal. Cutaneous infections manifest as skin papules and vesicles with associated cellulitis that evolve into a characteristic black eschar (scab). Pulmonary anthrax initially resembles upper respiratory infection and can evolve into severe respiratory compromise and death. The gastrointestinal form results in gastroenteritis with vomiting and dysentery.	Cutaneous transmission occurs through direct contact. Respiratory transmission occurs through inhalation of bacteria or spores. Gastrointestinal transmission results from eating undercooked contaminated meat.	Enhanced barrier precautions, including eye protection and respiratory protection using a minimum of an N95 should be used when handling affected animals or working in their environments. Blood and secretions from anthrax suspects should not be allowed to contact skin. Necropsy should not be performed on animals that have died from anthrax.
Bordetella bronchiseptica • Gram-negative bacterium	Pigs, dogs, cats, rabbits, horses	Disease is rare in humans and occurs predominantly in immunocompromised individuals, resulting in pneumonia and upper respiratory tract infections.	Respiratory infection through contact and droplet routes.	Immunocompromised individuals should avoid contact with mucous membranes and nasal discharges of susceptible animal species. Barrier precautions and adherence to good hand-hygiene protocols will reduce the risk of exposure.
Brucella melitensis, B. abortus, B. suis, and *B. canis* (Brucellosis) • Gram-negative bacterium	Cattle, sheep, goats, camelids, pigs, horses, dogs, other species	Flu-like illness, gastrointestinal signs occur frequently in adults but less often in children; irritability, insomnia, mental depression, and emotional instability sometimes develop. Recurrent fevers are the hallmark of chronic infections in addition to fatigue, arthritis, and cardiac and other complications.	Contact, droplet, or aerosol exposure to infected fetuses, placenta and placental fluids, or infected tissues; contact with contaminated fomites. Ingestion of unpasteurized milk or milk products.	Avoid contact with fluid or tissues from abortions. Use of barrier precautions including gloves, protective eyewear, and a minimum of N95 respiratory protection is recommended when performing obstetrical procedures or performing necropsies on high-risk animals.
Burkholderia mallei (Glanders and Farcy) • Gram-negative bacterium	Horses and other equid species	Flu-like symptoms, photophobia, lacrimation, diarrhea, septicemia, pneumonia, ulcerative and suppurative cellulitis, lymphadenopathy, splenic and hepatic abscesses.	Direct contact or droplet exposures to skin or mucous membranes; prolonged contact with infected animals is generally required for infection.	Enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when working with infected animals.
Campylobacter jejuni and *Campylobacter coli* • Spirochete bacterium	Cattle, sheep, goats, camelids, pigs, poultry, dogs, cats, other species	Disease varies from mild gastrointestinal distress that resolves within 24 hours to fulminating or relapsing colitis. Signs may include watery diarrhea, fever, nausea, vomiting, abdominal pain, headache, and muscle pain. Feces may contain frank blood. The acute symptoms usually diminish in 2-3 days and resolve in 7-10 days. Complications are rare but include Guillain-Barré syndrome, a disorder of the nervous system.	Fecal-oral transmission after contact with infected animals or their environments is a suspected but not well documented risk factor. Ingestion of contaminated water and food including undercooked poultry or meat, raw milk.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.

TABLE 46-3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible through Occupational Exposures to Veterinary Personnel*—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Clostridium difficile • Gram-positive, spore-forming, anaerobic bacterium	Pigs, horses, cattle, dogs, cats, other species	Colitis leading to fever, abdominal cramps, and diarrhea or dysentery, dehydration, and electrolyte imbalances. Rarely, severe colitis can lead to life-threatening complications such as toxic megacolon, peritonitis, and colonic perforation.	Oral-fecal exposure through contact or droplet exposure to infected animals or their environments.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments; personnel should use respiratory protection when cleaning practices may produce droplet exposure. Avoid eating or drinking near animals or their environments.
Clostridium perfringens • Gram-positive, spore-forming, anaerobic bacterium	All species	Wound infections can result in gas gangrene with accompanying fever, swelling, and erythema of affected area, systemic signs as disease progresses. Oral exposure is associated with abdominal cramps, diarrhea, and in rare cases necrotic enteritis and septicemia.	Wound contamination through contact or droplet exposure, ingestion of food contaminated with large numbers of bacteria, potentially oral-fecal exposure through contact or droplet exposure to infected animals or their environment.	Routine use of protective outer garments or dedicated attire when working with animals or their environments. Strict adherence to good hand-hygiene protocols, and appropriate cleaning and management of wounds.
Coxiella burnetti (Q fever) • Gram-negative, spore-forming, intracellular bacterium	Primarily sheep, goats, cattle, but also camelids, horses, dog, cats, other species	Symptoms of Q fever include fever, chills, headache, fatigue, and chest pains. Pneumonia and hepatitis can occur in serious cases. In pregnant women, infections can cause premature delivery, abortion, and infection of the placenta. In people with preexisting heart valve disease, endocarditis may occur.	Contact, droplet, or aerosol exposure to urine, feces, milk, and especially fetuses and placental tissues from infected animals. Respiratory exposure to contaminated dust, occasionally ingestion of unpasteurized milk or milk products.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Caution is warranted when handling tissues or fluids of infected animals or aborted fetuses. Consider use of eye protection when performing obstetric procedures on high-risk animals. Enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when working with infected animals.
Cryptosporidium parvum (Crypto) • Apicomplexan protozoal parasite	Ruminants, pigs, horses, poultry, dogs, cats, other species	Gastrointestinal disease, including signs of abdominal pain, nausea, anorexia, and profuse watery diarrhea. Severe infections can require hospitalization for fluid therapy and electrolyte imbalances. The disease is usually self-limiting but may be chronic and debilitating in immunocompromised individuals.	Oral-fecal transmission primarily through contact with infected animals or their environments, but also through droplet exposures during cleaning.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments; personnel should use respiratory protection when cleaning practices may produce droplet exposure. Avoid eating or drinking near animals or their environments.

TABLE 46-3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible through Occupational Exposures to Veterinary Personnel*—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Dermatophilus congolensis • Gram-negative, actinomycete bacterium	Cattle, sheep, goats, camelids, horses, rarely pigs, dogs, cats, other species	Pustular desquamative dermatitis.	Direct contact with lesions on affected animals.	Use gloves when handling affected animals; strict adherence to good hand-hygiene protocols.
Erysipelothrix rhusiopathiae (Erysipelas in pigs, erysipeloid in humans) • Gram-negative, facultative anaerobic bacterium	Pigs, other species	Characteristic cellulitis with raised red lesions, edema, and intense pruritus. Skin infections can progress to involve other cutaneous sites and also rarely to systemic infections with flu-like illness, septicemia, and arthritis.	Primarily via direct contact with infected animals, contamination of skin wounds. There are rare reports of transmission through ingestion of undercooked pork.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be used when working with clinically affected animals. Avoid eating or drinking near animals or their environments.
Escherichia coli O157:H7 • Gram-negative bacterium	Cattle	Fever, enteritis, diarrhea, or dysentery. In children under 5 and the elderly, infections can cause hemolytic uremic syndrome (hemolysis and kidney failure).	Oral-fecal transmission via contact or droplet exposure through exposure to cattle or their environment or through ingestion of contaminated water and food.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
Francisella tularensis (Tularemia) • Gram-negative bacterium	Sheep, rabbits, cats, other species	Flu-like illness, rashes, nausea, splenomegaly, papular or ulcerative lesions at site of cutaneous exposure, lymphadenopathy and ulcerative lymphadenitis, pleuropneumonia from inhalation or hematogenous spread; ingestion is associated with enteritis, stupor, and delirium.	Contact, droplet, or aerosol exposure to tissues or secretions of infected animals, ingestion of tissues from infected animals.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments is warranted when handling tissues or fluids of infected animals or aborted fetuses. Gloves, eye protection, and a minimum of N95 respiratory protection should be used when performing obstetric procedures on high-risk animals.
Foot-and-mouth disease virus • Nonenveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, pigs, other species	Infection in humans is very rare; headache, fever, vesicular lesions on the hands or feet or in the mouth.	Contact, droplet, or aerosol exposure to infected animals.	When working with infected animals, enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols.
Giardia lamblia • Flagellated protozoal parasite	Ruminants, pigs, poultry, dogs, cats, other species	Gastrointestinal disease, including signs of diarrhea, intestinal gas, stomach cramps, and nausea. A significant proportion of patients develop lactose intolerance while infected. The illness usually last 1 to 2 weeks but chronic infections can last months to years.	Oral-fecal transmission through contact with infected animals, their environments, or through ingestion of ingestion of contaminated water or food.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
Hendra virus • Enveloped, single-stranded RNA virus	Horses, other species	Fever, lethargy, respiratory distress, neurologic signs including headache and disorientation.	Occupational contact with infected horses or their tissues.	Classified as a Biosafety Level 4 agent; contact with infected animals or their tissues should be avoided unless personnel are specifically trained to work with this agent.

TABLE 46-3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible through Occupational Exposures to Veterinary Personnel*—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Influenza virus • Enveloped, single-stranded RNA virus	Pigs, aquatic fowl; influenza viruses are generally host restricted.	Cross-species infection with influenza strains is unusual under normal circumstances, but has been rarely documented with swine and avian influenza viruses resulting in fever, malaise, upper respiratory illness, and pneumonia.	Close contact with infected pigs leading to respiratory exposure through contact, droplet, and aerosol routes.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments, or dedicated attire when working with animals or their environments. When working with infected animals, use enhanced barrier precautions, gloves, eye protection, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols.
Leptospira spp. (Lepto) • Spirochete bacterium	All mammals appear to be susceptible to at least one species of *Leptospira*.	Severity of illness varies greatly; signs include flu-like illness with fever, chills, headache, and severe myalgia. Aseptic meningitis can occur, and 5% to 10% of cases may be associated with multiple organ failure.	Skin or mucous membrane contact with urine or less commonly with blood and tissues of infected animals, ingestion in contaminated water or food.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. A minimum of N95 respiratory protection may be appropriate if droplet exposure to urine is likely. Avoid eating or drinking near animals or their environments.
Listeria monocytogenes • Gram-positive bacterium	All species	Contact can result in papular lesions on hands and arms. Most commonly, flu-like illness and gastroenteritis. Less commonly, infections can result in a mononucleosis-like syndrome (glandular listeriosis) or in fetal infection, abortion, still birth, neonatal septicemia, or meningoencephalitis. Meningoencephalitis is also noted in the elderly and immunocompromised.	Immunosuppression greatly increases the risk of infection. Direct contact of skin or mucous membranes with infectious material, feces, or contaminated soil. Respiratory exposure to secretions from infected animals via droplet or aerosol routes. Oral-fecal exposures through contact, droplet, or aerosols, or ingestion of contaminated foods.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments, especially among immunocompromised people. Avoid eating or drinking near animals or their environments. Enhanced barrier precautions, gloves, eye protection, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when performing obstetric procedures on high-risk animals or when handling aborted fetuses or tissues and fluids of infected animals.
Mycobacterium tuberculosis, M. bovis, M. avium complex • Acid-fast bacterium	All species	Signs depend on the organ system involvement. General signs of infections include anorexia, weight loss, fatigue, fever, and chills. Signs of pulmonary infection include coughing and hemoptysis. Skin lesions are characterized by ulcers, papular lesions, and suppurative lesions. Signs of other organ involvement relate to the specific system.	Inhalation and oral exposure through respiratory droplet and aerosol transmission from infected animals, oral or cutaneous exposure through contact with infected tissues or contaminated surfaces, ingestion of raw or unpasteurized milk and milk products.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. A minimum of N95 respiratory protection may be appropriate if working with infected animals with clinical pulmonary disease or if performing necropsy.
Nipah virus • Enveloped, single-stranded RNA virus	Pigs, other species	Fever, neurologic signs including drowsiness, headache, disorientation and confusion, shortness of breath, and coughing.	Occupational contact with infected pigs.	Classified as a Biosafety Level 4 agent, contact with infected animals or their tissues should be avoided unless personnel are specifically trained to work with this agent.

TABLE 46-3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible through Occupational Exposures to Veterinary Personnel*—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Parapox viruses (Orf and bovine papular stomatitis viruses [BPSV]) • Enveloped, double-stranded DNA virus	Sheep and goats (Orf virus), cattle (BPSV)	Papular lesions at areas of contact (usually hands or arms). Lesions can be 1 cm in diameter, and surrounding tissues often become swollen and painful.	Contact with lesions on animals, scabs, or contaminated objects.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be worn when examining mouths of animals suspected of being infected.
Rabies virus • Enveloped, single-stranded RNA virus	All mammals	Encephalitis with accompanying behavioral and physical signs.	Bite injuries from infected animals, contact with infected animals, and contact with bats or their habitats are the most common methods of human exposure. Contact, droplet, and aerosol exposure to saliva and respiratory secretions of infected livestock is also thought to be a possible method of infection, but is not well documented.	Complete isolation of animals suspected of infection, minimizing contact with personnel. When necessary to examine or manage suspect animals, use enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, eye protection, and strict adherence to good hand-hygiene protocols. Personnel that may be exposed to rabies should be vaccinated in accordance with CDC recommendations.[60]
Rift Valley fever virus • Enveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, other species	Flu-like illness, photophobia, neck stiffness, and vomiting, which may progress in severe cases to one of three characteristic syndromes: eye disease, meningoencephalitis, or hemorrhagic fever. Retinal lesions are the prominent sign associated with eye disease.	Contact with blood, other body fluids, or tissues of infected animals. Accidental inoculation through sharps injuries or by inhalation of droplet or aerosols. People may also become infected by mosquitoes, or possibly from ingestion of raw milk.	Extreme caution should be taken when working with animals during epidemics. An inactivated vaccine has been used experimentally to protect veterinary and laboratory personnel at high risk of exposure. Enhanced barrier precautions, gloves, eye protection, and a minimum of N95 respiratory protection are strongly recommended when working with high-risk animals or their tissues. Universal precautions should be taken when obtaining and processing specimens from patients. Samples should only be handled in laboratories by trained staff and processed in suitably equipped laboratories. Control of the mosquito vectors and use of personal protection are important.
Rhodococcus equi • Gram-positive facultative intracellular bacterium	Horses, also found in feces of sheep and cattle	A problem with growing recognition, infections in immunocompromised people commonly lead to life-threatening chronic, progressive, granulomatous pneumonia. In contrast, infections are very rare in immunocompetent people and are typically less severe.	Regular contact with horses is a documented risk factor for infection, presumably through oral-fecal exposure via direct contact or droplets, although there is often no documented direct exposure to horses.	Immunocompromised people working with horses should adhere to good hand-hygiene protocols and routinely use protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.

TABLE 46-3

Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible through Occupational Exposures to Veterinary Personnel*—cont'd

Agent/Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
Ringworm (*Microsporum* and *Trichophyton* spp.) • Fungi	Cattle, horses, dogs, cats	Characteristic circular, well-circumscribed, red lesions that are pruritic. In immunocompetent people, infection is limited to the keratinized layers of the skin and hairs. However, in immunocompromised people, infections may extend to deep tissues or become systemic.	Direct contact with lesions on affected animals or with objects that have contacted affected areas.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be worn whenever working with animals known to have dermatophytosis.
Salmonella enterica • Gram-negative bacterium	All species	Flu-like illness, gastroenteric disease, diarrhea or dysentery, septicemia.	Oral-fecal transmission through contact with infected animals, their environments, contaminated items, or through ingestion of contaminated water or food.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with animals or their environments. Enhanced barrier nursing precautions are needed when working with clinically affected animals. Avoid eating or drinking near animals or their environments.
Staphylococcus aureus (methicillin resistant, MRSA) • Gram-positive bacterium	Horses, pigs, dogs, cats, other species	*Staphylococcus aureus* commonly colonizes the anterior nares and other sites without causing clinical signs. Infections most commonly involve skin and soft tissues, either as a primary infection or by infecting cuts or other skin injuries, including sites of intravenous injection or catheterization. Infections of the respiratory tract and urinary tract are also noted. The risk of infection may be increased in immunocompromised people. Skin infections most commonly result in swollen, painful, erythematous lesions that can often be purulent.	Direct contact with colonized or affected animals; droplet or aerosol exposure to discharge from infected sites.	Strict adherence to good hand-hygiene protocols, and routine use of protective outer garments or dedicated attire when working with horses or pigs. Enhanced barrier nursing precautions and gloves should be required when working with animals known to be colonized or infected. Cuts and abrasions should be kept bandaged and disinfected regularly.
Vesicular stomatitis virus • Enveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, pigs, horses, other species	Infections in humans are very rare, and typically result in flu-like symptoms. Less commonly, oral vesicles and cervical lymphadenopathy can be noted.	Mucosol exposure via direct, droplet, or aerosol exposures with clinically infected animals.	Enhanced barrier nursing precautions and gloves can be used when working with animals known to be colonized or infected. Eye protection and N95 respiratory protection may also be warranted when examining or treating lesions.

*This is not a complete list of all zoonotic diseases; less common diseases and those with vector-borne or solely foodborne routes of transmission are not included.

to detect, particularly in situations when the index case is infectious prior to developing clinical disease. The most important control aspect related to the first generation of cases is prompt identification so that an outbreak can be recognized early enough to implement measures to reduce the risk of further transmission to a second generation of cases. Often, outbreaks are not identified or addressed until multiple generations of transmission have occurred, thereby increasing the overall morbidity and mortality and complicating the response.

General principles of outbreak response include identification of the infectious agent, identification of infectious animals, identification of animals that have likely been exposed, determination of the mode of transmission, and prevention of further transmission by means such as isolation, implementation of barrier precautions, active surveillance, environmental surveillance, increased environmental disinfection, restriction of animal and personnel movement, and under extreme conditions minimizing new exposures through restricting admission of new patients.

VetBooks.ir

While useful, initial intervention measures do not require definitive identification of the etiologic agent. In the absence of a confirmed etiology (i.e., diarrhea cluster of unknown cause), outbreak intervention can still be performed using general infection control practices combined with knowledge of appropriate response to the most likely causes. General principles such as isolation of infected/affected animals and their direct contacts, use of barrier precautions, close attention to personal hygiene, restriction of animal and human movement, regular examination of animals and careful attention to cleaning and disinfection are important measures that are useful for most types of infectious disease outbreaks. Indeed, these measures alone will often constitute the full response after an etiologic agent is identified.

Identification of animals likely to be shedding the agent responsible for the outbreak is critical. Definitive confirmation is not required, and a syndromic response is often better. For example, in the midst of a *Salmonella* outbreak, it is wise to consider all animals with diarrhea, depression, or fever as likely to be infected and shedding bacteria even if culture results have been negative. The same would be true for horses that develop fevers when others suspected of having herpesvirus myeloencephalitis or influenza are hospitalized in the same facility. This will result in some misclassification, but erring on the side of being overly sensitive in identifying infectious animals is the more appropriate response when trying to halt the spread of disease. The main problem with this type of response is imposing excessive strain on available resources (e.g., isolation stalls, personnel time) because of excessive misclassification.

Identification of potentially exposed animals is also critical. Depending on the pathophysiology of disease, these animals may or may not require segregation or isolation. For some pathogens, clinical disease precedes development of the infectious state, so exposed animals can be monitored and isolated if required. For example, horses exposed to *S. equi* consistently develop fever prior to shedding the organism,[61] so close monitoring of body temperature of exposed animals and prompt isolation of animals developing fever may be sufficient to prevent propagation of an outbreak. For many pathogens, screening of all potentially exposed animals can be useful. In particular, the use of rapid screening techniques that can provide a turnaround time of a few hours (e.g., antigen detection test for equine influenza, *S. equi* PCR) can be very useful. However, testing strategies should also include some use of culture so that whole organisms will be available to aid epidemiologic investigations and must be based on good understanding of the pathophysiology of disease (e.g., when shedding typically occurs). Widespread screening of hospitalized animals will often be required to determine the extent of the outbreak and facilitate removal of infectious animals from the population. Therefore, if imposed as a response to suspected spread of HCAI, it is essential that screening not be an elective procedure. As such, it is prudent for facilities to have previously considered how costs for diagnostic testing will be distributed in the event of suspected HCAI. Surveillance for shedding of specific contagious agents at the time of admission can facilitate prevention of outbreaks as well as intervention responses. In situations in which recently exposed animals do not necessarily develop consistent overt clinical signs or in which rapid diagnostic testing is not available, it may be necessary to segregate all potentially exposed animals, either in an isolation unit or in the main hospital.

Determination of the likely mode(s) of transmission is also required for initiation of an effective response. This is usually relatively clear based upon the identity of the known or suspected pathogen. However, in general, all agents of concern for HCAI will spread through contact and common vehicle transmission, and thus controlling all methods of contact exposure to patients will be critical in response to suspected outbreaks. Although droplet transmission might be most important for respiratory agents, practicalities of cleaning hospital environments for large animals usually necessitates use of large volumes of water, which can also create hazards related to droplet transmission. As such, the potential for droplet transmission should also be tightly controlled in response to suspected outbreaks. Generally, only highly contagious viral respiratory agents pose a hazard through airborne transmission. However, in situations in which routes of transmission are not clear, it is prudent to assume the worst and manage the outbreak as if the pathogen is highly transmissible by multiple routes until proven otherwise.

Prevention of further transmission is obviously one of the most important goals of outbreak response. A variety of factors need to be considered to achieve this. In addition to identification of infectious animals, measures need to be established to prevent direct and indirect contact of these animals with other animals and the general hospital environment. Isolation and the use of barrier precautions can achieve this. The response to implemented infection control measures should be monitored closely to determine their adequacy, with an understanding that there is an inherent lag time from implementation of measures to control of the outbreak that is proportional to the incubation period for infectious diseases.

At times, partial or complete closure of the facility may be useful or necessary. Restricting new admissions decreases the number of newly susceptible individuals that might promote propagation of an outbreak. Further, if new infections appear to be occurring despite implementation of best control efforts, it is important to consider whether it is prudent or ethical to continue admitting new patients. It is also critical to consider the tremendous burden that can be necessitated by the need to deal with infection control measures and the possible effects on patient care. During outbreaks, stall space, particularly isolation space, may become limited, and decreasing the number of admissions facilitates depopulation of the facility for proper cleaning and disinfection. Clinical personnel are often overworked during outbreaks because of the number of ill animals, and excessive workload can contribute to breaches in protocols. Although there may be reluctance among some people to restrict hospital admissions because of potential negative impacts related to public relations and finances, early, short-term closure of a facility to stem a small but developing outbreak is much better than a subsequent longer closure in response to a larger outbreak with more affected animals. A key component of facility closure is proper communication to staff and the public, emphasizing the proactive approach that is being taken to protect patients and clients and to prevent a major problem from developing. Regardless of whether it is deemed necessary to restrict admission of new patients, as described previously, whenever outbreaks of HCAI are suspected, it is critical to consider whether standard informed consent procedures suitably convey the risks associated with hospitalization to clients.

If environmental contamination is suspected of being widespread, complete depopulation of a ward or even the entire hospital may be necessary to allow for thorough cleaning and disinfection. The availability of multiple wards can facilitate this process as individual problem wards can be closed and disinfected while allowing the hospital to remain functioning. Assuming sensitive culture or other antigen detection methods are available, post-disinfection environmental screening may be indicated for certain pathogens (e.g., *Salmonella enterica*) prior to reopening.

Although vaccination is often perceived as being a cornerstone of infection control, the indications and limitations of vaccination must be considered. No vaccine confers 100% protection, and vaccination should never be used as a replacement for good infection control practices. A more appropriate perspective is that vaccination is principally useful when more useful infection control methods have failed.

Requiring vaccination prior to hospital admission is an area that has received limited commentary in large animal practices. Although vaccination requirements are difficult to enforce in animals admitted for emergency procedures, it may be reasonable for facilities to consider encouraging or requiring vaccination against relevant pathogens prior to admission for elective procedures. For example, requiring vaccination prior to admission for influenza in horses or BVD in pregnant cattle or alpacas could decrease the risk of infection and transmission in hospitals. Problems that might be encountered with such an approach include the lack of relevant efficacy data for

VetBooks.ir

many vaccines, potential concerns regarding adverse effects with some vaccines, difficulty ensuring compliance, and competitive issues if all competing practices do not have the same standards.

Vaccination may be a useful intervention measure during some outbreaks, but it is important to note that efficacy of vaccines typically has not been evaluated in this specific situation. It is important to remember that there are three possible outcomes associated with any intervention: it may help, it may have no effect, or it may be harmful. For vaccination during an outbreak to be helpful in control efforts, the vaccine must be given to susceptible animals prior to exposure, must initiate a protective response before natural exposure, and must not be harmful when administered to animals that are incubating disease. These criteria are often difficult or impossible to meet in the midst of an outbreak. The greatest potential use for vaccination during an outbreak is likely intranasal influenza vaccination, since this type of vaccine can provide a rapid and effective immune response and is not contraindicated in exposed animals.

Infection Control Issues Related to Specific Pathogens

Although all contagious diseases have the potential to be important hazards for the health of individual patients, there is more empirical evidence regarding the importance of some diseases. Further, while safeguarding the health of veterinary personnel must be a priority for all veterinary practices, some zoonotic diseases have been shown to be of greater concern. Information is listed as follows, regarding control of diseases of particular importance as hazards for HCAI and zoonotic disease.

Salmonella

Salmonella enterica is the agent most commonly reported in association with outbreaks of HCAI and closure of large animal hospitals. In a survey of teaching hospitals from AVMA-accredited institutions, 20 of 38 (65%) participating institutions reported identifying epidemics of *Salmonella*-associated HCAI during the previous 5 years.[13] Seventeen of these hospitals restricted admissions in order to facilitate management of the outbreaks, and 11 reported closing completely to admissions as a control measure. *Salmonella enterica* is recognized as a pathogen around the world, and HCAI have been identified in many countries. However, the average risk among large animal patients varies tremendously among species, production practices, and even geographically within a country. In North America, the general risk of shedding is very low among animals raised in the northernmost regions and can be very high in warmer latitudes. All species are susceptible to infection, but large, intensively managed populations generally often have the highest prevalence of shedding, and the likelihood of shedding in patients while hospitalized is greatly influenced by the prevalence of infection in animals at home premises. Cattle and swine from large populations often have a higher likelihood of shedding compared with horses, camelids, and small ruminants. Given these factors that are associated with variability in infection rates, it is prudent for large animal hospitals to objectively assess the risk of shedding among their patient population in order to appropriately adjust the rigor of surveillance and control efforts.

A notable number of patients shed *Salmonella* without evidence of associated illness, but infected patients are significantly more likely to shed if they show signs of gastrointestinal illness or are systemically ill. Numbers of organisms shed per gram of feces are generally much greater in clinically affected animals. Animals known or suspected to be infected with *Salmonella* should be managed in isolation with strict barrier precautions and hand-hygiene protocols. Shedding tends to be more commonly detected in the summer and fall and may also be generally more common in warmer climates. Whereas outbreaks of HCAI are usually detected in association with the spread of clinical disease, subclinical infections can be more common than clinical infections during outbreaks. Zoonotic infections in veterinary personnel have been commonly detected in association with outbreaks of HCAI. There is apparent variability among strains in regard to virulence, infectivity, and ability to persist in the environment, and this strain variability may be a very important determining factor regarding outbreaks of HCAI. Environmental contamination near infected patients is the rule rather than the exception, and active surveillance has shown that contamination can become disseminated to quite distant areas of the hospital from only a single infected patient. In one study, a total of 12% of 452 environmental samples collected over 10 weeks in a nonepidemic period using electrostatic household wipes were positive for *Salmonella*.[57] Experience has shown that environmental contamination is even greater during outbreaks. In nonepidemic situations, there tends to be great variability in phenotypic markers (serogroup, serotype, and antimicrobial susceptibility) among isolates recovered from patients over time, which often makes it possible to differentiate isolates in epidemiologic investigations. In other situations, especially when certain strains are circulating actively in the region of a hospital, use of genetic analysis may be necessary in order to differentiate strains of *Salmonella* for purposes of epidemiologic investigations. Methods used in diagnostic laboratories for culture and molecular diagnostics are highly variable, which can significantly impact reliability of assays. As such, veterinarians should seek out laboratories that are known to have optimized laboratory methods for use in diagnostic situations. Polymerase chain reaction assays for *Salmonella* are available commercially at a number of laboratories. However, because of the importance of phenotypic and genotypic comparisons of isolates for epidemiologic investigations conducted as part of prevention and control efforts, PCR assays are not recommended for regular use in surveillance programs without parallel analysis using culture. Active surveillance programs are commonly used in large hospitals as a management tool to detect clinical and subclinical infections in large animal patients. In addition, environmental surveillance is sometimes used as adjunct to detect environmental contamination. All common disinfectants are effective against *Salmonella* organisms under optimal conditions. However, its common association with fecal material, other organic matter, and dirt requires careful adherence to good cleaning (physical disruption of surface matter using detergents) and disinfection procedures in order to minimize the likelihood of environmental persistence. Mitigation in response to outbreaks of HCAI requires thorough decontamination of all environmental surfaces, which may only be possible after closure to new admissions, although disinfectant misting may be a useful alternative in some situations.[62]

Clostridium difficile

Although less commonly implicated in outbreaks of diarrheic disease than *Salmonella enterica, C. difficile* can be an important pathogen in horses. Despite the documented risk for health care–associated transmission within human hospitals, this does not seem to be common among equine patients. *Clostridium difficile* should be considered as a differential diagnosis in horses with diarrhea and duodenitis-proximal jejunitis. Standard infection control methods used for salmonellosis should be adequate to control transmission of *C. difficile,* with the exception of disinfection. Because *C. difficile* is a spore-forming bacterium, disinfection can be difficult. Clostridial spores are highly resistant to environmental degradation and most disinfectants that kill *Salmonella* are ineffective against bacterial spores, with the exception of bleach (hypochlorite solutions) and accelerated stabilized peroxide. Peroxygen disinfectants may also be effective under optimal circumstances. An additional, albeit unsubstantiated, concern is the potential for zoonotic transmission of *C. difficile* from horses or cattle to humans. The strains of *C. difficile* isolated from animals are often indistinguishable from those that cause disease in humans. Therefore, animals infected with *C. difficile* should be considered as potential sources of zoonotic infections in humans.

Cryptosporidium parvum

Animals of all ages in a variety of host species have been shown to shed *C. parvum* oocysts, but the shedding prevalence is much greater in young animals, and the primary infection control hazard involves

VetBooks.ir

shedding by diarrheic neonates, especially calves. This is because of the extraordinary numbers of oocysts shed by affected young animals, the small infectious dose, and the hardiness of organisms. Affected calves can shed more than 10^7 oocysts per gram of feces during peak shedding, whereas humans and other animals can be clinically infected with fewer than 100 oocysts, although there does appear to be some difference among individuals as well as among strains. To further complicate control, oocysts are profoundly resistant to all disinfectants that can be regularly used in hospitals. Research has shown there are different lineages of *C. parvum* that relate to host range; genotype 1 appears to only infect humans whereas genotype 2 (sometimes called *bovine genotype*) infects a wide variety of other species including domestic large animals and humans. Cryptosporidiosis is an important zoonotic disease hazard in veterinary personnel, and there are a number of documented outbreaks involving animal caretakers. *Cryptosporidium* is considered to be a relatively common nonviral cause of self-limiting diarrhea in immunocompetent persons, particularly children. Clinical disease can be severe and even life threatening in immunocompromised persons. Diarrheic neonates can be easily and inexpensively screened using direct microscopic examination of fecal smears prepared with acid-fast stains. Regardless, it is very prudent to house diarrheic neonates in isolation and handle with strict barrier precautions and hand-hygiene protocols. Personnel cleaning these housing areas should avoid using high-pressure water to minimize the risk of aerosol and droplet exposure. This is complicated by the inherent resistance of coccidian parasites to all disinfectants, which necessitates the reliance upon vigorous scrubbing with soap and rinsing with copious amounts of water in decontamination efforts. The likelihood of inadvertent oral exposures while cleaning can be reduced by using face shields or disposable masks along with gloves and fastidious attention to hand hygiene.

Equine Rotavirus

Although outbreaks of rotavirus are fairly common on breeding farms, outbreaks in veterinary clinics are rare. Equine rotavirus is of most concern in facilities with a large neonatal caseload. Rotavirus may be shed in the feces of affected foals, clinically normal foals, and adult horses. Thus, prevention of exposure is difficult. However, it is likely that clinically affected foals are the most common source of infection, through direct contact or common vehicle exposure. As a result, isolation of affected animals and the use of barrier precautions are the most important infection control measures. With the exception of disinfectants, protocols directed at control of *Salmonella enterica* should be adequate for rotavirus control. Little specific information is available regarding the relative effectiveness of different disinfectants on equine rotavirus. However, as a nonenveloped virus, equine rotavirus should be expected to be resistant to environmental degradation and many disinfectants commonly used in veterinary medicine. The use of phenolics has been recommended because of their better activity in the presence of organic debris, but evidence of efficacy is lacking and toxicity is a concern. Oxidizing agents probably have similar to superior effectiveness and may be preferable because they have a much lower potential for toxicity.

Bovine Viral Diarrhea Virus and Border Disease Virus

The closely related members of the genus *Pestivirus* are not commonly considered disease hazards caused by HCAI, but this may be more because of a lack of detection than the lack of occurrence. The main infection control hazard is related to exposure of susceptible pregnant cattle, sheep, goats, or camelids to persistently infected (PI) animals, which continuously shed large amounts of virus. The long period between infection of pregnant females and the birth of affected offspring complicates the ability to make relevant observations about the origin and frequency of HCAI. As such, it may be important to encourage or require vaccination of valuable pregnant cattle or alpacas prior to admission. In addition, animals known or suspected to be PI should be managed in isolation with barrier precautions to minimize transmission. This includes neonates showing signs of congenital infection. Increased infection control precautions should also be used with animals from herds with a recent history of disease related to these viruses. Direct contact with PI animals is an efficient method of transmission, but limited research shows that calves can be infected through contact with contaminated stalls and through droplet or aerosol exposure over a distance of at least 1.5 m.[63] Appropriate use of cleaning and disinfection methods should readily decontaminate the environment, and all common disinfectants are effective against these viruses under optimal conditions.

Strangles (*Streptococcus equi equi*)

An important aspect of *S. equi* control is identification and management of subclinically infected animals. Syndromic guidelines for isolation upon admission (i.e., isolation when patients are admitted from farms with a recent history of clinical *S. equi* infections, or isolation of horses with fever of unknown origin or unexplained nasal discharge) can help in managing potentially infectious horses so that they can be isolated pending the results of screening. The ubiquitous nature of *S. equi* and the possibility that essentially any hospitalized horse could be a subclinical carrier means that there is an ever-present, if low, likelihood of *S. equi* introduction into the hospital environment. Experience suggests that routine universal screening of horses admitted to veterinary hospitals is not necessary to control HCAI caused by *S. equi*. However, screening and isolation of horses from farms with endemic *S. equi* would be a reasonable control strategy. Standard infection control measures, including preventing direct contact of hospitalized animals, optimizing hand hygiene, using appropriate cleaning, and disinfection, should be useful for reducing the risk of *S. equi* transmission should a colonized horse be admitted. Prompt examination and isolation of horses developing fever of unknown origin during hospitalization can indicate which horses should be removed from the general population before the onset of bacterial shedding. Vaccination in the face of an outbreak with vaccines that are currently available is not recommended because of a lack of proven efficacy and concerns regarding development of purpura hemorrhagica. There is also no evidence of a need to require vaccination of elective cases prior to hospital admission. *S. equi* is susceptible to all common disinfectants, when used properly.

Equine Influenza

Influenza is one of the most contagious diseases affecting horses. Immunity is transient and horses can be repeatedly affected during their lifetime. There is no carrier state, and maintenance in a population is dependent upon transmission from one acutely infected horse to another. In horse populations aggregated at racetracks, shows, or other venues, attack rates can reach 15% to 30%.[64] The incubation period from exposure to onset of clinical signs is typically about 2 to 4 days, which commonly coincides with the onset of virus shedding, although viral shedding can sometimes start before the onset of clinical signs. Horses are often febrile and obtunded at the onset of disease. Paroxysmal coughing is a classical sign of influenza infection that develops in some horses as disease progresses. Because of its contagious nature, identification of multiple acutely febrile horses can be an early indication that influenza virus is spreading in the population. Rapid identification and confirmation of animals shedding virus allows initiation of efforts to minimize contagious spread. Antigen detection assays are commercially available and very useful for rapid confirmatory testing (e.g., Directigen Flu A, BD Diagnostic Systems, Sparks, Md.). However, this assay has limited sensitivity; virus shedding was detected in only approximately 30% of clinically affected horses during outbreaks using this assay, so tests should be performed on multiple clinically affected horses and interpreted in the aggregate for the population.[65] Negative test results for individual samples should be interpreted with caution because of the consequences associated with not using appropriate control measures during an outbreak of a highly contagious disease. PCR tests are available and may be more sensitive than antigen detection assays, but published validations of these assays are generally unavailable.

VetBooks.ir

Influenza virus can be transmitted through aerosol, droplet, and contact transmission and can easily be transmitted over several feet in respiratory aerosols generated by coughing horses. As such, horses confirmed to be infected should be managed in complete isolation with full barrier precautions, paying strict attention to hand-hygiene protocols. Influenza virus can survive on surfaces at most for a few days in a cool, moist environment. As an enveloped virus, influenza is susceptible to damage from extreme environmental conditions and is readily inactivated by all common disinfectants if they are properly applied. Whereas clinically affected animals are the most likely to shed large amounts of virus, in nonaffected horses sampled during large outbreaks, seroconversion and virus shedding can be found in about 30% and 5% of the exposed populations, respectively.[64,65] As such, it is prudent to increase infection control precautions for all exposed but apparently unaffected horses in order to minimize risks of transmission. Early vaccination of all horses with intranasal vaccine may be of value in abbreviating the course of an epidemic. If new admissions are allowed when there is an elevated risk of influenza virus infection, horses should be required to be recently vaccinated prior to admission with vaccines having proven efficacy (preferably a minimum of 2 weeks prior to admission). Regardless of vaccination history, it is unwise to admit very young or immunocompromised horses when there is an increased risk of infection with influenza virus. Influenza virus is susceptible to all common disinfectants, when used properly.

Equine Herpesviruses

Equine herpesvirus types 1-5 are ubiquitous in horse populations and are highly contagious. EHV-1 and EHV-4 are the most widely recognized as important causes of outbreaks of disease in horses, and HCAI have been noted for both agents. EHV-4 infections are associated with contagious respiratory disease that principally affects horses under 3 years of age. EHV-1 infections are associated with respiratory disease, neurologic disease, peracute pulmonary vasculitis, abortion, and neonatal mortality in congenitally infected foals. The potential for contagious spread of herpesvirus myeloencephalitis was dramatically highlighted in 2011 when infections among horses at a horse show in Ogden, Utah, resulted in subsequent spread to documented clinical infections in 180 horses (29% with neurologic disease) on 63 premises located in 14 states and Canadian provinces, and subsequent euthanasia/death of 14 horses.[14,15] Documented spread of infections within hospitals as well as at home premises of previously hospitalized horses further highlight risks for HCAI with EHV-1.[8-10] Immunity is relatively short lived, and infections likely occur throughout the life of horses. Many, if not most, of these infections are undetected or occur with only mild clinical signs. The most common clinical sequel of infection is mild respiratory disease during the first 2 years of life. More infrequently, EHV-1 infections can result in more severe complications such as abortions in pregnant mares or paralysis. All EHV-1 and EHV-4 infections originate in the respiratory tract, but epidemiologic evidence suggests that contact and droplet transmission among horses in relative proximity is much more common than aerosol transmission over greater distances. Fever is commonly the initial clinical sign exhibited by infected horses, and identification of multiple acutely febrile patients can be an early indication of nosocomial spread of equine herpesvirus in the population. Most horses can be shown to be latently infected with EHV-1 and EHV-4 by the time they reach adulthood, and subsequently any hospitalized horse might serve as a source of infection for other patients by recrudescing virus in response to stresses of disease, hospitalization, and transport. However, clinical experience suggests that EHV-associated HCAI most commonly originate from clinically affected horses. As such, rapid identification of animals suspected of being infected, isolation of affected horses with complete segregation of materials used in their care, and use of barrier precautions with appropriate hand-hygiene protocols are generally effective for minimizing risks for HCAI. All horses exhibiting ascending weakness, paresis, or paralysis should be suspected of EHV-1 infection and managed in isolation until the animal can be proven to have stopped shedding or another diagnosis is confirmed. Herpesvirus infection should also be promptly ruled out in horses with upper respiratory disease or fever of unknown origin. Use of PCR testing as an adjunct to thorough clinical investigation is often extremely useful for this purpose. Herpesviruses are enveloped viruses and routine cleaning and disinfection procedures should be adequate for decontamination of surfaces, assuming appropriate protocols are followed. PCR testing of nasal secretions is the most useful assay for rapid confirmatory testing. Serial testing of horses is useful for establishing that shedding has stopped because field data and study involving experimental infection have shown that shedding can be intermittent and negative results for individual tests must be interpreted with caution.[10] Although many laboratories offering PCR testing now provide information about the ORF30 genotype (D vs. N or sometimes labeled as "neurotropic" and "non-neurotropic" genotypes), both genotypes can cause neurologic disease, both genotypes of virus are contagious, and both genotypes can cause epidemics of disease. As such, this information should not affect the level of caution that is taken with infected or exposed horses.[66] Without adjunctive testing, infected horses should be quarantined for a minimum of 28 days after cessation of disease. Using serial testing as a confirmatory adjunct, this quarantine period might be shortened to 14 days after cessation of disease.[9,66] Field data from one outbreak suggest that about 60% of horses can be shedding virus at the onset of clinical disease irrespective of the severity of clinical signs, and shedding can persist for 10 to 14 days after disease onset.[10]

EHV-3 is less commonly considered as a problem regarding HCAI, but it has been noted to be spread through contact with contaminated materials during reproductive procedures as well as between horses during coitus. As such, it is a notable hazard for practices that specialize in reproductive services. EHV-3 causes coital exanthema, a pustular disease affecting the vulva and vagina of mares and the penis and prepuce of stallions. Appropriate cleaning and disinfection of materials used in reproductive examinations, avoiding use of examination sleeves and gloves with multiple horses, and rigorous adherence to sound infection control precautions for breeding populations should control the spread of EHV-3. The prevalence of latent EHV-3 infections is not well documented. Recently, evidence association between respiratory disease in young horses and EHV-2 or EHV-5 infection has been published,[67] but the significance of these agents in the occurrence of HCAI is unknown.

Enveloped viruses, including all herpesviruses, are susceptible to all common disinfectants, when used properly.

Methicillin-Resistant *Staphylococcus aureus*

MRSA is emerging as an important veterinary and zoonotic pathogen. In large animals, MRSA infections have been most commonly identified in horses and pigs. Transmission of MRSA between these species and attending personnel can occur, and MRSA colonization and infection appear to be an emerging occupational risk associated with large animal veterinary practice. Transmission of MRSA is thought to mainly occur through direct or indirect contact between infected or colonized people or horses, and hospitalized horses. Aerosol transmission from MRSA-contaminated dust is a concern in intensive indoor housing situations, particularly swine barns. The potential for droplet and airborne transmission in less intensive situations is unknown and may be limited. The largest problem related to HCAI with MRSA in large animals has been associated with the infection and colonization of equine patients. Infections are principally noted at surgical sites and wounds, whereas colonization predominantly occurs in the nasal passages, although gastrointestinal colonization has also been noted. If not identified by active surveillance, colonized horses can be silent yet prolific reservoirs for infection of humans and horses. Prevention of MRSA transmission requires careful attention to practices that prevent contact and common vehicle transmission, including use of good hand-hygiene practices, restriction of horse contacts and isolation of infected or colonized animals, and use of specific measures aimed at identifying carriers. All colonized or infected horses should be treated as

VetBooks.ir

infectious, housed in isolation and handled with strict attention to contact barrier precautions. Screening by culture of nasal swabs collected at the time of admission can help control MRSA in areas where it is endemic in the community or the horse population; however, the need for routine screening varies depending on the facility, the MRSA prevalence in the patient population, and other factors. Although colonized personnel can be a source of infection of patients, staff screening is fraught with complex issues (e.g., privacy, occupational health) and is difficult to justify in the absence of an ongoing outbreak that is uncontrolled with improvement in routine infection control practices. Various studies have demonstrated high rates of MRSA carriage among equine veterinary personnel, so it is reasonable to assume that all equine facilities regularly have one or more colonized staff. For this reason, good attention to standard hygiene and infection control practices is critical. *Staphylococcus aureus* is susceptible to most disinfectants, if used properly.

Coxiella burnetti

Coxiella burnetti is the causative agent associated with Q-fever. Although most infections in humans are subclinical, personnel who contact livestock have a greater risk of infection and disease that can be severe and even fatal in a small portion of cases. It is also highly infectious, has a low infective dose, and can be transmitted through contact as well as by droplet and airborne routes. *Coxiella burnetti* can be found in a variety of animal species, but zoonotic transmission is most commonly associated with periparturient ruminants (especially small ruminants) and aborted fetuses. Serum antibody tests, antigen detection assays, and PCR can be used to identify infected animals, but the sensitivity of these assays has been questioned. Because of the potential significance of clinical infections in humans, all attending personnel should be appropriately aware of the zoonotic potential and risks associated with Q-fever. The risk of serious clinical consequences should be noted in particular by pregnant women and people with valvular heart disease or who are immunosuppressed. Medical histories for individuals and flocks should be considered to determine if there is an indication that *C. burnetti* may be a greater than average risk. Infection control measures that could be used to minimize hazards to people with a high risk of clinical infection include isolating periparturient small ruminants, paying strict attention to hand-hygiene protocols, and use of respiratory protection and barrier nursing precautions when handling potentially infected animals. Particular care should be taken during parturition and when handling aborted fetuses and newborn small ruminants. For animals known to be infected, care should be used when cleaning and disinfecting stalls or other housing environments, and contaminated bedding and other materials should be handled cautiously. *Coxiella burnetti* is susceptible to most disinfectants, if used properly.

Antimicrobial Resistance and Drug Use

While antimicrobials are undoubtedly required for proper management of a significant percentage of hospitalized large animals, it is reasonable to consider whether antimicrobial resistance and antimicrobial drug use impacts the occurrence or the ability to control HCAI. The first relates to outbreaks of HCAI with bacteria that are resistant to multiple antimicrobial drugs. These outbreaks are not extremely common but are a noted occurrence in human and veterinary hospitals and often occur in association with care in specific hospital units such as a critical care or surgery facility. Agents frequently identified in association with these outbreaks include enteric organisms such as *Escherichia coli* and enterococci, commensal opportunists such as *S. aureus,* as well as *Pseudomonas* and other bacteria. Significant research into these organisms has identified specific strains and even specific genes that are commonly identified in association with agents responsible for these outbreaks (e.g., MRSA, vancomycin-resistant enterococci [VRE], and extended spectrum β-lactamase–producing Enterobacteriaceae). The role that antimicrobial use in specific patients or even in specific hospitals has in promoting the occurrence of outbreaks of HCAI is not always conclusive. However, some experimental evidence does show that treatment with a specific antimicrobial drug is associated with an increased propensity for shedding of bacteria that are resistant to analogous drugs,[68] and the presence of multiple resistance genes can result in co-selection of resistance for multiple drugs following use of a single antimicrobial. Thus, common use of a particular drug within a hospital could apply selective pressure that more generally promotes colonization with resistant bacteria,[69] or it could enable or promote the survival of specific bacterial strains capable of causing epidemics of HCAI (e.g., VRE and MRSA). These concerns are supported by specific documentation that antimicrobial drug exposure can be associated with increased likelihood of shedding of enteropathogens[70,71] and multidrug-resistant pathogens.[72] In addition, antimicrobial drug exposure is a recognized risk factor for colitis in horses, which can be one of the most important infection control concerns in large animal facilities. Thus, efforts to reduce antimicrobial use and ensure logical (prudent) use can be beneficial to the individual patient and other hospitalized animals, in addition to the more abstract concerns about pressure toward emergence of antimicrobial resistance.[68] Surveillance aimed at benchmarking the use of antimicrobial drugs over time or to monitor use for specific conditions or in specific circumstances (e.g., outside of regular hours) may be useful for guiding policy decisions, but it is not useful for identifying specific occurrences of imprudent use. Of greatest importance is education so that all individuals with prescribing power understand the issues and the reasons for careful antimicrobial use. Measures such as developing selection algorithms for patients with specific types of disease and restricting the use of certain drug classes (e.g., glycopeptides) used by some facilities may decrease the likelihood of some occurrences of HCAI.[29]

Management of Donor Animals

It is increasingly common to use animals owned by hospitals or veterinary personnel as donors for blood and ingesta (e.g., rumen fluid) transfer to patients. Animals used for this purpose should be known to have a very low risk of contagious diseases, should be housed away from hospitalized patients, should be clinically healthy at the time of specimen recovery, and should be screened periodically for diseases that could be transmitted by use of transfer products. Diseases of concern that might be transferred by blood products from ruminants include bovine leukemia virus, bovine viral diarrhea and border disease viruses, and anaplasmosis; similarly, horses should be screened for equine infectious anemia infection. Ingesta donors should be screened for Johne's disease *(Mycobacterium avium paratuberculosis)* and *Salmonella enterica*.

Prevention, Detection, and Response to Transboundary (Foreign) Animal Diseases

PAMELA JOANNE HULLINGER, *Consulting Editor*

Perhaps a private veterinary practitioner's most critical responsibility is his or her role as the nation's front line for detection and defense against exotic and transboundary animal diseases (TADs). These are important, transmissible livestock diseases that are presently absent from the United States. If introduced, they would cause significant adverse economic or national animal, public, or environmental health consequences. Although many of these disease threats are known, new or "emerging" diseases may also impact the United States and affect human, animal, or ecosystem well-being. The U.S. Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS), Veterinary Services (VS) has primary responsibility for addressing foreign and emerging diseases of livestock and poultry, and works closely with state animal health officials (SAHOs), private veterinary professionals, and the livestock industry to monitor for and to detect, control, eradicate, or mitigate the impacts of TADs on the livestock industries and the public. Box 47-1 shows a list of the diseases successfully eradicated from the United States. The *Code of Federal Regulations* (CFR), Title 9, part 53[1] details the federal government's list of reportable diseases of livestock and poultry and its policies and procedures for the diagnosis, appraisal, euthanasia, and disinfection of livestock and poultry infected with these diseases. The list specifically includes foot-and-mouth disease (FMD), rinderpest, contagious pleuropneumonia, exotic Newcastle disease (END), highly pathogenic avian influenza (HPAI), and "any other communicable disease of livestock or poultry that in the opinion of the Secretary constitutes an emergency and threatens the livestock or poultry of the United States."[1] In addition to the federal reportable disease list, many states require the reporting of additional specific disease conditions beyond those named in the Code of Federal Regulations (CFR). Additional diseases specified by states may include diseases of public health importance, such as equine encephalomyelitis, or other endemic diseases of industry concern, such as bovine trichomoniasis. Licensed, practicing veterinarians are responsible for maintaining a familiarity with the federal reportable disease list as well as those of the states in which they practice. The reportable disease list for each state can be obtained through the office of the state veterinarian. States may also have their own more specific policies and procedures for the diagnosis, appraisal, euthanasia, and disinfection of livestock and poultry infected with such reportable diseases. Box 47-2 lists some reportable diseases of horses.

The World Organization for Animal Health, Office of International Epizootics (OIE)[2] is an international organization, representing more than 167 member countries, that seeks to provide leadership and guidelines to ensure transparency and solidarity in the management of the global animal disease situation. The OIE publishes health standards for international trade in animals and animal products as well as criteria for the validation and certification of diagnostic assays. Policies and procedures that the federal government implements to manage the intrusion of TADs into the United States are often aligned with the OIE health standards and guidelines to help ensure the most rapid and efficient recovery of U.S. exports. Another equally important function of the OIE is to provide an early warning system to enable countries to have rapid situational awareness and to act quickly to protect themselves when outbreaks of OIE-reportable diseases are confirmed in member countries. More than 130 animal diseases are reportable to the OIE. It is important to remember that some of the domestic diseases that are present in the United States, such as bluetongue, are reportable to the OIE and have implications on U.S. trade with countries that are free of those diseases.

To protect the long-term overall health and viability of U.S. animal agriculture, any incursion of a TAD must be rapidly identified and controlled. In the United States, ideally control of an outbreak of a TAD leads to the complete eradication of the disease and return to pre-outbreak disease status. These TAD eradication efforts present significant short-term costs to affected industries as well as the government and the public. In some cases these effects become long term, lasting for years, and industries may never fully recover. Most TAD incursions have a significant economic cost associated with disease control and the eradication efforts. The costs associated with TAD control include the direct costs of disease control as well as the potential loss of foreign trade and the indirect costs to the affected industries that result from the implemented control measures, such as livestock movement restrictions and biosecurity. Direct costs to the government include personnel costs, indemnity costs (cost to buy diseased animals from producers for destruction), and the cost of necessary supplies and equipment for euthanasia, carcass management, and disinfection. In addition to these direct control costs, one of the most immediate consequences of a TAD occurrence in the United States would be the loss of export markets and disruption of normal industry business continuity in the United States. The indirect costs to the affected livestock sectors and other affected industries that would result from the disruption of the normal business continuity are likely to be the most significant economic costs. One example of an indirect cost or loss associated with disease control may be the reduction or loss of income for a dairyman who is no longer able to ship his raw milk across state lines to his customary milk processor. For all TADs, early detection and rapid application of situational awareness to assess the extent of the outbreak, followed by efficient implementation of necessary controls to minimize further spread, will minimize the overall impact of the outbreak on the

U.S. Department of Agriculture (USDA) Accreditation Requirements

- Graduate from an AVMA-accredited school.
- Complete an initial accreditation training and attend a core orientation program.
- Complete a state-specific orientation.
- Submit accreditation application to the appropriate USDA Veterinary Services office.
- Be licensed and accredited in each state in which you plan to perform official work.

BOX 47-4

Standards for Accredited Veterinarians (9 Code of Federal Regulations, 161.3)

- Immediately report program diseases.
- Know current regulations.
- Perform activities according to regulations.
- Accurately complete all forms.
- Personally inspect all animals.
- Properly identify reactors.
- Maintain proper biosecurity.
- Use regulated materials according to the regulations.
- Maintain security of official tags, forms, and certificates.

affected producers, the affected industries, and the U.S. economy as a whole.

The risk of a TAD incursion into the United States today is much greater than it has been in the past, for two main reasons. First, there has been a rapid expansion of international trade and travel. With a greater volume of people, animals, and animal products entering the United States on a daily basis, the opportunity for a TAD to be unintentionally introduced is much higher than it has been in the past. Second, in the wake of the terrorist attacks in the United States on September 11, 2001, there is heightened awareness and concern about the possibility of agroterrorism, or the deliberate introduction of a biologic agent targeting livestock for the purposes of inflicting economic damage and societal instability in the United States. Whether a TAD is intentionally or unintentionally introduced, the detection of the first case as soon as possible is critical to minimizing the overall impact of the resulting outbreak.

Private veterinary professionals need to be familiar with the clinical signs associated with TADs, especially those that can be easily confused with clinical signs of domestic or endemic diseases. When veterinary professionals are concerned about the possibility of a TAD in clients' animals, they need to contact a federal or state animal health official, who will consult with them on the history of the herd or flock and then may examine the affected animals and take and submit necessary samples for testing at no expense to the producer or veterinarian. Testing will be prioritized by disease and level of concern after understanding the history and clinical status of the livestock of concern. Both the livestock producer and private veterinarian should be contacted with regular updates as test results become available. Several hundreds of investigations such as these occur annually in the United States, and fortunately most lead to the determination that a TAD is not involved. It is the TAD that goes undetected or unreported for some time because of lack of vigilance or reluctance to report that will cause major economic harm to the livestock industry and the nation. Veterinary practitioners should not be concerned about reporting a suspected TAD and having it turn out to be a domestic disease problem, since it is important that the animal disease emergency response system be tested regularly to ensure that it is as efficient and effective as possible. Most importantly, the impact of a delay in detection of a true TAD could be catastrophic.

U.S. Department of Agriculture National Veterinary Accreditation Program[3]

The USDA established the national veterinary accreditation program in 1907 to provide a mechanism to enable private veterinary practitioners to work on behalf of the federal government to certify animals for certain types of interstate and international movement and to assist in controlling damaging animal diseases. The current mission of the National Veterinary Accreditation Program (NVAP) is to ensure the health of the nation's livestock and animal population and to protect public health and well-being. NVAP's goal is to maintain the effective cooperation and use of private veterinary practitioners for regulatory work in a manner that is consistent with international trade requirements and enables the safeguarding of animal health. APHIS VS administers the NVAP. Participation in NVAP is voluntary and is not mandated by the federal government. Box 47-3 provides a list of the requirements for a veterinarian wishing to become accredited by the USDA. Accredited veterinarians participating in NVAP must carry out their duties according to the Standards for Accredited Veterinarian Duties described in CFR Title 9, Part 161. Box 47-4 lists the standards for accredited veterinarians. USDA veterinary accreditation is specific to a given state, so one needs to contact the USDA APHIS VS office in the state where he or she is practicing to obtain accreditation in that specific state. requirement of USDA VS for accredited veterinarians is reporting of all suspected TADs to state or federal animal health officials for evaluation and any necessary testing. Box 47-5 lists some of the clinical signs that should alert a private veterinarian that a TAD should be considered.

Accredited veterinarians are the backbone of U.S. regulatory programs for livestock and poultry diseases in the United States. The responsibilities of an accredited veterinarian are extraordinary. In fact, the United States depends extensively on accredited veterinarians for many official functions (e.g., inspecting, testing, and certifying animals trade). Livestock producers who ship animals domestically or export animals internationally rely on the expertise of accredited veterinarians to help ensure that exported animals meet the requirements of the receiving location and will not introduce diseases into the receiving state or country. The accreditation program has served the animal industry well for many years and remains integral to its continued growth. There are currently more than 60,000 active accredited veterinarians in the national database, and these accredited veterinarians are instrumental in providing national capability to perform competent health certifications and to maintain extensive disease surveillance and monitoring. Today, more than 80% of all U.S. veterinarians are accredited and work cooperatively with federal and state animal health officials in NVAP.

The accreditation process has changed dramatically over the years. In the 1980s and early 1990s, veterinarians were required to pass a written examination, but currently accreditation requires completion of an initial accreditation training and then attendance at a core orientation program in addition to meeting the other requirements listed in Box 47-4. In 2006, APHIS proposed two different categories or levels of accreditation. Category I includes all animals except food and fiber species, horses, birds, farm-raised aquatic animals, all other livestock species, and zoo animals that can transmit exotic animal diseases to livestock. Category II is for all animals. At the same time APHIS published a proposal to amend the regulations in the Federal Register, which added requirements for supplemental training and renewal of accreditation for both categories every 3 years. Details of the renewal process can be found at the USDA APHIS VS accreditation website (http://www.aphis.usda.gov).[3]

Overview of Foreign Animal Disease Investigation and Response

Protecting the nation's livestock and poultry industries, and therefore a large segment of the U.S. agricultural economy from TADs, involves four basic principles or phases of emergency management: prevention, preparedness, response, and recovery. To be effectively executed, these phases require preplanning, cooperation, and communication among individuals, groups, and organizations at the local, state, regional, and national levels. Livestock and poultry owners; veterinarians in private clinical practice; industry groups; federal, state, and local governments; universities; veterinary diagnostic laboratories; and the consideration of public opinion and perception must all be included in emergency response preparation and planning. A response to a TAD outbreak will be carried out in accordance with the guidelines established by the National Response Plan (NRP) and using the National Incident Management System (NIMS) and the incident Command System (ICS). Veterinarians who are interested in participating in either TAD emergency response or animal disaster response efforts, either as temporary employees or volunteers, must be familiar with these systems before an event occurs, in order to be effectively integrated into the response effort. There are both online and classroom-based training programs offered by federal, state, and local emergency response agencies to provide basic ICS training and certification. The Federal Emergency Management Agency (FEMA) offers several Web-based, self-paced courses.[4]

Although the details of the clinical signs and epidemiology of the TADs themselves are discussed in detail in other sections of this book, many additional references and resources are available to practicing veterinarians to help them keep apprised of the clinical presentation and importance of these diseases as well as to whom to report suspected cases. Two excellent references for disease-specific information are *Foreign Animal Diseases: "The Gray Book,"* revised in 2008[5] (available at http://www.usaha.org/Portals/6/Publications/FAD.pdf), and the website of the Center for Food Security and Public Health of Iowa State University,[6] http://www.cfsph.iastate.edu.

Prevention and Preparedness

Early recognition of a TAD may be difficult because many domestic diseases seen by veterinarians on a more routine basis have clinical signs or presentations similar to those of a TAD (e.g., foot-and-mouth disease [FMD]) and because some TADs may have mild clinical signs that could allow it to spread undetected for a period of time (e.g., low pathogenic form of classical swine fever [CSF]). Examples of both domestic and transboundary vesicular or ulcerative diseases, which may be difficult to distinguish clinically in cattle, are presented in Box 47-6. A similar list for small ruminants is provided in Box 47-7. The increased likelihood and severe consequences of an introduction of a TAD into the United States requires private

VetBooks.ir

veterinarians to be continually vigilant for unusual emerging animal health conditions or situations. To be best prepared to identify these uncommon disease conditions, veterinary practitioners must understand how they may manifest and what clinical signs they may possess. Participation in continuing education programs aimed at increasing awareness of the clinical signs and presentations of TADs can facilitate this necessary awareness. Education and awareness should also be extended to livestock producers and their employees who will likely be the first individuals to recognize an unusual problem in the herd or flock they work daily.

An important component of the prevention programs for TAD incursions in the United States is the implementation by APHIS VS of policies and procedures related to the importation of live animal species or products into the United States. These import rules vary by animal and product, as well as by country of origin. APHIS VS monitors the OIE reports of the world animal health status and continually updates these importation requirements accordingly. These requirements may dictate the quarantine and possible testing of specified animal species for specific periods before animals are allowed to enter the United States. As of 2012, there were three animal import centers, located in New York, Miami, and Los Angeles, through which animals could enter the country legally. Illegal importation of such animals and animal products via other channels poses a significant risk to U.S. agriculture. APHIS port veterinarians are responsible for the examination of the animals, their identification, and evaluation of health certificates and permits for accuracy at the importation stations. If the requirements are not met or the animals are found to be diseased, the animals are refused entry. Once it has been determined that an animal is healthy, all the test results are negative, and all the requirements have been met, then the animal can be released to its owner and the state of destination is notified of the animal's movement into that state.

Detection

Although historically, border controls and import procedures have been largely effective in keeping TADs out of the United States, there is always the possibility that a TAD could appear in the United States by either unintentional or intentional means. The responsibility for rapidly detecting, confirming, and effectively responding to incursions of TADs is primarily that of APHIS VS in cooperation with livestock and poultry owners, veterinarians in private clinical practice, and state animal health officials. An additional challenge for early detection of TADs is that very few ongoing active surveillance programs exist that routinely test for TADs in targeted, high-risk livestock populations or in conjunction with screening for clinically indistinguishable domestic diseases in state or regional animal diagnostic laboratories. Because many of the TADs can mimic domestic diseases, a TAD may not be properly identified for some time if the condition is believed to be a domestic disease problem and if it is investigated with only that limited differential in mind. Even a single day's delay in identifying a TAD can result in significantly greater disease spread or economic impact owing to the large amount of livestock movement that occurs in the United States on a daily basis. Prompt reporting, investigation, and diagnosis can prevent a TAD from spreading further, can reduce the overall economic impact of the event, and can reduce the likelihood that the disease may become endemic in a wildlife or arthropod reservoir.

The most likely person to initially suspect a TAD is the producer or private veterinarian called by the producer to investigate an unusual disease condition. It is critical that any time a TAD is suspected, it is reported to state or federal animal health officials for expedited investigation and testing as necessary. The state animal health official, usually the "state veterinarian," and federal veterinarians working for USDA APHIS VS routinely work to increase awareness of such conditions and reporting information among the state's private veterinarians and livestock producers. These activities require the support and assistance of state and university veterinary diagnostic laboratories, the Cooperative Extension Service, state and federal meat and poultry inspection services, universities, animal scientists, market operators, livestock and poultry producers, and private veterinarians.

For TAD outbreaks to be detected quickly, any suspicious signs or situations indicative of a TAD must be promptly reported to a state veterinarian, a USDA VS federal veterinarian, or both so that a TAD can be confirmed or ruled out. Private veterinarians are knowledgeable regarding the occurrence of various domestic animal diseases in their practice area and the history of such diseases on their clients' farms and ranches. This type of historical information and a herd's vaccination and animal movement history are critical to assessing the likelihood of a suspected TAD. Working with the herd veterinarian and the producer, the investigating state or federal, specially trained, foreign animal disease diagnostician (FADD) will use the herd history and clinical investigation to assess the likelihood that the situation involves a TAD and to determine the appropriate sample(s) to collect, the method of sample delivery, and what precautions must be taken at the site while test results are pending. Samples are submitted to the National Veterinary Services Laboratories (NVSL) in Ames, Iowa, or to the Foreign Animal Disease Diagnostic Laboratory (FADDL) at Plum Island, New York, to confirm the presence or absence of a TAD. On the basis of initial TAD investigation findings, often before the laboratory has completed testing of the samples, state and federal officials in the affected state may take action to quarantine affected animals at the site of the suspected case, increase surveillance in the area, and initiate steps to gather further information to assess the situation and characterize and control the outbreak if necessary.

An improvement to TAD testing options in the United States at laboratories who are members of the National Animal Health Laboratory Network (NAHLN) is that under USDA directive 580.4, select laboratories have been trained and proficiency-tested to run tests for TADs, with the permission of the NVSL director, the state animal health official, the USDA area veterinarian in charge and USDA VS may run designated tests in parallel with NVSL or FADDL. When approved, this parallel testing process can provide more timely "preliminary" results, which may facilitate local decision making. At present assays for FMD, CSF, HPAI, and END have been successfully transitioned to some NAHLN laboratories for use in national surveillance programs.

Other diagnostic tools that may be available in the near future include deeply multiplexed nucleic acid, antibody, or protein assays that could allow the simultaneous screening for many disease agents (domestic and TADs) in one reaction at a reduced cost per agent. Although these types of assays are still undergoing development and validation in the veterinary community, similar assays are in use as part of the BioWatch program, a human biothreat agent surveillance system operated by the Centers for Disease Control and Prevention in Atlanta, Georgia. Once validated and accepted as useful components of national TAD surveillance programs, such assays could become useful components of targeted surveillance programs in the United States.

Response, Management, and Control

A TAD response will be conducted according to the guidelines set forth in the NRP. This response plan incorporates best practices and procedures from various emergency management disciplines and integrates them into a unified structure that forms the basis of how the federal government coordinates with state, tribal, and local governments and the private sector during all national response incidents, including animal disease outbreaks. Under the NRP, the USDA is the lead agency coordinating the protection of agriculture and natural resources. All national responses are conducted in accordance with NIMS, which established a national emergency response framework to allow local, state, tribal, and federal agencies to more efficiently and quickly work together in an emergency. The NIMS uses the ICS to organize the response. The ICS is designed to be expandable and to meet the needs associated with incidents of all

VetBooks.ir

sizes, to allow individuals from a variety of agencies to meld more efficiently into a common management structure, to be cost-effective by reducing duplication of effort, and to provide needed logistic, administrative, and operational staff. There are five main management functions in the ICS: incident command, operations, planning, logistics, and finance and administration. Most veterinarians work in the operations or planning sections during a TAD response. The operations section is where the bulk of the tactical field work is conducted, such as diagnosis, surveillance, and depopulation.

Once a TAD has been confirmed by the USDA, the notification and coordination process for all involved parties begins. This includes federal, state, international, local, industrial, and public stakeholders. Conference calls, electronic notification, and press conferences may be used to communicate key messages. In addition, if agroterrorism is suspected, the Federal Bureau of Investigation and the Department of Homeland Security will be involved in the response efforts. If a zoonotic disease is suspected, the state and federal public health departments will also become involved. Federal officials will notify the OIE of the situation so that the international communities will be made aware of the change in the nation's animal health status. Throughout the response, the goal will be to maintain accurate, timely communications regarding the status and progress of the eradication efforts.

Once the diagnosis of the initial case is confirmed, there is still much information to be gathered to determine the true magnitude and extent of the situation. The species affected, history of the diseased herd or flock (including recent animal movements), and stage of disease in the affected animals will provide valuable information regarding the likely extent of disease. Outbreaks can be large or small, simple or complex, and localized or widespread. Timely development of situational awareness will be critical for mobilizing the necessary resources to effectively respond to the situation.

Tactical measures or procedures used to control an outbreak may include quarantine and/or animal movement restrictions; biosecurity; epidemiologic investigations; surveillance for disease in surrounding areas; vaccination, euthanasia, or treatment of affected animals; carcass disposal; disinfection; vector control; and education campaigns. The exact approach to control will vary by disease, affected region, and extent of the outbreak. In many cases federal and state veterinarian resources will be sufficient to respond to and control the situation quickly. However, if the outbreak is large or widespread, it may require the use of additional personnel resources.

When APHIS VS requires temporary personnel to assist with disease eradication, it uses the National Animal Health Emergency Response Corps (NAHERC),[7] a roster of preregistered private veterinarians and animal health technicians, to assist with the control efforts. Private veterinarians may be enlisted to examine herds or flocks for clinical disease, vaccinate animals, collect laboratory samples, perform necropsies, collect epidemiologic data, and euthanize infected animals. During the United Kingdom's (UK) 2001 FMD epidemic, many private veterinarians found that their practices had little business because their clients stopped using routine services as a precaution to reduce the chances that their farms would become infected. In other situations, veterinarians found that their clients' farms were lost (eliminated) as a result of disease control efforts. In many cases these private veterinarians joined the UK FMD task force as temporary veterinary inspectors (TVIs) working on behalf of the British government to assist in the control of the epidemic. Veterinarians in the United States who may be interested in registering for NAHERC should contact their state USDA APHIS VS office or go to the NAHERC website for details (http://www.aphis.usda.gov/animal_health/emergency_management/naherc.shtml).

Recovery

The goal of a recovery process is to return the nation to a status equal to or better than what existed before a TAD outbreak. Full recovery can be a long and arduous process. Recovery activities include payment for animals and materials destroyed for disease control purposes, successful decontamination, clean-up and restocking of affected premises, renegotiation and reestablishment of international trading status, and government and industry's reassurance to the consumers and the public that the outbreak has been managed successfully. The OIE's international animal health code sets the minimum standards that guide when a country may recover its disease-free status. The OIE standards, which are a key component to the resumption of international trade, serve to reassure the international community that trading with a previously affected country is now safe.

The ultimate cost of an outbreak for a country, its producers, affected industries, and the public can be quite high. Many of the costs beyond those to the directly affected industries can be significant yet difficult to quantify.

The Future of Foreign Animal Disease Detection and Response

A comprehensive review of the national framework for addressing animal diseases was conducted by a committee assembled by the National Academies and published in 2005.[8] The committee's findings and recommendations support the compelling need for significant changes to create a new future for animal health in the United States. Some of the key findings included the need for new tools for detection, diagnosis, and risk analysis and the expansion of the NAHLN's capabilities for both routine and emergency diagnostics. The committee called for the colleges of veterinary medicine to lead an effort to develop a national animal health education plan to educate and train individuals from all sectors in disease prevention and early detection and to recruit veterinary students into careers in public health, food systems, biomedical research, diagnostic laboratory investigation, pathology, epidemiology, ecosystem health, and food-animal practice. Since animal health has broad implications, ranging from the health of individual animals and the well-being of human communities to issues of global security and the adequacy of the global food supply, there is significant need to plan carefully for the future. The committee concluded that given the changing nature of the risks to animal health in this country, it is unlikely that the current philosophy on how to protect animal health will be adequate in the future.

Extraordinary changes including continued globalization will continue to present new threats to U.S. agriculture and necessitate the continued vigilance of the veterinary and agricultural communities. Although state and federal governments are working to provide more targeted, active surveillance programs, private veterinary practitioners, who on a daily basis provide health care to the national herd, will remain the core of the nation's early warning system for TAD surveillance. Therefore, their awareness of TADs and willingness to serve in the critical role of being part of the nation's early warning system for TADs will continue to be a cornerstone of national defense against the intrusion and the devastating impact of such diseases.

Current Concepts in Equine Vaccination and Infectious Disease Control

W. David Wilson and Nicola Pusterla, *Consulting Editors*

General Considerations

Programs for controlling infectious diseases are important components of management practices directed toward maximizing the health, productivity, and performance of horses.[1] Infectious disease in an individual horse or outbreaks of infection in a group occurs when horses experience challenge with an infectious agent at a dose sufficient to overcome resistance acquired through previous natural exposure to the disease or through vaccination. For this reason, programs for controlling infectious diseases should have the following three goals:

1. To reduce exposure to infectious agents in the horses' environment
2. To minimize factors which diminish resistance
3. To enhance resistance through the use of vaccines (vaccination alone cannot be expected to prevent disease; management practices must reduce challenge with infectious pathogens)

The incidence of infectious disease in horse populations tends to rise with an increased number and stocking density of susceptible horses at a facility, with movement of horses on and off the facility, and with favorable external environmental and management influences. Other factors that influence the risk of acquiring infection and developing disease include the age, type, breed, gender, and use of the animals; geographic, climatic, and other environmental factors; facilities' layout and management practices; and history of exposure to or vaccination against individual diseases.

The conditions on breeding farms, in performance and show horse barns, and at racetracks are ideal for introduction and transmission of infectious diseases, particularly those of the respiratory tract. On breeding farms, the introduction and commingling of horses of various ages and origins and the high proportion of young susceptible horses and pregnant mares create a situation that poses special problems and demonstrates some important considerations in the practice of disease control. The risk of acquiring infection can be reduced by maintaining distinct groups by age and function. Resident mares and foals should be kept separate from weanlings, yearlings, horses in training, and visiting mares. Visiting mares and other horses entering the farm should have a negative test result for equine infectious anemia (EIA), either by ELISA or the Coggins AGID test, and should be appropriately vaccinated and dewormed before arrival. They should be received and maintained in barns and paddocks separate from the resident farm population. Preferably, a specific group of caretakers should attend to incoming horses, and footbaths, separate equipment, and a clean change of coveralls and boots should be used.

New arrivals should be quarantined for 30 days and monitored for signs of contagious disease. The rectal temperature should be recorded at least once daily, and any prophylactic procedures not done before arrival should be performed. Foaling mares being sent to a distant breeding farm for breeding should be transported 6 to 8 weeks before foaling; this permits timely exposure to resident pathogens at the destination farm, which allows the mare's immune system to mount a response and concentrate antibodies in the colostrum to improve passive protection of the foal. Mares being shipped short distances for breeding can be transported during estrus and returned to the farm on the same day to reduce the risk of the foal acquiring infection.

Regardless of the type of equine facility, any horse that becomes ill with a possibly contagious disease should be isolated, preferably in an air space separate from the remainder of the herd, for at least 10 days beyond complete abatement of clinical signs. Separate equipment should be used, and if a separate group of caretakers is unavailable for these animals, workers should always complete their work with healthy horses before handling sick horses. Caretakers should wash their hands and boots thoroughly between horses and wear different outer clothing or coveralls. Stalls that have housed sick horses should be cleaned thoroughly, disinfected, allowed to dry, and left empty as long as possible. This approach is particularly important in dealing with organisms such as *Streptococcus equi* that can survive in a protected moist environment for several weeks.[2]

In most equine enterprises, vaccination is important to the overall management program for controlling infectious diseases. No "standard" vaccination program can be recommended for all horses; each situation must be evaluated individually by weighing the risk of acquiring infection and the medical and economic consequences of infection against the cost and expected efficacy of the product or products being considered for inclusion in the program, and their potential for inducing adverse reactions. Cost should include expenses incurred and money lost during the time the horses are out of competition, labor and medication expenses if the animals develop clinical disease and require treatment, and the expenses in time, labor, and vaccines required for proper immunization. The client's expectations should be realistic, and the veterinarian should explain the following points carefully:

VetBooks.ir

- Vaccination minimizes the risk of infection but does not prevent disease in all circumstances.
- The primary series of vaccines and booster doses should be administered appropriately before likely exposure.
- Horses in a population are not all protected equally nor for an equal duration after vaccination.
- Whenever possible, all horses in a herd should be vaccinated on the same schedule; this simplifies record keeping, minimizes replication and transmission of infectious agents in the herd, and optimizes herd immunity by protecting those animals that responded poorly to vaccination.

A properly administered licensed product should not be assumed to provide absolute effective protection during any given field epidemic. Copies of the vaccination and health maintenance records should accompany each horse leaving the facility for sales, training, or breeding. Similarly, owners of equine facilities should establish prerequisites for vaccination of all horses entering the facility and request that copies of the vaccination records accompany those horses.

Client expectations and the goals of disease control programs vary considerably. In performance horses, the goal generally is to minimize time spent out of training and thereby maximize earning potential. In this case, an enforced period of rest owing to infectious disease has much more profound economic consequences than a similar recommendation for a barren broodmare or backyard horse. On the other hand, many owners of backyard horses diligently vaccinate against even low-risk diseases, despite the expense involved, to keep their horses healthy.

Only federally licensed vaccines should be used, and strict attention must be paid to the manufacturer's recommendations for storage, handling, and routes of administration to maximize the product's efficacy and safety. However, research or clinical experience may support alternate protocols for vaccination that will improve the vaccine's efficacy without increasing adverse effects. The length of time necessary to induce a protective immune response should be considered in relation to expected exposure. When inactivated (killed) vaccines are administered by intramuscular (IM) injection, for example, optimal protection is generally not achieved until 2 to 3 weeks after completion of the primary series, or 1 or more weeks after administration of a booster dose. Inactivated vaccines administered IM generally induce a greater serologic response when an initial series of 3 doses is given rather than the 2-dose series recommended by most vaccine manufacturers. Whereas a 3- to 4-week interval between the first and second doses of vaccine is generally appropriate, a longer interval of 3 to 5 months between the second and third doses appears to optimize priming of the immune system and protection.

The primary role of authorities charged with licensing vaccines in North America has traditionally been to ensure vaccine purity and safety, with less emphasis placed on documentation of efficacy.[3-5] Consequently, little published information was available in the past documenting the efficacy of most vaccines licensed in North America. The situation has improved substantially in recent years, to the extent that published efficacy data are available for almost all equine vaccines licensed in North America since 1999. Field experience and some experimental evidence suggest that the efficacy of vaccines directed against different diseases varies considerably and that efficacy also varies among the vaccines from different manufacturers directed against the same disease.[6-8]

Vaccination is unlikely to confer protection more durable than that produced by recovery from natural disease, especially when the route of vaccination (usually IM) is different from the route of natural infection; this is because vaccines frequently do not evoke the full array of protective immune responses induced by natural infection.[9,10] For example, the efficacy and durability of protection induced by parenteral vaccines against respiratory tract pathogens are frequently questioned.[4,5,10] In part this reflects the fact that parenterally administered vaccines are generally poor inducers of the local mucosal immune responses that are important for effective protection against infection of the respiratory tract.[4,9,10] In addition, immunity achieved after natural infection with some respiratory tract pathogens is short lived.

Considerations for Use of Vaccines in Broodmares

The primary goals of vaccination programs for broodmares are (1) prevention of diseases that pose a risk to the mare or her fetus, and (2) maximizing the level of colostral antibodies that will be passively absorbed by the neonatal foal after nursing, thus providing it with protection against diseases that pose a risk during the first few months of life. Additional considerations in selecting vaccines for use in pregnant mares include (3) safety to the mare and fetus, (4) the potential for interference between multiple vaccines administered simultaneously, and (5) the influence of pregnancy on vaccine responses.

PROTECTING THE MARE AGAINST DISEASES THAT POSE A RISK TO THE MARE OR HER FETUS. Broodmares are at risk of exposure to the same diseases as performance and pleasure horses, so they should be regularly vaccinated against all core and specific risk-based diseases according to published recommendations. The high horse traffic and high concentration of foals and young horses that typify many breeding farms contribute to a high risk of exposure to contagious respiratory diseases, including equine herpesvirus (EHV)-4, EHV-1, influenza, and strangles. Inclusion of influenza in vaccination protocols for broodmares is routinely recommended, and addition of EHV-4 and strangles vaccines is frequently recommended when conditions of significant risk are anticipated. Vaccination of mares against equine viral arteritis (EVA) before breeding may be indicated when they are to be bred to a known or suspected EVA carrier stallion, either by natural cover or by artificial insemination. Whereas protection of the broodmare, fetus, or herdmates against the abortifacient effects of EHV-1 or EVA is the primary goal underlying inclusion of these antigens in vaccination protocols for broodmares, the goal of protecting the foal features at least as prominently in the rationale for vaccinating mares against tetanus, West Nile virus (WNV), eastern equine encephalitis (EEE), western equine encephalitis (WEE), rabies, influenza, EHV-4, and strangles. Inclusion of rotavirus and botulism vaccines in protocols for pregnant mares is directed almost exclusively at protecting the young foal against these diseases.

MAXIMIZING MATERNALLY DERIVED ANTIBODY TRANSFER. Maintaining consistent broodmare vaccination protocols, which typically include administration of booster doses of vaccines during the last 2 months of gestation, will not only protect the mare but also maximize the likelihood that a uniformly high level of maternally derived antibody (MDA) transfer and passive protection will be achieved within the foal crop. This is particularly important for diseases that pose a risk to the foal during the first few weeks of life. Whereas intranasally administered vaccines may afford good protection to the mare, they are typically less effective than parenterally administered inactivated vaccines in stimulating high levels of circulating immunoglobulin (Ig)G, the isotype that is passively transferred to the foal in highest concentration. Parenterally administered vaccines are preferred over intranasally administered vaccines for vaccination of mares during late gestation.

VACCINE SAFETY IN BROODMARES. Consideration of vaccine safety in broodmares must take into account risks to the pregnancy and safety to the fetus. Potential adverse effects of vaccines on pregnancy are difficult to document even when large numbers of mares are used, unless obvious problems occur. Because fetal organogenesis occurs early in gestation, and this period is also characterized by substantial embryonic loss, even in normal mares it is sound practice to avoid administering vaccines to mares during the first 60 days of gestation unless conditions of imminent risk prevail. Few vaccines carry specific label recommendations for use in pregnant mares and little published data exists to specifically document the safety of equine vaccines during pregnancy. Licensed vaccines that carry label

VetBooks.ir

recommendations for use in pregnant mares include two inactivated EHV-1 vaccines (Pneumabort-K+1b [Zoetis] and Prodigy [Merck Animal Health]) marketed for use in pregnant mares as an aid in prevention of EHV-1 abortion, the Calvenza line of inactivated influenza (Calvenza-03 EIV [equine influenza virus]), EHV-1 (Calvenza EHV), and influenza/EHV-1 combination (Calvenza-03 EIV/EHV) vaccines from Boehringer Ingelheim, one inactivated Potomac horse fever vaccine (Equine Potomavac [Merial]), and one vaccine licensed for prevention of type B botulism in foals (BotVaxB [Neogen]). One conditionally licensed vaccine (Equine Rotavirus Vaccine [Zoetis]) for prevention of rotavirus infection in foals is labeled for use in pregnant mares. While not specifically labeled for administration during pregnancy, widespread use in practice over many years has failed to document that any of the inactivated vaccines currently marketed for use in horses pose an unacceptable risk to pregnant mares. Therefore, pregnant mares are routinely vaccinated with inactivated vaccines directed against tetanus, EEE, WEE, WNV, influenza, EHV-4, strangles and, to a lesser extent, Potomac horse fever (PHF), rabies, and Venezuelan equine encephalitis (VEE). Similarly, adverse impacts on pregnancy have not been documented for modified live intranasally administered strangles (Pinnacle I.N. [Zoetis]) and influenza (Flu-Avert [Merck Animal Health]) vaccines or the modified live parenterally administered EHV-1 vaccine (Rhinomune [Boehringer Ingelheim]). Safety of the recombinant WNV and influenza vaccines (Recombitek [Merial]) should not be a significant concern because the modified live canarypox vector lacks the ability to infect mammalian cells. In addition, the equivalent canarypox-vectored influenza vaccine (ProteqFlu [Merial]) marketed in the United Kingdom is labeled for use during pregnancy. Although the *Flavivirus* chimera WNV vaccine (PreveNile [Merck Animal Health]) was not specifically labeled for use during pregnancy while it was on the market, more than 300 pregnant mares were vaccinated during safety trials for licensing, without apparent adverse effects on the conceptus. In contrast, modified live virus (MLV) VEE vaccines and live anthrax spore vaccines should not be used in pregnant mares. Protection of mares against the potential abortigenic effects of EVA infection is best accomplished by completing the primary immunization series before the mare enters the broodmare band and by administering subsequent boosters during the open period before rebreeding.[11]

The practice of booster vaccinating mares against multiple diseases to maximize colostral transfer of antibodies to the foal results in the typical broodmare receiving multiple doses of many vaccine antigens and adjuvants during her lifetime. In addition to stimulating high levels of antibody against a range of antigens, this practice may also predispose these mares to a higher rate of local and systemic adverse reactions, an issue that not only warrants further investigation but may force horse owners and veterinarians to carefully consider strategies for revaccination.

POTENTIAL INTERFERENCE BETWEEN MULTIPLE ANTIGENS ADMINISTERED CONCURRENTLY. The possibility that "competition" between multiple antigens will compromise the response to some or all of the administered antigens should be considered. When administration of multiple vaccines late in gestation is indicated, it is good practice to administer no more than 4 antigens at one time and to allow an interval of 3 to 4 weeks between administering different vaccines.

INFLUENCE OF PREGNANCY ON VACCINE RESPONSES. It is widely assumed that pregnant mares are fully capable of mounting appropriate cellular and humoral immune responses to vaccines, but this issue has received little research attention. Mares that have been primed before breeding appear to mount appropriate anamnestic responses to vaccines, but preliminary data suggest that the humoral response to primary vaccination with several inactivated vaccines, including West Nile Virus and rabies, may be downregulated during gestation, resulting in failure of some vaccinated mares to passively transfer specific antibodies to the foal via colostrum.

Vaccination of Foals and Influence of Maternal Antibodies on Vaccine Responses

Maternally derived antibodies (MDAs) and perhaps other immune effectors (e.g., lymphocytes) that are concentrated in colostrum and are passively transferred to the foal play a crucial role in defense against pathogens encountered during the first few months of life while endogenous immune function continues to mature. Passive transfer of MDAs should therefore be exploited in immunization programs for foals by consistently administering booster doses of selected vaccines to mares 4 to 8 weeks before foaling and by ensuring that foals ingest adequate amounts of high-quality colostrum within 24 hours of birth. Besides passively protecting the foal, MDAs may also exert a profound inhibitory effect on the active immune response of the foal to antigens, including those contained in vaccines. This phenomenon is known as *maternal antibody interference*.

Several studies reported during the 1990s brought this issue into focus by demonstrating that foals younger than 6 months of age consistently failed to mount serologic responses to inactivated influenza vaccines.[12-18] Of potentially greater concern was the finding that a high proportion of foals vaccinated under the cover of MDAs not only failed to seroconvert in response to the recommended primary series of two or three doses of influenza vaccine, but many also failed to respond to multiple additional doses administered during the next year, suggesting induction of a potentially detrimental immunotolerance-like phenomenon.[15,16,19] Our studies confirmed an apparent lack of response of foals to multiple doses of inactivated influenza vaccines when the hemagglutination inhibition (HI) test was used to detect serologic responses, but responses were detected when the same samples were assayed using sensitive isotype-specific enzyme-linked immunosorbent assay (ELISA). Rather than representing true tolerance, it appears MDAs may cause misdirection of the immune response away from the more important virus neutralizing IgGa and IgGb subisotypes in favor of the less effective IgG(T) sub-isotype of IgG.[12] Subsequent studies in which titers of total rather than antigen-specific IgG subisotypes were determined documented that the age-related increase in concentrations of IgGb lagged significantly behind increases in concentrations of other isotypes and remained below adult levels beyond 6 months of age.[20]

Maternal antibody interference has now been documented to be a significant issue for many other antigens, including tetanus, EEE, WEE, EHV types 1 and 4, contained in vaccines administered to foals.[12,21-25] Even low levels of antibody below those detectable by many routine serologic tests and below those thought to be protective can completely block the serologic response to some vaccines, resulting in a potentially prolonged period of susceptibility before the foal is capable of responding appropriately to vaccines.[24] These findings also indicate that it is not typically feasible to serologically test samples from foals to predict whether they will respond to particular vaccines. We now recommend that primary immunization with most vaccines containing inactivated antigens should be delayed until foals are 6 months of age or older, and with the exception of rabies vaccine, three doses of vaccine should be included in the primary series rather the two doses routinely recommended by vaccine manufacturers. Typically, the third dose stimulates a serologic response of greater magnitude and durability than two doses and may also contribute to a higher "set-point" for the response to subsequent booster doses.[12,24,26,27] In contrast to the results cited, maternal antibodies do not appear to exert a marked inhibitory effect on the immune response of foals to the inactivated, live recombinant, live chimera, or DNA West Nile virus vaccines, thereby permitting antibody-positive foals as young as 3 months of age to be immunized successfully.[26,28,29] Similarly, the canarypox-vectored recombinant influenza vaccine has been shown to efficiently prime foals in the presence of MDA.[30]

Study results should be interpreted with caution because only humoral responses are typically assessed in MDA interference studies, and infectious challenge is not performed to confirm that lack of serologic response equates to lack of protection. Lack of a serologic response may correlate well with lack of protection for some

VetBooks.ir

diseases and some vaccines, whereas for others this may not be the case. In contrast, the presence of a serologic response may not correlate well with protection, as is frequently the case for respiratory tract pathogens. Because many commercially available vaccines are inactivated, adjuvanted, and administered by IM injection, they have limited potential to stimulate cellular and mucosal responses, so serologic responses induced by these vaccines likely correlate well with their potential to induce protection. In turn, MDA interference with serologic responses to inactivated vaccines likely equates to failure to induce protection. In contrast, failure to detect a serologic response to a modified live, vectored, DNA, or mucosally administered vaccine may not equate to lack of protection, because vaccines of these types induce a broader array of systemic and local responses that may not be affected by MDAs.

If MDA interference were not an issue, the approach to vaccination of foals would be greatly simplified because primary vaccination against all of the important diseases could be completed before MDAs had declined to non-protective levels. In effect, the "window of susceptibility" would be eliminated. In reality, an attainable goal is to maximize the beneficial effects of MDAs while minimizing their negative impact on primary immunization. To best meet this goal it is necessary to decide which one (or both) of the following is the primary focus: (1) to protect the foal and weanling against specific high-risk infectious diseases that affect this age group and have the potential to cause significant disease, either directly or by predisposing to other secondary infections, or (2) to initiate primary immunization to protect against disease later in life.

Assessing risk takes into account both the likelihood the foal will become infected and the risk of serious sequelae or death if the horse does become infected and develop disease. If the disease affects the foal early in life, such as is the case with rotavirus (RV) infection, there is usually insufficient time to induce a protective immune response by actively immunizing the foal. Under these circumstances, the approach should be to maximize the degree of protection passively transferred from the dam via colostrum. Other diseases like rabies can affect horses of all ages, but the risk of acquiring infection is generally low.

Diseases of Moderate to High Risk to Young Foals but Low Risk to Adults

Diseases of moderate to high risk to young foals but low risk to adults include RV infection (on certain breeding farms in certain years) and, in geographic areas such as Kentucky and some other Eastern states, type B botulism. For these diseases, the following approach is appropriate:

- Booster-vaccinate the dam before foaling to maximize uniformity of passive transfer.
- Ensure good passive transfer of maternal antibodies.
- Introduce management practices to reduce exposure to the infectious agent.
- Vaccinate the foal if risk continues beyond the first few months of life.

Diseases of Moderate to High Risk for Weanlings and Older Horses but Lower Risk to Young Foals Born to Vaccinated Mares

Diseases of moderate to high risk for weanlings and older horses but lower risk to young foals born to vaccinated mares include EHV-4, EHV-1, strangles, influenza, tetanus, EEE, and WNV infection. For these diseases, the following approach is appropriate:

- Vaccinate the dam before foaling to maximize uniformity of passive transfer.
- Ensure good passive transfer of maternal antibodies.
- Start foal vaccination after the risk of maternal antibody interference is no longer present in *most* foals. When several vaccine types are available for a particular disease, the vaccine that is least subject to MDA interference should be used. Introduce management practices to reduce exposure to the infectious agent while primary vaccination is being completed.
- If a two-dose primary series is recommended for adult horses, use three or more doses of vaccine in the primary series to improve the chances that foals that do not respond to earlier doses will respond to additional doses administered later.

Diseases of Low Risk to Foals

Diseases of low risk to foals in most circumstances include rabies, PHF, WEE, and EVA. For these diseases, the following approach is appropriate:

- Vaccinate the dam before foaling if the disease is a significant risk to adult horses and a vaccine shown to be safe for use in pregnant mares is available. If the available vaccines are not considered safe for use in pregnant mares, administer boosters before breeding.
- Ensure good passive transfer of maternal antibodies.
- Start foal vaccination after the risk of maternal antibody interference is no longer present in *any* foal (typically 9 months to 1 year of age)

Adverse Reactions to Vaccines

Though uncommon, the possibility always exists for adverse reactions (including anaphylaxis) associated with vaccine administration, so vaccines should be administered by or under the direct supervision of a veterinarian. Adverse reactions should be reported to the vaccine's manufacturer and the U.S. Department of Agriculture (USDA) (1-800-752-6255) or the U.S. Pharmacopeia (USP) Veterinary Practitioners Reporting Program (forms may be obtained or reports submitted by calling the USP at 1-800-487-7776). Anaphylaxis constitutes a life-threatening emergency requiring prompt treatment with epinephrine (0.01 to 0.02 mg/kg; equivalent to 5 to 10 mL of a 1:1000 dilution IM for a 450-kg horse). Repeated doses of epinephrine can be administered at 15-minute intervals if necessary. It has recently been shown that horses vaccinated with viral vaccines can develop IgE responses to non-target antigens, including bovine serum albumin (BSA), suggesting that subsequent administration of another viral vaccine containing the same component could elicit an adverse response, including anaphylaxis.[31]

Local irritant tissue reactions occur more frequently, particularly when polyvalent combination vaccines and injectable strangles vaccines are used. These reactions usually are self-limiting, but resolution can be promoted by parenteral or oral (PO) administration of nonsteroidal antiinflammatory drugs (NSAIDs), topical application of warm compresses or the cutaneously absorbed NSAID diclofenac (Surpass [IDEXX Pharmaceuticals, Greensboro, N.C.]), and gentle exercise. Significant reactions in the neck muscles may make the horse reluctant to lower or raise its head; feed and water buckets should be positioned accordingly. Occurrence of externally visible local reactions can be reduced by administration of the vaccine deep in the semimembranosus and semitendinosus muscles of the hindleg rather than in the neck, and by allowing the horse to exercise after vaccination. Horses that repeatedly react to polyvalent vaccines may benefit from NSAID administration before vaccination, administration of the individual antigenic components separately in different sites, use of a different brand of vaccine, use of a vaccine that can be administered by a route other than IM, or use of a vaccine that contains a different adjuvant or no adjuvant at all.

Some horses develop transient self-limiting systemic signs that may include fever, anorexia, lethargy, colic, diarrhea, tachycardia, and congested mucous membranes after IM administration of vaccines. Systemic signs are perhaps more common with certain vaccines but can be associated with any vaccine.[32,33] In addition, inactivated Immune Stimulating Complex (ISCOM) and live recombinant vectored tetanus and influenza combination vaccines have been shown to elicit a prominent acute phase inflammatory response of several days' duration in vaccinated horses.[34] A similar response likely occurs with other vaccines. It is therefore inadvisable to give horses any injectable vaccine within 2 weeks before a show, performance event, sale, or prolonged transportation. It may also be beneficial to minimize environmental dust when vaccinating horses known to have allergic airway disease or hypersensitivity.[32]

TABLE 48-1

Types of Equine Vaccines Licensed in the United States

	Dead Vaccines		Live Vaccines		
Disease	Inactivated	Subunit	Modified-Live	Recombinant	DNA Vaccine
Tetanus		X			
Western equine encephalitis (WEE)	X				
Eastern equine encephalitis (EEE)	X				
Venezuelan equine encephalitis (VEE)	X				
West Nile	X			X, X (chimera)	X
Equine influenza	X		X	X	
Equine herpesvirus 1	X		X		
Equine herpesvirus 4	X				
Strangles		X	X		
Equine viral arteritis			X		
Rabies	X				
Potomac horse fever (equine neorickettsiosis)	X				
Botulism		X			
Rotavirus (conditional license)	X				
Equine rhinitis A virus (conditional license)	X				

If unacceptable reactions occur repeatedly, the need for continued annual or more frequent revaccination against individual antigens should be carefully reevaluated, taking into account risk of disease balanced against the risk of an adverse reaction. Many horses that experience adverse reactions have received many doses of many vaccine antigens, repeated over many years. In this situation, the vaccination protocol should be "pared down" so only the most essential antigens are administered and the maximum possible interval between boosters is employed. For diseases like rabies and tetanus for which resistance can reasonably be correlated with circulating antibody titer, one possible approach to define the maximum or optimal interval between booster doses would be to measure the antibody titer. Unfortunately, this approach is currently limited by the paucity of laboratories that offer this type of testing on a routine basis, inexpensively, and with a short turnaround time. Introduction of commercially available ELISA testing for antibodies to the SeM protein of *Streptococcus equi* subsp. *equi* (Equine Biodiagnostics-IDEXX, Lexington, Ky.) and neutralizing antibody testing for WNV virus (Cornell University, Colorado State University, the University of Florida, and the USDA Animal and Plant Health Inspection Service [APHIS] National Veterinary Services Laboratory) in recent years has made it possible to refine vaccination protocols for these diseases in horses that experience adverse reactions to vaccination. Testing for rabies antibodies is available through Kansas State University, and testing for antibodies to other pathogens may be available through state diagnostic laboratories.

Available Vaccines and the Concept of Core and Non-Core Vaccines

Fully licensed vaccines are now available in North America as aids to the prevention of tetanus, viral encephalomyelitis (EEE, WEE, VEE), WNV infection, influenza, EHV-1 and EHV-4 infection, strangles, rabies, EVA, PHF, and type B botulism. In addition, conditionally licensed vaccines are available to immunize horses against rotavirus and equine rhinitis A virus (ERAV). Tetanus, rabies, and viral encephalomyelitis caused by EEE, WEE, and WNV pose a threat to horses in all geographic areas and are therefore considered to be core diseases against which all horses in North America should be vaccinated. The abortigenic potential of EHV-1 warrants inclusion of this disease in the core for all pregnant broodmares. Although influenza is not routinely included as a core disease, vaccination against this highly contagious respiratory tract infection is strongly recommended for all horses likely to be co-located with horses from other facilities during transportation or at sales, shows, trail rides, races, or other events. The remaining diseases for which vaccines are available are considered "non-core" or "risk based." Indications for use of vaccines against these diseases will be discussed in relevant sections that follow later in this chapter. Table 48-1 details the types of vaccines licensed for use in horses in the United States. Tables 48-2 through 48-4 provide general guidelines for use of the most frequently indicated equine vaccines in foals, weanlings, yearlings, and adult horses under various management conditions and in various geographic locations.

Vaccination Recommendations for Specific Diseases

Tetanus

All horses are at risk for developing tetanus, an often fatal disease caused by a potent neurotoxin elaborated by the anaerobic spore-forming bacterium *Clostridium tetani*. Infection of tissues typically occurs via puncture wounds (particularly those involving the foot or muscle), open lacerations, surgical incisions, exposed tissues like the umbilicus of foals, and the reproductive tract of the postpartum mare (especially in the event of trauma or retained placenta). *C. tetani* is present in the intestinal tract and feces of horses, other animals, and human beings, and spores are abundant as well as ubiquitous in soil. Spores of *C. tetani* survive in the environment for many years, resulting in an ever-present risk of exposure of horses and people on equine facilities. Because tetanus is expensive to treat and has a high mortality rate, all horses should be actively immunized using tetanus toxoid as part of the core vaccination program. Active immunization reduces the need to administer tetanus antitoxin, the use of which is associated with risk of inducing potentially fatal serum hepatitis.

Protection against tetanus is mediated by circulating antibodies; toxin binding inhibition (ToBi) antibody titers of greater than 0.2 IU/mL are considered to be protective in the horse.[27,35] The many available vaccines are formalin-inactivated, adjuvanted toxoids that are inexpensive, safe, and potent antigens that induce an excellent serologic response and solid long-lasting immunity when administered according to manufacturer recommendations. Primary immunization involves administration of 2 doses of toxoid at 3- to 6-week intervals. Titers of specific antibody increase to protective levels within 14 days after administration of the second dose in the primary series and, in adult horses, persist at detectable levels for 12 months or longer, depending on the adjuvant system used in the vaccine.[27,35-37] A recent study documented substantial differences between currently licensed combination tetanus-encephalomyelitis vaccines with regard to the magnitude of the vaccine-induced tetanus specific IgGb and IgG(T) antibody responses.[8] The vaccine containing a Carbopol adjuvant induced substantially higher antibody titers

TABLE 48-2

Guidelines for Vaccination of Adult Horses, Excluding Broodmares, Against Core and Non-Core (Risk-Based) Diseases

Disease/ Vaccine	Adult Horses (>1 Year of Age) Previously Vaccinated Against Disease Indicated	Adult Horses (>1 Year of Age) Not Previously Vaccinated Against Disease Indicated or Lacking a Vaccination History	Comments
Core Diseases*			
Tetanus (toxoid)	Toxoid: annual revaccination	Toxoid: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate annually.	Booster at time of penetrating injury or surgery if last dose was administered > 6 months previously
Eastern and Western equine encephalomyelitis (EEE, WEE)	Inactivated: annual revaccination in spring, prior to onset of vector season	Inactivated: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate annually prior to onset of next vector season.	Consider a 6-month revaccination interval for horses residing in endemic areas with a prolonged vector season (e.g., southeastern states).
West Nile virus (WNV)	Inactivated vaccine or live recombinant canarypox-vectored vaccine: annual revaccination in spring, prior to onset of vector season	Inactivated vaccine or live recombinant canarypox-vectored vaccine: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate annually prior to onset of next vector season. Inactivated *Flavivirus* chimera vaccine: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually prior to onset of next vector season. Live *Flavivirus* chimera vaccine: 1-dose primary series Revaccinate annually prior to onset of next vector season.	When using an inactivated product or live recombinant product, consider a 6-month revaccination interval for: • Horses residing in endemic areas with a prolonged vector season • Juvenile horses (<5 years of age) • Geriatric horses (>15 years of age) • Immunocompromised horses For naive horses being imported into an endemic area during vector season, preferred approach is to complete primary vaccination series prior to importation. If this approach is not feasible, protect horses from being bitten by mosquitoes if possible, and vaccinate them with one of the vaccines (canarypox-vectored or live *Flavivirus* chimera) that have most rapid onset of immunity.
Rabies	Inactivated: annual revaccination	Inactivated: 1-dose primary series Annual revaccination	Booster vaccination induces persistently elevated levels of anti-rabies antibody.
Non-Core (Risk-Based) Vaccines†			
Anthrax (rarely indicated)	Live spore vaccine: annual revaccination	Live spore vaccine: 2-dose primary series; second dose 3-4 weeks after first dose Annual revaccination	Use only in endemic areas or in the face of an outbreak. Antimicrobial drugs must not be given concurrently with this vaccine. Administer subcutaneously in neck. Use caution during storage, handling, and administration. Consult a physician immediately if human exposure to anthrax vaccine occurs by accidental injection, ingestion, or otherwise through conjunctivae or broken skin.
Botulism	Toxoid: annual revaccination	Toxoid: 3-dose primary series; second dose 4 weeks after first dose; third dose 4 weeks after second dose Annual revaccination	
Equine herpesvirus (EHV)	Inactivated or modified live: semiannual (6-month interval) to annual revaccination (see comments)	Inactivated or modified live: 3-dose primary series; second dose 4-6 weeks after first dose; third dose 4-6 weeks after second dose	A 6-month revaccination interval is recommended for: • Horses < 5 years of age • Horses on breeding farms or in contact with pregnant mares • Horses housed at facilities with frequent equine movement on and off the premises • Performance or show horses at high risk

VetBooks.ir

TABLE 48-2

Guidelines for Vaccination of Adult Horses, Excluding Broodmares, Against Core and Non-Core (Risk-Based) Diseases—cont'd

Disease/ Vaccine	Adult Horses (>1 Year of Age) Previously Vaccinated Against Disease Indicated	Adult Horses (>1 Year of Age) Not Previously Vaccinated Against Disease Indicated or Lacking a Vaccination History	Comments
Equine influenza	Modified live cold-adapted intranasal, inactivated, or live canarypox-vectored recombinant vaccine: semiannual for horses with ongoing risk of exposure Annual for horses at low risk for exposure	Modified live cold-adapted intranasal vaccine: 1-dose primary series Revaccinate semiannually to annually. Inactivated vaccines: 3-dose primary series; second dose 4-6 weeks after first dose; third dose 3-6 months after second dose Revaccinate semiannually to annually. Live canarypox-vectored recombinant: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate semiannually to annually.	
Equine viral arteritis (EVA)	Modified live virus vaccine: annual revaccination. Stallions and teasers: vaccinate 3-4 weeks before start of breeding season. Mares: vaccinate when open.	Modified live virus vaccine: 1-dose primary series (see comments)	Prior to initial vaccination, intact males and any horses potentially intended for export should undergo serologic testing and be confirmed negative for antibodies to EAV. Samples for testing should be collected shortly before, or preferably at, the time of vaccination. All first-time vaccinated stallions should be isolated for 3 weeks after vaccination before being used for breeding.
Potomac horse fever (PHF)	Inactivated vaccines: semiannual to annual revaccination	Inactivated vaccines: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate semiannually to annually.	Because protection following vaccination is incomplete and short lived, a revaccination interval of 3-4 months has been advocated in endemic areas when disease risk is high. However, strategic revaccination to maximize immunity prior to expected peak challenge in summer and fall is the preferred approach if vaccination is elected as an adjunct to strategic environmental control measures.
Rotavirus	Not applicable	Not applicable	
Strangles	Inactivated M-protein subunit or modified live intranasal vaccines: semiannual to annual revaccination	Inactivated M-protein subunit vaccines: 2- to 3-dose series; second dose 2-4 weeks after first dose; third dose (when recommended by manufacturer) 2-4 weeks after the second dose. Revaccinate semiannually. Modified live intranasal vaccine: 2-dose primary series administered IN; second dose 3-4 weeks after first dose Revaccinate semiannually to annually.	Vaccination is not recommended as a strategy in outbreak mitigation, but vaccination may be warranted on farms with endemic strangles, with the understanding that the risk of adverse vaccine reactions is higher in exposed horses.

Modified with permission from recommendations developed by the AAEP Infectious Disease Committee and posted on the AAEP website (aaep.org).

*Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

†Non-core (risk-based) vaccines are selected for use based on assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of non-core vaccines will vary between individuals, populations, and/or geographic regions.

than those containing either saponin or squaline combined with surfactants.[8] Revaccination once annually is recommended.

No published challenge studies are available to document the speed of onset or duration of protection induced by tetanus toxoid preparations currently licensed in North America. Conclusions regarding their efficacy are therefore based on the serologic response obtained in horses and laboratory animals and on field experience. However, a challenge study conducted in Europe almost 60 years ago found that horses were resistant to challenge 8 days after receiving a single injection of tetanus toxoid, before antibody could be detected in their serum.[38] A second study demonstrated that a series of 3 doses of tetanus toxoid induced protection lasting for at least 8 years, and perhaps for life, even when antibodies could no longer be detected.[35] A recent study in Europe documented that protective levels of antibody (>0.2 IU/mL as measured by tetanus toxin-binding ELISA) persist for at least 18 months after revaccination of horses previously primed with a 2-dose series of a tetanus toxoid/influenza ISCOM vaccine.[39] In contrast, tetanus has been documented in vaccinated horses in North America,[40] although survival was strongly associated

TABLE 48-3

Guidelines for Vaccination of Broodmares Against Core and Non-Core (Risk-Based) Diseases

Disease/Vaccine	Previously Vaccinated Broodmares	Broodmares Not Previously Vaccinated or Lacking a Vaccination History	Comments
Core Diseases*			
Tetanus	Toxoid: annual revaccination 4-6 weeks prepartum	2-dose primary series; second dose 4-6 weeks after first dose Revaccinate 4-6 weeks prepartum, depending on timing of second dose.	Booster at time of penetrating injury or surgery if last dose was administered more than 6 months previously
Eastern and Western equine encephalomyelitis (EEE, WEE)	Annual, 4-6 weeks prepartum	2-dose primary series; second dose 4 weeks after first dose Revaccinate 4-6 weeks prepartum, depending on timing of second dose.	Consider a 6-month revaccination interval for mares residing in endemic areas with a prolonged vector season (e.g., southeastern states).
West Nile virus (WNV)	Annual, 4-6 weeks prepartum	It is preferable to vaccinate naive mares when open. When risk is high, initiate primary series as follows: Inactivated vaccine or live recombinant canarypox-vectored vaccine: 2-dose primary series; second dose 4-6 weeks after first dose Revaccinate 4-6 weeks prepartum, depending on timing of second dose. Inactivated *Flavivirus* chimera vaccine: 2-dose primary series; second dose 3-4 weeks after first dose Revaccinate annually, prior to onset of the next vector season. Live *Flavivirus* chimera vaccine: 1-dose primary series Revaccinate 4-6 weeks prepartum, depending on timing of first dose.	When using an inactivated product or live recombinant product, consider a 6-month revaccination interval for mares residing in endemic areas with a prolonged vector season. For naive mares being imported into an endemic area during the vector season, preferred approach is to complete the primary vaccination series prior to importation. If this approach is not feasible, protect them from being bitten by mosquitoes if possible, and vaccinate them with one of the vaccines (canarypox-vectored or live *Flavivirus* chimera) that have the most rapid onset of immunity.
Rabies	Annual, prior to breeding OR 4-6 weeks prepartum	1-dose primary series Annual revaccination prior to breeding OR 4-6 weeks prepartum	Because booster vaccination induces persistently elevated levels of anti-rabies antibody. This vaccine may be given post foaling, but prior to breeding, to reduce the number of vaccines given to mares prepartum.
Equine herpesvirus (EHV)	3-dose series with product labeled for prevention of EHV-1 abortion Administer during fifth, seventh, and ninth months of gestation.	3-dose series with product labeled for prevention of EHV-1 abortion Administer during the fifth, seventh, and ninth months of gestation.	
Non-Core (Risk-Based) Vaccines†			
Anthrax	Not recommended for use during gestation	Not recommended for use during gestation	
Botulism	Annual, 4-6 weeks prepartum.	3-dose series: first dose during eighth month of gestation; second dose 4 weeks after first dose; third dose 4 weeks after the second dose	
Equine influenza	Inactivated vaccines: semiannual, with one dose administered 4-6 weeks prepartum Canarypox-vectored vaccine: semiannual, with one dose administered 4-6 weeks prepartum	Inactivated vaccine: 3-dose primary series; second dose 4-6 weeks after first dose; third dose 4-6 weeks prepartum Canarypox-vectored vaccine: 2-dose primary series; second dose 4-6 weeks after first dose but no later than 4 weeks prepartum	The MLV intranasal influenza vaccine can be used to protect pregnant mares against influenza, but its use for prepartum booster is not recommended because it does not reliably stimulate high levels of circulating antibody. Administration of an inactivated or canarypox-vectored vaccine for the pre-foaling booster is the preferred approach.
Equine viral arteritis (EVA)	Administration during pregnancy is not recommended unless risk of exposure is high.	Administration during pregnancy is not recommended unless risk of exposure is high.	Mares potentially intended for export should undergo serologic testing immediately prior to initial vaccination and be confirmed negative for antibodies to EAV.

TABLE 48-3

Guidelines for Vaccination of Broodmares Against Core and Non-Core (Risk-Based) Diseases—cont'd

Disease/Vaccine	Previously Vaccinated Broodmares	Broodmares Not Previously Vaccinated or Lacking a Vaccination History	Comments
Potomac horse fever (PHF)	Semiannual, with one dose administered 4-6 weeks prepartum	2-dose primary series: first dose: 8-10 weeks prepartum; second dose 4-6 weeks prepartum	Strategic environmental control measures are important for effective control.
Rotavirus	3-dose series: first dose at 8 months' gestation; second dose 4 weeks after first dose; third dose 4 weeks after second dose	3-dose series: first dose at 8 months' gestation; second dose 4 weeks after first dose; third dose 4 weeks after second dose	Check serum concentration of immunoglobulin in foal to verify adequate passive transfer.
Strangles	Inactivated M-protein subunit vaccines: semiannual, with one dose given 4-6 weeks prepartum	Inactivated M-protein subunit vaccines: 3-dose primary series; second dose 2-4 weeks after the first dose; third dose 4-6 weeks prepartum	The MLV intranasal strangles vaccine can be used to protect pregnant mares, but its use for the prepartum booster is not recommended because it does not reliably stimulate high levels of circulating antibody. Administration of an inactivated M-protein vaccine for the pre-foaling booster is the preferred approach.

Modified with permission from recommendations developed by the AAEP Infectious Disease Committee and posted on the AAEP website (aaep.org).

*Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

†Non-core (risk-based) vaccines are selected for use based on assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of non-core vaccines will vary between individuals, populations, and/or geographic regions.

TABLE 48-4

Guidelines for Vaccination of Foals, Weanlings, and Yearlings Against Core and Non-Core (Risk-Based) Diseases

Disease/Vaccine	Foals and Weanlings (<12 Months of Age) of Mares Vaccinated during Prepartum Period Against Disease Indicated	Foals and Weanlings (<12 Months of Age) of Mares Not Vaccinated during Prepartum Period	Yearlings	Comments
Core Diseases*				
Tetanus (toxoid)	Toxoid: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose 3-5 months after second dose (i.e., 10-12 months of age)	Toxoid: 3-dose primary series; first dose at 1-4 months of age; second dose 4-6 weeks after the first dose; third dose 3-5 months after second dose	Annual	
Eastern and Western equine encephalomyelitis (EEE, WEE)	Inactivated vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age, prior to onset of next vector season	Inactivated vaccine: 3-dose primary series; first dose at 3-4 months of age; second dose 4 weeks after first dose; third dose 4-8 weeks after second dose (shorter interval applies to foals receiving their primary series during mosquito season)	Annual in spring, prior to onset of vector season	Month of birth and geographic location influence risk of exposure to insect vectors at specific foal ages. Scheduling of primary immunization series may be amended by administration of EEE/WEE vaccines to foals at an earlier age if vectors are present. In the southeastern United States where vectors are present year-round, an additional dose should be added to primary series, beginning at 2-3 months of age. Fourth dose in the primary series should be administered at 10-12 months of age.

VetBooks.ir

TABLE 48-4

Guidelines for Vaccination of Foals, Weanlings, and Yearlings Against Core and Non-Core (Risk-Based) Diseases—cont'd

Disease/ Vaccine	Foals and Weanlings (<12 Months of Age) of Mares Vaccinated during Prepartum Period Against Disease Indicated	Foals and Weanlings (<12 Months of Age) of Mares Not Vaccinated during Prepartum Period	Yearlings	Comments
West Nile virus (WNV)	Inactivated vaccine or live recombinant canarypox-vectored vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age, prior to onset of next vector season	Inactivated vaccine or live recombinant canarypox-vectored vaccine: 3-dose primary series; first dose at 3-4 months of age; second dose 4 weeks after first dose; third dose 4-8 weeks after second dose (shorter interval applies to foals receiving their primary series during mosquito season)	Annual in spring, prior to onset of vector season	Month of birth and geographic location influence risk of exposure to insect vectors at specific foal ages. Scheduling of primary immunization series may be amended by administration of WNV vaccines to foals at an earlier age if vectors are present. In the southeastern United States where vectors are present year-round, primary vaccination series should be initiated at 3 months of age.
	Live *Flavivirus* chimera vaccine: 2-dose primary series; first dose at 5-6 months of age; second dose at 10-12 months of age, prior to onset of next vector season	Live *Flavivirus* chimera vaccine: 2-dose primary series; first dose at 5-6 months of age; second dose at 10-12 months of age prior to onset of next vector season		There are no published data regarding use of the live *Flavivirus* chimera product in foals <5 months of age. If administered to foals <5 months of age, the recommended schedule for primary vaccination should be completed by administration of a dose of vaccine at 5 months of age or older.
Rabies	2-dose primary series: first dose at 6 months of age; second dose 4-6 weeks after first dose; next dose at 10-12 months of age	1- or 2-dose primary series: first dose at 3-4 months of age; second dose 4-6 weeks after first dose (not necessary if dam is seronegative); next dose at 10-12 months of age	Annual	For foals of mares with an unknown vaccination history, either follow approach outlined for foals of vaccinated mares, or determine serologic status of foal (or mare) and use results to classify foal as either being from a vaccinated or unvaccinated mare.
Non-Core (Risk-Based) Vaccines[†]				
Anthrax (rarely indicated)	Not applicable because vaccination of pregnant mares is not recommended	No age-specific guidelines are available for this vaccine. Manufacturer's recommendation is for primary series of 2 doses administered subcutaneously (in the neck) at a 2-3–week interval.	Annual, in spring	Anthrax vaccination is rarely indicated—only in focal endemic areas. Antimicrobial drugs must not be given concurrently with this vaccine. Exercise caution during storage, handling, and administration of this live bacterial product. Consult a physician immediately should accidental human exposure (via mucous membranes, conjunctivae, or broken skin) occur.
Botulism (type B toxoid)	3-dose primary series: first dose as early as 2-3 months of age; second dose 4 weeks after first dose; third dose 4 weeks after second dose	3-dose primary series: first dose as early as 1-3 months of age; second dose 4 weeks after first dose; third dose 4 weeks after second dose	Annual	Limited information suggests that maternal antibody does not interfere with vaccination, so foals at high risk may be vaccinated as early as 2 weeks of age.
Equine herpesvirus (EHV)	Inactivated EHV-1, EHV-1/4, or modified live EHV-1 vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose 3-5 months after second dose (i.e., 10-12 months of age)	Inactivated EHV-1, EHV-1/4, or modified live EHV-1 vaccine: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose 3-4 months after second dose (i.e., 10-12 months of age)	Semiannual (6-month interval)	The benefit of intensive vaccination programs directed against EHV-1 and EHV-4 in foals and young horses is not clearly defined because, despite frequent vaccination, infection and disease continue to occur. It is difficult to induce active immunity before weanlings experience field challenge.

VetBooks.ir

TABLE 48-4

Guidelines for Vaccination of Foals, Weanlings, and Yearlings Against Core and Non-Core (Risk-Based) Diseases—cont'd

Disease/ Vaccine	Foals and Weanlings (<12 Months of Age) of Mares Vaccinated during Prepartum Period Against Disease Indicated	Foals and Weanlings (<12 Months of Age) of Mares Not Vaccinated during Prepartum Period	Yearlings	Comments
Equine influenza	Inactivated vaccine: 3-dose primary series; first dose at 6-7 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age	Inactivated vaccine: 3-dose primary series; first dose at 6-7 months of age; second dose 4-6 weeks after first dose; third dose at 10-12 months of age	Semiannual (6-month interval)	An unusually high risk of exposure may warrant vaccination of younger foals. Because potentially interfering maternal anti-influenza antibody is likely to be present, a complete primary vaccination series should be given after 6 months of age.
	Live canarypox-vectored recombinant vaccine: 3-dose primary series: first dose at 5-6 months of age; second dose 5 weeks after first dose; third dose at 10-12 months of age	Live canarypox-vectored recombinant vaccine: 3-dose primary series; first dose at 5-6 months of age; second dose 5 weeks after first dose; third dose at 10-12 months of age	Semiannual (6-month interval)	
	Modified live cold-adapted intranasal vaccine: 1-dose primary series: first dose at 11 months of age If vaccination earlier than 11 months is elected, use a 2-dose primary series: first dose at 6-10 months of age; second dose at 11-12 months of age	Modified live cold-adapted intranasal vaccine: 1-dose primary series: first dose at 11 months of age If vaccination earlier than 11 months is elected, use a 2-dose primary series: first dose at 6-10 months of age second dose at 11-12 months of age	Semiannual (6-month interval)	The modified live intranasal vaccine is licensed for administration to horses 11 months of age or older with a label recommendation of 1 dose for primary immunization. If vaccine is given before 11 months of age, a second dose should be administered at 11 months or older.
Equine viral arteritis (EVA)	Colt (male) foals: single dose at 6-12 months of age (see comments)	Colt (male) foals: single dose at 6-12 months of age (see comments)	Annual for colts intended for use as breeding stallions	Prior to initial vaccination, colt (male) foals should undergo serologic testing and be confirmed negative for antibodies to EAV. Maternally derived anti-EAV colostral antibodies can persist in foal for up to 6 months, so testing and vaccination should not be performed prior to 6 months of age. Keep colts isolated for 3 weeks after vaccination.
Potomac horse fever (PHF)	3-dose primary series: first dose at 5-6 months of age; second dose 3-4 weeks after first dose; third dose at 10-12 months of age	3-dose primary series: first dose at 5-6 months of age; second dose 3-4 weeks after first dose; third dose at 10-12 months of age	Semiannual to annual	If warranted by risk, vaccine may be administered to younger foals, in which case additional doses should be administered at 4-week intervals until foal is 6 months of age.
Rotavirus	Not recommended in foals	Not recommended in foals	Not applicable	
Strangles	Inactivated M-protein subunit vaccines: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after first dose; third dose 4-6 weeks after second dose	Inactivated M-protein subunit vaccines: 3-dose primary series; first dose at 4-6 months of age; second dose 4-6 weeks after the first dose; third dose 4-6 weeks after second dose	Semiannual	Vaccination is not routinely recommended as a strategy in outbreak mitigation but may be warranted on farms with endemic strangles, with the understanding that risk of adverse vaccine reactions is higher in exposed horses.
	Modified live intranasal vaccine: 3-dose primary series; first dose at 6-9 months of age; second dose 3-4 weeks after first dose; third dose at 11-12 months of age	Modified live intranasal vaccine: 3-dose primary series; first dose at 6-9 months of age; second dose 3-4 weeks after first dose; third dose at 11-12 months of age	Semiannual	If warranted by risk, the modified live vaccine (MLV) may be safely administered to foals as young as 6 weeks of age. However, vaccine efficacy in this age group has not been determined. If the MLV product is administered to foals < 6 months of age, administration of third dose of vaccine should be timed 2-4 weeks prior to weaning if possible.

Modified with permission from recommendations developed by the AAEP Infectious Disease Committee and posted on the AAEP website (aaep.org).

*Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

†Non-core (risk-based) vaccines are selected for use based on assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of non-core vaccines will vary between individuals, populations, and/or geographic regions.

VetBooks.ir

with previous vaccination. Thus it would not be prudent to recommend extension of the annual interval for revaccination with tetanus toxoid products available in North America, pending publication of data documenting duration of immunity (DOI). Vaccinated horses that sustain a wound or undergo surgery more than 6 months after receiving their previous tetanus booster should be revaccinated with tetanus toxoid immediately at the time of injury or surgery.

Annual revaccination of pregnant mares should be completed 4 to 8 weeks before foaling to protect the mare if she sustains foaling-induced trauma or retained placenta and to enhance concentrations of specific immunoglobulins in colostrum. Colostrum-derived antibodies significantly interfere with the immune response of foals vaccinated with tetanus toxoid until they are about 6 months old.[12,36]

Primary vaccination of foals that have received appropriate transfer of colostral antibodies from a vaccinated mare should include 3 doses of tetanus toxoid beginning at age 6 months or older. Optimally, the interval between the first 2 doses of vaccine should be approximately 4 weeks, and the interval between the second and third doses should be 3 to 5 months. The 3-dose primary series is recommended for foals, because a high proportion of foals fail to seroconvert in response to 2 doses of tetanus toxoid regardless of whether maternal antibodies are detectable at administration of the first dose.[12,36] For foals born to non-immune mares, this initial 3-dose series can start at 1 to 4 months of age.

Tetanus antitoxin is produced by hyperimmunization of donor horses with tetanus toxoid. Administration of 1 vial of antitoxin (1500 IU) to nonvaccinated horses induces immediate passive protection that lasts not more than 3 weeks.[36] More prolonged protection may be accomplished with higher doses. In addition to the use of high doses of tetanus antitoxin to treat tetanus, indications frequently cited include administration to newborn foals born to unvaccinated mares and to unvaccinated horses that sustain an injury. In these cases the concurrent administration of tetanus antitoxin and tetanus toxoid at different sites using separate syringes has been advocated, followed by administration of additional doses of toxoid at 4- to 6-week intervals to complete the primary series.[41] Because a small but significant number of horses experience serum sickness and fatal hepatic failure (serum hepatitis) several weeks after receiving tetanus antitoxin,[42,43] a preferred approach to the unvaccinated horse that sustains a puncture or deep laceration is to thoroughly clean and débride the wound, initiate active immunization by administering tetanus toxoid, and institute a course of antimicrobial treatment with penicillin or alternate antimicrobial that is active against *C. tetani*.

Equine Encephalomyelitis (Sleeping Sickness)

The equine encephalomyelitis viruses (EEE, WEE, and VEE) belong to the *Alphavirus* genus of the family Togaviridae. They are transmitted by mosquitoes (and infrequently by other bloodsucking insects) to horses from wild birds or rodents that serve as natural reservoirs for these viruses. Risk of exposure and geographic distribution of the encephalomyelitis viruses vary by season and from year to year with changes in distribution of insect vectors and wildlife reservoirs. The distribution of EEE has historically been restricted to the eastern, southeastern, and some southern states, with recent northward encroachment. WEE has caused minimal disease in horses in North America during the past 3 decades, but the virus continues to be detected in mosquitoes and birds throughout the western states. In the past, outbreaks of WEE have been recorded in the western and midwestern states, with sporadic cases in the northeastern and southeastern United States. Because EEE, WEE, or both are endemic in most areas of North America, vaccination against these diseases should be part of the core vaccination program for all horses. VEE is a reportable foreign animal disease. Epidemics of VEE occur when the virus undergoes genetic change and develops greater virulence for avian and mammalian hosts. These viral variants are able to multiply to high levels in the horse, and then the horse becomes a reservoir for infection in these outbreaks. VEE occurs in South and Central America but has not been diagnosed in the United States or Mexico for many years; routine vaccination of horses in these regions against VEE is not recommended at this time unless transportation to endemic areas is planned.

Available vaccines are formalin inactivated, adjuvanted, bivalent or trivalent, whole-virus products containing EEE, WEE, and VEE, typically in combination products containing other antigens such as tetanus, influenza, WNV, or EHV. Although correlates for protection against EEE, WEE, and VEE are not well established, circulating antibodies are assumed to be important because infection is acquired by vascular injection (mosquito bites), and current inactivated vaccines appear to have good efficacy.[44,45] A study evaluating the serologic response of horses to commercial encephalomyelitis-tetanus combination vaccines showed that the EEE neutralizing antibody responses to Encevac T (Merck Animal Health, Carbopol adjuvant) and Equiloid Innovator (Zoetis, squaline and surfactant adjuvant) were of greater magnitude and persistence than responses to Cephalovac EWT (Boehringer Ingelheim, saponin adjuvant).[8] However, no comparative randomized challenge studies have been performed using these vaccines to document whether differences in serologic responses equate to differences in efficacy. Early testing of bivalent (EEE/WEE) vaccines was performed by intracranial challenge with either EEE or WEE; the formalin inactivated preparations demonstrated 100% protection.

Primary immunization of unvaccinated adult horses is accomplished by administering 2 doses of inactivated vaccine 3 to 6 weeks apart. In areas where EEE is not a threat and mosquito vectors are active for less than 6 months of the year, annual revaccination in the spring, before the peak insect vector season, is recommended. In areas like the Gulf States where EEE is endemic and mosquitoes are active virtually year-round, many veterinarians prefer to revaccinate horses semiannually to ensure more uniform protection throughout the year. Inactivated encephalomyelitis vaccines are considered safe for use during pregnancy, so booster vaccination of pregnant mares 4 to 8 weeks before foaling is routinely recommended to enhance colostral concentrations of specific immunoglobulins. Neutralizing antibodies to WEE and EEE are transferred passively to foals through colostrum and decline with an estimated half-life of 33 and 20 days, respectively. MDAs appear to confer protection and are detectable in the serum of many foals from vaccinated mares for at least 3 months and up to 7 months, depending on the post-nursing titer.[23,46-48]

Several studies have shown that MDAs exert a profound inhibitory effect on the ability of foals to mount serologic responses to inactivated bivalent WEE/EEE vaccines, which likely accounts for some of the reported cases of vaccine failure and resultant clinical EEE in vaccinated horses, particularly those younger than 2 years of age.[19,23,24,46,47] Studies have shown that 3-month-old foals born to immune mares consistently failed to mount a serologic response to 2 doses of inactivated bivalent WEE/EEE vaccine, and the majority had not responded even after administration of a third dose.[24,26] Whereas many 6-month-old foals failed to seroconvert after administration of 2 doses of vaccine, most responded following administration of a third dose.[24] Based on these data, inclusion of a third dose in the primary series, 2 to 5 months after administration of the second dose, is strongly recommended for primary immunization of foals and yearlings.

WEE has a lower mortality rate than EEE, and prevalence of WEE in many western states is sufficiently low that the risk of foals acquiring infection during their first year of life is also low. Therefore, primary vaccination of foals of vaccinated mares in areas where mosquitoes die off in the winter and the risk of infection is low is best completed when foals are 5 to 6 months of age or older in order to minimize the potential for MDA interference. Because foals born in the late spring and summer months are still less than 6 months of age by the time the mosquito season comes to an end in many regions, primary vaccination of these foals can be delayed until the spring of the yearling year. In contrast, EEE is a highly fatal disease that poses a significant risk to foals during their first year of life, particularly in the Gulf States where competent vectors are present year-round.[19,47,49] Most veterinarians in these regions recommend commencing

VetBooks.ir

primary vaccination of foals at 3 to 4 months of age using a 3-dose primary series, followed by a fourth dose before the onset of the next mosquito season and semiannual boosters thereafter to maximize the chances of overcoming the inhibitory effects of MDAs and inducing protection.[47]

West Nile Virus

Only a few years after West Nile virus infection was first diagnosed in horses in the northeastern United States in 1999, it had spread across the entire North American continent and is now considered endemic in all mainland areas of North America and Mexico, where it has become an important consideration in the differential diagnosis of horses presenting with signs of neurologic disease. Since 1999, the disease has been confirmed in more than 25,000 U.S. horses, about 35% of which have died or been euthanized. Roughly 40% of horses that survive acute illness caused by WNV exhibit residual effects (e.g., gait and behavioral abnormalities) 6 months post diagnosis.[50]

WNV, a member of the family Flaviviridae, is transmitted by mosquitoes and infrequently by other bloodsucking insects to horses, human beings, and a number of other mammals from avian hosts, which serve as natural reservoirs for these viruses. Horses and humans are considered to be "dead-end" hosts of WNV and therefore do not contribute to the transmission cycle. The virus is not directly contagious from horse to horse or from horse to human. Similarly, indirect transmission via mosquitoes from infected horses is highly unlikely because horses do not experience a significant level of viremia.[51] Risk of infection and death appears to increase with increasing age, but the disease has been confirmed in foals as young as 3 weeks of age. Although cases have been seen virtually year-round in the southeastern United States, the risk of acquiring infection is highest during those months in which mosquito activity peaks, typically July, August, September, and October in most areas of North America. WNV infection is a core disease against which all horses residing in the continental United States and Canada should be vaccinated.

As of April 2013, six WNV vaccines (West Nile-Innovator [Zoetis], Recombitek Equine rWNV vaccine [Merial], Equi-Nile [Merck Animal Health], Vetera WNV Vaccine [Boehringer Ingelheim], PreveNile [Merck Animal Health], and West Nile-Innovator DNA [Zoetis]) are licensed for use in horses in North America. All six vaccines have met USDA requirements for safety in tests, each involving more than 640 horses. West Nile-Innovator is an inactivated whole-virus vaccine that contains a metabolizable oil adjuvant.[52] This vaccine is available as either a monovalent (single component) or as several multicomponent vaccines containing other encephalitis virus antigens (EEE, WEE, VEE) and tetanus. Recombitek Equine rWNV vaccine is a Carbopol-adjuvanted canarypox-vectored recombinant modified live vaccine,[53-55] which is also available as a multicomponent containing inactivated EEE, WEE, and tetanus antigens. PreveNile is a nonadjuvanted chimeric yellow fever 17D-vectored vaccine.[56-59] This vaccine was voluntarily withdrawn from the market in May of 2010 after an unacceptably high number of adverse reactions were reported and has not yet been reintroduced. Merck Animal Health has since produced and tested an inactivated version of this chimera vaccine, which was released in 2011 as a single-component vaccine (Equi-Nile), as well as several multicomponent vaccines that also contain EEE, WEE, tetanus, EHV-1, EHV-4, and influenza antigens (Encevac + WNV; Encevac T + WNV and Prestige V + WNV). Similarly, the Vetera line of vaccines from Boehringer Ingelheim includes both single and multicomponent (up to 8 components) versions containing an inactivated WNV antigen. West Nile-Innovator DNA is a plasmid DNA vaccine with a metabolizable oil adjuvant.[28] It appears that Zoetis is not currently marketing this vaccine.

Needle and mosquito challenge models have shown that West Nile-Innovator, Recombitek, and West Nile-Innovator DNA all significantly reduce the magnitude of viremia in experimentally infected vaccinated horses compared to nonvaccinated control horses for as long as 12 months after primary vaccination with 2 doses of vaccine.[28,52,53] Although viremia was reliably induced in nonvaccinated control horses in these challenge models, clinical disease was not. Therefore, these vaccines are labeled as aids to the prevention of viremia due to WNV infection. In contrast, an intrathecal challenge model that reliably induced severe clinical disease was used to test the efficacy of PreveNile in studies for licensure.[57] In this model, a single dose of PreveNile prevented clinical disease as well as viremia in 4- to 6-month-old horses challenged 1 year after vaccination; therefore, PreveNile was labeled for protection against viremia and as an aid in the prevention of disease and encephalitis caused by WNV.[57] Subsequently, Recombitek was shown to induce a high level of clinical protection when tested using this rigorous intrathecal challenge model in a placebo-controlled study in which horses were challenged 14 days after completion of a 2-dose vaccination series.[54] The comparative efficacy of West Nile-Innovator, Recombitek, and PreveNile has now been tested in a randomized blinded, placebo-controlled intrathecal challenge study in which groups of 5 or 6 horses 6 months of age or older were challenged intrathecally 28 days after completion of the 2-dose (West Nile-Innovator and Recombitek) or 1-dose (PreveNile) primary vaccination series.[60] In this study, all 6 unvaccinated control horses developed grave neurologic signs post challenge, whereas all vaccinated horses survived and none developed detectable viremia. Clinical disease was prevented in 100% of PreveNile-vaccinated horses, 80% of Recombitek-vaccinated horses, and 33% of Innovator-vaccinated horses.[60] These findings support the results of field studies that provide clear evidence that when used according to manufacturer recommendations, all available licensed WNV vaccines reduce the risk of disease and death after natural challenge, although clinical disease may not be fully prevented with all vaccines.[61-65]

Directions for primary immunization using inactivated whole virus, inactivated *Flavivirus* chimera, and recombinant vaccines include administration of 2 doses of vaccine 3 to 6 weeks apart (consult the specific label). Optimal protection cannot be expected until 2 weeks after administration of the second dose, although Recombitek has been shown to induce significant protection as early as 26 days after administration of the first dose when tested in both the mosquito challenge and intrathecal challenge models.[54,55] Primary immunization with PreveNile requires 1 dose. A challenge study in yearlings showed that 83% (5 of 6) were protected when challenged intrathecally 10 days after vaccination with 1 dose, indicating that onset of immunity is rapid.[57] Rapid onset of immunity is an important feature when faced with the challenge of protecting naive horses that are being introduced into an endemic area, as is the case when horses from Europe and other non-endemic countries are imported into North America.

Vaccine manufacturers recommend revaccination of previously vaccinated horses on an annual basis, or more frequently when local conditions are conducive to a prolonged period of potential exposure to infected mosquito vectors. Annual revaccination is best completed in the spring (late February through early April), before the onset of the insect vector season. In areas like the southeastern states where the mosquito season is prolonged, revaccination twice annually, once in the spring and again in the late summer or early fall (late July through early September) has been advocated in the past to maximize protection, although the rationale for semiannual vaccination against WNV has not been tested in controlled studies.

None of the licensed vaccines currently marketed in the United States carry label recommendations for administration to pregnant mares, so mares are best vaccinated before breeding whenever possible. It is well recognized, however, that pregnant mares are at risk of acquiring infection from infected mosquitoes. Consequently, it has become accepted practice by many veterinarians to administer vaccines to pregnant mares on the reasonable assumption that the risk of adverse consequences of WNV infection far exceeds the reported adverse effects of use of vaccines in pregnant mares. Thousands of doses of West Nile-Innovator vaccine have been administered safely to pregnant mares, and a published study failed to document vaccine-associated adverse effects in a large population of pregnant mares.[66] Although the Recombitek vaccine is a live vectored vaccine, the

VetBooks.ir

canarypox vector is incapable of replication in mammals and does not induce a viremia that could infect a fetus. In addition, a canarypox-vectored influenza vaccine available in Europe is licensed for use in horses during pregnancy, so the vectored WNV vaccine is unlikely to be associated with an increased risk of adverse effects in pregnant mares. As with other vaccines, it is sound practice to avoid administering West Nile vaccines to mares during the first 60 days of gestation unless conditions of imminent risk prevail.

Booster vaccination of previously primed pregnant mares 4 to 8 weeks before foaling appears to induce a strong anamnestic serologic response that provides their foals with passive colostral protection lasting at least 3 to 4 months.[26] In contrast, a significant proportion of naive pregnant mares failed to seroconvert when the primary series of WNV-Innovator vaccine was administered during the second half of gestation, perhaps reflecting pregnancy-associated downregulation of Th2 responses.[26] This observation adds further justification to the recommendation that when inactivated West Nile-Innovator vaccine is used, the primary series is best completed before breeding. In a similar study, pregnancy did not appear to suppress the response of mares to primary immunization with Recombitek (Wilson WD and colleagues, unpublished observations, 2007).

In contrast to findings with many other vaccines in the foals of immune mares, MDAs do not block the response of foals as young as 3 months of age to vaccination with the inactivated West Nile Innovator vaccine or the recombinant, chimera, or DNA WNV vaccines.[26,29] Although this finding is somewhat surprising for the inactivated vaccine, it might reasonably have been expected for the other vaccines because the vector systems accomplish transfection of cells and expression of the major E-peptide and M-peptide antigens of WNV on the surface of antigen presenting cells (APCs) in association with major histocompatibility complex (MHC) class I and class II antigens. These peptide antigens are therefore not free in the tissues and circulation to be neutralized by MDAs. The impact of MDAs on the recently marketed inactivated whole virus (Vetera WNV Vaccine [Boehringer Ingelheim]) and inactivated chimera vaccines (Equi-Nile [Merck Animal Health]) is not known.

Primary vaccination of foals from properly vaccinated mares can be started by administration of the first dose of either an inactivated or recombinant vaccine as early as 3 to 6 months of age (consult the specific product label), followed by a second dose approximately 3 to 6 weeks later, then a third dose 3 to 5 months after the second dose. This third dose increases the likelihood that foals with high MDA levels that may have attenuated the response to the first dose of vaccine will become primed and protected. Even in foals that have no maternally derived WNV antibodies after nursing, the third dose of inactivated vaccine in the primary series induces significantly higher and more persistent levels of antibody than two doses. A booster should be administered during the spring of the yearling year, after which the recommendations for vaccination of adult horses should be followed. Primary vaccination of foals from unvaccinated unexposed mares should commence at 3 months of age or younger (as early as 1 month of age), depending on month of birth and seasonal level of activity of mosquito vectors in the area. The three-dose primary vaccination protocol previously outlined should be followed. Revaccination should be performed before the onset of the next mosquito season.

The influence of MDAs on the response of foals to PreveNile was recently evaluated in 3-month-old and 5-month-old foals vaccinated with a single dose. Although significant titer responses were not observed post vaccination, sensitization of cell-mediated responses was accomplished, as evidenced by significant increases in expression of granzyme B, interleukin (IL)-2, perforin, and transforming growth factor (TGF)-β, and non-significant increases in interferon (IFN)-γ expression in WNV-stimulated PBMC from foals vaccinated at 5 months of age.[29] Similar, although non-significant, trends were seen in 3-month-old foals.[29] When available, PreveNile was labeled for administration of a single priming dose to foals 5 months of age or older, primarily because 5 months was the minimum age of foals used in challenge trials for licensure. Results of the above cited study suggest that foals younger than 5 months of age could be immunized successfully with PreveNile. Regardless, a second dose of vaccine should be administered before the onset of the next mosquito season. Preliminary data suggest that the plasmid West Nile-Innovator DNA vaccine is able to circumvent the potentially interfering effects of MDA, but the vaccine was labeled for use in horses 8 months of age or older.[28]

As with EEE, horses that have recovered from clinical WNV infection will likely be protected for the reminder of their lives and should not need to be revaccinated unless changes in their immune status, as might occur with prolonged corticosteroid administration, alter their susceptibility to infection.[67]

It is remarkable that in little more than 10 years after WNV disease was first encountered in the Americas, six vaccines with documented efficacy based on challenge studies were licensed for the benefit of horses, including three that apply the most modern technologies available for either animals or humans at the time.

Rabies

Rabies is an infrequently encountered neurologic disease of equids resulting from inoculation of the rabies virus through the bite of infected (rabid) wildlife. Wildlife species that serve as the natural reservoirs for rabies virus differ among regions of North America but include raccoons, foxes, skunks, and bats. Horses most often sustain bites on their muzzle, face, or lower limbs. The rabies virus then migrates via nerves to the brain where it initiates rapidly progressive encephalitis. Even though the incidence of rabies in horses is low, the disease is invariably fatal and has considerable public health significance. All horses kept in areas where rabies is endemic in the wildlife population are at risk and should be vaccinated as part of the core vaccination program. Therefore, vaccination of horses against rabies is recommended by, or under the direct supervision of, a veterinarian using one of the three inactivated tissue culture–derived products currently licensed for use in horses (Rabvac3 [Boehringer Ingelheim], RM Imrab3 [Merial], and EquiRab [Merck Animal Health]). These vaccines are potent immunogens that induce strong serologic responses that peak within 28 days after IM administration of a single dose.

Although correlates for protection against infection with rabies virus in horses are not well defined, it is logical to assume that protection correlates with titers of circulating antibody. In humans, post-vaccination antibody titers are used to predict protection. In dogs, however, postvaccination serologic test results were not found to be completely predictive of resistance to challenge exposure during tests performed with certain inactivated vaccines.[68] Challenge studies demonstrating efficacy are required for licensing of all rabies vaccines, including those labeled for use in equids in the United States. The challenge studies are conducted by the vaccine manufacturers as outlined in the Code of Federal Regulations (CFR) from the USDA. These studies indicate a DOI of 12 months and a minimum of 80% of vaccinated animals must be resistant to severe challenge with rabies virus. A DOI of 14 months was documented in a placebo-controlled challenge study in which 4-month-old foals were vaccinated with 1 dose of EquiRab and challenged by masseter injection of virulent rabies virus 14 months later (see product data sheet).

For primary immunization, label directions on inactivated rabies vaccines licensed for use in horses suggest administration of 1 dose to horses aged 3 months or older followed by a second dose 1 year later. Thereafter, annual revaccination is recommended. Although none of the licensed vaccines carries a specific label approval for use in pregnant mares, it is important to acknowledge that only a limited number of equine vaccines are specifically licensed for use in pregnant mares, and veterinarians do administer inactivated rabies vaccines to pregnant mares. Alternatively, veterinarians may recommend that mares be vaccinated against rabies before breeding in order to reduce the number and type of vaccines given in the period before foaling. Because rabies antibodies persist in serum for a prolonged period, foals born to mares that are revaccinated while open acquire substantial titers of rabies antibody after ingesting colostrum.

VetBooks.ir

Documentation of rabies in supposedly vaccinated horses, most of which were younger than age 2, brought into question the efficacy of label recommendations for primary vaccination of foals against rabies.[69] Recent studies in our laboratory have shown that the serologic response of most 3-month-old foals from antibody-positive mares is completely blocked, even when a 2-dose primary vaccination series is used. Although the response to the first dose of vaccine is typically blocked in 6-month-old foals from antibody-positive mares, these foals appear to seroconvert after administration of a second dose 4 weeks later. Primary vaccination of foals from vaccinated mares should therefore be delayed until they are 6 months of age or older and should include 2 doses of inactivated vaccine administered approximately 4 to 6 weeks apart, followed by a third dose at 1 year of age. For foals of mares known not to be vaccinated against rabies, the primary vaccination series can be started according to manufacturers' recommendations as early as 3 months of age and may comprise only 1 dose, followed by a second dose at 1 year of age. For foals from mares of unknown vaccinal history, either of the two following options is rational and can be used: (1) Assume the mare to be antibody positive, and follow the above recommendation for foals from mares known to be vaccinated against rabies, starting at 6 months of age. (2) Document the serum antibody status of the foal by testing serum collected from the foal at 24 hours of age or older or from the dam during the periparturient period, and determine which of the approaches to follow based on the presence or absence of rabies antibodies.

Equine Influenza

Infection of the respiratory tract of horses with the orthomyxovirus influenza A/equine/2 (H3N8) remains one of the most common causes of rapidly spreading outbreaks of respiratory disease. The influenza A/equine/1 subtype (H7N7) has not been recognized as a cause of clinical disease for many years and is likely extinct in nature. Influenza is endemic in the equine populations of the United States and much of the world. Evidence of influenza infection has never been documented in resident horses in New Zealand and Iceland. Whereas outbreaks of influenza have previously been reported in Singapore, Japan, South Africa, and Australia, rigorous control measures have apparently been successful in eliminating the virus from these countries. Rapid national and international transportation of horses facilitates spread of the virus. Concentrating young horses at racetracks, training facilities, boarding stables, breeding farms, shows, or similar athletic events increases the risk of infection, as does a low serum concentration of specific antibody.[70] Older horses are generally less susceptible to infection but may become ill when partial protection is overwhelmed by exposure to horses excreting large amounts of virus. Explosive outbreaks occur at intervals of several years when immunity of the equine population wanes and sufficient antigenic drift has occurred to generate a new viral strain. In contrast to herpesviruses, EIV is not maintained in asymptomatic carrier horses and does not circulate constantly, even within large groups of horses. Rather, the disease is introduced sporadically by a symptomatic or an asymptomatic infected horse. This epidemiologic finding and rapid elimination of the virus by the equine immune response suggest that infection can be avoided by preventing entry of the virus into an equine population (e.g., quarantine of newly arriving horses for at least 14 days) and appropriate vaccination.[71]

EIV is highly contagious and spreads rapidly through groups of horses in aerosolized droplets dispersed by coughing. Contaminated buckets, grooming or feeding equipment, tack, and transport vehicles may serve as fomites, because the virus can survive for hours on such objects. Severity of clinical signs of influenza, which include nasal discharge, fever, lethargy, anorexia, cough, and myalgia, depends on the degree of existing immunity and other factors. Infected horses shed virus for up to 10 days in their nasal secretions. Inactivated vaccines do not induce sterile immunity, so recently vaccinated horses can become infected, shed virus, and contribute to interepidemic persistence of infection within the equine population and propagation of infection during outbreaks.[6]

Immunity to the same (homologous) strain of H3N8 virus after natural infection persists for more than a year and involves both local and systemic humoral and cellular mechanisms These include induction of large amounts of virus-specific neutralizing IgG and secretory IgA antibody in nasal secretions, high levels of circulating IgG antibodies, and genetically restricted antigen-specific cytotoxic T lymphocytes (CTLs) that kill infected cells.[72-76] Memory CTLs can be detected in peripheral blood for at least 6 months after infection, and solid immunity persists even when circulating antibody titers have declined to low or undetectable levels.[73,74,77,78] Similarly, protection induced by the licensed modified live intranasal influenza vaccine (Flu-Avert I.N. [Merck Animal Health]) is presumably mediated through induction of local immune responses in the respiratory tract, because this vaccine does not typically induce high levels of circulating antibody.[7,79] With the exception of ISCOM vaccines, inactivated vaccines administered by IM injection have limited potential to induce CTL or nasal secretory IgA responses, and induce only low levels of neutralizing antibody in nasal secretions.[72,78,80,81] The degree of protection induced by inactivated influenza vaccines is highly correlated with postvaccination titers of circulating antibody, predominantly of the IgGa and IgGb subisotypes, as measured by HI or single radial hemolysis (SRH) tests.[70,82-84] SRH levels of 100 mm^2 or greater are considered to be at least partially protective, but levels above 140 mm^2 are required for successful prevention of disease.[82] The partial protection induced by inactivated vaccines is of limited duration (up to about 7 months, depending on the vaccine) and is manifested as a reduction in clinical signs and attenuation of viral shedding in horses exposed to infection.[71,72]

The magnitude of the serologic response to inactivated influenza vaccines depends on many factors, the most important of which are the quality and quantity (mass) of the viral antigen and choice of the adjuvant.[82,85,86] Carboxypolymer-based compounds (carbomer, Carbopol) and ISCOMs are contained in some of the most efficacious inactivated influenza vaccines, whereas some commonly used adjuvants (e.g., alum) have been associated with induction of a nonproductive immune response.[72,85] History of previous vaccination or infection, interval since the last dose of vaccine, antibody titer at the time of vaccination, age, maternal antibody status, and relatedness of the vaccine strain to circulating field strains of influenza virus are other important determinants of efficacy, at least for inactivated influenza vaccines.[84,87,88]

Antigenic drift of the A/equine/2 subtype has resulted from point mutations in the genes encoding the amino acid sequences of the hemagglutinin (H) and neuraminidase (N) glycoprotein antigens on the surface of the virus. The result is emergence of viral strains representing two antigenic lineages, American and Eurasian, of the H3N8 virus. Further antigenic drift within each lineage has generated variants that, as with the prototypical strain A/equine 2/Miami 63, are named according to the location and year in which they were first isolated. The American lineage further evolved during the 1990s into Kentucky, Florida, and South American sublineages.[89] For the Florida sublineage, two clades have been identified: clade I represented by Ohio 03 and South Africa 03, and clade II represented by Richmond 07. According to the OIE surveillance panel, clade I representatives of the Florida sublineage are present in North America, Europe, South Africa, and Japan; clade II representatives are present in Europe, India, and China.[89]

Antigenic drift, by generating antigenically heterologous viruses, reduces the degree and duration of protection conferred by previous infection or vaccination because of the specificity of immunoglobulins, and it allows horses with high titers to become infected and develop clinical signs of disease if the vaccine strain is not closely related to the drifted infectious field strain.[90] Although antigenic drift of EIV is slower than that of human influenza viruses, it is recommended that inactivated equine influenza vaccines include viral antigens from isolates obtained within the most recent 5 years. An expert surveillance panel meets annually to recommend strains that should be included in influenza vaccines in subsequent years (www.equiflunet.org.uk). In the past, federal U.S. regulations made

VetBooks.ir

updating of equine influenza vaccines through inclusion of recently isolated strains so costly and time-consuming that vaccines typically lagged more than the recommended 5 years behind the antigenic drift of field viruses, resulting in suboptimal protection. Recent changes in vaccine licensing regulations should make more frequent updating of equine influenza vaccines feasible. Even though Flu-Avert I.N. contains only a 1991 H3N8 strain of North American lineage, it has been shown to be protective against challenge with Eurasian strains and recently isolated North American strains.

The short-lived immunity after vaccination with inactivated equine influenza vaccines was the impetus for past recommendations for frequent revaccination, at intervals as short as 2 months. However, too short an interval may compromise efficacy because an optimal anamnestic response to influenza vaccination is inhibited in horses with a high antibody titer.[91] An additional consideration that potentially limits the efficacy of influenza vaccines is the phenomenon termed *original antigenic sin*, whereby horses exposed to a drifted field A/equine/2 virus will mount an anamnestic immune response directed more strongly against the strain with which they were vaccinated initially than against the drifted field virus.[86]

A considerable amount of published efficacy data based on both challenge studies and field epidemiology studies has been available for many years in Europe to support the use of influenza vaccines. In contrast, information regarding the efficacy of influenza vaccines marketed in North America has remained sparse until recently. Furthermore, studies conducted in North America during the late 1990s showed that the inactivated influenza vaccines in use at the time failed to provide much benefit in terms of reducing the risk of infection and clinical disease during field outbreaks.[6,70] Serologic testing performed during these and other studies indicated that vaccine failure was caused by failure of the influenza vaccines in use at the time to induce protective antibody titers.[6,70,92]

Fortunately, vaccine manufacturers in North America have responded to the challenge of producing more efficacious equine influenza vaccines during the past 15 years by incorporating more relevant recent viral strains, increasing antigenic mass of relevant strains, eliminating the seemingly irrelevant H7N7 strain, modifying adjuvant systems, and introducing novel technologies. An important advance occurred in 1999 when Heska Corporation marketed an attenuated live cold-adapted influenza vaccine (Flu-Avert I.N. [Merck Animal Health]) for intranasal administration. This vaccine, which contains a Kentucky/1991 strain of North American lineage, was found to be highly efficacious in blinded controlled challenge studies conducted 5 weeks, 6 months, and 1 year after administration of a single dose to naive horses.[7] Subsequently, Flu-Avert I.N. was shown to cross protect against European H3N8 strains, as well as against North American strains isolated during the late 1990s and early 2000s, and to induce a rapid onset of protection within 7 days of administration of a single dose to naive horses.[79,93] Although horses challenged 1 year after administration of a single dose showed a significant but only partial reduction in severity of clinical signs and virus shedding, a more marked reduction in clinical signs and viral shedding was found when the challenge was performed 6 months after vaccination.[7] Based on these results, revaccination at 6-month intervals is recommended. Field experience indicates that this regimen induces solid clinical protection after natural challenge. Currently, Flu-Avert I.N. is licensed for use in non-pregnant horses 11 months of age or older, primarily because this was the youngest age of the horses used in the challenge studies for licensing. Horses may shed small amounts of vaccinal virus for several days after vaccination with Flu-Avert I.N., but the amount of virus shed is so low that in-contact horses will not generally become infected or immunized with vaccinal virus shed by recently vaccinated horses, and the likelihood of reversion to virulence is extremely low.[94]

In recent years, several vaccine manufacturers in North America have updated their inactivated vaccines and demonstrated efficacy in challenge studies. Inactivated influenza vaccines containing one or more relevant H3N8 strains are currently marketed by Boehringer Ingelheim (Calvenza EIV), Zoetis (Fluvac Innovator), and Merck Animal Health (Prestige II). Each of these vaccines contains at least one American-type and one Eurasian-type strain of EIV. These companies also market a large number of multicomponent combination vaccines that contain the same inactivated influenza antigens as in their single-component products but also contain tetanus, WEE and EEE virus, EHV, or WNV antigens.

A study in which naive 9-month-old horses were challenged by aerosol with a recent influenza H3N8 strain (KY/99) 16 weeks after the last dose of a 3-dose vaccination series (0, 4, and 16 weeks) documented that Calvenza EIV and two EIV/EHV combination vaccines (Prestige II and Fluvac EHV-4/1) reduced clinical signs and viral shedding in vaccinated horses compared with nonvaccinated control horses.[96] The group vaccinated with Calvenza EIV developed significantly higher serum antibody titers after vaccination and experienced less fever, nasal discharge, and viral shedding than horses vaccinated with either Prestige II or Fluvac EHV-4/1. Based on these findings, the authors concluded that Calvenza EIV, a vaccine developed, formulated, and efficacy-tested according to European Union guidelines, was the most effective inactivated influenza vaccine available in North America at that time. This vaccine is adjuvanted with Carbopol and contains the KY/95 and Ohio 03 North American strains and the Newmarket 93 Eurasian H3N8 strains. The initial two doses of this vaccine are administered IM; subsequent doses may be administered IM or intranasally. It is proposed, but not proved, that administration of booster doses by the intranasal route may provide a stronger local mucosal immune response. This vaccine is licensed for use in horses older than 6 months of age, including pregnant mares. Prestige II currently contains the KY/93 and KY/2002 North American strains and the Newmarket 93 Eurasian H3N8 strains. The metabolizable oil (MetaStim) adjuvanted Fluvac vaccine evaluated in the above challenge study contained the KY/92 strain of H3N8 virus. This strain has since been replaced with a KY/97 strain and the product is now named Fluvac Innovator. Although OIE has recommended that it is no longer necessary to include Eurasian H3N8 strains in vaccines, Fluvac Innovator is the only equine influenza vaccine in North America that does not contain a Eurasian strain.

In 2006, Merial was granted a North American license to market an injectable canarypox-vectored recombinant equine influenza vaccine that has been used with success in Europe for several years. This vaccine, Recombitek Equine Influenza Virus vaccine, has been shown to induce strong protection in challenge studies and has the potential to positively impact influenza prevention in North America.[95] The vaccine incorporates the HA gene from the Ohio 03 and Newmarket 93 H3N8 strains into the same vector delivery platform as the efficacious WNV virus vaccine (Recombitek) and contains a carbomer polymer adjuvant in the diluent.[95] Consequently, this vaccine invokes a broad array of humoral and cellular immune responses. Challenge studies document onset of protection as soon as 2 weeks after completion of a 2-dose primary series and persistence of solid protection for at least 5 months. Administration of a booster dose at 5 months induced a strong anamnestic response that provided solid protection persisting for at least 12 months.[96] This vectored influenza vaccine can circumvent the inhibitory effect of maternal antibodies, an issue that significantly impacts primary immunization of foals using inactivated influenza vaccines.[30] Recombitek Equine Influenza Virus vaccine is licensed for vaccination of healthy horses as young as 5 months of age.

VACCINATION PROTOCOLS FOR INFLUENZA. Influenza should be considered a core vaccine on all facilities that are not totally closed so as to preclude contact with "outside" horses from other locations. As with other diseases, the full benefit of vaccination against influenza can be realized only if the primary vaccination series is completed, or booster doses of vaccine administered, several weeks before anticipated exposure. The following 5 issues should be considered when planning an influenza vaccination program: (1) primary vaccination of adult horses, (2) routine revaccination, (3) vaccination of pregnant mares, (4) primary vaccination of foals, and (5) vaccination in an outbreak.

VetBooks.ir

Primary Vaccination of Adult Horses

The following are options for primary vaccination of adult horses that have not previously been vaccinated:

- Flu-Avert: administer a single dose intranasally. A second dose administered 3 months later may be beneficial, particularly for horses vaccinated at younger than age 11 months.
- Inactivated IM-administered vaccines: administer 2 doses 3 to 6 weeks apart according to label directions. Although not specifically recommended by some manufacturers, administration of a third dose of vaccine 3 to 5 months after the second dose is indicated because it significantly enhances the magnitude of the primary response and duration of persistence of antibodies at protective levels.
- Recombitek Equine Influenza Virus vaccine: administer 2 doses 4 to 6 weeks apart, and revaccinate 5 months later.

Routine Revaccination

Improvements in injectable vaccines and introduction of new vaccine types during the past 15 years has extended the duration of clinical protection achievable through vaccination. A routine revaccination interval of 6 months appears to be appropriate for most of the influenza vaccines currently marketed in North America. This routine protocol should be customized by adjusting timing of boosters or inclusion of an additional booster to achieve maximum protection during periods when the risk of exposure is high. For example, strategic revaccination 1 month before being placed at high risk of exposure, such as at a show or sale or being transferred to a training or boarding facility, is justified to maximize protection.

Vaccination of Pregnant Mares

For the mare to produce colostrum that contains a high level of antibodies against equine influenza, she should be revaccinated 4 to 8 weeks before foaling with a vaccine that stimulates a robust serologic response. Although the intranasally administered Flu-Avert I.N. vaccine induces good protection, it does not routinely stimulate high levels of circulating antibody, at least when used for primary immunization. An inactivated injectable vaccine is therefore recommended for pre-foaling booster vaccination of pregnant mares at this time.[26]

Vaccination of Foals

The antibody status of a mare at the time of foaling is the main determinant of the postnursing circulating antibody titer in her foal and therefore has a profound impact on the ability of the foal or weanling to respond to influenza vaccines administered during the first year of life. Foals born to seronegative nonvaccinated mares respond appropriately to influenza vaccines, so primary vaccination can commence at 3 months of age or younger if significant risk of exposure to influenza exists. In contrast, maternal antibodies have been shown to completely block the serologic response of foals to a primary immunization series comprising 2 or more doses of inactivated influenza vaccines when the first dose is administered at 6 months of age or younger.[12-18,24] Interference from MDA may persist until 9 months of age or beyond for foals with high antibody titers post nursing.[12-18,24,26] Studies in Newmarket, United Kingdom, have shown that influenza virus infection is rare in Thoroughbred yearlings before they enter training, suggesting that the risk of influenza is low in horses younger than age 1 year born to mares in herds that are well vaccinated.[88,97,98] There appears to be little justification to vaccinate young foals from vaccinated mares against influenza, as was recommended in the past.[48,99,100]

The intranasal modified live vaccine (Flu-Avert I.N.) is licensed for vaccination of horses 11 months of age or older. Whereas this vaccine has been shown to be safe in foals as young as 2 months of age,[101] published data regarding the potential for MDAs to interfere with the response are lacking. Unpublished observations suggest that MDA interferes with the response of foals between 3 and 6 months of age, whereas foals with maternal antibody vaccinated at 7 months of age were protected against virulent challenge (Holland and Chambers, personal communication). Pending publication of well-controlled studies, it is recommended that if the first dose of Flu-Avert I.N. vaccine is administered before 11 months of age, a second dose should be administered at 11 months of age or older.[102]

The European-licensed live canarypox-vectored recombinant influenza is labeled for use in pregnant mares and foals as young as 4 months.[78] The North American–licensed Recombitek Equine Influenza Virus vaccine has been shown to be safe in foals as young as 4 months, but the minimum age recommended for vaccination of foals from immunized dams is 5 months. The recombinant vaccine has been shown to efficiently prime foals aged 10 to 20 weeks that had detectable MDA at the time of vaccination.[30] These foals showed clear evidence of an anamnestic antibody response when a secondary vaccination with the same vaccine was performed. The canarypox-vectored recombinant influenza vaccine therefore offers a unique opportunity to overcome the limitations of early life vaccination in the face of maternally derived immunity in foals.[30] If the foal experiences failure of passive transfer of maternal antibodies, or if the mare is seronegative for influenza, the manufacturer recommends commencing vaccination at 4 months of age and including an additional dose in the primary series.

Vaccination in an Outbreak

Definitive diagnosis of equine influenza infection should be pursued during outbreaks of suspected viral respiratory disease, because specific measures can then be instituted to contain spread of the disease. Rapid (same-day) diagnosis of influenza can be accomplished using the highly sensitive and specific polymerase chain reaction (PCR) or antigen-capture ELISA tests. In addition, virus isolation should be pursued during outbreaks to characterize new isolates and assess efficacy of current vaccines. The decision to vaccinate in an outbreak is dependent on many factors, the most important of which are the age, vaccination status, and size of the population of horses at risk; the elapsed time since onset of the outbreak; the rapidity with which a diagnosis can be confirmed; the layout of the physical facilities; and availability of personnel. Outbreaks of influenza at racetracks and similar large facilities typically take 1 month or more to spread through the entire population. Therefore, sufficient time exists to enhance immune protection of many at-risk horses while implementing other management strategies to minimize disease spread.[93] It is prudent to booster-vaccinate those horses that have been on a regular influenza vaccination program but have not been revaccinated within the previous 3 months. It is also important to induce protection as quickly as possible in horses that have not previously been vaccinated. Of the vaccines currently available, Flu-Avert I.N. induces protection most rapidly, within 7 days of administration of a single intranasal dose. This is currently the product of choice for vaccination of naive horses and those of unknown vaccination status in the face of an outbreak.[93] Adverse effects have not been reported when Flu-Avert I.N. is administered to horses that are incubating infection, although vaccination of horses that are already clinically ill is not recommended. Alternatively, an accelerated vaccination schedule using the canarypox-vectored vaccine with a primary intervaccination interval of 14 days and booster at 105 days has been shown to quickly confer long-lasting protective antibody levels.[103] All 14 vaccinates demonstrated high SRH antibody titers 14 days following V2, thereby achieving 100% herd immunity to homologous viral challenge. Rapid induction of high levels of acquired herd immunity is critical in containing an outbreak of such a highly contagious pathogen as EIV.[103] In addition to reducing clinical and economic impacts, early vaccination clearly played an important role, together with biosecurity measures and movement restrictions, in containing the 2007 equine influenza outbreak in Australia, as well as ultimate eradication of the disease from that country.[104]

FUTURE INFLUENZA VACCINES. A recombinant modified vaccinia Ankara (rMVA) vector that delivers genetic material encoding for relevant hemagglutinin (H) antigens of an H3N8 influenza virus has been developed.[105,106] The rMVA system is designed to focus the

VetBooks.ir

CTL response on the recombinant antigen and was initially tested in a prime-boost strategy in which the priming dose consisted of a DNA plasmid encoding for expression of the H antigen. The intent of this DNA prime-rMVA boost regimen was to invoke both cellular and humoral immune responses involved in protection.[106] A subsequent study showed that the rMVA system was capable of inducing virus-specific lymphoproliferative and IFN-γ messenger ribonucleic acid (mRNA) responses; antigen-specific IgGa, IgGb, and IgA antibodies; and protection from challenge, both with and without a priming dose of the DNA vaccine.[105] These data indicate that vaccination of horses with rMVA alone or as part of a prime-boost regimen is an effective means of inducing protective immunity to influenza virus infection.[105] Considerable research has been performed to document the efficacy of the DNA vaccine used in the above studies against equine influenza. However, the delivery system used (multiple sublingual, conjunctival, and subcutaneous [SC] injections delivered with a gene gun under general anesthesia) is impractical for use in the field.[105,107] Recent licensing of a naked plasmid DNA vaccine that can be conveniently administered to horses by IM injection to prevent WNV infection clearly documents the potential for development of a DNA vaccine to prevent influenza in horses in the future. Additionally, a DNA vaccine expressing the hemagglutinin protein of H3N8 influenza virus was recently shown to protect ponies against challenge when administered subdermally using a needle-free delivery system.[108]

Equine Herpesvirus (Rhinopneumonitis)

The respiratory tract is the primary route of infection for both EHV-1 and EHV-4, both of which cause respiratory tract disease that varies in severity from subclinical to severe and is characterized by fever, lethargy, anorexia, nasal discharge, and cough.[109] Seroepidemiologic studies indicate that the vast majority of foals become infected with EHV-1 and EHV-4 during the first year of life, but the clinical disease syndromes resulting from these infections are not always well defined, perhaps reflecting the modulating effect of MDAs.[110-112] Recurrent or recrudescent clinically apparent infections are seen in weanlings, yearlings, and young horses entering training, especially when horses from different sources are commingled.[109,113] In contrast, surveillance studies involving racehorses document that seroconversion to both EHV-1 and EHV-4 occurs sporadically during the course of a racing season, but these seroconversions are often not clearly associated with outbreaks of respiratory disease that follow an epidemiologic pattern consistent with an infectious agent.[114,115] EHV-1 and EHV-4 are spread by direct and indirect (fomite) contact with nasal secretions, by aerosolized secretions from infected horses, and in the case of EHV-1, by aborted fetuses, fetal fluids, and placentae associated with abortions. Management practices are therefore of primary importance for control of clinical disease caused by equine herpesviruses.

Viremia occurs frequently after infection with EHV-1, potentially leading to paralytic neurologic disease (equine herpes myeloencephalopathy [EHM]) secondary to vasculitis of the spinal cord and brain, abortion of virus-infected fetuses, or birth of infected nonviable foals. In contrast, manifestations of infection with EHV-4 (rhinopneumonitis) are generally confined to the respiratory tract because EHV-4 does not typically infect endothelial cells or produce a cell-associated viremia.[116] As with herpesvirus infections in other species, horses typically fail to clear primary infections with either EHV-1 or EHV-4, the result being that most horses in the population remain latently infected with both viruses.[109,112,117] Latently infected horses do not show clinical signs but may experience recrudescence of infection with or without clinical signs, an increase in antibody titer, and shedding of the virus when stressed. Consequently, many horses have detectable levels of SN antibody to both EHV-1 and EHV-4 in their serum.[109,112,117] These features of the epidemiology of herpesvirus infections seriously compromise efforts to control these diseases and explain why outbreaks of EHV-1 or EHV-4 can occur in closed populations of horses. Whereas most mature horses have developed some immunity to EHV-1 and EHV-4 through repeated natural exposure and do not typically show respiratory signs when they become reinfected, horses do not appear to become resistant to the abortigenic or neurologic forms of infection with EHV-1 even after repeated exposure.[118] In fact, previously exposed mature horses are more likely than juvenile horses to develop the neurologic form of the disease.[119,120]

The genetic basis underlying the apparent increased likelihood that some EHV-1 isolates will cause EHM appears to involve a single point mutation in the DNA polymerase *(DNApol)* gene.[121] This mutation results in the presence of either aspartic acid (D) or an asparagine (N) residue at position 752. More than 80% of EHV-1 isolates associated with EHM are of the D_{752} form, whereas less than 20% are of the N_{752} form.[121] Isolates of the D_{752} form have been designated "neuropathogenic strains" in recent publications, lay articles, and laboratory PCR result reports, whereas N_{752} isolates have been designated as "wild-type," "abortigenic," or "non-neuropathogenic." The latter terminology is unfortunate because both the D_{752} and N_{752} isolates are capable of inducing all syndromes (i.e., respiratory disease, abortion, neonatal death, and EHM).

Correlates for protection against EHV-1 and EHV-4 infection have been investigated extensively but are not yet fully defined. Infection with EHV-1 induces a strong humoral response, but protection from reinfection is short lived and is not achieved until the horse has experienced multiple infections with homotypic virus.[109,116] No clear relationship exists between protection from EHV-1 or EHV-4 infection and concentrations of circulating antibody induced by vaccination or infection, but clinical manifestations of disease and the duration and amount of virus shedding from the nasopharynx are reduced in animals with high levels of circulating neutralizing antibody.[116,122-126] Mucosal immunity and cell-mediated responses likely play a role at least as important as circulating neutralizing antibodies in protection against EHV-1 infection,[127] because the presence of MHC class 1–restricted CTL precursors in peripheral blood is correlated with protection.[116] Because EHV-4 replication is largely confined to epithelial cells of the upper respiratory tract, mucosal immunity is likely important in protection.[116]

Currently available vaccines include inactivated vaccines containing only EHV-1 or both EHV-1 and EHV-4, and one MLV EHV-1 (Rhinomune [Boehringer Ingelheim]). Several inactivated products are licensed only for protection against respiratory disease; currently, all contain a low antigen load. Two inactivated products (Pneumabort-K + 1b [Zoetis] and Prodigy [Merck Animal Health]) that contain a high antigen load are licensed for protection against both abortion and respiratory disease. Performance of the killed low-antigen-load respiratory vaccines is variable, with some vaccines outperforming others. Performance of the killed high-antigen-load abortion/respiratory vaccines is superior, resulting in higher antibody responses and some evidence of cellular responses to vaccination. This factor may provide good reason to choose the high-antigen-load abortion/respiratory vaccines when the slightly higher cost is not a decision factor. Alternatively, the Calvenza EIV/EHV (Boehringer Ingelheim) respiratory vaccine induces high titers of VN antibody comparable to those induced by the high-antigen-load abortion/respiratory vaccines.[8] The MLV EHV-1 vaccine (Rhinomune [Boehringer Ingelheim]) has been shown to induce a level of clinical protection and reduction in viral shedding of similar magnitude to that provided by an inactivated high-antigen-load vaccine (Pneumabort-K + 1b) and of greater magnitude than is provided by one of the killed low-antigen-load respiratory vaccines.[128] Whereas vaccination with either EHV-1 or EHV-4 can provide partial protection against the heterologous strain, vaccines containing EHV-1 may be superior in this regard.

The principal indication for use of equine herpesvirus vaccines is prevention of EHV-1-induced abortion in pregnant mares, and reduction of signs and spread of respiratory tract disease (rhinopneumonitis) in foals, weanlings, yearlings, and young performance and show horses that are at high risk of exposure. Many horses do produce postvaccinal antibodies against EHV, but the presence of those antibodies does not ensure complete protection. Consistent vaccination appears to reduce the frequency and severity of herpesvirus-induced

VetBooks.ir

disease. Although convincing evidence is lacking, field experience suggests that whereas the incidence of sporadic EHV-1–induced abortion in individual mares has not changed, the incidence of abortion storms caused by EHV-1 has declined significantly since the introduction and widespread use of EHV-1 vaccines in the United States.[117,118] Outbreaks of abortion and associated perinatal foal death, however, do continue to occur on occasion in herds of vaccinated mares.

Of the vaccines currently licensed for use in pregnant mares in North America, only inactivated monovalent EHV-1 vaccines (Pneumabort-K + 1b and Prodigy) containing abortigenic strains of EHV-1 carry a label claim for preventing abortion, whereas at least one bivalent EHV-1/4 vaccine is licensed for prevention of abortion in Europe (Duvaxyn EHV-1/4 [Intervet]). One of the vaccines available in North America, Pneumabort-K + 1b, incorporates both the 1p and 1b subtypes of EHV-1 to reflect the documented increase in the proportion of EHV-1 abortions caused by the 1b subtype that occurred during the 1980s as compared to earlier years.[129] Pregnant mares should be vaccinated during the fifth, seventh, and ninth months of gestation. Some veterinarians also recommend a dose during the third month of gestation. Similarly, vaccination of mares with an inactivated EHV-1/4 vaccine at the time of breeding and again 4 to 6 weeks before foaling is commonly practiced to enhance concentrations of colostral immunoglobulin for transfer to the foal. However, no published reports document the effectiveness of this approach in raising titers of specific antibody in mares that have already been vaccinated against EHV-1 3 times during the previous 5 months. Vaccination of barren mares and stallions with either a bivalent EHV-1/4 vaccine or a monovalent EHV-1 vaccine before the start of the breeding season and thereafter at 6-month intervals is recommended, with the goal of increasing herd immunity in an attempt to reduce viral shedding and challenge to pregnant mares on breeding farms.[117]

An MLV EHV-1 vaccine (Rhinomune) has been used as an aid in prevention of EHV-1 abortion by some practitioners for many years,[130] even though this vaccine is not currently labeled for this use. Several recent developments have created renewed interest in the potential for use of MLV vaccines to protect horses against manifestations of EHV-1 and EHV-4 infection. Sequencing of the EHV-1 genome has made it possible to document the nature of the mutation encoding for attenuation, mediated through truncation of the gp2 glycoprotein of the KyA strain.[131] Similar studies may soon yield information regarding the mutation underlying attenuation of the RAC-H strain from which Rhinomune was derived.

Because currently available inactivated vaccines do not block infection with equine herpesviruses, the most we can hope for when using inactivated vaccines is reduction of severity of clinical signs and attenuation of virus shedding to help protect herdmates. Challenge studies in weanlings aged 5 to 8 months have clearly demonstrated the efficacy of an inactivated whole virus EHV-1/4 vaccine in reducing clinical manifestations and virus shedding induced by virulent EHV-1 challenge administered 2 weeks after completion of the 2-dose primary series.[125] Efficacy was clearly correlated with vaccine-induced antibody levels at the time of challenge in this study.[125]

Specific antibodies against both EHV-1 and EHV-4 are passed in colostrum.[22,25,132-134] Field studies with EHV-1 MLVs indicate that colostral antibodies exert a profound inhibitory effect on serologic responses to vaccination up to at least 5 months of age.[21,135,136] However, a cytotoxic cellular immune response to both EHV-1 and EHV-4 was induced in a substantial percentage of foals vaccinated with an EHV-1 MLV in the presence of maternal antibody, even though humoral responses were often absent.[137] It is uncertain whether these responses would provide protection against natural challenge. Recent studies with two different commercially available inactivated bivalent EHV-1/4 vaccines and one inactivated EHV-4/influenza vaccine have shown that the majority of foals from EHV-vaccinated mares do not mount a detectable neutralizing antibody response to vaccines administered at 3 and 4 months of age, even when 3 doses are administered in the primary series.[22,24,25] An increased proportion of foals responded when vaccinated with a 3-dose series starting at 5 or 6 months of age, but a substantial number still failed to seroconvert.[24,25] Some foals with low or undetectable levels of SN antibody at the time of vaccination failed to mount a serologic response, suggesting that low levels of antibody, below the lower limit of detection of the SN test based on EHV-1 antigen, are capable of inhibiting the serologic response to inactivated EHV-1/4 vaccines.[25] The failure of a large proportion of foals younger than 6 months of age to mount serologic responses to inactivated EHV-1/4 vaccines and the influence of antibody titer at the time of vaccination on failure to respond has been confirmed using sensitive gD and gG ELISAs in studies on commercial stud farms in Australia.[138] In parallel studies, these researchers concluded that mares were the source of infection for foals, and intensive use of inactivated EHV-1/4 vaccines on breeding farms in Australia had a minimal impact on the infection rate of young foals and weanlings with EHV-1 and EHV-4.[110,112,139]

Considering the uncertainty regarding the role of EHV-1 and EHV-4 as causes of clinically important respiratory disease, the lack of published data regarding the efficacy of available vaccines in preventing infection and establishment of latency, and results of a recent study documenting the poor serologic responses of naive horses to a number of killed low-antigen-load EHV respiratory vaccines currently marketed in North America,[8] there appears to be little rationale to support the common practice of frequent revaccination of foals, weanlings, yearlings, and young performance horses against EHV-1 and EHV-4.[5] Furthermore, an obvious dilemma in designing a vaccination strategy to prevent EHV-1 and EHV-4 infection in foals and weanlings is that if primary immunization is delayed until 6 months of age or older to reduce the likelihood of MDA interference, foals are likely to encounter field infection before the 3-dose primary series can be completed. It is therefore unreasonable to expect a high degree of efficacy for vaccination programs designed to protect foals and weanlings against EHV infection using available vaccines. Despite these uncertainties, many practitioners elect to vaccinate against both EHV-1 and EHV-4. Under these circumstances, a reasonable compromise would be to start foal vaccination at 4 to 6 months of age using 2 doses of an inactivated bivalent vaccine or an EHV-1 MLV administered 3 to 4 weeks apart, followed by administration of a third dose 2 to 5 months later. Revaccination at 4- to 6-month intervals, thereafter using either an inactivated bivalent vaccine or a modified live EHV-1 vaccine, appears appropriate for yearlings and young performance or show horses that experience contact with other horses. Frequent vaccination of non-pregnant mature horses (except those on breeding farms) with EHV vaccines is generally not indicated.

Available vaccines make no labeled claim to prevent EHM, and there is no evidence that current vaccines can prevent EHM in the field. Frequent revaccination of mature horses to help prevent EHM is not justified in most circumstances because EHM is a relatively rare disease from a population standpoint, and most mature horses have previously been infected with EHV-1 and are latent carriers. Currently available vaccines do not reliably block infection, development of viremia, or establishment of latency, and EHM has been observed in horses vaccinated against EHV-1 regularly at 3- to 5-month intervals with inactivated or modified live vaccines.[119,120,140,141]

Based on the presumed similar pathogenic mechanism between EHV-1 abortion and neurologic disease,[142,143] parallels likely exist in terms of the requirement for immunologic protection. The control of cell-associated viremia is thought to be critical for preventing EHV-1 abortion and, presumably, neurologic disease. Therefore, the goal of any vaccination program aimed at the prevention of EHV-1 abortion or neurologic disease is to stimulate those immune responses that can reduce or eliminate cell-associated viremia. Two recent studies have investigated the protective effect of commercially available killed and MLV vaccines against experimental challenge with neurotropic EHV-1 strains 24 or 29 days after completion of a 3-dose vaccination series.[122,123] A significant reduction in the level of viremia

VetBooks.ir

was noted in ponies challenged after vaccination with either Calvenza or Pneumabort-K + 1b, both of which are inactivated vaccines.[122,123] Reduction in viremia post challenge was not observed in ponies vaccinated with another inactivated vaccine (Prodigy) or the MLV vaccine (Rhinomune).

A challenge study performed almost 30 years ago to test the efficacy of Pneumabort-K + 1b in preventing abortion and a recent study to test the efficacy of Rhinomune against challenge with a "neuropathogenic" strain of EHV-1 provided some evidence that these vaccines may have a place in control of outbreaks of EHM.[126,128] Interestingly, the Army 183 EHV-1 strain used as the challenge virus in the Pneumabort-K + 1b efficacy study has now been shown to carry the D_{752} mutation, as has the Findlay 03 strain used in the Rhinomune study. However, the low numbers of horses used in these studies, the failure of either vaccine to prevent infection or significantly reduce the level of viremia, the lack of statistical significance of results pertaining to prevention of neurologic signs, and the well-known difficulties encountered in accomplishing a consistent and reproducible challenge model for neurologic EHV-1 infection justify caution in interpretation.

The significant reduction in viral shedding observed in vaccinated horses provides reasonable justification for booster vaccination of nonexposed horses at risk for infection to reduce viral shedding in the event they do become exposed to EHV-1. By enhancing herd immunity, it is hoped that the level of infectious virus circulating in the at-risk population will be reduced, and in turn the risk that individual horses in the population will develop disease may be reduced.[140] This approach also relies on the assumption that the immune system of most mature horses has already been "primed" by prior exposure to EHV-1 antigens through field infection or vaccination and can therefore be "boosted" within 7 to 10 days of administration of a single dose of vaccine. Although the validity of this approach has not been critically evaluated for prevention of EHV-1 neurologic disease, its implementation seems rational when faced with one or more horses with confirmed clinical EHV-1 infection (any form) at a particular facility. Whereas booster vaccination of horses likely to have already been exposed is not recommended, it is rational to booster vaccinate nonexposed horses, as well as those that must enter the premises, if they have not been vaccinated against EHV-1 during the previous 90 days. Use of the Rhinomune MLV or one of the inactivated EHV-1 vaccines known to stimulate high circulating titers of neutralizing antibody appears justified for this purpose. Horse owners must develop an understanding of the concept of boosting herd immunity to help protect the group of horses rather than focusing on the as yet unattainable expectation that the veterinarian can reliably protect an individual horse from developing potentially fatal EHM by administering one of the vaccines currently marketed as aids to prevention of clinical manifestations of EHV-1 infection. Ultimately, enforcement of strict biosecurity measures and hygiene practices are likely to be more effective than widespread vaccination in reducing the risk of acquiring infection.

FUTURE VACCINATION STRATEGIES TO PREVENT HERPESVIRUS INFECTION. To be completely effective in blocking primary infection and establishing a lifelong carrier state with EHV-1 and EHV-4, future vaccination strategies should be directed at inducing a strong mucosal immune response in the upper respiratory tract during the first few weeks of life, at a time when high levels of maternal antibodies are present. Promising progress toward this goal was reported by Patel and colleagues,[144] who documented that intranasal administration of a single dose of temperature-sensitive modified live EHV-1 vaccine to maternal antibody-positive foals aged 1.4 to 3.5 months afforded partial but significant protection against febrile respiratory disease, viremia, and virus shedding after intranasal challenge with virulent EHV-1 performed 8 weeks after vaccination. This vaccine has also been shown to provide significant protection against abortion in challenge studies, and because it is capable of preventing the development of viremia, shows potential to prevent EHM.[127,145] Recent studies with vaccinia and canarypox-vectored recombinant vaccines and DNA vaccines have generated promising results, but more research will be needed to identify the immunodominant protective antigens of EHV-1 and their interaction with the equine immune system before these approaches will be applicable for use in the field.[146-150]

The recent Third International Havemeyer Workshop on Equine Herpesvirus Type 1 highlighted the need to improve vaccines, with MLV being identified as the vaccine type most likely to be successful in inducing a protective immune response.[151] The identified goals of future vaccine candidates will be to stimulate both humoral and cell-mediated immunity, be able to differentiate infected from vaccinated animals (DIVA), provide minimal gaps in immunity, induce a rapid onset and long-lasting immunity, be effective in the presence of maternally derived antibody to prevent infection early life, provide a wide clinical and virologic cross-protection, be safe and effective against the development of EHM, suppress reactivation of latent EHV-1 infection, and be safe when used in the face of an outbreak.[151]

Streptococcus equi subsp. *equi* Infection (Strangles)

Strangles is a highly contagious disease caused by the bacterium *Streptococcus equi* subsp. *equi (S. equi)*. Strangles primarily affects young horses (weanlings and yearlings), although horses of any age can become infected if not protected by previous exposure to the organism or by vaccination. The organism is transmitted by direct contact with infected horses or subclinical carriers, or indirectly by contact with water troughs, feed bunks, pastures, stalls, trailers, tack, or grooming equipment contaminated with nasal discharge or pus draining from lymph nodes of infected horses. The organism survives for several weeks in the environment, particularly in aquatic locations and when protected from exposure to sunlight and disinfectants, and can be a source of infection for new additions to the herd. Because *S. equi* is a clonal organism, there is minimal antigenic variation between different isolates even though isolates vary in their pathogenicity.

Most horses develop a solid immunity during recovery from strangles, which persists in over 75% of animals for 5 years or longer,[152] indicating that induction of durable protection through vaccination is biologically feasible if the protective antigens can be identified and presented in an appropriate manner.[153] Although the basis for acquired resistance to strangles is not completely understood, the finding that recovered horses rapidly clear intranasally inoculated *S. equi* despite not making circulating antibody to its surface proteins indicates that to be highly effective a strangles vaccine must stimulate local nasopharyngeal tonsillar immune clearance responses and that serum antibody is of lesser importance.[154] This conclusion is further supported by the finding that ponies with high levels of circulating antibody to multiple unique surface-exposed and secreted proteins after systemic vaccination remained susceptible to challenge with *S. equi*.[154] The cell wall M protein of *S. equi* (Se-M) is recognized in the acquired immune response to *S. equi* infection, a response that involves both production of local antibodies in the nasopharynx and circulating opsonophagocytic antibodies.[155-157] The predominant opsonophagocytic antibodies are of the IgGb subisotype but also include IgGa and IgA, whereas IgGb and later mucosal IgA predominate in nasopharyngeal secretions.[156,158]

Strangles vaccines licensed and marketed for use in North America include one inactivated adjuvanted M-protein cell wall extract (Strepvax II [Boehringer Ingelheim]) and one attenuated live vaccine (Pinnacle I.N. [Zoetis]) derived from a nonencapsulated mutant of *S. equi* for intranasal administration.[159] Infection of horses with *S. equi* continues to cause troublesome outbreaks of strangles throughout North America, despite the availability and widespread use of these vaccines, indicating that their efficacy is suboptimal.[160] M-protein vaccines induce a good opsonophagocytic antibody response in serum but a minimal mucosal IgA response, which likely accounts for the incomplete protection observed when they are used in the field.[156,161] However, data do exist to document that vaccination using injectable SeM vaccines reduces the attack rate and

VetBooks.ir

severity of strangles in herds with endemic infection.[161-163] The live intranasal vaccine has been shown to induce a relevant mucosal immune response and partial or complete protection but may do so without inducing a strong serologic response.[160,164] Because vaccinal organisms in the intranasal vaccine must reach the inductive sites for immunity in the pharyngeal and lingual tonsils, accurate vaccine delivery is critical to vaccine efficacy.

Vaccination against *S. equi* is not routinely recommended for pleasure or performance horses kept in low-risk situations, but it is a consideration for horses that are resident on or being transported to premises like breeding farms where strangles is a persistent endemic problem or where a high risk of exposure is anticipated. The bacterial MLV is generally preferred over the inactivated injectable vaccine for primary vaccination of foals and weanlings and for routine use in older horses at high risk for infection. On breeding farms, efforts should be concentrated on preventing infection of foals and weanlings by booster-vaccinating broodmares 4 to 6 weeks before foaling to maximize colostral content of antibodies. Whereas the intranasal vaccine has been shown to be safe for use in mares at all stages of pregnancy and can be used in mares in the face of an outbreak, it does not reliably stimulate high levels of circulating antibody. For this reason, the IM-administered inactivated SeM product is preferred for pre-foaling booster immunization of mares. Antibodies of the IgG and IgA class recognizing the SeM are passively transferred to the foal through colostrum and are also present in the milk of immune mares.[165] Antibodies of predominantly the IgGb isotype are absorbed from colostrum and redistribute to the nasopharyngeal mucosa.[158] These IgGb antibodies, along with the SeM-specific IgA antibodies that are present in milk and passively coat the pharyngeal mucosa of nursing foals, provide protection to most nursing foals up to the time of weaning.[157,158,165] Resistance of nursing foals to strangles during the first few months of life appears to be mediated by IgGb antibodies in nasal secretions and milk and not by IgA.[165] Serologic (ELISA) responses to M-protein vaccines are poor in foals, most likely owing to the inhibitory effect of maternal antibodies.

Whereas the intranasal MLV may be less susceptible than the inactivated extract vaccines to MDA interference, this issue has not been investigated, and the manufacturer does not recommend administration of this vaccine to horses younger than 9 months of age. Considering that on farms where strangles is endemic, foals often become infected around the time of weaning (age 4 to 8 months), it is difficult to protect them if vaccination is delayed until age 9 months. A reasonable compromise on breeding farms where the risk of strangles infection is high and mares are on a regular vaccination program would be to begin primary vaccination of foals using the intranasal live vaccine as early as 4 months of age. The recommended 2-dose primary series administered 2 to 3 weeks apart should be followed by a third dose 3 to 4 months later and boosters at 6- to 12-month intervals thereafter, depending on risk of infection. The intranasal vaccine has been administered to foals as young as 5 or 6 weeks of age during outbreaks. If a vaccine is used in this manner, a third dose of the vaccine should be administered 2 to 4 weeks before the foal is weaned to optimize protection during this high-risk period. Although there are few reports of adverse effects attributable to use of the intranasal strangles vaccine in young foals, the inability of foals to mount an adequate mucosal IgA response during the first month of life and the potential for interference by maternal antibodies suggests that foals are unlikely to fully benefit from intranasal strangles vaccine administered before 4 months of age. When an inactivated M-protein vaccine is used for primary vaccination of foals, it is recommended that the initial series begin at 4 to 6 months of age, using 3 doses administered at 4- to 6-week intervals, followed by semiannual boosters for as long as high-risk conditions prevail.

Strangles vaccines should be administered only to healthy nonfebrile horses free of nasal discharge and should not be administered to those that are known to have had recent direct exposure to clinically ill animals.[153] However, outbreaks of strangles generally persist for several months to more than 1 year, particularly on breeding farms where each foal crop adds new susceptible animals to the population. Thus, strangles vaccines are frequently administered in the face of an outbreak as an adjunct to management practices designed to bring outbreaks under control, and it is not always possible to accurately determine the exposure status of each horse. Under these circumstances, the likelihood of preventing strangles is greatest for horses that have not yet been exposed and can be kept isolated from infected horses until 2 weeks after the vaccination protocol can be completed. Horses that have been vaccinated previously will generate a response more rapidly than naive horses. Similarly, the intranasal MLV is preferred over inactivated vaccines for immunization of naive horses in an outbreak because it is likely to generate a protective immune response more rapidly.

Injectable strangles vaccines tend to cause local reactions at the site of injection more often than other equine vaccines. Injection in the gluteal muscles is not recommended because gravitational drainage along fascial planes can prove troublesome in the event an abscess develops at the injection site. In addition, purpura hemorrhagica, a serious and sometimes life-threatening systemic immune complex (Arthus-type) vasculitis manifested as edema with or without petechial hemorrhages on mucosal surfaces, has been observed with low frequency in the weeks after administration of strangles vaccines. Inactivated extract vaccines are implicated more often than the intranasal MLV, but all strangles vaccines have the potential to induce purpura hemorrhagica. The antigen present in immune complexes is SeM, along with antibodies of the IgA class. Because a high serum IgG titer against *S. equi* appears to be associated with an increased risk of developing purpura, routine testing for specific IgG antibodies using a commercially available ELISA test has been recommended as a means of preventing vaccine-associated purpura hemorrhagica.[160] Horses with titers of 1:1600 or greater in the SeM ELISA and those known to have had strangles during the previous year should not be vaccinated.[160] A recent study investigated the factors associated with likelihood of horses having a high serum *S. equi* SeM-specific antibody titer.[166] This study indicated that older horses, horses other than Thoroughbreds and warmbloods, and horses that had been vaccinated with an attenuated live intranasal *S. equi* vaccine between 1 and 3 years previously had an increased likelihood of having a serum SeM-specific antibody titer of 1600 or higher. Recommendations of when to vaccinate horses after an *S. equi* outbreak largely depend on how long horses maintain a serum SeM-specific antibody titer of 1600 or higher, which can range from 9 to 27 months. Therefore, the recommendation is to wait 2 years after an outbreak before vaccinating horses against *S. equi* and to test for *S. equi* SeM-specific antibody titer 12 to 24 months following the outbreak.[167]

The bacterial modified live vaccine for intranasal administration will cause injection site abscesses if inadvertently injected IM. To avoid inadvertent contamination of other vaccines, syringes, and needles, it is advisable and considered good practice to administer all parenteral vaccines before handling and administering the intranasal strangles modified live vaccine. Other reported adverse responses after administration of the intranasal modified live vaccine include nasal discharge, submandibular or retropharyngeal lymphadenopathy with or without abscessation, limb edema, internal abscesses (bastard strangles), and purpura hemorrhagica. The overall frequency of adverse events is low but appears to be higher than reported to the manufacturer (4.8 per 10,000 doses). The majority of reported adverse events, including the development of nasal discharge, lymph node abscesses, and purpura hemorrhagica, occurs in horses on farms with endemic or epidemic strangles, so it is often uncertain whether the adverse event was caused by the vaccine or by a wild strain of *S. equi*.

RECENT DEVELOPMENTS IN STRANGLES VACCINES. The non-specifically attenuated Pinnacle strain of *S. equi* was produced by chemical mutagenesis to induce random mutations throughout the bacterial genome.[157,168] Because the point mutations responsible for attenuation have not been specifically defined, the potential exists for back mutation and reversion to full virulence.[168] In contrast, the

VetBooks.ir

live attenuated vaccine strain TW 928 contained in a strangles vaccine (Equilis StrepE [Intervet]) formerly licensed in Europe was stably attenuated by targeted deletion of the *aroA* gene.[169] This allowed development of a companion PCR test that was used in molecular epidemiologic studies to determine whether strangles in vaccinated horses was caused by the vaccine or by wild-type strains.[170] Although this development proves that targeted gene deletion is a promising route for generating stable candidate mutants for inclusion in future vaccines, the high residual virulence, unconventional route of administration (submucosal in the upper lip), and short duration of immunity induced by Equilis StrepE limited its use to the extent that the vaccine was recently withdrawn from the market.

The incomplete protection afforded by bacterins and SeM extracts administered parenterally or by attenuated live vaccines administered intranasally or submucosally, as well as the undesirable side effects associated with some of these products, has prompted research to investigate other potential vaccine antigens and vaccination strategies. Promising results have recently been achieved in challenge studies involving horses vaccinated IM and intranasally with combinations of up to seven recombinant antigens including EAG (a protein that binds α_2-macroglobulin, albumin, and IgG), CNE (a collagen-binding protein), SclC (a collagen-like protein), and two IgG endopeptidases, IdeE and IdeE2.[171,172]

Equine Neorickettsiosis (Potomac Horse Fever)

Equine neorickettsiosis, also known as *Potomac horse fever* (PHF), is caused by *Neorickettsia risticii* (formerly *Ehrlichia risticii*). Originally described in 1979 as a sporadic disease affecting horses residing in the northeastern United States near the Potomac River, the disease has since occurred in horses in 43 U.S. states, three Canadian provinces (Nova Scotia, Ontario, Alberta), South America (Uruguay, Brazil), Europe (The Netherlands, France), and India. The disease does not appear to be directly contagious, and it now appears that accidental ingestion of aquatic insects harboring metacercaria infected with *N. risticii* is at least one mode of transmission.[173] PHF is seasonal, occurring between late spring and early fall in temperate areas, with most cases in July, August, and September at the onset of hot weather. The disease may sporadically affect individual horses or cause outbreaks involving multiple horses. Foals appear to be at low risk for the disease. If PHF has been confirmed on a farm or in a particular geographic area, cases will likely occur in future years. Documentation of the involvement of operculate freshwater snails and aquatic insects like caddis flies and mayflies in the life cycle of *N. risticii* has permitted formulation of focused control measures directed at minimizing exposure of horses to the habitats occupied by these species during the summer and fall months when disease risk is highest in endemic areas.[173] Risk reduction is best accomplished by turning off barn lights at night, covering hay or storing it indoors, preventing horses from drinking at natural water sources like ponds or streams, and staying informed about local hatches of aquatic insects.[174]

Recovery after natural infection with *N. risticii* induces a strong antibody response and durable protection from reinfection lasting 20 months or longer. However, the presence of antibodies does not necessarily correlate with protection, and cell-mediated responses likely play a crucial role.[175] A β-propiolactone inactivated host cell-free *N. risticii* vaccine protects mice against homologous challenge.[176] Only one inactivated PHF vaccine for IM administration (Equine Potomavac [Merial]) is licensed and available for use in horses as an aid in prevention of PHF. The high rate of serious complications and mortality associated with this disease has been considered adequate justification for vaccinating horses residing in or traveling to endemic areas. In a series of studies in which ponies were challenged IV with *N. risticii* approximately 4 weeks after completion of the 2-dose primary vaccination series using a formalin-inactivated aluminum hydroxide–adjuvanted vaccine (PHF-Vax [Schering-Plough]) that is no longer marketed, Ristic's group (1988) reported that 78% of experimentally infected ponies were protected against all clinical manifestations of disease except fever, and 33% were protected against all signs including fever.[177] A published non-controlled field study involving the same vaccine documented induction of serologic responses in most vaccinated horses and a substantial reduction in disease prevalence, morbidity, and mortality compared with data collected in a previous year when horses were not vaccinated.[175,178]

In contrast to the results of the studies cited, an epidemiologic investigation involving a large number of horses failed to demonstrate any clinical or economic benefit from annual vaccination with currently available vaccines in New York State.[179,180] Failure of a substantial number of individual horses to mount an immune response to inactivated PHF vaccines, heterogeneity of *N. risticii* isolates, the presence of only one *N. risticii* strain in vaccines, and much more rapid waning of immunity after vaccination than after natural infection likely account for the observed failure of vaccines to provide protection against field infection.[175,181] Despite the lack of documented efficacy of approved vaccines to prevent infection in the field setting, many practitioners who work in endemic areas believe that severity of disease is attenuated and mortality is reduced in vaccinated horses when vaccines are administered at 4- to 6-month intervals, with administration of one booster timed to precede the anticipated period of peak challenge.

If vaccination is elected, a primary series of 2 doses should be administered 3 to 4 weeks apart. The manufacturer recommends revaccination at 6- to 12-month intervals, but some veterinarians encourage a shorter revaccination interval. Because the disease has a distinct seasonal pattern, revaccination in the late spring, about 1 month before the first cases are expected, followed by a second dose 4 months later, appears to be a reasonable approach for strategic immunization to maximize the chances of protection during the period of peak challenge. The available vaccine is licensed for use in stallions and pregnant mares and can be administered to gestating mares 4 to 8 weeks before foaling to maximize passive transfer of specific antibodies to foals through colostrum. Whereas about 67% of foals from antibody-positive mares were antibody negative by 12 weeks of age, antibody was detectable in 33% of foals up to 5 months of age. On the basis of these findings, the low risk of clinical disease in young foals, and the apparent susceptibility to infection of 2 foals vaccinated earlier than 12 weeks of age, primary vaccination of foals from antibody-positive dams should begin with a 2-dose primary series starting at age 5 months or older, followed by administration of 1 subsequent booster dose 8 to 12 weeks later.[178] However, the efficacy of this recommended regimen requires further study. If the primary series of 2 vaccinations is initiated before age 5 months, additional doses should be administered at monthly intervals up to 5 months of age to maximize the likelihood that an immunologic response is achieved. Vaccination of foals in endemic areas is further complicated by the distinct seasonal incidence of disease in July, August, and September, a time when most foals are between 2 and 6 months old and may be subject to maternal antibody interference with vaccination.

Botulism

Botulism is a neuromuscular paralytic disorder caused by one of eight distinct neurotoxins (A, B, Ca, Cb, D, E, F, G) produced by *Clostridium botulinum,* a soilborne, spore-forming, saprophytic, anaerobic, gram-positive bacterium.[182] Botulinum toxins are among the most potent biological toxins known and act by blocking transmission of impulses at motor end plates, resulting in weakness progressing to paralysis, inability to swallow, and frequently death. Of the seven serogroups (A through G) of *C. botulinum,* types A, B, C, and D have been reported to cause disease in horses, with types B and C responsible for most cases.[182] Three forms of botulism—toxicoinfectious botulism (shaker foal syndrome), forage poisoning, and wound botulism—have been observed in horses. *Forage poisoning* results from ingestion of preformed toxin produced by decaying plant material or animal carcasses present in feed, whereas *wound botulism* results from vegetation of spores of *C. botulinum* and subsequent production of toxin in contaminated wounds. *Shaker foal syndrome,* almost all cases of which are caused by *C. botulinum* type

VetBooks.ir

B, results from toxin produced by vegetation of ingested spores in the intestinal tract. This syndrome is a significant problem in foals between the ages of 2 weeks and 8 months in Kentucky and the Mid-Atlantic seaboard states and occurs sporadically in other areas.[183-185] Toxicoinfection with *C. botulinum* type C is currently being investigated as a cause of equine grass sickness, a largely fatal pasture-associated dysautonomia mainly affecting horses in Great Britain, continental Europe, and Australia, with reports of isolated U.S. cases.

A toxoid vaccine (BotVax-B [Neogen Corporation, Tampa, Fla.]) directed against *C. botulinum* type B is licensed for use in horses in the United States. Its primary indication is prevention of shaker foal syndrome via colostral transfer of antibodies induced by vaccination of the mare. For primary vaccination, mares should be vaccinated during gestation with a series of 3 doses administered 4 weeks apart, scheduled so the last dose will be administered 4 to 6 weeks before foaling to enhance concentrations of specific immunoglobulin in colostrum (i.e., months 8, 9, and 10 of gestation). Subsequently, mares should be revaccinated annually with a single dose 4 to 6 weeks prior to foaling. A similar type B toxoid is available to protect foals in endemic areas in Australia.[186]

Passively derived colostral antibodies appear to protect most foals for 8 to 12 weeks, although foals from properly vaccinated dams can present with botulism.[184-186] Insufficient production of specific antibody by the dam in response to the vaccination, failure of passive transfer of specific immunity to botulinum toxin, overwhelming toxin production, and loss of passive immunity by the time exposure to the toxin occurs may be reasons for vaccine failure. The clinician should be aware of the status of MDA transfer of each foal.

Maternal antibodies do not appear to interfere with the response of foals to primary immunization against botulism,[187] so a primary series of 3 doses of vaccine administered 4 weeks apart can be started when foals in endemic areas are 2 to 3 months of age or older. Other horses can be immunized using a primary series of 3 doses of vaccine administered at 4-week intervals, followed by annual revaccination. No licensed vaccines are available at present for preventing botulism due to *C. botulinum* type C or other subtypes, and because cross-protection between the B and C subtypes does not occur, routine vaccination against *C. botulinum* type C is not currently practiced. A type C toxoid approved for use in mink was administered to horses under special license to protect them during an outbreak of forage poisoning caused by contaminated alfalfa cubes in southern California in 1989. The C-terminal part of the heavy chains of botulinum neurotoxin types C and D (HcBoNT/C and D) have been expressed in *Escherichia coli* and have been shown to effectively immunize horses when administered as recombinant mono- or bivalent vaccines.[188,189] These vaccines are not yet licensed.

Horses and foals with clinical botulism may be treated with botulinum antitoxin administered IV. Antitoxin is not effective against toxin that has been translocated to motor end plates, so clinical signs may progress for 12 to 24 hours after administration of the antitoxin or until all internalized toxin has attached to motor end plates. The dose of botulinum type B antitoxin recommended for treating a foal is 30,000 IU and for an adult is 70,000 IU. Foals of unvaccinated mares born in or being moved to endemic areas may benefit from transfusion with plasma from a vaccinated horse or from administration of *C. botulinum* type B antitoxin. The efficacy of these practices warrants further study. Vaccination with type B toxoid as described earlier is an alternative to passive immunization.

Equine Viral Arteritis

Equine viral arteritis (EVA) is a contagious disease of equids caused by equine arteritis virus (EAV), an RNA virus found in the horse populations of many countries. EAV is the prototype virus in the family Arteriviridae of the genus *Arterivirus,* order Nidovirales. Although all horse breeds appear to be equally susceptible to EAV, the prevalence of infection, as determined by seroconversion, is much higher in some breeds (notably Standardbreds and warmbloods) than in others. Despite the high seroprevalence of infection in Standardbreds, clinical disease is rarely observed in this breed, indicating that subclinical infection is common.[11,190] Conversely, Thoroughbreds and most other breeds have a low seroprevalence of infection but are more likely to show fulminant clinical signs when they become infected. Most primary EAV infections are subclinical or asymptomatic. Clinical signs, if they occur, typically develop 3 to 7 days post infection and vary in severity, both within and between outbreaks, but may include some or all of the following: fever, anorexia, depression, localized or generalized urticaria, supraorbital or periorbital edema, conjunctivitis, lacrimation, serous or mucoid nasal discharge, and dependent edema involving the limbs, prepuce, scrotum, mammary glands, or ventrum. EAV is of special concern because abortion is a frequent sequel to infection in the unprotected pregnant mare. EAV can also cause life-threatening pneumonia or pneumoenteritis in young foals, and infection of the post-pubertal colt or stallion may establish a long-term carrier state.[11,191] Transmission most frequently occurs through direct or aerosol contact with virus-infective respiratory secretions, leading to widespread dissemination of the virus among susceptible horses in close proximity. Indirect transmission, though less significant, can occur through contact with virus-contaminated fomites. Venereal transmission from infected carrier stallions to mares via semen during natural breeding or artificial insemination with fresh, chilled, or frozen semen can play a significant role in introduction and spread of infection on or between breeding farms or other equine facilities. The virus can persist in the reproductive tract of stallions for many years and possibly result in lifelong infection.

Historically, large-scale outbreaks of EVA have been relatively infrequent. However, the number of confirmed occurrences appears to be increasing, likely because of increased global movement of horses, increased accessibility of carrier stallions, and increased utilization of shipped cooled or frozen virus-infected semen. Outbreaks can be associated with serious economic consequences, as clearly exemplified by the 2006 multistate outbreak in Quarter Horses that was propagated by widespread shipment of semen from the index cases, two inapparently infected carrier stallions in New Mexico. Because the carrier stallion is widely accepted as the natural reservoir of EAV and the source of diversity among naturally occurring strains of the virus, identifying these individuals through serologic testing followed by PCR testing or virus isolation from semen forms the cornerstone of eradication measures. Vaccination also constitutes an important means of controlling spread and minimizing the consequences of infection.

A modified live vaccine based on an attenuated strain of EVA virus was developed by researchers in Kentucky in 1969.[192] This vaccine (Arvac [Zoetis]) was first used extensively in the field during the 1984 outbreak of EVA in Kentucky and proved safe and effective in bringing the outbreak under control.[11] This vaccine was developed further and licensed for use in North America. Vaccination of stallions, non-pregnant mares, and prepubertal colts has been shown to be a safe and effective means of controlling EVA. Strategic use of the MLV has formed the cornerstone of a highly successful program to control EVA in the Kentucky Thoroughbred breeding population for many years.[11] Indications for vaccination against EVA are to:

- Protect stallions against infection and subsequent development of the carrier state
- Immunize seronegative mares before being bred with EAV-infective semen
- Curtail outbreaks in nonbreeding populations. Vaccination in the face of an EVA outbreak in concentrated populations of performance horses at racetracks has been successful in controlling horizontal disease dissemination within 7 to 10 days.

Primary immunization with the modified live vaccine involves IM administration of a single dose, with a booster administered annually thereafter. Virus-neutralizing antibodies are induced within 5 to 8 days after vaccination and persist for at least 2 years.[11,193] Revaccination induces high VN antibody titers that persist for several breeding seasons.[194] Although the current modified live vaccine is highly attenuated and has been shown to be safe and effective in stallions and non-pregnant mares, a small proportion of first-time vaccinated

VetBooks.ir

horses develop mild febrile reactions and transient lymphopenia after vaccination, and vaccine virus may be isolated sporadically from the nasopharynx and buffy coat for 7 days (occasionally up to 32 days) after vaccination.[11,193,195,196] Vaccinated stallions do not shed vaccine virus in either semen or urine.[194]

Primary vaccination provides sustained clinical protection against EVA but does not prevent reinfection and subsequent limited replication and shedding of field strains of virus.[197] However, the frequency, duration, and amount of viral shedding via the respiratory tract are significantly reduced in vaccinates. Vaccinated mares may transiently shed field virus after being bred to carrier stallions, so isolation of these individuals for 21 days after breeding is recommended.[11]

Annual revaccination of breeding stallions 28 days before the start of breeding season is highly recommended as a means of preventing establishment of the carrier state.[11] Annual revaccination of mares being bred to carrier stallions should occur at least 21 days before breeding. The modified live vaccine is not recommended for use in pregnant mares, especially during the last 2 months of gestation, or in foals younger than 6 weeks of age, except in emergency situations when there is a high risk of exposure. Apparent fetal infection with the modified live vaccine strain after vaccination of pregnant mares has been documented in rare instances.[193,198] A recently published study in which 73 pregnant mares were vaccinated during mid- to late gestation concluded that it is safe to vaccinate healthy pregnant mares up to 3 months before foaling and during the immediate postpartum period. Vaccinating mares during the last 2 months of gestation was associated with an increased risk of abortion.[199] The authors concluded that when faced with substantial risk of natural exposure to EAV, the risk associated with vaccination must be weighed against the much greater risk of widespread abortions in unprotected populations of pregnant mares.[199]

Foals born to seropositive mares become seropositive after ingesting colostrum. MDAs decay with a mean half-life of approximately 32 days, with the result that foals become seronegative between 2 and 7 months of age.[200,201] Maternal antibodies are unlikely to interfere with the response to vaccine administered at 7 months of age or older.[200] However, when foals younger than 6 months are vaccinated during conditions of high risk, they should be revaccinated after age 6 months. Establishment of the carrier state appears to depend on the high levels of androgens circulating in intact stallions and can be prevented by vaccinating colts, preferably before puberty and before they are used for breeding.[11] Vaccination of prepubertal colts at age 6 to 12 months is therefore central to effective control of the spread of EAV infection and should be strongly encouraged in breeds like Standardbreds and warmbloods in which EVA is prevalent and on facilities where risk of infection is high. Persistent infection has never been documented in a stallion properly vaccinated with the licensed modified live vaccine prior to exposure.[11]

REGULATORY AND EXPORTATION CONSIDERATIONS WITH VACCINATION AGAINST EVA. Horses vaccinated with the MLV can be expected to become seropositive for life. Titers resulting from vaccination cannot be distinguished from titers resulting from natural infection, so vaccination may complicate testing of horses for export. When planning a vaccination program against EVA, it is important to consult with state and/or federal animal health officials to ensure that any such program is in compliance with the state's control program for EVA if one exists. It is strongly recommended that before vaccination, all first-time male vaccinates be tested and confirmed negative for antibodies to EAV by a USDA-approved laboratory (http://www.aphis.usda.gov/cvbapps/Labs.jsp). Mares intended for export should be similarly tested. In instances where there is uncertainty or concern over whether vaccination against EVA could prevent export of a horse to a particular country, it is advisable to consult the federal area veterinarian (http://www.aphis.usda.gov/vs/area_offices.htm#CO) in charge in the state to determine the specific import requirements of that country. Several countries bar entry of any equid that is serologically positive for antibodies to EAV, regardless of vaccination history. Countries that do accept EVA vaccinated horses typically require stallions or colts to have a certified vaccination history and confirmation of prevaccination negative serologic status.

FUTURE DIRECTIONS. Development and marketing of a marker vaccine that not only affords protection but also allows vaccinated horses to be distinguished serologically from inapparently infected carriers would greatly facilitate control and even eradication of EAV from horse populations. Several new-generation EAV vaccines that potentially meet these criteria have been developed in recent years. These include an MLV DIVA vaccine with a deletion in the GP5 ectodomain,[202,203] a DNA vaccine that incorporates open reading frames (ORFs) 2b, 5, and 7,[204,205] and a subunit EAV vaccine using recombinant replicon particles derived from a vaccine strain of VEE virus that includes genes encoding both major envelope proteins (GP5 and M) of EAV.[206,207]

Rotaviral Diarrhea

Equine rotavirus, a non-enveloped icosahedral RNA virus possessing a genome comprising 11 segments of dsRNA, is one of the most important causes of infectious diarrhea in foals during the first few weeks of life and often causes outbreaks involving the majority of the foal crop on individual farms.[208-210] Older foals and adult horses are more resistant to infection. Equine RV is transmitted via fecal-oral contamination and causes diarrhea by damaging the tips of villi in the small intestine, resulting in cellular destruction, maldigestion, malabsorption, and diarrhea. The genus *Rotavirus* is one of five genera of the family Reoviridae and is divided into 7 serogroups (A through G) based on differences in the inner capsid protein, VP6.[210,211] All equine rotavirus isolates to date are in group A, which is further subdivided using neutralizing antibodies to the VP4 and VP7 outer capsid proteins into P (protease-sensitive, VP4-positive) and G (glycoprotein, VP7-positive) serotypes, respectively.[211] Five P serotypes (P1, P6, P7, P12, and P18) and eight G serotypes (G1, G3, G5, G8, G10, G13, G14, G16) have been identified and characterized in horses.[212-214] Molecular genome analysis strongly suggests that the vast majority of the currently circulating equine group A rotavirus strains are highly conserved, with only limited genetic diversity.[215] Most are of the P12 and G3 serotype and include 2 subtypes (A and B).[216]

An inactivated rotavirus A vaccine (Equine Rotavirus Vaccine [Zoetis]) containing the P12, G3 serotype (H2 strain) in a metabolizable oil-in-water emulsion is conditionally licensed in the United States and is indicated for administration to pregnant mares in endemic areas as an aid for preventing diarrhea in their foals caused by infection with RVs of serogroup A. Foal vaccination is not indicated; no data suggest that vaccinating the newborn foal with inactivated rotavirus A vaccine has any benefit in preventing or reducing infection severity. Label recommendations call for a 3-dose vaccine series to be administered to mares during each pregnancy at 8, 9, and 10 months' gestation. This protocol has been shown to induce significant increases in serum concentrations of neutralizing antibody in vaccinated mares and in antibody concentrations of the IgG (but not IgA) subclass in colostrum and milk of vaccinated mares.[217,218] It is essential that the newborn foal receive an adequate amount of good-quality colostrum so it absorbs sufficient anti-RV antibodies. After nursing from vaccinated mares, the concentration of passively derived RV-specific antibody of the IgG subclass in the serum of foals up to 90 days of age is significantly higher than that measured in serum of foals born to unvaccinated mares.[217,218] A field study showed this vaccine to be safe when administered to pregnant mares and provided circumstantial evidence of at least partial efficacy. An approximately twofold higher incidence of rotaviral diarrhea was found in foals from unvaccinated mares compared to those from vaccinated mares, although this difference did not prove to be statistically significant.[217] Similarly, a controlled field study in Argentina in which an inactivated aluminum hydroxide–adjuvanted vaccine containing the SA11 (G3P2), H2 (G3P12), and Lincoln (G6P1) strains was administered to 100 mares at 60 days before foaling and again

VetBooks.ir

30 days later, demonstrated a substantial reduction in the incidence and severity of rotaviral disease in foals from vaccinated mares compared with foals from unvaccinated mares.[219] As MDA titers wane at about 60 days of age, foals may develop rotaviral diarrhea, but the severity of diarrhea is generally milder and of shorter duration than in foals that become infected during the first 30 days of life.

Challenge studies involving two inactivated RV vaccines administered in a similar manner to pregnant mares in Japan showed that their foals were not completely protected against infection but had a substantial reduction in severity of clinical signs after challenge.[214] The major correlate for protection against rotaviral infection appears to be mucosal immunity, predominantly mucosal IgA, in the gastrointestinal tract. Studies of the immunoglobulin isotype responses of mares after parenteral vaccination with inactivated RV vaccines, and of antibodies passively transferred to their foals via colostrum, indicate that this approach is unlikely to provide foals with intestinal mucosal protection in the form of IgA.[218] Consequently, it is not surprising that current protocols do not provide complete protection. In addition, because the conditionally licensed vaccine available in the United States contains only the G3 serotype of the A serogroup, it cannot be expected to protect against infection with all field strains.

Equine Rhinitis A Virus

Two rhinitis viruses, equine rhinitis A virus (formerly known as *equine rhinovirus 1,* genus *Aphthovirus,* family Picornaviridae) and equine rhinitis B virus (formerly known as *equine rhinovirus 2,* genus *Erbovirus,* family Picornaviridae), have been identified in horses.[220-225] Seroprevalence studies confirm that both viruses are active in horse populations worldwide, with prevalence ranging from 20% to 90%, depending on the age group and use of the horses sampled.[221,222,226] The rhinitis viruses have been largely overlooked as potential causes of clinically apparent respiratory disease for many years, but recently investigated outbreaks of contagious respiratory disease, as well as challenge studies, suggest that ERAV and ERBV may indeed be important pathogens of horses, causing both lower and upper respiratory tract disease.[223,225,226] Clinical manifestations include pyrexia, nasal discharge, cough, lethargy, anorexia, pharyngitis, and submandibular lymphadenopathy.[223,225] It has also been suggested that ERAV may play a causative role in inflammatory airway disease.[226] A unique feature of ERAV is persistent shedding in urine but only transient shedding in nasal secretions after respiratory tract infection.[220]

An inactivated ERAV vaccine (Equine Rhinitis A Vaccine [Boehringer Ingelheim]) was granted a conditional license in late 2012; efficacy and potency tests are in progress. The vaccine is labeled for vaccination of healthy horses 4 months of age or older. The manufacturer recommends a primary vaccination series of three 1-mL doses administered IM at 3- to 4-week intervals, followed by revaccination annually or prior to anticipated exposure. Pending publication of more data regarding vaccine efficacy, as well as the role of ERAV as a cause of respiratory disease, these authors are unable to provide recommendations regarding use of this vaccine.

Anthrax

Anthrax is a serious and rapidly fatal septicemic disease caused by proliferation and spread of the vegetative form of *Bacillus anthracis* in the body. *B. anthracis* is acquired through ingestion, inhalation, or skin penetration through contamination of wounds by soilborne spores of the organism. Anthrax is encountered only in limited geographic areas where moist alkaline soils, particularly those with high organic content, favor survival, germination, and sporulation of the organism. Vaccination is indicated only for horses pastured in endemic areas.

The only vaccine currently licensed for vaccination of livestock, including horses, contains viable live Sterne's strain 34F2 nonencapsulated spores in saponin (Anthrax Spore Vaccine [Colorado Serum Company, Denver, Colo.]). A primary series consisting of 2 doses of that vaccine should be administered SC 2 to 3 weeks apart, followed by annual revaccination. Mild to moderate swelling at the injection site is common, and adverse systemic reactions may occur occasionally, particularly in young and miniature horses. Little objective information is available regarding use of this vaccine in horses, but clinical evidence suggests that it provides protection. Vaccination of pregnant mares is not recommended.[227] Because it is a live bacterial product, appropriate caution should be used during storage, handling, and administration of the vaccine to prevent accidental inoculation of people and maintain vaccine potency. Concurrent administration of antimicrobial drugs effective against *B. anthracis* is contraindicated if the vaccine is to function as intended.

Ovine and Caprine Vaccination Programs

Amanda J. Kreuder • Paul J. Plummer

Factors Affecting Vaccine Availability, Choice, and Usage

Labeled vaccines for several important diseases of sheep and goats are currently available for use in the United States, but the small market share for small ruminant vaccines has negatively affected the funding available for vaccine research and development compared to other domestic species. As a consequence of low funding and difficulties in recouping development costs, vaccines currently being produced for small ruminants in the United States, except one modified live vaccine for bluetongue virus, are either killed bacterin products or virulent live products. These products are more basic to develop and cheaper to produce and market. Modified live products typically require increased costs related to development and production and thus are not widely available for small ruminant–specific diseases. A current list of vaccine targets available for labeled use in sheep and goats in the United States is presented in Table 48-5, and example vaccination schedules for sheep (Table 48-6) and goats (Table 48-7) are also provided. All vaccines must pass basic efficacy and safety testing by the USDA Center for Biologics; however, for the majority of vaccines currently marketed, there is an overall lack of field-based comparative vaccine efficacy data available for the practitioner's use to determine which vaccines to select. Because the value of individual animals in flocks may be low and the cost associated with vaccination for certain diseases high, a cost/benefit analysis should be performed prior to developing a vaccine program for a particular herd. This analysis should include not only the cost of the vaccine itself but also the high cost of labor associated with administration, as compared to the anticipated risk of infection of the herd and direct costs associated with the disease.

Most available vaccines are bacterins, so avoiding maternal antibody interference and ensuring timely booster administration are key concepts for developing effective vaccine programs. Similar to other food animal species, proper vaccine administration and adherence to meat quality assurance are important. Vaccines should be administered SC whenever possible, either in the neck or behind the shoulder in the axillary region. Confusion over vaccine reactions that can lead to swellings that resemble lymph nodes infected with *Corynebacterium pseudotuberculosis* should be kept in mind when choosing a vaccination location. Compared to sheep, goats are known to exhibit more severe vaccine reactions. If vaccines labeled for other species are to be used off label in goats, it is recommended that a small number of animals be vaccinated first to observe for reactions prior to vaccinating the entire flock.

Clostridial Vaccines

The only vaccine currently recommended for routine use in all small ruminants is yearly administration of a *Clostridium perfringens* C and D plus tetanus toxoid. Vaccination or protection via passive immunity (colostrum or antitoxin administration) is particularly important prior to common husbandry tasks like tail docking and castration (tetanus), as well as introduction to high-grain diets (*C. perfringens* type D). Ideally, all ewes and does should receive a booster

vaccination 3 to 4 weeks prior to parturition; previous research in sheep indicates that passive immunity acquired from properly immunized ewes confers protection for up to 12 weeks in lambs.[1] Current recommendations for vaccination include an initial series of 2 doses 3 to 4 weeks apart, followed by yearly boosters. Appropriate timing of the booster in the first series of immunizations is essential in the formation of an adequate immune response for the remainder of the animal's life. When to initiate the first series of vaccinations is a topic of debate because there is little evidence-based literature on which to form a decision. The following guidelines are used by the authors in clinical practice. Lambs and kids from vaccinated dams with no evidence or suspicion of failure of passive transfer (FPT) may be vaccinated starting at 8 to 12 weeks of age. In animals born to unvaccinated dams or those with suspected FPT we recommend earlier use of the initial dose; these animals should be vaccinated starting at 1 to 3 weeks of age, with a booster in 3 to 4 weeks and consideration for an additional booster 1 month later. It is relatively common for producers to vaccinate ewes/does prior to parturition and then still initiate the vaccination of kids/lambs at 1 to 2 weeks of age. In such cases the practitioner should discuss the implications of passive maternal immunity on the immune response elicited by the kid/lamb, and should consider either additional boosters (after the period of maternal antibody wane) or delaying initiation of the vaccines. In cases of puncture wounds or injury, a tetanus booster should be administered if it has been longer than 6 months since the last vaccination. An additional booster may also be given to animals entering a feedlot or to those on a high-grain ration year-round (e.g., dairy animals) to aid in prevention of enterotoxemia.

Multiple combination commercial products are available, including *C. perfringens* C/D only, stand-alone tetanus toxoid, and 7-way or 8-way clostridial combination products. There is little evidence that vaccination with multivalent clostridial products is beneficial, but these may frequently be chosen to decrease cost. If multivalent clostridial vaccines are selected, care should be taken to ensure the vaccine contains a tetanus toxoid; in some vaccines, *C. sordellii* may be substituted in place of *C. tetani*.

Rabies Vaccines

Highly efficacious vaccines for the rabies virus are commercially available for sheep in the United States. Vaccination for rabies is recommended in endemic areas, especially in animals with increased human exposure, such as pets, show animals, and petting zoo exhibits. Vaccination of valuable animals is also recommended. Despite the availability of highly effective vaccines, administration to all small ruminants is not routinely recommended, owing to the high cost associated with vaccination. In addition, unlike rabies vaccination in cats and dogs, previous vaccination of small ruminants does not necessarily constitute protection in regard to quarantine versus destruction of exposed animals. None of the currently available vaccines are labeled for goats, but they are considered relatively safe to use in this species in similar instances as with sheep. Initial vaccination after 3 months of age, followed by yearly revaccination is recommended; following the initial yearly booster, vaccination frequency can be decreased to every 3 years in some cases, depending on vaccine label.

TABLE 48-6

Ewe and Lamb Vaccination Schedule for North America

Type of Vaccine		Timing of Vaccination					
		Ewes				Lambs	
Recommendation	Antigen	Prebreeding	Breeding	Prelambing	Lambing	Post Lambing	Weaning
Required	Clostridial enterotoxemia Tetanus			Yearly booster in all ewes 1 month prior to lambing		*Vaccinated ewe and no FPT*: first vaccine at 8-12 weeks; booster 3-4 weeks later *Unvaccinated ewe or FPT*: first vaccine at 1-3 weeks; booster twice, 3-4 weeks and 6-8 weeks later	May booster vaccine at this time, especially in high-risk animals
Optional, depending on farm history	Rabies	Yearly booster; some vaccines may only require revaccination every 3 years following initial series.					Initial vaccination after 3 months
	Vibriosis	Initial 2-dose series followed by annual booster (exact timing different based on vaccine chosen)					
	Enzootic abortion	Initial 2-dose series followed by annual booster					
	Caseous lymphadenitis	Yearly booster					Initial 2-dose series
	Contagious ecthyma					Scarification and administration of vaccine to naive animals in endemic herds	
	Bluetongue	Annual vaccination at least 3 weeks prior to breeding					Initial vaccination after 3 months
	Pasteurellosis	Yearly booster					Initial 2-dose series
Not recommended for routine use	Anthrax Ram epididymitis						

FPT, Failure of passive transfer.

Foot Rot Vaccines

Commercial bacterin vaccines labeled for foot rot in sheep and targeting 10 strains of *Dichelobacter nodosus* and *Fusobacterium necrophorum* were once available in the United States. These vaccines are no longer commercially available in the United States, but the *D. nodosus* vaccine may be imported with USDA approval on a case-by-case basis. Localized vaccine reactions were common in both sheep and goats, and vaccine efficacy on a large scale has long been debated. Available evidence suggests that antigenic competition may reduce the effectiveness of simultaneous vaccination against multiple serogroups of *D. nodosus*.[2,3]

Current research performed in regions other than North America suggests newer approaches to vaccination for this disease may be more beneficial. In areas or flocks where only one or two strains may be present, targeted use of monovalent or bivalent autogenous vaccines in combination with culling of non-responders may be of benefit in eradicating the disease.[4-6] However, it is considered uncommon for only one or two strains to be present; instead, multistrain infections are thought to more commonly occur.[7] Use of multiple bivalent autogenous vaccines with sequential administration staggered every 3 months may help avoid antigenic competition while allowing for prolonged protection against multiple serotypes.[8] Development of a "universal" vaccine through comparative genomics, transcriptional profiling, and serologic screening for potential candidate antigens has also shown promising results.[9] When these newer technologies will be commercially available in the United States remains to be seen. Given the difficulties and limited availability of vaccines for foot rot, veterinary practitioners are encouraged to consider alternate management strategies that include antibiotic therapy and potentially footbaths.

Reproductive Disorder Vaccines

Commercial vaccines are currently available for sheep only to aid in control of some of the important infectious abortion diseases and contagious epididymitis in the United States. Again, many of these vaccines lack comparative or published field efficacy data, so blanket recommendations for use cannot be made. For additional information on vaccination strategies in reproductive diseases, two excellent reviews have recently been written with a more in-depth discussion of each of the following diseases.[10,11]

An inactivated *Brucella ovis* vaccine is available in the United States for use in rams to aid in prevention of epididymitis, but it is not recommended for routine use. Inactivated vaccines are not believed to confer protective immunity to this organism but are known to interfere with serologic testing to detect carrier animals. In countries where *Brucella melitensis* is present, the Rev-1 live mutant

TABLE 48-7

Doe and Kid Vaccination Schedule for North America

Type of Vaccine		Timing of Vaccination					
		Does				Kids	
Recommendation	Antigen	Prebreeding	Breeding	Prekidding	Kidding	Post Kidding	Weaning
Required	Clostridial enterotoxemia Tetanus			Yearly booster in all ewes 1 month prior to lambing		*Vaccinated doe and no FPT*: first vaccine at 8-12 weeks; booster 3-4 weeks later *Unvaccinated doe or FPT*: first vaccine at 1-3 weeks; booster twice at 3-4 weeks and 6-8 weeks later	May booster vaccine at this time, especially in high-risk animals
Optional depending on farm history	Rabies*	Yearly booster, some vaccines may only require revaccination every 3 years following initial series					Initial vaccination after 3 months
	Contagious ecthyma					Scarification and administration of vaccine to naive animals in endemic herds	
	Caseous lymphadenitis	Yearly booster					Initial 2-dose series
	Enzootic abortion*	Initial 2-dose series followed by annual booster					
	Bluetongue		Annual vaccination at least 3 weeks prior to breeding				Initial vaccination after 3 months
	Pasteurellosis	Yearly booster					Initial 2-dose series
	Coliform mastitis			2-3 doses pre- and post kidding			
Not recommended for routine use	Anthrax						

*Constitutes off-label use of vaccine in this species.

FPT, Failure of passive transfer.

vaccine may be useful in controlling both diseases; however, in *B. melitensis*–free countries like the United States and Canada, its use is prohibited.

There are currently two commercially available bivalent bacterin vaccines for abortion due to *Campylobacter fetus* subsp. *fetus* and *C. jejuni* in the United States. In general, there is minimal cross-protection between these organisms, and sheep appear to be much more susceptible than goats to abortions caused by these agents. Recommendations for use on farms with diagnosed abortions due to *Campylobacter* spp. include an initial series of 2 doses in ewe lambs, followed by administration of an annual booster; exact timing varies based on the vaccine chosen. Recently a new tetracycline-resistant strain of *C. jejuni* (IA 3902) has emerged in the United States and is now thought to be the leading cause of *Campylobacter*-associated abortion.[12] Studies in guinea pig abortion models suggest that vaccination with certain commercial vaccines may be more beneficial than others in providing cross-protection to prevent abortion associated with this IA 3902 strain.[13] Following an abortion storm, herd immunity may initially be high, and in future breeding seasons the extent of disease may be limited to naive animals. Over time, immunity may wane, and infections may reoccur.

Chlamydophila abortus (formerly *Chlamydia psittaci*) is a common cause of abortion in both sheep and goats worldwide. Following abortion, ewes and does will develop immunity to future abortion but will often continue to shed the organism and infect other naive animals. Currently, only an inactivated culture vaccine (bacterin) is available in North America for use in sheep. Some producers have used this vaccine in goats, and it appears to be generally safe in this species. Vaccination with this type of vaccine will not prevent shedding of the organism but may decrease the rate of abortions. Vaccine efficacy is unpredictable, owing to variation in the amount of antigen present and loss of antigenicity following in vitro culture during vaccine production. Strain variation from farm to farm may also play a role in perceived vaccine failures. An attenuated live vaccine is available in other countries and is thought to be more efficacious in preventing abortion as well as shedding but is not without drawbacks. Live attenuated *C. abortus* organisms can be infective to humans handling the vaccine, and the vaccine strain has recently been

VetBooks.ir

identified in aborted placentas in the United Kingdom.[14] Newer vaccine technologies such as DNA vaccines or bacteriophage-delivered DNA may eventually offer a solution to the problems identified with current vaccine strategies.[15,16]

Vaccines for other important reproductive diseases like Q fever *(Coxiella burnetii)* and toxoplasmosis *(Toxoplasma gondii)* are not available in the United States even though they remain important causes of abortion in sheep and goats. A phase I inactivated *C. burnetii* vaccine is commonly used in many areas of Europe, with observed reductions in shedding and decreased abortion rates. This vaccine is currently part of the mandatory vaccination program in The Netherlands.[17] This vaccine is neither marketed nor approved for importation into the United States at present by the USDA. A modified live toxoplasmosis vaccine consisting of freeze-dried tachyzoites is available in Europe and New Zealand; it provides excellent long-term immunity. Both of these vaccines are potentially zoonotic and therefore must be handled carefully. Licensing of the *C. burnetii* vaccine has been considered in North America but may be hindered by licensing cost and market size. A vaccine for toxoplasmosis is not likely to become available in the United States in the near future, owing to the small market compared to overseas.

Caseous Lymphadenitis Vaccines

Vaccination for *Corynebacterium pseudotuberculosis* has been attempted with a number of different vaccine modalities; all currently marketed products in the United States are bacterin-toxoids sold as either separate or combination products. Experimental trials have demonstrated a decrease in the occurrence of both internal and external abscesses following inoculation in vaccinated animals.[18] Based on these and other data, the vaccine may have a place in some herds to decrease disease prevalence. While a large amount of research into vaccines has been done overseas,[19,20] little other U.S. vaccine research for this disease has been done. The available vaccines will not prevent all animals from developing abscesses, and animals must be vaccinated prior to exposure. Vaccine reactions (lameness, lethargy, depression) may occur and can be significant. Despite frequent use in goats, the fully licensed vaccine is not labeled for use in this species and may result in severe injection site reactions that can lead to decreased milk production and poor appetite. Recently a new conditionally licensed vaccine specific for goats has come on the market. At this writing, very little data are available regarding its clinical use. It is not approved for use in all states, so practitioners should consult their state veterinarian or the manufacturer for more information. Initial vaccination requires a 2-dose series 4 weeks apart, with annual revaccination required. Producers must be aware that vaccination will lead to a positive result on serologic testing.

Contagious Ecthyma Vaccines

Virulent live virus vaccines are available in the United States and labeled for use in both sheep and goats to decrease the severity of disease caused by contagious ecthyma virus (soremouth, orf). Use of these vaccines should be limited to herds where endemic disease is present or in outbreak situations where the disease has been newly introduced to the farm. Use of the vaccine on a farm without previous evidence of infection will result in contamination of the farm with live virulent vaccine virus. The goal of vaccination is to induce mild disease while creating immunity to future exposure. An area free of wool or hair is selected (axilla, flank, inner thigh) and a 1-in^2 area is scarified with a provided instrument, followed by application of vaccine. Development of a scab in the region of scarification is indication of successful vaccination. The vaccine is a virulent live virus, so care should be taken with administration; it poses a zoonotic risk of infection. Vaccination failures are known to occur, and it has been suggested that the increased occurrence of vaccine failures, particularly in goats, may be due to strain variation between sheep and goat isolates. Efforts are under way to develop goat-specific vaccine strains.[21]

Respiratory Vaccines

Despite the long list of bacterial and viral organisms thought to play a role in respiratory disease in small ruminants, the only available labeled vaccines in the United States are combination killed bacterins of *Mannheimia haemolytica* and *Pasteurella multocida*. Most vaccine strains are derived from bovine isolates; small ruminant strains, particularly for *M. haemolytica,* are not the same as those found in bovine cases.[22] Cross-reactivity among strains is variable, so the efficacy of these vaccines in small ruminants is inconsistent. In addition, many previously reported cases of *P. multocida* may instead have been caused by the newly classified *Bibersteinia trehalosi* (formerly *P. multocida* type T). If disease is truly caused by *P. multocida,* the vaccines may have some efficacy, but if *B. trehalosi* is the causative agent, none of the available vaccines are believed to offer significant protection to disease caused by this organism. There are currently no labeled vaccines for viral agents of respiratory disease in small ruminants, and there are no published studies evaluating the safety and efficacy of the use of bovine vaccines in these species.

Other Vaccines

An MLV vaccine is available for bluetongue virus in the United States, but it is thought to be of limited efficacy in the field because it contains only one of the six serotypes known to circulate in North America. Cross-protection among serotypes is thought to be very limited, so vaccination will only offer protection against the vaccine strain (serotype 10). The vaccine is known to cause fetal malformations in pregnant ewes and has the potential to be transmitted to unvaccinated animals during vector season.

A conditionally approved (California only) endotoxin vaccine is labeled for use in milking goats to decrease the severity of toxic mastitis caused by *E. coli*. In other areas of the country, some of the endotoxin vaccines commonly administered in dairy cattle are used off label in milking goat herds. Because of the low incidence of toxic mastitis in this species, routine use is not recommended. If these vaccines are used, administration will not prevent infection but will decrease disease severity.

Bovine Vaccines and Herd Vaccination Programs

Victor S. Cortese, *Consulting Editor*

With the increasing size of today's cattle operations and the extensive movement of cattle, disease exposure continues to occur at a high rate. These exposures often put pressure on the efficacy of the vaccines used and may give field experience as to how well they can protect cattle. The wide diversity in uses of cattle and management practices makes a single vaccination protocol impossible for all cattle production systems. Today it is even more important to scientifically choose a vaccine or design a vaccination program based on good information. When designing programs, several variables must be considered[1]:

- The presence and degree of challenge of the particular diseases on the farm or ranch (Boxes 48-1 and 48-2)
- Management practices on the facility that support or hinder vaccination programs
- The times or ages when disease problems occur and whether the diseases are associated with any stressors
- The immune system components necessary to afford protection against various diseases
- Some basic immunologic concepts
- The information available on products being considered and the source and quality of the information
- Required vaccines for a particular use of the animal (e.g., 4-H shows)

BOX 48-1

Bovine Vaccines Seldom Needed on Most U.S. Ranches and Farms*

Anthrax vaccine
Clostridium septicum (malignant edema) bacterins
Leptospira grippotyphosa bacterins
Leptospira icterohaemorrhagiae bacterins
Leptospira canicola bacterins
Clostridium botulinum toxoids
Clostridium novyi bacterins
Rabies vaccine
Tetanus toxoids
Erysipelas bacterins
Clostridium sordellii (malignant edema) bacterins

*These vaccines also are not cost-effective.

BOX 48-2

Bovine Vaccines for Ranch- and Farm-Specific (Soilborne) Diseases

Blackleg bacterins
Clostridium haemolyticum (redwater) bacterins
Anthrax vaccine
Clostridium novyi (infectious necrotic hepatitis) bacterins

BOX 48-3

Vaccines Recommended for Use in Adult Beef Cows

Vaccines Highly Recommended for All Herds

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Leptospira borgpetersenii var. *hardjo*
Leptospira pomona bacterins
Campylobacteriosis bacterins*

Vaccines That May Be Useful or Necessary in Specific Herds or Geographic Locations

Tritrichomonas foetus vaccine
Anaplasmosis vaccine (inactivated)
Rotavirus-coronavirus (calf scours) vaccine (inactivated)
Fusobacterium necrophorum (foot rot) bacterin
Escherichia coli bacterins
Clostridium haemolyticum (*Clostridium novyi* type D [redwater]) bacterins
Clostridium perfringens type C (enterotoxemia) toxoids
Anthrax vaccine
Clostridium novyi bacterins

*Highly recommended except in herds from which this disease can be reliably excluded (by virtue of the closed status of the herd and by isolation from other potentially infected herds by distance, terrain, and/or "bull-proof" perimeter fencing).

BOX 48-4

Vaccines Recommended for Use in Adult Beef Bulls

Vaccines Highly Recommended for All Herds

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Leptospira borgpetersenii serovar *hardjo*
Campylobacteriosis bacterins*

Vaccines That May Be Useful or Necessary in Specific Herds or Geographic Locations

Tritrichomonas foetus vaccine
Anaplasmosis vaccine (inactivated)
Leptospira pomona bacterins
Fusobacterium necrophorum (foot rot) bacterin
Clostridium haemolyticum (*Clostridium novyi* type D [redwater]) bacterins
Anthrax vaccine
Clostridium novyi bacterins

*Highly recommended except in herds from which this disease can be reliably excluded (by virtue of the closed status of the herd and by isolation from other potentially infected herds by distance, terrain, and/or "bull-proof" perimeter fencing).

Challenge

The level of disease challenge and the degree of protection continually fluctuate. Biological variability makes the degree of protection different in every vaccinated animal. The same is true for the level of exposure to a pathogen. Overwhelming challenge can override immunity and lead to disease even in well-vaccinated animals.[2]

Timing of Disease

On many farms, certain diseases occur at consistent times. Timing may give some insight into stresses that occur in the management of the cattle. Correcting these stresses can have a positive impact on vaccination and lessen animals' susceptibility to disease. This type of history is also helpful in determining the timing of vaccinations, a concept that is often underused in veterinary medicine. Knowing when a problem historically has occurred allows vaccinations to be scheduled when they will induce maximum immune responses in preparation for expected challenges.

Assessing Vaccine Efficacy

The efficacy of a vaccine can be extremely difficult for the practitioner to assess. Traditionally, serologic data showing pre- and post-vaccination titers has been equated with protection. For many diseases, however, the correlation is poor between the antibody measured and the protection generated by the vaccine in the animal.[3] Recently a study comparing BVDV protection showed an inverse relationship between antibody levels and the ability of the vaccines to prevent development of persistently infected calves.[4] Cell-mediated immune function tests have been added to show a more complete stimulation of the immune response after vaccination.[5] Although these tests provide more information about the vaccine, they still do not answer the basic question of how well a vaccine truly protects. This question can be answered only by well-designed challenge studies. There are many examples of well-designed studies involving both viral[6,7] and bacterial[8,9] agents. To assess a challenge study, the following information is needed:

1. Trial design, including animal characteristics
2. Statistical analysis of the results
3. Determination of whether statistical differences are biologically important
4. Route of administration of the challenge
5. Characteristics of the challenge organism
6. Consistency of the challenge model with the desired protection sought (e.g., respiratory vs. reproductive protection)
7. Method of clinical score assignment
8. Level of disease seen in the control unvaccinated cattle
9. Publication of the results in a peer-reviewed article

Unfortunately, the challenge model is not well established for many diseases. Field trials are even harder to assess but are valuable for judging the effectiveness (i.e., efficacy in a particular situation) and efficiency (i.e., cost-effectiveness) of a vaccine[10] (Boxes 48-3 to 48-12; also see Boxes 48-1 and 48-2). Several good references on field trial analysis are available.[11,12] Recently the Center for Veterinary Biologics (CVB) began giving vaccines different labels depending on the strength of the efficacy data submitted to them in the licensing trials.

BOX 48-5

Vaccines Recommended for Use in Beef Calves*

Highly Recommended Vaccines

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Bovine respiratory syncytial virus (BRSV) vaccines
Parainfluenza type 3 (PI-3) vaccines
Leptospira borgpetersenii serovar *hardjo*
Leptospira pomona bacterins
Brucellosis vaccine†

Vaccines That May Be Useful or Necessary in Specific Herds or Geographic Locations

Blackleg bacterins
Moraxella bovis (pinkeye) bacterins
Histophilus somni (formerly *Haemophilus somnus*) bacterins
Anaplasmosis vaccine† (modified live)
Clostridium haemolyticum (*Clostridium novyi* type D [redwater]) bacterins
Anthrax vaccine
Fusobacterium necrophorum (foot rot) bacterin
Clostridium novyi bacterins
Mannheimia haemolytica vaccines (new)

*Under 12 months of age.
†Heifer replacements only.
‡Heifer and bull replacements only.

BOX 48-6

Vaccines Recommended for Use in Stocker Cattle

Highly Recommended Vaccines

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Bovine respiratory syncytial virus (BRSV) vaccines
Parainfluenza type 3 (PI-3) vaccines
Mannheimia haemolytica vaccines (new)
Leptospira pomona bacterins

Vaccines That May Be Useful or Necessary in Specific Herds or Geographic Locations

Blackleg bacterins
Histophilus somni (formerly *Haemophilus somnus*) bacterins
Moraxella bovis (pinkeye) bacterins
Clostridium haemolyticum (*Clostridium novyi* type D [redwater]) bacterins
Anthrax vaccine
Fusobacterium necrophorum (foot rot) bacterin
Clostridium novyi bacterins

BOX 48-7

Vaccines Recommended for Use in Beef Replacement Heifers

Vaccines Highly Recommended for Use in All Herds

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Leptospira borgpetersenii serovar *hardjo*
Leptospira pomona bacterins
Campylobacteriosis bacterins*

Vaccines That May Be Useful or Necessary in Specific Herds or Geographic Locations

Blackleg bacterins
Tritrichomonas foetus vaccine
Anaplasmosis vaccine (modified live)
Rotavirus-coronavirus vaccine (inactivated)
Escherichia coli bacterins
Fusobacterium necrophorum (foot rot) bacterin
Moraxella bovis (pinkeye) bacterins
Histophilus somni (formerly *Haemophilus somnus*) bacterins
Clostridium haemolyticum (*Clostridium novyi* type D [redwater]) bacterins
Clostridium perfringens type C toxoids
Anthrax vaccine
Clostridium novyi bacterins

*Highly recommended except in herds from which this disease can be reliably excluded (by virtue of the closed status of the herd and by isolation from other potentially infected herds by distance, terrain, or "bull-proof" perimeter fencing).

BOX 48-8

Vaccines Recommended for Routine Administration to Cattle Entering Feedlots

Essential Vaccines

Infectious bovine rhinotracheitis (IBR) vaccine (modified live)
Bovine virus diarrhea (BVD) vaccine (modified live)
Bovine respiratory syncytial virus (BRSV)

Highly Recommended Vaccines

Mannheimia haemolytica vaccine*
Leptospira pomona bacterins

Vaccine That May Be Needed in Some Groups of Cattle in a Feedlot

Clostridium haemolyticum (redwater) bacterins

Vaccines Necessary Only in Specific "Problem" Feedlots

Blackleg bacterins
Bovine respiratory syncytial virus (BRSV) vaccines
Fusobacterium necrophorum (foot rot) bacterin

*Some commercial modified live cytopathic virus BVD vaccines trigger severe fatal BVD in cattle that are chronically infected with noncytopathic strains of BVD virus and immunologically tolerant as a result of prenatal infection.

Cattle Vaccines

Bovine vaccines tailored for use against 8 viral diseases, more than 28 bacterial pathogens, and 1 protozoal disease (trichomoniasis) are currently federally licensed in the United States (Table 48-8). These vaccines have been designed to aid in preventing a myriad of diseases in cattle, including reproductive, respiratory, generalized septicemic, and toxic (endotoxic and exotoxic) diseases. The vaccines have demonstrated some degree of protection against the pathogen for which they were designed, but they may not have proved protective against all the various syndromes known to be caused by a specific infectious agent. The challenge models for each pathogen and the release requirements for each vaccine are monitored by the Veterinary Biologics division of the USDA's Animal and Plant Health Inspection Service (USDA/APHIS) and can be found in Book 9 of the Code of Federal Regulations.

During gestation the bovine reproductive system, with its multilayered placenta, leaves the fetus in a naive environment susceptible to infection. Abortions may be due to infection of the placenta, inflammation of the ovary, death of the fetus, or disruption of the cervical plug. It is therefore difficult to achieve protection against reproductive diseases. Vaccination must minimize the amount or duration (or both) of the viremia or septicemia, or it must prevent the pathogen from moving through the cervix or crossing the placenta. Only a few currently licensed vaccines have proved protective against the reproductive forms of various diseases, and the duration of immunity they afford has not been established.

BOX 48-9

Vaccines Recommended for Use in Adult Dairy Cows

Vaccines Highly Recommended for Use in All Dairy Herds

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Bovine respiratory syncytial virus (BRSV)
Leptospira borgpetersenii serovar *hardjo*
Leptospira pomona bacterins

Vaccine Highly Recommended for Cows in Specific Infected Herds

Core endotoxin vaccines

Vaccines Highly Recommended for Dairy Cows Grazing in Specific Endemic Areas

Clostridium haemolyticum bacterins
Anthrax vaccine
Clostridium novyi bacterins

Vaccines That May Be Useful in Controlling Specific Disease Problems in Individual Dairy Herds

Escherichia coli (calf scours) bacterins
Rotavirus-coronavirus (calf scours) vaccine (inactivated)
Fusobacterium necrophorum (foot rot) bacterin
Clostridium septicum (malignant edema) bacterins
Clostridium sordellii (malignant edema) bacterins

BOX 48-10

Vaccines Recommended for Use in Adult Dairy Bulls

Vaccines Highly Recommended for Bulls in All Commercial Dairy Herds

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Leptospira borgpetersenii serovar *hardjo*
Campylobacteriosis bacterins*

Vaccines Highly Recommended for Bulls Grazing in Specific Endemic Areas

Anaplasmosis vaccine (inactivated)
Clostridium haemolyticum (*Clostridium novyi* type D, redwater) bacterins
Anthrax vaccine
Clostridium novyi bacterins

Vaccines That May Be Useful in Specific Herds or Geographic Locations

Leptospira pomona bacterins
Fusobacterium necrophorum (foot rot) bacterin

*Highly recommended except in herds from which this disease can be reliably excluded (by virtue of the closed status of the herd and by isolation from other potentially infected herds by distance, terrain, or "bull-proof" perimeter fencing).

Each manufacturer's development and production of cattle vaccines is different, so the composition of vaccines varies substantially among manufacturers. Outlines of production are proprietary for each manufacturer, but some information can be found in technical and marketing materials. For example, some viral vaccines are grown on bovine-derived kidney cell lines, and others are grown on porcine-derived kidney cells. Some vaccines are grown only on calf serum, whereas others are grown on both calf and fetal calf serum. Variability is seen in the strain or strains chosen for the vaccine, number of growth cycle passages chosen for attenuation, growth medium, and number of viral or bacterial particles in the vaccine.

BOX 48-11

Vaccines Recommended for Use in Dairy Calves*

Vaccines Highly Recommended for Calves in All Dairy Herds

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Bovine respiratory syncytial virus (BRSV) vaccines
Parainfluenza type 3 (PI-3) vaccines
Leptospira borgpetersenii serovar *hardjo*
Leptospira pomona bacterins
Brucellosis vaccine

Vaccines Highly Recommended for Calves Grazing in Specific Endemic Areas

Blackleg bacterins
Clostridium haemolyticum bacterins
Anthrax vaccine
Clostridium novyi bacterins

Vaccine Highly Recommended for Calves in Herds with Adult Cows Grazing in Specific Endemic Areas

Anaplasmosis vaccine (modified live)

Vaccines That May Be Useful in Controlling Specific Disease Problems in Individual Dairy Herds

Mannheimia haemolytica vaccines (new)
Histophilus somni (formerly *Haemophilus somnus*) bacterins
Moraxella bovis (pinkeye) bacterins
Fusobacterium necrophorum (foot rot) bacterin

*Up to 12 months of age.

BOX 48-12

Vaccines Recommended for Use in Yearling Replacement Dairy Heifers

Vaccines Highly Recommended for Use in Heifers in All Dairy Herds

Infectious bovine rhinotracheitis (IBR) vaccines
Bovine virus diarrhea (BVD) vaccines
Bovine respiratory syncytial virus (BRSV) vaccines
Leptospira borgpetersenii serovar *hardjo*
Leptospira pomona bacterins

Vaccines Highly Recommended for Dairy Heifers Grazing in Specific Endemic Areas

Blackleg bacterins
Anaplasmosis vaccine (Anavac* or Anaplaz)
Clostridium haemolyticum (*Clostridium novyi* type D [redwater]) bacterins
Anthrax vaccine
Clostridium novyi bacterins

Vaccines That May Be Useful for Controlling Specific Disease Problems in Individual Groups of Dairy Heifers

Fusobacterium necrophorum (foot rot) bacterin
Moraxella bovis (pinkeye) bacterins

Vaccines Administered to Springing Heifers That May Be Useful for Controlling Specific Disease Problems in Specific Dairy Herds

Gram-negative core antigen (coliform mastitis) vaccines
Escherichia coli (calf scours) bacterins
Rotavirus-coronavirus (calf scours) vaccine (inactivated)
Clostridium septicum (malignant edema) bacterins
Clostridium sordellii (malignant edema) bacterins

*Anavac (BioLOGIC Laboratories, Davis, Calif. 95616) is the preferred vaccine for use in dairy herds where adult cows are grazing in an endemic area.

TABLE 48-8

Antigens Available in Currently Licensed* Cattle Vaccines

Antigen Type	Common Name of Disease or Vaccine	Pathogen
Virus	BRSV	Bovine respiratory syncytial virus
	Rednose	Bovine herpesvirus type 1, infectious bovine rhinotracheitis virus (IBRV)
	BVD-MD	Bovine virus diarrhea virus (types 1 and 2)–mucosal disease
	PI-3	Parainfluenza type 3 virus
	Rabies	*Lyssavirus* spp.
	Warts	Bovine papillomavirus, bovine rotavirus, bovine coronavirus
Bacteria	Anthrax	*Bacillus anthracis*
	Bangs	*Brucella abortus*
	Vibriosis	*Campylobacter fetus* subsp. *veneralis*
	Blackleg	*Clostridium chauvoei*
	Redwater disease (bacillary hemoglobinuria)	*Clostridium haemolyticum*
	Black disease	*Clostridium novyi*
	Enterotoxemia	*Clostridium perfringens* type C
	Foot rot	*Fusobacterium necrophorum*
	Heel warts	*Treponema bacteria*
	Haemophilis, TEME	*Histophilus somni*
	Hemorrhagic bowel syndrome	*Clostridium perfringens* type A
	Overeating	*Clostridium perfringens* type D
	Malignant edema	*Clostridium septicum, Clostridium sordellii*
	Mycoplasma pneumonia and mastitis	*Mycoplasma bovis*
	Tetanus	*Clostridium tetani*
	Endotoxin vaccines	J5 *Escherichia coli*
		R mutant *Salmonella* vaccine
	Coliform scours	*E. coli* K99 and non-K99
	Food safety	*E. coli* O157 (SRP-conditionally licensed)
	Foot rot	*Fusobacterium necrophorum*
	Pinkeye	*Moraxella bovis*
	Leptospirosis	*Leptospira borgpetersenii* serovar *hardjobovis*
		Leptospira interrogans serovar *hardjobovis*
		Leptospira interrogans serovar *cannicola*
		Leptospira interrogans serovar *icterohaemorrhagiae*
		Leptospira interrogans serovar *grippotyphosa*
		Leptospira pomona
	Johne's disease	*Mycobacterium avium* subsp. *paratuberculosis*
	Salmonella	*Salmonella* Dublin, *Salmonella* Typhimurium
		Salmonella sideophore vaccines (SRP-conditionally licensed)
	Shipping fever	*Mannheimia haemolytica (Pasteurella haemolytica)*
		Pasteurella multocida
	Endotoxin vaccines	R *Salmonella*, J5 *E. coli*
	"Staph" mastitis	*Staphylococcus aureus*
Rickettsiae/protozoa	"Trich"	*Tritrichomonas foetus*
	Anaplasmosis	*Anaplasma marginale* (not federally licensed)

*Licensed by the Animal and Plant Health Inspection Service, U.S. Department of Agriculture.

Three types of vaccines represent the basic technologies currently available in cattle viral and bacterial vaccines[2,13-17]:

1. *Modified live (attenuated) vaccines* contain living bacterial or viral organisms. These organisms usually are collected from a field disease case and then grown in abnormal host cells (viruses) or media (bacteria) to change or attenuate the pathogen. Each completed replication cycle is known as a *passage,* and the changed pathogen then is administered back to the animal to determine if it is still virulent. After several passages the pathogen begins to lose virulence factors because it cannot cause "disease" in the unnatural host cells. Once the pathogen can no longer cause "disease" in the target species, it is tested to see if it can confer protection. The final vaccine is usually passed a number of times beyond the passage where virulence disappears in order to reduce the risk of reversion to a virulent pathogen. These vaccines require good quality control to reduce the risk of a contaminant entering the vaccine.
2. *Inactivated (killed) vaccines* are easier to develop because virulence after growth is not a problem. The same pathogen is isolated from a disease outbreak. The pathogen is grown and then chemically or physically killed. The inactivation is usually achieved either by adding a chemical to the pathogen or by using ultraviolet rays. The major concern with inactivation is the potential loss of important epitopes. An adjuvant is normally added to inactivated vaccines to heighten the immune response. The vaccine is then tested for efficacy.
3. *Genetically engineered vaccines* have been genetically altered, usually through a mutation. This mutation may be induced by several different methods, but the resulting bacterium or virus has different properties that may alter virulence or growth characteristics. Most of these vaccines are modified live mutants (e.g., temperature-sensitive viral vaccines or streptomycin-dependent *Mannheimia/Pasteurella* vaccines), but inactivated marker vaccines are also genetically engineered. These vaccines have been engineered to delete a gene and cause an immune response deficient in antibodies to a certain epitope; this allows diagnostic methods to distinguish between vaccine and natural exposure responses (e.g., gene-deleted infectious bovine rhinotracheitis [IBR] vaccines).

Once its efficacy has been established, the vaccine is put through a series of experiments to determine the minimum dose required to

VetBooks.ir

achieve adequate protection, called the *minimum immunizing dose* (MID). The vaccine will contain more than the MID to ensure that it contains at least the MID at the expiration date found on the label. In effect, a vaccine's efficacy is not determined by the final product used by the veterinarian but at a reduced level of immunogens from the amount contained in the final vaccine.

Autogenous Vaccines

In addition to the vaccines licensed by the USDA, several companies will make autogenous vaccines for use by veterinarians and cattle owners. These vaccines do not fall under any particular USDA/APHIS guidelines and are usually derived from cultures (e.g., viral or bacterial) isolated from specimens submitted by the particular farm. Such vaccines can be used only on that particular facility and cannot be sold for use on other farms. These vaccines are not tested for efficacy or safety, and the components found in the vaccines may vary from batch to batch; this adds some element of risk when they are used. Nevertheless, this type of vaccine may be an option to consider when federally licensed vaccines are unavailable for a specific farm problem.

Maternal Antibody Interference Revisited

It is an accepted belief that maternal antibodies can block immune responses from vaccination. This belief has been based on a procedure of vaccination followed by a titer evaluation in the vaccinates. Many studies have shown that vaccinated animals may not display increased antibody levels if high levels of maternal antibody to that antigen are present. However, recent studies have shown that both B-cell memory responses and cell-mediated responses can be stimulated despite high maternal antibody for the same antigens.[18-20] Seropositive calves vaccinated at a young age with modified live (MLV) bovine herpesvirus type 1 (BHV-1), parainfluenza type 3 (PI-3), and/or bovine respiratory syncytial virus (BRSV) vaccines have shown higher antibody responses on revaccination than control calves vaccinated only at the second date. These young vaccinates typically do not show increased antibody responses after the initial vaccination in the presence of high maternal antibody. Cell-mediated immune responses, as indicated by antigen-specific T-cell blastogenesis, have been demonstrated in the face of high maternal antibody levels[21] when attenuated BRSV and BHV-1 vaccines were used. Similar responses have been reported in laboratory animals as well.[22-24] One study also demonstrated higher levels of protection at challenge if calves were vaccinated with a modified live BRSV vaccine.[20] It is clear from these studies that maternal antibody interference with vaccines is not as absolute as once thought. The animal's immune status, the specific antigen, and the presentation of that antigen should be considered when designing vaccination programs in which maternal antibody may be a factor.

Impact of Stress

Stress affects the immune system of all cattle, as can a number of other factors. The release of corticosteroid that occurs during the birthing process has a dramatic impact on the newborn's immune system. Newborns also have a higher number of suppressor T cells than adults.[2] These factors and others dramatically diminish systemic immune responses for the first week of life.[25] Other stresses should be avoided at vaccination time to maintain the integrity of the immune system. Procedures like castration, dehorning, weaning, and movement have to be considered as stressors in cattle, and all have the potential to temporarily diminish immune system functioning.[26-28]

Systemic vaccinations should be avoided during high-stress times because of these diminished responses and because vaccination at such times may even have undesired effects.

Booster Importance

It is important to follow the label directions for administering vaccines. Many inactivated vaccines and some modified live BRSV vaccines require a booster before protection is complete. The first time an inactivated vaccine is administered, the primary response occurs. This response is not very strong, is fairly short-lived, and is predominantly composed of IgM antibodies (Fig. 48-1). The response seen after a booster vaccination is called the *secondary* or *anamnestic response.* This response is much stronger, of longer duration, and is primarily composed of IgG antibodies.[2,12] If the booster is given too early, the anamnestic response does not occur, and if too much time elapses before the booster is given, it acts as an initial dose, not as a booster.

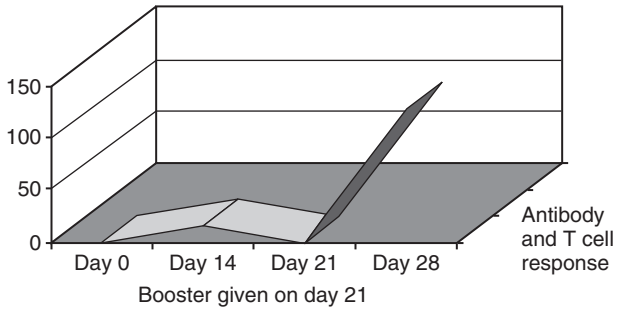

FIG. 48-1 Anamnestic response seen after booster dose is administered to vaccinates.

With most MLV vaccines (except for some BRSV vaccines), the primary vaccination also stimulates the secondary response without the necessity of a booster, because the virus or bacterium is replicating in the animal.

Adverse Reactions

Adverse reactions are a risk with any vaccination and can be categorized as one of the following two primary types of hypersensitivities[2,4,29-34]:

1. *Type I (immediate) hypersensitivity* is mediated by IgE stimulation and release of granules from basophils and mast cells. This reaction is seen within minutes of vaccination and often begins with shaking or sweating. Most of these animals respond to IV injection of epinephrine. Every vaccine can occasionally elicit an anaphylactic reaction. Cattle should always be kept under observation for at least 30 minutes after administration of a vaccine. Epinephrine should be administered at a dosage of 1 mL of 1:1000 solution per 50 kg of body weight, preferably by IV injection, at the first sign of weakness, staggering, or dyspnea. With most vaccines, anaphylactic reactions occur no more often than 1 case per 5000 to 10,000 doses administered. The rate of occurrence may be much higher after administration of *Salmonella, E. coli,* and some *Moraxella bovis* bacterins, which may have high levels of endotoxin.
2. *Type III (immune complex) hypersensitivity* is mediated by attachment of an antibody-antigen complex to complement and the ensuing activation of the complement cascade. The resultant reaction may occur locally or systemically. The reaction may be delayed, as the complexes form and the cascade begins, or subsequent, as products begin to exert their effects. The signs are similar to those of an immediate hypersensitivity reaction, and the treatment is administration of epinephrine.

One of the more common reactions seen in dairy cattle has been associated with the endotoxin and other bacterial components found in most gram-negative vaccines.[32-35] Currently, there are no requirements for monitoring or reporting the amount of endotoxin found in cattle vaccines, and the level of endotoxin may vary dramatically between vaccines and between serials of the same vaccine. Furthermore, the potency of endotoxin varies among different gram-negative bacteria. This type of reaction is seen primarily in Holsteins because of a genetic predisposition and may be seen after administration of any gram-negative bacterin. The signs vary depending on the farm's or the individual's sensitivity to gram-negative bacterial components. The number or potency of the gram-negative fractions in

VetBooks.ir

vaccinations administered simultaneously are also instrumental in causing these reactions. As a general rule, no more than two gram-negative vaccines should be administered to dairy cattle on the same day because of the possibility of adverse reactions, which may include anorexia and transient decreases in milk production, early embryonic death, abortion, and gram-negative bacterial shock (endotoxic shock), which requires treatment with flunixin or ketoprofen, steroids, antihistamines, and fluids.

Site reactions are common sequelae to many vaccines. These granulomas are usually caused by overreaction to the adjuvants, but they may also be directly aimed at the antigen or antigens. This has been a major focus of beef quality programs and has generated a push to have all vaccines labeled and to have them administered SC to avoid damaging the muscle.

Read the Labels

The vaccine label is a wealth of information that is approved by the CVB/APHIS. The CVB evaluates the supportive efficacy data supplied by the vaccine manufacturer and decides whether the vaccine can be licensed or not. They also determine what type of efficacy claim can appear on the vaccine labels and in advertising. Included are dosage, route of administration, precautions, timing, indications, storage information, withdrawal period, and shelf life. As found in Veterinary Services Memorandum 800.202 (June 2002), the CVB also does some preliminary rating of vaccine efficacy by granting one of five level of protection statements (in order of highest efficacy to lowest): Prevention of infection, Prevention of disease, Aid in the prevention of infection, Aid in disease control, Other miscellaneous claims. The label can be a good starting point for comparing vaccines.

Summary

Designing a vaccination program requires a good history of the individual farm and a basic understanding of the immune system. Vaccines that should be considered for routine or optional use in various classes of pastured beef cattle, feedlot cattle, and dairy cattle are listed in Boxes 44-3 to 44-12. The vaccines chosen should be supported by good, solid efficacy studies (and by effectiveness and efficiency studies if possible) to ensure that the product can fulfill the needs of the farm or ranch (see Table 44-8). Management decisions may be made that do not maximize the potential of the product chosen, and realistic expectations of all products should be well explained to the producer before the vaccines are administered. The owner should be involved in the vaccine decision-making process, and all information on the product should be shared.

Establishing good baseline immunity of replacement heifers and the foundation vaccination program can have dramatic effects on the health and profitability of the herd, so such programs must be well planned.

Bovine Respiratory Disease Vaccines

Bovine Herpesvirus Type 1 Vaccines

Robert W. Fulton

In 2012 more than 100 vaccines against BHV-1 were available in the United States for use in cattle.[1] These vaccines were either monovalent or in combination with other viral and/or bacterial immunogens. Vaccination protocols for beef and dairy cattle in the United States routinely incorporate use of one or more vaccines against BHV-1. These vaccines are classified into five types: (1) MLV vaccines for parenteral administration (IM and/or SC); (2) MLV intranasally administered vaccines; (3) chemically altered, live virus, temperature-sensitive vaccine for parenteral use; (4) inactivated viral (killed [KV]) vaccines for parenteral use; and (5) a combination of parenteral MLV and inactivated viral vaccine. These vaccines may be single-component (monovalent) vaccines (e.g., BHV-1 alone) or may contain several immunogens, including various combinations of bovine viral diarrhea viruses (BVDV) types 1 and 2; bovine parainfluenza type 3 (PI-3) virus, bovine respiratory syncytial virus (BRSV), *Leptospira* spp., *Histophilus somni, Mannheimia haemolytica, Pasteurella multocida,* and/or *Campylobacter* spp.[1] BHV-1 vaccines in the United States are principally derived from the Cooper/Colorado 1 strain, and in some cases the temperature-sensitive mutant RLB106.[1] The characteristics of the BHV-1 vaccines are described below.

BHV-1 MLV parenteral vaccines induce both B-cell (humoral) and T-cell (cell-mediated) active immune responses in vaccinated animals.[2,3] Calves born to dams with circulating BHV-1 antibodies may absorb the colostrally derived maternal antibodies to BHV-1 and other viruses.[4] The mean half-life of viral antibodies to BHV-1 in calves receiving maternal immunity was 21.2 days.[4] Potentially, calves receiving passive immunity to BHV-1 may have reduced response to BHV-1.[5] Calves seronegative to BHV-1 were given BHV-1 neutralizing antibody IM and subsequently given MLV BHV-1 intranasally. The passive BHV-1 immunity via BHV Ig reduced the efficacy of the MLV BHV-1.[5] The passively administered BHV-1 antibodies protected against viral shedding in viral challenged calves.[5]

MODIFIED LIVE VIRUS PARENTERAL VACCINES. The MLV parenteral vaccines were the initial vaccines licensed for use in cattle for protection against BHV-1.[6] Vaccines are attenuated by multiple passages in cell culture and often retain their ability to replicate in a susceptible animal, possibly causing a viremia. MLV parenteral vaccines are relatively inexpensive, offer a convenient route of administration, and stimulate a rapid onset of immunity (i.e., within 3 to 5 days of administration).[7-12] In general, one dose given to a susceptible animal stimulates protective immunity, which varies in duration depending on the clinical form of the disease challenge.[3,12] Duration-of-immunity studies are important to determine length of protection after initial vaccination. Calves receiving a combination MLV vaccine with BHV-1 were protected for at least 126 days after vaccination, as measured by protection against infection.[13] Licensure of BHV-1 vaccines in the United States requires efficacy studies using a standard challenge with the BHV-1 USDA Cooper strain. In addition, administration of a combination modified live BHV-1 vaccine yielded protection against virulent field strains of BHV-1.[14] The MLV parenteral vaccines may cross the placenta and infect the fetus, causing abortion.[15] Most MLV BHV-1 parenteral vaccines are not approved for use in pregnant heifers/cows or nursing calves.[1] In recent years, companies have received label claim approval for BHV-1 and BVDV MLV vaccine use in pregnant cows, providing they were initially vaccinated with that line of vaccines prior to breeding and within 12 months thereafter, and to nursing calves, provided their dams were vaccinated within 12 months as described above.[1,16] The impact of MLV BHV-1 and concurrent *M. haemolytica* vaccines have potential negative interactions. Administration of MLV vaccine containing BHV-1 and PI3V in combination with *M. haemolytica* vaccine reduced the efficacy of the *M. haemolytica* vaccine in preventing respiratory disease morbidity, respiratory disease mortality, and fibrinous pneumonia mortality and reduced the antibody response to *M. haemolytica* leukotoxin in a feedlot study.[17] In another study, coadministration of MLV BHV-1 and *M. haemolytica* immunogen interfered with the serum antibody response to *M. haemolytica* leukotoxin.[18,19] However, this interference was not seen when two intranasal vaccines containing the TS IBR were used concurrently.[20]

MODIFIED LIVE VIRUS INTRANASAL VACCINES. MLV intranasal vaccines can generally be divided into two types based on the attenuation process: (1) those modified by passage in a cell culture[19,21] and (2) those modified by treatment such that they become "temperature sensitive"[22] (i.e., they do not replicate at internal body temperature). MLV intranasal vaccines stimulate protection in susceptible animals with only one dose, in contrast to the chemically altered MLV parenteral vaccines. The label directions for some but not all

VetBooks.ir

MLV intranasal vaccines may indicate that they can be safely used in pregnant cattle.[1] These vaccines induce a rapid onset of protection (within 3 days of administration), possibly through interferon in the nasal secretions.[19] One benefit of the MLV intranasal vaccines is that they stimulate immunity at the upper respiratory tract, the portal of entry of the virus. Another benefit is their potential to immunize calves that are already seropositive because of maternal (humoral) antibodies passively transferred through colostrum.[23] Animals vaccinated with the MLV intranasal vaccines may transiently shed vaccine virus in nasal secretions and therefore might infect susceptible contact animals.[24]

CHEMICALLY ALTERED LIVE VIRUS VACCINES. The chemically altered BHV-1 vaccine strain was modified by nitrous acid treatment, which caused changes in the viral genome that resulted in a strain (RLB 106) that is temperature sensitive (TS), meaning it has limited replication at internal body temperature.[25] Presumably because of the limited viral replication, the vaccine requires two doses to stimulate immunity. Because it is temperature sensitive, the vaccine can be used in pregnant cattle.[1,25,26] This TS vaccine protected calves against respiratory disease after challenge and protected challenged pregnant cattle against abortion and stillbirth.[25] In one study, heifers received two doses of the vaccine and were challenged with BHV-1 7 months later (at 6 months' gestation). These heifers showed a significant reduction in the number of abortions and stillbirths compared with controls.[26]

INACTIVATED VIRAL VACCINES. Inactivated viral vaccines are prepared by chemical inactivation of virus grown in cell culture. An adjuvant is added to the inactivated strain to help stimulate an immune response. Inactivated BHV-1 vaccines require 2 doses (14 to 28 days apart) when used for the initial vaccination of susceptible cattle. Inactivated vaccines were once thought to induce a shorter duration of immunity against viruses than MLV vaccines and did not confer protection against mucosal infections. Experiments have shown inactivated BHV-1 vaccine protected calves against BHV-1 in a respiratory disease study and also protected pregnant cattle against BHV-1–induced abortions.[27,28,29] Controlled studies should be performed to determine the duration of immunity induced by inactivated BHV-1 vaccines and MLV vaccines, both for respiratory disease and fetal infections. A disadvantage of inactivated vaccines is that the onset of protection may not be as rapid as with MLV parenteral or MLV intranasal vaccines. An advantage of the inactivated vaccines is that they can be used in pregnant cows and nursing calves.

Use of Vaccines to Prevent and Control Bovine Herpesvirus Type 1 Diseases

Many vaccines are available for preventing and controlling the different forms of BHV-1 disease, and each vaccine has certain characteristics that should be considered when designing a vaccination program. Each vaccine also has both benefits and limitations. Probably more important is the management of the cattle.

PREGNANT ANIMALS OR ANIMALS NEARING BREEDING SEASON. MLV parenteral vaccines may infect the fetus if pregnant susceptible heifers or cows are vaccinated. Abortions have been reported subsequent to vaccination with MLV parenteral vaccines.[15] The MLV vaccine virus may also result in corpus luteum infection or disease.[30,31] Experimental studies have indicated a reduced conception rate in susceptible cattle that received an MLV parenteral vaccine 3 to 4 days before or 14 days after breeding.[30,31] It has been reported that pregnant cattle raised in contact with calves recently vaccinated with MLV parenteral vaccines had a greater incidence of BHV-1 abortion than those that did not have contact with vaccinates.[32] Consequently, the labels of MLV parenteral vaccines have usually stated that the vaccine should not be used in calves nursing pregnant cows. Recent studies have shown that calves given an MLV parenteral vaccine did not shed virus in their nasal secretions, nor did contact animals become infected with the vaccine virus.[33,34,35] Several companies have received label claim approval for the MLV vaccine containing BHV-1 and BVDV for pregnant cows, provided the cows had received the same line of vaccines with the MLV BHV-1 and BVDV prior to breeding and within 12 months thereafter.[1] Likewise, that vaccine could be used in nursing calves of cows previously vaccinated with that line of vaccines within 12 months.[1] Another concern is that the MLV vaccine virus may recrudesce, with resulting shedding of virus in cattle either stressed or receiving corticosteroids.[36] Realistically, concern about transmission of BHV-1 to animals in contact with those receiving MLV parenteral vaccines would be negligible if the contact animals were properly immunized and immune to BHV-1.

Until the vaccine labels on many MLV parenteral vaccines are changed, MLV intranasal vaccines or the inactivated or chemically altered live virus vaccines are usually recommended for pregnant cattle or those near breeding. The exceptions are the approved vaccines cited.[1] Vaccine recommendations should be weighed, with the benefits of vaccination as a guide and especially with the realization that properly vaccinated cattle are better protected when exposed to either field (virulent) or vaccine strains shed by vaccinated animals.

RAPID ONSET OF IMMUNITY. Cattle that are susceptible and likely to be exposed to BHV-1 should receive either an MLV parenteral vaccine or an MLV intranasal vaccine; both types induce immunity within 3 days of the initial dose. Rapid onset of immunity is desirable in situations like stocker calf and feedlot operations, in which calves are transported long distances to pastures or feedlots, stressing the animals and making them more susceptible to infection. Such calves also are exposed to infection with BHV-1 from contact cattle in the markets. The drawback to inactivated vaccines is that two doses are required to obtain good immunity.

DURATION OF IMMUNITY. Controlled studies on the duration of immunity are limited. A degree of protection against challenge existed at 6 to 9 months after vaccination with an MLV intranasal vaccine or an inactivated vaccine.[37,38] A parenteral BHV-1 MLV vaccine provided protection up to 126 days after vaccination.[13] Challenge studies for licensure are usually performed on calves within days of vaccination at the time of peak immunity. Also, the challenge may be for only one form of disease, usually the respiratory type. Such challenges may detect only protection against a severe form of the respiratory disease. Other manifestations of BHV-1 disease (e.g., abortions, neonatal disease, genital disease [male and female], conjunctivitis) occur, yet little or no data are available about vaccine efficacy against these other forms of disease. In one case, the genital form of BHV-1 disease (infectious pustular vulvovaginitis) occurred in heifers that had received an MLV parenteral vaccine 5 months earlier.[39] Given the lack of duration-of-immunity studies for BHV-1 vaccines and the cost of vaccines, breeding animals are usually vaccinated at least annually. In some feedyard situations, the animals may be revaccinated during the feeding period. It is industry practice that feedlot cattle receive a monovalent BHV-1 or multivalent viral combination MLV parenteral vaccine at reimplant time approximately 100 days after arrival. There have been field reports of BHV-1 respiratory disease (IBR) in feedlot cattle a few months after entry/processing, at which time they received MLV vaccines containing BHV-1.[40]

VACCINATION OF CALVES WITH MATERNAL ANTIBODY. The possibility exists that maternal BHV-1 antibodies acquired by the calf through ingestion and absorption of colostrum may interfere with vaccination. The level of these serum BHV-1 antibodies in the calf depends on the amount in the colostrum, amount absorbed, and half-life of the particular antibody (for BHV-1, 21.2 days).[4] Some calves receive no BHV-1 antibodies through colostrum, or they may lose them within 1 month. Some calves, however, may have serum BHV-1 antibodies for up to 6 months after birth.[36]

VetBooks.ir

Vaccination recommendations for neonatal calves include use of multiple doses of an MLV parenteral, an inactivated, or a chemically altered live virus vaccine or administration of an MLV intranasal vaccine. Maternal antibodies may block parenterally administered MLVs or inactivated vaccine, but the MLV intranasal vaccine may induce BHV-1 humoral and cell-mediated immunity.[23,41] Calves are often revaccinated at age 6 to 8 months regardless of their prior vaccination history.

ADVANCES IN VACCINES. Molecular techniques of biotechnology have been applied to the study of vaccines and the response to vaccination (vaccinology). These advances are especially noted for herpesviruses, including BHV-1. In addition to conventional vaccines manufactured via propagation of MLV and inactivated BHV-1 strains, current and future technologies offer opportunities for other vaccines.[42,43] These include subunit vaccines with a portion of the virus, deletion mutants with specific viral genomic fragments deleted, live vectored strains, DNA vaccines using plasmids, and plant-based vaccines. DNA vaccine comprising combinations of plasmids encoding for genes along with immunostimulatory CpG motifs have been evaluated for safety and efficacy in vaccinated cattle.[44] Use of deletion mutant BHV-1 vaccines as marker vaccines along with diagnostic tests for the deleted glycoprotein genes may permit identification of vaccinates under control programs.[45,46] Recently needle-free delivery of vaccines has been developed and implemented.[42] By high-pressure gas delivery, vaccines may penetrate the skin and be administered intradermally, SC, or IM.[42] Such delivery is designed to minimize damage resulting from IM injections. Two studies compared needle-free IM injection of multivalent MLV vaccine containing BHV-1 with conventional SC injection via syringe in dairy calves and feedlot cattle. In both studies, antibody titers to BHV-1 were higher at day 21 post vaccination in cattle vaccinated using the needle-free system than in those vaccinated using conventional needle injection.[47,48]

Vaccination Programs

The best possible vaccine provides protective immunity in the host against infection (viral replication) when challenged, protects the animal against all forms of disease (including multiple organ and systemic forms), and provides lifelong mucosal and systemic immunity. Ideally the vaccine recommendations would incorporate the results of field trials that are carefully designed to show the efficacy of the vaccine against a pathogen. Unfortunately, little information is available, as can be seen by a review of the literature, for evaluating the field efficacy of the respiratory disease vaccines.[49] The summary of results was mixed for BHV-1 vaccines and for other respiratory viral and bacterial vaccines. However, vaccines evaluated under field conditions may have included cattle already incubating the virulent infectious agent at the time of vaccination or animals that had been stressed and were unable to mount an effective immune response. Animals receiving vaccines prior to commingling and feedlot entry developed immunity that provided protection against respiratory disease, resulting in less morbidity, mortality, and treatment costs and often resulted in greater economic return to the producer.[50,51]

Veterinarians must make recommendations based on (1) experimental studies of vaccination followed by challenge under controlled laboratory conditions apart from the field conditions of normal cattle management and (2) clinical experience with vaccines. Data from challenge studies are often under the control of universities, the federal government, or a biologic manufacturer and may not be published. Government licensure studies require efficacy and safety evaluations, but these studies may not be available in scientific publications for review by those making recommendations. For these reasons, the veterinarian may not have access to all the data needed to make a good decision on vaccines.

The veterinarian's dilemma is confounded by other factors. First, licensure may be granted for vaccination efficacy that demonstrated protection against one form of disease, such as respiratory type. However, the virus may be just as important a pathogen of other organs, such as the developing fetus, as is the case with BHV-1. Second, information about the duration of immunity induced by each BHV-1 viral vaccine commercially available is unavailable or limited. Licensure studies may use challenge of vaccinated animals within 2 to 4 weeks of initial vaccination, yet cattle may be in feedyards (months) or breeding herds (years) after vaccination. Third, vaccines may induce a strong parenteral immunity, yet the surface mucosal defenses at the portal of entry may still be susceptible to infection even in presumably well-vaccinated animals. Thus it is entirely possible that natural infections could still occur in vaccinated animals. Ecologically, this point is reinforced because viruses, for which there are good immunization products, are still circulating in cattle populations after years of vaccination.

The veterinarian must therefore weigh both the benefits provided by vaccines and their limitations. This probably is best done by focusing on the real economic effects of certain disease manifestations, including morbidity, mortality, and treatment and prevention costs. Historically this approach has been applied to two important forms of BHV-1 disease: the respiratory form, singularly or in combination with pneumonic bacterial diseases, and the fetal disease (abortions). As a result, most vaccine regimens focus on preventing respiratory disease in both young and adult animals and on protecting the pregnant breeding herd of cows and heifers against abortions. Another fact to be considered is that many vaccines contain multiple viral or bacterial components (or both), some of which may require multiple doses for effective immunization, whereas others may require only one dose.

GUIDELINES

Calves. Calves may be vaccinated at weaning or 30 days before weaning. Calves vaccinated before age 6 months should be revaccinated because the earlier vaccination may have been blocked by maternal antibodies. The MLV parenteral and intranasal vaccines require only one dose in susceptible calves, whereas the chemically altered live virus or inactivated vaccines require two doses. Although the labels for most MLV parenteral vaccines state that the vaccine should not be used if the calf is nursing a pregnant cow, the likelihood of infection of the pregnant cow may be minimal, especially if she is already immune. Yet as described above, MLV parenteral vaccines are available for use in pregnant cows and nursing calves.

Breeding Cows and Heifers. Yearling heifers (12 to 14 months of age) should be vaccinated at least 1 month before breeding. Any of the vaccines may be used, but if two doses are required, the second dose should be given at least 1 month before breeding.

Pregnant cows may be vaccinated with a vaccine that has a label description warranting such use; these include MLV intranasal vaccines, chemically altered live virus vaccines, inactivated vaccines, and approved MLV parenteral vaccines. Generally one dose is used, primarily because of management considerations. However, following the vaccine label recommendations for number of doses and safety for pregnant cow use is important. Administering booster doses of BHV-1 vaccines may have two conflicting outcomes as a result of booster dose stimulation of an increase in colostral BHV-1 antibodies transferred to the newborn calf in the colostrum: (1) it may be beneficial to the calf to have increased BHV-1 serum antibodies for protection against BHV-1 disease, or (2) the calf may have longer duration of BHV-1 antibodies, which may block BHV-1 immunization. There are no published multiyear duration-of-immunity studies in vaccinated cattle challenged with virulent BHV-1. Because of the relatively low cost of BHV-1 vaccines and the need to vaccinate against other pathogens, many breeding cows are given a BHV-1 vaccine annually.

Stocker and Feeder Cattle. Cattle to be shipped to forage pasture after weaning (wheat pasture or native grass) or to feedyards should be vaccinated 2 to 3 weeks before shipment. However, management practices and marketing may only permit vaccination at initial collection point, market site, or stocker/feedlot delivery. Any of the major types of BHV-1 vaccines may be used, but those that require only one dose have two advantages: rapid onset of immunity and less handling required (1 dose vs. 2).

VetBooks.ir

Cattle presented for purchase immediately before shipment, with no known vaccination history, pose a challenge. Presumably healthy cattle may be candidates for the one-dose MLV parenteral or MLV intranasal vaccines, because these calves may benefit from rapid induction of immunity. Cattle already infected with BHV-1 may not be protected by vaccination.

Cattle entering the feedyard usually receive either the MLV parenteral or MLV intranasal vaccine, particularly for rapid onset of immunity.[52] Cattle are routinely revaccinated while in the feedyard in some operations to ensure protection against BHV-1 disease throughout the feeding period.[41]

Breeding Services. Veterinarians should consult the breeding bull center for vaccination requirements for bulls, especially relating to collection and export shipment of semen for artificial insemination (AI). MLV intranasal vaccines have been used in AI bulls, because these vaccines are less likely to cause latent infections than MLV parenteral vaccines.[53,54] As mentioned previously, MLV parenteral vaccines cause latent infections that may recrudesce with stress or administration of corticosteroids, which means the virus would be present in semen.[36,52]

Bovine Virus Diarrhea Virus Vaccines

Victor S. Cortese

Our knowledge of the different vaccines' ability to protect against infection with BVDV is rapidly increasing. Currently, three kinds of BVDV vaccines are available: MLV vaccines, temperature-sensitive vaccines (available only in Europe), and inactivated virus vaccines (Table 48-9). MLV BVDV vaccines have demonstrated advantages over the newer inactivated vaccines. Most of these advantages are common to all MLV vaccines[1,2]: (1) MLV vaccines are less expensive, (2) postvaccination anaphylactic reactions occur less often than after administration of some inactivated vaccines, (3) immunity is achieved more rapidly after administration of a single dose (within 7 to 10 days), (4) MLV vaccines produce much higher levels of serum neutralizing antibodies,[3] (5) immunity lasts longer,[4-6] (6) MLV vaccines are effective against a broader spectrum of viral strains,[3] and (7) MLV BVDV vaccines are better able to protect the developing fetus from infection.[7]

On the other hand, MLV BVDV vaccines have certain disadvantages compared with inactivated BVDV vaccines: (1) some MLV vaccines can produce mild immunosuppression for brief periods after administration,[5] (2) some have been associated with what is usually a rather low incidence of a highly fatal disease syndrome, postvaccinal mucosal disease[8,9] (see later), and (3) until recently, MLV vaccines were not ordinarily recommended for routine use in pregnant cattle.

Studies have shown that the duration of cross-neutralizing antibodies stimulated by inactivated BVDV vaccines depends on the antigenic similarity between the vaccine strain and the wild-type virus to which the cow is exposed.[10,11] If there are few common proteins, the ability to neutralize can be as short as 4 months; if there are many common antigenic sites, neutralization may last a year. MLV BVDV vaccines stimulate cross-neutralizing antibodies that can still be detected 18 months after vaccination.[3] This longer duration was further demonstrated by a modified live BVDV vaccine receiving a USDA label containing a 1-year duration of immunity against the birth of both type 1 and type 2 persistently infected calves.[12]

Recent studies have demonstrated the ability of both modified live[13,14] and inactivated type 1 vaccines[15] to provide protection against

VetBooks.ir

type 2 BVDV strains, although the protection afforded by the MLV vaccine was more complete. The USDA/APHIS has established a licensing protocol for BVDV vaccines to obtain a type 2 BVDV protection claim. Most of the vaccines licensed against both BVDV type 1 and type 2 contain BVDV type 1 and type 2 isolates. The question of current vaccines' ability to cross-protect against BVDV type 1b strains has been raised,[16] and further studies are needed to determine the level of protection afforded by current vaccine strains.

Vaccination and Mucosal Disease

Mucosal disease (MD) is seen when an animal that is persistently infected is exposed to another closely related cytopathic strain of BVDV. Also, theoretically a noncytopathic BVDV strain can mutate spontaneously into a cytopathic strain, resulting in MD without any subsequent exposure. High stress and immunodepression may be involved in this mutation.[17,18]

A major concern with the MLV vaccines is whether they can cause MD.[10,19,20] For MD to occur, the cytopathic strain in the MLV vaccine must be closely related to the noncytopathic strain in the persistently infected animal. With the degree of attenuation of MLV vaccines today, an animal must be nutritionally deficient or severely stressed, or both, to face an increased likelihood of developing MD from the vaccine. This suggests that a specific set of circumstances is required and that MD caused by vaccination, when it occurs, is rare.

Bovine Virus Diarrhea Virus Vaccines and Reproductive Control

Control of BVDV centers on prevention of persistent infection and elimination of persistently infected cattle; this means identifying and removing persistently infected animals and continued vaccination to prevent persistent infection are necessary for effective control. Persistent infections occur through in utero infection of the fetus (up to roughly 125 days' gestation) with a noncytopathic strain of BVDV.[3,17] Although the mechanism of transplacental transfer of BVDV is unknown, small amounts of virus in the dam's bloodstream appear to be sufficient to produce these immunotolerant cattle. Protection of the dam may or may not correlate with protection of the fetus from subsequent persistent infection if viremia of the dam occurs. To break the cycle of in utero infection and persistent infection, it is essential that vaccination provide fetal protection.

Several studies have been performed to assess the ability of vaccines to protect the fetus against either natural or artificial challenge. Results of these studies showed that most inactivated vaccines failed to provide much fetal protection,[7,10,21-26] except for one experimental vaccine, which is reported to give a high level of fetal protection. With the experimental vaccine, inability to isolate the virus from offspring of vaccinated animals indicated good protection.[27] However, the challenge of controls resulted in only about a 50% rate of persistent infection. Only one inactivated vaccine has demonstrated a high level of fetal protection and was given the appropriate label by the USDA (see Table 48-8). Other published reports demonstrated that MLV BVDV vaccines were more effective at protecting the fetus[7,28-30] and that inclusion of a type 2 vaccine broadened the strains against which vaccinates were protected.[31] To date, vaccines licensed in the United States have not been required to provide fetal protection. However, label indications are being granted by the USDA to vaccines that demonstrated the ability to prevent development of persistently infected calves. Several vaccines have achieved this label claim (see Table 48-8).

Bovine Virus Diarrhea Virus Vaccination Programs

Because BVDV infections can cause severe death loss and immunosuppression, all herds of cattle should be vaccinated against BVDV. Although it was once thought that BVDV vaccines would not immunize calves that were passively immune to BVDV,[32,33] recent studies have shown that immunization can occur with certain inactivated vaccines[34] and with MLV vaccines (when the passive antibody titer against BVDV is 1:64 or below).[13,35] When required, BVDV vaccines can be administered to young calves, with the possibility of gaining some degree of protection. In most calves the maternal antibodies against BVDV drop below the 1:64 level by 5 to 6 months of age. If an early BVDV problem does not exist, waiting to administer the first BVDV vaccine until at least 6 months of age increases the number of animals that respond to vaccination.

Among cows given MLV BVDV vaccines in the last trimester of pregnancy, 86% of the calves from seronegative cows[36] and some calves (0[36] to 52%[37]) from seropositive dams were actively immune at birth. In addition, the calves' level of passive immunity to BVDV was enhanced, in that seronegative cows seroconverted and serum antibody titers were boostered in 52% of the seropositive cows. The rate of occurrence of BVD in neonatal calves was reduced.[38] Administration of an MLV BVDV vaccine to seronegative cows after day 118 of gestation did not result in adverse effects.[38,39] However, vaccination with an MLV noncytopathic virus vaccine before day 118 resulted in fetal resorption, abortion, congenital defects, and the birth of undersized, weak, persistently infected calves. Several authors have recommended vaccination of cows with an MLV BVDV vaccine during the last trimester of pregnancy.[22] Three MLV BVDV vaccines are now labeled for use in pregnant animals. To ensure the safety of these vaccination schedules, label directions must be adhered to.

It is important to consider the epidemiologic nonresponse rate to any vaccine when designing a BVDV vaccination program. Therefore, even though MLV BVDV vaccines do not require a booster dose, a second dose may be advised to stimulate protection in animals that did not respond to the initial vaccination. BVDV vaccination programs should include the following features:

1. A virus isolation and cull program should be instituted, along with a vaccination program that includes administration of at least one dose of an MLV BVDV vaccine to all replacement animals.
2. Vaccination with killed vaccines should be increased to 2 or 3 times a year, or an MLV BVDV vaccine should be given to open cows 3 weeks before breeding or turning in the bull.
3. The vaccines used should have been proved to stimulate protection against BVDV type 1 and type 2.

Bovine Respiratory Syncytial Virus Vaccines

John A. Ellis

Bovine respiratory syncytial virus (BRSV) is a pneumovirus in the paramyxovirus family that endemically infects cattle populations worldwide. Although the virus can cause disease in all ages of cattle, it primarily clinically affects calves in recurrent seasonal outbreaks.[1-3] Resulting respiratory disease is characterized by pyrexia, coughing, and tachypnea, which can progress rapidly to severe expiratory dyspnea.[2,4] BRSV is also considered one of the viral agents that predisposes animals to secondary bacterial infections in the bovine respiratory disease (BRD) complex; however, secondary infections are often absent in fatal BRSV-associated respiratory disease.[5,6] Subclinical BRSV infection or mild respiratory disease due to BRSV infection in dairy cattle may have a negative impact on milk production.[7]

Parenteral Vaccines

MLV and inactivated parenteral BRSV vaccines have been commercially available since the 1980s. Most of these vaccines are formulated in combination with other viral respiratory pathogens, including PI-3, BHV-1, and BVDV. The efficacy of commercial MLV nonadjuvanted and adjuvanted combination BRSV vaccines in conferring

VetBooks.ir

significant disease-sparing subsequent to experimental infection with a virulent field isolate has been demonstrated.[8] Most vaccinated calves shed virus, but the peak virus titer was suppressed compared with unvaccinated controls. Viral clearance was coincident with the simultaneous appearance of mucosal antibody, cytotoxic T cells in the lungs, and anamnestic or primary serum antibody responses. In contrast, virus clearance in unvaccinated calves was coincident with the appearance of BRSV-specific cytotoxic cells before mucosal antibody was detected.[8]

The efficacy of parenterally delivered MLV vaccines in calves with MDAs, the most relevant candidates for vaccination in the field, remains controversial and unresolved. In studies conducted in the 1980s, administration of attenuated BRSV by the IM route to passively immune calves reportedly did not elicit mucosal memory IgA or serum antibody responses or even prime for such responses,[9] but T-cell responses have been demonstrated after parenteral vaccination in passively immune calves.[10] Whether these responses correlate to a protective cell-mediated memory response when maternal antibodies decline has not been determined. The ability of modified live BRSV vaccines to prime for protective immunity in the context of MDAs is likely to vary with the concentration of MDA, the antigenic mass of the vaccine, and/or vaccine formulation.[11]

Investigations using the same challenge model in BRSV-seronegative calves as used to demonstrate the efficacy of MLV vaccines have shown a similar disease-sparing efficacy of some combination of inactivated vaccines containing BRSV formulated with different adjuvants.[12,13] Clinical protection was associated with serum concentrations of BRSV-specific IgG as determined by ELISA,[12,13] and in one case[12] the presence of IFN-γ–secreting BRSV-specific $CD4^+$ T lymphocytes in the blood of vaccinated calves. There are conflicting data concerning the ability of commercial inactivated BRSV vaccines to override maternal antibodies and stimulate protective responses after parenteral immunization, which may be related to the vaccine formulation and adjuvant.[14,15] Relevant to the importance of vaccine formulation in affecting efficacy in the context of MDAs, recent studies have demonstrated clinical protection following experimental challenge of seropositive calves that were vaccinated with BRSV antigens that were adjuvanted Quil A,[16] either together with anhydrogel or in immune-stimulating complexes (ISCOMs).[17]

Most experimental studies concerning the efficacy of commercial BRSV vaccines are consistent with previous field trials, demonstrating the safety and efficacy of parenterally administered vaccines.[18,19] In addition, one study suggested the usefulness of combination vaccines in reducing the impact of subclinical BRSV infections.[12]

Protection against BRSV infection and disease is associated at least in part with an IgA response,[1-3] but serum IgG acquired from either passive or active immunization can significantly reduce the severity of clinical respiratory disease that results from BRSV infection. Several studies have reported that the incidence and severity of disease in calves were inversely related to the maternal antibody titers.[19-21] In the case of herd immunity, passive antibodies were detectable in 50% of the calves for 3 months after birth and were present in some calves until 7 months of age.[22] Therefore administration of BRSV vaccines to cows in late gestation to booster colostral antibody titers is a rational strategy to deal with BRSV-induced respiratory disease in young calves (1 to 3 months of age) in problem herds, without having to be concerned about the immunizing potential of particular parenteral vaccines in young seropositive calves.

Intranasal Vaccines

Because BRSV is an endemic infection in most cow herds, most young calves will have BRSV-specific maternal antibodies unless there is failure of passive transfer. Given the endemic nature of BRSV, many calves are likely exposed to BRSV early in life and will contract BRSV-associated respiratory disease if their passive protection is poor or has waned. These biological factors, together with the mixed results (to date) with parenteral administration of BRSV vaccines to young seropositive calves, has stimulated interest in intranasal vaccines for BRSV. Combination intranasal vaccines containing ML BRSV are commercially available in North America and Europe. Conceptually, it was demonstrated in the late 1980s that intranasal inoculation of tissue culture–attenuated BRSV to passively immune calves primed for mucosal memory and an anamnestic IgA response subsequent to challenge.[23] Subsequent studies with culture-attenuated BRSV confirmed this phenomenon.[24] It was also demonstrated that parenteral combination MLV vaccines containing BRSV can be efficacious if administered intranasally.[25,26] Single intranasal administration of these vaccines to young calves primed for protective responses to subsequent experimental challenge. In one of these studies,[25] results demonstrated that effective priming was achieved in BRSV-seropositive calves, confirming the previous observations with experimental single-component BRSV vaccines.[24,26] Subsequent studies have further demonstrated the efficacy of combination MLV vaccines containing BRSV in young seronegative calves[27,28] and to a lesser extent in seropositive calves.[27] As with parenteral vaccines, available data indicate that the efficacy of intranasal vaccines in the context of MDAs is not an all-or-none phenomenon and is likely somewhat dependent on the concentration of MDAs at the time of vaccination and probably factors related to vaccine formulation.[27] Currently, there is little information about the duration of the protective response after vaccination. It has been shown that cattle can be experimentally reinfected by 35 days after initial infection with virulent BRSV even in the presence of circulating antibody.[3] Consistent with this, available data indicate that the duration of effective clinical immunity after a single intranasal dose of ML BRSV to neonatal calves may be less than 4 months.[27] A major focus of current research is determining the appropriate dose, antigenic form, route of administration, and interval to use to most effectively boost neonatal priming by intranasal vaccination.

Adverse Reactions to Bovine Respiratory Syncytial Virus Vaccines

A major factor hampering development of a vaccine for human respiratory syncytial virus (HRSV) is the dramatic HRSV vaccine failure in the 1960s, in which vaccination with a formalin-inactivated (FI), alum-adjuvanted HRSV predisposed children to more severe disease after subsequent HRSV infection.[29] Although this same disease-enhancing phenomenon has been demonstrated in some studies of experimental FI-BRSV vaccines in cattle,[30,31] it is unlikely that modern manufacturing practices would use formalin inactivation for BRSV or other viral vaccines. Nevertheless, there are documented cases of apparent enhancement of BRSV-associated respiratory disease in cattle that received either inactivated or MLV vaccine in the field, indicating that some commercial vaccine formulations may stimulate potentially pathogenic immune responses in some cattle.[32,33] The immunologic mechanisms responsible for vaccine-associated disease enhancement are not completely understood. The current hypothesis is that some BRSV vaccines, notably FI-BRSV, mainly prime T helper cell (Th)2-like responses involving eosinophil influx into the lung and production of high concentrations of BRSV-specific IgE.[30,31] Several studies have consistently documented a disparity in the type of antibody responses induced in cattle by MLV and inactivated BRSV vaccines.[30-36] Parenterally administered MLV BRSV vaccines generally stimulate moderate to high concentrations of VN antibody in the serum, whereas inactivated vaccines stimulate high concentrations of partially neutralizing or non-neutralizing antibody. The data are conflicting concerning the prophylactic or disease-enhancing properties of these different types of vaccine-induced antibody responses.[30,34] Alternatively, as was suggested in the case of disease enhancement after parenteral administration of a combination MLV BRSV vaccine,[32] the timing between vaccination and infection could be a critical factor. This may be related to the stage of the immune response—specifically, a predominance of BRSV-specific IgM at the time of infection may somehow predispose to enhanced disease. Collectively, evidence from numerous studies with commercially

VetBooks.ir

available BRSV vaccines indicate that some combination of cell-mediated and antibody-mediated immunity can be involved in disease sparing in BRSV-infected cattle. Available data suggest that the dichotomization of RSV-specific Th cell responses into Th1 (protective) versus Th2 (potentially pathogenic)[37] is an oversimplification of a complex biology. As the epidemiology of BRSV-associated respiratory disease in the field indicates, disease caused by reinfection is usually less severe than that after the initial infection.[1-3] These observations indicate that most cattle do not develop clinically significant allergic (IgE) response to BRSV from naturally acquired infections, or to most BRSV vaccines, in the vast majority of cases. Nevertheless, given the history of adverse reaction to RSV vaccines in humans and, to a lesser extent, cattle, care should be taken in making assumptions about the efficacy and safety of BRSV vaccines without supporting data.

Parainfluenza Type 3 Virus Vaccines

John A. Ellis

Parainfluenza virus type 3 (PI-3V) is a ubiquitous paramyxovirus in cattle populations worldwide.[1] In uncomplicated experimental PI-3V infections, clinical signs of coughing, tachypnea, and fever have been observed from 4 to 12 days after infection.[1] Although the virus was originally detected in calves with respiratory disease (often in the absence of other agents), has been used to experimentally reproduce respiratory disease, and exposure to the virus has been detected by seroconversion in animals with BRD complex, its importance as a pathogen is currently somewhat controversial.[1,2] Consequently, very little primary research has been conducted on this virus in the past 2 decades. Generally PI-3V is viewed as a potentiating agent in mixed infections, predisposing the animal to bacterial pneumonia by altering bacterial clearance in the upper and lower airways and by infecting both respiratory epithelia and alveolar macrophages.[1]

Five types of PI-3V vaccines are commercially available: (1) MLV IM vaccines, (2) MLV temperature-sensitive IM vaccines, (3) MLV intranasal vaccines, (4) MLV temperature-sensitive intranasal vaccines, and (5) inactivated virus vaccines. All PI-3V vaccines available in North America are combined with at least a BHV-1 vaccine. A single-antigen MLV PI-3V intranasal vaccine that was available in Europe had demonstrated efficacy in a challenge model that produced severe disease that was typical of that reported in the original descriptions of the virus.[1,3] Generally, the challenge models previously and currently used result in minimal if any clinical disease, making it difficult to assess the clinical immunity induced by PI-3V vaccines.[4,5] In most vaccine efficacy studies, the use of attenuated challenge results in minimal disease. This probably contributes to the impression that PI-3V is not a significant pathogen. The latter assumption was also commonly made about BRSV before more robust challenge models were developed and used.[1]

Opinions are divided as to the relative importance of mucosal versus systemic immune responses in achieving protection from PI-3V–associated respiratory disease and, by extension, the comparative efficacy of intranasal and IM vaccines. Some comparative studies[6,7] reported that intranasal vaccination resulted in better protection against experimental challenge; others[8] were unable to demonstrate any advantage to the use of one vaccine or route of administration over the other. A notable exception, however, was young calves with maternal antibodies, in which intranasal administration was thought to produce a more effective immune response. Passive antibodies may persist in calves until 8 months of age and may interfere with active immunization.[9] Consequently, calves vaccinated parenterally before 6 months of age should be revaccinated after reaching 8 or 9 months of age.[9]

Although not experimentally documented, as in the case of BRSV, it is likely that given the similar biology of PI-3V infection, a mucosal (IgA) response is necessary to prevent PI-3V infection, but that passively (maternal) or actively acquired serum IgG is likely to mediate significant sparing of clinical disease subsequent to infection. The cell-mediated (cytotoxic T cell) response in the clearance of PI-3V is a poorly documented but probably important effector mechanism stimulated by MLV vaccines, as is the case with BRSV.[1]

There is debate about the overall utility and economic benefit of using PI-3V (and BRSV) vaccines in the field.[10,11] Much of the uncertainty is undoubtedly related to the difficulties involved in determining the relative importance of a particular agent in a multifactorial disease process such as BRD complex. Few studies[1,11] address the economic impact of subclinical paramyxovirus infections in cattle. No recent studies (in the past 5 years) directly address the economic impact of inclusion of PI-3V in combination vaccines. There are conflicting data from studies conducted under commercial feedlot conditions as to the economic benefit of including PI-3V in a vaccination program.[12-14] One study found no decrease in morbidity or mortality when 2 versus 1 dose of a combination viral vaccine containing PI-3V was used in a feedlot environment.[15] A limitation of these studies and such studies in general is the difficulty in obtaining, or failure to attempt to obtain, specific etiologic diagnoses, making it difficult to determine whether an immune response against one or more antigens was responsible for any disease sparing.

Mannheimia haemolytica, Pasteurella multocida, Histophilus somni, and *Bibersteinia trehalosi*

Jared D. Taylor • Anthony W. Confer

Mannheimia haemolytica Vaccines

M. haemolytica serotype 1 (formerly *Pasteurella haemolytica* A1) is the organism responsible for the clinical signs and lesions of severe bovine fibrinous pleuropneumonia (shipping fever).[1,2] The bacterium is a gram-negative commensal of the bovine upper respiratory tract, and its presence in the nasopharynx is not predictive of impending disease.[3,4] It is hypothesized that immunosuppression due to stress or viral infection permits the bacterium to proliferate, evade clearance by normal protective mechanisms, and establish infection within the lungs. Once lung colonization is established, it stimulates a series of pathologic events leading to acute severe fibrinopurulent inflammation and necrosis. The bacterium was renamed *Mannheimia haemolytica* owing to substantial genomic differences between it and other members of the *Pasteurella* genus; however, commercial vaccines may still refer to it by its previous name, *Pasteurella haemolytica*.[5]

Immunity to *Mannheimia haemolytica*

Twelve serotypes of *M. haemolytica* occur (A1, A2, A5, A6, A7, A8, A9, A12, A13, A14, A16, and A17), and only partial cross-serotypic protection is seen following vaccination.[6] Serotypes A1, A2, and A6 are the most prevalent.[7-9] Because *M. haemolytica* is strictly an extracellular organism, humoral immunity is far more important to controlling infection than cell-mediated immunity. There is substantial evidence that cattle entering a feedlot with preexisting serum antibody titers to *M. haemolytica* have less respiratory disease and fewer deaths than those without serum antibodies.[10,11] Maternal antibodies to *M. haemolytica* and *P. multocida* can be found in both dairy and beef cattle but decline to undetectable levels between 30 and 90 days of age.[12] Natural exposure to the nasal flora causes most calves to subsequently and spontaneously develop antibodies to these bacteria.[12] Unfortunately, this antibody response is typically short lived, and calves seem to become susceptible following decline in antibody levels. Antibody responses following natural exposure target numerous cellular components and secreted products. Those with the most potential for stimulating immunity include capsular polysaccharide, lipopolysaccharide (LPS), outer membrane proteins (OMPs), iron-regulated OMPs, a secreted leukotoxin (LKT), a serotype-specific antigen, and several other secreted

VetBooks.ir

enzymes including neuraminidase, a sialoglycoprotease, and bovine immunoglobulin-specific proteases.[13,14] The central dogma of *M. haemolytica* vaccination is that immunity to the organism requires stimulation of antibodies that neutralize LKT and antibodies that bind to surface antigens, allowing for complement-mediated killing and/or phagocytosis of the bacterium.[15] There is no agreement as to what are the most important surface antigens, but OMPs and iron-regulated OMPs are the major candidates based on many in vitro and in vivo studies.[16-20] Capsular polysaccharide is theoretically an important surface antigen because it is the first surface molecule encountered by cellular and humoral components of the immune system, and its presence enhances *M. haemolytica* resistance to phagocytosis and complement-mediated killing.[21] However, antibody responses to *M. haemolytica* capsular polysaccharide do not always correlate with resistance, and vaccination with purified capsular polysaccharide failed to protect against challenge.[22,23] LPS is also a surface antigen, but antibodies to *M. haemolytica* LPS failed to correlate with resistance to experimental challenge, and passive antibodies to *M. haemolytica* LPS were not protective in experimentally challenged calves.[24,25]

Use of *Mannheimia haemolytica* Vaccines in Beef Calves

Several studies have examined how rapidly various commercial *M. haemolytica* vaccines induce antibody response and how long after vaccination antibodies remain detectable. Antibody responses quickly reach their maximum (typically within 14 days after vaccination) and abruptly wane (significantly lower by day 28, and sometimes returning to baseline by day 42).[26,28] Revaccination an extended period after initial vaccination (140 days in one case) may stimulate rapid anamnestic responses,[27] but it is unclear whether this suggests efficacy in protecting against disease.

When designing a vaccination program for prevention of bovine respiratory disease, four questions should be addressed:

1. Should calves be vaccinated for *M. haemolytica?*
2. What type of *M. haemolytica* vaccine should be used?
3. How many doses of *M. haemolytica* vaccine should be given?
4. When should the vaccination be given?

We will attempt to provide a basis for answering some of these, but the clinician ultimately must make decisions in consideration of the type of operation (cow-calf, stocker, dairy, or feedlot), management practices, interpretation of published literature, consultations with colleagues, and personal experience.

SHOULD *MANNHEIMIA HAEMOLYTICA* VACCINE BE USED?

This may be the most difficult question for the practitioner to answer. Vaccine efficacy has been primarily demonstrated with experimental models of pneumonia using one of several challenge methods, including direct *M. haemolytica* challenge via intratracheal, intrabronchial, or transthoracic routes or using a combination viral (usually BHV-1) and *M. haemolytica* challenge.[13] The majority of published reports examining vaccination efficacy through experimental challenge have used experimental vaccines, not commercial ones. There are few published reports of efficacy of individual commercial vaccines against experimental *M. haemolytica* challenge, but published studies have generally supported the efficacy of commercial vaccines, although not in all cases.[29-31]

Clinical studies examining field efficacy of vaccines are abundant and frustratingly inconsistent. Numerous studies have found a protective factor from vaccinating.[32-36] Similar numbers of studies found vaccination to be ineffective or inconclusive.[37-39] Perino and Hunsaker[40] reviewed 10 published studies of several commercial live and subunit *M. haemolytica* vaccines with respect to their efficacies in field studies of feedlot cattle. Their report concluded that commercial *M. haemolytica* vaccines available at the time did not consistently reduce morbidity or mortality or increase weight gains. Of those studies, five showed positive outcomes based on reduced morbidity, mortality, or increased weight gain, whereas five studies demonstrated no positive outcome. Three of those studies demonstrating positive outcomes involved the same *M. haemolytica* bacterin toxoid given at arrival in the feedlot; however, two clinical trials with the same vaccine showed no significant differences when given at arrival and/or 3 weeks before shipment. A more recent rigorous review of *M. haemolytica* vaccines trials using feedlot cattle found that conclusions remain conflicting at times. However, their meta-analysis determined vaccination against *M. haemolytica* offers a modest reduction in morbidity but not in mortality.[41]

When examining vaccine efficacy in field trials, it is relevant to note that diagnosis and treatment in such studies is based upon undifferentiated BRD rather than disease solely due to *M. haemolytica.* Although *M. haemolytica* is the predominant bacterial isolate associated with BRD, it is not the sole pathogen. To conclude that *M. haemolytica* vaccine is efficacious in reducing BRD, a study would require a high power (large number of cattle enrolled), a relatively high incidence of BRD, and a large proportion of that disease attributable to *M. haemolytica.* This may play a role in the lack of definitive evidence of vaccine efficacy. Given these considerations, if a clinician chooses to recommend vaccination, questions 2 to 4 posed earlier must be addressed.

WHAT TYPE OF *MANNHEIMIA HAEMOLYTICA* VACCINE SHOULD BE USED?

Numerous commercially available bovine biologics contain *M. haemolytica* antigens.[42] *M. haemolytica* vaccines are often in combination with viral vaccines, *H. somni* or *P. multocida* bacterins, and occasionally *Clostridium* spp. biologics. Despite the various licensed *M. haemolytica* biologics available, formulations of *M. haemolytica* vaccines fall into one of 9 categories, 7 of which are non-living vaccines. These are described by their manufacturers as follows: (1) bacterin with aluminum hydroxide adjuvant, (2) bacterin with water-in-oil adjuvant, (3) outer membrane extract, (4) bacterin-toxoid (leukotoxin toxoid), (5) toxoid cell–associated antigen, (6) adjuvanted toxoid (culture supernatant), (7) recently introduced recombinant leukotoxin-extracted OMP vaccine, (8) autogenous (herd-specific) bacterins produced from isolates submitted by practicing veterinarians, and (9) live streptomycin-dependent mutant. The latter vaccine is the only currently licensed live *M. haemolytica* biologic. In the past, several live *M. haemolytica* vaccines were commercially available and showed potential efficacy. However, untoward side effects like severe local and systemic reactions often occurred after vaccination. Studies have occasionally compared commercially available vaccine products under field conditions.[43-44] Unfortunately, they often are supported by industry funding (creating a potential conflict of interest) and typically do not include a negative control group, so the significance and validity of findings from these studies are unclear.

Most studies comparing commercial vaccines have relied upon antibody titers (typically to LKT and/or whole bacterial cell preparations) as the outcome of interest. Although antibodies appear important to protection, it is unclear what antigens are most important, what titer is sufficient for protection, or if a higher titer is always better. Therefore, conclusions from those studies are difficult to interpret. Direct comparisons of two or more commercial *M. haemolytica* vaccines against experimental challenge have rarely been published. In one such comparison between a commercial *M. haemolytica* bacterin toxoid and the live streptomycin-dependent mutant vaccines, the bacterin-toxoid elicited the greatest serologic responses and significantly reduced lung lesions after experimental challenge.[31] Calves receiving the live mutant vaccine had lesions that were not significantly lower than for control cattle. Demonstration of protection against experimental challenge, however, may not necessarily indicate that the vaccine will be efficacious against natural disease under field conditions.

HOW MANY DOSES OF *MANNHEIMIA HAEMOLYTICA* VACCINE SHOULD BE GIVEN?

Although many of the currently available *M. haemolytica* biologics are licensed for only one injection, manufacturers recommend a booster if possible. Of course, administration of two doses of *M. haemolytica* vaccine is not practical for most

VetBooks.ir

cow-calf operations. Shewen[45] demonstrated that one of the reasons one dose of *M. haemolytica* vaccine often stimulates adequate antibody response is that most cattle carry *M. haemolytica* in their nasopharynx and have a primed immune system that can produce a rapid anamnestic response to vaccination. However, as already noted, it is unclear whether this suggests continued efficacy in protecting against disease.

WHEN SHOULD *MANNHEIMIA HAEMOLYTICA* VACCINE BE GIVEN? Given the short persistence of elevated titers following vaccination, administering *M. haemolytica* vaccine at the appropriate time becomes critical.[46-48] Manufacturers of *M. haemolytica* biologics usually recommend vaccination between 15 and 21 days prior to "weaning, shipping, or exposure."[42] If vaccination was more than 2 to 3 weeks prior to the time of greatest risk, a booster should be given prior to shipment. This protocol is incompatible with routine management of most cow-calf operations, making it difficult to recommend vaccination as a standard practice in this segment of the industry. Further adding to the challenge of identifying an optimal time for vaccination is the possibility that concurrent administration of MLV vaccines may interfere with response to *M. haemolytica* vaccination. Cortese et al[28] examined serologic response to vaccination with four commercially available *M. haemolytica* vaccines in calves naive to BHV-1 and *M. haemolytica*. When the vaccines were given concurrent with an MLV product, the antibody response against LKT was consistently lower than when the *M. haemolytica* product was administered alone. It is unclear whether this would impact the efficacy of the vaccines in reducing disease, although previous work with an experimental vaccine suggests it could.[49] A similar effect on titers was not seen with intranasal administration of MLV vaccine, although only one product was examined in this study.[50] Concurrent vaccination with intranasal MLV and *M. haemolytica* vaccines resulted in an initial titer equivalent to that produced by the *M. haemolytica* vaccine alone. Moreover, a robust anamnestic response occurred when a booster of the *M. haemolytica* vaccine was given 90 days later in conjunction with a parenteral MLV. Thus, it appears that some of the negative effect of concurrent MLV vaccination may be muted if calves are not naive for BHV-1 and/or other viral agents.

Vaccination of cattle against pneumonic pasteurellosis upon arrival at the feedlot is somewhat controversial for numerous reasons. Most importantly, it may not allow enough time for development of solid protection prior to the period of highest morbidity.[51] Secondly, if cattle were vaccinated 2 to 3 weeks prior to shipment and had an appropriate immunologic response, antibody titers may be adequate, making revaccination not cost-effective. Finally, vaccination with an MLV vaccine at arrival is nearly universal, which may interfere with response to the *M. haemolytica* vaccine if the calves have not previously been vaccinated or exposed to respiratory viruses.[28] Vaccination history is rarely known for cattle entering a feedlot, so it may be impossible to make an informed decision regarding these considerations. Nonetheless, vaccination with an *M. haemolytica* product upon feedlot entry is often practiced.[46-48] Results in several field trials indicate that this practice can potentially afford some protection against shipping fever during the first 14 days in the feedlot.[46] Selective use of *M. haemolytica* vaccines has also been advocated. Some feedlots designate cattle as high risk and low risk for respiratory disease. Managers may be more willing to vaccinate low-risk cattle because high-risk cattle are either sick upon arrival or can break with disease soon after entry into the feedlot.[47] Therefore, vaccination of high-risk cattle would not have time to stimulate immunity. However, low-risk cattle are less likely to break with disease soon after entry into the feedlot, and when they are vaccinated there is often adequate time for immunity to develop before a respiratory outbreak occurs.[47] While this is arguably rational, research to support or refute its effectiveness is lacking. As stated earlier, a meta-analysis of vaccination for *M. haemolytica* in feedlot cattle found a modest reduction in morbidity (relative risk [RR] 0.93; 95% confidence interval [CI], 0.89-0.98) but no significant reduction in mortality (RR 0.75; 95% CI, 0.56-1.04).

In summary, there is some evidence that use of *M. haemolytica* vaccination can be beneficial, but *M. haemolytica* vaccination is not warranted or appropriate in all situations. It would likely provide the most benefit when employed by cow-calf producers, but doing so correctly would require administration at an appropriate time (2 to 3 weeks prior to shipping). It would also be preferable to not concurrently perform MLV vaccination unless an intranasal product is used or the MLV is a booster of previous administration. Whether this additional cost and effort is justified is questionable, since weaning for at least 40 days seems more important than vaccination in reducing disease.[52] For stocker/backgrounder and feedlot operations, use of *M. haemolytica* may offer less benefit and is particularly questionable in lightweight high-risk calves. These calves are likely to develop disease before vaccination could produce an immune response, and the endotoxin burden may have negative effects, including decreased feed intake. Usage may be justified in backgrounded or yearling cattle that are more likely to respond to vaccination prior to the period of greatest risk for disease.

Use of *Mannheimia haemolytica* Vaccination in Dairy and Veal Calves

Management differences between dairy and beef calves could be expected to impact disease incidence and severity as well as immune status in these two classes of cattle. In addition, evidence suggests that purebred Holstein calves may not respond immunologically as well as beef or Holstein crossbred cattle,[53] so it would seem prudent to consider this population separately. Unfortunately, studies of *M. haemolytica* vaccination in dairy and veal calves have been published less frequently than those in beef calves. In general, vaccination of young dairy calves has failed to produce significant antibody responses.[54,55] This is probably due to interference by colostral antibodies. As passive immunity wanes, calves develop anti–*M. haemolytica* antibodies as a result of natural exposure.[55] In terms of protection against natural disease, vaccinated calves had incidences of respiratory disease similar to unvaccinated controls.[56,57] In another study, an *M. haemolytica* bacterin toxoid was found to be less effective than a commercial streptomycin-dependent mutant *M. haemolytica* and *P. multocida* vaccine in reducing respiratory disease in veal calves.[58] Failure of *M. haemolytica* vaccines to provide protection in dairy and veal calves could be because *P. multocida* is usually the most common isolate from dairy calf pneumonia.

Vaccination for *Pasteurella multocida*

P. multocida, particularly serogroup A serotype 3 isolates, is the second most common bacterial species associated with pneumonia in beef cattle and the most common bacterium isolated from pneumonia in dairy calves.[2] Although *M. haemolytica* has traditionally been the major pathogenic bacterium associated with shipping fever, some studies have suggested that the incidence of *P. multocida* in BRD has increased in beef cattle.[1,48]

The antigenic makeup of non-living *P. multocida* vaccines presently available are proprietary and are described in the *Compendium of Veterinary Products* as bacterial extracts, cell-associated antigens, soluble antigens, and/or bacterins. Conventional formalin-inactivated, whole-cell, aluminum hydroxide–adsorbed bacterins have been the industry standard and are not considered highly efficacious.[42] A commercial live streptomycin-dependent mutant *P. multocida* and *M. haemolytica* vaccine is available. Its efficacy against *P. multocida* is not well documented in the literature.

The immune mechanisms involved in resistance to *P. multocida* lung infections in cattle are poorly understood. Antibodies are presumed to be important in protecting against disease, and serum antibody levels have been correlated with severity of lesions following challenge[59,60] as well as decreased risk of natural disease.[10] However, there are few peer-reviewed studies examining efficacy of vaccination in field conditions, and those that have been published suffer from severe shortcomings (typically sponsored by a manufacturer and

VetBooks.ir

often lacking a nonvaccinated control group). A meta-analysis[41] reported three trials of vaccination of feedlot cattle with products containing *P. multocida* along with *M. haemolytica*. Results of these trials were not examined separately, but instead were combined with results of studies examining only *M. haemolytica*. Nonetheless, the reported results are not compelling (one reduced BRD, one increased BRD, and one trial showed no effect). Little work has been done regarding commercial *P. multocida* vaccines in dairy calves, despite the prevalence of *P. multocida* in respiratory disease in that population. In the one trial identified, a combined *M. haemolytica–P. multocida* vaccine was no better than control.[56] There is more published work related to vaccines against *P. multocida* serogroups B and E, which cause hemorrhagic septicemia in cattle and water buffalo,[61] but those have limited or no relevance to BRD.

Studies suggest that *P. multocida* OMPs or iron-regulated OMPs could be important immunogens for protecting cattle against pneumonia, and vaccination of calves with outer membrane preparations substantially enhanced resistance against experimental challenge.[13,62,63] Although the *P. multocida* toxin, which is produced primarily by serogroup D isolates, is an important virulence factor and immunogen for *P. multocida* in atrophic rhinitis of swine, there is no evidence this toxin is important in pneumonia of cattle, nor would it be beneficial to include the toxin in a cattle vaccine.[13]

In summary, significantly less is known about the immunogenicity and vaccinology of *P. multocida* than for *M. haemolytica*. Products currently available are generally unrefined and have limited evidence of efficacy. As such, it is difficult to make recommendations regarding their use. It seems reasonable to presume these products will work no better than *M. haemolytica* vaccines and suffer from many of the same challenges, so their usefulness (if any) is likely restricted to vaccination at least several weeks prior to maximum risk. Vaccination of lightweight high-risk calves is probably of limited benefit and should be avoided owing to the potential impact of endotoxin contained within vaccine preparations. Inadequate information exists to comment on potential usefulness of *P. multocida* vaccination in dairy and veal calves.

Vaccination for *Histophilus somni* (formerly *Haemophilus somnus*)

Histophilus somni (formerly *Haemophilus somnus*) is the cause of thrombotic meningoencephalitis (TME), septicemia, and reproductive disorders in cattle. It is also the third most common bacterial isolate from beef cattle pneumonia in most epidemiologic surveys.[1,2] Cases of *H. somni*–induced pneumonia are often associated with concurrent myocardial necrosis. Potential immunogens have been experimentally studied in *H. somni* and consist of lipo-oligosaccharide (LOS),[64] several OMPs (including immunoglobulin-binding proteins that bind the Fc receptor of bovine immunoglobulin and are associated with serum resistance of pathogenic strains),[65,66] and iron-regulated OMPs.[67] As in most gram-negative bacteria, *H. somni* LOS is a dominant antigen that stimulates an antibody response to the polysaccharide moiety following natural or experimental exposure. Interestingly, *H. somni* LOS has been demonstrated to exhibit phase variation in its epitopes (i.e., antigenic drift), thus allowing the bacterium to escape the immune response.[64] Currently, there is no evidence those anti-LOS antibodies are protective.[68] Likewise, several OMPs and iron-regulated OMPs have been shown to be immunogenic in cattle. The major *H. somni* OMP is weakly immunogenic and shows strain antigenic variability.[69] Their role in stimulating immunity is unknown. Recent studies have demonstrated that immunoglobulin-binding protein A (IbpA) not only binds immunoglobulins but is cytotoxic for bovine alveolar type II epithelium.[70] In addition, vaccination of calves with recombinant subunits of IbpA enhanced resistance against experimental intrabronchial *H. somni* challenge.[71]

Several approved *H. somni* biologics are available, often in combination with respiratory viruses or other bacterial pathogens (*Clostridium* spp.). Currently licensed *H. somni* biologics are formalin-killed bacterins with aluminum hydroxide as adjuvant. Efficacy of *H. somni* bacterins has been generally favorable in stimulating protection against experimental pneumonia, against IV and intracisternal *H. somni* challenge as a model of TME, and against natural TME. Overall, vaccine-induced immunity has been best against experimental and natural TME.[41,51,72,73] Using an experimental challenge model of *H. somni*–induced pneumonia, significant protection was afforded calves vaccinated twice with *H. somni* bacterin.[74] Resistance correlated with a high serum antibody response to the bacterium. One study demonstrated a reduced risk for respiratory disease in cattle that had high antibody titers to *H. somni* upon arrival in a feedlot.[75] Therefore, the potential would appear to exist for stimulating resistance to *H. somni*–associated pneumonia. Unfortunately, commercial *H. somni* vaccines can stimulate IgE antibodies and thus potentially increase the risk for type I hypersensitivity.[76]

Under field conditions, commercial *H. somni* bacterins have had limited success in inducing protection against respiratory disease.[40] In the three trials reviewed by Perino and Hunsaker, *H. somni* vaccination resulted in reduced treatment rate,[77] an increased rate of cattle being treated for respiratory disease,[78] and no significant difference from unvaccinated controls.[79] In a more recent study, partial reduction in feedlot respiratory disease was associated with vaccinating for *H. somni,* whereas a significant reduction in respiratory disease was associated with *H. somni* vaccine in combination with *M. haemolytica* or *M. haemolytica* vaccine alone.[80] Ribble et al[81] demonstrated reduced steer mortality following *H. somni* vaccination, but not heifer mortality. A meta-analysis demonstrated no benefit associated with *H. somni* vaccines in beef cattle,[41] but the authors acknowledged that the very few published trials offered little power to find a benefit if it existed.

Vaccination for *Bibersteinia trehalosi*

B. trehalosi was originally classified as *Pasteurella haemolytica* biotype T and consists of four serotypes (T3, T4, T10, and T15).[6,82] In 2007, Blackall et al proposed the new classification of the bacterium using phenotypic and molecular characteristics of 43 European isolates, 14 of which were from cattle, and 9 of those were isolated from lung (the authors did not indicate whether those isolates were from pneumonic lungs). Traditionally, *B. trehalosi* has been associated with diseases of sheep, primarily septicemia in domestic sheep and fatal pneumonia in Bighorn sheep.[83] In recent years, *B. trehalosi* has been isolated from bovine pneumonia, and there is concern among cattlemen, dairymen, and veterinarians that the bacterium is an emerging pathogen.[84] *B. trehalosi* was isolated sporadically from bovine pneumonia as early as 1971, with occasional subsequent descriptions of isolations.[85-89] Much of the currently available information about *B. trehalosi* prevalence in bovine pneumonia is anecdotal and not well documented in the scientific literature. What little data are documented, however, indicate a low prevalence of the bacterium. The Veterinary Laboratories Agency (VLA) laboratories in the United Kingdom have documented 65 isolates of *B. trehalosi* from bovine pneumonia cases since four initial cases were recorded in 2003.[90] Isolations ranged from 0 (2005) to 22 (2009), with over two thirds of the isolates occurring in the past 3 years. Isolates have been from both beef and dairy cattle, and all ages have been affected. In 72% of the cases, *B. trehalosi* was isolated in combination with one or more other bacterial or viral respiratory pathogens. From 2007 to 2009, *B. trehalosi* was isolated from 20 to 45 cases of respiratory disease in dairy cattle annually.[84] That report also documented multiple cases of respiratory disease in two dairies and one beef cattle operation.

Little is known about immunity against *B. trehalosi,* and commercial vaccines are not currently available. There is only about 35% homology between the genomes of *B. trehalosi* and *M. haemolytica*.[91] Some *B. trehalosi* strains are hemolytic and produce leukotoxin that is antigenically related to *M. haemolytica* leukotoxin and can be neutralized by anti–*M. haemolytica* leukotoxin antibodies.[45] However,

VetBooks.ir

only about 15% of the bovine isolates have been reported to produce leukotoxin.[82] Other potential antigens (e.g., OMPs) appear to be substantially different from those of *M. haemolytica*.[92] Therefore, vaccination of cattle with an *M. haemolytica* vaccine that stimulates antileukotoxin antibodies may provide some level of immunity against leukotoxin-positive *B. trehalosi* strains, but that immunity would likely be inadequate for complete protection.

Bovine Reproductive Disease Vaccines

Victor S. Cortese • Carole A. Bolin

As discussed earlier, cows have a multilayered placenta that leaves the fetus susceptible to infection. Infection of the placenta, inflammation of the ovary, death of the fetus, or disruption of the cervical plug all may cause abortion. Reproductive disease is therefore the most difficult disorder to achieve protection against. Vaccination must minimize the amount or duration (or both) of the viremia or septicemia, or it must prevent the pathogen from moving through the cervix or crossing the placenta.

Reproductive diseases and protection against them through vaccination are areas of active research. With current research, a vaccination program can be designed to help control reproductive diseases, but there is little or no research on the efficacy of many vaccines currently used to prevent reproductive disease. Given that the causes of reproductive failure are so numerous (infectious agents account for only a small percentage), vaccination to prevent infectious reproductive losses many not appear to be effective. This is often because diagnostic testing has not been attempted or has not determined the cause of reproductive inefficiencies. A vaccination program may be inappropriately instituted when the cause is not infectious, or the current program may unfairly be deemed ineffective. Use of viral vaccines to help prevent reproductive diseases was discussed earlier in the chapter.

Brucella abortus Vaccine

Brucella vaccination has best shown the effectiveness of vaccination in controlling a reproductive disease. Successful control and even eradication of *Brucella abortus* in many areas of North America are a testament to the ability of a program involving testing, culling, and vaccination to control a reproductive disease with zoonotic consequences; vaccination with either strain 19 or strain RB51 *Brucella* has proved to be effective. However, many herd owners have stopped vaccinating against this disease as states have been declared *Brucella* free.

Abortions caused by *B. abortus* are usually seen after 5 months' gestation. Retained placentae and subsequent metritis usually follow. The abortion is due to severe placentitis. *Brucella* infections have also been associated with a decrease in conception rates and an increase in services per conception. A higher number of dead and weak calves has also been demonstrated in infected herds. Orchitis, seminal vesiculitis, or both may characterize infections in bulls.

Only heifer calves can be vaccinated for brucellosis. Both of the two licensed *B. abortus* vaccines are modified live bacterins, and vaccination of bulls may lead to orchitis.[1] Legal use of the vaccines is usually confined to heifer calves 4 to 12 months of age, because vaccination of older animals with the strain 19 vaccine may lead to false-positive results on routine *Brucella* screening tests. Because the strain 19 vaccine may cause septicemia, clinical illness, and occasionally death,[2] sick, unhealthy, or stressed cattle should not be vaccinated. The RB51 strain vaccine is an O antigen–deficient mutant of the *B. abortus* strain 2308. The RB51 vaccine has three primary advantages:

1. Antibodies induced by this vaccine do not react with the serologic tests routinely done to diagnose *Brucella* infections.
2. The vaccine can be used in adult cattle at a lower dosage under special circumstances and with USDA permission.
3. The vaccine tends to cause less post-vaccination fever and stress than the traditional strain 19 vaccines.

The long-term immunity conferred by *Brucella* vaccination is the cell-mediated type.[3,4] Calfhood vaccination does not prevent a herd of cattle from becoming infected with *B. abortus,* but it does largely prevent abortions and protects 65% to 75% of the cattle in the herd from infection while infected reactors are identified and slaughtered.[5] For these reasons, in addition to vaccination, a control program should include testing and culling of all animals that test positive.

Leptospira Bacterins

Leptospirosis occurs worldwide and is caused by infection with the spirochete *Leptospira*. The pathogenic leptospires were formerly classified as members of the species *Leptospira interrogans;* the genus has recently been reorganized, and pathogenic leptospires are now identified in 7 species of *Leptospira*.[6] As part of this reclassification, the serovar names have remained the same, but some of the common leptospiral pathogens of cattle have different species names than before. The key changes for this discussion include (1) *L. interrogans* serovar *grippotyphosa* is now *L. kirschneri* serovar *grippotyphosa,* and (2) the two types of serovar *hardjo* have been formally split into two species, serovar *hardjo* type *hardjobovis* (found in the United States and much of the world) is now *L. borgpetersenii* serovar *hardjo,* and the less common serovar *hardjo* type *hardjoprajitno* (found primarily in the United Kingdom) is now *L. interrogans* serovar *hardjo.*

Although traditionally associated with abortions, infection with various serovars of *Leptospira* are associated with a variety of clinical signs, including severe systemic disease (most often in young animals), decreased milk production, birth of weak calves, and infertility. In addition, infected cattle are known to present a risk of zoonotic transmission of the infection to humans. Many different serovars of *Leptospira* have been shown to cause reproductive failure and abortions in cattle. Of these serovars, *hardjo, pomona,* and *grippotyphosa*[7-10] are more common, with serovars *canicola, icterohaemorrhagiae,* and *bratislava* occasionally implicated. The epidemiology of infection of cattle with these serovars differs with cattle serving as the reservoir or maintenance host for serovar *hardjo* and as an incidental host for the other serovars. In general, maintenance host infections are associated with a high prevalence of infection, a poor immune response, and long-term infection and shedding, whereas incidental host infections are characterized by low overall prevalence of infection with epidemics recognized, a vigorous immune response, and short-term infection and shedding. These differences in the epidemiology of leptospirosis caused by different serovars of *Leptospira* require different strategies for prevention.

Leptospirosis can cause abortion storms in which a high number of cattle may abort within a short period. There may also be an increased number of stillbirths and births of premature and weak calves during these periods.[11] Although serovars *pomona* and *grippotyphosa* tend to cause abortions in the last trimester of pregnancy, serovar *hardjo* can cause abortions at any stage of pregnancy. Abortions are usually due to fetal infection and subsequent fetal death, although placentitis may also occur. Serovar *hardjo* can also colonize the oviducts and uterus,[8,2-13] diminishing fertility. After an initial serovar *hardjo* infection, cattle may remain infected and shed the spirochete for long periods,[14-15] whereas infection and shedding of the other serovars is relatively brief.

Current bacterins generally contain combinations of leptospiral serovar *pomona, grippotyphosa, canicola, icterohaemorrhagiae,* and either *L. interrogans* serovar *hardjo* type *hardjoprajitno* or *L. borgpetersenii* serovar *hardjo* type *hardjobovis.* A monovalent *L. borgpetersenii* serovar *hardjo* type *hardjobovis* vaccine is also available. There has been considerable debate in recent years regarding the efficacy of leptospiral bacterins for cattle. The bacterins have label claims that indicate they are to be used as an "aid in the prevention

VetBooks.ir

of disease." These bacterins should therefore be expected to decrease the severity of clinical signs, including abortion, associated with infection. In general, the evidence supports such claims for serovars for which cattle are an incidental host (i.e., serovars *pomona, grippotyphosa, canicola,* and *icterohaemorrhagiae*). Protection mediated by bacterins for these serovars is thought to occur because of induction of antibodies directed against the LPS on the surface of the *Leptospira*.[16] However, vaccination does not always prevent infection and leptospiruria caused by serovar *pomona*.[17-19]

The efficacy of bacterins for prevention of infection, leptospiruria, and clinical signs associated with serovar *hardjo* infection is significantly more controversial. Evidence that the efficacy of traditional serovar *hardjo* vaccines is less than optimal includes induction of a relatively poor antibody response in vaccinated animals, the common presence of *hardjo* infection in herds despite routine vaccination, and experimental trials that did not demonstrate protection afforded by these traditional vaccines for prevention of infection, colonization of the renal or genital tract, or transplacental infection upon challenge with *L. borgpetersenii* serovar *hardjo* type *hardjobovis*.[20-22] In these studies, cattle were not protected from infection despite the induction of antibody directed against serovar *hardjo* LPS. Further investigation and evaluation of other serovar *hardjo* bacterins has led to a hypothesis that cell-mediated immunity may play a role in protective immunity against serovar *hardjo* in cattle.[23-27] Newer serovar *hardjo* bacterins have been introduced in monovalent and polyvalent formats, and there is evidence these bacterins provide significant protection of cattle against infection, tissue colonization, shedding, and transplacental infection.[23,28,29] Other new bacterins for serovar *hardjo* are also entering the marketplace, but as of this writing, extensive data regarding the performance of these products for reproductive protection are unavailable in the literature.

Some *Leptospira* bacterins are labeled as single initial dose products, but a booster dose is recommended approximately 1 month after the first dose.[18] *Leptospira* bacterins must be administered by IM or SC injection. Although some manufacturers specify revaccination at 12-month intervals, this duration of immunity has been questioned, and more frequent revaccination is often necessary to control *Leptospira* abortions.[19-21] A 1-year duration of immunity has been documented for two of the newer serovar *hardjo* bacterins, but this duration has not been documented for other *hardjo* vaccines or for the other serovars, making vaccination every 6 months a reasonable recommendation in many circumstances. Nevertheless, because leptospiral abortions are uncommon during the first half of pregnancy, it may be possible to use an annual vaccination schedule (serovar *hardjo* excepted) in seasonally calving herds like beef herds. Cattle in such herds can be vaccinated when they are 2 to 4 months pregnant, usually at the time pregnancy is diagnosed, and protected through the remainder of the pregnancy with a single annual dose.[19]

Prevention of leptospirosis caused by serovar *hardjo* requires a somewhat different approach. Pre-breeding vaccination of heifers that is effective in managing reproductive sequelae of other types of leptospirosis may be too late to prevent the consequences of serovar *hardjo* infection. Heifers exposed very early in life may remain infected well into the time of breeding. Therefore, efforts to control serovar *hardjo* infection should be targeted at preventing the initial infection and is best done by vaccinating young stock well before the time when they are mixed with older animals. In addition, bulls can carry serovar *hardjo* and transmit the infection quite readily during breeding.[29] Therefore, bulls should be fully included in efforts to control serovar *hardjo* infection by vaccination.

Bovine Genital Campylobacteriosis Vaccines

Originally classified as *Vibrio, Campylobacter fetus* subsp. *veneralis* causes a venereal infection of cattle. The bacteria are introduced during natural breeding by infected bulls or by artificial insemination (AI) with infected semen. Bulls are usually infected by breeding with infected cows, but contact with infected bedding may also be a cause. Older bulls (>4 years of age) are more likely to be infected. After deposition in the vagina, the bacteria rapidly colonize the vagina and cervix, and in 25% of these cows are found in the oviducts. The organism can persist for months after infection of these sites. It has been shown that fertility never returns to normal in some infected animals, and some may be permanently sterile because of the damage caused by salpingitis.

Vaccination with *Campylobacter* vaccines has been shown to be effective in protecting heifers even when vaginal cultures test positive for the bacteria.[30] It appears that the uterus is very resistant to the bacteria after vaccination. Studies have demonstrated improved breeding efficiency in vaccinated herds.[30] Vaccination of bulls with oil-adjuvant vaccines not only prevents infection of bulls for up to 1 year[31] but also aids in prevention of mechanical transfer of organisms during natural service.[32] Vaccination with two doses has been shown to be effective at clearing infections from carrier bulls.[33,34]

Vaccination

Use of *C. fetus* bacterins is recommended in all breeding herds that use bulls, even if only on selected cows. In heifer herds using virgin bulls or in 100% AI-bred herds, vaccination against *Vibrio* organisms is not necessary.

Several different *C. fetus* vaccines are available, including oil-adjuvanted and aluminum hydroxide–adsorbed types. Oil-adjuvant *C. fetus* bacterins have proved to be more effective[35] and provide longer lasting protection after a single dose.[36] Unfortunately, oil-adjuvant vaccines cause localized granuloma formation and fibrosis at the site of injection. This may cause visible blemishes, which may be objectionable in registered stock or show cattle. Administration no earlier than 4 months before the breeding season is preferred.[36] When aluminum hydroxide–adsorbed *C. fetus* bacterins are used, a priming dose should be administered at least 6 weeks before the immunizing (booster) dose, and the booster should be administered 10 days before the beginning of the breeding season.[37] After administration of an aluminum hydroxide–adsorbed bacterin, serum antibody concentrations peak rapidly and decline precipitously, falling to susceptible levels by 4 weeks after 1 dose or 11 weeks after 2 doses.[39] Some aluminum hydroxide–adsorbed bacterins do not require an initial booster.

Campylobacteriosis (vibriosis) is most effectively controlled when all breeding-age animals, including bulls, are included in the vaccination program.[32] Vibrin (Zoetis) is the only *C. fetus* bacterin available in the United States that has been evaluated in bulls.[30] Two 5-mL doses are administered to breeding bulls at 4-week intervals beginning 8 weeks before the start of the breeding season.[30] In subsequent years, a single booster dose is administered 4 weeks before the start of the breeding season.[33] This dosage is 2.5 times that recommended for vaccination of cows.

Bovine Trichomoniasis Vaccines

Bovine trichomoniasis is a venereal infection of cattle caused by the protozoal agent *Tritrichomonas foetus.* Early in the course of the disease, abortions with pyometra may be seen in 5% of infected cows; these abortions occur early in gestation.[38] However, infertility is the most common sign, with long interservice intervals.[39,40] Early embryonic death is followed by a period of conception failure. Some natural resistance develops after infection, but carrier cows may be an important component of the epidemiology of this disease. In rare cases, uterine destruction may leave a cow sterile after an infection.[41]

The efficacy of *Tritrichomonas* vaccines is questionable,[42-45] but the vaccines do appear to reduce actual reproductive losses.[46] Heifers, cows, and breeding bulls should be vaccinated twice at 2- to 4-week intervals, the second dose given 4 weeks before the beginning of the breeding season[46]; SC administration is recommended. In subsequent years a single annual booster vaccination should be given 4 weeks before the beginning of the breeding season.

In a problem herd, trichomoniasis vaccination must be coupled with other control measures like culturing, culling, and treatment to effectively control the disease.

Neonatal Calf Enteric Disease Vaccines

Gerald E. Duhamel

Neonatal calf enteric diseases (NCEDs) can have a devastating impact on the profitability of beef cow-calf and dairy operations. In addition to mortality, medical, and labor costs, NCED can significantly reduce body weight of beef calves at weaning and performance of replacement dairy heifers.[1]

Several well-characterized infectious causes of NCED have been described.[2] Some of the more common infectious agents are group A RVs, coronavirus (CV), enterotoxigenic *E. coli,* salmonellae, and *Cryptosporidium* spp.[3-9] Sporadic outbreaks of necrohemorrhagic enteritis affecting 3- to 10-day-old calves have been associated with infection with *C. perfringens* type C.[10] Other less well-characterized viruses (group B RV, calicivirus, torovirus, astrovirus), bacteria (enterotoxigenic *Bacteroides fragilis,* attaching-effacing enteropathogenic and enterohemorrhagic *E. coli, Enterococcus durans*), and protozoans *(Giardia duodenalis)* have also been associated with NCED.

Because of the continuous calving and constant introduction of replacement heifers on dairy farms and the continuous flow of susceptible calves on veal calf operations, infections caused by more than one agent should be suspected in these types of operations.[3-9,11-13] In addition to different infectious agents, mixed infections with different groups and serotypes or genotypes of viruses and bacteria can also occur. Consequently the severity, duration, and spread of clinical disease associated with complicated infections are usually greater than with a single agent, and control may be more challenging. When scours occurs in a herd that has been vaccinated against enteric diseases, possible contributing factors should be considered, including concurrent infection with pathogens not present in the vaccine (e.g., *Cryptosporidium* spp., salmonellae, nongroup A RVs, other pathogens), suboptimal management of colostrum feeding, and poor control of environmental contamination. Under these conditions, strategic improvement in husbandry practices might be sufficient to reduce the infectious threshold for NCED and obtain the full benefit of pathogen-specific vaccination. In any situation, thorough laboratory diagnostic investigation is essential to correctly identify the primary cause of NCED and any other possible contributing factors and to serve as a basis for appropriate control strategies for present and future calf crops.[14]

Management practices and risk factors associated with development of NCED are sufficiently different between dairy and beef herds that control measures can be tailored according to the type of production. For example, in dairy herds, high turnover of older cows and continuous introduction of replacement heifers pose a higher risk of introducing new enteric disease pathogens in a susceptible population than in closed beef herds. Similarly, continuous calving and proximity of susceptible calves on dairy farms create an ideal environment for recirculation of enteric disease agents back into the adult population. This in turn may increase and broaden herd immunity such that the efficacy of a vaccine in these herds might be enhanced, partly because of the booster effect vaccine can have on preexisting immunity. Beef cattle herds, in contrast, are generally relatively closed, and a susceptible calf population is present only for a relatively short period annually during the calving season. Introduction of new pathogens or new strains of enteric disease agents, particularly during the calving season, can have a devastating effect because of the potential for exposure of a high number of susceptible animals over a relatively short period of time. Conversely, after an outbreak, herd immunity might be more stable and the occurrence of NCED might be reduced during the following calving seasons.

Under both types of production systems, vaccination for NCED is rarely successful without reasonably good management programs aimed at providing adequate intake of high-quality colostrum and minimizing environmental contamination through effective sanitation. General herd health management steps that can affect the success of a vaccination program for NCED should include a calving cow-calf care plan aimed at minimizing exposure of newborn calves to infectious agents that can overwhelm innate or passively acquired immunity. This is accomplished by careful monitoring of colostrum intake, eliminating all potential means of NCED transmission, and by reducing the load and duration of exposure to pathogens present in the calving environment. The following are eight simple recommendations to accomplish these goals:

1. Establish a sound biosecurity program, including purchase of replacement animals only from reputable sources and a complete ban on the introduction of foster calves, which pose a high risk of introducing new NCED agents.
2. Provide adequate protein and energy feed, including proper concentrations of vitamin and micronutrients (e.g., copper and selenium) and abundant clean drinking water throughout gestation and calving. This can ensure heifers and cows have acceptable body condition scores at calving, produce an adequate volume of high-quality colostrum and milk, and their calves are healthy and vigorous at birth, with a fully developed and functional immune systems.[15]
3. Avoid crowding, and keep the calving area and equipment clean, dry, and protected from the elements, particularly winter wind. Provide sufficient bedding in calving pens so calves are not born in a wet, manure-contaminated environment. Separate feeding and bedding grounds should be available in the calving area. Similarly, to minimize infectious disease transmission, separate equipment for feeding and manure handling should be used.
4. Limit the spread of infectious disease agents from younger, more susceptible and potentially shedding pairs to the main herd by segregating first-calf heifer pairs from the mature cow herd during the calving season until the youngest calf is at least 4 weeks old. Because of potential problems associated with nursing in first-calf heifers, newborn calves in this group should be monitored closely for colostrum intake and early detection of failure of passive transfer so rapid intervention can be implemented.[15-17] Because first-calf heifers are at a competitive disadvantage with mature cows, segregation of pregnant first-calf heifers also ensures free access to feed and water at all times.
5. Ensure that each calf ingests roughly 10% of its body weight (at least 4 L [1 gallon]) of colostrum divided into half as soon as possible and preferably within the first 2 to 3 hours of birth, then the rest 4 to 6 hours later, but always before the calf is 24 hours old. Consider heat-treating colostrum at 60° C for 60 minutes to reduce total coliform count and thus reduce the risk of illness (including scours) as a function of improved passive transfer of maternal immunity.[18] In dairy herds, do not rely on the calf nursing the dam for adequate colostrum intake; instead routinely use nipple/bottle or bucket feeding and esophageal tubing. If a calf is unable to suckle or is at risk for failure of passive transfer of maternal immunity, force-feed fresh or freshly thawed frozen colostrum from the calf's dam or from a mature cow in the same herd or a neighboring herd.
6. Thoroughly scrub and disinfect all equipment with detergent and bleach, and let them completely dry between uses for feeding colostrum and treating sick calves. This includes such items as nipple bottles, esophageal tubes, buckets, balling guns, and calf carts.
7. Move cow-calf pairs away from the calving area as soon as possible after birth in dairy herds. In beef herds, segregate calves by age by scheduled movement of dams that have not calved to new calving pastures—the so-called Sandhills Calving System (http://vetext.unl.edu/stories/200703050.shtml).
8. Develop a calf-care program including rapid identification and isolation protocols for scouring calves from healthy calves in dairy herds, or sick cow-calf pairs from healthy pairs in beef herds, to minimize environmental build-up of infectious agents.[15]

Giving calves a healthy start maximizes their genetic production potential while reducing the costs and labor associated with treating sick animals.

Rotavirus and Coronavirus Vaccines

RVs and CVs are ubiquitous in the cattle population; most adult cattle have VN serum antibodies.[19-23] RV infections are widespread in both dairy and beef cow-calf production systems, whereas infection with CV most often occurs as sporadic outbreaks of severe diarrhea in beef cow-calf herds or chronic low-grade diarrhea in dairy and veal calf operations. In addition to causing NCED, CV has been associated with winter dysentery in adult cattle[24] and respiratory tract infections in calves[25] and as a contributing infectious cause of BRD complex in feedlot cattle.[26] Fecal shedding of RV and CV is common among adult cattle,[27-30] providing an immediate source of viral challenge for naive newborn calves and allowing persistence of these agents at the herd level.

Although only one type of CV is known to cause NCED,[31] different subtypes of CVs can be identified on the basis of minor genomic and antigenic differences.[31-35] On a herd basis, however, affected calves can display a range of clinical signs from enteric only to mixed enteric and respiratory signs. A molecular epidemiologic investigation based on comparative analyses of a gene encoding a major structural protein of bovine CV revealed (1) identical CV strains in different animals from the same herd and from paired nasal and fecal samples from the same animals, suggesting herd outbreaks are associated with a single strain circulating among susceptible cattle, (2) identical CV strains in affected cattle from different herds in the same region, suggesting transmission between herds, and (3) different CV strains in cattle affected during different outbreaks occurring over several years in the same herd, suggesting herd outbreaks are associated with the introduction of new strains in a recovered herd.[36]

Currently, RVs are classified into at least seven distinct groups, A through G.[37] Although RVs that belong to groups A, B, and C have been found to naturally infect cattle,[30,37-41] group A RVs are by far the most prevalent group.[39,41] Members of group A RVs are further classified according to antigenic and genetic differences in their outer protein layer, composed of viral protein 7 (VP7) or G (for glycoprotein) and spikes of protease-activated attachment protein VP4 or P (for protease sensitive).[42-44] Because both of these proteins are involved in neutralization of infectivity in vitro and protection in vivo,[45-47] and multiple types of each protein can segregate independently in progeny virus, resulting in wide variations in the relative frequency of individual type and G/P combinations according to geographic location, individual farm, and calf, consideration of the G/P configuration of RVs is critical to development of an effective vaccination program for prevention of NCED.

Although a good correlation has been found between the antigenicity of the G proteins and their corresponding gene sequences, a similar relationship has not been found for the P proteins. Nevertheless, the binary G/P serotyping of group A RVs classification has largely been replaced with a G/P genotyping system based on nucleotide sequence of the corresponding genes.[48] Globally, 27 different G genotypes (G1 to G27) and 35 P genotypes (P1 to P35) have been described among group A RVs infecting animals and humans.[48] Although at least 8 distinct G types (G1, G2, G3, G6, G8, G10, G11, and untypeable) can infect cattle in the United States,[49,50] G6 appears to be the most widespread, while G8 and G10 account for lower percentages of infections.[23,50-55] Similarly, RVs with any of four P types (P1, P5, P11, and untypeable) are known to infect cattle in the United States, with P5 the most prevalent.[50,53,56]

The genome of RVs is composed of 11 gene segments that can be exchanged among RV strains when animals are infected by more than one virus differing in G/P types at the same time.[43] Therefore, mixed infections produce progeny RV with a genetic makeup derived from either parental strain by a mechanism called *gene reassortment.* Because the G and P proteins are independently involved in generation of specific VN antibodies, reassortment of the genes encoding these proteins during mixed infections can generate new progeny viruses that can evade what once was a protective immune response.[55] Genetic reassortment is a well-characterized mechanism of immune evasion that allows persistence of RVs in susceptible populations but can also promote interspecies transmission.[57] Some RV strains appear to be host specific; however, zoonotic spread of bovine RVs to humans is increasingly recognized.[57-60] In the case of bovine group A RVs, the potential for emergence of virus strains carrying any of 36 possible antigenic configurations (4 Ps × 8 Gs = 32 potential types) underscores the limitation of vaccination programs and also the importance of sound management practices designed to minimize exposure by limiting environmental contamination.

Vaccination Programs

Two approaches are widely used in an attempt to protect calves against RV and CV infection and diarrhea. The most common approach involves passive protection of the suckling neonate by transfer of high levels of specific VN colostral antibodies induced by parenteral vaccination of the pregnant dam.[21,61-69] The mechanism of passive protection with this approach is due to the continuing presence of an amount of specific VN antibodies in the intestinal lumen sufficient to neutralize infectious virus before infection of the intestinal villous enterocytes.[19,66,70-74] The continuous presence of VN antibodies in the gut lumen may also reduce the severity of the disease if infection has already developed. In addition, some of the VN colostral antibodies that are absorbed into the bloodstream are secreted onto mucous membranes and may provide local immunity later in life.[75] However, colostral transfer of immunity is less efficient in ruminants than in other species; high concentrations of maternal antibodies are present for less than 3 days postpartum, and these concentrations often fall below protective levels within 1 week of parturition.*

A delicate balance exists between passive protection afforded by lactogenic immunity and development of the calf's own innate and adaptive local immunity to RV and CV. Because most calves' level of resistance to the adverse clinical effects of RV and CV infection increases with age, disease caused by these agents can be controlled under certain circumstances by continuous hand-feeding of fresh, frozen, or fermented colostrum from vaccinated cows throughout the first 3 to 4 weeks of life.† The goal with this approach is to allow development of subclinical infection while the milk VN antibody concentration is partially protective.[63,74,79] Conversely, lactogenic immunity might interfere with development of adaptive immunity, or some calves might not be exposed to RV and CV infection until after milk antibody concentrations have fallen below protective levels, leaving the calf fully susceptible to infection.[61,63,80]

An RV and CV vaccine for parenteral administration to pregnant cows (Calf-Guard [Zoetis]) first became commercially available in 1979. This vaccine contained a single live attenuated G6:P1 strain of group A RV. However, because VN antibody concentrations in the colostrum and milk of vaccinated cows were low,[21,22,63,81] this product was later replaced by a formulation containing inactivated RV and CV, and current formulations of this vaccine contain G6 and G10 strains of group A RV (ScourGuard 4KC [Zoetis]). Meanwhile, an inactivated RV and CV vaccine (Scour Bos 9 [Novartis Animal Health U.S. Inc., Larchwood, Iowa]) containing three strains of group A RV was licensed for use in pregnant cattle in the United States. A third inactivated RV and CV vaccine (Guardian [Intervet Inc., Merck Animal Health, Omaha, Neb.]) containing two strains of group A RV and two strains of CV has since been licensed for SC administration in pregnant cattle in the United States.

Vaccination of pregnant cows with inactivated RV and CV vaccine can raise the level of VN antibodies in the colostrum.[21,61-70,82] Although there are reports of successful protection of calves against NCED by parenteral vaccination of pregnant cows with RV and CV,‡ negative results have also been reported. Failure of this vaccination strategy is generally attributed to failure of passive transfer of colostral antibodies to the calf or overwhelming virus challenge. An alternative

VetBooks.ir

explanation might be that the serotypic specificity of the passively transferred maternal antibodies may affect the protective efficacy of the RV vaccine.[91]

Information on protective immunity against infection of calves with group A RVs having the same or a different G/P serotype configuration as the vaccine strain is incomplete.[51,82,92-96] Although immunity to RV appears to be G/P serotype specific with some strains,[51,82,92,95] there is some indication that immunity directed against certain strains can neutralize in vitro[51,96] and protect challenge-exposed calves in vivo[51,95] against RV strains with different G/P configurations. Also, parenteral vaccination of seropositive cows with a single strain of RV can elicit serum VN antibodies to a broad spectrum of RV serotypes and genotypes, suggesting that this strategy may provide a means of enhancing passive protection against a range of potential RV serotype and genotype challenges.[83,93,95] However, a difference in the P protein between the vaccine RV and the infecting RV was suggested as the basis for failure of the inactivated monovalent RV and CV vaccine in beef cow-calf herds.[97,98]

Although antigenic and genotypic variation has been documented among bovine CVs,[31-35] reduced protection of nursing calves after challenge with a strain of bovine CV different from the vaccine strain has not been demonstrated. Consequently, addition of more than one strain of bovine CV in certain vaccines might not be justified at this time.

Another approach for preventing NCED caused by RV and CV involves oral vaccination of calves with an MLV vaccine (Calf-Guard) that contains an attenuated G6:P1 strain of group A RV.[99-109] The mechanism of disease prevention with this vaccine is unknown, but interference with infection by virulent virus, followed by development of secretory IgM and IgA and/or CMI in the intestinal mucosa, have been proposed.[80,102] To achieve adequate protection, the manufacturers recommend that the vaccine be given immediately after birth, before the calf has nursed. This regimen might be applicable to calves whose dams have not been vaccinated. However, because the colostrum of most heifers and cows contains some level of VN antibodies arising from natural exposure,[§] administration of colostrum should be delayed for several hours after vaccination to avoid inactivation of the vaccine virus. Under commercial conditions, it is nearly impossible to administer vaccine within minutes of birth or to effectively regulate colostrum intake in relation to the time of vaccination. Therefore, infection before vaccination, neutralization of the vaccine virus by colostral antibodies, and overwhelming challenge with infectious virus shed by unvaccinated diseased calves might explain a lack of efficacy with this approach.[64,104-107] This is evident from the data obtained in vaccine efficacy evaluation studies in which only a portion of the calves on a farm or a ranch are vaccinated in double-blind or odd/even–day vaccination trials.[76,108,109] When all calves are either vaccinated or not vaccinated in sequential comparisons, morbidity and mortality rates from NCED are significantly reduced by this vaccination strategy,[70,99-101,108,109] but the design and statistical validity of the latter kinds of trials have been questioned.[90,105]

Although not recommended by the manufacturer, the oral attenuated vaccine has been administered to calves with unknown immune status that were raised as veal calves or replacements in heifer development operations.[6] Under these circumstances, vaccination might provide active immunity and protection against potential virus challenge when calves from several different sources are commingled.

Rotavirus and Coronavirus Vaccination Products

ScourGuard 4KC

ScourGuard 4KC consists of inactivated bovine G6 and G10 strains of group A RV and a bovine CV strain combined with K99 *E. coli* bacterin and *C. perfringens* type C toxoid. For first-calf heifers and mature cows that have not previously been vaccinated, a two-dose series of vaccine should be administered by IM injection 3 weeks apart, starting 6 to 9 weeks pre-calving. The second dose should be given 3 to 6 weeks before the expected calving date. A single annual booster dose should be administered 3 to 6 weeks before each subsequent calving.

Scour Bos 9

Scour Bos 9 consists of inactivated bovine group A RV strains G6, G8, and G10 and a CV strain combined with bacterins from four *E. coli* K99 serotypes and *C. perfringens* type C toxoid. The first vaccine should be administered by IM injection into the neck of pregnant cows and heifers 8 to 16 weeks before the expected calving date, with a booster dose of Scour Bos RV and CV vaccine 4 weeks prior to the expected calving. Only one annual dose at 8 to 10 weeks before calving is required thereafter.

Guardian

Guardian consists of inactivated bovine group A RV G6 and G10 strains together with type 1 and type 3 bovine CV strains combined with enriched K99 pili from *E. coli* and type C and D toxoids of *C. perfringens*. The vaccine should be administered by SC injection of pregnant cows and heifers up to 12 weeks before the expected calving date. A booster dose of vaccine must be given approximately 3 to 6 weeks later during the first year. One annual dose administered up to 5 to 7 weeks before calving is required thereafter.

Calf-Guard

Calf-Guard is a modified live bovine G6 strain of group A RV and bovine CV recommended for oral vaccination of newborn calves. The vaccine should be administered immediately after birth, before the calf has nursed. As indicated earlier, interference by maternal antibodies may limit the efficacy of the vaccine, so vaccination of calves older than 1 day may be ineffective.

Bacterial Scours Vaccines

Gerald E. Duhamel • Victor S. Cortese

Enterotoxigenic *Escherichia coli* (Calf Scours) Bacterins

Neonatal calf diarrhea associated with enterotoxigenic *E. coli* (ETEC) usually occurs within the first 72 hours of life. The majority of calf scour cases are caused by ETEC that produces the F5 (K99) fimbrial adhesin that mediates adherence to specific receptors located on the brush border of small intestinal villous enterocytes, resisting normal peristaltic clearance mechanisms and thus promoting bacterial infection.[1-3] Adherent ETEC produces enterotoxins that stimulate water and electrolyte loss into the intestinal lumen, leading to dehydration and electrolyte imbalance that can be fatal. These ETEC strains may also express other types of fimbriae, including F41 and F1 (type 1), sometimes in combinations by the same strain of ETEC.[1,4] Intestinal colonization and villous attachment by strains of ETEC expressing adhesive fimbriae can be prevented by vaccination of the dam with a bacterin that contains a single fimbrial antigen in common with the challenge strain.[1,4] However, disease may occasionally be caused by ETEC expressing fimbrial antigens different from the most common, $F5^+$; therefore typing of *E. coli* isolates obtained from diarrheic calves can assist with proper selection of an ETEC fimbriae-based vaccination program.[5,6]

Because calf scours associated with ETEC strains occurs so early in life, there is not enough time for a newborn calf to mount a protective immune response through vaccination. Therefore, control of ETEC-induced calf scours is aimed at (1) limiting calf exposure to bacterial pathogens, (2) vaccinating dams to provide high levels of fimbriae-specific colostral antibodies (i.e., usually against the F5

VetBooks.ir

antigen), and (3) providing adequate volume of colostrum as soon as possible after birth to prevent bacterial colonization of the calf intestinal tract.[3] Pregnant cows are vaccinated in late gestation to ensure high concentrations of anti-F5 colostral antibodies. When colostrum from vaccinated cows is fed to newborn calves, the antibodies prevent bacteria expressing fimbrial adhesin from binding to specific host cell receptors located on the brush border of small intestinal villous enterocytes, mostly in the jejunum and ileum.[1,8] Unbound ETEC bacteria are passed into the feces by intestinal peristalsis and thus prevented from colonizing the small intestine and causing disease. By 72 to 96 hours of age, calves are highly resistant to ETEC infection and will rarely show clinical signs of diarrhea.[1,9] Thus, feeding calves colostrum with a high concentration of antibodies against F5 fimbrial antigen, even though restricted to the first day of life, is often sufficient to prevent severe diarrheal disease.[4] Passive circulating serum antibodies that are absorbed into the bloodstream from the intestinal tract are thought to play little or no role in protective immunity against neonatal enteric disease caused by ETEC.[1] However, for maximum efficacy of ETEC vaccine programs, a concurrent well-managed colostrum program should be in place.

Nearly all strains of ETEC that have been isolated from neonatal calves have F5 fimbriae. Currently there is no evidence that a bacterin with multiple types of fimbrial antigens is more effective than products with only F5, so long as the vaccine and the challenge strains share a common fimbrial antigen.[1] However, vaccines with multiple fimbrial antigens are more likely to have at least one of the antigens found on the challenge ETEC strain. Besides non-F5 ETEC strains potentially causing calf scours, a lack of efficacy of fimbriae-based ETEC vaccines may be due to *E. coli* belonging to pathotypes other than ETEC, including attaching and effacing *E. coli* (EPEC) and Shiga toxin–producing *E. coli* (STEC), which cause hemorrhagic enteritis in 1- to 6-week-old calves. Given that EPEC and STEC strains do not produce fimbrial adhesins, fimbriae-based ETEC bacterins will not protect against these strains.[6,7] Unfortunately, commercially available vaccines for prevention of calf scours associated with EPEC and STEC are not currently available.

Escherichia coli Vaccination Programs

The general recommendations for use of fimbriae-based ETEC vaccine (bacterin) are summarized in Table 48-10. ETEC bacterins are offered as single-antigen vaccines and in combination with other antigens designed to protect against other diseases in addition to ETEC infection. Oil-adjuvant ETEC bacterins are administered by IM injection in a single dose 2 weeks to 6 months before calving, and administration is repeated annually.[10] Non–oil-adjuvant ETEC bacterins are recommended for IM or SC injection in 2 doses administered at a 2- to 4-week interval, with the second dose given 3 to 6 weeks before calving. In subsequent years a single booster dose should be administered 3 to 6 weeks before calving. ETEC bacterins do not protect calves that do not ingest adequate amounts of colostrum soon after birth. Also, because this protection is based on passive immunity, high challenge levels may overwhelm the limited amount of antibodies present in the lumen of the calf's small intestine. This is consistent with the higher prevalence and severity of clinical ETEC infections in the close confinement of large numbers of replacement dairy heifers than in less intensive cow-calf beef operations. Environmental control of bacterial contamination is paramount to effective calf scour management.

Salmonella Vaccines

Salmonellosis is due to infection by various pathogenic *Salmonella enterica* serotypes (see Chapter 32). Disease severity varies according to serotypes and strain-specific virulence determinants but is also based on the number of infective organisms, route of entry, and host natural and acquired resistance mechanisms. Bovine salmonellosis is caused predominantly by *S. enterica* serotypes Typhimurium (*S.* Typhimurium) and Dublin (*S.* Dublin), and although both serotypes can cause enteritis, clinical disease associated with each serotype is different.[11] With disease caused by *S.* Typhimurium, a ubiquitous group B *Salmonella* serotype is most often associated with enteritis resulting in diarrhea in young calves. The host-restricted serotype group D *S.* Dublin most often causes systemic infections that may result in asymptomatic shedding or in abortion in pregnant cows. Consequently, commercially available *Salmonella* vaccines contain single or combinations of *S.* Typhimurium and Dublin. Because *Salmonella* serotype Newport and other group C *Salmonella* have increased in prevalence, serotyping of *Salmonella* is critical to implementing an effective vaccination program. All currently licensed products are formalin-inactivated, whole-cell, aluminum hydroxide–absorbed bacterins, except for a genetically altered stable nonreverting aromatic dependent (*aroA* mutant) modified live *S.* Dublin vaccine (Entervene-D [Boehringer Ingelheim Vetmedica Inc., St. Joseph, Mo.]) and a siderophore receptor protein (SRP)-based vaccine (SRP *S.* Newport Vaccine, Conditional USDA License [Zoetis, Florham Park, N.J.]) One *S.* Typhimurium and three *E. coli* mutant lipopolysaccharide (LPS) core antigen vaccines can provide protection from morbidity and mortality associated with salmonellosis.

A modified live and genetically altered (via deletion of *aroA*) *S.* Dublin vaccine marketed for parenteral use is effective in 2-week-old calves against challenge with *S.* Dublin but also provides cross-protection to challenge with *S.* Typhimurium.[12,13] As with many gram-negative bacterial vaccines, adverse reactions to this vaccine have been reported. Anecdotal reports of effective oral use in calves younger than age 2 weeks indicate that this route may help avoid some adverse reactions associated with injection of an endotoxin-containing product. Killed *Salmonella* bacterins can produce measurable serum antibody responses to bacterial proteins in calves and adult cattle. However, calves vaccinated with a killed bacterin are unable to produce anti-LPS antibodies until age 12 weeks,[14] and optimum responsiveness does not occur until age 1 year.[15] Most controlled studies in which calves were vaccinated with a killed *Salmonella* bacterin and orally challenged have reported a lack of protection.[16-18] One small study that reported good protection after vaccination of 3- to 6-week-old calves with 2 doses of killed bacterin used IM challenge.[19] Another study in 6-month-old cattle found that a single intradermal dose of heat-killed *S.* Dublin protected against IV challenge.[20] Vaccination of cattle 3 months of age or older with 2 doses of killed *Salmonella* bacterins is likely to be useful for preventing salmonellosis. Although little has been published on the efficacy of a conditionally USDA-licensed SRP *S.* Newport vaccine, the clinical impression is that it is safe and effective at reducing fecal shedding of *Salmonella* but also capable of controlling disease caused by different serotypes of *Salmonella.*

Vaccination of adult cows, with passive transfer of antibody to calves through colostrum, is frequently used in dairies to control salmonellosis in neonates. Controlled trials evaluating passive protection have produced mixed results, with some indicating a lack of protection[18,21] and others demonstrating some protection in very young calves (5 days old).[22] Vaccination of dry cows may be useful for control of salmonellosis in calves younger than 3 weeks of age but is minimally effective for controlling salmonellosis in calves older than 3 or 4 weeks. There are anecdotal reports of protection against salmonellosis by repeated vaccination of young calves with an *S.* Typhimurium mutant LPS core antigen vaccine (ENDOVAC [IMMVAC Inc., Columbia, Mo.]). A J-5 *E. coli* Rc-mutant LPS core antigen–based bacterin (J-VAC [Merial Ltd., Athens, Ga.], J-5 [Zoetis, Florham Park, N.J.], and Hygieia [Biological Laboratories, Woodland, Calif.]) improved survival and reduced morbidity rate from naturally occurring bacterial infections in dairy calves vaccinated at 3 and 17 days of age.[23]

Gram-Negative Mutant Lipopolysaccharide Core Antigen Bacterins

All genera and species of gram-negative bacteria share a common set of LPS core antigens that are present within the inner layers of the bacterial cell wall.[24] Endotoxin from gram-negative bacteria is

thought to play an important role in producing clinical signs, biochemical and hematologic alterations, and lesions associated with a wide variety of bovine diseases caused by gram-negative bacteria,[24] including salmonellosis and coliform mastitis, variously caused by *E. coli, Klebsiella* spp., *Enterobacter aerogenes,* and *Serratia* spp. Vaccines based on *S.* Typhimurium or *E. coli* with mutated LPS core antigen are designed to provide broad protection against related gram-negative infections by reducing the severity of clinical signs associated with sepsis and endotoxemia.

General Considerations

Gram-negative mutant LPS core antigen oil-adjuvant vaccines are currently marketed. Three use a J-5 Rc-mutant strain of *E. coli* that lacks the serotype-specific O-chain LPS components that ordinarily prevent deeper cell wall antigens from eliciting adaptive host immune response and production of antibodies against gram-negative core antigens.[24] Another commercial vaccine uses an Re-mutant strain of *Salmonella* Typhimurium.

Theoretically, gram-negative mutant LPS core antigen vaccines are expected to reduce the severity of disease but not the rate of occurrence of infection. In four different clinical trials, however, the incidence of clinical coliform mastitis in dairy cows was reduced by 69%, 72%, 80%, and 82%, respectively, by vaccination with a J-5 *E. coli* vaccine.[25-27] Data are consistent with the hypothesis that antibodies induced against gram-negative LPS core antigens assist in either the control of bacterial infection, neutralization of bacterial endotoxin, or a combination of both. In the trial where clinical coliform mastitis was reduced by 82%, however, vaccination did not reduce the incidence of subclinical intramammary coliform infections that were present at the time of calving.[27]

Vaccination Programs

Recommendations for use of bacterins to prevent disease associated with salmonellosis are summarized in Table 48-11. Cows should not receive other vaccines containing gram-negative organisms (*Pasteurella, Salmonella, Brucella, Campylobacter [Vibrio], H. somnus, E. coli,*

	ENVIRACOR J-5 (bacterin)	*Cows or heifers:* 3 doses starting at 7 and 8 months of gestation and 2 weeks after calving	Zoetis (Florham Park, NJ)
	Escherichia coli Bacterin	3 doses 4-6 weeks apart	Hygieia Biological Laboratories (Woodland, CA)

or *M. bovis* bacterins) within 5 days of vaccination with J-5 *E. coli* bacterin.

A J-5 *E. coli* bacterin has also successfully reduced morbidity and mortality in experimental *S.* Typhimurium infection in calves.[28] However, because of the short half-life of passively acquired antibodies stimulated by mutant LPS core antigen vaccines,[29] vaccination of dry cows is unlikely to be an effective control measure for salmonellosis in calves except when calves are exposed to and infected with *Salmonella* in the first week or two after birth. Salmonellosis in dairy calves often occurs after 2 weeks of age. However, when vaccinated at age 3 and 10 days with an oil-adjuvant J-5 *E. coli* bacterin, calves do develop strong antibody responses by age 17 days; this strong antibody response occurs even in the presence of passively acquired antibodies to LPS core antigens.[30] Consequently, a combined program in which both dry cows and neonatal calves are immunized against LPS core antigens might be a useful approach for reducing the severity of salmonellosis in neonatal dairy calves.

Clostridial Vaccines

J. Glenn Songer

Clostridial enteric disease may be mild (e.g., *C. difficile* and *C. perfringens* type A infection in neonatal pigs) or catastrophic (e.g., *C. perfringens* type C infection in neonates), producing acute and frequently fatal disease. Infections of internal organs and soft tissues are, on the other hand, uniformly serious and, in the absence of prior vaccination or very aggressive therapy, nearly always fatal. In either case, pathogenesis is most often mediated by toxic proteins.[1] Prevention is based on immunoprophylactic amelioration of the effects of these molecules. Unfortunately, the ready availability of inexpensive, efficacious bacterins, toxoids, and bacterin-toxoids has not eliminated clostridial infections, mainly because these immunoprophylactic products are sometimes used poorly or not at all. Duration of immunity (DOI) is poor. Accurate diagnosis remains an important component in management of clostridial diseases.[2,3]

VetBooks.ir

Immunization against clostridial diseases can be complicated by the development of site reactions, leading to trimming at slaughter.[4] These problems are exacerbated by the multivalent nature of many modern vaccines and have stimulated the biologics industry to seek a new paradigm for preparation and delivery of vaccines. Approaches have included concentration of the antigen into smaller doses and use of alternate adjuvants. Recombinant proteins delivered by conventional means, application of slow-release media, in vivo expression from attenuated bacterial delivery systems, and production in vivo by replicon particles from alpha viruses will likely be a major focus of effort.

In a recent study, transdermal vaccination resulted in bovine serum antibody titers similar to those resulting from SC vaccination, and injection site reactions were significantly smaller. Thus transdermal vaccination may be effective for raising protective immunity against clostridial diseases in cattle while minimizing local reactions.[5]

Clostridium chauvoei (Blackleg) Bacterins

Blackleg is frequently diagnosed despite long-term availability of generally effective bacterins. The most common route of exposure in cattle is likely ingestion, and dormant spores seeded to skeletal muscle germinate when muscle damage provides appropriate conditions. Signs in affected animals include fever, anorexia, depression, and lameness, with extensive dry and emphysematous to edematous, hemorrhagic, and necrotic lesions. In diagnosis, differentiation between blackleg and malignant edema is important.

Vaccination against blackleg is universally advocated, especially in cattle younger than 2 years. Dogma holds that protection arises from the immune response to a heat-labile soluble antigen, but *C. chauvoei* produces alpha toxin and several other toxic factors that may be equally important targets.[6,7] Recommendations for immunization are summarized in Table 48-12.

TABLE 48-12

General Considerations for Use of Clostridial Seven-Way and Eight-Way Bacterin-Toxoids*

Protection, by Species	Coverage Designation*	
	Seven-Way	Eight-Way
Clostridium chauvoei	x	x
Clostridium septicum	x	x
Clostridium novyi B	x	x
Clostridium sordellii	x	x
Clostridium perfringens type C	x	x
Clostridium perfringens type D	x	x
Clostridium perfringens type B†	x	x
Clostridium haemolyticum (novyi type D)	x	
Dose (mL)	2-5	5
Recommended boosters	After 2-4 weeks for *C. sordellii* and *C. perfringens* C and D; after 5-6 months for *C. novyi* type B and *C. haemolyticum*. Calves initially vaccinated at <3 months of age should be revaccinated at 4-6 months (or at weaning).	
Comment	No use <21 days preslaughter	

*Note that many combinations are available commercially, including some that also contain immunogens against nonclostridial diseases. Some of these combinations also include tetanus toxoid.

†No currently licensed product is produced by use of cultures of *C. perfringens* type B, but protection against type B infection is implied by the inclusion of toxoid prepared against type C (beta toxin) and type D (epsilon toxin) strains.

Clostridium septicum (Malignant Edema) Bacterins

Malignant edema, the typical wound infection caused by *C. septicum*,[8] usually follows direct contamination of a traumatic wound, including genital tract infections after mismanaged deliveries. Infection spreads along fascial planes, and lesions that are initially warm and pitting become crepitant and cold. Death commonly occurs in less than 24 hours. "Braxy" is a form of *C. septicum* enteric infection that occurs most commonly in calves.[9] Diagnosis is often by use of a fluorescent antibody test.[10]

Cattle are protected by a single immunizing dose of *C. septicum* bacterin, but annual booster vaccination is recommended in areas with a substantial incidence of the disease[11] (see Table 48-9). Vaccines elicit antibody responses to both somatic and toxin antigens, and recent findings suggest a central role for *C. septicum* alpha toxin.[12,13]

Clostridium novyi Types A and B (Bighead and Infectious Necrotic Hepatitis) Bacterins

Clostridium haemolyticum (*Clostridium novyi* type D) (Bacillary Hemoglobinuria) Bacterins

C. novyi toxigenic types A and B cause myonecrosis in humans (gas gangrene) and domestic animals (bighead of sheep), as well as infectious necrotic hepatitis (black disease) of sheep and cattle.[14] The hallmark lesion is edema that results from vascular damage caused by alpha toxin. Dormant spores in Kupffer cells germinate when liver injury provides appropriate conditions. Type C strains are nontoxigenic and therefore nonpathogenic.[15]

Redwater is caused by *C. haemolyticum* (*C. novyi* type D). Beta toxin, a homolog of *C. perfringens* alpha toxin (CPA), mediates the pathogenesis, usually in well-nourished animals at least 1 year of age. Tissue damage caused by migrating liver flukes allows germination of dormant spores in Kupffer cells. Vegetative growth yields a local lesion that is often quite small (golf-ball size is not uncommon), and dissemination of beta toxin via the bloodstream results in intravascular hemolysis, hemorrhage, and hemoglobinuria.[16,17] When urine takes on the color of port wine, about 50% of the red cells have lysed, and death ultimately results from anoxia. A vaccination program is essential for herds pastured in endemic areas. When light exposure to fluke metacercariae is expected, a single annual dose of bacterin-toxoid should be administered to all cattle older than age 6 months, before they are pastured in the spring. With heavy exposure to flukes, a booster dose should be administered in season. The prominent roles of alpha and beta toxins suggest they may find use in second-generation vaccines.

Clostridium botulinum (Botulism) and *Clostridium tetani* (Tetanus) Toxoids

Botulism is caused by *C. botulinum* neurotoxins, which block acetylcholine release from cholinergic nerve endings.[18,19] Cattle in the United States are most commonly affected by type C. Direct contamination of feeds by the organism sometimes leads to intoxication, but it is more commonly associated with an animal carcass in the feed. Clinical signs include incoordination, flaccid paralysis, and difficulty in swallowing; respiratory paralysis causes eventual death.[20,21]

Toxoids of botulinum toxins can be employed for immunoprophylaxis, but vaccination is usually practiced only in populations at immediate risk, such as beef cattle grazed on phosphorus-deficient range land.[22] Vaccination is not practiced in the United States. Feeding of poultry litter poses a similar problem, in that it may contain animal remains, but this practice has now been suspended in the United States.

Spores of *C. tetani* are found in soil, and animal hosts are usually infected in association with some traumatic event. Spores introduced to tissue under proper conditions of anaerobiosis germinate and produce tetanus neurotoxin.[23] Tetanus can develop in postparturient

VetBooks.ir

dairy cows and in calves after castration by the elastrator method.[24] Toxin moves retrograde, binding to presynaptic axonal terminals and resulting in muscular tremor and increased stimulus response; continued motor neuron hyperactivity causes sustained tetanic spasms in the innervated muscles and then permanent rigidity. Death is due to respiratory failure.

Acquired resistance to tetanus is based on circulating antitoxin, and widespread vaccination with toxoid in populations at risk has dramatically lessened the impact of tetanus on animal production. Neonatal passive immunity acquired from the dam is followed by active immunization with toxoid after 2 to 3 months. Boosters are commonly recommended at 1- to 5-year intervals. Passive immunotherapy is intended to neutralize preformed toxin, although it is much more effective when used prophylactically than therapeutically. Universal vaccination is not usually recommended as a cost-effective means for control of tetanus.

Clostridium perfringens Toxoids

C. perfringens causes various diseases in domestic animals, and those of greatest importance affect the gastrointestinal tract[25] (Table 48-13) (see ruminant section of Chapter 32). Type B disease is extraordinarily rare in the United States. Pathogenesis can be explained by additive or synergistic effects of beta and epsilon toxins. Type C strains multiply rapidly in the neonatal gut, and in this trypsin-poor environment, beta toxin accumulates and produces local hemorrhage and necrosis, as well as systemic effects.[26] Type D strains fill vacant intestinal niches, often those opened by sudden dietary changes. Epsilon toxin monomers bind to enterocytes and interact with other monomers to produce a pore. The toxin facilitates its own uptake and, in circulation, damages the central nervous system and other systems distant from the gut.[27] Type E causes hemorrhagic enteritis in calves, and its virulence is apparently based on the action of iota toxin.[28]

Type A infections are somewhat enigmatic. Long accepted as causes of lamb enterotoxemia,[29] poultry necrotic enteritis, and canine and equine enteritis, they are increasingly found to be causes of enteritis in piglets and calves. Little is known about the pathogenesis of some type A enteric infections, but our understanding of poultry necrotic enteritis has increased dramatically, and we can easily reproduce disease in chicks and piglets. Experimental reproduction remains challenging, but type A strains are commonly found in natural cases of tympany, abomasitis, and abomasal hemorrhage and ulceration in calves.[30,31]

Some say routine vaccination against type C enterotoxemia is required only in herds where the disease has been documented, but in our experience, vaccination of all dams prior to farrowing or calving is recommended. Immunity is provided to piglets or calves via immune colostrum. Initial immunization should be followed by a booster after 3 to 4 weeks, with the second dose (and subsequent boosters pre-farrowing or pre-calving) administered approximately 2 to 3 weeks before parturition. Type D enterotoxemia occurs sufficiently infrequently in cattle that vaccination may not be cost-effective. No commercial products are licensed in the United States for use against infections by strains of types A and E, and production of autogenous toxoids or bacterin toxoids has become quite common; anecdotal evidence suggests remarkable efficacy in some cases. Similar products have been produced from strains of type E. These should be used with the awareness that unlike beta and epsilon toxin concentrations in commercial products, toxin concentrations in autogenous toxoids may not be optimal.

TABLE 48-13

Diseases of Cattle Caused by *Clostridium perfringens*

Clostridium perfringens Type	Diseases in Domestic Animals	Major Toxins
A	Myonecrosis, enterotoxemia, abomasitis, possible sudden death	Alpha
B	Neonatal hemorrhagic enteritis	Alpha, beta, epsilon
C	Neonatal hemorrhagic or necrotic enterotoxemia	Alpha, beta
D	Enterotoxemia	Alpha, epsilon
E	Enterotoxemia	Alpha, iota

Clostridium sordellii Bacterins

C. sordellii is commonly found in feces of domestic animals, as well as in the soil, and is sometimes a cause of fatal myositis, liver disease, and sudden death in cattle. Subendocardial hemorrhage and edema in the subcutaneous tissues and along fascial planes of muscles are common. The organism produces numerous toxic or putatively toxic substances, foremost of which are toxins that resemble toxins A and B of *Clostridium difficile*.[32] Immunization is achieved by administration of multiway bacterin-toxoids (see Table 48-10).

Miscellaneous Bovine Rickettsial, Bacterial, and Viral Disease Vaccines

Derek A. Mosier

A number of bovine vaccines are available for anaplasmosis, infectious bovine keratoconjunctivitis, staphylococcal mastitis, anthrax, interdigital necrobacillosis (foot rot), papillomatous digital dermatitis (foot warts), rabies, and fibropapillomas. These are discussed individually next and summarized in Table 48-14.

Anaplasmosis

Anaplasmosis is a vectorborne or mechanically transmitted disease caused by the rickettsia *Anaplasma marginale*.[1,2] The disease occurs worldwide and is most prevalent in tropical and semitropical areas. Anaplasmosis is the only major tickborne disease of cattle in North America, being enzootic in the southeastern and some midwestern and western states and sporadic in the northern states and Canada.[1,2,3] In enzootic areas with adequate numbers of arthropod vectors, most adult cattle become naturally immune through repeated exposure. Maternal antibodies protect calves until they also become subclinically infected and develop immunity. Disease is more severe in older cattle than in calves, and nonimmune older cattle are particularly at risk when they are moved into an endemic area.[1,4] Susceptibility to disease occurs when there is a lack of arthropod vectors to maintain natural infection and immunity or when a nonimmune adult is introduced into an enzootic area. In these situations or when vector or environmental conditions suggest an increased risk of disease, vaccination can be beneficial.

No widely marketed commercial vaccines against anaplasmosis were available as of 2012 in North America. A killed vaccine (Anaplasmosis Vaccine, University Products LLC, Baton Rouge, La.) is available in some states, including Arkansas, California, Florida, Indiana, Illinois, Iowa, Kansas, Kentucky, Louisiana, Mississippi, Missouri, Nevada, Oklahoma, Oregon, Tennessee, Texas, Wisconsin, and Puerto Rico. The vaccine consists of an emulsion of concentrated inactivated *A. marginale* antigens and adjuvant suspended in 10% oil, similar to the last widely available commercial vaccine that was discontinued in 1999 (Plazvax [Schering-Plough Animal Health]). The killed vaccine is not USDA licensed, but it is USDA approved for use as an experimental vaccine. The vaccine has reportedly been used successfully in cows at all stages of pregnancy without an episode of neonatal isoerythrolysis. In endemic areas the vaccine is recommended for use just before the onset of the vector season. Vaccine-induced immunity does not generally occur until 2 weeks after

VetBooks.ir

administration of the second dose of an initial series or 2 weeks after a booster dose in previously immunized cattle.[5,6] Vaccination does not prevent infection or clinical disease and does not eliminate *A. marginale* from a herd, but it does reduce the severity and incidence of disease.[1,6] Inactivated vaccines could be used in conjunction with oxytetracycline in the face of outbreaks to provide both temporary and more prolonged protection.

A sheep-passaged modified live vaccine (Anavac [PHL Associates, Davis, Calif.]) has been used in California and Latin America.[7] Because this vaccine causes mild clinical disease, it has limited use for vaccination of mature susceptible cattle.[1,7] If the vaccine is administered to cattle older than 2 years of age, anemia, severe clinical disease, and death may occur, especially in bulls and heavily lactating cows.[7] The vaccine is recommended for use in healthy cattle between age 1 month and 2 years and is most commonly administered to 7- to 24-month-old cattle in herds in endemic areas. Concurrent use of certain antibiotics or other live or MLV vaccines is contraindicated.

A live vaccine (Frozen Anaplasmosis [Tick-borne gallsickness] vaccine for cattle [Onderstepoort Biological Products, Onderstepoort, South Africa]) composed of *A. marginale* subsp. *centrale,* a less pathogenic species or subspecies of *A. marginale,* is used in some countries including Africa, Australia, Israel, and Latin America but not in North America.[6,8,9] This vaccine consists of standardized and frozen red blood cells from splenectomized cattle that were infected with *A. marginale* subsp. *centrale.* The vaccine is recommended for use in 4- to 9-month-old cattle; older cattle have an increased risk of severe vaccine-induced disease. The vaccine produces mild disease but protects against subsequent severe disease caused by *A. marginale.* Immunity is considered long term or possibly for life if subsequent natural exposure occurs to ensure development of durable immunity.

Immunity to *A. marginale* is proposed to involve humoral responses to a variety of major surface proteins and enhanced macrophage phagocytosis and killing, both mediated by IFN-γ–producing $CD4^+$ T lymphocytes.[1,10,11] Inadequate protection from vaccines during field use can result from antigenic variability of the organism, geographic differences in the organism that result in a lack of cross-reactivity between *A. marginale* strains, and weak immune responses to protective *A. marginale* antigens.[1,4,12-14] Purified native, recombinant, and tick culture–derived *A. marginale* immunogens and DNA vaccines are being investigated for possible commercial use in the future.[6,9,12,13,15-17]

Infectious Bovine Keratoconjunctivitis

The most common infectious agent associated with infectious bovine keratoconjunctivitis (IBK) is *Moraxella bovis.*[1] Vaccination is most effective when done before fly season in herds with a history of problems. Certain breeds (e.g., Herefords, Hereford crosses) are particularly susceptible and may benefit from vaccination.[1,2] Commercial vaccines used to help prevent the disease consist of inactivated cultures of various strains of *M. bovis.*[3] Some products recommend 2 doses given 3 weeks apart for initial vaccination, beginning as early as 3 weeks of age to no earlier than 5 months of age. Other products recommend a single dose administered 3 to 6 weeks before the predicted onset of the disease season, with annual vaccination thereafter. *M. bovis* bacterins are also available in combination with 7-way clostridial bacterin-toxoids.[4] Although multivalent *M. bovis* bacterins can provide some protection in field use, efficacy varies depending on the *M. bovis* strains present in the bacterin and those responsible for disease.[1,5-7] Seven different disease-producing serogroups of *M. bovis* are recognized based on differences in pili, and there is variable cross-reactivity between serogroups.[3] Pilin gene rearrangements and pilin-type switching can allow *M. bovis* to switch from expression of one type of pilus antigen to another, making it difficult to predict what serogroup(s) may be necessary for protection.[2,3,6] Monovalent bacterins are generally ineffective in field use, and multivalent bacterins provide neither consistent nor reliable protection.[3,5-7] Vaccines must incorporate pili from all major serogroups or conserved immunogenic portions of all serogroups to provide optimum protection.[3,6,7] Experimental recombinant vaccines containing cloned pili of various serogroups have demonstrated some promise for future vaccines.[5,6] Another immunogen considered important for protection is *M. bovis* B-hemolytic corneotoxic and leukotoxic cytotoxin.[1-3] Experimental vaccines containing hemolytic cytotoxin preparations alone or in combination with pilus antigens have shown some efficacy in experimental trials.[1,3,8-10] Other potential immunogens include iron-regulated OMPs, proteases, fibrinolysins, and phospholipases.[1-3] Vaccine-induced protection is correlated predominantly with a suitable lacrimal immune response (predominantly IgA but also IgM and IgG) and not with serum antibody levels to *M. bovis* antigens.[1-3] Therefore an antigen delivery system that enhances lacrimal and mucosal immunity is an important feature of an effective vaccine.[11] The presence of other agents contributing to IBK (e.g., *Moraxella [Branhamella] ovis, Mycoplasma bovoculi,* or BHV-1) should also be considered when there is poor *M. bovis* vaccine efficacy.[12] Autogenous *M. bovis* or *M. bovis* plus *M. bovoculi* vaccines have not been consistently effective against the disease.[1,13,14] Use of MLV vaccines for IBR is contraindicated in the presence of an outbreak of IBK because it may exacerbate the IBK.[1]

Staphylococcal Mastitis

Staphylococcus aureus is considered one of the most important causative agents of bovine mastitis.[1] Vaccination against *S. aureus* may be beneficial in dairy herds that have an existing mastitis problem,[1,2] but vaccination in well-managed dairy herds with a low level of staphylococcal mastitis may not provide much economic benefit.[2] Staphylococcal bacterins contain conserved antigens or antigens from multiple strains or serotypes of *S. aureus.*[3-5] The typical recommended vaccination protocol is 2 doses given 2 weeks apart, followed by revaccination at 6-month intervals. Vaccination can start at 6 months of age, and one of the semiannual doses should be given 3 to 4 weeks before calving. Vaccination with *S. aureus* bacterins does not generally eliminate disease but can substantially reduce clinical mastitis and the incidence of subclinical and chronic staphylococcal infection.[1,2,5,6] Vaccination may be more effective in heifers because of their initial lower basal immunity compared with older cows.[6] The benefits of immunity induced early in life include the abilities to clear the organism and resist chronic infection on initial natural exposure. Vaccination during the dry period may be more effective than vaccination during lactation. In some but not all studies, vaccination has reduced somatic cell counts in milk.[5,6] Vaccination in combination with antimicrobial therapy has been successfully used to eliminate chronic staphylococcal mastitis.[7]

In considering the use of staphylococcal vaccines, the prevalence of various pathogens that can cause mastitis must be considered. For mastitis caused by *S. aureus,* differences between the *S. aureus* strains in vaccines and the strains specifically responsible for the disease may diminish vaccine efficacy.[1,4,8] Both long-standing bacterins and some newer-technology vaccines have achieved positive results.[1,9] Experimental trials suggest that more effective vaccines may be derived by stimulating immune responses to combinations of *S. aureus* capsular polysaccharide.[10] A vaccine based on technologies used for human staphylococcal vaccines that incorporates capsular polysaccharide from the three *S. aureus* serotypes most commonly associated with mastitis stimulated immunologic parameters necessary for protection.[11] Other vaccines have utilized highly conserved membrane proteins, iron-regulated proteins, a staphylococcal superantigen conserved by many mastitis strains, and DNA vaccines directed against adhesin proteins in attempts to achieve the "universal" *S. aureus* vaccine.[5,12-14]

In herds where other pathogens are a major cause of mastitis, *S. aureus* vaccines may be of minimal benefit.[2] Other important causes of bovine mastitis include *Streptococcus* spp. (e.g., *Streptococcus uberis, Streptococcus dysgalactiae,* and *Streptococcus agalactiae*) and coliform bacteria (e.g., *E. coli*). Recombinant vaccines containing *S. aureus* and *S. agalactiae* have shown some promise in experimental

models.[15] Experimental vaccines composed of bacterial proteins derived from *S. uberis* and *S. dysgalactiae* reduced somatic cell counts compared with controls after challenge.[16,17] *E. coli* J5 vaccines have also been used to successfully reduce the severity of mastitis (reviewed elsewhere in this section).

Anthrax

Anthrax is an acute, highly fatal disease caused by *Bacillus anthracis.*[1] Vaccination has proven to be an effective means of controlling the disease in endemic areas and in the face of outbreaks.[1-3] Bovine anthrax vaccines are derived from the live toxigenic, nonencapsulated spore vaccine developed by Sterne and consist of spores suspended in a diluent containing saponin and glycerin.[1] Annual vaccination of livestock in areas of endemic anthrax is recommended 4 weeks before outbreaks are expected, typically in the spring to provide protection during the summer months.[1] A single dose generally provides adequate immunity for about a year, but a second dose given 2 to 4 weeks after the first is sometimes recommended. Cattle should not be vaccinated within 42 days of slaughter. Antibiotics should not be administered within 7 days of vaccination to avoid interference with in vivo growth of the vaccine organism. Outbreaks can occur sporadically but often occur in areas with a history of flooding followed by drought.[4,5] Vaccination in the face of an outbreak does not protect all cattle, but the spread of infection and the number of new cases generally declines within 10 days.[3,5] Localized subcutaneous edema can develop at the injection site within 24 hours; it may last for several days and is sometimes severe.[2] Since the intentional release of *B. anthracis* via the mail system in 2001, there has been increased interest in technologies for the development of an efficacious long-acting human vaccine for anthrax.[2,6-8] Some of these technologies could hold promise to reduce some of the localized side effects of the current bovine vaccine,[9] but it is unlikely a new bovine vaccine will match the safety, efficacy, and cost-effectiveness of the Sterne strain vaccine in the foreseeable future. All anthrax outbreaks should be reported to local regulatory and public health officials, and appropriate guidelines for vaccination should be followed, including quarantine and vaccination of all susceptible livestock on affected and surrounding premises.

Interdigital Necrobacillosis (Foot Rot)

Interdigital necrobacillosis (foot rot) in cattle results from interdigital infection with *Fusobacterium necrophorum,* with lesser contributions from *Porphyromonas levii* (previously classified as a subspecies of *Prevotella [Bacterioides] melaninogenica*) and sometimes *Dichelobacter (Bacterioides) nodosus* (the most common cause of foot rot in sheep) and other bacteria.[1-3] Commercial *F. necrophorum* bacterins to aid in the prevention of foot rot (and hepatic necrobacillosis) are available for use in cattle. Recommendations for initial vaccination are two doses given 3 to 4 weeks apart, followed by annual revaccination. Vaccination is also recommended when endemic conditions exist or when exposure is imminent. The efficacy of *F. necrophorum* vaccines is unclear because hepatic abscesses are sometimes the study focus, but some benefit for foot rot has been demonstrated in experimental studies and field trials.[4] Vaccination is especially recommended in herds with a high incidence of disease. Protective immunity most closely correlates with the level of antileukotoxin antibodies.[5] In experimental models, truncated recombinant leukotoxin proteins provide protection and presumably would have some benefit against interdigital *F. necrophorum* infection.[6,7] Most foot rot infections involve single rather than multiple strains of *F. necrophorum,* so a vaccine that targets the specific strain involved should be effective.[8]

Papillomatous Digital Dermatitis (Foot Warts)

Papillomatous digital dermatitis, or foot warts, can be a serious problem in dairy cattle.[1] The disease is characterized by ulcerative to proliferative digital lesions that most often occur in replacement heifers and younger cows after introduction into a milking herd.[1,2] Risk is greatest in larger dairy breeds in herds of greater than 500 head. *Treponema* spp. are most commonly isolated from lesions and are considered the most important cause of foot warts. A wide variety of *Treponema* are incriminated, including *T. phagedensis, T. denticola, T. vincentii/T. medium,* and *T. pedis.*[3-5] No virus was seen in biopsies from multiple warts from dairy cattle in two herds.[6] Several bacterial species have also been isolated from lesions, including *Fusobacterium necrophorum, Serpens* spp., and *Porphyromonas levii.*[7,8] However, the precise combinations of these agents necessary to produce disease remain unclear. Commercial bacterins are available for use as preventives and/or aids to treatment and consist of killed cultures of *Serpens* spp. or *Treponema* spp. organisms. Recommendations are for 3 doses administered SC at 3- to 4-week intervals, followed by revaccination every 4 to 6 months. Company field trials report reduced onset of new infections and sometimes more rapid resolution of existing infections in vaccinated cattle. However, some trials failed to show significant improvement in vaccinated cows compared with unvaccinated ones.[8,9] The requirement for frequent boosters and the high recurrence rates of natural infection suggest that immunity to the disease is short lived or weak.[2]

Rabies

Rabies is a highly fatal zoonotic neurologic disease caused by a rhabdovirus.[1] Bovine rabies in North America is generally uncommon, and routine vaccination of cattle is not recommended in most situations.[2] However, vaccination may be a consideration in rural areas of Latin America, where vampire bats are important sylvatic vectors, or Africa, where exposure to infected dogs is a major cause of bovine rabies.[3,4] In endemic areas, vaccination of valuable cattle or herds may be a reasonable precautionary measure. This is particularly true in situations where cattle are in frequent contact with human beings, in order to reduce the anxiety of animal workers and minimize the likelihood of human exposure. Currently licensed rabies vaccines for cattle contain inactivated cell culture–derived virus.[5] The recommended regimen is initial vaccination at 3 months of age followed by annual vaccination thereafter. Because the duration of protective neutralizing antibody levels after initial vaccination can vary, some experts have suggested that a second booster dose be given either 1 month after initial vaccination or at 6 months of age.[6] Subsequent annual revaccination induces strong anamnestic responses that persist for 1 year or longer.[6] In Latin America, modified live vaccines are sometimes used but do not stimulate the same level of immunity as inactivated virus vaccines. A Capripoxvirus vector expressing rabies virus glycoprotein has shown promise in providing long-term protection against rabies (and lumpy skin disease) and may be a cost-effective mechanism for rabies control in cattle in some developing countries.[7,8]

Fibropapillomas (Warts)

Fibropapillomas (warts) are manifested in a variety of forms and locations, each caused by one of over 13 different types of bovine papillomaviruses (BPV).[1,2] Lesions associated with papillomaviruses can occur in the epidermis of the head, face, neck, and legs (BPV-1 and BPV-22), upper alimentary and urinary tracts (BPV-4), teats and udder (BPV-1, BPV-3, BPV-5, and BPV-6), and genital epithelium (BPV-1).[1,2] Immunity after infection or vaccination is virus type specific and is induced by viral structural proteins.[1] Therefore, the efficacy of both autogenous and commercial vaccines depends on which viral antigens are incorporated into the vaccine and which virus type is responsible for the disease. Vaccines containing BPV-1 and BPV-2 are generally effective for prevention, with some reports that BPV-2 also aids in regression of existing lesions.[1,3] Vaccines are usually ineffective for treatment or prevention of disease caused by BPV-3 and BPV-5.[3] Vaccination with structural capsid proteins of BPV-4 generally induces long-lasting immunity and is effective in preventing

VetBooks.ir

papillomas caused by BPV-4.[1] However, in immunocompromised cattle (e.g., those ingesting braken fern), papillomas may spread and can progress to squamous cell carcinoma.[2,4] Interpreting the response to vaccination against fibropapilloma can be complicated by spontaneous regression of some lesions. Lesions associated with BPV-1, BPV-2, and BPV-4 usually regress spontaneously within 1 to 12 months, whereas lesions caused by BPV-3 and BPV-5 do not normally regress spontaneously.[2,3]

Commercial vaccines consist of inactivated virus-laden tissue extracts derived from bovine papillomas.[5] The recommended regimen is an initial dose divided and given in at least 2 different sites, followed by a second dose in 3 to 5 weeks. Vaccination should continue for at least 1 year after elimination of disease from the herd. Autogenous vaccines can be made by homogenization and inactivation (0.3% formalin) of excised wart tissue, followed by dilution of the homogenate in physiologic saline and filtration through gauze. Three 1- to 5-mL intradermal injections given at 1-week intervals are recommended. Because autogenous vaccines generally contain the virus type associated with the disease, these often provide favorable results for both regression and prevention.[6] Vaccination is most commonly used with valuable animals destined for competitive shows or overseas sale.[3] Recombinant or native BPV proteins derived from multiple virus types have shown promise in experimental studies and could form the basis for a vaccine that protects against all BPV types.[7]

• CHAPTER 49

Parasite Control Programs

SHERRILL A. FLEMING, *Consulting Editor*

VetBooks.ir

The traditional approach to parasite control programs has focused on using the appropriate anthelmintic at appropriate intervals. Parasitic disease in domestic animals is assumed to be the result of not dosing the animals often enough with anthelmintics. Scant consideration has been paid to the interaction of the parasite with the host and the environment because of the reliance on anthelmintics. These drugs have been placed directly into the hands of the livestock owner because the expertise of a veterinarian did not seem necessary in the control of parasites. However, reports of resistance to anthelmintics and emergence of new manifestations of parasitism are surfacing throughout the world. It has become increasingly apparent over the past 20 years that this approach to parasite control is no longer sustainable.

Secondary to the notion that parasitism is under control is the decrease in research to develop new anthelmintics. Currently there is little in pharmacologic development other than variations on the current anthelmintics. Research programs in parasitology of domestic animals are facing funding reductions as research priorities are shifted to other diseases. As producers and owners struggle to deal with the realities of anthelmintic resistance, veterinary medicine must reassess traditional approaches to parasite control programs. Veterinarians will need to reeducate themselves away from the traditional tools of deworming, anthelmintic rotation, and pasture rotation. Integrated management strategies incorporating selective use of anthelmintic agents, enhancement of host immunity to parasitic infection, and grazing/environmental management have become increasingly important in the design of sustainable parasite control programs.

The impact of parasitic infection varies widely with geographic area and management system. General guidelines may be suggested for parasitic control, but it is inadvisable to adhere to any rigid anthelmintic schedules or even management recommendations. The best parasite control programs are those designed with the goals of the producer in mind, as well as the costs and returns of treatment. Other factors that must be considered include the animal's environment, climatic variations, and geographic location. Although many producers and owners would like a "cookbook" approach to parasite control, these are rarely effective across the various management conditions. It is unfortunate that an epidemiologically and economically sound parasite control program designed for animals in one geographic area may be neither efficient nor effective in another location.

The most important concept in the design of sound parasite control programs is the interaction of the parasite with the host and the environment. An understanding of the life cycle and epidemiology will suggest the most effective methods for parasite control. In this chapter parasite factors, host factors, and environmental factors affecting transmission and disease expression are discussed for each major class of parasites in each host species (horses, cattle, small ruminants). The methods of monitoring parasite infections and anthelmintic resistance are presented in detail. The classes of anthelmintics and their modes of action are discussed and, finally, coccidiosis in cattle and small ruminants is summarized at the end of the chapter.

Equine Parasitic Disease

Martin Krarup Nielsen

The changed approaches being promoted for control of equine gastrointestinal helminths are based on a number of scientific concepts outlined in the following section. The recommendations given today are based on experts' best knowledge of parasite and host biology, as well as mechanisms of anthelmintic resistance. As time passes, some of these recommendations are likely to change as new information is generated. In essence, the traditional strategies used for equine parasite control were based on the best scientific evidence available at the time, and the recommendations now given are merely a response to the experiences gathered over the past decades. The concepts underlying the modern approaches for equine parasite control are presented in the following.

Anthelmintic Resistance

Anthelmintic resistance can be defined as "the loss of treatment efficacy of a given anthelmintic formulation that used to have efficacy against the same parasite species and stage in the same host animal, at the same dosage, and by the same route of administration." This sentence implies several things: (1) If a drug formulation never had efficacy against the parasite and stage in question, then veterinarians are not facing resistance. (2) In case of nonlabeled usage of anthelmintics, veterinarians cannot make any conclusions regarding resistance because they have no information about the expected level of efficacy. (3) Horses are always infected with several different species of parasites at the same time, and resistance often occurs in some, but not all, of these species. (4) The expected level of efficacy needs to be defined for each parasite species for each drug in order evaluate the possible presence of resistant parasites.

The current levels of anthelmintic resistance in equine parasites are presented in Table 49-1. Generally speaking, resistance has been widely documented in cyathostomins (small strongyles) and *Parascaris equorum*. It is worth noticing that as a general pattern, the resistance profiles are almost completely complementary between the two parasite categories. The drugs that seem to still work well against *P. equorum* often have no or little efficacy against cyathostomins and vice versa. However, levels of anthelmintic resistance are constantly developing and this pattern may therefore be shifting. Recent work has documented signs of emerging ivermectin and moxidectin resistance in cyathostomins,[1-4] and total drug failure is a realistic possibility in this parasite group. No new anthelmintic formulations

VetBooks.ir

TABLE 49-1

Current Levels of Resistance by Major Nematode Parasites to the Three Anthelmintic Classes in Managed Horse Herds

Drug Class	Cyathostomins	Large Strongyles	*Parascaris equorum*
Benzimidazoles	Widespread	None	Early indications
Pyrimidines	Common	None	Early indications
Macrolide lactones	Early indications	None	Widespread

BOX 49-1

Fecal Egg Count Reduction Test (FECRT) for Equidae

The FECRT evaluates the efficacy of an anthelmintic drug on the basis of its ability to reduce the fecal egg output after treatment. Fecal egg counts (FECs) are performed just before (or at the time of) and 14 days after treatment. The fecal egg count reduction (FECR) is calculated for each individual horse according to the formula:

$$\%\,\mathrm{FECR} = \left(\frac{FEC_{pre} - FEC_{post}}{FEC_{post}}\right) \times 100\%$$

It is recommended to use an egg-counting technique with a detection limit of fewer than 25 eggs per gram (EPG). Use the same technique consistently. Include horses with the highest possible pretreatment egg counts, and never use horses with counts below 200 EPG.

The FECRT should be established on the farm level by calculating the FECR for a number of individual horses and then calculating the average FECR for the treated group. It is recommended to include at least 5 to 10 horses on each farm if possible.

Suggested cutoff values for resistance depend on the drug tested and the number of horses investigated, but the following cutoff values are recommended as general guidelines for strongyle and ascarid nematodes:

Benzimidazoles:	95%
Pyrantel:	90%
Ivermectin:	95%
Moxidectin:	95%

If the farm average FECR falls below these values, anthelmintic resistance should be suspected. However, it is important to rule out other causes of decreased efficacy, such as misdosing and inadequate storage. One must also consider how many horses were tested and how high the starting FECs were. Due to inherent variability in the measurement of FEC when performing FECRT, interpretation of the data can sometimes be difficult when results fall into the borderline zones. In such cases, it is recommended to repeat the FECRT.

There are currently no available methods for diagnosis of anthelmintic resistance in equine tapeworms.

with new modes of action are expected to be introduced to the equine market in the foreseeable future.

The only available method for evaluating anthelmintic efficacy in horses is the fecal egg count reduction test (FECRT). This method is outlined in Box 49-1 along with some suggested cutoff values for determining anthelmintic resistance.

Egg Reappearance Period

Egg reappearance periods (ERPs) are defined as the period of time from anthelmintic treatment until parasite eggs are found in the feces again. Although ERPs could potentially be established for a number of different parasite categories, they are most often referred to for strongyle (i.e., cyathostomin) parasites. The ERPs were initially defined for each anthelmintic class to help identify the optimum interval between anthelmintic treatments, and this was the basis for launching the so-called interval dose program in the 1960s.[5]

TABLE 49-2

Prepatent Periods of Some Important Equine Parasites

Species	Prepatent Period	References
Cyathostomins	2-3 mo*	113
Parascaris equorum	2½-3 mo	114
Anoplocephala perfoliata	1½-4 mo	115
Strongylus edentates	11-12 mo	115
Strongylus equinus		115
Strongylus vulgaris	6-7 mo	112

*Encysted larval stages can remain dormant for years.

Nowadays, ERPs are used for an entirely different purpose. It has been observed that the first sign of developing anthelmintic resistance to a given drug is often a gradual shortening of the ERP until reduced efficacies can finally be found with the FECRT. The most prominent example of this is the observed ERPs of ivermectin and moxidectin against cyathostomin parasites. Initially, ERPs were reported to be at least 8 and 12 to 16 weeks for ivermectin and moxidectin, respectively,[6-8] but recent publications reported egg reappearance at around weeks 4 to 5 for both drugs.[1, 4] Two necropsy-based studies have suggested that these observations were due to survival of luminal yet premature stages of cyathostomin larvae.[2,3]

Prepatent Period

Prepatent periods (PPPs) should not be confused with the egg reappearance periods defined earlier. While the latter defines a response to anthelmintic treatment, the PPPs are defined in the absence of anthelmintic intervention. The PPP for any given parasite is defined as the time elapsed from the uptake of the infective stage of the parasite until it reaches patency and starts shedding eggs to be detected in the feces. Thus the PPP represents the duration of the parasitic part of the life cycle. Table 49-2 presents PPPs for some of the most important equine helminth parasites. It should be noted that although the PPPs for cyathostomin parasites are generally relatively short, they can undergo arrested development for up to several years, which thereby dramatically lengthens the PPP. [9]

Information about PPPs can be taken into account for identifying optimal times for routine collection of fecal samples and anthelmintic intervention.

Parasite Distributions

Regardless of parasite and host species, distributions of parasites among their hosts always seem to follow the same pattern. Hosts of similar age and breed and kept under identical management grazing the same pasture can have widely different parasite burdens. Parasites never follow a symmetric normal distribution but are rather said to be overdispersed.[10] Technically speaking, this means that the variance is larger than the mean, but in practical terms this has been translated to the so-called 20/80 rule.[11] This refers to the observation that about 20% of the host animals harbor approximately 80% of the parasites. Similarly, about 20% of horses are shedding 80% of the total strongyle egg output. This phenomenon is most pronounced in adult horses, where a large majority is shedding low numbers of strongyle eggs and

VetBooks.ir

very few individuals can be observed with very high counts. This pattern has been found to be consistent in individual horses over time, and the tendency is particularly strong among horses with 0 or low strongyle egg counts.[12-14] Taken together, these observations have become the foundation for the selective therapy principle covered later in this chapter.

Parasite Refugia

The term "parasite refugia" has become generally accepted as perhaps the most important factor affecting the rate of development of anthelmintic resistance in large animal parasites.[15] Parasites in refugia are the parts of any given parasite population (including all stages, both internal and external) that are not exposed to the anthelmintic drug at the time of treatment. It can be said that these parasite stages in a way "escaped" the drug and can be viewed as refugees, hence the terminology. Logically, all stages on pasture, such as eggs and preinfective larvae, are always in refugia. In addition, animals left untreated can be viewed as contributing to the refugia, and some parasitologists therefore distinguish between "pasture refugia" and "animal refugia." Finally, some anthelmintic formulations have no efficacy against some parasite stages within the horse, and these can be regarded as part of the refugia as well. Examples of this include pyrantel formulations, which have no efficacy against parasite stages present outside the gastrointestinal lumen, and ivermectin, which has no documented efficacy against encysted cyathostomin larvae.

The parasites in refugia are hypothesized to play a role in diluting out resistant parasites whenever the animals are dewormed. A simplistic explanation of this concept is the larger the refugia, the more the dilution of resistant parasites, and the slower the development of resistance. In a theoretic example, consider a horse herd that is dewormed with a drug that has efficacy against all parasitic stages of the parasites, and the treatments are carried out at a time of the year when no eggs or larvae are present on pasture. This would represent a scenario with no parasite refugia. Because no anthelmintic treatment is 100% efficacious, there will always be a few parasites surviving and passing their genes on to the next generation. In a situation with low or even no refugia, all eggs being passed in the feces after deworming will be progeny of resistant parasites mating in the intestinal tract. However, if some of the horses in the herd were left untreated and/or treatments were carried out under circumstances with eggs and larvae present on pasture, then the few resistant worms surviving treatment would be diluted out by the many nonresistant worms, eggs, and larvae, and the progression of resistance in the parasite population would be much slower.

The role of parasite refugia in the development of anthelmintic resistance was initially shown in a sheep study,[16] and recent work with a combination of computer simulations and field studies with ruminants has provided solid evidence behind the concept.[17-19] There have been no such studies performed in horses, so this understanding of parasite refugia is mainly extrapolated from the work performed with ruminants.

Important Parasites Infecting Horses

Over the past five decades the emphasis has shifted several times in terms of which parasites are considered the major targets of the control programs. When the first modern paste dewormers were introduced in the 1960s, the large strongyle *Strongylus vulgaris* was considered the most important threat to equine health and was therefore identified as the main target for the interval dose program.[5] As time went on and new anthelmintic drug classes were introduced, this parasite went from being virtually present in all horses to becoming rare.[20-21] At the same time, cyathostomins were recognized as major pathogens and were identified as the primary target of parasite control programs.[22] More recently, the tapeworm *Anoplocephala perfoliata* has been associated with an increased risk of specific colic types.[23] In addition, *Parascaris equorum* is identified as the major parasitic pathogen in foals.[24-25] These are the four major parasite pathogens, but others can play a role as well. Less important but widely occurring parasites include *Strongyloides westeri, Oxyuris equi,* and the bot larvae of *Gastrophilus* spp. Finally, the insect-borne nematodes *Thelazia* spp., *Habronema* spp., *Draschia* spp., and *Setaria* spp. can occur at significant levels in certain habitats and are included in this chapter.

Parascaris equorum

The equine roundworm has gained status as perhaps the most significant parasitic threat to equine health in managed horse populations. The major reason for this shift of emphasis is the high levels of ivermectin and moxidectin resistance observed worldwide (see Table 49-1). *P. equorum* is the primary parasite in foals until about the time of weaning. At the age of approximately 6 to 12 months, most horses clear infection with this parasite and the strongyles become the predominating parasite group instead. Equine ascarids are ubiquitous in foaling operations, although prevalence differences can be observed between individual farms.[26-27] Patent infection is not uncommon in adult horses, particularly broodmares that are highly exposed to infection.

The life cycle is classic ascarid. Eggs are perceived to be highly resilient to environmental influences and can allegedly survive in the environment for several years. Work with eggs of the pig roundworm *Ascaris suum* has substantiated this, but little work has been done with *P. equorum* eggs. The infective stage is the embryonated egg, which hatches in the stomach and small intestine of the horse. Larvae then penetrate the mucosal lining and migrate the classical hepatotracheal route. Passing through the lungs has been associated with airway symptoms in young foals,[28] but the major pathogenic role is played in the small intestine. Here, the parasites compete with their hosts for nutrients, which can result in ill-thrift, weight loss, rough hair coat, and pot-bellied appearance.[25,28] The major clinical impact is associated with verminous small intestinal impactions.[24] As with any type of small intestinal impaction, the prognosis for full recovery is guarded and surgery is often required to relieve the condition. In severe cases, the small intestinal walls will rupture and foals will have to be euthanized. Rather ironically, anthelmintic treatment has been shown to be a significant risk factor for this condition.[24] The instant paralysis elicited by most dewormers can cause the worms to aggregate in the lower parts of the jejunum and ileum. Benzimidazole-type drugs are not acting through paralysis of the worms and appear to be less associated with this condition. Given the fact that these drugs have maintained efficacy against roundworms, they appear to be a good first choice for this parasite in most instances.

Cyathostomins

Historically, this group is also referred to as *small strongyles*. It consists of 50 different species belonging to 14 different genera.[29] However, some of these species and genera have been described infecting other equids than horses, such as donkeys and zebras. Horses are always infected by multiple species, and currently there is limited knowledge about the pathogenic role of individual cyathostomin species. Cyathostomins are truly ubiquitous, and all grazing horses are exposed to infection.

The cyathostomins all follow the same basic strongyle life cycle. Strongyle eggs are passed in the feces, where they will hatch, and larvae will develop through the first (L_1) and second (L_2) stage until they finally reach the third infective stage (L_3). Hatching and subsequent larval development is highly temperature dependent. At temperatures below 6° C, eggs do not hatch but remain viable. Hatching and larval development occur at increasing rates up to about 40° C. At temperatures above this level, eggs and larvae quickly die out. Optimal conditions for development of eggs and larvae are in the temperature range of 25-33° C, where the L_3 is reached within 3 to 4 days. In comparison, this will take several weeks at around 10° C. When molting from L_2 to L_3, the larvae retain their L_2 cuticle on the outside of the new sheath. This makes the L_3 particularly resistant to environmental influences such as desiccation and freezing. Thus, for this stage, the widespread notion of the "killing frost" is a myth. In addition, intact fecal balls provide excellent protection for larvae,

VetBooks.ir

enabling them to further withstand desiccation and freezing temperatures well.[30] Due to the double-layered cuticle, the L_3 cannot uptake feed and thus lives on carbohydrates and lipids stored in its cells. The more active these larvae are, the shorter they live. Because larval activity is highly temperature dependent, it can be deduced that the higher the temperature, the shorter the survival. Dry conditions as achieved with freezing or desiccation limit larval movement and therefore facilitate their survival. However, repeated cycles of alternation between frost and thaw have a deleterious effect on most free-living stages of strongyles, although this can be mitigated by snow cover, which tends to stabilize temperatures right at the freezing point, which is optimal for survival of eggs and L_3s.[30]

Inside the horse, the L_3s exsheath in the stomach and subsequently reach the colon and cecum. Here, they enter the glands of Lieberkühn and penetrate cells at the base. From here, some species appear to penetrate deeper into the submucosa, while others remain in the mucosa. A fibrous capsule is formed around each larva, and a fluid-filled cyst is formed. Larvae can remain encysted for several years,[9] but encystment appears to be a strategy for the parasites to make it through the winter, where conditions on pasture are unfavorable for parasite transmission. Interestingly, in warmer climates, encystment appears to occur over the hot summers. Horses can harbor several hundred thousand encysted cyathostomin larvae without showing any sign of discomfort. The major clinical consequences are associated with the process of excystment, where the L_4 penetrate their cysts and migrate the short distance back to the intestinal lumen. This causes a small local inflammatory reaction around the vacated cyst. In rare cases, synchronous emergence of large numbers of larvae from their cysts can cause a severe generalized acute typhlocolitis, termed *larval cyathostominosis.*[22] This is characterized by profuse watery diarrhea and pronounced dehydration, as well as protein loss and ventral edema. This acute condition is associated with a case fatality rate of 50%.[22] Identified risk factors for larval cyathostominosis include horses aged 1 to 4 years, anthelmintic treatment within 14 days prior, and late fall, winter, or early spring in temperate climates.[31] The luminal worm burden appears to elicit some sort of a repressive signal, which prevents the encysted stages from resuming development. If the luminal burden is removed by anthelmintic treatment, the repressive signal disappears abruptly and a synchronous emergence is triggered. Treatment of acute larval cyathostominosis involves intensive fluid therapy, which can be combined with antiinflammatory drugs and antibiotics. The anthelmintic drug of choice is a single dose of moxidectin (400 µg/kg orally [PO]) because of its efficacy against encysted larvae. The 5-day elevated dose of fenbendazole (10 mg/kg PO) is also labeled for treatment of encysted cyathostomins, but the wide occurrence of fenbendazole resistance in cyathostomins makes that regimen unlikely to have maintained full efficacy once resistance has been documented to the single dose.[4,32]

Chronic cases of larval cyathostominosis also occur. These are typically characterized by weight loss and loose feces or intermittent diarrhea, often over an extended period of time. Plasma protein and albumin levels can be lowered, and ventral abdominal edema can be observed. Horses usually recover, although it may take time for them to regain full body condition.

Tapeworms

Three species of tapeworm infect horses: *Anoplocephala perfoliata, Anoplocephala magna,* and *Anoplocephaloides* (s. *Paranoplocephala*) *mamillana.* Of these, *A. perfoliata* is by far the most common, and it is the only species that has been associated with clinical disease. Being a cestode, the life cycle involves intermediate hosts, which are oribatid mites that feed on the organic material present in the feces. During this process, the mites can ingest tapeworm eggs present in the feces. Inside the mite, eggs develop to infective cysticercoids over a period of approximately 2 to 4 months. Horses inadvertently ingest these mites during grazing. In the gastrointestinal tract, the cysticercoids are liberated from the mites and the scolexes attach to the mucosal lining around the ileocecal valve in the cecum.

Prevalences of *A. perfoliata* have been reported to vary widely between farms and regions, often ranging from 20% to 80% of horses.[33] Prevalence appears to be habitat dependent, and it is likely associated with conditions favoring survival of the oribatid mites. However, the most significant factor appears to be access to pasture. The longer the time spent on pasture, the higher the tapeworm exposure seems to become.[34] Horses younger than 2 and older than 15 years of age have been reported to have significantly larger *Anoplocephala* burdens than horses in between these ages.[35] Although this could be explained by the assumed incomplete levels of immunity in these age groups, it is equally likely that they simply spend more time on pasture. Tapeworm burdens appear to accumulate through the grazing season to reach their highest in the fall and winter.[36-41]

Tapeworm infection has been associated with certain types of colic in the horse. Numerous case studies have illustrated an association of *A. perfoliata* and ileocecal intussusceptions, which are sometimes complicated by intestinal rupture.[42-43] One epidemiologic study identified *A. perfoliata* as significantly associated with ileal impactions and spasmodic colic.[23] A Canadian study attempted to reproduce these findings but was unable to find any associations between tapeworms and colic.[34] Taken together, these studies indicate that tapeworms may play a role in the development of colic, but this is largely confounded by the multifactorial nature of colics and regional differences in climate and management.

Two anthelmintics are labeled for treatment of equine tapeworms: praziquantel and pyrantel pamoate. Praziquantel is a sole tapeworm drug that has no efficacy against nematodes. For this reason, it is most often formulated in combination with ivermectin or moxidectin, although it exists in a stand-alone formulation for horses in Europe.[36] Pyrantel, on the other hand, is widely acting against luminal stages of nematodes and cestodes. At the dosage labeled for nematode treatment (6.6 mg/kg PO), the efficacy of pyrantel pamoate is greater than 80% against *A. perfoliata*.[44] A double dosage of pyrantel pamoate (13.2 mg/kg) is labeled for tapeworm treatment, and the efficacy of this has been found to be greater than 95%.[45]

Strongylins (Large Strongyles)

The strongylin group comprises the three *Strongylus* species: *S. vulgaris, S. edentatus,* and *S. equinus,* as well as *Triodontophorus* spp., *Craterostomum acuticaudatum,* and *Oesophagodontus robustus.* As mentioned earlier in this chapter, large strongyles have generally become rare in managed equine establishments. The most common of these species is probably *Triodontophorus* spp., but the *Strongylus* species, particularly *S. vulgaris,* are considered the most pathogenic of helminths infecting the horse.

The development of the external stages of the strongylins is virtually identical to what has already been described for the cyathostomins. Inside the horse, larval migrations are widely different. The three *Strongylus* species all have PPPs of 6 months and above, and they spend several months migrating in various tissues and organs of the horse. Major pathologic lesions have been ascribed to these migrations, whereas the adult worms are found to do little harm to their hosts. The lesions caused by migrating stages of *S. vulgaris* are classic in equine parasitology and well described.[46-49] Third-stage larvae (L_3) invade the mucosa of the small intestine, cecum, and colon. They then molt to L_4 before they enter local arterioles. Inside these, they migrate beneath the endothelium toward the root of the cranial mesenteric artery, leaving characteristic fibrous tracts to be seen on the intimal surface. Upon reaching their destination about 14 days post infection, they enter the lumen of the vessel and remain there, embedded in thrombus masses. Here, they grow in size and molt to L_5, while causing a pronounced verminous endarteritis with roughened intima, fibrosis of arterial walls, and increased diameter of the vessels. After about 4 months, the L_5s are transported by the bloodstream to the walls of the ventral colon and cecum, where pus-filled nodules are formed around them in the submucosa. These nodules eventually open into the intestinal lumen, and the young adult worms emerge. After another 6 weeks, the worms become sexually mature and start shedding eggs. Although the lesions are

VetBooks.ir

pronounced, they are relatively rarely accompanied by disease. A classical syndrome of thromboembolic colic, in which thrombi detach from the arteritis lesions and are carried distally until they reach a terminal branch sufficiently small to become occluded, has been described.[46] This causes ischemia and infarction of intestinal segments, which is painful to the horse.

Larvae of *S. edentatus* migrate via the portal system to the liver, where they molt to the fourth stage within the parenchyma. They migrate within the liver and then migrate subperitoneally and retroperitoneally via the hepatorenal ligament to the adipose tissue in the abdominal walls. Larvae can also be found located in the perirenal fat tissue. Here, larvae eventually molt to L_5 and migrate back to the intestinal walls. Described lesions include a filamentous peritonitis, especially around the liver and diaphragm, as well as hemorrhagic and inflammatory lesions in the abdominal wall.[50] The third *Strongylus* species, *S. equinus,* is probably the rarest, at least in managed horses in the northern hemisphere, where it is hardly encountered at all. As opposed to *S. edentatus,* it migrates within the peritoneal cavity and passes through the pancreas, where it can cause significant damage.[51] Despite their obvious pathologic impact, neither *S. edentatus* nor *S. equinus* have been associated with defined clinical syndromes.

None of the strongylins has been reported resistant to any of the anthelmintic drug formulations available. Treatment efficacies against *S. edentatus* appear to be more variable than in the other species,[52] but this seems to always have been the case and can thus not be concluded to be resistance.

Other Parasites

Other parasites frequently infect equines but are generally considered of lower importance. For completion, they are briefly covered in the following.

Strongyloides westeri, or the equine threadworm, parasitizes the small intestine of suckling foals. This parasite is remarkable because it can maintain a full life cycle outside its host, and only female worms seem to infect the foals. Infection occurs via three possible routes: skin penetration by third-stage larvae, ingestion of these larvae from the environment, or lactogenic transmission from the mare.[53] Infection usually occurs within the first weeks of life, and infected foals are usually asymptomatic. However, one study reported an association between diarrhea and high *Strongyloides* egg counts (>2000 EPG),[54] and another study described a "frenzy" syndrome in foals exposed to apparent percutaneous penetration of L_3 from the environment.[55] Because of *S. westeri,* it has become a widely used practice to deworm mares at or just before foaling. As a result, the prevalence of this parasite has been reduced to low levels in managed horse populations.[56]

Oxyuris equi, the equine pinworm, is widely prevalent, but eggs are rarely encountered in fecal samples because they are laid outside the digestive tract. Adult worms live in the descending colon and rectum. The female worm protrudes from the anus and deposits her eggs in patches on the perianal skin. When these egg patches dry up, they become itchy to the horse, and they begin rubbing their tails against various objects. This serves as an excellent means to spread eggs in the environment. The infective stage is the embryonated egg, which is inadvertently ingested from the contaminated environment. Besides the tail rubbing, *O. equi* does not cause disease or discomfort to the horse, and there is no justification for routinely targeting this parasite in the parasite control program. Recent observations made by veterinary practitioners have led to speculations whether populations of *O. equi* have developed resistance to ivermectin,[57] but this has not been verified in research studies.

Gasterophilus spp. are the widely occurring botflies, whose larval stages overwinter in the intestinal tract and then pass in the feces during the spring. They then pupate in the loose soil for a couple of months until the adult flies emerge. The two most common species are *G. intestinalis* and *G. nasalis*. Eggs are glued onto the haircoat, and larvae make their way into the oral cavity by either crawling on the skin *(G. nasalis)* or when the horse grooms itself or another herd member *(G. intestinalis)*. In the mouth, the larvae spend several weeks burrowing into the tongue and subsequently spending time in the interdental spaces before reaching the stomach.[58] In the stomach, *G. intestinalis* attaches to the mucosal lining by the margo plicatus, whereas *G. nasalis* can be found in the gastric fundus and the duodenum. Characteristic lesions have been described at the attachment site,[59] but these have not been consistently associated with disease. With the emergence of equine dentistry over the past decades, the lesions in the oral cavity are gaining more attention. It remains possible that *Gasterophilus* spp. can cause oral discomfort, but this has not been substantiated in research studies.

The equine eye worm, *Thelazia lacrymalis,* is transmitted by muscid flies and can be found within the conjunctival sac of horses, where it generally appears to do little or no harm to the eye. However, abscess formation and inflammation of the lacrimal glands have been described.[60] Prevalence rates have been reported in the range of 20% to 42% in managed horses.[61-62]

The group of stomach worms comprises *Habronema* spp., *Draschia* spp., and *Trichostrongylus axei. Habronema* and *Draschia* spp. have similar life cycles. Like *Thelazia* spp., they are both transmitted by muscid flies. The flies acquire the infective larvae while feeding on the feces. Horses get infected by accidentally ingesting infected flies. Here, the larvae eventually reach the stomach, where *Habronema* larvae apparently cause no gross lesions, while adult specimens of *Draschia* spp. can be found embedded in large tumor-like fibrous masses around the margo plicatus.[63] Common to both these species is that the larvae can be deposited by the flies in or near wounds or mucocutaneous junctions. For the parasite, this represents a dead-end pathway, from which the life cycle cannot be completed.[64-65] When larvae are deposited in this manner, they cause a condition usually referred to as *cutaneous habronemiasis/draschiasis* or *summer sores.* This is characterized by persistent, eosinophilic granulomatous lesions with eosinophilia and fibrosis. A rare, pulmonary form of habronemiasis has been described as well.[66] Anthelmintic resistance has not yet been reported in *Habronema* or *Draschia* spp., but several veterinary practitioners from subtropical and tropical regions report that skin lesions consistent with cutaneous habronemiasis do not resolve on treatment with a macrocyclic lactone (ivermectin or moxidectin). The prevalence of *Draschia* spp., on the other hand, seems to have decreased dramatically after the introduction of ivermectin.[67] *Trichostrongylus axei* possesses the rare capacity of infecting both ruminants and monogastrics such as pigs and horses. The external part of the life cycle is similar to that of the strongyle parasites described in this chapter. Inside the horse, it develops within the gastric glands, where it can cause hypertrophy of the mucosa.[68] In horses, *T. axei* has not been found to affect pH or levels of plasma pepsinogen.[69] The parasite is a rare finding in horses, but prevalence has been found to increase when horses are co-grazed with sheep.[70-71]

Setaria and *Onchocerca* spp. are filarial nematodes infecting horses. Infective L_3 larvae are transmitted by blood-sucking arthropods feeding on the horses. The larvae then migrate to their predilection site, which is the connective tissues (*Onchocerca* spp.), and the abdominal cavity *(Setaria equina)*. Here, they develop into adult worms, which then release microfilariae into the bloodstream. These microfilariae, in turn, will enter the blood-feeding arthropods, and the cycle is complete. The intermediate hosts for *Onchocerca* spp. are biting midges (*Culicoides* spp.) and black flies (*Simulium* spp.), whereas it is mosquitoes for *Setaria equina*. The latter parasite is regarded as nonpathogenic, while *Onchocerca* spp. has been associated with pronounced skin reactions. Microfilariae of *Onchocerca cervicalis* tend to congregate in certain regions of the body, including the ventral midline and face, where they are ingested when *Culicoides* feed in these regions.[72] This results in a verminous dermatitis characterized by intense pruritus.[73] Lesions can be effectively treated with macrocyclic lactones.[74] However, there is no known therapy to eliminate adult *O. cervicalis* from the connective tissue around the ligamentum nuchae of horses. Therefore, infected horses will need periodic retreatment with ivermectin or moxidectin to prevent or

VetBooks.ir

control recurrence of clinical signs.[75-77] Treatment of the skin-dwelling microfilariae has been associated with an inflammatory reaction to the dying parasites,[78] which can be confused with the widely occurring *Culicoides* hypersensitivity (summer eczema, sweet itch).

Adult *Parafilaria multipapillosa* is another filarial nematode that occurs in subcutaneous and intermuscular connective tissue of horses outside North America. Nodules form in the overlying skin and may rupture and bleed or leak tissue fluids. This condition is often referred to as "summer bleeding,"[79] not to be confused by the "summer sores" described with cutaneous habronemiasis/draschiasis. First-stage larvae are present in the exudate from bleeding lesions and are ingested by feeding horn flies *(Haematobia irritans)*. Larvae develop to the infective third stage within the fly and are transferred to horses when flies feed on lachrymal secretions or skin wounds. The larvae then migrate in the subcutaneous tissues and develop to the adult stage within a year. Eggs and microfilariae can readily be identified in smears taken from lesion exudates.[80] Little is known about anthelmintic efficacy, but lesions have been observed to recur after treatment with macrocyclic lactones.

The equine lungworm, *Dictyocaulus arnfieldi,* will be covered in the lungworm section in this chapter.

Halicephalobus gingivalis is a free-living nematode belonging to the order Rhabditida. It is widely present in the soil and humus but possesses a capacity to also invade living tissues. Infection appears to occur through soil-contaminated wounds or nasal mucosal membranes with apparent predilection in the head region,[81-84] but penile infection has also been described.[85] Inside the host, the nematode reproduces tremendously and the larvae invade deeper into the tissues. Larvae appear to have a special affinity for the central nervous system (CNS) and the kidneys.[83] Lesions are multifocal, eosinophilic, and pyogranulomatous. Once the CNS is affected, symptoms often slowly progress into a grave state. Symptoms include blindness, ataxia, loss of proprioception, head pressing, coma, recumbency, and death.[83,86-87] Treatment options are limited. Surgical debulking can be combined with repeated high oral doses of fenbendazole (50 mg/kg) or ivermectin 0.55 mg/kg),[88] but the overwhelming majority of published cases had a fatal outcome. Similarly, *Halicephalobus* spp. infection has been reported to be extremely rare but fatal in humans.[89-91]

Diagnostics

The cornerstone of diagnostics in equine parasitology remains the fecal egg counting methods. Before these are discussed, it should be emphasized that egg counts can be performed for at least three purposes: (1) evaluation of anthelmintic efficacy with the fecal egg count reduction test (see Box 49-1); (2) identification of low, medium, and high strongyle egg shedders for a targeted treatment approach; (3) for diagnosing parasite infection in clinical cases. When discussing the usefulness of fecal egg counts, it is important that this largely depends on the purpose. In other words, fecal egg counts are not equally useful for all three purposes.

Numerous techniques exist with various names such as Stoll,[92] Wisconsin,[93] or McMaster,[94] but they are all based on the same simple principle. A flotation medium is usually constructed with some sugar or chemical salt solution to have a specific density higher than most parasite eggs but lower than the fecal matter. Examples of components used in flotation media include glucose, sucrose, $NaNO_3$, NaCl, $MgSO_4$, and HgCl. Frequently used media are saturated glucose-NaCl and Sheather's sugar solution, which are relatively cheap and easy to compose. The numerous different egg counting techniques and the even more modifications of these can appear confusing, but in reality there are only three factors to consider when the choice of method must be made: (1) the detection limit of the technique; (2) the level of variability associated with the technique; and (3) the equipment requirements and time consumption in the laboratory.

The choice of detection limit will depend on the purpose with the egg count. If FECRTs are performed, it is crucial to be able to detect low egg counts in the posttreatment samples to possibly discover early signs of reduced anthelmintic efficacy. A crude McMaster, which is performed by many practice laboratories, usually comes with a detection limit of 25 or 50 EPG, which makes it unsuitable for the FECRT unless the pretreatment levels are high. However, the egg counting methods with lower detection limits are generally more laborious and often include a centrifugation step, so the choice of egg counting technique is always a tradeoff between detection limit and ease of use. For identification of high strongyle shedders for a targeted treatment approach, the detection limit is not important and McMaster methods can be used.

Egg counting methods are generally associated with high levels of variability, and it has once been estimated that every egg count generated by the McMaster technique should be interpreted with a ±50% margin of error.[95] In other words, an egg count of 400 eggs per gram (EPG) really represents the range of 200 to 600. This variability is important when interpreting the FECRT; if only one egg count is performed before and after treatment, each of these will represent one data point out of a distribution. With the chance variability both before and possibly also after treatment, there is room for high levels of variability in the FECRT. This is the reason why the FECRT always has to be performed by averaging values across several horses on each farm. Performing two or three repeated egg counts and averaging these greatly reduces this variability.

The most thorough work with validating various flotation media for detection of a large array of parasite eggs has been performed with the FLOTAC egg counting technique, which is an advanced modification of the McMaster technique.[96] By using large flotation chambers, the FLOTAC can be adjusted to perform with a detection limit of 1 EPG. Although this can also be achieved by a more traditional technique such as the Wisconsin, the FLOTAC has been shown to have much less variability.[96]

Until recently, there were no published studies evaluating egg counts as a diagnostic test for horses. From the database generated over 50 years of equine parasitology research at University of Kentucky, fecal egg counts were related to total intestinal worm counts in close to 700 horses.[97] Results indicated a high positive predictive value, indicating that an egg count–positive horse is likely to also harbor worms in the intestine. However, the negative predictive value was low, emphasizing that 0 EPG does not necessarily indicate 0 worms. Further, there were no direct linear correlations between strongyle and ascarid egg counts and the corresponding intestinal worm burdens. Thus, higher egg counts do not necessarily equal larger worm burdens. However, strongyle egg counts in the range of 100 to 500 EPG did correspond to significantly smaller strongyle burdens than egg counts above this level.[97] Taken together, this information illustrates that fecal egg counts can be used to qualitatively detect presence of strongyle or ascarid burdens, but there are considerable limitations to these techniques as clinical diagnostic tools. Further, it should be borne in mind that much of the parasitic disease observed in horses is caused by migrating or encysted larvae that are not shedding any eggs. Detecting eggs in the feces cannot be used to estimate the probable presence of larval burdens. Also, strongyle eggs are practically ubiquitous in equine fecal samples, and their mere presence cannot be used to suggest parasitic disease. In foals and weanlings, egg counts can be useful for determining whether parasite burdens are dominated by strongyles or ascarids, which is crucial information for selecting the right anthelmintic (see Table 49-1).

Another weakness of strongyle fecal egg counts is that up to 50 strongyle species infecting horses have been described,[29] and it is not possible to morphologically distinguish between their eggs. Larval cultures can be performed to differentiate large and small strongyles and for species-specific detection of the three *Strongylus* species.[98-99] In a retrospective validation, larval cultures were found to have high positive and moderate negative predictive values with no direct linear correlation between larval counts and worm counts.[97] Thus, larval cultures should be interpreted with the same caution as egg counts. A pragmatic approach has been to pool feces from several horses into one pool, but this cannot be recommended because diagnostic

VetBooks.ir

sensitivity is greatly lost with this approach and the negative predictive values are likely to be much lower.

Diagnosing tapeworm infection is a particular challenge despite the availability of several different techniques. Anoplocephalid eggs may show up on routine egg counts from time to time, but validation studies have shown that diagnostic sensitivities are low. The reason for this is believed to be the uneven distribution of tapeworm eggs in the feces. Eggs are released in clumps often retained within a tapeworm segment, which then disintegrates on its way through the cecum and colon. The eggs remain in their clumps, and egg counting methods examining just a few grams of feces can easily miss detecting these eggs. A modified egg counting technique that analyzes 40 g of feces has been found to have a diagnostic sensitivity and specificity of 0.61 and 0.98, respectively.[100] However, this was based on detection of cestode burdens comprising only a single worm. If the threshold were adjusted to detect 20 or more tapeworms, the sensitivity improved to about 90%.[100-101] Thus, the tapeworm infections most likely to not being detected with this method are small burdens unlikely to cause clinical disease. The group led by Proudman developed a serologic (ELISA) assay for detection of specific antibodies against *A. perfoliata*.[102] This assay has been found useful for evaluating the level of tapeworm exposure on the herd level. OD values correlate positively with the worm burden, and the assay can be helpful for generating information to help balance the level of tapeworm-directed treatments on each farm. It should be emphasized that this assay is not useful for diagnosis on the individual level. Antibody levels are too variable, horses remain titer positive for months after tapeworm treatment,[103] and one recent study suggests cross-reactivity with the less common *A. magna*.[104] In the United States, the diagnostic laboratory at the University of Tennessee, College of Veterinary Medicine offers a modified version of the *Anoplocephala* ELISA, but no information is available on the performance of this test. There are currently no available methods for diagnosis of anthelmintic resistance in equine tapeworms.

Integrated Parasite Control

It is often said that a "one-size-fits-all" parasite control program does not exist. There is no simple chart to just hang on the wall in the horse barn and then have all horses follow the same guidelines. To the frustration of many horse owners, farm managers, and veterinary practitioners, it is much less straightforward to identify what to do. This section outlines elements to incorporate in a modern evidence-based equine parasite control program.

The most important evidence to incorporate on each farm is the efficacy of the anthelmintic drugs that are used. Although Table 49-1 can be used to predict the drugs more likely to still have efficacy on a particular farm, the only way to really know is to evaluate the efficacy with the FECRT as described in Box 49-1. Ideally, all drugs used should be tested on every farm each year. Regardless of the deworming program incorporated, it is highly necessary to know the efficacy of the drugs used. Veterinary practitioners giving recommendations regarding the choice of anthelmintic should realize that these cannot be given without knowing the efficacy on the given farm. For ivermectin and moxidectin, the efficacies measured on day 14 post treatment should still be 100% in the large majority of instances, but the ERP may be shortened considerably on some farms. Thus, it may be a pragmatic solution to perform the posttreatment egg counts in week 4 or 5 to evaluate whether there is evidence of a shortened ERP. A shorter ERP should not necessarily discourage people from using the drug because there may not be valid alternatives, but it provides useful information about the level of parasite control achieved by using these drugs.

Egg counts can also be employed for two other purposes. In foals, they can readily tell whether parasite burdens are predominantly *P. equorum* or strongyles. This is crucial information because the drugs that are likely to work against *P. equorum* would not have efficacy against strongyles on many farms, and vice versa. In adult horses, a few repeated egg counts over time can be used to identify horses that are consistently shedding low, moderate, and high egg numbers.[11,105,106] This can then be used in a targeted selective approach, where the consistent high shedders can receive more anthelmintic treatment, and horses consistently shedding low numbers can receive less treatment. Simulations have shown that treating all horses shedding 200 strongyle EPG or above with a drug with a 99.9% efficacy yields an overall reduction of the strongyle egg shedding of 94%.[11] But when using 200 EPG as a treatment threshold, only about 50% of adult horses will need treatment, so with just half as many treatments close to the same overall egg count reduction can be reached. This selective approach, which increases parasite refugia and slows down the development of anthelmintic resistance, is widely implemented in some countries.

Recent studies have illustrated that in a system basing all anthelmintic treatments on fecal egg counts, some horses will not be dewormed for years.[107] This gives room for the large strongyle species, particularly *S. vulgaris,* to reemerge, which has been documented in Denmark.[107-108] Here, about 80% of farms using selective therapy had at least one horse infected with *S. vulgaris,* which was twice as much as in farms not using selective therapy. Although none of the horses showed clinical signs of disease, the pathogenic potential of *S. vulgaris* does suggest that horse populations would benefit from a basic foundation of anthelmintic treatments applied to all horses. Given the long life cycles and no apparent development of resistance in large strongyle species, just one or two yearly treatments with ivermectin or moxidectin would effectively reduce the occurrence. Further treatments beyond this basic foundation should be directed at high strongyle shedders in a selective approach as described earlier.

Tapeworms need to be considered in every parasite control program. They should be assumed to be present under most circumstances, although large regional differences in prevalence can occur.[33] As indicated in the previous section, the serum ELISA could be useful for generating information about the level of tapeworm exposure in a given herd. If OD values are consistently high (i.e., many horses above the level of 1 to 2), or if confirmed clinical cases have occurred, a more aggressive treatment approach can be taken. But in most cases, annual treatments in the fall appear to be of greatest benefit to minimize burdens and prevent the development of gravid forms that will otherwise contaminate pastures in the coming season. With an ivermectin/praziquantel combination formulation, this could easily be incorporated into the basic treatment foundation described earlier.

It has been a widely used strategy to regularly rotate between anthelmintic drugs when deworming horses. The theoretic basis for this strategy makes good intuitive sense; parasites carrying genes that enable them to survive treatment with one drug can be killed by applying another drug with a different mode of action. Unfortunately, there is no evidence to support this hypothesis. In fact, one equine study clearly suggested that rotating drugs with each treatment did not appear to slow development of resistance.[109] Computer modeling studies with ruminant parasitology data have convincingly shown that rotating drugs does not prevent accumulation of resistant genetic alleles and therefore does not slow down the development of resistance.[110-111] Besides, rotation would only make sense if there were several anthelmintic drugs available to which no resistance had already developed. When considering the information presented in Table 49-1, it is clear that there are only three drug classes to choose from. Thus, it will be difficult to find many horse farms without resistance already developed to one or maybe even two of them. Further, when rotation is carried out blindly without testing the efficacy of all the drugs used, the alternation between drugs may very well mask resistance, so it takes longer for it to be discovered. In summary, drug rotation does not appear to prevent or reduce the development of resistance and may create a false sense of security for the horse owner, who believes a solid strategy is in place.

Foals and young horses require specific consideration with regard to parasite control because they are the most susceptible to infection, often shed the highest egg numbers, and are more at risk for parasitic disease than their older counterparts. As a rough guideline, most

VetBooks.ir

foals should require approximately four anthelmintic treatments during their first 15 months of life. Higher treatment intensity can be justified in cases of high infection pressure or documented clinical problems in the herd. Fewer than four treatments would be considered inadequate unless low parasite transmission levels or absence of *P. equorum* can be consistently documented.

The major helminth pathogen in foals younger than 6 months of age is *Parascaris equorum*. Treatments targeting this parasite should be timed around the age of 2.5 to 3 months, when the first worms will have reached the intestine and started shedding eggs. Considering the increased risk of impactions from paralytic anthelmintics, benzimidazoles may be the best choice at this time. If this treatment is delayed just a couple of months, the worms will have grown much larger and increased in numbers, posing an increased threat of verminous impaction. A second deworming treatment should be targeted around or preferably just before the time of weaning. This is a stressful period for the foal, and large parasite burdens are undesired at this time. At weaning, the main parasitic threat is still likely to be *P. equorum,* but strongyle parasites may start to play a role as well. Therefore, fecal egg counts yield useful information about the presence of ascarids and strongyles and help guide the veterinarian to select the right anthelmintic.

Benzimidazoles are unlikely to be effective against cyathostomins on many farms, so other drug classes should be considered. Similarly, ivermectin has lost efficacy against *P. equorum* across the world. Again, it is crucial to routinely evaluate the efficacy of the anthelmintics chosen with the FECRT. A third treatment should be considered for the yearlings during the subsequent spring. This should coincide with the fecal testing and treatments that are carried out for adult horses on many farms. In areas with defined grazing seasons, a fourth treatment should be considered about midway through the grazing season. Yearlings are considerably more susceptible to parasitic infection than older horses, and leaving them untreated for an entire grazing season of 5 to 6 months' duration puts them at risk of acquiring large parasite burdens.

Gastrointestinal Nematode Infections in Cattle

Lora Rickard Ballweber

Cattle are hosts to numerous species of gastrointestinal nematodes (GINs) that, together, cause parasitic gastroenteritis (PGE).[1-3] Within the strongyle-type nematodes, *Ostertagia ostertagi* and species of *Cooperia* have been the most prevalent parasites across the United States, followed by species of *Haemonchus, Trichostrongylus,* and *Oesophagostomum*. Other species within the genera *Nematodirus* and *Trichuris* complete the GIN population in the United States. The various nematodes do differ somewhat with respect to their site of infection and pathologic effects, but their general life cycle patterns are quite similar.

Life Cycle Adult female nematodes produce eggs that are passed out of the host with the feces. Under optimal conditions in the external environment, first-stage larvae (L_1) can develop and hatch from eggs within 24 hours. L_1 grow and develop to second-stage larvae (L_2), which in turn grow and develop into third-stage larvae (L_3). In general, the third stage is the infective larval stage. After ingestion, L_3 develop into fourth-stage larvae (L_4), which then develop into immature adults. Sexually mature adult nematodes develop within 2 to 4 weeks after ingestion of the L_3 unless arrested development occurs. The life cycle of *Nematodirus* is the same except that development to infective L_3 occurs within the egg before hatching. For *Trichuris,* development to the infective L_1 occurs within the egg, which does not hatch until ingested by the animal. Approximately 8 weeks are required before sexually mature *Trichuris* are present.[1,3]

Climate and management of pastures and animals are among the numerous factors that influence the level and extent of parasitism. Although temperature is considered to be the driving force behind larval development, larval development can proceed only in the presence of adequate moisture. Larvae of all stages can be killed by extremely low temperatures, desiccation, and/or exposure to direct sunlight. Larval development and transmission tend to occur in predictable seasonal patterns based in part on regional climatic differences.[1-4] In the southern United States, infective L_3 persist longest when conditions are cool and wet (October to May) but die off quickly during the summer after rain-induced liberation from the fecal pat.[5,6] Nematodes acquired by grazing cattle during the summer months come from eggs recently deposited on pasture. In the northern United States, infective L_3 may be on pasture year-round. Significant numbers of *Cooperia* and *Nematodirus* may be acquired for up to 12 months after deposition of eggs on pasture, with acquisition of fewer numbers for up to 24 months. Acquisition of low levels of *Ostertagia* can occur for at least 14 months after deposition of eggs. In subtropical climates, seasonality may be much less marked and pasture infectivity may follow the rainfall pattern. In arid climates, large numbers of larvae may be present on the pasture whenever local conditions permit lush grass growth.[2,7-9]

Not only can larvae survive on pasture, but some species can arrest development within the host. This usually occurs when adverse environmental conditions would decrease larval survival in the external environment. Best known for this phenomenon is *O. ostertagi.* In northern temperate climates, pasture larval populations peak in the summer and early fall, and L_4 tend to overwinter in the host, resuming development in the spring. In warmer climates with hot, dry summers, the highest numbers of infective larvae may be found in the late spring to early summer, and L_4 tend to oversummer in the host, resuming development in the fall.[2,10,11]

Pathophysiology Of all the cattle nematodes, *O. ostertagi* has long been considered to be the most pathogenic nematode in temperate regions. The pathophysiology of ostertagiasis centers on the development of larvae within the gastric glands of the abomasum. As the larvae develop within the lumen of the glands, hyperplasia and intense eosinophilic infiltration occur. Mucosal glandular cells lose their differentiation, and cell junctions are weakened. Albumin is lost into the lumen. Parietal cells cease to function, causing a decrease in HCl production. The change in pH stimulates overproduction of gastrin, which initiates cell proliferation and hyperplasia. Alkalinity also decreases the bacteriostatic activity of the abomasum. When the pH exceeds 5, the conversion of pepsinogen to pepsin is inhibited. As a result, pepsinogen is released into the blood through permeable cell junctions. Initially, cellular changes occur within the parasitized glands, but as the glands distend due to nematode growth, the changes encompass the surrounding, nonparasitized glands as well. Widespread hyperplasia creates the typical "Moroccan leather" appearance of the abomasum. In experimental models, *Ostertagia* infection in calves is also associated with elevated peripheral eosinophil counts and decreased lymphocyte counts.[3,4,12]

Populations at Risk Although infections with some GINs readily induce immune responses that limit future populations of nematodes within the gut, cattle remain susceptible to *O. ostertagi* for many months. Protective immunity is usually not evident without prolonged exposure and may not occur until the animals are 2 years of age or older.[4] Consequently, clinical type I ostertagiasis occurs primarily in young cattle (up to ≈18 months of age) during their first grazing season (primary exposure), with type II disease present in older animals (2 to 4 years of age). Adult cattle, after the second grazing season, rarely show signs of nematode infection or require anthelmintic treatment. Although mature cattle ingest infective larvae, fewer larvae establish infections, so parasite numbers and the magnitude of fecal egg shedding are generally decreased. Most preventive and treatment strategies therefore are directed at young grazing stock, primarily beef calves and dairy replacement heifers.

Clinical Manifestations In young animals, GINs may simply cause poor growth and ill thrift, or they may cause serious

clinical illness and even death. Inappetence, a common feature of PGE, contributes to reductions in weight gain, growth, and, possibly, onset of puberty.

The synchronous development and maturation of inhibited larval *O. ostertagi* can result in severe clinical disease, called *type II ostertagiasis*. Usually seen in cattle months after their first grazing season on contaminated pastures, it is characterized by intermittent profuse watery diarrhea accompanied by thirst, anorexia, ill thrift, and hypoproteinemia. Fever, anemia, and submandibular edema may also be present. Conversely, type I ostertagiasis results from the rapid acquisition of large numbers of larvae that complete development to the adult stage within the usual 3-week time frame. The primary physiologic change is appetite suppression. Although the underlying mechanism for the two types is the same, the seasonal occurrence of each type varies in accordance with the epidemiologic patterns of the area.[1,3]

For both types I and II ostertagiasis, reduced feed intake and diarrhea has a negative effect on animal weight; however, leakage of endogenous protein into the gastrointestinal tract has greater impact on the loss of production. The need to replace these proteins (e.g., albumin, immunoglobulins) occurs at the expense of muscle proteins and fat deposition.[3]

Compounding the effects of *O. ostertagi* are the other GINs. Larval and adult *Haemonchus* parasites are blood feeders, capable of producing anemia. *Trichostrongylus axei* produces local and systemic changes similar to those produced by *O. ostertagi,* resulting in similar clinical signs. *Cooperia* species can induce tissue changes resulting in fluid, electrolyte, and protein losses and reduced feed intake. Infection with *Oesophagostomum radiatum* produces structural and functional changes including anemia, hypoproteinemia, diarrhea, anorexia, and weight loss.[1,3,13,14]

Control of Gastrointestinal Nematodes

ANTHELMINTICS. Anthelmintics and their doses used in cattle are given in Table 49-3. Given the higher stocking rates today versus 20 years ago and the concomitant reduction in alternative control practices, maintaining acceptable levels of animal production in the face of GINs relies heavily on the use of these compounds.[15,16] Animals benefit from the removal of the parasites, as well as by preventing immediate reestablishment of infections by those compounds with persistent activity. Macrocyclic lactones and benzimidazoles are, currently, the most popular compounds in use. Levamisole and morantel tartrate are less commonly used, and availability in some areas is limited. Drug withdrawal times must always be considered and the manufacturers' recommendations followed.

Historically, anthelmintic resistance by GINs has been far less of a problem in cattle than in sheep or goats. Unfortunately, this situation has changed. Anthelmintic-resistant nematodes of cattle have been confirmed in the United States and elsewhere, with resistance reported in all classes of compounds currently available.[4,16-20] Species of *Cooperia,* which are the dose-limiting parasites for the macrocyclic lactones, are most commonly associated with these reports; however, resistant species of *Ostertagia, Haemonchus,* and *Trichostrongylus* have also been documented.[15-18] Regrettably, producer concerns regarding anthelmintic resistance remains secondary to the production benefits gained by their use.[21] And, even where anthelmintic resistance is identified as a problem for the beef cattle industry, preventive steps taken actually contribute to the selection for anthelmintic resistance alleles.[22] Such strict reliance on anthelmintics without regard for good pasture parasite management will lead to more rapid selection of nematodes with resistance alleles.

Producer concerns may also be influenced by the fact it is species of *Cooperia* that are most commonly associated with anthelmintic resistance, and these species are considered to be of minor pathogenic importance. Thus, resistance in *Cooperia* would be a less severe problem than resistance in the highly pathogenic *O. ostertagi.* Recently, though, negative production effects associated with *Cooperia punctata* have been demonstrated,[23] as has an increased pathogenicity in an isolate of macrocyclic lactone-resistant *Cooperia oncophora* compared with a susceptible wild-type isolate.[19]

TABLE 49-3

Efficacy of Various Anthelmintics against Gastrointestinal Nematodes in Ruminants

Drug	Dose (mg/kg)* Sheep†	Dose (mg/kg)* Cattle	Adults	Hypobiotic Larvae
Benzimidazoles				
Albendazole	5-7.5	10	+	+
Febantel	5	7.5-10	+	±
Fenbendazole	5	5-10	+	±
Mebendazole	15-20		+	±
Netobimin	7.5	7.5	+	+
Oxfendazole	5	7.5	+	+
Oxibendazole	15	15	+	±
Ricobendazole	5		+	–
Levamisole and Morantel				
Levamisole	5-7.55	5-7.5‡	+	–
Morantel	5-12.5	10	+	–
Pyrantel	25		+	–
Macrocyclic Lactones				
Ivermectin	0.2	0.2§	+	+
Doramectin	0.2	0.2§	+	+
Eprinomectin		0.5‖	+	+
Moxidectin	0.2	0.2§	+	+
Other Drugs				
Closantel	5-10		+¶	–
Nitroxynil	10		+¶	–

*All doses are for oral administration unless otherwise indicated.

†Goats must be given a higher dose for equal efficacy.

‡10 mg/kg for topical administration.

§0.2 mg/kg for oral, subcutaneous, or intramuscular administration; 0.5 mg/kg topically as a pour-on.

‖Available only for topical administration at 0.5 mg/kg; not recommended for sheep.

¶Effective against *Haemonchus contortus* only.

+, Highly effective; ±, moderately effective or effective according to some authors; –, ineffective.

Note: Administration of some of these products may constitute extralabel use in sheep and goats; follow manufacturers' guidelines for meat and milk withdrawal in cattle.

Simultaneous administration of anthelmintics with a similar spectrum of activity but different mechanisms of action and of resistance has been suggested as a means of prolonging the effective life of available compounds. Computer simulation models and field data in sheep (and others) indicate that use of combination anthelmintic products along with deliberately increasing prevalence of unselected genotypes (refugia) will slow the development of anthelmintic resistance. However, once efficacy of the constituent compounds becomes less than 70%, their value in slowing anthelmintic resistance is lost.[24,25] Although combination anthelmintic products are available elsewhere in the world, they are not currently allowed licensure in the United States. This rule may change in the future.

Treatment Intervals. The choice of drug and treatment interval should be formulated for an individual herd or farm, as part of an overall GIN control program. Factors to consider include the geographic location, time of year, and grazing management.[26] There are several options for preventing clinical disease and maximizing gains in first-season grazing calves using strategic anthelmintic treatments. It should be noted, however, that these recommendations reflect the practices currently in use and assume anthelmintic resistance is not an issue on the farm in question. Recommendations are based on the calendar in the northern hemisphere, and not all products are available in every country.

VetBooks.ir

VetBooks.ir

- Prophylactic anthelmintic use. (1) Two or three treatments between turnout and midsummer to minimize the number of eggs deposited on pasture. For calves turned out in early May, two treatments 3 and 6 weeks later are used. For calves turned out in April, three treatments at 3-week intervals are recommended. If using parenteral or pour-on macrocyclic lactones, the interval is extended to 5 (ivermectin) or 8 (doramectin, eprinomectin, moxidectin) weeks due to the residual activity against ingested larvae.[3,20] (2) Use of an intraruminal bolus at turnout or weaning. These provide either the sustained release of anthelmintic drugs or pulse release of therapeutic doses of anthelmintic at 3-week intervals. This strategy may be most cost-effective on farms where pasture infectivity is high. However, evidence suggests that young cattle protected with these products are more susceptible to infection in their second year at grass.[3]
- "Dose-and-move" strategy. This strategy consists of treating calves with a single dose of anthelmintic, then moving them to a "safe" pasture (risk of infection is low) just before the anticipated peak in pasture infectivity (e.g., early to midsummer in temperate climates). This strategy minimizes the number of anthelmintic treatments during the grazing season. However, it is effective only on farms where such pastures are available. Furthermore, any residual nematodes left behind will likely possess resistant genes; therefore contamination of the "safe" pasture will be with resistant nematodes. This must be taken into account when planning for the future use of the pasture (see later). Also, sufficient numbers of overwintering L_3 *O. ostertagi* may be present in the spring in some years, resulting in heavy infections and clinical disease.
- Targeted strategic treatment. This strategy relies on the selective use of anthelmintics by targeting individual animals within a herd rather than whole-herd treatments. Promoted for sheep and horses, this strategy has not been embraced by the beef cattle industry. However, a recent investigation of dairy cows indicates that selective treatment strategies can compete economically with whole-herd treatment strategies.[27]

Integrating effective pasture management can reduce the number of anthelmintic treatments necessary[28]; however, there currently is no realistic alternative to the continued use of available compounds in intensive production systems. Therefore it is imperative that the efficacy of these compounds be maintained for as long as possible. Recommendations designed to promote this in beef cattle include the following: (1) do not treat second-year (unless not previously pastured) or adult cattle to maintain a population of unexposed nematodes (refugia) on the farm; (2) do not graze first-year calves on the same pasture each year (avoids exposure to larvae produced from resistant nematodes); and (3) do not use the same family of anthelmintic year after year in calves.[29]

Adult Cattle. In general, the cattle most at risk for clinical disease and production losses are beef calves and dairy replacement heifers in their first season at pasture.[2] Development of immunity should protect the animals during their subsequent grazing seasons. Treatment of adult beef cattle is generally unnecessary, unless immunity is inadequate or pasture infectivity is exceptionally high. Anthelmintic treatment may be warranted in first-calf heifers and newly acquired cows that may not have been pastured as heifers. In some situations it may be beneficial to treat beef cows after spring calving. Despite these recommendations, a recent survey showed that approximately 86% of U.S. beef cow/calf producers routinely treat their cows one or more times per year.[22] Benefits of treating adult dairy cattle depend on a variety of factors including grazing management options and levels of GINs.[27]

OTHER STRATEGIES. Alternate grazing of cattle and sheep is promoted as an effective control measure. Ideally, a 3-year rotation of cattle, sheep, and crops is used. Few GINs cross-infect cattle and sheep. Adding this to the infective L_3 lifespan on pasture of less than 1 year, this scheme could provide good control of bovine ostertagiasis. Annual rotation of beef cattle and sheep in marginal areas has been reported to provide adequate parasite control.[3] However, in areas where *Haemonchus* is prevalent or where *Haemonchus contortus* cycles in cattle,[15,17] co-grazing these two species may be dangerous.[3] Rotational grazing of calves with adult cattle has been shown to be an effective control practice.[2,3]

Vaccination for the control of *O. ostertagi* has been an ongoing area of research for many years with mixed results.[30,31] Given that it has taken more than 20 years for development of a commercially viable vaccine against *H. contortus,* which is only beginning testing for licensure, it is unlikely a viable *O. ostertagi* vaccine will come to market within the near future.

EVALUATION OF CONTROL PROGRAMS. Success of control programs is based on the producer's expectations. Because most control programs are based on anthelmintic use, the response to treatment is the criteria by which control programs are currently evaluated.[15,22] As long as animal production meets producer expectations, the control program is considered to be a success. Fecal egg counts are most useful as a tool to evaluate pasture contamination and assess treatment efficacy; however, most U.S. producers do not have this done. In fact, most cow/calf producers do not even involve a veterinarian in the diagnosis or treatment of PGE.[22]

Lack of expected response to anthelmintic treatment may be the first indication of program failure in the form of a resistance problem.[15,17] However, inappropriate administration or underdosing of the anthelmintic may also be responsible, and determining the root cause of the treatment failure is vital for future control efforts. Detection of anthelmintic resistance currently depends on the fecal egg count reduction test (FECRT). This test only detects clinical resistance or when less than an expected response to treatment occurs. This usually occurs only when the frequency of resistant alleles in the population reaches 25%.[32] The FECRT estimates anthelmintic efficacy by comparing pretreatment and posttreatment fecal egg counts. Fecal samples are collected immediately before or at the time of treatment and then 10 to 14 days later. Although guidelines for using FECRT in cattle were proposed in 1992, they lack detail, particularly in interpretation of data.[19,33] A recent comparison of FECRT with controlled efficacy studies showed FECRT results to be reliable for detecting ivermectin-resistant *C. oncophora* and *O. ostertagi* and moxidectin-resistant *O. ostertagi*. However, due to reduced fecundity of moxidectin-resistant female *C. oncophora,* FECRT results were equivocal, with day 7 results showing efficacy but day 14 results indicating resistance.[34] Thus, for cattle, waiting the full 14 days before collection of the second sample is vitally important.[1,4] Because cattle tend to have lower fecal egg counts than sheep, use of appropriate flotation techniques capable of handling low fecal egg counts is important.[35]

Clinical Management

DIAGNOSIS. Antemortem diagnosis of ostertagiasis in young animals is primarily based on clinical signs of inappetance, weight loss, and diarrhea at a time of the year that is consistent with the parasite's epidemiology.[3] In temperate areas, type I disease usually occurs in fall, with type II in the late spring. Grazing history is important because clinical disease can develop in older animals with no prior grazing. Affected farms usually also have a history of previous outbreaks. Plasma pepsinogen levels are useful in animals up to 2 years old; however, the test is less reliable in older cattle.[3]

The most reliable method for diagnosis of ostertagiasis or PGE is necropsy. The "Moroccan leather" abomasal lesion is pathognomonic for *Ostertagia*. For PGE, casual examination of the lumen of the gastrointestinal tract is unlikely to find any of the strongyle-type nematodes because the worms are small and easily overlooked and close inspection is necessary to find these nematodes. Adult *Nematodirus* are larger and may be more readily seen, but alone they are unlikely to be the case of PGE. Nodules associated with larval *Oesophagostomum* can be found in the wall of the lower small intestine, as well as the upper large intestine, and adults can be found in the contents of the large intestine. *Trichuris* will be embedded within the cecum; removing the contents is necessary in order to see them.

Abomasal wall digestion techniques can be used to identify the presence of larval *Ostertagia*.[1-4]

TREATMENT. Animals with type I ostertagiasis can be expected to respond well to treatment with the standard dose of any of the current anthelmintics. Animals should also be moved to a less contaminated pasture. Because any parasites not removed by proper administration of the drug will have resistance alleles, tactical treatment, rather than whole-herd treatment, may be beneficial in keeping the population of resistant nematodes low.

Successful treatment of animals with type II ostertagiasis requires compounds that are effective against arrested larvae, as well as the developing larvae and adults. Only the modern benzimidazoles and macrocyclic lactones are effective at standard doses. Even though the larvae may be killed, the damage to the abomasal mucosa may limit complete recovery. Animals with profound hypoproteinemia and dehydration respond poorly compared with those showing only mild diarrhea and slight hypoalbuminemia. Severely affected animals may need supportive treatment to survive. Recovered animals often fail to thrive.

Gastrointestinal Nematode Infections in Sheep and Goats

Sherrill A. Fleming

Gastrointestinal nematode infections (GINs) in sheep and goats are responsible for severe clinical syndromes and profound production losses. Young animals, periparturient ewes and does, and animals on substandard planes of nutrition are most susceptible to outbreaks of parasitic disease. The GIN of small ruminants include *Haemonchus contortus, Teladorsagia circumcincta* (formerly *Ostertagia*), *Trichostrongylus axei, Nematodirus* spp., and *Cooperia* spp.[1] The proportions of each of these nematodes in small ruminant populations vary according to geographic location. *H. contortus* is usually the most significant pathogen in wet, temperate climates. *T. circumcincta* may be the predominant infection in northern or arid climates. *H. contortus* and *T. circumcinta* represent the majority of parasite burdens seen in small ruminants, with *H. contortus* being present in highest numbers. Anthelmintic resistance is present in all these parasites, but the prevalence is highest for *H. contortus,* making it the most economically important GIN of sheep and goats.[2]

The problem of anthelmintic resistance in GINs of small ruminants has been reported in South Africa, Australia, New Zealand, Malaysia, Spain, France, Denmark, United Kingdom, Brazil, and the United States.[2-6] In the United States resistance has been documented to all classes of anthelmintics.[4,5] Recently resistance to two and three classes of anthelmintic was found on 14 out of 15 farms and 6 out of 18 farms, respectively, in a survey of 18 goat flocks in Georgia and South Carolina.[6] The first report of total anthelmintic failure was made on a meat goat farm in Arkansas in 2005.[7] It is no longer acceptable to plan parasite control programs solely on the basis of the use of anthelmintics. Veterinarians and producers must customize programs to control exposure to infection and reduce the use of anthelmintics. A thorough knowledge of the biology of GIN is necessary to plan effective control programs.

Life Cycle[7,8]

The life cycle of GIN is direct and consists of a host phase and a free-living phase. Worms mate in the host and females lay eggs that pass in the feces. Eggs hatch and develop to infective larvae while remaining in the fecal mass. Infective larvae then move from the fecal mass onto the surrounding forage, where they can be consumed during grazing, thus completing the cycle. The time from ingestion of infective larvae to egg-laying adults, the prepatent period, is about 3 weeks. The time for development from egg to infective larvae can be as short as 4 to 10 days (especially during the summer months); therefore transmission (reinfection) and continual pasture contamination can be rapid. During the colder months development is delayed and may take 1 to 2 months to reach the infective larvae stage, so pasture contamination and reinfection are minimized. The infective larvae have a protective sheath making them relatively resistant to adverse environmental conditions and they can survive for months, thus extending transmission potential. As long as the temperature and moisture conditions remain favorable, development and survival continues; conditions that are too hot, too cold, and/or too dry threaten parasite survival.

Epizootiology[7,8]

The life cycle of a GIN has four phases:

PHASE 1—SYMBIOTIC/PARASITIC PHASE. Phase 1 is the interaction between host and parasite. During this phase, the parasite has to develop and survive in the host. After ingestion, infective larvae lose their protective sheath and invade the mucosa of the abomasum, small intestine, or large intestine depending on the GIN species involved. While in the mucosa, larvae develop to the next larval stage and then return to the surface of the gut mucosa, where they become adult worms. The major host defense mechanism is immunity. When an infectious agent enters the body, the immune system reacts to mobilize various components (antibodies, killer cells, etc.) to inhibit or kill the invaders. These components act on larval stages in the mucosa and the adults in the lumen. The strength of the immune response depends on the age of the host, nutritional status, and concurrent stressors. The immune system matures with age, leaving young animals relatively more susceptible to infection and older animals more resistant. As a result, young animals usually harbor the highest GIN populations and suffer the most severe consequences while adult animals harbor lower infection levels. Under poor nutrition and/or stressful conditions, the immune system is compromised and cannot respond adequately regardless of the age of the animal.

The prepatent period of most worms is about 3 weeks, but this period can be extended for worms that have the capability to enter a period of delayed development called *hypobiosis.* This occurs during the season of the year when the environmental conditions are unfavorable for development and survival of the free-living larval stages. Depending on the worm and the environment, this happens either during summer or winter.

PHASE 2—CONTAMINATION PHASE. Phase 2 results from eggs passed in the feces. The magnitude of this phase is affected by stocking rate, age of the animals, season of the year, and hypobiosis. The higher the stocking rate, the more feces are deposited on the grazing area, thus more eggs, and vice versa. More eggs are also passed from young versus older animals. Most worms have a definite seasonality resulting in higher egg production and deposition during different times of the year. Of particular note is the periparturient rise (PPR) in fecal egg count (FEC). This occurs at or around parturition and extends through most of the lactation period. Because parturition and lactation are stressful conditions, the dam's immune system is compromised. This allows the existing female worms to increase the number of eggs deposited in the feces. If a worm species undergoes hypobiosis, the development time to the adult stage is extended. This will result in fewer adult worms over time and fewer eggs deposited in feces. However, when these hypobiotic larvae resume development, massive numbers become mature adults over a short period of time and the resultant egg production and deposition in the feces can be high.

PHASE 3—FREE-LIVING PHASE. Phase 3 involves larval development and survival, which depend on prevailing environmental and nutritional conditions. Initially, development and survival from egg to first-stage (L_1) then to L_2 and finally to L_3 or infective larvae occurs within the fecal mass. L_1 and L_2 are unprotected and require oxygen and energy (feeding on nutrients and microorganisms) to grow. The L_3 are enclosed in a protective sheath and do not feed. Temperatures conducive for normal development and survival are between 65° F and 85° F. With lower or higher temperatures, development and survival are reduced. Moisture is also crucial for development and

VetBooks.ir

VetBooks.ir

survival. Because the initial development and survival occur within the fecal mass, moisture is usually adequate to allow development to the infective larvae; however, if the fecal mass dries out quickly, due to high temperatures and/or physical disruption of the fecal mass, the L_1 and L_2 are susceptible to desiccation and will die. Generally, L_3 can survive very low temperatures, but sustained temperatures above 95° F are usually lethal. When infective larvae migrate out of the fecal mass, they are relatively resistant to environmental conditions encountered due to their protective sheath. Temperature is usually the only factor that may adversely affect L_3. The moisture conditions at ground level under forage cover are usually adequate for L_3 to move around and survive. Because they do not feed, length of survival depends on how fast they use energy reserves. The hotter it is, the faster they move and use up energy stores, which decreases survival. Eventually, infective larvae move up and down the forage when there is a moisture medium (i.e., advancing and receding dew). Rain also provides a moisture medium for larval movement on forage. For the most part, infective larvae do not move much past 30 to 50 cm from the fecal mass or 5 to 6 cm up the forage. Therefore, the lower the animals graze and the closer to the fecal mass, the greater the consumption of L_3.

PHASE 4—INFECTION PHASE. Phase 4 occurs when available L_3 are consumed during grazing. This phase is affected by stocking rate in two ways. If the same (phase 2) animals remain on the same pasture, the stocking rate determines how many eggs initially contaminated the pasture and, consequently, how many L_3 will be available to consume. If the initial contaminating animals are removed and replaced by new animals, the new stocking rate will determine the level of exposure each animal has to infective larvae during grazing (i.e., the higher the stocking rate, the more chance of exposure and vice versa). It is well known that grazing animals usually do not graze close to fecal masses, so the greater the distance between masses, the less the exposure. Eventually fecal masses disintegrate, forage grows well with the fertilization, and animals will graze over the area where exposure can be high. Natural sources of water, such as streams, ponds, or lakes, provide moisture along the banks, where forage can grow readily. When animals congregate to drink and consume the attractive forage, defecation in these areas usually leads to increased contamination and eventually more L_3. Essentially a high stocking rate has been artificially created in a relatively small area. The same can be said for areas where supplements, especially hay, are fed if conditions are right for development and survival of the free-living stages. Once L_3 are consumed, phase 1 is repeated.

Pathophysiology of Gastrointestinal Nematode Parasites

The damage done by *H. contortus* is the result of the blood sucking by L_4 and adult parasites. The pathogenesis of *Teladorsagia* in sheep is similar to that described for *Ostertagia* in cattle and is a result of destruction of abomasal mucosa. *T. axei* causes abomasitis, whereas *Trichostrongylus colubriformis* penetrates beneath the intestinal mucosa and causes blood loss and enteritis.

Clinical Signs of Gastrointestinal Nematode Parasites

Most animals acquire mixed infections of nematodes. Clinical signs may therefore reflect the effects of more than one species of parasite. There appears to be some synergism between *T. circumcincta* and *T. colubriformis,* which makes the effect of the combined infection more severe than that of either alone. Although mixed infections with GINs are assumed, the actual population of parasites in small ruminants will vary depending on the geographic location. In general, the majority of clinical illnesses results from *H. contortus* infections. Most parasitic infections in small ruminants are associated with altered gut function, anorexia, ill thrift, weight loss, and hypoproteinemia. Diarrhea is a variable sign. Animals may die suddenly without overt clinical signs or may exhibit chronic wasting. Clinical signs of *H. contortus* infection can vary from peracute to chronic and result from decreased nutrient utilization and anemia/hypoproteinemia. The most common signs are failure to thrive, weight loss, and decreased appetite. Weakness, bottle jaw, pale mucous membranes, poor capillary refill time, and possibly diarrhea develop with more severe or long-term infections. Following sudden exposure to large numbers of L_3, animals can die acutely, even before the infection is patent. Other diseases such as pneumonia and heat stress may result secondarily.

Anemic Crisis/Patient Management

The anemia created by *H. contortus* is due to blood consumed by the parasite and is usually chronic. Parasitized patients present with lethargy and weight loss and often have hematocrits less than 10%, yet many are still capable of rising and walking. Addressing the anemia by blood transfusion must be weighed carefully against stress to the patient caused by restraint, jugular catheterization, and blood administration, as well as by the hemolysis of these same cells several days later. Obviously, in life-threatening circumstances (the patient that is unable to stand), administration of whole blood can be critical. In the noncrisis situation (patient rising and/or eating), treatment with an effective anthelmintic should eliminate the parasite and halt blood loss. Because *H. contortus* consumes blood, the affected animal actually loses substrates essential to erythrocyte production (iron, cobalt, copper). Providing supplemental iron and B-complex vitamins should speed reversal of the anemia. Assuming blood loss has been halted, a 1- to 1.5-point rise in the hematocrit per day is expected when the bone marrow is maximally stimulated. In most parasitized patients, a rise of one half this value is a more realistic expectation.[9]

If blood is to be given, it is essential to be certain that the donor has a normal packed cell volume. Blood collected from animals in the same environment may be as anemic as the patient, but the individual is more capable of dealing with the anemia. In lambs weighing less than 45 kg, 1 unit of whole blood (≈450 mL) is often sufficient to survive a crisis, provided *H. contortus* has been controlled.

Populations at Risk

Young animals are most susceptible to infection and clinical manifestations of disease. Lambs and kids may become heavily infected with parasites and shed large numbers of nematode eggs. In sheep, some degree of immunity develops as the animal approaches 1 year of age. Adult animals typically have complete immunity against *Nematodirus* and variable resistance to *Trichostrongylus* spp. Some immunity to *Haemonchus* and *Teladorsagia* spp. develops with age; compared with lambs or kids, adults are more resistant to infection with these species. However, even mature animals may succumb to parasitic infection when malnourished or challenged with heavily contaminated pasture. A periparturient rise in fecal egg production is seen in ewes and does.

Goats are more susceptible to gastrointestinal nematode infections than are sheep. The difference lies in part in the host's immunologic responses to nematode antigens. Goats prefer to browse on brush and trees and only graze grass when forced to by management. Under natural conditions, goats would have a low level of exposure to infective larvae and this may explain their lower level of natural immunity compared with sheep.[10,11]

Refugia

Biologically, refugia refers to isolated populations of once widespread animal or plant or in this case, parasite species. Most parasitologists now consider levels of refugia as the single most important factor contributing to selection for anthelmintic-resistant parasites.[12,13] Worms in refugia provide a pool of genes susceptible to anthelmintics, thus diluting the frequency of resistant genes. For many years parasitologists and veterinarians have recommended that all animals on a premise should be treated with an anthelmintic at the same time. However, this strategy has proven problematic, and a selective approach is now recommended. Only those animals in danger of severe parasitism should actually receive medication. This selective approach is highly compatible with host-parasite dynamics because 20% to 30% of animals harbor about 80% of the parasites.[14] Animals with low worm burdens are an important source of refugia, are not in danger of the negative effects of parasitism, and should not be treated.

VetBooks.ir

Management of Gastrointestinal Nematodes in Small Ruminants The traditional approaches of deworming often, rotating class of anthelmintics, and moving to clean pastures have only served to develop anthelmintic resistance to all classes of drugs and disseminate these resistant parasites over a wide area. It is obvious that drastic changes in the management of GIN in sheep and goats are long overdue.

FAMACHA OR SMART DRENCHING METHOD.[15] In order to maintain adequate levels of refugia, it is necessary to leave a portion of the herd or flock untreated. FAMACHA is a selective approach that targets the portion of the herd or flock with high worm burdens, including those animals that are poorly resilient to worm infections.[16] This approach will successfully control parasites in the entire group while significantly reducing drug costs and delaying the development of anthelmintic resistance. The use of this system is not without risk because individuals are not routinely treated with anthelmintics. Failure to observe animals closely for clinical signs may result in the death of some individuals. It is necessary to know which anthelmintics are effective before beginning this system. The differences among farms in overall quality of management, stocking rates, breeds of animals, preexisting levels and spectrum of anthelmintic resistance, presence of nematode species other than *H. contortus,* and production targets need to be considered before implementing FAMACHA on individual farms.

FAMACHA is a novel system developed in South Africa for identifying sheep that are anemic, and it has been extended to use in goats.[17] In this method the ocular mucous membranes of sheep and goats are categorized by comparison with a laminated color chart bearing pictures of sheep conjunctivae classified into five categories ranging from red (A/1; normal) to practically white (E/5; severe anemia). Because anemia is the primary pathologic effect from infection with *H. contortus,* this system can be an effective tool for identifying animals that require treatment (but only for *H. contortus*). FAMACHA has been tested extensively and validated in both sheep and goats in South Africa and in the southern United States.[18,19] In all studies, the numbers of false negatives were low, suggesting that when using FAMACHA according to recommended guidelines, death from anemia would be rare.

On the basis of the results of recent studies in the United States and numerous studies performed in South Africa, guidelines for using FAMACHA have been developed, and it is suggested that these guidelines be read in their entirety before FAMACHA is practiced.[16] Individual animals are scored 1 to 5 by comparing their mucous membrane color with a laminated chart. It is recommended that treatment is withheld until animals score a 4 or 5 as long as animals are in good body condition and good overall general health, are examined frequently (e.g., every 2 weeks), and good husbandry is used to identify animals in need of treatment (e.g., unthrifty, anorexic, lagging behind, bottle jaw) between FAMACHA examinations. Using this approach, the number of anthelmintic treatments administered will be reduced greatly, resulting in significantly diminished selection pressure for resistance and therefore a reduction in drug costs. Due to the increased handling of animals, labor costs will be increased. *Only adult animals should be managed with this system.* Lambs and kids have comparatively small blood volumes, poor immunity, and poor resilience and can progress rapidly from moderate to severe anemia. This precaution should also be extended to ewes and does during the periparturient and early lactation period because these animals have decreased immunity to GINs.[15,20-22] These and other animals that may be stressed by disease or in poor body condition should always be treated if scored as 3. Alternatively, in the northern parts of the country where *H. contortus* is an important problem but resistance prevalence is much lower, it may be reasonable to be more liberal when making treatment decisions (i.e., treat all 3, 4, and 5). Many more treatments are given when all scores of 3 and higher are dewormed, but a significant number of animals will remain untreated to supply refugia. These refugia combined with a relatively short transmission/treatment period are likely to produce a slow evolution of resistance, but the more intensive treatment protocols will improve animal productivity.

On farms where low to moderate levels of resistance have been diagnosed to one or more drugs (60% to 90% reduction in FEC), a useful strategy to help gain the full benefits of both treatment and resistance prevention could be to use these "less effective" drugs either singly or in combination on all animals scored as 3. There is evidence that using dewormers with different modes of action in combination have greater efficacy and do not cause a more rapid development of resistance.[23] Using drugs that are less effective in this group is unlikely to lead to clinical problems because the few 3 scores that are moderately anemic and in need of treatment should receive a sufficient reprieve from infection until the next FAMACHA examination, and the majority of the 3 scores that are not anemic do not need to be treated. This strategy will help preserve the efficacy of the drugs that are still fully effective by saving them only for the 4 and 5 categories and will also help to decrease egg contamination of pastures.

Training of producers is critical in the use of this method. It is the responsibility of veterinarians and other animal health professionals to ensure that standards of training are maintained by using the "Train the Trainer" seminars through the American Consortium of Small Ruminant Parasite Control (ACSRPC, formerly Southern Consortium or SCSRPC) at www.acsrpc.org. When using FAMACHA, it is extremely important that efficacy of anthelmintics is known because animals are not treated until they become anemic. Treating anemic animals with a drug that has moderate to poor efficacy due to worm resistance may result in animal deaths. Other important precautions for using FAMACHA include but are not limited to (1) the card is an aid in the control of *Haemonchus* spp. only; (2) the system should be used by producers only where technical assistance is available from a veterinarian or other animal health professional; (3) other management-based worm control practices must be maintained; (4) smart drenching principles should be used; (5) paleness or reddening of the conjunctivae may have other causes; (6) animals should always be scored with the help of the chart, not from memory; (7) animals are examined at least every 2 to 3 weeks at the beginning of the expected period of *Haemonchus* spp. challenge in climates where a seasonal incidence of infection occurs, and during critical periods weekly examinations may be necessary; (8) the card is protected from light when not in use and replaced after 1 year of use.[4,24]

Maintaining records of treatments that are included with the FAMACHA kits gives the owner the ability to rate the genetic merits of individuals on the premises. Host resistance to infection with *H. contortus* measured on the basis of FEC and PCV is a moderately heritable trait, and it has been demonstrated that the same animals tend to exhibit the highest FEC and lowest PCV on each occasion they are measured.[25-27] Importantly, data from recent investigations examining the heritability of resistance and resilience of Merino sheep to infection with *H. contortus* indicate a high heritability for the clinical estimates of FAMACHA scores.[18] Removing the most susceptible animals from the breeding pool each year will have the long-term effect of improving the overall innate genetic resistance and/or resilience of the herd or flock to *H. contortus*.

FIVE-POINT CHECK.[28] Because FAMACHA is based on anemia and focuses on parasitism by *H. contortus,* a combined system that could identify problems with a variety of other potentially pathologic parasites is in the early stages of development. This is the Five-Point Check that includes checking for nasal discharge, submandibular edema, back body condition scoring, and fecal staining of perineum in addition to ocular membrane color. Anthelmintic recommendations were made on the basis of the points that had poor scores. Pilot studies showed good acceptance and usefulness of this system, but further studies need to be completed to determine the efficacy and economy of this approach.

GRAZING STRATEGIES. The goal of pasture management is to provide safe pastures for grazing by reducing the exposure of

VetBooks.ir

susceptible hosts to infective larvae.[29,30] A safe pasture is one that has had no sheep or goats grazed on it for 6 months during cool/cold weather or 3 months during hot, dry weather. Weaning sheep and goats at 2 months of age and rotating them through pastures ahead of the adults while forage is longer will minimize the exposure of susceptible animals to infective larvae. Pastures should be subdivided into smaller lots to allow longer rest periods between grazings. Pastures that are overgrown provide a good environment for larval survival because ultraviolet light and dry conditions are effective in killing larvae. Keeping pastures clipped will also assist in weed and parasite control and improve forage quality. Short-duration grazing carries pasture rotation to a level that maximizes forage production and harvesting by controlled animal grazing. It is management intensive but can be effective in controlling parasite burdens. Tilling and reseeding heavily contaminated pastures will convert them to safe pastures and provides an opportunity to improve the forage quality. Taking a cutting of hay from a pasture assists in reduction of infective larvae, but one report indicates GINs and tapeworms developing in "worm-free" lambs after feeding hay from heavily infected pastures. During the most dangerous part of the grazing season, it may be necessary to dry lot the flock and feed hay and grain from elevated feeders.

Stocking rate is an important consideration in parasite control because it affects the exposure to infective larvae and the contamination of the pasture. It is impossible to make a general recommendation on stocking rate because this will vary according to the type of pasture, time of year, current weather conditions, and type of animal being grazed. Thumb rules include five to seven goats or five sheep being the equivalent of one cow and suggest five to seven goats/acre. Goats prefer to browse brush and trees, whereas sheep prefer to graze near the ground. Pasture management must include monitoring the condition of herbage to ensure that overgrazing does not occur and to maintain a productive pasture.

In the early spring or at the onset of the rainy season, reduced pasture contamination is the most important aspect of control. The ewe or doe in the periparturient relaxation of resistance, even if she has the genetic capacity for resistance, will be a source of eggs for the environment. Strategic deworming to remove arrested or recently emerged larvae before they contaminate the pasture will have a great impact on pasture contamination. Treatment 2 weeks after a rain that removes recently acquired worms before they can begin passing eggs will also decrease pasture contamination. Providing sufficient dietary protein is vital during the periparturient period and during rapid growth so that animals will tolerate the worm burden better, as well as increase resistance to infection.[31-33] A strong link between nutrition and parasitism has been illustrated between protein intake and resistance to GIN infection. The most dramatic has been the abolishment of the periparturient egg rise in lambing ewes by providing protein at 130% of requirements. Immunity is closely related to protein repletion. GINs increase the demand for amino acids by the sheep. Lambs will voluntarily select a higher protein diet when infected with GINs compared with uninfected lambs. There is conflicting documentation that sheep will decrease feed intake when initially infected with GIN. Some authors hypothesize that the decrease in intake may be due to stimulation of the immune system or that the host is becoming selective in its diet.

Pastures may be used for hay cropping and grazed during the last half of the grazing season to effectively reduce GIN challenge. When plants high in condensed tannins are grazed, incoming larvae are adversely affected and these plants provide bypass protein for the host.[34-36] There is growing evidence in work from New Zealand and Europe that grazing or feeding of plants containing condensed tannins (CTs) can reduce FEC, larval development in feces, and adult worm numbers in the abomasum and small intestine. Preliminary tests with *Sericea lespedeza* (SL, *Lespedeza cuneata*), a perennial warm-season legume, have shown positive effects of reduced FEC in grazing goats, and in sheep and goats in confinement when the forage was fed as hay. In addition, an effect on reducing worm burden has also been reported. *S. lespedeza* is unfortunately considered to be an invasive exotic in the United States. Similar results have been observed using quebracho extract for small intestinal worms, but not abomasal worms. In addition to its potential use in controlling worms, SL is a useful crop for limited resource producers in the southern United States. It is adapted to hot, dry climatic conditions and acid, infertile soils unsuitable for crop production or growth of high-input forages, such as alfalfa. It can be overseeded on existing pasture or grown in pure stands for grazing or hay. In addition to hay, SL is being evaluated in the form of meal, pellets and cubes to be fed as a supplement to grazing animals, or as a deworming method under temporary short-term confinement. The physical structure of some plants may challenge larvae to ascend vegetation or may provide protection from adverse pasture conditions. If animals are allowed to browse, their chances of acquiring larvae diminish as the distance from the ground increases. Most infective larvae are found within 2 inches (50 mm) of the soil surface.

Alternate or co-grazing with other species of livestock may harvest *Haemonchus* larvae from the pasture. Small ruminants can graze after cattle, and this is considered to be a safe pasture, assuming adequate parasite control in the cattle. For the most part, each livestock species harbors its own parasite fauna with the exception of overlap between sheep and goats. Only *T. axei,* a minor abomasal worm, is found in all livestock species. In general, the *Haemonchus* in sheep and goats do not do well in cattle and vice versa. However, some populations of *H. contortus* may thrive in calves. If practical, cattle and small ruminants can be grazed together where each consumes the parasites of the other, which reduces available infective larvae for the preferred host species.

Anthelmintic administration should be coordinated with the weather. During hot, dry weather, there will be little or no exposure to L_3. As soon as there is significant rainfall (0.5 to 1 inch), larvae exposure goes up exponentially as previously inactive larvae become active and new larvae are hatched. Producers should be trained to plan deworming within 3 weeks of significant rain after a dry spell. Similar strategies can be used during cool weather. Once ambient temperatures drop below 50° F, the flock can be dewormed and no further treatments are necessary until temperatures become favorable to larval development and activity.

ALTERNATIVE THERAPIES

1. **Copper oxide wire particles (COWPs)** have been marketed for years as a supplement for livestock being managed in copper-deficient areas.[37] COWPs come in adult cattle, calf, and ewe boluses (25, 12.5, and 4 g, respectively). Only the cattle boluses are available in the United States. Due to potential toxicity in sheep, only one dose per year is recommended. It is also well known that copper has some anthelmintic activity against abomasal worms but not other gastrointestinal worms. That makes COWP a narrow-spectrum product. But in view of anthelmintic resistance by *H. contortus,* recent work has revisited the possibility of using COWP to specifically target *H. contortus*. Such work has shown that as little as a gram or less and 2 g may remove substantial numbers of *H. contortus* in lambs and ewes, respectively. Similar work in goats has not been tested adequately to establish what is needed, but similar doses may be appropriate. As mentioned, copper must be used cautiously in sheep because toxicity can develop due to liver accumulation. Toxicity may not be an issue in goats because they have been reported as not being as sensitive to excess copper intake. Thus, higher doses and/or more treatments during haemonchosis season may be useful in goats.
2. **Other nutritional considerations** include phosphorus, cobalt, and molybdenum.[38] Supplementation with phosphorus has been shown to prevent worm establishment. Cobalt deficiency has also been associated with reduced immunity to GINs. The addition of molybdenum at 6 to 10 mg/day decreased worm burdens in lambs. This effect was not attributable to the expected copper deficiency. Molybdenum may have a role in increasing jejunal mast cells and blood eosinophil numbers.
3. **Nematode-trapping fungi** included in feed or supplements have demonstrated potential for biological control of the free-living

VetBooks.ir

stages of GIN parasites under experimental and natural conditions.[39-41] These fungi naturally inhabit soil throughout the world where they feed on a variety of free-living soil nematodes. These fungi capture nematodes by producing sticky traps on their growing hyphae. Of the various fungi tested, *Duddingtonia flagrans* possesses the greatest potential for survival in the gastrointestinal tract of ruminants. After passing through the gastrointestinal tract, spores germinate and looped hyphae trap the developing larval stages in the fecal environment. This technology has been applied successfully under field conditions and is an environmentally safe biological approach for control of worms under sustainable, forage-based feeding systems. The major drawback is that the fungal spores must be fed daily. Daily feeding, which ensures that all animals consume an equivalent amount of feed, is necessary. For adequate control of larvae during the transmission season, spores must be fed for a minimum of 60 days. This can be expensive and time consuming. A bolus prototype that would allow a single administration where spores would then be slowly released over a 60-day period is being developed. This product is not available in the United States at this time.

4. **Vaccines** have been explored for management of the negative consequences of parasitism.[42-44] Successful vaccines have been developed for lungworms in cattle and tapeworms in sheep. The most promising vaccine for small ruminant worms has been what is called a "hidden gut" antigen and specifically targets *H. contortus*. This antigen is derived from the gut of the worm and, when administered to the animal, antibodies are produced. When the worm ingests blood during feeding, it also ingests these antibodies. The antibodies then attack the target gut cells of the worm and disrupt the worm's ability to process the nutrients necessary to maintain proper growth and maintenance, thus killing the worms. This vaccine has been tested successfully in sheep under experimental conditions but has had limited success under field conditions. Vaccines for other worms that do not feed on blood have focused on using antigens found in worm secretory and excretory products. Protection has been quite variable, and marketing of such products has not been pursued.
5. **Genetic improvement in resistance** to nematode infection is most likely based on inheritance of genes that play a primary role in expression of host immunity.[45-47] Based on survival of the fittest management conditions, several breeds around the globe are known to be relatively resistant to infection. Such breeds include Scottish Blackface, Red Maasai, Romanov, St. Croix, Barbados Blackbelly, and the Gulf Coast Native. Katahdin sheep have been considered as being more parasite resistant, but studies to document this are few and not conclusive. Using such breeds exclusively or in crossbreeding programs would certainly lead to improved resistance to worm infection, but some level of production might be sacrificed. Selection of more resistant stock can be accelerated by identifying sires that produce relatively resistant offspring. Computer programs have been used in New Zealand and Australia to rank sire genetics on the basis of resistance to GIN infections, but change takes up to 8 to 10 years. Heritabilities for FEC, a common measurement for assessing parasite burden, range from 0.22 to 0.40, which is relatively high. Thus, selection for resistance using a measurement such as FEC has been moderately successful.

ANTHELMINTIC USE. Anthelmintics have deliberately been left to the end of this section because drugs cannot be considered to be the most important aspect of a parasite control program. Guidelines for drug dosages are contained in Table 49-3. At this time, only oral administration of anthelmintics is recommended in small ruminants. In general, goats require 1.5 to 2 times the dosages of sheep, with the exception of levamisole, due to more rapid gastrointestinal transit times. It is critical that producers accurately assess weights of individual animals and dose appropriately. If an approximate dose is going to be used in all animals, that dose should be for the lightest animal in the group.

The challenge of anthelmintic resistance is life threatening in small ruminants. There is no point in repeatedly deworming with expensive drugs, if that drug is no longer effective. See the following section on Monitoring Parasite Control programs for information on detecting anthelmintic resistance. On farms where low to moderate levels of resistance have been diagnosed to one or more drugs (60% to 95% reduction in FEC), a useful strategy to help gain the full benefits of both treatment and resistance prevention could be to use these "less effective" drugs either singly or in combination. Drugs in the benzimidazole family may be effective if multiple-day dosing regimens are used.

Lungworm Infection in Large Animals

Lora Rickard Ballweber

Traditionally, lungworms are those nematode parasites that reside in the lung as adults. In domestic ruminant and equine species, most clinical cases of lungworm involve the genus *Dictyocaulus.* Species of *Dictyocaulus* tend to be host specific with *Dictyocaulus viviparus, Dictyocaulus filaria,* and *Dictyocaulus arnfieldi* found in the bronchi of cattle, small ruminants, and equids (horses, ponies, donkeys), respectively. Sheep and goats may also be infected with *Protostrongylus rufescens* and *Muellerius capillaris*.[1-2] This section focuses on *Dictyocaulus* infection, with a brief discussion of other lungworm parasites found in small ruminants.

Because verminous pneumonia requires specific treatment, it is important to distinguish it from diseases caused by other infectious agents. Often the role of lungworm in the cause of respiratory disease is obscured by a parasite-induced hypersensitivity response or by superimposed secondary bacterial infections.

Life Cycle The life cycle of *D. viviparus* is direct, with no intermediate host involved. Adults produce embryonated eggs that hatch shortly after oviposition. L_1 migrate up the trachea and are passed in the feces, where they develop to L_2 and infective L_3 within a week under optimal environmental conditions. After the L_3 are ingested, they exsheath within the abomasum and migrate through the wall of the intestine to the mesenteric lymph nodes, where they molt to the L_4. The L_4 then migrate through the lymphatics and bloodstream to the lungs, arriving as early as 7 days after infection. L_4 may then develop to sexually mature adult worms, or they may arrest development as late L_4 or molt to immature adults and arrest. Arrested development can prolong the normal prepatent period from 3 to 4 weeks to approximately 5 months.[1-2]

Most problems with cattle lungworms in North America occur in areas of moist climates where larvae on pasture are protected from desiccation and larval dispersal away from the fecal pat onto herbage is facilitated. Under favorable conditions, infective L_3 can survive on pasture for as long as 11 months.[1] These larvae plus the larvae produced from carrier animals harboring small numbers of adults or adults developing from arrested larvae can result in high levels of contamination on spring pastures. In subtropical climates, larvae are virtually absent during the hot summers; larval contamination of the pasture peaks in the autumn as a result of carrier animals.[2]

The life cycle of *D. filaria* is similar to that of *D. viviparus* including the ability of the larvae to arrest development. The prepatent period is approximately 26 days, with peak larval output occurring 39 to 57 days post infection. As with *D. viviparus, D. filaria* is more prevalent in moist climates and larvae can survive on pasture throughout the winter. Spring pastures contaminated with overwintering larvae and larvae produced from adults developing from arrested larvae in carrier animals are sources of infection for susceptible lambs or kids.[1-2]

The life cycle of *D. arnfieldi* is similar to that of other species of *Dictyocaulus* except that larvated eggs are passed in the feces with the L_1 hatching almost immediately thereafter. The prepatent period is 2 to 3 months.[2-4]

VetBooks.ir

Unlike species of *Dictyocaulus, M. capillaris* and *P. rufescens* have indirect life cycles that involve molluscan intermediate hosts. Adults, occurring in the parenchyma *(M. capillaris)* or small bronchioles *(P. rufescens),* produce eggs that develop and hatch. L_1 are passed with the feces; once on pasture, larvae invade the foot of a susceptible species of snail or slug and develop to infective L_3. Sheep and goats become infected when ingesting the mollusk while grazing. The larvae penetrate the intestine and migrate to the lung in much the same manner as *Dictyocaulus.* Early L_4, developing L_4, and adult *M. capillaris* become embedded in fibrous nodules within the parenchyma. *Protostrongylus* larvae mature in the alveoli and enter the bronchioles as adults. The prepatent period for both species is 5 to 6 weeks, although arrested development may prolong the prepatent period of *M. capillaris.* Patency for both species is very long (>2 years).[2-4]

Pathophysiology Clinical bovine dictyocaulosis is characterized by bronchitis and pneumonia. The disease process is divided into four phases: penetration, prepatent, patent, and postpatent. In the penetration phase (days 1 to ≈7), no clinical sign or significant respiratory pathology occurs as the larvae migrate to the lungs. The prepatent phase (days 7-8 to 25) starts with the arrival of larvae in the alveoli and ends with immature adults in the bronchi. An eosinophilic infiltrate blocks bronchioles; excess mucus production and alveolar collapse occur. Respiratory failure as a result of severe interstitial emphysema and pulmonary edema can result in death of heavily infected animals beginning about day 15 onwards. The patent phase (days 25 to 55-60) is associated with egg-laying adults in the bronchi and trachea. Bronchial and tracheal epithelial damage occurs, air passages are blocked by exudate, and consolidation of lobules results from aspiration of eggs and L_1 into bronchioles and alveoli. Bronchitis, tracheitis, and pneumonia follow. The postpatent phase (days 61 to 90) is normally the recovery phase and is associated with the expulsion of adult nematodes. Clinical signs begin to diminish; however, peribronchial fibrosis and epithelialization of alveoli may remain. A frequently fatal syndrome, called *postpatent parasitic bronchitis,* can occur in about 25% of heavily infected animals during the postpatent phase. This syndrome is characterized by proliferation of type 2 pneumocytes in the alveoli, impaired gas exchange at the alveolar surface, interstitial emphysema, and pulmonary edema and is thought to result from the aspiration of dead and dying worm material into the alveoli. Fatal secondary bacterial infections, resulting from weakened pulmonary defenses, may also occur.[1-2]

Goats tend to be more susceptible to infection with *D. filaria* and more severely affected than sheep, although individual susceptibility to infections does occur. Heavy infections in both species produce bronchitis, pulmonary edema, atelectasis, and emphysema, although death is uncommon. As with *D. viviparus,* secondary bacterial infections can occur.[1]

The characteristic lesions of dictyocaulosis in horses and donkeys are similar. Pathologic changes include discrete circular areas of overinflation (not emphysema) surrounding affected bronchi primarily in the caudal lung lobes. Histologically these areas contain a small bronchus packed with nematodes. The small airways are often occluded with exudate. Adult worms may also be found in the main bronchi surrounded by small amounts of mucus with little cellular reaction; however, if L_1 are present, they are surrounded by an intense mucopurulent reaction. In horses, in addition to these types of lesions, many immature nematodes are present in smaller bronchi, accompanied by bronchial epithelial hyperplasia with large amounts of mucus and pus. Many areas of alveolar hemorrhage and edema are also present.[2-4]

Pathologic changes caused by *P. rufescens* result from occlusion of small bronchioles by mature worms, resulting in clogging of lesser branches with eggs, larvae, and cellular debris. Other changes include desquamation of alveolar and bronchial epithelium and cellular infiltration and proliferation of connective tissue. The results are small areas of lobular pneumonia that appear as gray to yellowish conical lesions whose base is on the surface of the lung. In sheep and goats infected with *M. capillaris,* distinct subpleural nodules containing adults and L_1 are common. However, infections in both hosts may be more diffuse with interstitial pneumonia, bronchopneumonia, or fibrinous pleuritis. Secondary bacterial infections can also occur.[1-2,5]

Populations at Risk Clinical dictyocaulosis occurs most frequently in pastured calves, lambs, and kids in the first grazing season. Clinical disease is also reported in adult cattle either as a result of primary exposure as adults, exposure of a previously immune animal whose immunity has waned due to lack of premunition, or exposure of an immune animal to a massive challenge of infective larvae *(reinfection syndrome).*[1-2, 6-8] Although dairy or dairy-cross calves are most frequently affected, beef calves are also susceptible to *D. viviparus.*[2,9-10] Many infections with either *M. capillaris* or *P. rufescens* are subclinical; however, goats do appear to be affected clinically more often than sheep with *M. capillaris.*[1-2]

Immunity to *D. viviparus* occurs after first exposure and can develop before the end of the first grazing season. However, it is variable in both degree and duration. Exposed cattle may be immune for 7 to 12 months after infection. In subsequent infections most larvae are either killed before reaching the lung or are inhibited from maturing into adults. Usually the immunity developed during the first grazing season is boosted by exposure in subsequent years and prevents manifestations of disease. However, without reexposure to infective larvae or vaccination, immunity wanes and disease can occur in adult cattle.[1-2,8]

Occasionally, outbreaks of acute lungworm disease are seen in adult cattle on pasture whose immunity is overwhelmed by exposure to large numbers of larvae. This condition is called the *reinfection syndrome.* Although most ingested larvae are killed or fail to mature, some reach the lung and incite an acute, immune-mediated reaction.[2]

Both sheep and goats develop a strong immunity to *D. filaria.* Thus disease is more common in young animals. As with cattle, the strength and duration of immunity depend on the level of and number of reexposures, as well as the length of time between exposures.[1] Although not common, cattle can be infected with *D. filaria.* Patent infections do not establish but clinical disease may occur.[1,11]

Individual horse/pony susceptibility to infection with *D. arnfieldi* is evident, with infections occurring during any time in the life of the animal. Patent infections can establish in foals (<5 months old) without accompanying clinical signs. Patent infections are rarely established in older animals, where clinical disease is more common. Donkeys apparently do not develop an immunity to infection, with larval excretion increasing with age.[2-4]

Although immunity to *M. capillaris* appears to be incomplete (adult nematodes can live for up to 4.5 years), responses to subsequent exposures do limit the numbers of adults that develop and the numbers of larvae shed in the feces. However, reexposure may be cumulative, resulting in older animals harboring larger numbers of worms.[1]

Clinical Manifestations Clinical disease ("husk") caused by *D. viviparus* in cattle can occur within 1 or 2 weeks of the introduction of susceptible animals onto contaminated pasture. However, disease most often occurs 2 to 4 months into the grazing season. Severity of disease depends on the number of larvae ingested, the animal's level of immunity, and the number of larvae reaching the lungs. Within an affected group, differing degrees of clinical severity will occur. Coughing, dyspnea, and loss of condition are typical. Slight increases in respiratory rate may progress to severe tachypnea and dyspnea characterized by the classic "air-hunger" position of head and neck extended with open-mouth breathing. Auscultation of the lungs reveals vesicular murmurs and bronchial tones that progress to moist rales as fluid accumulates. Emphysema may occur with crackling noises heard on auscultation. Mild pyrexia may be present. Milk production is usually depressed in adult dairy cattle.

VetBooks.ir

Morbidity rates are high, with most animals gradually recovering. Secondary bacterial infections can lead to recurrence of clinical signs during the postpatent phase leading to acute interstitial pneumonia.[1-2,7] Acute dictyocaulosis in calves, resulting from a massive primary infection, can occur during the prepatent period with sudden onset of severe dyspnea followed by death within 24 to 48 hours.[2] Reinfection syndrome in adult cattle shows frequent coughing and slight tachypnea and, for dairy cattle, a sudden drop in milk production starting approximately 2 weeks after exposure to heavily contaminated pastures. Deaths rarely occur.[2]

Coughing and unthriftiness are the usual signs of infections with *D. filaria*. In severe cases, dyspnea, tachypnea, and nasal discharge can occur. Death is uncommon.[1-2]

In horses, lungworm infection may or may not cause clinical signs. When present, the typical syndrome is similar to chronic obstructive pulmonary disease and includes persistent coughing, nasal discharge, and increased respiratory rate; death is uncommon. Donkeys tend to remain asymptomatic, although hyperpnea and harsh lung sounds may be present on close examination.[2,4]

Infections with *M. capillaris* are generally asymptomatic; however, impaired pulmonary gas exchange, reduced weights and breeding performance, and increased mortality have been reported.[1,12-13]

Control of Lungworm Infection

Control of dictyocaulosis in cattle has depended on vaccination and/or prophylactic use of anthelmintics, whereas management strategies designed to decrease exposure to infective larvae are more common recommendations for sheep and goats. These strategies include provision of dry pastures to decrease larval development and survival; grazing of older, clinically immune animals that shed larvae away from susceptible lambs and kids; and grazing lambs on pastures that have not been grazed by adults during the previous year. Treating or culling infected adults can also help reduce pasture contamination. For cattle, leaving contaminated pastures ungrazed for at least 6 weeks during the summer in temperate regions can reduce pasture infectivity because larvae will not survive the dessication. Young, susceptible stock may be given a prophylactic treatment in midspring or early summer to prevent or limit clinical disease. Housed animals, in particular 1- to 2-year-olds with subclinical but potentially patent infections, should be treated before being turned out to pasture in the spring. All early clinical cases should be treated in an effort to limit disease severity and decrease pasture contamination.[1-2,14-15]

Control of lungworms in horses/ponies depends on control in donkeys. Co-grazing with donkeys should not occur. If it does, donkeys should be monitored for L_1 and treated to reduce larval output and pasture contamination. Limiting contact with intermediate hosts and provision of mollusk-free housing will decrease infections with parasites that require these intermediate hosts. Treatment of animals before the start of the grazing season has also been suggested to reduce infection levels in the intermediate hosts.[1-2]

ANTHELMINTICS. Several anthelmintics are effective against lungworms (Table 49-4).[1,3-4,16-19] The macrocyclic lactones are particularly effective against both adult and developing L_4 stages and have prolonged residual activity that prevents appearance of larvae in the feces for at least 60 days.[20-21] Concerns that such highly efficacious anthelmintics would prevent induction of immunity in first-season grazing animals by killing ingested larvae, before they can penetrate the intestine and thus stimulate an immune response, appear to be largely unfounded. The immune response may be attenuated, but exposed animals still develop some degree of immunity to lungworm infection despite prophylactic treatment with these drugs.[22-26] The exception to this may be sustained-release intraruminal devices containing either ivermectin, levamisole, or a benzimidazole. Although their use can prevent clinical disease for several weeks or months during the grazing season,[26-31] some studies have shown that use of these delivery systems impaired the development of immunity in treated calves.[26,30] Other studies, however, showed that treated calves can develop immunity during the grazing season.[32]

TABLE 49-4

Drugs Used to Control Lungworm

Drug	Dose*
Macrocyclic Lactones	
Cattle: ivermectin, abamectin, doramectin, eprinomectin, moxidectin	0.2 mg/kg PO, 0.5 mg/kg topical
Sheep: moxidectin, ivermectin	0.2 mg/kg PO, SC
Goats: ivermectin	0.2-0.3 mg/kg PO, SC
Equids: ivermectin, moxidectin; eprinomectin	0.2 mg/kg, 0.4 mg/kg PO; 0.5 mg/kg topical
Others	
Albendazole	7.5-10 mg/kg PO (O, C, B)
Fenbendazole	7.5 mg/kg PO (O); 15-30 mg/kg PO (C); 5 mg/kg PO (B)
Mebendazole	15-20 mg/kg PO (O, C)
Oxfendazole	4.5 (B), 7.5-10 mg/kg PO (O, C)

*Dose depends on the product and species; follow manufacturers' recommendations; multiple treatments may be warranted depending on host species; sheep and goats should be dewormed by mouth; be aware some recommendations constitute off-label use.

B, Bovine; *C,* caprine; *IM,* intramuscularly; *O,* ovine; *PO,* by mouth; *SC,* subcutaneously.

Regardless, vaccination of treated animals before their second grazing season may be advisable.[2, 8]

VACCINES. An effective vaccine has been developed against *D. viviparus* in cattle and is available in the United Kingdom and parts of western Europe. Two doses of live, irradiated larvae are administered by mouth 4 weeks apart. The larvae migrate to mesenteric lymph nodes and provoke an immune response but die before they reach the lung. Management considerations associated with use of the vaccine include the following: (1) calves must be at least 2 months old; (2) vaccinated calves should not be placed on pasture for at least 2 weeks after the second dose; (3) vaccinated calves must not be exposed to heavily infected pastures, nor should they be mixed with animals showing signs of lungworm disease or with unvaccinated calves; (4) animals should not be treated with an anthelmintic during vaccination or the larvae in the vaccine will be killed; (5) immunity is not long-lasting, so animals must continue to be exposed to low levels of infective larvae to maintain immunity; and (6) the vaccine has a short shelf life and is relatively expensive. Farms with contaminated grazing areas and a history of lungworm disease benefit most from vaccination.[8,14,33]

Evaluation of Preventive Programs

The efficacy of preventive programs is best assessed by evaluating the number of susceptible animals that demonstrate signs of infection. Because total eradication of the parasite is difficult[16] and low numbers of parasites produce minimal problems and maintain immunity, a useful goal is the control of clinical signs and achievement of production parameters.

Clinical Management

DIAGNOSIS. Presumptive diagnosis of clinical lungworm infection is based on clinical presentation, farm history, seasonal prevalence, and response to treatment.[1-2,4] Verminous pneumonia may mimic respiratory diseases caused by other agents that require specific treatment. Although definitive diagnosis is difficult, it is important.

To document the presence of lungworm infection, it is necessary to demonstrate larvae or adult worms. In cattle and small ruminants, the presence of L_1 in fresh feces indicates lungworm infection.[1,14,34] The Baermann technique is the technique of choice for detection of L_1 in feces and is considered to be very sensitive for the diagnosis

VetBooks.ir

of patent primary bovine lungworm infections beginning about 3.5 weeks after infection, provided a sufficient number of animals are sampled.[34] Antibody detection tests have also been developed and are commercially available for use in cattle. Evaluation of their application for testing bulk milk tank samples indicates these tests appear to be most useful in diagnosing suspected dictyocaulosis in moderate to severe outbreaks. In mild outbreaks where just a few animals are coughing or on farms where prevalence is low (<20%), examination of serum and/or feces from individual animals is preferred.[35-36]

Although examining donkeys co-grazing with horses has been the standard recommendation for the antemortem diagnosis of *D. arnfieldi,*[4] diagnosis of lungworm infection in horses is often presumptive and usually based on resolution of clinical signs after treatment.[2-3]

Transtracheal wash may demonstrate a large number of eosinophils, which is supportive of verminous pneumonia, and eggs or larvae are occasionally seen with patent infections. This procedure can also help rule out bacterial pneumonia. Finding nematodes at necropsy is definitive. Adult *Dictyocaulus* are usually found in the bronchi or bronchioles, whereas adult *P. rufescens* tend to be in the bronchioles and adult *M. capillaris* are found in subpleural nodules on the dorsal aspect of the diaphragmatic lobes. Nematodes and the eggs may also be found in histologic section of the lung.

TREATMENT. Animals that are only coughing and/or tachypneic usually have small numbers of *D. viviparus,* and their treatment should result in a rapid recovery. For animals that are dyspneic and anorexic with or without a fever, lung damage is likely severe and anthelmintic treatment is unlikely to result in complete recovery. In some animals, anthelmintic treatment worsens the signs, and some heavily infected animals die. In severely affected individuals, hydration status should be monitored, particularly if the animal is not drinking. Antihistamines and antibiotics may also be included in the therapeutic regimen. Goats infected with *M. capillaris* may need multiple treatments.[2,8,14]

Evaluation of Parasite Control Programs

Sherrill A. Fleming

The efficacy of a given parasite control program should not be assumed; it should be assessed on a regular basis. The routine performance of quantitative tests for parasite burdens allows veterinarians to identify the development of anthelmintic resistance. Although fecal flotation is useful in identifying the presence of parasites, the use of the McMaster technique allows an estimation of the numbers of parasites. Both procedures are relatively simple and can easily be performed in the practice setting. Other specialized laboratory procedures are also discussed. Once resistance has been documented, it is important to identify the species involved through larval identification.

FEC and FEC Reduction Tests[1-5] (Box 49-2)

Determining numbers of nematode eggs in feces is the simplest and least invasive way to evaluate a parasite control program. Fecal examination may be of limited value in an individual animal because animals dying of parasitic infection may have no eggs in the feces, whereas animals with high FECs may be clinically normal. Nevertheless, FECs can provide information on the level of infection present in an individual animal, particularly when egg counts are repeated over the course of 2 to 3 weeks. Herd average FECs are more useful and provide an accurate reflection of the degree of environmental contamination and rate of infection. Pretreatment and posttreatment FECs can also be used to establish the efficacy of an anthelmintic in a particular group of animals. A quantitative McMaster or Stolley technique, rather than simple flotation, is crucial for accurate monitoring.

It is suggested that guidelines published by the World Association for the Advancement of Veterinary Parasitology (WAAVP) be used to perform and evaluate data from an FECRT test, applying practical modifications to fit the situation on the farm.[2] Briefly, groups of 15 animals that have not been treated within the past 8 weeks are randomly allocated to treatment groups, and FECs are performed using a modified McMaster technique 10 to 14 days after treatment. An untreated control group must be included. If fewer than 12 to 15 animals per group are available, then treatment groups should be balanced by performing a pretreatment FEC. Animals are then stratified by FEC from highest to lowest, blocked by number of treatment groups, and then within each block randomly assigned to treatment. Alternatively, where *Haemonchus* is the primary parasite, animals may be scored using the FAMACHA method as they come through the chute, blocked by FAMACHA score, and then randomly assigned to treatment within blocks. This approach is a bit more complicated but will result in groups that are balanced, which will result in a more accurate test. Calculations are performed using the following formula:

$$\text{FECR\%} = 100 \times \left(1 - \frac{X_{t_2}}{X_{t_1}} \frac{X_{c_1}}{X_{c_2}}\right)$$

where X_c and X_t are the geometric mean or arithmetic mean EPG for control (c) and treated (t) groups before (1) and after (2) treatments, respectively.[5] Software is available for free that performs all calculations and gives data interpretation.[6,7] If the RESO calculator is used, the assignment of resistance status is based on both percent reduction and the 95% confidence intervals. If the RESO calculator is not used, the following guidelines can be applied: reductions of greater than 98% indicate high efficacy, reductions of 90% to 98% indicate efficacy, reductions of 80% to 89% indicate moderate efficacy, and reductions of <80% indicate insufficient efficacy. FECRT yields reliable data only if FECs are sufficiently high to properly measure a reduction from treatment. If the control group's mean FECs are below 150 epg, then objective assessment of resistance will not be reliable. Group mean FECs of less than 150 epg can be common in adult sheep; therefore when FECRT is performed on a sheep farm it is preferable to use weaned lambs if available. With goats, low FECs are usually not a problem.

Larval Identification

Ideally, if there is less than a 90% egg count reduction, the eggs should be hatched and the larvae species identified. In the majority of cases these will be *H. contortus,* but other species, especially *Trichostrongylus* species, readily develop resistance as well. One can sometimes be fooled into an improper interpretation of egg count reduction results if mixed species are present and only one is resistant.

Egg Hatch Assays and Larval Development Tests[1]

Eggs from feces are incubated with concentrations of the anthelmintic to be tested and the eggs hatched. A dose-response curve is generated (DrenchRite test from Horizon Technology, Sydney, Australia).[1] The advantage of this test is that a single fecal sample can be tested for all available classes of anthelmintics simultaneously. The cost of this test has recently increased and may discourage owners from pursuing this diagnostic. However, when compared with the cost of using anthelmintics that are ineffective, it is easy to justify the use of this test. It is important to read instructions for submitting this test and scheduling a testing date before the samples are collected.

Larval Culture

Larval cultures can be used to distinguish between large and small strongyles in horses and to identify the various nematode species in ruminants. Most parasitology laboratories can perform this examination. It requires submission of 200 to 400 g of fresh feces. Pooled samples from several herd members are often used.

Pasture Larval Counts[8]

Counts of parasitic larvae on herbage are useful to indicate the level of exposure experienced by the grazing animal. This examination is

VetBooks.ir

BOX 49-2

Modified McMaster Technique (Fecal Egg Count)

This is one method for performing a McMaster fecal egg count. Similar protocols are used routinely in many laboratories, so you may see a slightly different procedure recommended elsewhere. The important point is to use the same procedure each time.

The first step is to collect freshly passed feces uncontaminated by soil or bedding. The best way is to wear a rubber glove and extract feces directly from the rectum. Alternatively, feces can be picked up off the ground if done soon after deposition. The collection container should be labeled with the identification of the animal and the date of collection. Fresh samples work best, but accurate results can be obtained if the sample is refrigerated during the interim. If samples are not refrigerated, the eggs will hatch within 12 to 24 hours. Once hatched, eggs cannot be counted.

Materials

Compound microscope
Scale
Saturated sodium chloride (table salt)
50-mL centrifuge tube, with screw cap and marked with milliliter increments
Pipette (1-mL syringe or eye dropper works well)
McMaster egg counting slide (Chalex Corporation, Issaquah, Wash.)
Paper towels
A fresh fecal sample, refrigerated until tested

Procedure

1. Weigh out 2 g of feces into a 50-mL centrifuge tube and fill to 30-mL line with salt solution. It is recommended to purchase a small scale and weigh feces, but if you do not have a scale you can still get a close estimation by putting 28 mL of salt solution into a 50-mL centrifuge tube first and then adding feces until a volume of 30 mL is achieved.
2. Pour off approximately 25 mL of the salt solution into another small container, keeping feces in the tube (use tongue depressor).
3. Soak feces for a few minutes and mix (soft feces) or break up (fecal pellets) with tongue depressor.
4. Add back approximately one half of the salt solution and mix well, breaking up any remaining feces as well as possible.
5. Add back the remaining salt solution and screw the cap back onto the tube.
6. Shake tube vigorously for approximately 1 minute to disrupt any remaining feces as much as possible.
7. Set tube aside for a few minutes to let bubbles dissipate.
8. Wet McMaster chamber with water and dry top and bottom on paper towels.
9. Rock (do not shake) tube several times to thoroughly mix solution without causing large air bubbles to form.
10. Immediately pipette (using 1-mL syringe or eye dropper) a sample of the suspension and fill both sides of counting chamber. Work quickly. If it takes more than a few seconds to load the first chamber, mix the fecal solution again and refill pipette before loading the second chamber.
11. Let the sample stand for 1 to 2 minutes to allow eggs to float.
12. Count all eggs inside of grid areas (more than one half of eggs should be inside grid) using low-power (10×) objective. Focus on the top layer, which contains small air bubbles (small black circles; if numerous large air bubbles are visible, remove the fluid and refill).
13. Count only trichostrongyle and strongyle eggs (oval shaped, approximately 80 to 90 microns long). Do not count *Strongyloides* species (oval, ≈50 microns long), tapeworm eggs (triangular or D shaped), or coccidia (various sizes). Note the presence of other species, but count only the trichostrongyle and strongyle eggs.
14. Once filled, the chambers can sit for no longer than 60 minutes before counting without causing problems. After 60 minutes, drying and crystal formation may begin.
15. Total egg count (both chambers) × 50 = epg (eggs per gram).

Notes

This is a dilution technique, and theoretically this ratio of feces to flotation solution will not detect infections with fewer than 50 eggs per gram of feces (one egg seen on slide), so it is not accurate for samples with low numbers of eggs. On a practical level this is not important because from a clinical standpoint, slight differences in results when egg counts are low do not matter.

Fairly soon after counting is complete, thoroughly rinse out the McMaster chamber with warm running water. Doing so will keep the chamber clean and ready to be used again. If fecal solution dries in the chamber, do not soak in soapy water for long periods because this will cause the chamber to become cloudy. If the chamber gets dirty, soak for only a few minutes in water containing dish soap and then rinse completely with tap water.

somewhat tedious but can be performed by many university laboratories. A 2-kg sample of forage is gathered for submission to the laboratory. The grass is sampled by walking a V pattern across the acreage and stopping every three paces to sample grass. The samples are subsequently washed and passed through screening to isolate and identify larvae.

Necropsy Evaluation

The nature and magnitude of parasitic infections can be established by necropsy examination. Gross examination and an estimate of adult worm population in the gut lumen are often sufficient. Many worms detach from the mucosa as the carcass cools; however, the damage done by the parasites can be seen on gross or histologic examination. Occasionally it is necessary to use digestion techniques or histologic examination to document the presence of hypobiotic larvae.

Anthelmintic Use[1]

Sherrill A. Fleming

An anthelmintic is defined as an agent that acts to destroy or expel parasitic intestinal helminths. Anthelmintic drugs are used to treat animals that are suffering the adverse effects of a parasitic burden. They may also be used to prevent and minimize the economic losses associated with parasitic infection. Anthelmintics may be used on individual animals or a group of animals.

Drug Action

To use an anthelmintic properly, it is necessary to consider its mode of action, spectrum of activity, and duration of effect. The pharmacodynamics of an anthelmintic is specific for each species that is treated. Efficacy for a given drug may be defined as its ability to kill adult or larval parasites, suppress parasitic egg production, or promote the expulsion of worms from the gastrointestinal tract.

The emergence of drug-resistant strains of nematodes has necessitated the use of each class of anthelmintic to be customized to the premise where it will be used. Package inserts should be regarded as guidelines rather than gospel. Please refer to the sections on Anthelmintic Drugs and the Evaluation of Parasite Control Programs for particulars on anthelmintic performance. Readers should refer to the sections on horses, cattle, and small ruminants for more specific recommendations.

Anthelmintic Drugs (see Table 49-4)[1,2]

Avermectins and Milbemycins

The avermectins and milbemycins are macrocyclic lactones. They act by increasing the permeability of parasite cell membranes to

VetBooks.ir

chloride ions, which results in nonspastic paralysis and death of the parasite. These drugs may also act by potentiating presynaptic release of γ-aminobutyric acid (GABA), an inhibitory neurotransmitter, although this theory has been challenged.

These products have a high level and broad spectrum of activity against adult and larval nematodes. They are also effective against various ectoparasites such as mites, lice, ticks, bots, and cattle grubs; however, they are ineffective against flukes and tapeworms. These drugs suppress nematode egg production for longer than other anthelmintics. Because of its long duration of effect, moxidectin suppresses fecal egg counts and protects against reinfection for longer than ivermectin. Concern has been expressed about the environmental impact of these long-acting anthelmintics in grazing animals.

Several products have been developed for use in animals. The avermectins include ivermectin, abamectin, doramectin, and eprinomectin. The milbemycins include nemadectin and moxidectin. Oral (drench, sustained-release intraruminal device), topical (pour-on), and injectable formulations are available, depending on the drug. Ivermectin is safe to use during pregnancy, but currently it is not approved for use in lactating dairy animals or females of breeding age. Similarly, doramectin and moxidectin are not approved for use in female dairy cattle of breeding age. Eprinomectin is unique in that it has no withholding period for milk or meat, so there are no restrictions on its use in cattle. At labeled doses, moxidectin is a safe drug; however, accidental overdosage has caused neurologic signs in foals and miniature horses.

A new product that maintains extended therapeutic levels in cattle has recently been released. This product is designed to have a shortened subtherapeutic period that should lessen the selection for resistant nematodes. However, it will not help with parasites that are already resistant to this class of anthelmintic.

Benzimidazoles

The benzimidazoles (BZDs) comprise a large class of anthelmintics that interfere with parasitic carbohydrate metabolism by inhibiting the enzyme fumarate reductase. Many BZDs have been developed and marketed. They include albendazole, fenbendazole, mebendazole, oxfendazole, oxibendazole, parbendazole, ricobendazole, thiabendazole, triclabendazole, and the probenzimidazole drugs febantel and netobimin.

BZDs are widely used in horses and ruminants. In general they exhibit a high degree of safety and a broad spectrum of activity against gastrointestinal nematodes (GINs) and lungworms. Some members of this class (e.g., albendazole) are also active against liver flukes and certain cestodes in ruminants. Albendazole and netobimin can cause teratogenicity and embryo toxicity in sheep when given during early pregnancy. Fenbendazole, oxfendazole, and oxibendazole are considered to be safe for use in pregnant animals.

Resistance to BZDs has been documented in certain equine, ovine, and caprine parasites (see species-specific sections). In general a strain of parasite resistant to one BZD drug quickly develops resistant to other BZDs or pro-BZDs, a phenomenon known as *side resistance*.

Levamisole

Levamisole acts by causing neuromuscular depolarization and paralysis of the parasite. It has been widely used in ruminants to treat GINs and lungworm infections. However, levamisole resistance has become a problem in many areas. Levamisole is the only anthelmintic that has shown resistant parasites reverting to sensitivity if not used for several years. Recurrence of resistance will develop fairly rapidly with reuse of levamisole.

The dose of levamisole should be calculated carefully because toxic doses are only one to two times therapeutic doses. Signs of toxicity may mimic those of organophosphate (OP) toxicity, including muscle fasciculations around the lips and eyelids, hypersalivation, spastic movements, depression, and diarrhea. In ruminants, muzzle foam may develop after oral administration of the drug but usually disappears within a few hours after administration. In horses, transitory excitement has been seen after treatment. Levamisole is not recommended for use as an anthelmintic in horses. Concurrent administration of morantel, pyrantel, diethylcarbamazine, or OPs could enhance the toxic effects of levamisole.

Morantel and Pyrantel

The tetrahydropyrimidines morantel and pyrantel are cholinergic agonists that exert their anthelmintic effect by depolarizing neuromuscular junctions and causing irreversible paralysis of susceptible parasites. Morantel is slower in its onset of action but much more potent than pyrantel. These products are effective against many species of adult nematodes but do not appear to be active against larval stages. Pyrantel is also effective against tapeworms in horses when given at twice the recommended dose. The margin of safety is relatively wide, and there is no contraindication to use with other cholinergic drugs. However, it is recommended that morantel and pyrantel not be used concurrently and that neither be given with levamisole. Piperazine antagonizes the effects of morantel and pyrantel, so it should not be used with either of these drugs. Resistance to morantel and pyrantel has been documented in strains of *H. contortus* and in some cyathostomes (equine small strongyles).

Organophosphates

OPs block neurotransmission by inhibiting acetylcholinesterase. Various formulations of OP drugs are available for treating gastrointestinal nematodiasis. Commonly used OPs include haloxon, coumaphos, trichlorfon, and dichlorvos. Toxicity occurs with these products in a dose-related manner, so dosages should be calculated with care. In addition, the potential danger to humans administering these products should not be overlooked. Atropine is recommended in cases of overdose in livestock.

Phenothiazine

The mode of action of phenothiazine (PTH) has not been clarified; it is thought to interfere with anaerobic metabolism of nematodes. The various formulations of PTH differ in purity and particle size. The purified product (99% PTH) with small particle size (2 μm) is the most effective.

Although PTH is effective against a wide spectrum of GINs, resistant strains of parasites have emerged in several species. The drug is synergistic with piperazine; combinations of these drugs have effective activity against PTH-resistant nematodes. PTH used in combination with piperazine can be administered at a much lower dose.

PTH toxicity has been reported. Toxic reactions include corneal inflammation, abortion, ataxia, hemolytic anemia, photosensitization, and nephrotoxicity. The drug should not be administered to debilitated or anemic animals or to animals in the last month of pregnancy.

Piperazine

Piperazine salts block neuromuscular transmission, resulting in paralysis of susceptible GINs. The worms are then passively removed from the gastrointestinal tract by intestinal peristalsis. Piperazines have low toxicity and are safe in young or pregnant animals. However, their spectrum of activity is limited, in practical terms, to ascarids. Piperazine must be used with caution in horses heavily infested with ascarids because the paralyzed ascarids can cause an impaction that may culminate in bowel rupture. Diethylcarbamazine is a piperazine derivative that has been used to control lungworm infection in sheep and cattle.

Praziquantel

Praziquantel is a cesticidal drug that causes spastic paralysis, decreased glucose uptake, and disruption of the tapeworm's tegument. Although not approved for this use, praziquantel is effective for treating tapeworm infestation in horses. It has also been used to control various cestodes in small ruminants.

VetBooks.ir

Monepantel

Monepantel is a new amino-acetonitrile compound that has a unique mode of paralyzing nematodes and is intended to be used as an oral drench. This product has been released for use in New Zealand but is not available in the United States at this time. The responsible use of this drug to prevent or slow the development of resistance to this anthelmintic is crucial.

Coccidiosis in Food Animals

Lora Rickard Ballweber

Coccidiosis causes serious economic losses in a variety of food animal species. Regular infections with a mixture of species generally occur throughout the life of the animal. Infections tend to be asymptomatic and self-limiting unless management or other factors allow the abnormal concentration of oocysts in the environment or when host defenses are compromised. Kids are especially susceptible to coccidiosis and may develop chronic diarrhea as a consequence. In many production operations, coccidiosis is an annual event.

Life Cycle Coccidiosis in ruminants is caused by intracellular parasites of the genus *Eimeria.* They are strictly host specific, developing within cells at species-specific sites along the intestinal tract. The life cycle is complex, involving both sexual and asexual phases within the same host. Unsporulated oocysts are passed in the feces and subsequently sporulate (1 to 4 days under ideal conditions) in the environment to become infective. The sporulated oocysts are ingested by the host with contaminated food or water. Digestive enzymes activate the sporozoites within the oocysts, which excyst in the intestine and enter intestinal cells. The asexual phase of development, in which two or more cycles of merogony occurs, is then initiated. Asexual fission results in the production of merozoites. Mature meronts rupture (along with the host cell), releasing merozoites, which enter other cells and repeat the cycle or progress to the sexual phase of development (gamegony). In this phase, merozoites enter new cells and produce macrogametes and microgametes. Microgametes are released by cellular rupture and fertilize a macrogamete to form a zygote. A cyst wall then forms around the zygote, resulting in the next generation of oocysts. Once again the host cell ruptures, releasing oocysts into the lumen of the intestine, where they are then passed with the feces. The prepatent period is generally 1 to 4 weeks, depending on the particular species of *Eimeria.*[1-3]

Pathophysiology Most intestinal *Eimeria* develop exclusively in the intestinal epithelial cells, although a few exceptions (e.g., *Eimeria bovis*) do exist. As a result of the developmental cycle, infected host cells are destroyed. However, the degree of damage depends on the species of *Eimeria* involved, the site of infection (see later), the number of oocysts ingested, and various host factors including age, physical condition, and premunition.[1-3] If the number of oocysts ingested is low, nonimmune healthy animals may tolerate infection and show no signs of disease. However, if nonimmune animals ingest many oocysts, widespread rupture and exfoliation of intestinal cells alter gut function, allowing loss of blood, fluid, albumin, and electrolytes into the gut. Secondary bacterial invasion can also occur. Sections of sloughed intestinal mucosa and fibrin casts may be seen in the feces, which may be blood tinged.

The most pathogenic species of ruminant coccidia are those that destroy the cells of the large intestinal mucosa (*E. bovis* and *E. zuernii* in cattle; *E. crandallis* and *E. ovinoidalis* in sheep; *E. ninakohlyakimovae* and *E. caprina* in goats) or involve deeper layers of the lower small intestine (*E. christenseni* in goats). Because the ruminant small intestine is very long, providing many host epithelial cells, enormous parasite replication can occur with minimal damage. If nutrient absorption is compromised, the large intestine can compensate to a certain extent. Conversely, the rate of cell turnover in the large intestine is much lower than that in the small, it is much shorter in length, and other regions of the gut cannot compensate for its impaired function.[3]

A condition called nervous coccidiosis has been described, primarily in weaned beef cattle.[4-8] The pathophysiology of this manifestation has never been definitively established, and conflicting theories have been proposed, including copper imbalance, plasma electrolyte imbalances, a neurotoxin, and a combination of stressors in which coccidia are only one factor.[2,4,7,8]

Populations at Risk Infections with mixtures of pathogenic and nonpathogenic species of *Eimeria* occur throughout the life of most ruminants and usually do not cause clinical signs because species-specific immunity is acquired quickly and maintained by continuous reinfection. The net effect of the immune response is a reduction in clinical signs and a decrease in oocyst production.[1,3] Therefore, adults help maintain the parasite but are not usually the source of heavy environmental contamination; rather, nonimmune animals, whose infections result in excretion of massive numbers of oocysts, are primarily responsible.[1-3] Clinical coccidiosis is therefore a disease of young, nonimmune animals that ingest large numbers of sporulated oocysts from heavily contaminated environments. Conditions favoring coccidiosis include overcrowding, housing multiple age groups together, and pens that are not cleaned regularly.[3,9] Thus coccidiosis is a disease of management. Although stress, such as from shipping, weaning, dietary changes, and/or adverse weather, appears to facilitate outbreaks, the mechanisms are not fully understood.[1-3,10]

Even though reported in range animals, coccidiosis is chiefly a disease of confinement. Clinical disease usually occurs in cattle 3 weeks to 6 months of age. In dairy cattle, coccidiosis is most common in calves when they are taken from hutches into group calf pens or mini–free-stall barns. In beef cattle the disease is most prevalent in feedlot calves. In sheep, disease is usually limited to lambs younger than 6 months old. Coccidiosis is most common in intensively reared lambs, although suckling lambs on pasture in constant use at high stocking rates are also at risk. Young kids appear particularly susceptible to coccidiosis, with clinical disease especially prevalent 2 to 3 weeks after weaning.[11] Occasionally, adult animals develop coccidiosis either from impaired cellular immunity or when stressed (moved into a new herd, prolonged travel, extreme weather conditions).[2,3]

Clinical Manifestations The destruction of epithelial cells and subsequent loss of blood, albumin, fluid, and electrolytes typically cause a profuse, sometimes bloody, diarrhea. Despite the blood loss, anemia is not usually apparent. Death is usually from dehydration. Light to moderate infections in cattle may cause watery feces, poor condition, and reduced weight gain. Severe infections cause projectile, bloody diarrhea with mucus, rectal tenesmus, inappetence, dehydration, and weight loss. Clinical signs last approximately 1 week. In lambs, clinical signs are similar to those of cattle except blood and tenesmus do not usually occur. In kids, clinical signs include pasty, watery diarrhea and dehydration.[11] Sudden death can occur in both lambs and kids, but the case fatality rate is usually low in most outbreaks. After recovery from the disease the gut does not return to normal function for several weeks, and concurrent appetite suppression leads to poor growth and/or stunting.[1]

Cattle considered to have nervous coccidiosis exhibit muscle tremors, hyperesthesia, nystagmus, and seizures. Interictal periods are normal or near normal. The mortality rate is high.[2,5,6]

Control of Coccidiosis

The presence of coccidiosis depends on the prevalence of oocysts in the environment. The level of infection is directly related to the level of fecal contamination. Houses and pens used for sequential groups of young animals often become highly contaminated and serve as the source of infection for subsequent groups. Therefore minimizing exposure of susceptible animals to infective oocysts depends on

TABLE 49-5

Drugs Used for Treatment and Prevention of Coccidiosis in Ruminants

Drug	Treatment*	Prevention*
Amprolium	10 mg/kg bwt for 5 days (B) 25-40 mg/kg bwt for 5 days (O, C) 65 mg/kg bwt once (O, C)	5 mg/kg bwt for 21 days (B) 50 mg/kg bwt for 21 days (O)
Decoquinate		0.5 mg/kg bwt for 28-30 days
Diclazuril		1 mg/kg bwt once; a second dose can be given 14 days later
Lasalocid		1 mg/kg bwt continuously (B) 25-400 mg/ton feed, continuously (B, C) 80 mg/kg milk replacer (neonatal calves) Free choice in salt at 0.75% total salt mixture
Monensin	2 mg/kg bwt for 20 days (O)	1 mg/kg bwt for 28 days 10-20 ppm in feed, continuously 16-33 g/ton of feed, continuously
Nitrofurazone	15 mg/kg bwt for 5-7 days In feed at 0.04% or in water at 0.0133% for 7 days	33 mg/kg bwt for 14 days In feed at 0.04% for 21 days
Salinomycin		10 ppm in feed (O)
Sulfadimethoxine		50 mg/kg bwt for 5 days (O)
Sulfamethazine	247 mg/kg day 1, 123 mg/kg days 2-5 140 mg/kg bwt for 3 days 140 mg/kg bwt once, then 70 mg/kg bwt for 5-7 days	35 mg/kg bwt for 15 days (B) 25 mg/kg bwt for 7 days (O) 55 g/ton of feed (C)
Sulfaquinoxaline	10-20 mg/kg bwt for 5-7 days	
Toltrazuril	20 mg/kg bwt	20 mg/kg bwt once, timing depends on production system

*Oral administration; dose or regimen may vary among references.

B, Bovine; *bwt,* body weight; *C,* caprine; *O,* ovine.

Note: Coccidiostats used in poultry feeds may be toxic to ruminants.

management techniques that focus either on sanitation to avoid the buildup of environmental contamination or the elimination of environmental conditions conducive to oocyst survival or both.[2,3,9] Decreased stocking rates, proper manure disposal, elevated feed bunks, and routine cleaning of water troughs will help reduce contamination and exposure to oocysts. Sunlight and low humidity will kill oocysts, as does disinfection with formaldehyde, ammonia, or methylbromide; however, proper cleaning is a prerequisite for efficient disinfection.[1-3,9] Reduction of average barn temperature to 15° C and of humidity to a maximum of 80% was shown to decrease clinical coccidiosis.[1] Prophylactic use of coccidiostats is inevitable if conditions of animal husbandry cannot or do not improve.

DRUGS. The various drugs that have been used to prevent or treat coccidiosis in ruminants are listed in Table 49-5.[12-16] These drugs are most often administered in the feed or water. Therapeutic anticoccidials are used in acute outbreaks; particularly useful here in calves are the benzene acetonitrile compounds (diclazuril, toltazuril).[2] Scouring calves should be removed from the group, and supportive therapy, including electrolytes, glucose, and antidiarrheals, may help improve survival.[1,3,11]

Often outbreaks of coccidiosis can be predicted on the basis of farm history. Thus to prevent losses from coccidiosis, it is best to use drugs prophylactically or metaphylactically rather than therapeutically. Administration of coccidiostats during this time does not completely prevent infections but prevents clinical disease without interfering with the production of protective immunity.[1,2]

OTHER STRATEGIES FOR MINIMIZING CLINICAL INFECTIONS. No vaccine for ruminant coccidiosis exists. Immunization of calves with a "trickle dose" of oocysts before turnout onto infected pasture attenuates the effects of natural challenge[17] but is not commonly used. Use of growth implants containing estradiol and progesterone can attenuate the effects of high oocyst challenge in dairy calves but is not used for this purpose.[18] It has been reported that oocysts of *Eimeria alabamensis* may survive the hay-making process,[19] and hay from infected pastures should not be used to feed susceptible calve. However, whether all species of *Eimeria* can survive the hay-making process or how common survival is with various types of hay production is unknown.

Evaluation of Preventive Programs

Evaluation of any coccidiosis prevention plan is based on the presence and/or extent of clinical disease. Herds/flocks that require preventive strategies do so because they usually have a history of prior disease. Program efficacy, therefore, is evaluated on the basis of a decrease in prevalence of clinically ill animals.

Clinical Management

DIAGNOSIS. Diagnosis is based on history, which may include a stressful event, thorough knowledge of the herd management, and clinical signs of severe diarrhea (usually young animals). Postmortem findings of inflammation, hyperemia, and thickening of the cecum with masses of gamonts and oocysts in mucosal scrapings will be confirmatory. Because pathogenicity varies by species, fecal oocysts counts are not helpful *if the respective species are not identified.* Due to the short life cycle, oocyst counts are highest in early patency and drop quickly after about 1 week. Thus fecal samples should be collected when diarrhea first starts. Any standard fecal flotation method can be used to find oocysts.[1,3,11]

TREATMENT. Drugs used in the treatment of coccidiosis are listed in Table 49-5. Supportive therapy, when indicated, is primarily directed at replacing fluid losses and supporting the animal until the gut epithelium regenerates.

• CHAPTER 50

Nutrition of the Sick Animal

MERI STRATTON-PHELPS, *Consulting Editor*
RAYMOND W. SWEENEY

The influence of nutrition on the recuperation of veterinary patients is often overlooked, although the effects of nutritional status on recuperative ability are well known. Many patients are in a state of protein calorie malnutrition when first presented to the clinician. Early intervention with supplemental calories, protein, and other essential nutrients provides the patient with the dietary resources needed to optimize immune function, promote wound healing, and improve the recovery of the animal.

Multiple research studies have demonstrated that the immune response of an animal is directly related to the nutritional state of the animal.[1-4] A deficiency of calories, protein, minerals, or vitamins alters the production of inflammatory cytokines, adversely affects leukocyte function, and decreases host resistance to bacterial infections.[1,2] Clinical studies in hospitalized horses have demonstrated an improved recovery after gastrointestinal surgery in patients supplemented with intravenous nutrition.[5]

Different forms of diet therapy may be used, depending on the clinical condition of the animal and the ability of the animal to tolerate different types of supplemental nutrition. Enteral nutrition (EN) is the preferred method of nutrition support because it provides nutrients directly to enterocytes in a physiologically normal manner. EN can be provided to large animal patients that have a functional gastrointestinal tract and can tolerate placement of a nasogastric (NG) or esophageal feeding tube. Intravenous nutrition can be provided by adding dextrose to a patient's intravenous fluids to provide energy, or supplemental nutrients can be administered in a parenteral nutrition (PN) formulation. PN may be the only suitable long-term (longer than 4 days) nutrition support choice for animals that cannot tolerate placement of an NG tube, that do not have a functional gastrointestinal tract, or that are recumbent.

Assessment of Nutritional Status

Before initiation of dietary therapy, the large animal patient must be examined to determine its nutritional needs. Animals may be anorectic owing to systemic disease, or they may be dysphagic owing to a mechanical (foreign body, abscess, poor dentition) or neurologic (botulism, tetanus, viral encephalitis) disease. Assessment of the nutritional status of the patient should include a measurement of the body weight (BW) and body condition score (BCS) of the animal. BW measurements should be taken at the time that the large animal patient is presented to the clinician and as frequently as possible during hospitalization. If a scale is not available, estimations of BW can be made with a weight tape or by using length and girth measurements (see Chapter 9). The BCS also helps in the evaluation of the nutritional status of the patient. The BCS system enables the clinician to subjectively assess the endogenous protein and lipid stores in a large animal patient. A list of BCS descriptions for different species is provided in Chapter 9. Changes in weight or BCS are often easily overlooked in day-to-day observations of the patient if a concerted effort is not made to detect them. Palpation of the animal (ribs, dorsal vertebral processes) is necessary in sheep with a heavy fleece, camelids with long fiber, and horses with a thick winter hair coat. Animals with a low BCS (1 to 3 of 9; 1 to 1.5 of 5) have minimal protein and lipid stores and are at greater risk for developing protein calorie malnutrition after a period of anorexia. Large animal patients with a high BCS (7 to 9 of 9; 3.5 to 5 of 5) that are anorectic may have an increased risk for developing complications (hyperlipemia, hepatic lipidosis) from abnormal lipid metabolism. A clinician should initiate dietary therapy in a large animal patient that loses 3% to 5% of its initial BW or whose BCS diminishes by 1 grade or more.

Biochemical tests provide another method to evaluate the nutritional status of the large animal patient. Endogenous protein catabolism is a normal physiologic response to anorexia in animals. To date, few biochemical tests are available to assess protein malnutrition in large animals. Although anemia and hypoproteinemia (hypoalbuminemia) are occasionally seen in cases of malnutrition, they are not specific and frequently are associated with another primary disease process such as parasitism or protein-losing enteropathy. Severe protein malnutrition can result in abnormally low serum urea nitrogen (SUN) concentrations in horses and ruminants. Liver disease also decreases the formation of urea nitrogen and must be ruled out when evaluating the animal. Protein malnutrition can result in an increase in the urinary excretion of 3-methylhistidine, a myofibril amino acid that is not metabolized. Measurement of this metabolite in the future may be a useful tool to monitor protein catabolism in large animal patients.[6]

Underfed horses develop a mild hyperbilirubinemia (unconjugated) that, although not directly related to nutritional status, is readily reversed when food intake resumes.[7,8] Animals that are in negative energy balance rely on endogenous stores of lipid as an energy source. Serum non-esterified fatty acids (NEFAs) and/or triglycerides are expected to rise in these animals. Once nutritional support or refeeding is initiated, these lipid metabolites usually decrease. Pathogenic elevations in serum triglyceride (greater than 500 mg/dL) develop in some equine patients that are anorectic and that have a high daily energy requirement (lactation, pregnancy), but hypertriglyceridemia can also occur in patients with insulin resistance, renal failure, obesity, and in predisposed breeds (miniature horses, ponies). Ketone bodies have a glucose-sparing effect in the body and are normally produced from fatty acids and amino acids in animals that are in negative energy balance. Ketonuria develops after the excess production of ketones and can be used to indirectly monitor the severity of caloric malnutrition in ruminants. Hypoglycemia is a common complication in large animal neonates that are malnourished but is an uncommon finding in adults. Both adult and neonatal large animals may develop glucose intolerance and hyperglycemia during periods of systemic illness and may require

VetBooks.ir

treatment with a diet that will not exacerbate the hyperglycemia. Electrolyte and mineral derangements including hypocalcemia, hypomagnesemia, hyponatremia, hypochloremia, hypophosphatemia, and hypokalemia may develop in inappetent, systemically ill large animals or during the refeeding process.[9,10] Chronically malnourished animals must be closely monitored, and biochemical signs of the refeeding syndrome should be managed with appropriate electrolyte supplementation.

Nutrient Requirements of Large Animals during Clinical Illness

Although it is generally accepted that sick animals have increased nutritional requirements, these requirements have not been quantified for specific disease conditions. Therapeutic nutrition is designed to provide adequate caloric intake during a period of hypophagia. Both overfeeding and undernutrition should be avoided when nutritional support is offered.[11] Currently, the best estimation of energy and protein requirements for hypophagic horses and ruminants is calculated from the animal's BW (see Chapter 9) or they can be determined from the National Research Council (NRC) tables.[12] For adult horses, the resting digestible energy (DE) requirement is calculated as DE_{rest} (Mcal) = 0.975 + 0.021 BW (kg), and maintenance crude protein (CP) requirement is calculated as CP (g) = 1.26 BW (kg).[12] For a 450-kg horse, these would equate to a 10.4-Mcal resting energy requirement and a 567-g crude protein requirement. The ideal BW should be used for calculating the energy requirement of an obese animal. Protein requirements can be calculated using an obese animal's current BW as long as protein restriction is not required based on the patient's clinical disease. Indirect calorimetry provides the best estimation of a patient's resting energy requirements, but currently is only available for critically ill neonatal foals who have an estimated resting energy expenditure of 40 to 50 kcal/kg BW/day.[13,14] Older foals can be fed between 70 and 100 kcal/kg BW/day. Dietary protein for foals ranges between 2 and 5 g protein/kg BW/day. For calves, the resting energy requirement is approximated as DE (Mcal) = 0.07 BW (kg) and digestible protein as DP (g) = 3.5 BW (kg), which would equate to 3.50 Mcal (3500 kcal) and 175 g of protein for a 50-kg calf. These calculated values represent starting points for formulating dietary therapy, and adjustment based on clinical response or specific medical conditions may be necessary.

Vitamin and mineral requirements, also available from NRC tables, can usually be met if an enteral diet is formulated with commercial complete feed pellets or pelleted hay. Parenteral solutions can be supplemented with vitamins and minerals. Although B-vitamin deficiencies do not occur naturally in horses and cattle, supplementation may be beneficial in large animals with gastrointestinal diseases that result in the disruption of the normal tract flora that produce B vitamins.

Oral Supplementation

The animal's feed intake should be monitored during treatment. If the animal is losing condition despite consuming all feed offered, more or higher-quality feed should be provided. If the animal's appetite is poor, the patient should be offered a variety of highly palatable feeds, including fresh grass, dried forages, and complete commercial feed pellets. Although sweet feeds are palatable, they contain a high concentration of soluble carbohydrates (sugar, starch) and their use should be limited to a top dressing of other feeds. Ruminants in particular may consume small quantities of fresh feed if it is offered frequently, whereas if the same quantity is offered in one feeding, it may be ignored after a few bites. Many dairy cows can be coaxed into eating hay if it is placed in the back of the pharynx by the clinician, and oropharyngeal stimulation may result in increased voluntary feed consumption. Fresh silage and dried brewer's grain frequently appeal to the hypophagic cow. Many sick horses and ruminants benefit from grazing if grass is available.

A hospital feeding chart should be created to facilitate monitoring of the feed consumed by a hospitalized patient. Use of an inexpensive farm scale is the most accurate way to measure the amount of feed offered to a patient. Feed that is not consumed within a few hours should be weighed and discarded to prevent the accumulation of stale, and possibly fermented, malodorous feed. If the animal does not voluntarily consume enough feed to meet 75% of its resting energy requirements or 75% of its maintenance protein requirements, or if the animal loses weight or condition, dietary therapy with a liquid diet by intragastric administration should be considered. Dysphagic animals can also be managed with a tube-fed liquid diet as the sole source of nutrition.

Liquid Diets for Horses

Adult Horses

Enteral feeding (EF) with a liquid diet should be used in horses that require nutritional support to maintain their energy and protein intake during a short period (2 to 14 days) of partial or complete anorexia. Horses that are good candidates for EF do not have gastrointestinal ileus or gastric reflux and are able to tolerate an indwelling NG tube, repeated intubation, or an esophagostomy tube. Horses fed using EF should be standing. Diet choice will depend on product availability and nutrient requirements. Energy, protein, vitamin, and mineral requirements should be calculated for each equine patient to ensure that the appropriate concentration of nutrients is administered. Enteral diets may be administered to provide partial or complete nutrient supplementation to an adult horse.

TYPES OF ENTERAL DIETS. Liquid diets may be classified into four categories: (1) commercial equine enteral diets, (2) complete feed blender diets consisting of liquefied or finely ground whole food suspended in water, (3) composition diets containing highly digestible whole protein (usually casein or soy), fat, and carbohydrate, and (4) commercially available liquid enteral diets sold for human use. Because of the large variety of equine enteral diet options, human formulations are the least desirable choice for EF and should only be used when other diet options are not available.

Commercial equine enteral diets offer a convenient option for managing a horse that requires supplemental EN. WellSolve Well-Gel (Purina Mills, LLC, St. Louis, Mo.) and Enteral Immunonutrition Formula (Platinum Performance, Inc., Buellton, Calif.) are two diets currently available for use. Both diets are mixed with water and can be administered through a small-diameter nasogastric tube. These diets can also be fed orally while a horse is being transitioned to a regular ration. Diets should be introduced gradually and fed in multiple small meals throughout the day.

Blenderized equine commercial complete feeds or hay pellets are inexpensive ($5 to $10/day), and the ingredients are usually available at most veterinary hospitals or barns. Most products contain 14% to 25% crude fiber (dry matter [DM]) and vary in energy density from 2.6 to 3.1 Mcal/kg of diet. A list of commercial feeds that can be fed as a liquid enteral diet is provided in Table 50-1. Feeds with less than 18% non-structural carbohydrates (NSC) are preferred. Between 3.4 and 6.0 kg of diet per day is required to meet the resting energy requirements of a 450-kg horse. In some equine patients, protein supplementation may be required. If tolerated, a small volume of oil (113 to 227 mL) can also be added to increase the energy density of the diet. If a plain hay pellet is used, vitamin and mineral supplementation should be considered. This type of a diet may be prepared either by grinding one quarter to one third of the daily requirement of dry pellets in a blender and suspending the blended product in water or by soaking the pellets in water before blending to create a slurry. Each meal should be made fresh. The total amount of water that is added to the preparation should be recorded and added to the daily fluid administration log for the patient. The total daily volume of the diet should be divided into three to six meals and fed throughout the day. If only partial supplementation is required,

or if a horse is being managed in a field setting, a smaller volume can be administered twice a day. A gradual introduction to feeding a blenderized diet is important.

An ingredient-based composition diet can be designed by combining finely ground forage to provide structural carbohydrates with a concentrated source of protein. One such diet (Table 50-2) composed primarily of dehydrated cottage cheese, dextrose, and alfalfa meal requires considerable preparation by the clinician.[15] Oil (113 to 227 mL) can be added as an energy source if the horse is not hyperlipemic. The omega-3 and omega-6 content of the oil should be considered when formulating a ration to provide for the nutritional management of inflammation. Any enteral diet that contains a high concentration of oil, dextrose, or NSC should be avoided. Structural carbohydrates should comprise 50% to 75% of the diet DM. The approximate cost for complete supplementation with the homemade equine diet is $40 to $50/day for a 450-kg horse. As indicated in Table 50-2, the homemade diet is introduced gradually over a period of 7 days.

Vital HN and Osmolite HN (Ross Products Division, Abbott Laboratories, Columbus, Ohio) are human liquid enteral diets that have historically been administered to adult horses.[16,17] These diets were used before better options for EF were developed for horses, and now should only be used if no other enteral diet options are available. Abbott Laboratories produces a variety of human liquid enteral products, including formulations that contain oat and soy fiber. All human formulas contain a high percentage of calories from simple sugars and starch (greater than 50%) and should be used with caution in any horse that has laminitis or that is intolerant of soluble carbohydrates. A partial list of formulas that can be administered to adult horses is provided in Table 50-3. These products are designed for administration through a small-diameter tube and are an option for horses that can only tolerate an 18-French feeding tube (Mila NG18100, Mila International, Erlanger, Ken.). Most products contain approximately 1 kcal/mL and 4.1 to 4.2 g of protein/100 kcal. Almost 10.5 L of a human enteral product would be required to meet the stall resting energy requirement of 10.4 Mcal for a 450-kg horse, at a cost ranging from $80 to $200/day. The protein content (approximately 450 g) in 10.5 L of Osmolite or Vital HN will not meet the protein requirement of 567 g for a 450-kg horse, and supplemental protein (casein, lactalbumin, whey, soy) may need to be added to the formulation to ensure adequate protein intake. The nutrient composition and ingredient list of a human formulation should be evaluated to ensure that the horse is receiving the most appropriate product. Diets that contain a high (greater than 15%) proportion of calories as fat are contraindicated in horses with hyperlipemia and hepatic lipidosis. Any commercial human product should be fed starting at approximately 25% of the horse's resting energy requirement, with the volume gradually increased over 4 to 7 days to the target quantity.

ENTERAL DIET ADMINISTRATION. All liquid enteral diets should be gradually introduced over 3 to 7 days. The consistency of any formulation can be adjusted by blending the ingredients with water to ensure that the formulation can be delivered through the NG tube that has been selected for administration. Larger diameter NG tubes (>0.65-cm inner diameter) must be used when fiber is included in the diet. The diet should be tested using the NG tube before the tube is placed in the animal to ensure that the tube will not be clogged with the feed. The total daily enteral diet volume should be divided into three to six feedings per day and should be administered slowly enough to ensure that feed does not reflux around the NG tube. No more than 6 to 8 L of total fluid volume should be administered at one time. This volume must be appropriately lowered when treating a pony or miniature horse. Before feeding, the amount of residual fluid in the stomach should be checked. Horses with less than 2 L can be fed the meal, but if the volume of gastric fluid is greater than 2 L, the feeding should be

VetBooks.ir

*Abbott Nutrition, Abbott Laboratories, North Chicago, Ill.

delayed for 2 hours. Horses with persistent gastric reflux should not be fed enterally, and instead the clinician should consider treatment with PN. After the diet has been administered, the tube should be flushed with at least 500 mL of water before the tube is capped. Excessive distention of the stomach must be avoided. If the NG tube will remain in place between feedings, a muzzle may be used to prevent the horse from removing the tube. During treatment, horses should be offered palatable feeds to encourage a transition to voluntary food consumption. The equine patient can gradually be weaned from EF once it is consuming 75% of its DE_{rest} on a daily basis.

Horses treated with EF should be monitored with a regular physical examination and blood work (PCV, TP, serum electrolytes, glucose and serum triglyceride). Adjustments in the nutrient composition of the enteral diet can be made based on the horse's response to the diet. Liquid enteral diets may result in a mild, self-limiting diarrhea when fed as the sole source of nutrition, possibly because of lack of dietary fiber or because of fermentation of the highly soluble ingredients in the large colon.[15,16,18] This may be ameliorated by addition of a fiber source such as alfalfa meal. Horses that develop diarrhea should be evaluated to ensure the diarrhea is not associated with an infectious agent. Probiotic therapy can be considered as an adjunct therapy during EF.

Foals

Mare's milk is the ideal supplemental diet for orphan or critically ill foals. Healthy neonatal foals with normal gastrointestinal tract motility can initially be fed a volume of milk sufficient to meet 10% of BW (100 mL/kg BW) each day. Critically ill neonatal foals may need to be started at a lower volume (5% to 7.5% BW) for the first few days of nutritional therapy to ensure dietary tolerance. The volume should be incrementally increased until the foal is consuming 20% of its BW (200 mL/kg/day). If indigestion occurs despite a slow introduction to the milk replacer, both the frequency and volume of feeding should be decreased until the indigestion resolves. Neonatal foals should be offered milk every 2 hours as long as the feedings are tolerated and should be encouraged to nurse from their dams once they develop a strong suckle reflex. Foals that are 4 weeks of age or older can be fed every 3 to 4 hours, with a decreased frequency of feeding as the foal ages. A small-diameter NG feeding tube can be used for milk supplementation until the foal can nurse voluntarily. Foals have minimal endogenous energy stores and require supplemental nutrients within 6 to 12 hours of losing the ability to nurse. Any foal that cannot tolerate enteral feedings should be placed on PN to ensure that its dietary requirements are met.

If mare's milk is not available, foals can be fed 20% of their BW per day using a commercial foal milk replacer (Mare's Match [Land O' Lakes, Arden Hills, Minn.], Mare's Milk Plus [Mars Horsecare US Inc., Dalton, Ohio], or Foal Lac [Pet Ag, Hampshire, Ill.]). More information on milk replacers and colostrum supplements and substitutes can be found in Chapter 21. If a foal milk replacer is not available, goat's milk can be fed as a short-term substitute but is not recommended for long-term use because the nutrient profile is different from that of mare's milk and can result in constipation. Because indigestion often occurs when using milk substitutes in foals, dietary changes should be instituted gradually over a period of 1 to 2 days at a minimum.

Orphan foals should be fed from a pan or bucket because it forces the foal to actively ingest and swallow the milk and also decreases behavioral complications that can develop when an orphan foal is bottle-fed. Foals that are not ready to transition to bucket or pan feeding can be fed from a bottle. If a foal will be bottle-fed, the nipple should be checked to ensure that milk does not freely flow from the nipple. Improper use of a bottle can result in aspiration pneumonia if the foal does not have a normal swallow response.

Liquid Diets for Ruminants

In most cases the most practical and least expensive way to force-feed ruminants is the blender-type or slurry diet. Hypophagic adult cattle may be force-fed a suspension of alfalfa meal and dried brewer's grain (3 to 5 kg each in 20 L of water) two or three times daily. If a ruminal fistula is necessary (e.g., tetanus), the diet may be directed into the rumen. Presumably similar preparations would be suitable for sheep and goats, although published reports are scarce. Administration of ruminal liquor obtained from a healthy donor cow provides a good source of microflora as well as volatile fatty acids as an energy source in hypophagic cows.[19] Calves can be fed cow's milk or a high-quality commercial milk replacer. For more on milk replacers and colostrum substitutes, see Chapter 21.

Intravenous Nutrition

Intravenous Dextrose

The simplest and least expensive form of intravenous feeding is the supplementation of intravenous crystalloid fluids with dextrose. This represents a short-term solution for boosting caloric intake when a rapid return to normal feed consumption is anticipated. Dextrose can be added to make a final solution with a concentration that ranges from 2.5% to 10%. If the fluids are infused at a rate to meet maintenance fluid requirements (2.2 mL/kg/h), the patient's renal threshold of glucose (10 mmol/L or 180 mg/dL for adult horses; 12 mmol/L or 216 mg/dL for foals) will usually not be exceeded. The energy provided may be calculated based on 3.4 kcal/g of dextrose. A 450-kg horse treated with fluids supplemented with 2.5% dextrose and infused at a maintenance rate of 1 L/h (24 L/day) will receive 2040 kcal from the dextrose (close to 20% of the patient's DE_{rest}). Although protein is not provided with the dextrose therapy, the supplemental energy will blunt the catabolism of endogenous lipid and protein stores. Dextrose-supplemented fluids can be administered as the sole source of nutrition for 24 to 72 hours. Patients treated with dextrose should have their blood glucose monitored closely. An animal that develops hyperglycemia with a 5% dextrose solution may require treatment with a 2.5% dextrose solution. If complications with glucose regulation persist at this low dextrose concentration, alternative methods of nutritional supplementation

VetBooks.ir

should be initiated. If an equine patient on intravenous dextrose therapy is unable to consume more than 75% of its resting energy requirement and/or more than 75% of its maintenance protein requirement, supplemental nutrition should be administered.

Parenteral Nutrition

PN is a means of providing more complete intravenous nutritional support to animals that do not have a functional digestive tract or animals that cannot tolerate placement of an NG tube. Because of the greater expense (approximately $100/day for foals and $450/day for adult horses), the need for special infusion supplies, and the risk of complications when compared with enteral feeding, PN should be reserved for cases in which bowel rest is necessary. Possible indications for PN include postoperative feeding after gastrointestinal surgery, nonsurgical intestinal obstruction or ileus (proximal jejunitis, botulism), dietary supplementation in a laterally recumbent patient, neonatal diarrhea in cases in which oral feeding exacerbates the diarrhea, gastrointestinal intolerance in premature neonates, and hypoxic ischemic gastrointestinal syndrome. Because EN provides nutrients directly to the enterocytes and promotes both intestinal barrier function and immune system function, a small volume of a liquid enteral diet should be administered whenever possible in a patient receiving PN.

PN formulations are composed of dextrose and lipids as an energy source, and amino acids as a protein and nitrogen source. Compatible vitamin and mineral supplements can be added to the PN formulation. A variety of PN mixtures can be designed to meet the nutritional requirements of a clinically ill large animal patient. Sufficient calories in the PN solution must be provided in the form of carbohydrates and lipids to promote the incorporation of amino acids into protein instead of the catabolism of amino acids for energy. Glucose provides 3.4 kcal/g, amino acids provide 4 kcal/g, and lipids provide 11 kcal/g; amino acids include 0.16 g of nitrogen per gram. The ideal calorie-to-nitrogen ratio for adult horses is extrapolated from data calculated for critically ill humans, in whom the ideal ratio is 120:1 to 150:1 for healthy individuals, and 80:1 to 90:1 for acutely ill humans.[20] Animals with systemic inflammatory diseases or severe protein loss and large animal patients recovering from major surgery will probably benefit from a therapeutic enteral or parenteral diet that has a calorie-to-nitrogen ratio between 80 and 100, as long as protein supplementation is not contraindicated in the patient. Although PN solutions can be formulated with dextrose alone as the energy source, the addition of lipids provides many advantages. Because of the larger size of the molecule and higher energy density on a per-gram basis, replacement of dextrose with lipid lowers the PN osmolarity and/or infusion volume required to meet the energy needs of the patient and reduces the hyperglycemic effect of PN administration. The lipid content of the PN solution is usually targeted as approximately 50% but no more than 80% of the nonprotein calories in the formulation. Animals with hypertriglyceridemia (>500 mg/dL) or hepatic lipidosis that require PN should be treated with a formulation that is restricted in lipid, or that is lipid-free, whereas the concentration of dextrose or the PN administration rate should be restricted in animals with hyperglycemia. If long-term administration (longer than 5 days) is expected, calcium (200 mg/kg/day), phosphorus (110 mg/kg/day), and other micronutrient supplementation of the PN solution should be considered. Commercial multiple vitamin (e.g., INFUVITE, Baxter Healthcare Corporation, Deerfield, Ill.) and trace mineral (e.g., Multitrace5, American Regent, Shirley, N.Y.) supplements are available for addition to the PN mixture but may add as much as $20/day to the cost of the formulation.

All parenteral solutions must be mixed aseptically. A laminar flow hood should be used to prepare the formulation, but if this equipment is not available, the solution can be mixed in a clean room with low traffic such as a surgical instrument preparation room. Alternative options for PN compounding include human hospitals, human parenteral compounding companies, and the commercial compounding pharmacy CAPS (Central Admixture Pharmacy Services; http://www.capspharmacy.com). The formulation can be made in a 2- or 3-L all-in-one infusion bag (Vital Mix, Vygon Corporation, Lansdale, Penn.) in a sterile glass container, or in a sterilized carboy. Single-use infusion containers are preferred. Guidelines for PN compounding are listed in Box 50-1.

BOX 50-1

Instructions for Compounding a Parenteral Nutrition Solution

1. Compound the solution in a laminar flow hood, if available. Use a clean room in the hospital if a laminar flow hood is not available.
2. Clean the preparation area well, using alcohol as a final preparation on the counter.
3. Wear a gown, mask, and sterile gloves when compounding the parenteral nutrition (PN) solution.
4. Wipe off all injection sites and infusion ports with alcohol before connecting the infusion lines.
5. Use a new transfer set for each PN ingredient.
6. Add the dextrose and amino acid solution to the compounding bag or container. Mix gently.
7. Add the lipid solution *after* the dextrose and amino acid solutions have been mixed together.
8. Gently swirl the solution to mix the ingredients.
9. Add any vitamin or mineral supplements to the solution *after* the macronutrients (dextrose, amino acid, lipid) have been added. Ensure that there are no incompatibilities with the supplemental additives.
10. The PN formulation can be stored in the refrigerator for 24 hours, followed by 24 hours of storage at room temperature. Shield the solution from sunlight.

Parenteral solutions should be administered through a dedicated line in a large-diameter or central vessel (jugular, vena cava) to reduce complications from phlebitis but can be administered in a peripheral vein (lateral thoracic, cephalic) if the osmolarity of the solution is less than 900 mOsm/L. A multilumen polyurethane catheter (Arrow International Inc., Reading, Penn.) is ideal for PN infusion because one port can be reserved exclusively for PN infusion whereas the other port(s) can be used for blood sampling and medication or fluid infusion. In many settings, when this is not feasible, dual infusion ports can be added to a single-lumen Arrow catheter. Patient medications may not be compatible with the PN solutions and should be given through a separate line. If a separate line is not available, the PN line should be flushed with saline before and after administration of the medication. Potential drug incompatibilities should be discussed with a pharmacist. Electrolyte abnormalities should be managed by supplementation in a separate bag of crystalloid fluids. This allows a rapid adjustment in electrolyte therapy if the patient's condition changes without discarding the costly PN solution.

Administration of the PN solution should begin at 25% to 33% of the total infusion rate, and if the patient tolerates the PN, the rate should be gradually increased to the full rate over 12 to 36 hours. Patients will still benefit from PN at a partial infusion rate, and clinicians should not dismiss PN use if cost or metabolic intolerance necessitates provision of less than a full rate and PN formula volume. A fluid administration pump facilitates a constant rate of infusion and is an essential component of PN delivery. During PN therapy the patient should be monitored for hyperglycemia, hypertriglyceridemia, and serum electrolyte abnormalities. Hyperglycemia and hypertriglyceridemia should be managed first by reducing the rate of infusion and then by lowering the concentration of dextrose or lipid in the PN solution. If hyperglycemia is persistent, treatment with subcutaneous insulin zinc suspension (0.15 IU/kg, q12h) or regular insulin as a continuous rate infusion (0.005 to 0.01 U/kg/h) may improve glucose use and permit increased caloric intake without further hyperglycemia.[21] Similarly, heparin (40 IU/kg q12h) may be administered for a short period if hyperlipemia persists and if heparin therapy is safe for the patient. At the conclusion of therapy, PN should be gradually discontinued over 18 to 36 hours. Enteral feeding should resume as soon as possible.

Patient Information

1. Initial body weight (kg) _____ kg
2. Stall resting energy requirement: DE_{rest} (kcal/day) = 975 + 21 (BW in kg) _____ kcal
3. Maintenance energy requirement: DE_{maint} (kcal/day) = 33.3 (BW in kg) _____ kcal
4. Protein requirements: Crude protein (grams/day) = 1.26 (BW in kg) _____ g
5. Fluid requirements for maintenance: 60 mL/kg/day _____ mL

Parenteral Nutrition Formulation

6. Total kcal required/day (estimate between **2** and **3** calculated above) _____ kcal
7. Calculate volume of 10% amino acids required to meet protein requirement (from **4**)
   Protein (grams) x 1 mL/0.1 grams protein for a 10% amino acid solution _____ mL
8. Calorie contribution from 10% amino acid solution (from **7**)
   4 kcal/g protein x grams of protein in solution _____ kcal
9. Total kcal required/day (from **6**) minus total kcal provided by AA (from **8**) _____ kcal

**The caloric contribution from protein can be omitted from the following calculations, if desired.*

10. Determine amount of lipid required to meet 20-70% of the remaining energy requirements:
    10% lipid solution contains 1 kcal/mL, 20% lipid solution contains 2 kcal/mL
    Ex: If providing 50% of remaining energy requirements with 10% lipid:
    (kcal (from **9**) x 0.5) x 1 mL/1 kcal (substitute 0.5 mL/1 kcal if using 20% lipid) _____ mL

11. Calculate remaining energy requirements to be provided by 50% dextrose:
    Ex: Providing 50% of calories with dextrose: (kcal (from **9**) x 0.5) x 1 mL/1.7 kcal _____ mL

12. Add 1-2 mL of B vitamin complex/L _____ mL
13. Add up to 5 mL of trace minerals/day _____ mL
14. Determine the total volume of the PN solution (**7 + 10 + 11 + 12 + 13**) _____ mL
15. Determine the rate of PN infusion for a 24-hour period: mL (from **14**)/24 _____ mL/hour
16. Calculate the calorie:nitrogen ratio for the PN solution:
    Total kcal from PN solution (from **6**)/(total g of protein/6.25) _____
17. Calculate osmolarity of the solution:
    10% Amino acid _____ mL (from **7**) x 0.840 mOsm/mL = _____ mOsm
    10% Lipid _____ mL (from **10**) x 0.276 mOsm/mL = _____ mOsm
    50% Dextrose _____ mL (from **11**) x 2.550 mOsm/mL = _____ mOsm
    \+ _____ Total mL + _____ Total mOsm
    PN solution mOsm/L = Total mOsm/Total mL x 1000mL/L _____ mOsm/L

**An 8.5% amino acid solution with electrolytes contains 0.85 g protein/mL and 1.045-1.444 mOsm/mL.*

FIG. 50-1 Parenteral nutrition worksheet for adult horses. *PN,* Parenteral nutrition.

Parenteral Nutrition in Horses

Adult Horses

The stall resting digestible energy (DE_{rest}) and maintenance protein requirements, calculated as shown earlier, should be used as guidelines when formulating a PN solution for an adult horse. Although the exact energy requirements during a clinical illness have not been determined for the equine species, provision of enough nutrients to meet the stall resting requirements should provide the adult horse with sufficient energy to blunt the catabolic effect of anorexia and illness without the risk of hyperalimentation. Horses with a limited medical budget can be managed with a PN solution that provides a portion (33% to 66%) of the DE_{rest} energy.

The preferred way to formulate a PN solution is first to meet the calculated protein requirements of the horse with the amino acid solution and then to meet the remaining energy requirements with a combination of dextrose and lipid calories. A formula with approximately 50% of nonprotein calories as lipid and 50% as dextrose can be used for an initial formulation. The final composition of the lipid and dextrose in the PN solution can be altered to manage patients with hyperglycemia or hypertriglyceridemia. An example of a worksheet used to facilitate calculations for PN formulation for an adult horse is shown in Fig. 50-1. Alternatively, the clinician can calculate the daily requirements of dextrose, amino acids, and lipids on a dose per BW basis. The formula listed in Table 50-4 provides 2.8, 1.3, and 0.8 g of dextrose, amino acids, and lipids, respectively, per kilogram per day, providing the resting stall DE and maintenance protein requirements with a calorie:nitrogen ratio of 108:1, with 48% of nonprotein calories as lipid and an osmolarity of 1026 mOsm/L. Approximate cost is $450/day not including administration sets. If the clinician is willing to forgo the benefits of lipid inclusion, the lipid component in Table 50-4 can be replaced with an additional 2.8 g/kg/day of dextrose, at a savings of nearly $200/day.

Commercially pre-prepared formulas that contain varying concentrations of amino acid and dextrose (e.g., Clinimix, 5% amino acid in 25% dextrose [Baxter Healthcare Corporation, Deerfield, Ill.]) serve as a convenient alternative to PN therapy because the formulations do not require special preparation. Clinicians can also add 50% dextrose (1.7 kcal/mL) and an amino acid solution (0.35 kcal/mL for a 10% amino acid mixture) to a bag of crystalloid fluids to provide energy and amino acids in a formulation that is less costly than a full PN solution. The final osmolarity of any PN formulation ideally

TABLE 50-4

Parenteral Nutrition Formulation for Adult Horses

Ingredient	Dosage Rate	Volume per Day (450-kg horse)
50% Dextrose	2.8 g/kg/day	2500 mL
10% Amino acids*	1.3 g/kg/day	6000 mL
10% Lipid†	0.8 g/kg/day	3500 mL

Begin administration at 0.3 mL/kg/h and gradually increase to target of 1.1 mL/kg/h (12 L/day for a 450-kg horse).

*Available as FreAmine III, B. Braun Medical Inc., Bethlehem, Penn., and Travasol, Baxter Healthcare Corporation, Deerfield, Ill.

†Available as Liposyn III, Hospira, Inc., Lake Forest, Ill.; 20% and 30% formulations available as Intralipid, Baxter Healthcare Corporation, Deerfield, Ill.

TABLE 50-5

Parenteral Nutrition Formulation for Foals (50 kg)

Ingredient	Dosage Rate	Volume/Day (50-kg Foal)
50% Dextrose	8.7 g/kg/day	870 mL
10% Amino acids	3.0 g/kg/day	1500 mL
10% Lipid	1 g/kg/day	500 mL

Formula provides 0.87 kcal/mL. Begin administration at 0.7 mL/kg/h and gradually increase to target of 2.4 mL/kg/h (2870 mL/day for a 50-kg foal).

should be less than 1200 mOsm/L for administration in a jugular vein and 600 to 900 mOsm/L if administered in a peripheral vein.

Foals

The nutrient density of a foal PN recipe should be evaluated before the formula is blended. Many older formulas may provide excess calories, which could be detrimental, especially in a critically ill neonate. The initial target energy intake for a critically ill neonatal foal is 40 to 50 kcal/kg/day. Hypertriglyceridemia (greater than 200 mg/dL) has been associated with higher mortality in neonatal foals.[22] To limit complications, lipid calories should comprise less than 50% of the non-protein calories in a PN formulation. A conservative lipid dose is 1 g lipid/kg BW/day. The PN formula in Table 50-5 is designed to provide 8.7, 3.0, and 1 g of dextrose, amino acid, and lipid, respectively, per kilogram BW per day, a total energy of 50 kcal/kg BW/day, a calorie : nitrogen ratio of 104 : 1, and an osmolarity of 1260 mOsm/L. The PN formulation contains 21% calories from protein, 20% calories from lipid, and 59% calories from dextrose with lipid comprising 25% of the nonprotein calories. If the foal tolerates the full infusion rate, additional calories can be added from all ingredients, to achieve a recipe that provides 70 to 100 kcal/kg BW/day. An anabolic state can be achieved solely with PN therapy, but because enteral feeding is the desired goal, EN or oral milk consumption should begin as soon as possible. Changes in the rate of infusion and in the PN formulation should be made to prevent hyperglycemia, but insulin can be administered if necessary to maintain blood glucose in a normal range.

Parenteral Nutrition in Ruminants

Because of cost, use of PN is usually limited to calves, and little information exists on the use of PN in the adult bovine or the ovine and caprine species. The most common indication for the use of PN in calves is diarrhea, particularly in chronic cases accompanied by weight loss.[23] In such cases, if sufficient milk is fed to meet the calf's nutritional needs, the diarrhea is exacerbated, and PN allows the quantity of milk to be reduced without compromising the nutritional status of the patient. The PN regimen provided for foals in Table 50-5 would also be suitable for calves. However, because amino acids and lipids are the most expensive components of PN, a modified formula based on a 10 : 2 : 1 glucose : amino acid : lipid ratio has been used with success.[23] For a 50-kg calf, this would result in administration of 1 L of 50% dextrose, 1 L of 10% amino acids, and 500 mL of 10% lipids daily, at an approximate cost of $60 per day. Eliminating the lipid emulsion from the formula is an acceptable alternative that will reduce the cost by approximately 15%. A multiple B-vitamin product may be added to the formula (approximately 1 mL of supplement per liter of PN), but trace minerals are not usually necessary for the short-term administration that is most common in calves.

Catheter-related complications are rare in calves, and a central venous catheter, although preferred, is not required. The author (RWS) has had success with 16-gauge, 3¼-inch, Teflon-coated, over-the-needle catheters available from several distributors. These are placed in the jugular vein, sutured or glued to the overlying skin, and left in place for up to 10 days if no signs of phlebitis or sepsis occur.

Special Diets

Numerous diseases require specific alterations in the macronutrient and micronutrient balance in the therapeutic ration because of metabolic disturbances that accompany these conditions. Recommendations are discussed in the individual chapters dealing with these diseases and include alterations in dietary protein for hepatic disease and restrictions in the protein and calcium content of the diet for horses with chronic renal failure. A nutritionist can develop therapeutic enteral and parenteral formulations to meet the unique nutritional requirements of individual patients.

Genetic Disorders

ANGELA M. HUGHES and KARI J. EKENSTEDT, *Consulting Editors*

VetBooks.ir

Inherited diseases and congenital defects are structural or functional abnormalities that may or may not be obvious at birth. There are a wide range of possible defects, from a single structural change (e.g., leg length) to the involvement of multiple organs or systems (e.g., storage diseases, chromosomal abnormalities), depending on the type and extent of toxic exposure during gestation or genetic mutation. It is important to identify animals with genetic or congenital disorders because of the economic and emotional impact on clients, but many disorders can be difficult to recognize and trace, particularly if they lead to embryonic or fetal death, abortion, dysmaturity, premature birth, or full-term stillbirth.

It is important to remember that not all congenital defects are genetic in origin and making the distinction between conditions caused by an environmental factor and a genetic cause will help clients make appropriate changes to prevent the disorder in the future. To determine the cause of a disorder, it is vital that each case be examined thoroughly. Each case should be subjected to a full, careful description of the disorder, including a complete necropsy. The environment and management conditions should be investigated for potential causative agents, and all available genetic information for the affected animal(s) and unaffected herdmates should be collected, including sex, birth date, and breed. Environmental teratogens affecting large animals include toxic plants, drugs, viruses, and physical agents (e.g., hyperthermia, irradiation). Although it may be difficult to identify inciting teratogens, analysis of affected herds will reveal patterns that follow seasonal or management changes or stressful events.

This chapter focuses on the essential genetic information that veterinarians require to inform their clients about genetic diseases and how to find information on diseases and traits with a genetic component.

Genetic Information

The basic blueprint for life in most organisms, the genetic material, is deoxyribonucleic acid (DNA). DNA is composed of two strands of *nucleotides:* adenine (A), thymine (T), guanine (G), and cytosine (C). These nucleotides, or bases, align to form complementary pairings such that A always pairs with T and G always pairs with C. These strands can be completely separated and replicated in preparation for cellular division. Alternatively, they can be partially separated temporarily, transcribed into ribonucleic acid (RNA), and translated into functional proteins.

The DNA sequence of a mammalian genome is divided into autosomes and a pair of sex chromosomes, X and Y. Each chromosome contains a variety of genes as well as "filler" DNA that does not code for proteins, but may determine where and to what degree each gene is expressed. Genes on each chromosome code for the various structural and enzymatic proteins required for life. One set of chromosomes, and thus one set of genes, is inherited from each parent. As a result, a mammal generally has two copies, or alleles, of any given gene. Simple traits or diseases involving these genes can be inherited in dominant or recessive patterns and involve the autosomes or sex chromosomes. Unfortunately, not all traits or inherited diseases are simple; many involve multiple genes and interactions between genes and the environment, which can make it difficult to diagnose and understand a complex disease or trait.

Recessive Inheritance

Traits or diseases with a recessive mode of inheritance require two affected alleles of the gene to express that trait or disease. These conditions can be *autosomal,* involving genes on the autosomes, or *sex-linked,* caused by genes on either the X or Y chromosome. Generally, autosomal recessive traits or diseases are caused by loss-of-function mutations in which the gene product has decreased ability or no ability to perform its original function. When an animal inherits the affected allele from both parents, it is *homozygous* for the gene and is unable to make functional copies of that specific protein. *Heterozygous* individuals inherit only one copy of the affected allele and they have a "backup" copy of the normal or wild-type allele to provide the functional protein. These heterozygous individuals are carriers of the trait or disease allele and can produce affected offspring if bred to another heterozygous or homozygous affected individual.

The hallmarks of autosomal recessive traits include that all offspring of two affected parents are affected and that approximately equal numbers of males and females are affected. Unaffected carrier parents can produce affected offspring, and thus the trait or disease can skip generations. In addition, mating an affected individual to a noncarrier (homozygous normal) produces all offspring that appear normal but carry the affected allele. Breeding two carrier individuals results in approximately 25% normal, 50% carrier, and 25% affected offspring.

An example of an autosomal recessive trait is spider lamb syndrome, or hereditary chondrodysplasia. Lambs affected with this syndrome display several skeletal abnormalities, including disproportionately long "spider" legs, curvature of the spine, facial deformities, rib and sternum deformities, lack of body fat, and muscular atrophy. The causative mutation is a single base-pair substitution, from a T to an A, altering a highly conserved amino acid in the fibroblast growth factor receptor 3 (FGFR-3) gene. This prevents the receptor from functioning to limit endochondral ossification and thus bone growth.[1]

Dominant Inheritance

Traits or diseases with a dominant mode of inheritance only require one affected allele to express the trait or disease, also known as the affected *phenotype,* and there is no distinguishable difference in the affected phenotype of a heterozygote and homozygote. Again, the genes that are responsible for these traits or diseases can be on the

VetBooks.ir

autosomes or sex chromosomes. Dominant traits or diseases may be caused by gain-of-function mutations that enable the mutant protein to have an altered structure or function. Alternatively, a single, functional copy of a gene may not be enough to achieve normal levels of function ("haploinsufficient"), resulting in the need for two normal copies of the gene to achieve a normal phenotype.

The main feature of an autosomal dominant trait or disorder is that affected individuals must have at least one affected parent (unless it is a new mutation), and thus the disorder does not skip generations. There is no sex bias with an autosomal dominant trait, and approximately half the offspring of a heterozygous affected individual bred to a normal individual will be affected. Breeding two heterozygous affected individuals will result in 75% affected (one third of which are homozygous and two thirds of which are heterozygous) and 25% normal offspring.

An example of an autosomal dominant disease is myotonia in goats. When startled or making sudden, forceful movements, these goats can develop severe, acute muscle stiffness causing immobility and sometimes falling over, resulting in descriptions such as "fainting," "nervous," "stiff-legged," or "epileptic" goats. A single nucleotide change, from a G to a C, was identified that substituted a proline amino acid for a conserved alanine in a chloride channel in the muscle fibers. This alteration in the chloride channel causes a diminished channel-open probability at voltages near the resting membrane potential of skeletal muscle, resulting in decreased chloride conductance and a significantly decreased electrical threshold for firing action potentials. Ultimately, this altered chloride channel allows conduction of repetitive impulses that result in sustained muscle fiber contraction and stiffness.[2]

Co-dominant Inheritance

The co-dominant (or semi-dominant) pattern of inheritance is distinguished by the fact that homozygotes can be differentiated from heterozygotes based on clinical features. A well-known example of a co-dominant disease is hyperkalemic periodic paralysis (HYPP) in Quarter Horses. In HYPP the voltage-gated sodium channels in the muscle fibers have a mutation that increases sodium permeability across the skeletal muscle cell membrane. This causes increased muscle mass, but also drooling, prolapse of the nictitating membrane ("third eyelid"), respiratory stridor, and weakness. Homozygous HYPP horses experience more frequent and severe clinical signs of disease than heterozygous horses.[3] Thus, it is important to counsel breeders to avoid producing homozygous affected horses by not mating two heterozygous horses, since approximately 25% of their offspring would be expected to be homozygous affected and 50% would be heterozygous, while only 25% would be homozygous normal. Breeding a heterozygous horse to an unaffected horse will also result in approximately 50% of the offspring being heterozygous with no possibility of producing a homozygous affected foal.

Sex-Linked Traits

Sex-linked traits and diseases involve genes located on either the X or the Y chromosome. Males have only one copy each of the X and Y chromosomes, so they are *hemizygous*. As a result, males are particularly susceptible to sex-linked conditions because if they have a mutant allele for one of the genes on either of the sex chromosomes, they lack a "backup" copy of the normal allele and will express the affected phenotype. Females generally are less likely to demonstrate sex-linked recessive traits or diseases because they have two copies of the X chromosome. However, because of random X inactivation in each cell during fetal development, some females may express an affected phenotype. To achieve this, the X inactivation must be skewed such that the unaffected chromosome is inactivated more often than the X chromosome carrying the affected allele. In rare cases in which the inactivation is significantly skewed, females may be mildly to severely affected, depending on the level of expression for the affected chromosome.

Key characteristics of X-linked recessive traits are that the trait appears with much greater frequency in males than females, half the sons of carrier females will be affected, half the daughters of carrier females will be carriers, and all of the daughters of affected males will be carriers. Hemophilia A, characterized by a strong tendency to bleed resulting from mutations in the clotting factor VIII gene on the X chromosome, is an example of an X-linked recessive disorder.

X-linked dominant traits are characterized by the following: affected offspring must have at least one affected parent, the disorder does not skip generations, and an affected male mated to normal females will transmit the mutation to all his daughters but not to his sons.

Very few Y-linked diseases are recognized in any mammalian species because of the small number of genes on the Y chromosome. In addition, the majority of the genes contained on the Y chromosome are involved in male fertility; thus, mutations in these genes generally render the animal sterile, resulting in no transmission of the mutations to future generations.

Polygenic Traits

In addition to the single-gene traits and diseases, numerous conditions are the result of two or more genes and may also involve genetic and environmental interactions. Some of these polygenic traits are economically important, such as milk quality and yield in dairy cows. For milk quality, a large number of genes may be contributing a small portion to the overall milk production of an animal.[4] In beef cattle, at least eight genes have been significantly associated with stature, and thus the physiology of growth.[5]

Now that most of our major large animal species have had their genomes sequenced, cattle and sheep livestock associations and producers are increasingly using whole-genome approaches for genetic evaluation, in an effort to tackle polygenic traits, as well as overall genetic value. For example, dairy cattle geneticists are now using single nucleotide polymorphism (SNP) markers spanning the entire genome, combined with progeny test data, in order to predict genetic merit for polygenic traits for any animal. This can be done prior to the animal's producing any offspring. The swine industry is also rapidly moving toward use of genome-wide data; however, much of these data are proprietary to specific corporations, so they may be difficult to access.

Teasing out the details of a complex polygenic system, such as assigning a specific gene and a measure of its contribution to a polygenic trait like milk production, is difficult; however, research is ongoing to identify the exact genes involved and the role each gene plays for many economically important traits and diseases. It is anticipated that our understanding of polygenic traits in large animals will increase sharply in the next few years.

Penetrance and Expressivity

For many simple traits, there is an obvious difference between the two phenotypes that can be translated to the alleles involved, or *genotype,* with 100% certainty. A good example of this is albinism, which is considered to be 100% penetrant, with *penetrance* defined as the percentage of individuals within a given genotype who actually show the phenotype associated with that genotype. Influences such as modifying genes or environmental interactions can alter the expression of certain genes such that the exact genotype is not expressed in the outward phenotype. Alternatively, the function of a gene may be subtle, making it difficult to measure distinctions adequately between genotypes. Genotypes that may not be expressed in every individual are considered to be "incompletely penetrant."

Another measure of genetic expression is the concept of *expressivity*. Modifier genes and environmental influences can affect the degree to which a genotype is expressed. For example, "variable expressivity" may be involved in pigment intensity when two individuals have the same genotype at the gene responsible for red pigmentation, but one has clearly darker red hairs than the other.

Incomplete penetrance and variable expressivity can greatly complicate analysis of genetic traits and diseases. These factors can also make breeding decisions more difficult because it may not be possible to classify an animal's genotype based solely on a phenotype. In these

VetBooks.ir

more ambiguous cases, genetic testing will play a vital role in the unequivocal determination of genotypes, allowing appropriate and informed breeding decisions.

Chromosomal Abnormalities

Occasionally, problems arise during mitosis, meiosis, or fertilization, resulting in chromosomal, or *karyotype,* abnormalities such as a chromosome missing from a pair *(monosomy)* or an extra chromosome *(trisomy).* Many karyotypic abnormalities have been identified in all large animal species, but not every chromosomal abnormality has been associated with an overt disease phenotype.[6,7] Some examples of common chromosomal abnormalities include the absence of an X chromosome, called *XO Turner syndrome,* which results in female infertility. An additional X chromosome in XXY Klinefelter syndrome causes underdeveloped males with underdeveloped male sexual behavior. In addition to abnormal numbers of sex chromosomes, rare trisomies of autosomal chromosomes have been observed in mammals; however, monosomies of autosomes are generally not compatible with life in mammals. An additional chromosomal abnormality can occur when two chromosomes unite into a single large chromosome, called a *Robertsonian translocation,* leading to reduced reproductive capacity in some species and early embryonic death in cattle. Because of possible chromosomal abnormalities, several countries have instituted mandatory karyotype examination of some breeding cattle. In addition, clinicians should consider karyotyping any animal that presents for reduced fertility or has multiple abnormalities.

Breeding Schemes

As a result of numerous advances in the field of genetics, the genetic causes of many diseases and traits are known and can be tested before using an animal in a breeding program. As research continues, more DNA-based tests are expected; however, clients may be interested in testing for a disease or trait that does not yet have a known genetic cause. For these situations, sires can be tested using breeding trials, as described in Table 51-1. For example, if a sire is bred to carrier females for a disease of concern, he would have to produce 10 normal offspring to ascertain that he is not a carrier with 95% confidence, 16 normal offspring to have 99% confidence, and 24 normal offspring to have 99.9% confidence that he is not a carrier for the disease of concern. The time required to complete test mating can be significantly shortened using superovulated affected females, insemination, and embryo transfer (two per recipient) followed by early cesarean section at 60 days and examination of the offspring for the genetic defect(s) of concern.

It has historically been common practice for artificial insemination (AI) studs to conduct such test matings for recessive genetic diseases. However, now that many of the deleterious mutations are known, genetic testing, rather than test mating, is the current preferred approach. As mentioned previously, the dairy and beef cattle, swine, and sheep industries are aggressively pursuing whole-genome genetic testing, often in combination with offspring data. Test matings are thus largely relegated to the arena of historical interest, although there may be unique situations or other species in which a test mating may still be a legitimate approach.

Positive and Negative Selection

Breeders can improve their breeding stock by selecting for or against specific traits and diseases. These processes are known as *positive* and *negative selection,* respectively. A breeder may choose to breed an animal because it has desirable genes or qualities (positive selection). Alternatively, they may choose not to breed an animal that has been shown, either through genetic or breeding tests, to carry an undesirable trait or disease (negative selection). Ultimately, both scenarios will achieve the goal of improved breeding stock.

Recommendations for Breeding Programs

When a genetic disease has been identified, it is recommended that parentage be verified by DNA analysis and the extended pedigree be confirmed. In addition, a pathologist should make appropriate examinations of tissues for an accurate diagnosis, and a certified statement detailing the condition should be written by a veterinarian or other third-party witness. The final decision with regard to the status of a particular animal should be withheld until all reasonable doubt has been removed; for bulls, this is usually at least two thoroughly documented cases or a positive genetic test, if available. The AI organization and breed registry should be informed of the status of each animal because disease information is important in future breeding decisions. Many AI organizations list any undesirable recessive alleles in their advertising, and some also remove carrier animals from service.

Depending on the value of the animal in question, a breeder may choose to remove the animal from the breeding program at the first sign of a potential genetic problem. In these cases, documentation of the abnormal conditions should still be conducted for completeness and for comparison with other cases that may be found in the future.

Caution should be exercised before drastic changes are made in breeding populations. Inbreeding and extreme narrowing of the gene pool, such as by excessive use of a small number of sires, are results that should be avoided. Maintaining diversity in the herd and overall breeding population is important in order to avoid inbreeding depression and the increase of recessive diseases. In some industries, such as swine, where crossbreeding is very common, this is less of a concern. In other industries, such as dairy, producers are increasing their utilization of cross-breeding over and above the historical standard. Most commercial AI studs and/or breed association mating programs in the dairy industry are now designed with an option to limit inbreeding, typically accomplished with simple pedigree analysis; however, the producer must choose to apply that option. Breed associations may eventually need to intervene by actively soliciting and providing incentives for outbred animals. Producers, as well as the commercial stud owners, must carefully balance the short-term gains that may come from inbreeding with the long-term consequences of the overall narrowing of the gene pool.

Obtaining Genetic Information

Because of the ever-increasing wealth of genetic information, the most complete and current information can be found using online resources. It is recommended that clinicians use websites produced by reputable institutions to obtain the most accurate and referenced information available (Box 51-1).

Alternatively, clinicians are encouraged to contact the Veterinary Genetics services available at many veterinary schools if they are unable to locate the information they require.

References

The reference list can be found on the companion website at www.largeanimalinternalmedicine.com.

• CHAPTER 52

Genetic Tests for Large Animals

DANIKA L. BANNASCH, *Consulting Editor*
CARRIE J. FINNO

Genetic testing based on deoxyribonucleic acid (DNA) involves the analysis of an animal's DNA to determine the individual's genotype for an inherited disorder, trait, or anonymous marker. Genetic testing can be used for positive or negative selection in a population, depending on whether it is being used to identify a disease (negative) or a trait (positive). Genetic testing can also be used for permanent individual identification and parentage determination. Many breed registries require parentage verification to ensure the accuracy of their pedigrees.

Using genetic testing results for selection requires an understanding of the mode of inheritance of the disease or trait. Most often, a genetic test will be performed for a recessive disorder to determine if an animal is a carrier. Carriers are asymptomatic but have the potential to produce diseased progeny. Because they have no outward manifestation of disease, a genetic test is extremely valuable for managing their breeding appropriately. Carrier animals can be bred to noncarriers if needed to retain valuable characteristics while not producing diseased offspring. In the case of positive selection for a trait of interest, carrier animals may have higher breeding values because they can produce a trait if bred to other carriers or to animals with the trait. Genetic tests may also be used for dominant disorders if the disease/trait has a late age of onset or if it is inherited in a co-dominant manner. DNA testing for traits that are controlled by more than one locus (polygenic) may also be used for selection for economically important traits. In these cases, one particular genotype may confer a slight advantage over another and therefore, in a large population, can have a significant effect on production. Box 52-1 defines key genetic terms; see also Chapter 51.

Individual Identification and Parentage Testing

Researchers use genetic markers distributed along all the chromosomes as tools to identify regions associated with diseases or traits. The markers are composed of small nucleotide repeats and are called *microsatellite* markers or *short tandem repeats* (STRs). These markers have a feature that makes them extremely useful to geneticists; the markers have been chosen to be "polymorphic" (show differences) between individuals. In other words, individual animals will have different lengths of the nucleotide repeats for each of these markers. The high level of polymorphism of this type of marker makes them useful for "mapping" (identifying the chromosomal location of diseases and traits).

The microsatellite markers are assayed by polymerase chain reaction (PCR) amplification using fluorescent-labeled primers. Primers are short (20 base pairs), single-strand lengths of DNA that are complementary to a specific region of the genome. PCR is the amplification of a section of DNA contained between two primers designed to complement the unique sequence flanking the STR. The PCR products are then resolved by electrophoresis based on their length. Figure 52-1 shows a single microsatellite marker in three different animals. This marker is polymorphic and would be a useful marker for individual identification or parentage. Because the markers show differences between individuals, a collection of these markers can be used as a form of identification of an animal. High statistical significance can be obtained with as few as 10 markers, depending on the species and breed. The DNA type of an animal will not change over its lifetime and can therefore be used as a form of permanent identification.

Many purebred registries require parentage verification for registration purposes. To accomplish parentage verification, a DNA sample must be available from both parents as well as the offspring. DNA samples are taken in the form of hair, blood, or buccal swabs (depending on the species and registry) and submitted at the time registration is requested. Each animal inherits one copy of each marker from its sire and one copy from its dam, so the markers can also be used to verify parentage. The most useful marker has a high polymorphism rate because that type of marker will be most likely to show differences not only between the sire and the dam, but also between the two copies (alleles) of the marker. A set of polymorphic markers (10 to 20) is used to verify parentage to ensure a high probability that the parentage is correct. Table 52-1 shows the allele sizes for a set of markers in a parentage case. For marker *A* the offspring inherited a 122 and a 126 allele. The 122 came from its dam, so the 126 came from the sire. Because sire 1 does not have a 126 allele, it has been excluded. In this example, sire 1 is excluded as the sire of the offspring, and sire 2 is verified on the basis of the results for all three markers.

Genome Maps

Early attempts to construct whole-genome maps of large animal species were based on two technologies that had been used to construct the first human genome maps: somatic cell genetics and in situ hybridization. This technology involved using labeled complementary DNA or RNA strands (i.e., probes) to localize a specific DNA or RNA sequence in somatic cells. Initial mapped markers were generally genes, or gene products, highly conserved across mammalian genomes. These markers, defined as syntenic (genes on the same chromosome but not necessarily linked) and cytogenic locations, were determined through sequences hybridizing specific DNA probes. Therefore, the first "genome maps" were defined as synteny groups: genes on the same chromosome defined by gene products that segregated in hybrid somatic cell lines. Synteny groups were developed for cattle, horses, and sheep. The next stage of mapping required the use of highly polymorphic markers, including microsatellites, within families of animals to create linkage maps. Collaborative efforts between researchers interested in large animal genomics were required to create these linkage maps for cattle, horses, sheep, and goats (Table 52-2). Radiation hybrid (RH) maps, which used x-ray breakage of chromosomes to determine the distances between DNA markers, followed. These RH maps allowed for the incorporation of genetic (i.e., linkage) and physical maps. The first RH maps

BOX 52-1

Definitions of Genetic Terms

Allele: One of the variant forms of a gene at a particular locus, or location, on a chromosome.
Base pairs: Two bases that form a "rung of the DNA ladder." A DNA nucleotide is made of a molecule of sugar, a molecule of phosphoric acid, and a molecule called a "base." The bases are the "letters" that spell out the genetic code. In DNA the code letters are A, T, G, and C, which stand for the chemicals adenine, thymine, guanine, and cytosine, respectively.
Genotype: Genetic makeup, either at a single locus or at all loci.
Genome-wide association study: A study that uses genome-wide markers, typically microsatellites or single nucleotide polymorphisms (SNPs) to determine an association between a phenotype and region of a particular chromosome.
Linked: Association of genes and markers that lie near each other on a chromosome; linked genes and markers tend to be inherited together.
Locus: Place on a chromosome where a specific gene is located; a type of "address" for the gene.
Marker: Segment of DNA with an identifiable physical location on a chromosome, the inheritance of which can be followed. A marker can be a gene or some section of DNA with no known function. Also known as a *genetic marker.*
Microsatellite: Repetitive stretches of short sequences of DNA used as genetic markers to track inheritance in families.
Phenotype: Observable traits or characteristics of an animal (e.g., coat color, weight, presence or absence of a disease).
Radiation hybrid mapping: A technique for mapping mammalian chromosomes that uses x-ray breakage of chromosomes to determine distance between DNA markers and their respective order on the chromosome.
Recombination: Genetic transmission process by which the combinations of alleles observed at different loci in two parental individuals become shuffled in offspring individuals.
Single nucleotide polymorphism (SNP): Differences in a single base pair of DNA (A,C,T,G) often used as genetic markers for linkage and association studies.
Splicing: Ribonucleic acid splicing removes introns and joins exons in a primary transcript.

involved only specific chromosomes, but later generations included whole genome RH and comparative maps. The isolation of bacterial artificial chromosome (BAC) clones for a large assortment of loci in the various large animal species was instrumental in facilitating chromosomal locations for these loci. In the horse, a complete physical BAC contig map of the entire genome was developed.

Whole genome sequencing and genome assembly of large animal species was completed in the early 2000s (horse, September 2007; cow, October 2011; sheep, August 2012; goat, December 2012). In the horse, a Thoroughbred mare (Twilight) was selected for sequencing because of her low heterozygosity rate (1/1380 base pairs). In 2010, a Quarter Horse mare underwent whole genome sequencing and was aligned to Twilight.[1] In cattle, a single partially inbred Hereford cow was selected to contribute 6x whole-genome shotgun (WGS) reads and another 1.5x came from individual animals of the Holstein, Angus, Jersey, Limousin, Brahman, and Norwegian Red breeds for detection of single nucleotide polymorphisms (SNPs). Following sequencing of each species, over 20,000 protein-coding genes were annotated on the sequences by virtue of previously sequenced cDNAs as well as by prediction software that compare known genome sequences in other species with newly sequenced genomes. These annotated genome databases are publicly available (see Table 52-2).

With the advent of whole genome sequencing and assemblies, there has been a rapid expansion in the number of SNPs discovered in the genomes of large animal species. SNPs are now considered the next generation of markers to conduct breed diversity and to map disease-causing traits. The availability of such a tool as an SNP-chip facilitates rapid mapping of diseases to specific chromosomal regions and analysis of candidate genes. SNP arrays are currently available on many large animal species (see Table 52-2) and are currently being used in mapping studies of various complex disorders. Haplotype structures are being identified across species with targeted resequencing and, most recently, whole genome next-generation sequencing, of animals from different breeds.

In addition to genomic mapping, functional genomic tools have become more readily available and affordable to researchers. Expression arrays have been designed in the horse, cow, and sheep (see Table 52-2). Most recently, sequencing of the transcriptome, through technologies such as RNA sequencing (RNA-seq), has allowed researchers to evaluate gene expression differences among tissues and between animals of different disease states.

Identifying Genetic Mutations

Initial genetic mutations in large animal species were discovered through the use of comparative genomics. Genes involved in a specific disease were targeted because of equivalent diseases in other species, namely humans. In the horse (Table 52-3), the genetic mutations for many diseases that have genetic tests currently available, including hyperkalemic periodic paralysis (HYPP)[2] and severe combined immunodeficiency (SCID),[3] were uncovered by evaluating candidate genes that had been associated with similar diseases in humans. With the sequencing and annotation of whole genome maps, other diseases were discovered through whole genome linkage mapping (hereditary equine regional dermal asthenia [HERDA][4]), genome-wide association studies with microsatellites (type I polysaccharide storage myopathy [PSSM][5]) and genome-wide association studies using SNP array technology (Lavender foal syndrome[6]).

A similar theme is evident in cattle. Initial genetic mutations were discovered based on sequencing of candidate genes known to cause similar disease in humans (bovine leukocyte adhesion deficiency [BLAD][7]). Later studies used microsatellite markers and performed linkage analysis (complex vertebral malformation[8]) and, most recently, the use of SNP-based genome-wide association studies has identified recessive defects (congenital muscular dystony types 1 and 2[9]). At the time of publication, there are 90 genetic tests available in cattle (Table 52-4). It is worth noting that the majority of genetic tests currently available are for diseases/traits that are inherited as autosomal recessive traits. With the current technologies available through SNP-association mapping and next-generation sequencing, we should expect to further our understanding of polygenic traits and diseases.

Disease Testing

Clinicians can use DNA testing in disease diagnosis or to determine an animal's potential for producing diseased progeny. Generally, disease diagnosis is based on clinical signs and other diagnostic tests, but occasionally DNA testing is used, in particular for later-onset diseases or diseases for which diagnosis by traditional methods is difficult or invasive. To offer a genetic test, the gene responsible must be known. Ideally, the actual mutation that causes the disease has been identified. Rather than knowing the exact gene or mutation, only a region of a chromosome may have been implicated in a particular disease. DNA tests can be divided into two categories: mutation tests and linked-marker or haplotype tests. *Mutation* tests are based on an actual mutation that causes disease, whereas the *linked-marker* or *haplotype* test is based on the region of the chromosome that is known to cause disease, but not necessarily the actual mutation. Usually, haplotype tests are offered instead of a mutation test because the mutation has not yet been identified.

Mutations that cause disease appear in many different forms. A change of a single base pair from one base to another can cause a disease either by changing an amino acid ("missense" mutation), truncating the amino acid chain ("nonsense" mutation), or altering expression or proper splicing. For example, missense mutations have

VetBooks.ir

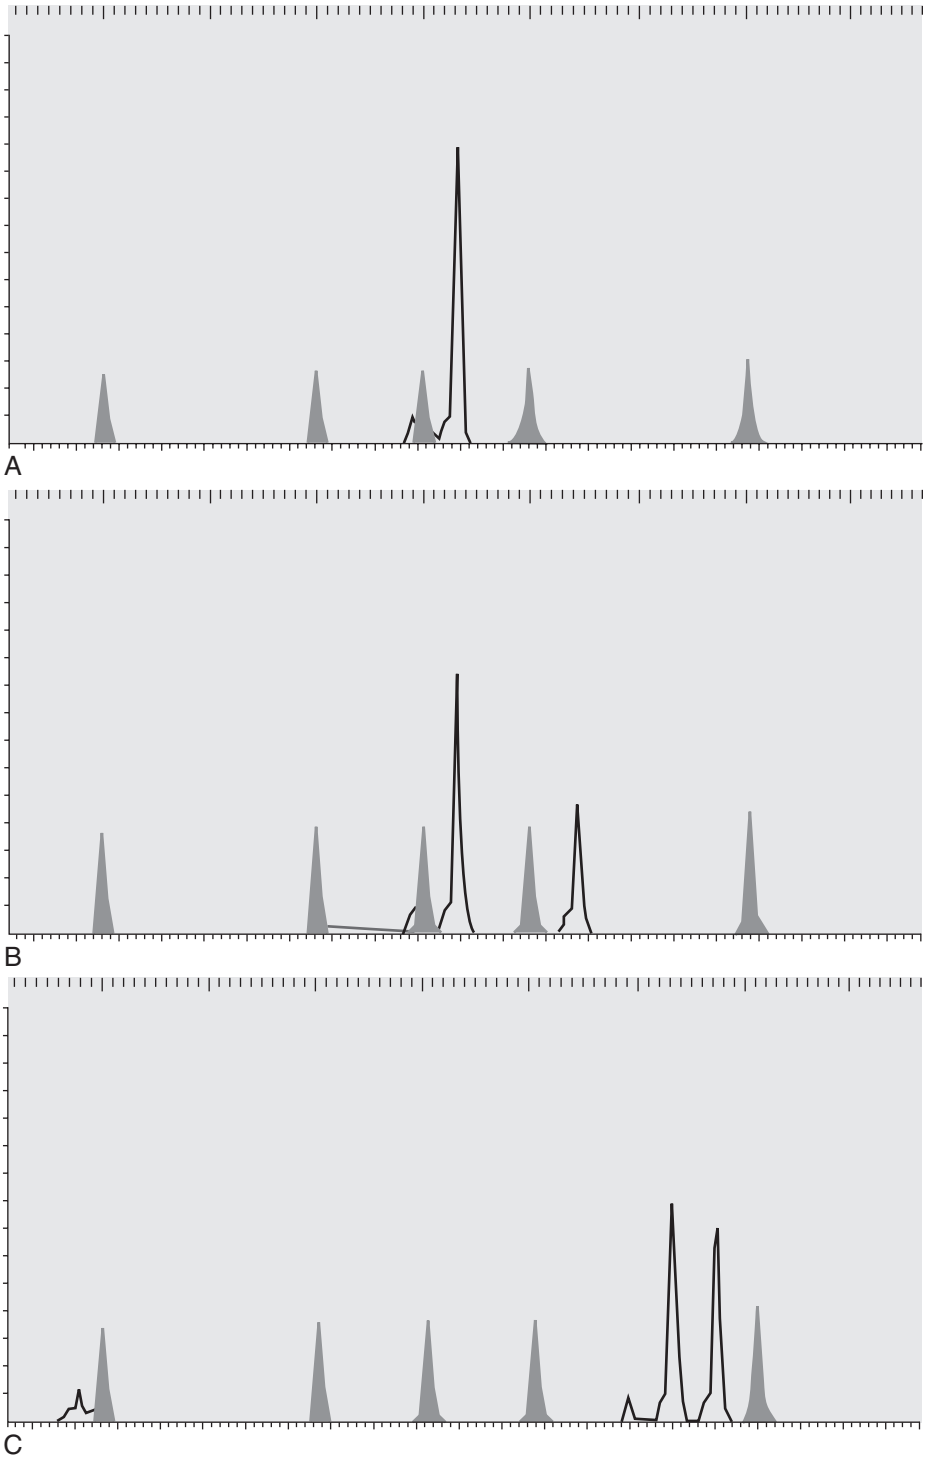

FIG. 52-1 Microsatellite markers are visualized after polymerase chain reaction (PCR) by running the fluorescent-labeled PCR product *(shown in black)* through capillary electrophoresis, which separates the products based on size relative to an internal size standard *(shown in gray).* Each panel **(A, B,** and **C)** shows the results for a different animal. Size (base pairs of DNA) is resolved along the *x* axis, and the *y* axis shows the fluorescence intensity.

been shown to cause lethal white foal syndrome in the American Paint horse.[10-12] Insertions or deletions of a single base pair (bp) can cause mutations in the coding sequence by altering the translational frame, which ultimately causes protein truncation. An 11-bp deletion in the myostatin gene causes a frameshift mutation and protein truncation in Belgian blue and Peidmontese cattle with the double-muscle phenotype.[13-15] Large deletions or insertions that remove hundreds and thousands of base pairs can also cause disease. For example, the polled intersexuality mutation in goats is caused by an 11.7-kilobase deletion that removes a regulatory element that controls the expression of two genes.[16] This endless array of possible changes in the DNA that result in disease makes each individual DNA-based genetic test different.

The basis for DNA testing is PCR. Primers can be designed specifically to amplify either the disease-causing allele or the normal allele. Alternatively, the PCR product can be digested with a restriction enzyme that cleaves the DNA at a particular sequence of bases. A restriction enzyme is chosen that shows a different cleavage pattern between the mutant and the normal version of the PCR product. Direct sequencing of a section of DNA can also be used to determine the animal's genotype. Many different methods are available to assay changes in DNA that lead to disease. Each company that offers a test may choose a different type of assay for the same mutation.

If the exact mutation that causes the disease has not been discovered, a linked-marker test can be used. A "linked marker" is a microsatellite marker similar to those previously described for individual

Beta-lactoglobulin, aberrant low expression	PAEP	Autosomal	41
Brachyspina	FANCI	Autosomal recessive	42
Cardiomyopathy and woolly haircoat syndrome	PPP1R13L	Autosomal recessive	43
Cardiomyopathy, dilated	OPA3	Autosomal recessive	44
Chediak-Higashi syndrome	LYST	Autosomal recessive	45
Chondrodysplasia	EVC2	Autosomal	46
Citrullinemia	ASS1	Recessive	47
Complex vertebral malformation	SLC35A3	Autosomal recessive	8
Congenital muscular dystonia 1	ATP2A1	Autosomal recessive	9
Congenital muscular dystonia 2	SCL6A5	Autosomal recessive	9
Deficiency of uridine monophosphate synthase (DUMPS)	UMPS	Autosomal recessive	48
Dominant white with bilateral deafness	MITF	Autosomal dominant	49
Dwarfism, Angus	PRKG2	Autosomal recessive	50
Dwarfism, Dexter	ACAN	Autosomal recessive lethal	51
Dwarfism, growth-hormone deficiency	GH1	Autosomal recessive	52
Ehlers-Danlos syndrome, Holstein variant	EPYC	Autosomal recessive	53
Ehlers-Danlos syndrome, type VII (Dermatosparaxis)	ADAMTS2	Autosomal	54
Epidermolysis bullosa	KRT5	Autosomal dominant	55
Epidermolysis bullosa, dystrophic	COL7A1	Autosomal recessive	56
Factor XI deficiency	F11	Autosomal recessive	57
Forelimb-girdle muscle anomaly	GFRA1	Autosomal recessive	58
Glycogen storage disease II (Pompe disease)	GAA	Recessive	59
Glycogen storage disease V	PYGM	Autosomal recessive	60
Goiter, familial	TG	Autosomal	61
Hemophilia A	F8	X-linked	62
Hypotrichosis	HEPHL1	Autosomal recessive	63
Ichthyosis congenita	ABCA12	Autosomal recessive	9
Lethal multi-organ developmental dysplasia	KDM2B	Autosomal recessive	64
Leukocyte adhesion deficiency, type I	ITGB2	Autosomal recessive	7
Mannosidosis			
Alpha	MAN2B1	Autosomal recessive	65
Beta	MANBA	Autosomal recessive	66
Maple syrup urine disease	BCKDHA	Autosomal recessive	67
Marfan syndrome	FBN1	Autosomal dominant	68
Mucopolysaccharidosis IIIB	NAGLU	Autosomal recessive	69
Multiple ocular defects	WFDC1	Autosomal recessive	70
Muscular hypertrophy (double muscling)	MSTN	Autosomal recessive	13-15
Myasthenic syndrome, congenital	CHRNE	Autosomal	71
Myoclonus	GLRA1	Autosomal recessive	72
Myopathy of the diaphragmatic muscles	HSPA1A	Autosomal recessive	73
Neuronal ceroid lipofuscinosis 5	CLN5	Autosomal recessive	74
Osteopetrosis	SLC4A2	Autosomal recessive	75
Ovotesticular disorder of sexual development	SRY	Y-linked	76
Polled and multisystemic syndrome	ZEB2	Autosomal dominant	77
Protoporphyria	FECH	Autosomal	78
Pseudomyotonia, congenital	ATP2A1	Autosomal recessive	79
Renal dysplasia	CLDN16	Autosomal recessive	80
Scurs, type 2	TWIST1	Autosomal dominant	81
Spherocytosis	SLC4A1	Autosomal incompletely dominant	82
Spinal dysmyelination	SPAST	Autosomal recessive	83
Spinal muscular atrophy	KDSR	Autosomal recessive	84
Syndactyly	LRP4	Autosomal recessive	85, 86
Tail, crooked	MRC2	Autosomal recessive	87
Thrombopathia	RASGRP2	Unknown	88
Trimethylaminuria	FMO3	Autosomal recessive	89
Yellow fat	BCO2	Unknown	90

Meat tenderness	Calpastatin	Polygenic	95, 96
	μ-Calpain	Polygenic	97, 98

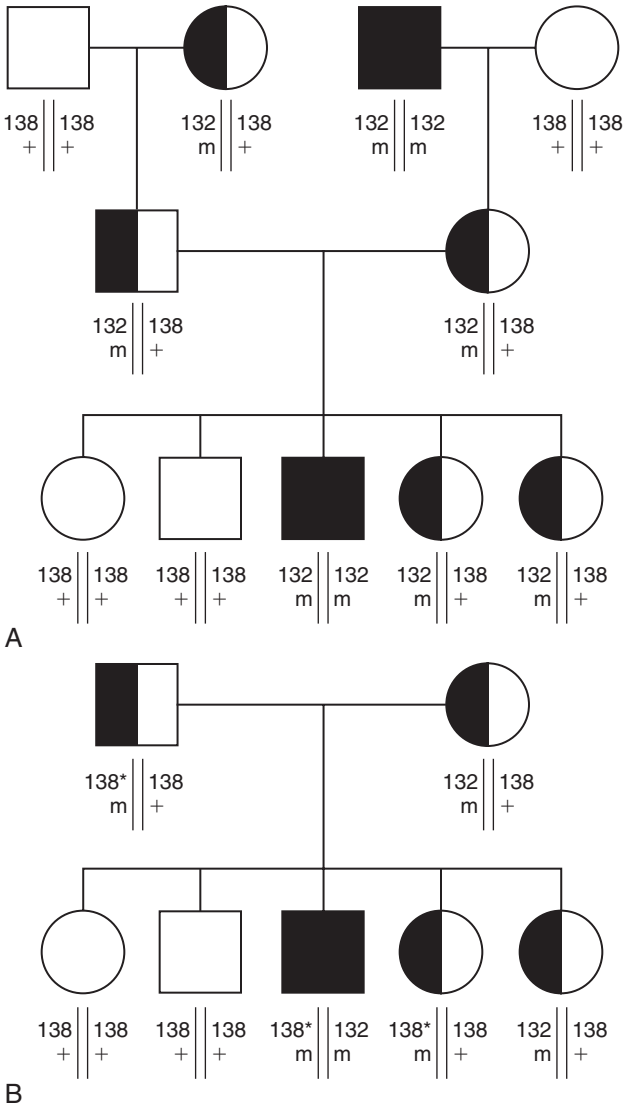

FIG. 52-2 In this pedigree, *squares* are males and *circles* are females. *Filled symbols* represent affected individuals, *half-filled symbols* represent carriers, and *open symbols* represent normal animals. The allele sizes for a marker linked to the disease locus are given below each symbol. For clarity, the genotype at the disease locus is also written below each symbol as *m* for the mutant allele and + for the normal allele. Panels **A** and **B** are two different families. The *asterisk* marks the allele in different linkage phase in family *B*.

identification and parentage analysis. The marker is "linked" along the chromosome to the disease gene. It can be used as a proxy for the actual mutation; the associated error rate can be decreased by using a set of markers that flank the gene causing the disease. When a set of markers is used, the test is called a "haplotype" test. Because the test does not directly test for the mutation, an error is still possible. Figure 52-2 shows a pedigree that is segregating a disease allele and a marker. In panel *A* the disease allele is in linkage phase with the marker allele 132. In this family the 132 allele is correlated to the disease locus. Panel *B* shows a family in which the linkage phase is different. In this family the sire has a 138 allele associated with the disease allele. Therefore, his affected son would be called a "carrier" and one of his daughters that is a carrier would be called "normal" based on this linked marker. Linked markers can be used in families with affected individuals to test for the presence or absence of the disease allele in other family members. The problem arises when a linked-marker test is used to test individual animals. The linkage phase is assumed based on research done in one family but may not be true for every animal in the breed.

There are limits to all genetic testing. In mutation tests the specific mutation being assayed is the only factor being evaluated. An animal may have a different mutation in that gene or a mutation in a different gene that causes the same phenotype (phenocopy). It is therefore correct to state that an animal has been "DNA tested negative" for this specific mutation rather than "DNA tested clear" of the disease. Linked-marker tests have these same sources of error, as well as additional sources. Recombination events between the markers and the disease gene can lead to false-positive and false-negative results. The use of multiple markers that flank the gene of interest (haplotype test) can increase the probability that a recombination event will be identified. If one is identified, the laboratory will know that the test

6	CLN6	Autosomal recessive	125
Porphyria cutanea tarda	UROD	Autosomal recessive	126
Spongiform encephalopathy (scrapie susceptibility)	PRNP	Autosomal recessive	127
Waardenburg syndrome, type 4A	ETBR	Autosomal recessive	128
Yellow fat	BCO2	Autosomal recessive	129

TABLE 52-6

Genetic Tests for Goats

Disease/Trait	Gene	Mode of Inheritance	Reference(s)
Casein, alpha-S1, reduced concentration	CSN1S1	Autosomal	130
Casein, alpha-S2, null allele	CSN1S2	Autosomal recessive	131
Casein, beta, null allele	CSN2	Autosomal	132
Goiter, familial	TG	Autosomal recessive	133
Horns/Polled	PISRT1, FOXL2	Autosomal	16, 134
Mannosidosis, beta	MANBA	Autosomal recessive	135
Mucopolysaccharidosis IIID	GNS	Autosomal recessive	136
Myotonia	CLCN1	Autosomal dominant	137

is not valid in this individual. The second source of error with either a linked-marker or a haplotype test occurs when there is an ancestral recombination event that changes the linkage phase of the alleles. The result is that the laboratory would interpret an animal's genotype at the disease locus incorrectly, based on the linked markers.

No association or committee evaluates quality control of DNA tests that are available in animals. Most tests are published in the scientific literature, not as tests, but as articles describing the discovery of the mutation. Because some cases involve patent issues, some tests are offered before publication. Much of the research done to identify the mutations involved in the tests is performed at universities and funded by granting agencies that have both financial and intellectual interest in patenting the tests. Companies then license the rights to offer the tests. A list of licensed testing labs is included in Box 52-2. Veterinarians should contact the laboratories to inquire about available genetic tests for large animal species because laboratories are licensed to run only particular tests.

Tables 52-3 through 52-6 list available genetic tests for traits and diseases other than coat color in horses, cattle, sheep, and goats, respectively. Only tests published in peer-reviewed journals are listed. Additional tests available in cattle for various forms of the milk proteins also are not listed in Table 52-4. The breeds of cattle are not listed because rapid changes in testing mean that tests are always being validated for new breeds. It is therefore recommended that a search be performed for the availability of a test for a particular breed each time the need arises. Coat color genetic tests are listed in Table 52-7, with each particular species in which the genetic mutation has been identified referenced.

The diseases or traits that are tested can be divided into two categories: those that have straightforward Mendelian inheritance patterns (recessive, dominant, and sex-linked) and those that are more complicated because many genes are involved with conferring the phenotype (polygenic). *Quantitative trait loci* (QTL) are the genes that contribute to a polygenic disease. In cattle, a vast number of QTL

Silver	PMEL17	Horse	155
White spotting	MITF	Horse	153
		Cow	147
	PAX3	Horse	153

have been placed in specific regions of chromosome for quantitative traits such as dairy form, milk production, and fertility.[17] Selection for these traits can be done with DNA testing (see Table 52-4). Because so many different QTL exist, however, selection can be challenging, and trade-offs need to be made.

Genetic testing relies on advances made in the field of genomics. Veterinarians and owners are fortunate that large animal species were chosen as economically important species for whole-genome sequencing. With the tools currently available, the number of disease- or trait-based tests available in the future will markedly increase.

Equine Immunologic Disorders

Lais R. Costa*

Complex defense mechanisms have developed to protect the host from outside challenges, particularly against the pathogenic effects of microorganisms. Diseases, especially infectious diseases, can result from failure of the host's normal defense mechanisms, as well as from overwhelming challenge from the outside. When animals are plagued by repeated or chronic infections, the clinician should always determine whether host factors are involved. On the other hand, the defense mechanisms might lead to exaggerated responses and result in immune-mediated injury of tissues and organs. The analysis of immunologic disorders, including immunodeficiency diseases, immunosuppression, and immune-mediated injury, depends on an understanding of the normal immune response.

Overview of Immunologic Disorders in Horses

Lais R. Costa*

Normal Immune Response in Horses

The immune response results from an intricate network of innate mechanisms of resistance and complex adaptive immune mechanisms. Cells and soluble factors of the innate branch of the immune system interact with cells of the adaptive (clonal) branch of the immune system by promoting chemotactic stimuli for leukocyte trafficking, providing co-stimulatory signals and antigen presentation. The adaptive immune mechanisms confer specific, anamnestic response following the initial encounter with an antigen or pathogen. The adaptive immune response is largely mediated by cells of the lymphocytic lineage that are capable of distinction of antigenic determinants or epitopes that are *self* from those that are *nonself,* providing constant surveillance to identify and eliminate cells and organisms recognized as foreign. The cellular and molecular mechanisms involved in the immune response of horses have been recently reviewed in detail.[1]

The innate immune mechanisms are the first line of defense and do not require previous exposure to the pathogen, allowing time for development of antigen-specific acquired immune response. Innate defense mechanisms are ever ready or induced immediately. They include soluble mediators, cells, and cell-associated molecules that lead to inflammatory reactions and effector mechanisms to eliminate the offending organism. Inflammatory reaction leads to increased blood flow, increased vascular permeability, and leukocyte migration and activation. Table 53-1 depicts some of the important soluble mediators of the innate immune mechanisms. Complement activation following association of factor C3b to microbial molecules (alternative pathway), to mannose-binding lectin (lectin pathway), or following specific immunologic recognition by antibodies (classical pathway) leads to a cascade of sequential proteolytic cleavages capable of remarkable amplification. Complement activation results in opsonization by factor C3b; release of soluble factors C3a and C5a, which increase vascular permeability and exert chemoattraction of leukocytes; and finally the formation of lytic multiprotein complex, the membrane attack complex (MAC) that lyses the cell or microorganism.

The diverse cellular components of the innate immune system include granulocytes (neutrophils, eosinophils, and basophils); macrophages; dendritic cells (DCs); mast cells; and natural killer (NK) cells. All these cells play critical roles in both innate and adaptive immune responses. Macrophages and neutrophils are capable of phagocytosis and destruction of the offending pathogen by oxidative burst. Neutrophils are quick responders specialized in killing invading organisms, particularly extracellular pathogens. They are the first effector cells to act on an invader, whereas macrophages compose the second line of defense and are particularly effective at dealing with intracellular pathogens. Macrophages originate from monocytes and become specialized phagocytic cells resident in various tissues; for instance, microglial cells in the brain, histiocytes in connective tissue, Kupffer cells in the liver, alveolar macrophages in alveoli of lungs, pulmonary intravascular macrophages in capillaries of lungs, and osteoclasts in bones. Macrophages have diverse functions in addition to phagocytic and antimicrobial functions, including secretion of cytokines that lead to amplification of the inflammatory response, stimulation of lymphocytes, modulation and even suppression of the immune response, and antigen processing and presentation. Subpopulations of macrophages exert specific immunologic functions. Macrophages along with DCs are the principal antigen-processing cells. Antigen processing and presentation in the context of major histocompatibility complex (MHC)-class II is a critical function linking the cells of the innate immune system and those of the adaptive immune system. Dendritic cells encompass a heterogeneous population of immune cells, originating either from myeloid or lymphoid precursors. Myeloid DCs, follicular DCs, and Langerhans cells comprise the population called *DC1 cells,* which originate from monocytes, and therefore are derived from myeloid precursors. They are the main antigen presenters, whereas plasmacytoid DCs, referred to as *DC2 cells,* are specialized in secreting type I interferon (IFN; i.e., IFN-α and IFN-β) during viral infections. Type I interferons activate lymphocytes and NK cells.

NK cells recognize cells under stress, including infected or tumor cells expressing antigenic epitopes that are recognized as foreign. NK cells are important in mediating antibody-dependent cell-mediated cytotoxicity (ADCC). γδ T cells comprise a heterogeneous population of T cells expressing γδ T-cell receptors (TCRs), and exert a wide

TABLE 53-1

Examples of Soluble Mediators of the Innate Immune System and Their Main Function

Categories of Mediators	Example of Soluble Mediators	Function
Acute phase proteins	C-reactive protein	Opsonization, complement activation
	Cerulloplasmin	Iron sequester (limiting nutrients required by microorganisms)
	Ferritin	
	Fibrinogen	Hemostasis
	Serum amyloid A	Leukocyte recruitment and activation
	C3, C4	Factors of complement, involved in activation
Protease systems	Complement	Mediate inflammation, opsonization and membrane attack complex formation
	Kinins	Mediate inflammation
	Clotting and fibrinolysis proteins	Hemostasis
Host defense peptides	Equine β-defensin, equine neutrophil antimicrobial peptide, equine cathelicidins	Antimicrobial (bacteriostatic and bacteriocidal) actions
Type I interferons (IFNs)	IFN-α, IFN-β	Antiviral glycoproteins mainly produced by macrophages, dendritic cells, and fibroblasts
Biogenic amines	Histamine, serotonin	Vascular smooth muscle relaxation (vasodilation) and endothelial cell contraction (leakage of plasma into tissues)
Chemokines	IL-8, MCP-1	Chemoattractants for cells of both innate and adaptive branches of the immune system
Proinflammatory cytokines	IL-1, IL-6, TNF-α	Mediate a variety of cellular responses such as chemotaxis of leukocytes, activation of leukocytes (including T and B cells), upregulation of iNOS and COX-2, and induction of fever
Prostanoids	Prostaglandins, leukotrienes, prostacyclins	Mediate and modulate acute inflammation

range of immune functions from response to heat-shock proteins, cytokine production, and antigen processing and presentation to promoting delayed hypersensitivity. NK cells and γδ T cells are lymphoid cells considered as the interface between innate and adaptive immunity. Lymphokine-activated killer (LAK) cells comprise a subset of cytotoxic effector cells with a wide target cell spectrum. LAK cells are distinct from T cells and NK cells.[2]

Cells of the innate immune system, including neutrophils, cells of the mononuclear phagocytic system, DCs, mast cells, NK cells, and a subset of γδ T cells, are capable of recognizing pathogen incursions by pattern recognition receptors (PRRs). The ligands for PRRs are collectively called *pathogen-associated molecular patterns* (PAMPs) and include toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD), and nucleotide-binding domain leucine-rich repeat containing protein (NLR).[3] In addition, the innate immune system detects markers of endogenous cell-damage, called *danger-associated molecular patterns* (DAMPs).[3,4]

The antigen-specific or adaptive immune response involves two major populations of lymphocytes, T cells (expressing αβ-TCR) and B cells (Fig. 53-1). Classically, T cells are associated with cell-mediated immune responses that confer protection against fungal, protozoal, intracellular bacterial, and viral infections. B cells are associated with humoral immunity, which provides defense against toxins, extracellular bacterial infections, parasites, and certain viral infections. T cells originate from stem cells, which probably develop in the fetal liver. These cells must undergo a maturation process in the thymus before becoming fully functional. T cells comprise about 70% to 80% of peripheral blood lymphocytes of horses and populate the periarteriolar regions of the spleen and the paracortical regions of lymph nodes. As with T cells, B cells originate from stem cells in the fetal liver. The site of B-cell maturation varies with species and includes several different organs, such as the bursa of Fabricius in birds and the bone marrow and certain Peyer patches in mammals. Of peripheral blood lymphocytes of horses, 15% to 30% are B cells. B cells populate germinal centers of the spleen and lymph nodes.[5,6]

T lymphocytes are important in regulating the adaptive immune response, both the humoral and cellular immune responses. T lymphocytes are characterized as helper T (Th) cells, cytotoxic T (Tc) cells, and regulatory T (Treg) cells based on their primary function. T cells might be differentiated on the basis of cell surface antigens, with most Th cells expressing the CD4 surface receptor and most Tc cells expressing CD8 surface receptor.[7,8] $CD4^+$ T lymphocytes recognize antigens in the context of MHC-class II expressed on the surface of antigen-presenting cells, and $CD8^+$ T lymphocytes recognize antigens in the context of MHC-class I. Further work has shown that the function of these cells is complex and that the pattern of cytokine expression is important in regulation of the immune response. On the basis of their profile of cytokine expression, $CD4^+$ cells have been further subdivided into distinct subsets (e.g., Th1, Th2, and recently identified Th17 cells) (Fig. 53-2). Although there is some species variation, Th1 cells generally produce IFN-γ and interleukin-2 (IL-2) and are involved primarily in the generation of cell-mediated immune responses, whereas Th2 cells produce IL-4, IL-5, and IL-13 and are involved in humoral responses. Th17 cells produce IL-17, IL-21, and IL-22 and are important in clearing extracellular pathogens during host defense reactions that are not efficiently cleared by Th1- and Th2-type immunity.[9,10] Protection from disease or development of lesions can be associated with the particular type of Th-cell response, and the clinical relevance of this is currently being investigated in a number of equine diseases.

The second major class of lymphocytes is B lymphocytes, which produce immunoglobulins (Igs) and are the precursors of plasma cells. There are several classes or isotypes of Igs. They are classified according to their heavy chain: IgG (γ heavy chain), IgM (μ heavy chain), IgA (α heavy chain), IgE (ε heavy chain), and IgD (δ heavy chain). Originally, four subisotypes of IgG were identified in the horse on the basis of their immune functions and properties, IgGa, IgGb, IgGc, and IgG(T). Recently, seven IgG heavy chain constant region genes were identified, and the IgG subisotypes were reassigned.[11,12] The original subisotype IgGa includes new subisotype IgG1, the original subisotype IgGb includes IgG4, and the original subisotype IgGc includes new subisotype IgG6. The formerly called IgG(T) includes two subisotypes, IgG3 and IgG5. The characteristics and immunologic functions of the equine Ig isotypes and subisotypes are summarized in Table 53-2.[11-15] Furthermore, B cells function as important antigen-presenting cells by processing and presenting antigens in the context of MHC-class II. In addition to antigen recognition by surface Igs, B cells also recognize TLR ligands.[3] A less appreciated function of subsets of B cells is the production of cytokines.[13] Subsets of B cells have recently been recognized as regulators of the immune responses during inflammation and autoimmunity.[16,17]

Factors Associated with Inadequate Immune Response

Numerous factors influence adequacy of the immune response of an individual animal to potential environmental pathogens. Important factors to consider in the horse are age, genetic predisposition, general fitness, training, the level of stress associated with exercise, state of health, including nutritional status, and the presence of concurrent diseases. Moreover, increased concentrations of corticosteroids can result in varying degrees of immunosuppression. The increase in endogenous corticosteroids may be associated with stress or disease. The most common condition in horses associated with increased endogenous corticosteroids is pituitary pars intermedia dysfunction (PPID). In addition, corticosteroid treatment is the most common iatrogenic cause of immunosuppression. Regardless if endogenously produced or exogenous in origin, increased concentrations of corticosteroids may exacerbate preexisting infectious diseases or decrease resistance to environmental pathogens.[18,19] Corticosteroids have a number of effects on the immune system, many of which are dose dependent. The effects of corticosteroids on the immune system are discussed later in "Drug-Induced Immunosuppression".

It is well recognized that nutritional status has a major impact on immune function, and nutritional deprivation produces impairment of immune response. Collectively called *nutritionally acquired immunodeficiency syndrome* (NAIDS), these immunologic dysfunctions include protein-calorie malnutrition and deficiencies of single nutrients. Protein-calorie malnutrition and deficiencies of single nutrients that assist in nucleic acid metabolism lead to dysfunction of the adaptive immune response, especially the T-cell functions, and result in atrophy of lymphoid tissues.[20] In these individuals, the cell-mediated immunity and humoral response to T cell–dependent antigens are subnormal. Deficiency of single nutrients can impair production of key proteins by lymphocytes and phagocytic cells.[20] Inadequate nutritional status may result from (1) increased and unmet nutritional requirement, including during growth, pregnancy, lactation, aging, and intense work, (2) disease state associated with altered nutrient intake such as conditions leading to hypophagia or anorexia, and (3) disease state associated with altered absorption of nutrients.[21] Young animals are more likely to develop NAIDS, followed by geriatric patients, contributing to the greater risk of infections in both age groups.

Age has been shown to affect immune function in multiple species. Altered immune function has been identified in both ends of the age spectrum, in foals and older horses. Foals are immunocompetent at birth, but their immune system is naive, therefore they rely on the transfer of maternal immunity through the colostrum for immunologic protection. Newborn foals have practically no circulating Igs of their own; however, they normally receive maternal transfer of colostral antibodies, especially IgG.[22-25] As the foals age, the maternal antibody levels decline and no longer provide comprehensive protection, but at the same time they might interfere with the foals' ability to mount an immune response. The immune response of foals differs from those of adults.[22-25] Phagocytocytic ability of neutrophils (when autologous serum is used as opsonin) is impaired until 3 weeks of age.[26] Killing capacity of neutrophil is reduced in neonates but gradually improves, reaching levels similar to adults by 3 months of age.[26] Oxidative burst activity and phagocytosis by peripheral blood leukocytes (only if adult serum is used as opsonin) and LAK cell activity do not differ significantly between foals from birth to 6 months of age and adult horses.[27] Total circulating lymphocyte counts at birth are similar to those of adult horses and increase linearly 2.5-fold from birth to 18 months of age.[25,27,28] This increase in circulating lymphocyte counts results principally from an increase in B cells and $CD4^+$ T cells.[25,27-29] Age-dependent changes in humoral immune response from birth to 6 months of age include the gradual increase in the numbers of peripheral blood B cells and in circulating IgM above those found in adult horses, concomitant with decline of maternal Ig levels.[25] Proliferative response of peripheral lymphocytes to mitogenic stimulation is slightly reduced at birth but rapidly increases.[27] The expression of MHC-class II on the surface of peripheral blood mononuclear cells is low in neonatal foals and gradually increases.[27] The vulnerability of foals between 2 and 4 months of age to respiratory tract infections, particularly the pathogens *Rhodococcus equi* and *Pneumocystic jiroveci* (formerly *Pneumocystis carinii*), was thought to reflect a general cellular immune-deficient state that is uncovered by the decline in protective maternal antibodies.[22,28,30] Studies evaluating cytokine production by lymphocytes of foals from birth to 6 months of age have yielded conflicting results. Mitogen stimulation of lymphocytes from newborn foals was shown to evoke a limited production of IFN-γ due to a diminished ability to express the IFN-γ gene, associated with hypermethylation of the promoter of the IFN-γ gene.[24,31] This ability was shown to increase steadily, reaching adult levels within the first year of life, suggesting that foals have an inherent inability to mount a Th1 immune response, which may contribute to their susceptibility to intracellular pathogens. Further studies showed that the number of IFN-γ and IL-4 producing cells vary with the type of mitogen used.[31] Regardless of the mitogen, the number of IFN-γ producing cells was equally low in foals younger than a week of age and at 3 to 4 months of age, compared with adult horses.[32] The number of IL-4 producing cells was low in foals younger than a week of age and even lower at 3 to 4 months of age.[32] Expression of IFN-γ, IL-4, and IL-10 by mitogen-stimulated lymphocytes from foals at 36 hours and 5 days was minimal and gradually increased by 6 and 12 weeks of age, although it remained inferior to that of adult horses.[33] Antigen-specific stimulation with *R. equi* of peripheral lymphocytes from foals during the first 3 weeks of life (i.e., days 1, 3, 7, 10, 15, and 20) induced expression of IFN-γ and IL-4 that was lowest at day 1 and gradually increased.[34] Immunization of neonates with a killed adjuvanted vaccine invoked a modest induction of vaccine-specific humoral and lymphoproliferative immune responses.[35] Both humoral and lymphoproliferative responses improved by 3 months of age, but their magnitude was far less than that of adult horses.[35] On the other side of the age spectrum, aging has been associated with an increased susceptibility to infection.[36,37] Immunosenescence is discussed in detail later in this chapter.

Exercise represents not only an increased nutritional requirement but also a physiologic stress that can significantly alter the immune response.[38,39] However, defining the precise effects of exercise on the equine immune system and susceptibility to disease has been difficult because of the complexity of the immune system; host factors (e.g., age, level of fitness); and the variable nature of exercise.[36,38,39] In general, it appears that exercise may have both positive and negative effects on the immune response.[36,38-44] Suppressive effects, such as a decline in the ratio of $CD4^+$:$CD8^+$ T cells, decreased lymphoproliferative responses, and suppression of the innate immune system, have been associated with strenuous high-intensity exercise, prolonged exhaustive exercise, or overtraining. In contrast, moderate exercise tends to have beneficial effects on the host defense mechanisms. Data in horses directly linking exercise-induced immunosuppression and increased susceptibility to infectious disease are limited. However, the potential immunosuppressive effects of exercise need to be recognized. In one study, unconditioned ponies vaccinated with a killed influenza vaccine and subjected to 5 days of strenuous exercise had an increased susceptibility to clinical influenza after challenge exposure compared with rested ponies.[45] However, ponies with exercise-induced immunosuppression responded to the administration of an intranasal modified-live equine influenza vaccine and were protected from challenge.[46] In a study of influenza infection in trained horses, moderate exercise led to increased signs of clinical disease, but the duration of disease was unaffected.[47]

Immunologic Disorders Resulting from Compromised or Deficient Immune Responses

Increased susceptibility to infections, either because of recurrence, chronicity, or severity of infectious illness beyond what is considered "normal," raises the suspicion of inadequate immune response. Inadequacy of the immune response due to deficiency of the innate, humoral, or cell-mediated immunity, or any combination of these,

VetBooks.ir

predisposes animals to infections that might culminate with their death. Pathogens most often associated with immunodeficiencies in horses include infections by *P. jiroveci, Candida* spp., *Aspergillus* spp., adenovirus, *Cryptosporidium,* and *R. equi* in adult horses.

General clinical features associated with immunodeficiencies include the following[5,21,48,49]: (1) onset of infections during the first 6 weeks of life, (2) repeated infections that respond poorly to standard therapy, (3) increased susceptibility to organisms with low pathogenicity, (4) infection with organisms rarely observed in immunocompetent individuals, (5) systemic illness after administration of attenuated live vaccines, (6) failure to respond to vaccination, and (7) persistent marked abnormalities in leukocyte numbers.

Immunodeficiency Disorders Characterized by Defects of Components of the Adaptive Immune Response

Immunodeficiencies of the adaptive immune response can be classified according to (1) the site of defect in the host defense system and (2) whether the mechanism is primary or secondary.[5,21,48,49] In primary disorders there is an inherent abnormality in the immune system that has a proven or suspected genetic basis, whereas in secondary disorders the host's initially normal ability to respond immunologically is altered. Both primary and secondary immunodeficiencies can affect various components of the immune system, and by careful dissection of the immune response, the site of the defect can often be identified. Some drugs, toxicities, neoplasia, and microbial infections lead to immunosuppression.[5,21,49] Immunosuppression associated with drugs, leukoproliferative and autoimmune conditions, and infectious processes are discussed later in this chapter. Table 53-3 depicts salient characteristics of immunodeficiency disorders of the horse. Table 53-4 lists some case reports of impaired or inadequate immune response in foals that do not fit any of the well-described immunodeficiency disorders.

Immunodeficiencies Characterized by Defects of Components of the Innate Immune Response

Inherited disorders of the innate immune system such as lethal trait A46, Chédiak-Higashi syndrome, and leukocyte adhesion deficiency have not been identified in horses. Pelger-Huët anomaly, an inherited disorder of neutrophils, occurs in horses. Heritability of Pelger-Huët anomaly has been recently described in Arabian horses.[50,51] Pelger-Huët neutrophils are characterized by reduced numbers of nuclear segmentation into lobes. They often resemble band forms, appearing mostly as bilobed dumbbell-shaped nuclei. Immunophenotyping of Pelger-Huët neutrophils of horses revealed normal expression of myeloid-specific markers and adhesion molecules, and evaluation of phagocytosis and oxidative burst via flow cytometry revealed normal neutrophil function.[51] Similar to the condition in other species, the functions of Pelger-Huët neutrophils are virtually normal, and the neutrophil survival is not affected. However, their inflexible nuclei restrict their ability to emigrate from blood vessels. Nonetheless, no clinical signs of immunodeficiency are observed and this morphologic anomaly represents an incidental finding during the evaluation of blood smears.

Inherited forms of complement dysfunction or factor deficiency have not been reported in the horse. However, depletion of complement C3 component associated with chronic infections, such as equine infectious anemia, has been reported. Moreover, the foal is born with low serum complement activity, and colostrum is not a significant source of complement. Therefore foals are transiently deficient in serum opsonic capacity and rely on their own production of complement after birth. In sepsis, complement C3 components are rapidly consumed, which delays the physiologic age-dependent increase otherwise observed in healthy foals.[52]

Immunologic Disorders Leading to Immune-Mediated Injury

Inappropriate or exaggerated immunologic responses can directly injure bodily tissues. The clinical manifestation of immune-mediated injury depends on the nature and site(s) of tissue injury. Immune-mediated tissue injury can be from humoral or cell-mediated immune responses, or a combination of both. Immune-mediated tissue/organ damage, often referred to as *hypersensitivity,* has been classified according to the nature of the immunologic pathway involved. Comprehensive reviews of these disorders in the horse may be found elsewhere.[1,53-56] Table 53-5 summarizes disorders caused by immune-mediated injury in the horse.

IgE-mediated hypersensitivity reactions, often referred to as *immediate* or *type I hypersensitivity,* consist of responses to antigens mediated by antibodies of the IgE isotype.[1,53-55] These reactions typically occur within 15 minutes from the time of reexposure to the triggering factor, unless the triggering antigen requires metabolic processing. Binding of the antigen (often referred to as *allergen*) to the IgE molecules bound to the surface of mast cells via high-affinity IgE receptors (FcεRI) leads to degranulation of mast cells and release of mediators such as histamine, serotonin, leukotrienes, prostaglandins, various chemokines, and cytokines. These mediators, broadly classified as to their ability to cause vasodilation, edema, smooth muscle contraction, and chemotaxis, are responsible for inflammation, which may be localized or systemic. Of clinical significance is that localized reactions may propagate to systemic reactions. The classic example of systemic IgE-mediated hypersensitivity is anaphylaxis. In horses anaphylaxis may be manifested as dyspnea, tachypnea, coughing, sweating, hypotension, and abdominal pain because the respiratory and gastrointestinal tracts are the shock organs in horses.

Immune complex–mediated hypersensitivity reactions are also referred to as *cytotoxic hypersensitivity.* They include reactions to cell-associated antigenic epitopes, or type II hypersensitivity, and reactions to soluble antigens, or type III hypersensitivity.[1,53-55] Immune complex–mediated hypersensitivity reactions to cell-associated antigenic epitopes or soluble antigens are mediated mostly by antibodies of the IgM or IgG isotypes. Some conditions are mediated by IgA isotypes. Immune complex formation activates complement and results in the deposition of C3b and iC3b. Complement deposition enhances destruction of antigen-bearing cells by formation of the MAC and by opsonization, which enhances phagocyte-mediated destruction. In addition, Igs also mark the cell target for ADCC by NK cells. Beyond cell destruction that is mediated by complement and ADCC, activation of C5a potently recruits neutrophils that release proteolytic enzymes (including acid phosphatases, acid hydrolytic enzymes, cathepsins, elastase, collagenase) and oxidative agents. Enzymatic and oxidative damage mediated by neutrophils and other chemoattracted cells leads to further tissue destruction. The binding of Ig molecules to antigenic epitopes on cells that are fixed in a tissue or on tissue structural elements, such as basement membrane, results in damage to the respective tissue. For instance, antibodies to pemphigus antigens of the keratinocyte desmosome are responsible for the immune complex–mediated damage that results in acantholysis, blistering, and desquamation in pemphigus complex.[56] If the antigen-bearing cell is circulating, as is the case in neonatal isoerythrolysis, the cell may be destroyed in circulation but more typically is removed by the mononuclear phagocytic system. Examples of hypersensitivity to antigenic epitopes on circulating cells include alloimmune reactions (e.g., neonatal isoerythrolysis, neonatal alloimmune thrombocytopenia, neonatal allogeneic neutropenia) and drug hypersensitivities (e.g., penicillin-induced hemolytic anemia). In the case of soluble antigens that are not cell associated, Ig binding results in Ag-Ab complexes that deposit in a variety of vascular beds, including lymph nodes, kidneys, joints, and skin. Tissue in the vicinity of the precipitated Ag-Ab complexes is damaged by the ensuing immune reaction. An important condition characterized by hypersensitivity reaction to soluble antigens in horses is purpura hemorrhagica.

Delayed hypersensitivity reactions, also referred to as *type IV hypersensitivity,* consist of exaggerated cell-mediated immune responses. Once sensitization has occurred, the reaction becomes evident within 24 to 48 hours from the time of reexposure to the

VetBooks.ir

TABLE 53-3

Features of Immunodeficiency Disorders of Horses

Disease Category	Age of Onset*	Breed	Peripheral Lymphocyte Count	B-Cell Count	IgM Concentration	Other Ig Concentrations	Lymphocyte Proliferation to Mitogens	Response to ID PHA	Response to Vx	Comments
SCID	1-3 mo	Arab, Appaloosa, Arab cross, Caspian†	Severe absolute lymphopenia (<1000/μL)	Low	None	Incapable of producing any Ig (evident when maternal Abs wane)	Absent	Absent	Absent	SCID-genetic testing available
Foal immunodeficiency syndrome	3-5 wk	Fell Pony, Dale Pony	Normal at birth, then progressive lymphopenia	Low	None	Incapable of producing any Ig (evident when maternal Abs wane)	Normal to PHA, ConA, PWM	NR	NR	Severe progressive nonregenerative anemia FIS-genetic testing available
X-linked agammaglobulinemia	2-6 mo	THB, STB, QH	Normal	None	None	Incapable of producing any Ig (evident when maternal Abs wane)	Normal to PHA, PWM; variable to ConA	Normal	Absent	No genetic testing available
Selective IgM deficiency	2-24 mo	Arab, QH, THB, STB, Paso Fino	Normal	Normal	None	Capable of producing Igs of other isotypes (IgG & IgA)	Normal to PHA, ConA, PWM	Normal	Normal	No specific testing available
Transient hypogammaglobulinemia	2-6 mo	Arab, THB	Normal	Normal	Persistently low (detectable)	Persistently low (delayed onset of Ig synthesis for variable period of time)	Normal	Normal	Delayed	No specific testing available
Failure of passive transfer of maternal immunity	Neonate (0-3 wk)	Any	Normal	Normal	Low	IgG < 800 mg/dL	Normal	Normal	Normal	IgG semi-quantitation (precipitation, latex agglutination, or ELISA) and IgG TIA
Common variable immunodeficiency	2-23 yrs (average 10 yrs)	THB, QH, WB, pony, Arab, Paint	Normal or low	Low	Undetectable	Low IgG of all subisotypes; IgA gradually declines over time	Normal to lower than normal response to PHA, ConA, PWM	NR	Poor, especially to toxoid	No specific testing available

*Onset of signs varies with the degree of transfer of maternal antibodies. Onset of signs listed in this table is in face of adequate colostral transfer of maternal immunity.

TABLE 53-5

Immune-Mediated Conditions and the Immune Mechanism Mediating Tissue Injury in the Horse

Organ/Tissue	Condition	Proposed Immunologic Mechanism Mediating Injury
Systemic	Systemic anaphylaxis	Abs of IgE bound to mast cell surface via high affinity FcεRI lead to degranulation and release of vasoactive and inflammatory mediators.
	Systemic lupus erythematosus (SLE)	Autoantibodies against nuclear structures, including nucleic acids and ribonucleoproteins, mediate tissue injury. Antinuclear Abs, or ANA, combine with Ags and deposit in basement membranes of skin, glomeruli, synovial membranes, and lymph nodes.
	Multisystemic eosinophilic epitheliotropic disease (MEED)	Chronic IgE-mediated hypersensitivity reaction against undefined Ag(s) characterized by eosinophilic infiltrate in multiple tissues/organs: GI tract (leading to malabsorption and enteric protein loss), GI-associated lymph nodes, liver, pancreas (resulting in maldigestion), and skin.
	Serum sickness	Generalized hypersensitivity reaction resulting from formation of large quantities of circulating immune complexes to exogenous Ags and deposition in disseminated vascular beds, leading to systemic disease.
Respiratory system	Recurrent airway obstruction (RAO)	Hypersensitivity to inhaled organic dusts characterized by neutrophilic infiltrate. Two proposed mechanisms: (1) increased expression of IL-4 and IL-5, with development of allergen-specific enhanced Th2 response, and (2) increased expression of IFN-γ, suggesting a Th1 response.
	Hypersensitivity pneumonitis	Lymphocytic/plasmacytic bronchiolitis and lymphocytic interstitial pneumonia, sometimes accompanied by granuloma formation and fibrosis, associated with inhalation of organic antigens such as chicken dust and fungi.
Renal system	Glomerulonephritis	Hypersensitivity reaction resulting from deposit of circulating immune complexes in glomerular vascular endothelium leading to (1) acute glomerulopathy, and (2) proliferative glomerulonephritis associated with activation of complement, vasculitis, influx of inflammatory cells, and proliferation of mesangial and endothelial cells.
Nervous system	Polyneuritis equi (PNE)	Progressive, insidious radiculoneuritis characterized by granulomatous inflammation of the nerve roots, hemorrhages, demyelination, axonal degeneration, and fibrosis. Inflammatory infiltrate of the perineurium consists of lymphocytes (including T cells and B cells), plasma cells, macrophages and giant cells, eosinophils, and neutrophils. Cases of PNE present antibodies to P2 myelin.
Hematopoietic and hemolymphatic systems	Autoimmune hemolytic anemia	As a primary disorder, antibodies directed against autologous RBC Ags activate complement, resulting in rapid destruction of RBCs or removal by phagocytic cells from the mononuclear phagocyte system.
	Neonatal isoerythrolysis	Alloantibodies of maternal origin (absorbed from colostrum) recognize Ags on the foal RBC that are inherited from the sire but absent in the mare. Igs mediates RBC damage and destruction. Alloantibodies are directed against RBCs' surface glycoproteins or glycolipids, known as *alloantigens.*
	Drug-induced immune-mediated hemolytic anemia	Three mechanisms: (1) drug (e.g., penicillin, sulfonamides, phenylbutazone) binds to RBC surface glycoproteins, is recognized as foreign and eliminated; (2) drug and Ab combine, resulting in direct activation of complement with RBCs destroyed as bystanders; (3) drug modifies RBC membranes such that Abs are passively adsorbed and the RBC is removed by phagocytic cells in the mononuclear phagocyte system.

TABLE 53-5

Immune-Mediated Conditions and the Immune Mechanism Mediating Tissue Injury in the Horse—cont'd

Organ/Tissue	Condition	Proposed Immunologic Mechanism Mediating Injury
	Neonatal alloimmune thrombocytopenia	Alloantibodies of maternal origin (absorbed from colostrum) recognize Ags on the neonate's (horse or mule) platelets. Ig-mediated damage and destruction ensue.
	Immune-mediated thrombocytopenia	Primary autoimmune disorder, in which Igs are directed at autologous platelet Ags, or secondary to infectious disease (e.g., equine infectious anemia) or lymphoma with foreign Ags precipitating on the platelets. Ags are recognized by Igs, and Ig-mediated damage and destruction ensue.
	Neonatal allogeneic immune-mediated neutropenia	Binding of alloantibodies of maternal origin (absorbed from colostrum) leads to destruction of foal's neutrophils.
	Hypersensitivity vasculitis	Immune-mediated vasculopathy resulting from deposit of immune complexes (type III hypersensitivity) in walls of small vessels (venules and arterioles) leading to neutrophil-induced damage of endothelial cells. Although most commonly the vasculitides are neutrophilic (leukocytoclastic), they may be eosinophilic, lymphocytic, or mixed. Generally lesions involve the skin, typically in dependent and nonpigmented areas.
	Equine purpura hemorrhagica (EPH)	Hypersensitivity vasculitis, most commonly after *Streptococcus equi* infection or vaccination, resulting from deposit of immune complexes, of the IgA isotype, in walls of small vessels (venules and arterioles). Commonly manifested as cutaneous and mucosal involvement, but when severe, EPH leads to extensive edema and hemorrhages of dermis, subcutaneous tissue, skeletal muscles, lungs, kidney, spleen, and intestinal wall.
Eye	Equine recurrent uveitis (ERU)	Immune-mediated ocular disease characterized by recurrent-remitting episodes of intraocular inflammation, mediated by an autoaggressive Th1 response directed against several retinal proteins, leading to destruction of intraocular structures.
	Immune-mediated keratopathy (IMK)	Primary, nonulcerative, noninfectious keratitis (progressive or chronic) characterized by mild to moderate cellular infiltrate (predominantly lymphocytes and plasma cells), corneal vascularization, and corneal edema.
Skin	Pemphigus complex	Includes pemphigus foliaceus and vulgaris; autoimmune vesiculobullous disorders of the skin or mucous membranes due to Abs to components of keratinocyte desmosome leading to release of proteolytic enzymes into extracellular space and acantholysis.
	Bullous pemphigoid	Autoimmune vesiculobullous and ulcerative disorder of the skin and oral mucosa due to antibodies to glycoprotein Ag (bullous pemphigoid Ag II, or collagen XVII) in the lamina lucida of the cutaneous basement membrane (BM). Antibody binding leads to complement activation, chemotaxis of neutrophils and eosinophils, and release of enzymes and oxidants that injure the BM.
	Cutaneous (discoid) lupus erythematosus	Autoantibodies against nuclear structures combine with Ags and attach to keratinocytes, leading to ADCC. Injured keratinocytes release IL-2, resulting in lymphohistiocytic infiltrate. Lesions may be induced or exacerbated by UV light.
	Erythema multiforme	Immunologic reaction leading to apoptosis of keratinocytes and resulting in formation of macules, papules, urticarial lesions, or vesicular bullous lesions.
	Hypersensitivity to insect bite	Salivary Ags are introduced by bites from *Culicoides* spp., or possibly *Simulium* spp., *Stomoxys calcitrans*, and *Haematobia irritans*, triggering two immunologic mechanisms: (1) an IgE-mediated hypersensitivity; or (2) a cell-mediated hypersensitivity reaction associated with Th2 lymphocyte response and nonspecific eosinophilic activation. Sensitized animals, upon reexposure to allergen, experience release of inflammatory mediators, leading to pruritus.
	Feed-related allergies	Hypersensitivity reactions mediated by IgE, immunocomplexes, or cellular responses to feedstuff (including malt, beet pulp, buckwheat, wheat, alfalfa, red or white clover, barley, bran, and oats).
	Atopic dermatitis	Genetically predisposed inflammatory and allergic skin reaction mediated by allergen-specific IgE, leading to degranulation of mast cells and release of inflammatory mediators that cause erythema, vascular leakage, and pruritus.
	Allergic urticaria	Hypersensitivity reaction mediated by 1 of 3 mechanisms: (1) IgE, (2) cytotoxic, or (3) immune complexes, leading to activation of tissue mast cells or blood basophils and resulting in release of mediators such as histamine, kinines, and prostanoids, culminating with formation of wheals.
	Allergic contact dermatitis	Cutaneous delayed-type hypersensitivity reaction to a nonirritant agent to which the horse had been previously sensitized.
	Neonatal ulcerative dermatitis, thrombocytopenia, and neutropenia	Multifocal ulcerative skin disease of neonatal foals associated with profound thrombocytopenia and mild neutropenia suspected to be caused by alloantibodies of maternal origin (absorbed from colostrum). Immunologically mediated damage and destruction ensue.
Muscle	Immune-mediated myositis	Rapid onset of muscle atrophy associated with mononuclear infiltrate of macrophages and lymphocytes (mostly $CD4^+$ cells, lesser $CD8^+$ cells, and clusters of B cells) and no evidence of IgG deposition.
Synovial	Immune-mediated polysinovitis/ polyarthritis	Nonerosive polyarthritis and effusion of other synovial sheaths, such as tendons and bursae, with deposition of immune complexes and mild lymphocytic/plasmacytic infiltrate of synovial tissue: (1) associated with remote infectious processes (e.g., *Rhodococcus equi* pneumonia); or (2) without concurrent infectious process.

VetBooks.ir

triggering agent. Initial exposure leads to development of antigen-specific memory T cells that remain dormant until reexposure to the antigen. Following reexposure, APCs capture and process the antigen to present it to T cells in the context of MHC. This interaction results in IL-1 production by APC, as well as production of IL-2 and clonal expansion of the antigen-specific T cell of the Th1 phenotype, culminating with the production of large amounts of Th1 cytokines (IFN-γ, macrophage inhibitory factor, TNF-α, and TNF-β). This cascade of cytokines recruits nonspecific circulating leukocytes, including monocytes, segmented neutrophils, and lymphocytes to infiltrate the site. Following infiltration, which is responsible for the hallmark sign of induration in type IV hypersensitivity reactions, these chemoattracted cells also produce inflammatory mediators and cytokines that amplify the reaction. Examples of delayed-type hypersensitivity in horses include insect-bite hypersensitivity, contact dermatitis often to heavy metals and aniline dyes found in tack, bedding, soaps, and blankets.[1,53-55]

Evaluation of Immunologic Response in Horses

Lais R. Costa[†]

Assessment of immune response encompasses in vivo, in vitro, and ex vivo measurements of immune function and can be divided into three categories: (1) assays for characterizing the adequacy of the immune response when an immunodeficiency or immunosuppression is suspected (e.g., assays to assess humoral, cellular, and innate immune responses); (2) assays for identifying inappropriate or exaggerated immunologic responses when immune-mediated injury is suspected (e.g., antinuclear antibody titer, assay for platelet surface–associated IgG, isotype-specific antibodies coating erythrocytes); and (3) assays of immunologic recognition of pathogens (e.g., antibody titer to specific antigens or pathogens) and protection against infectious agents.[1-4] The aspects of immune response evaluation discussed in this section include only assays for characterizing the adequacy of the immune response when immunodeficiency or immunosuppression is suspected. Assays for identifying inappropriate immunologic responses when immune-mediated condition is suspected are discussed elsewhere.[2-4] Assays of immunologic recognition of pathogens and protection against infectious agents are discussed in this book under body systems or found elsewhere.[3,4]

Characterizing the Adequacy of the Immune Response

Assessment of the adequacy of a patient's immune response is warranted when there is an increased recurrence, severity, or chronicity of infectious illness above and beyond what is considered normal, especially if the possibility of enhanced virulence of the pathogen involved has been ruled out. Because immunodeficiency disorders are uncommon, they should only be considered after more common causes of recurrent infection have been excluded. It is important to remember that inadequate immune response may occur in association with malnutrition, neoplasia (especially leukoproliferative disorders), autoimmune diseases, immunosuppressive therapy, and the presence of underlying diseases such as PPID. In addition, immunosuppression and immune evasion mediated by the infectious agent itself should be considered. Therefore the diagnostic plan should include evaluation of the patient's immune response, as well as ruling out conditions that may account for the inadequate immune response of the patient.

In foals, adequate transfer of maternal immunity can transiently mask the onset of signs resulting from immunodeficiency. Therefore immunodeficiency in foals with adequate passive transfer of maternal immunity may not be recognized early in life. Moreover, increased susceptibility to infections is often accompanied by failure to thrive and poor growth. Weight and height should be compared with breed-appropriate age standards, in order to recognize abnormal growth patterns.

A list of assays to assess and characterize the adequacy of adaptive (humoral and cell-mediated) and innate immune responses is depicted in Table 53-6. In horses, only a limited number of assays to evaluate immune response are available from a practical standpoint, and most are crude indicators of immune response and therefore detect only severe deviations from normal. Nevertheless, a number of immunodeficiency syndromes have been characterized in horses. Moreover, the clinician may be able to characterize the patient's immunosuppressive state. Reagent development for characterization of the equine immune response is evolving, and the large animal clinician is encouraged to search for up-to-date information on assays for equine immunology. Information can be found at the following websites: (1) available tests—http://www.vet.k-state.edu/depts/dmp/service/immunology/index.htm and http://www.vet.cornell.edu/labs/EquineImmuno/testOverview.cfm and (2) equine immunology reagents, including monoclonal antibodies to cell surface molecules, equine cytokine reagents and receptors, and cloned equine cytokines and chemokines—http://www.umass.edu/vetimm/equine/index.html and http://www.ca.uky.edu/gluck/HorohovDW_EIR.asp.

Failure of Passive Transfer of Maternal Immunity

Debra C. Sellon • Melissa T. Hines • Jill R. Johnson

Definition and Etiology Normal foals are immunocompetent at birth (i.e., they are capable of mounting an immune response). However, they are immunologically naive in that they have had no exposure to foreign antigens and have therefore not yet mounted any type of protective immune response or accumulated significant levels of immunoglobulins. Although foals are capable of producing antibodies, they are essentially devoid of immunoglobulin at birth, with the exception of small amounts of IgM normally produced in utero. Because they are "starting from scratch," foals are indeed more susceptible to infectious agents during the early neonatal period. Foals begin mounting immune responses and producing their own immunoglobulins immediately on exposure to antigens after birth, and immunoglobulins produced by the foal are detectable within 1 to 2 weeks of life and reach significant levels by 2 months.

Immunologic protection of the newborn foal relies on the transfer of maternal immunity through the colostrum. Under normal circumstances, temporary protection against infection for the first 1 to 2 months of life is provided to the foal in the form of passively transferred antibodies, from the dam (Fig. 53-3; Table 53-7). Because of the diffuse epitheliochorial nature of the equine placenta, no transplacental transfer of immunoglobulins occurs in horses. Instead, ingestion and absorption of immunoglobulin-rich colostrum are the sole means of passive transfer in foals. In a properly functioning system, maternal antibodies wane as levels of autologous antibodies increase, and thus the neonate is never left totally unprotected (Fig. 53-4; Table 53-8).

Failure of the foal to ingest or absorb sufficient quantities of colostrum, primarily as defined by absorption of IgG, is termed *failure of passive transfer* (FPT). *Complete* FPT is defined as a foal with a serum IgG concentration of less than 400 mg/dL at 24 hours of age. *Partial* FPT is defined as a foal with a serum IgG concentration of 400 to 800 mg/dL at 24 hours of age. The reported incidence of complete or partial FPT in foals varies from 3% to 37.8%.[1-8] Risk factors for FPT include month of foaling, adverse health events for mare or foal in the periparturient period, age of the dam, and colostral immunoglobulin content. Low total immunoglobulin content in colostrum is associated with breed (e.g., Standardbred), age of dam (e.g., older mares), and low total solar radiation (i.e., shorter days).[2,7,9]

TABLE 53-6

List of Assays to Assess and Characterize the Adequacy of Immune Response in Horses

Test	Description	Purpose	Comments
Complete blood count (CBC)[3,5]	Standard hemogram including evaluation of cell morphology.	Identify abnormalities in number and morphologic changes of lymphocytes, monocytes, neutrophils, and eosinophils.	Part of the initial assessment as the minimum database of any patient. Equine CBC can be performed by most clinical pathology laboratories.
Immunophenotyping of peripheral lymphocytes[3,4,6-14]	Enumeration of specific subsets of lymphocytes using fluorescent antibodies to cell surface markers and flow cytometry (FCM).	Determination of circulating lymphocyte types: B cells ($CD19^+$ like, $CD20^+$, $CD21^+$, $sIgM^+$), T cells ($CD2^+$, $CD3^+$, $CD5^+$), $CD4^+$ T cells, and $CD8^+$ T cells, and determination of CD4:CD8 ratio.	In normal horses, about 20% of circulating lymphocytes are B cells, about 62% are $CD4^+$ T cells, and 18% $CD8^+$ T cells. Normal CD4:CD8 ratio is 3.5 ± 1.0. Peripheral blood lymphocyte phenotyping is offered at the Animal Heath Diagnostic Center—Cornell University, and at the Clinical Immunology Laboratory—Kansas State University.
Immunophenotyping of lymphocyte types and subsets in tissues[10,11]	Immunohistochemistry using antibodies to specific cell markers in order to sort out different lymphocyte types and subsets.	Determination of B cells ($sIgM^+$), T cells ($CD3^+$), $CD4^+$ T cells ($CD4^+$), and $CD8^+$ T cells ($CD8^+$) in lymphoid tissue specimens (such as lymph node, spleen, and bone marrow).	Enumeration of cell types in tissue samples may be done in formalin-fixed (with limitations), fresh, or frozen samples; the proper preparation of sample must be confirmed with the pathology laboratory performing the procedure.
Immunophenotyping of lymphocyte types and subsets in body fluids[10,11]	Immunohistochemistry or FCM using labeled antibodies to specific cell markers in order to sort out different lymphocyte types and subsets.	Determination of B cells ($sIgM^+$), T cells ($CD3^+$), $CD4^+$ T cells ($CD4^+$), and $CD8^+$ T cells ($CD8^+$) in samples from CSF, pleural fluid, peritoneal fluid, bone marrow, and lymph node aspirates.	Enumeration of cell types in body fluids and aspirates using immunocytochemistry is offered at the Animal Heath Diagnostic Center—Cornell University; FCM is offered at the Clinical Immunology Laboratory—Kansas State University.
Histologic evaluation of lymph node[10,11,14]	Histochemistry and immunohistochemistry with specific antibodies to B-cell markers.	Lack of germinal centers and decrease or absence of expression of B-cell markers are indicative of B-cell deficiency.	Offered at most diagnostic laboratories and at the Animal Health Diagnostic Center—Cornell University.
Serum protein electrophoresis[3,4]	Separation of serum proteins by gel electrophoresis.	To quantitate γ-globulins, which are primarily Igs, and determine if they are monoclonal or polyclonal.	In horses with repeated infections, serum Ig levels are likely to be high and polyclonal in nature. Monoclonal hypergammaglobulinemia is evidence of lymphocyte malignancy. Low levels of γ-globulins are supportive of Ig deficiency. Assay is offered at most clinical pathology laboratories.
Semiquantitation of immunoglobulins (Igs)[3,15-18]	(1) Precipitation of Igs using serial concentrations of specific salts (e.g., zinc sulfate or sodium sulfite precipitation, glutaraldehyde coagulation). (2) Species-specific tests based on antigen-antibody reactions, either latex bead agglutination or enzyme-linked immunosorbent assay (ELISA).	Semiquantitative tests are quick and easy to perform and therefore useful for some conditions, such as failure of transfer of passive immunity after colostrum ingestion and plasma transfusion.	Commercial tests based on these principles are available: (1) zinc sulfate precipitation: Equi-Z test kit, VMRD, Inc.; (2) glutaraldehyde coagulation: GammaCheck E, Plasvacc USA; (3) latex bead agglutination: Foalchek, Centaur, Inc.; (3) ELISA: equine IgG ELISA, GenWay Biotech, Inc.; Horse IgG ELISA kit, Immunology Consultants Laboratory, Inc.; SNAP-Foal IgG Test, IDEXX Laboratories, Inc. Precipitation of Igs can be used in several species, although the test may work better in some species than others. ELISAs are species specific. Specificity and sensitivity vary among tests, and scientific literature should be consulted.

VetBooks.ir

TABLE 53-6

List of Assays to Assess and Characterize the Adequacy of Immune Response in Horses—cont'd

Test	Description	Purpose	Comments
Radial immunodiffusion (RID) for quantitation of Igs [3,15-18]	RID quantitates Igs of specific isotypes using a precipitation reaction to species-specific, isotype-specific immunoglobulin (where the precipitation area is proportional to the concentration of Ig).	Accurate method for quantitating specific classes of Igs (e.g., IgG, IgM, IgA). RID requires incubation for 18-24 hr. Not recommended for evaluation of foals for failure of transfer of passive immunity after colostrum ingestion because of long turnaround time.	RID kits for many Ig isotypes of domestic animals are available commercially. Although test reagents are for a single species, some cross-reactivity exists among species but must be standardized and calibrated accordingly. RID kits for equine Ig isotypes are commercially available: RID for Equine IgG (Plasvacc USA); RID Test Kit (Kent Laboratories USA); Horse IgG Test (IDBiotech France). RID for IgG and IgM is performed at several veterinary clinical immunology laboratories. Specificity and sensitivity varies among tests and scientific literature should be consulted. RID kit for equine IgA is not currently available.
IgG turbidimetric immunoassay (TIA)[19]	TIA is based on the principles of immunologic agglutination and light scattering of the agglutination products. The automated TIA is performed on a chemistry analyzer.	Accurate method for quantitating equine IgG, with good correlation with RID but shorter turnaround time. TIA can be used to evaluate foals for failure of transfer of passive immunity after colostrum ingestion.	TIA is a quantitative test with high sensitivity and specificity. Kits for equine IgG TIA are commercially available: Midland Bioproducts Corporation, for use on Roche Cobas Mira chemistry analyzers and Hitachi 704 automatic analyzers; Equine IgG serum/plasma test kit from HAR-VET for use with DVM Rapid Test Instruments. TIA for equine IgG is offered in veterinary diagnostic laboratories (e.g., Animal Health Diagnostic Center—Cornell University).
Measurement of specific antibody responses pre vaccination and post vaccination[10,11]	Paired serum samples pre vaccination and 15 to 20 days post vaccination are tested to measure Ag-specific Ab response.	To determine B-cell function by evoking an anamnestic response to a protein Ag.	Serum tetanus toxoid Ab titers pre vaccination and post vaccination are offered at the Equine Clinical Immunology Laboratory—Cornell University.
Peripheral blood phagocytic functions of opsonization capacity, phagocytosis, and oxidative burst[20-26]	Peripheral blood leukocytes are incubated simultaneously with oxidative sensitive dye dihydrorhodamine (DHR), and inactivated *Staphylococcus aureus* labeled with red fluorescent dye propidium iodide (PI), opsonized with pooled or autologous serum (heat-inactivated serum or no serum used as controls). Oxidation of DHR generates green-fluorescent rhodamine 123 (rho). Two-color FCM analysis is performed for rho and PI, for oxidative burst and phagocytosis, respectively.	To evaluate functions of the innate immune response: opsonization by serum complement components and Igs, phagocytosis by neutrophils and monocytes, and oxidative burst by neutrophils.	The opsonization capacity and phagocytosis are generally performed for research purposes. The oxidative burst activity in peripheral blood neutrophils is offered upon special request at the Equine Clinical Immunology Laboratory—Cornell University.
Intradermal (ID) skin testing with the plant lectin phytohemagglutinin (PHA)[27]	Measure the thickness of a skin fold before injection, then inject ID 50-µg of PHA dissolved in 0.5 mL of phosphate-buffered saline (PBS), and at a different site 10 cm (4 inches) away, 0.5 mL of PBS is injected as control. After 24 hr the skin thickness of both injection sites is measured.	PHA, unlike other compounds such as dinitrochlorobenzene, is capable of eliciting a delayed-type hypersensitivity response without requirement of prior sensitization. Increase in skin thickness should be greater than 0.6 mm; otherwise there is a defect in cell-mediated immunity.	The ID testing with PHA might yield false results; therefore confirmation with in vitro assay of lymphocyte blastogenesis assay is recommended.

TABLE 53-6

List of Assays to Assess and Characterize the Adequacy of Immune Response in Horses—cont'd

Test	Description	Purpose	Comments
Lymphocyte proliferation (blastogenesis) assay[11-14]	Lymphocytes are harvested from peripheral blood sample, incubated with serial concentrations of various mitogens, and labeled nucleotide. Incorporation of radiolabeled isotope into newly synthesized DNA is measured. Alternatively, proliferation analysis is evaluated using fluorescent-label and measured via FCM.	In vitro lymphocyte blastogenesis with pokeweed mitogen (PWM) requires both B- and T-cell function for normal responses, whereas in blastogenesis with PHA, concavalin A indicates primarily T-cell function.	No longer routinely offered. Generally performed for research purpose or academic interest by immunology laboratories (e.g., the Equine Clinical Immunology Laboratory—Cornell University).
Equine cytokine 5-plex assay[28]	Detects soluble equine IL-4, IL-10, IL-17, IFN-γ, and IFN-α in biological samples using paired monoclonal Abs specific for each cytokine and fluorescent bead/microspheres that are color coded.	Detects the concentration of each cytokine as pg/mL of biological sample in order to identify typical T-cell and antiviral cytokines in biological samples from horses.	Offered at the Animal Heath Diagnostic Center—Cornell University (see http://ahdc.vet.cornell.edu/docs/Equine_Cytokine_5plex_assay.pdf)
SCID genetic testing[29]	Collect a sample from a convenient source of DNA: (1) swab of the inside of the mouth with a mucosal brush and submit the brush containing mucosal cells, (2) blood sample in EDTA or ACD anticoagulant, or (3) pulled mane or tail hair, place in a clean bag, and submit to DNA testing.	A DNA-based carrier test for the genetic mutation affecting the DNA-dependent protein kinase (DNA-PK) located in chromosome 9.	Offered by VetGen, Ann Arbor, MI (see www.vetgen.com; http://www.vetgen.com/equine-scid-service.html)
Foal immunodeficiency syndrome genetic testing[30]	Collect a sample (pulled mane or tail hair), place in a clean bag, and submit to DNA testing.	A DNA-based carrier test for genetic defect affecting the sodium/myo-inositol cotransporter gene *(SLC5A3)* located in chromosome 26.	Offered at the Animal Health Trust, Newmarket, UK (see http://www.aht.org.uk/cms-display/genetics_fis.html)

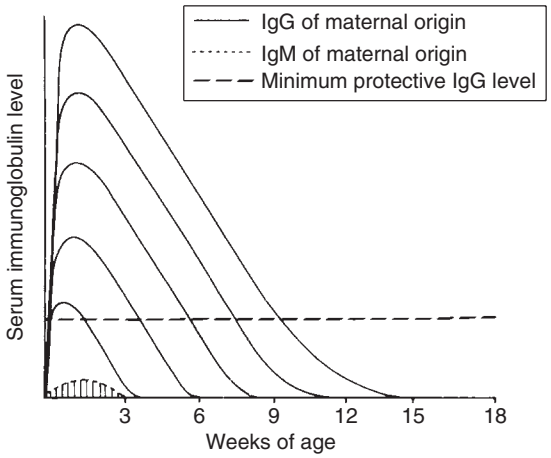

FIG. 53-3 The duration of protection provided by maternal immunoglobulins varies with the isotype of immunoglobulin and the quantity ingested during the first 24 hours of life.

Immunoglobulins are not produced locally in the mammary gland but rather are selectively concentrated from the mare's sera into colostrum in response to hormonal changes that occur in the last 2 weeks of pregnancy. The predominant immunoglobulin isotype in equine colostrum is IgG, followed by IgA and smaller quantities of IgM.[10] The reported amount of total IgG in equine colostrum is quite variable among different studies (see Table 53-7), but overall a good quality colostrum should contain 2500 to 5000 mg/dL. The reported amounts of IgA often range between 500 to 1500 mg/dL, whereas IgM generally range between 100 to 350 mg/dL. At birth the neonate has specialized enterocytes in the gastrointestinal (GI) tract that can absorb large molecules such as immunoglobulins intact by pinocytosis.[11] Absorbed proteins pass through the intercellular spaces and lacteals into the systemic circulation via the lymph. The window of gut absorptive capacity for immunoglobulins is narrow, lasting from birth until about 18 to 24 hours. Maximal absorptive efficiency occurs immediately after birth, declining to only 22% efficiency at 3 hours after birth and less than 1% by 20 hours.[12,13] The decline in immunoglobulin absorption is accompanied by transient proteinuria that peaks at 6 to 12 hours of age and declines by 24 to 36 hours of age. This proteinuria most likely reflects absorption and excretion of low-molecular-weight milk proteins.[13]

Diminished immunoglobulin absorption over the first 12 to 24 hours of life is the result of shedding of specialized enterocytes capable of pinocytosis and replacement by more mature cells that are incapable of absorbing immunoglobulins.[12,14] It has been hypothesized that delayed ingestion of macromolecules may prolong the duration of intestinal permeability to immunoglobulins. In one study, however, the type of fluid administered to foals before the ingestion of colostrum did not influence subsequent IgG absorption, suggesting that the process of gut closure is not mediated by a finite capacity for the uptake of macromolecules.[15]

The half-life for maternal antibodies in the foal's circulation varies between 20 and 30 days.[16-18] Concentrations decline as a result of normal protein catabolism, gradual dilution associated with an increasing plasma volume as the foal grows, and transfer of functional antibody into the GI tract. Most maternal antibodies are present in only negligible concentrations by 6 months of age, although antibodies to some infectious agents have been detected for up to 12 months after birth. As passive antibody concentrations decline, endogenous antibody production begins. There is a nadir in serum immunoglobulin concentrations in colostrum-fed foals at approximately 1 to 2 months of age, followed by gradually increasing concentrations until adult levels are reached at 5 to 10 months.[19,20] Serum

NA, Not available.

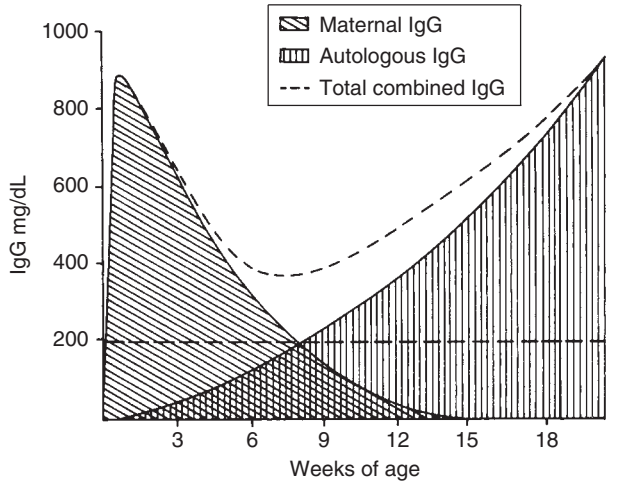

FIG. 53-4 Maternal immunoglobulin wanes, whereas the production of autologous immunoglobulin increases during the first several months of life. The combined total amount of immunoglobulin ideally remains above the level considered minimum for maintenance of good health.

immunoglobulin concentrations are similar in colostrum-fed and colostrum-deprived foals by 3 to 4 months of age.

In addition to antibody, other colostral factors may be important for optimal immune protection of foals. For example, colostrum influences cell-mediated immunity and activates granulocytes. Colostrum contains many constituents of innate immunity and immunomodulating agents, such as cytokines,[21] growth factors,[22] hormones,[22] enzymes,[23] lymphocytes, macrophages, neutrophils, and epithelial cells.[21] The cellular components of colostrum are likely to play an especially important role in local gastrointestinal immunity in the neonatal foal. Maternal cells are found in a variety of blood and tissues in the neonate after absorption of colostrum, suggesting that these cells may also play a role in systemic immunity.[21]

In foals, FPT may occur because of ingestion of poor-quality colostrum with a low immunoglobulin content, failure to ingest a sufficient quantity of colostrum, or failure to absorb colostral immunoglobulins from the GI tract.[24] Colostrum may have an insufficient quantity of immunoglobulin because of prelactation (lactation before parturition), premature foaling, a defect in the mare's ability to concentrate immunoglobulin in the colostrum, ingestion of endophyte-contaminated fescue grass or hay, or other factors. Premature lactation is most commonly associated with twin pregnancies, placentitis, and premature placental separation but occasionally occurs without any concurrent uterine, placental, or fetal pathology. Mares most likely to produce colostrum with low immunoglobulin content are those older than 15 years of age, those that foal early in the year, and Standardbred mares.[2,7,9] Insufficient colostral immunoglobulin concentration has also been associated with ingestion of endophyte-contaminated fescue grass or hay.[25,26]

Foals that are orphaned or rejected at birth, too weak to stand, or unable or lack the desire to suckle are unlikely to ingest sufficient colostrum to prevent FPT. Malabsorption is occasionally incriminated as a cause of FPT in foals that are observed to suckle adequate quantities of good-quality colostrum. This most often happens in premature or dysmature foals, possibly as a result of immature GI function, but may also occur in otherwise healthy and vigorous full-term foals.[27] Glucocorticoids enhance the maturation of small-intestinal epithelial cells and thus their loss of absorptive capacity, leading to speculation that endogenous corticosteroids released secondary to stress at parturition may impair immunoglobulin absorption in foals.[28,29] However, administration of adrenocorticotropic

VetBooks.ir

hormone (ACTH) failed to affect absorption in experimental foals, and stress has not been a consistent historic finding in foals with FPT caused by presumptive impaired immunoglobulin absorption.[5,30]

Clinical Signs and Differential Diagnoses The association between FPT and infection has been investigated in numerous studies.[1,2,4,7,8] Although the results have varied somewhat, FPT is generally considered a risk factor for infectious disease. By itself, FPT produces no clinical signs of disease and cannot be detected by physical examination. Clinical presentations that strongly suggest an underlying problem with FPT include onset of bacterial infections within the first 2 weeks of life, particularly septicemia, septic arthritis, pneumonia, and enteritis. Other immunodeficiencies or simply exposure to potent pathogens cannot be ruled out solely on the basis of the time of onset; however, even with other forms of immunodeficiency, clinical signs of infection usually do not show up for several weeks if passive transfer is adequate.

Clinical Pathology FPT is diagnosed by the demonstration of low serum concentrations of IgG in the foal as early as 6 to 12 hours after birth and probably for as long as several weeks after birth (see Table 53-7). The level of IgG considered adequate for protection against infectious disease is poorly defined and probably varies considerably with the environment. A serum IgG concentration greater than 800 mg/dL is considered adequate for most foals. However, levels of 400 mg/dL may be sufficient in healthy foals housed in clean environments. In contrast, an IgG concentration of 400 to 800 mg/dL in a foal at high risk for sepsis because of its environment or other factors indicates the need for treatment. Importantly, these figures only address *total* immunoglobulin content and not specific antibody titers, which also play a critical role in determining resistance to particular pathogens.

In healthy foals that nurse within 2 hours of birth, serum IgG concentrations become detectable at approximately 6 hours of age and peak at approximately 18 hours. Routine determination of serum IgG concentrations in apparently healthy foals is usually recommended at 18 to 24 hours of age. Foals considered to be at high risk for FPT and sepsis may be assessed as early as 6 to 12 hours of age.[31,32]

Methods available for IgG quantitation include single radial immunodiffusion, zinc sulfate turbidity, latex agglutination, glutaraldehyde coagulation, turbidimetric immunoassay, and enzyme-linked immunosorbent assay.[31,33-38] Selection of an appropriate screening test for a specific farm or foaling environment should be made after considering overall accuracy, time necessary to perform the test, simplicity of the testing procedure, technical skills and knowledge of the attending personnel, and cost. Single radial immunodiffusion is considered the most quantitatively accurate diagnostic test of those widely available to practitioners. However, this test is more expensive than some other screening tests, and results are not available for at least 24 hours, making it impractical when an at-risk foal needs rapid diagnosis and treatment. Total serum protein is not a reliable indicator of FPT in foals (unlike calves) because of the wide variation in total serum protein in cases of adequate transfer.[38] Many veterinarians prefer to use commercial kits based on enzyme-linked immunosorbent assay or glutaraldehyde coagulation technology for stall-side screening of foals.[39,40] Both types of tests have high sensitivity and negative predictive value. False-negative and false-positive results tend to be more common when attempting to accurately identify foals with partial FPT with an IgG concentration of 400 to 800 mg/dL.

No consistent changes in the hemogram and biochemical panel are seen in foals with FPT; however, a range of abnormalities related to secondary infection (e.g., neutrophilia, neutropenia), hyperfibrinogenemia, and hypoglycemia may be present. The presence and severity of these changes depend on the organisms and systems involved.

Necropsy Findings No specific necropsy findings are indicative of FPT. Necropsy findings reflect the site and severity of secondary infectious problems that have developed. Lymphoid tissue is normally developed, unless secondary infections have caused lymphoid necrosis or atrophy.

Treatment and Prognosis Treatment of FPT depends on the degree of FPT, the environment in which the foal is exposed, the foal's age at diagnosis, and the presence of secondary infectious problems. Treatment is aimed at minimizing exposure to pathogens, supplying immunoglobulins, and managing secondary infections, if present.

If FPT can be anticipated within hours of birth because of premature lactation, low specific gravity colostrum, or a weak or orphaned foal, treatment can include the provision of an alternative source of colostrum or antibody orally. Foals with complete colostrum deprivation require approximately 1.5 g IgG/kg body weight to achieve a peak serum IgG concentration of more than 800 mg/dL. In a 45-kg foal, administration of 1 to 3 L of colostrum with a specific gravity greater than 1.060, divided into multiple hourly feedings over the first 6 to 8 hours of life, is desirable. Mares that donate colostrum for feeding should be healthy, checked for blood type, negative for anti–red blood cell (RBC) alloantibodies (especially anti-A and anti-Q), and appropriately vaccinated during the last 4 to 6 weeks of gestation.

If equine donor colostrum is not available, bovine colostrum, a commercial colostrum substitute, or equine plasma may be administered orally to the foal.[41-48] Because bovine colostrum is often more readily available than equine colostrum, it may be substituted in emergency situations when equine colostrum is not available. Bovine colostrum is relatively well absorbed in the foal, but bovine immunoglobulins have a much shorter half-life in foals and do not contain antibodies specifically directed against equine pathogens. It is certainly better than no colostrum and, on the basis of a small experimental study, may be used without creating adverse reactions.[8,43-45] Approximately 2 to 4 L should be administered orally; many foals develop transient mild diarrhea.

Concentrated equine serum products such as Seramune Oral (Sera, Inc., Shawnee Mission, Kan.) are available for use in foals with FPT.[49] In one study, however, it failed to increase serum IgG concentrations in colostrum-deprived foals to adequate levels, probably because of the relatively low total IgG dose administered.[48] If the product contains 25 to 30 g of IgG per 300-mL bottle, approximately three bottles may be required to increase the serum IgG concentration of a 45-kg colostrum-deprived foal to greater than 400 mg/dL.[48]

If no other sources of immunoglobulin are available for a foal, oral administration of equine plasma or serum may be considered. This is an expensive source of oral immunoglobulin, however, and approximately 2 to 4 L are required to treat a colostrum-deprived 45-kg foal.

If the foal is older than 6 hours of age, the absorption of colostral antibody is significantly decreased, although a locally protective effect of the colostrum may still be present in the intestinal tract. If the foal is older than 12 hours of age, it is unlikely that sufficient colostrum will be absorbed; therefore immunoglobulin levels should be rechecked at 24 hours and intravenous (IV) plasma transfusion given, if indicated by persistently low serum immunoglobulin levels.

Some animals with FPT, particularly partial FPT, do well without treatment if they are systemically healthy, are not heavily exposed to pathogens, and have no preexisting infections. FPT itself is not necessarily fatal. If plasma transfusions are not administered, owners should be made aware of the risks, and these foals should be maintained in an environment with minimal exposure to potential pathogens. Foals with other risk factors for septicemia (e.g., prematurity, dysmaturity, placentitis) should receive IV plasma transfusions if they have blood IgG concentrations of less than 800 mg/dL at 12 to 24 hours of age.

If the decision is made to supplement plasma parenterally, equine plasma for transfusions can be collected and processed locally, or obtained commercially. Available sources of commercial

VetBooks.ir

equine plasma include Plasmune (formerly Foalimmune) and HiGamm-Equi (Lake Immunogenics, Inc., Ontario, NY); Equi-Plas and Polymune (Plasvacc USA, Inc., Templeton, Calif.); and Immuno-Glo Normal Equine Plasma (Mg Biologics, Inc., Ames, IA).[60] Commercial sources are convenient, save time, have been screened for anti-RBC antibody, are free of diseases such as equine infectious anemia, and originate from animals with known immunoglobulin levels. The major disadvantage is that plasma may not contain antibodies specific for the pathogens from the particular environment to which the foal is exposed.

Use of a local donor has the potential benefit of providing antibodies specific to the environmental pathogens to which the foal has been exposed. If a local donor is to be selected, several criteria should be met. First, the horse should be healthy, and results of agar gel immunodiffusion for equine infectious anemia should be negative. Second, no anti-RBC antibody should be detectable in the horse's serum. The donor's plasma should be screened for lysins and agglutinins by a blood-typing laboratory against a panel of cells representing all known blood groups. If plasma evaluated in this way is not available, the presence of anti-RBC antibody in donor plasma can be crudely evaluated with a minor crossmatch for agglutination using donor plasma and recipient blood cells. Lytic antibodies require an external source of complement for activity in vitro and may not be detected using this test.

Ideally, a third criterion is selection of a horse that is negative for blood group factors Aa and Qa. Even though there are dozens of blood group factors, Aa and Qa have been associated with the great majority of cases of neonatal isoerythrolysis (NI).[50-52] If plasma is collected and separated by sedimentation, it is inevitable that some RBC contamination be present. If Aa-positive (Aa+) RBCs are given to an animal that is Aa negative (Aa–) or if Qa+ RBCs are given to an animal that is Qa–, the recipients could become sensitized to these antigens. This sensitization would probably not have any immediate consequences for the recipient foal because the foal's cells would not be affected by the antibodies, but it has potentially sensitized any Aa– and Qa– females for production of an NI foal later (see section on allogeneic incompatibilities). To avoid these potential complications, the ideal donor should be Aa– and Qa– and possess no anti-RBC antibody in its serum. It is desirable to have identified this type of donor to avoid the need for immediate crossmatching in every case of plasma transfusion.

The volume of plasma needed to correct the measured IgG deficit in a foal can theoretically be calculated on the basis of the blood volume of the foal and the concentration of IgG in the foal's serum and in the donor plasma; however, these calculations do not reliably predict the actual levels of IgG achieved after transfusion.[31,53] A 20-mL volume of plasma per kilogram of body weight administered intravenously in general only raises serum IgG levels 200 to 300 mg/dL, and often two to three times this amount is necessary to bring serum IgG levels into the range considered minimum for protection (e.g., 400 to 800 mg/dL).[31,54] If the foal is already clinically ill, additional plasma will often be required to raise IgG levels an equivalent amount.[31,37] In a newborn foal (estimated 50 kg) with complete FPT, between 2 and 4 L of plasma is frequently necessary.

Plasma should be administered through an IV catheter placed aseptically in one jugular vein. Frozen plasma is thawed and warmed slowly to room temperature in a warm water bath. Microwave thawing or thawing with high temperatures is not recommended because this may denature important plasma proteins. An appropriate in-line blood filter should be used for IV administration of any blood product to remove fibrin clumps and other debris. Initial infusion rates should be slow (0.5 mL/kg over 10 to 20 minutes) to monitor for adverse reactions. Muscle fasciculations, piloerection, increased heart or respiratory rate, fever, respiratory distress, abdominal pain, blanching of mucous membranes, and collapse are indicative of transfusion reactions. In the absence of these or other adverse effects, the remainder of the transfusion may be administered at rates up to 40 mL/kg/h. Slower infusion rates are recommended for foals that are systemically ill. If other IV fluid therapy is being administered concurrently, slower infusion rates are also indicated to diminish the likelihood of inadvertent fluid overload.

Serum IgG concentrations in the foal should be rechecked 12 to 24 hours after plasma transfusion to confirm that the desired increase has been achieved. The delay from transfusion to IgG assessment is necessary to allow for distribution of immunoglobulin into extravascular spaces. Healthy foals transfused with plasma at 1 day of age experienced a 30% decrease in serum IgG concentrations by 7 days of age.[55] This decline might be even more dramatic in septic foals with increased vascular permeability, increased catabolism, and increased demand for utilization in immune responses.

Although several equine serum-derived products are marketed for IV administration in the treatment of foals with FPT, these products have been associated with significant adverse reactions in some foals. Administration of high-quality equine plasma is preferred for treatment of foals with FPT.

Prevention and Control Evaluation of colostral immunoglobulin content has proved to be valuable in predicting the occurrence of FPT and assessing the neonate's risk for FPT.[31,56] Colostrum with high immunoglobulin concentration tends to be sticky, yellow, and thick, but these subjective criteria are unreliable in assessing colostral quality. The quantity of immunoglobulin in colostrum may be more accurately estimated by single radial immunodiffusion (RID), refractometry, glutaraldehyde coagulation, or specific gravity.[55] Because 18 hours are required to read the results of RID, it is more practical in a field situation to assess specific gravity with a refractometer, glutaraldehyde coagulation test, or colostrometer. Sugar refractometry using a handheld Brix 0% to 50% sugar refractometer is a simple and cost-efficient stall-side screening test for assessing colostral quality.[57,58] A Brix reading of 20% to 30% correlates with adequate colostral quality; a reading greater than 30% indicates good-quality colostrum.[59] A commercial kit based on glutaraldehyde coagulation of immunoglobulins is the Gamma-Check-C (Veterinary Dynamics, San Luis Obispo, Calif.). Using a colostrometer such as the Equine Colostrometer (Lane Manufacturing Company, Denver, Colo.), colostral specific gravity should be a minimum of 1.060, corresponding to an IgG concentration of greater than 3000 mg/dL; levels of 6000 mg/dL or higher are desirable. Approximately 75% of foals that ingest colostrum with a specific gravity less than 1.060 will have serum IgG concentrations less than 400 mg/dL; when colostral specific gravity is greater than 1.060, foals usually attain serum IgG concentrations above 500 mg/dL.[56]

Some of the causes of FPT can be alleviated or recognized for early intervention by careful management. These include identification of mares that drip colostrum before parturition, attendance at foaling to ensure that foals suckle within several hours of birth or are supplemented artificially with colostrum, and screening of high-risk foals with doubtful nursing histories. Routine screening of foals at 18 to 24 hours of age allows early identification of FPT and potentially allows for therapy before the onset of infections. Although signs of septicemia secondary to FPT are often first observed on days 3 to 4 of life, a bacteremia may already be present at 24 hours of age or earlier.[56,59]

A colostrum bank can be established by collecting small amounts of colostrum from lactating mares (e.g., 200 to 250 mL) within the first 3 to 6 hours after foaling. This is only about 10% of the total colostrum produced by the average mare in the first 20 hours after parturition and therefore does not adversely affect the foal suckling the donor mare. Although the volumes are quite variable, mares produce about 300 mL of colostrum per hour and about 5 L during the first 18 hours. Colostrum can be stored frozen for at least 1 year at standard freezer temperatures, approximately −20° C (−4° F). Although frozen immunoglobulins are stable for much longer, the overall quality of the colostrum may deteriorate. Ideally, banked colostrum should be screened for the presence of anti-RBC antibodies as advised for plasma. Colostrum typically has low titers of agglutinins, which are probably not of significance unless they present a dilution of 1/8 or greater.

Severe Combined Immunodeficiency

Melissa T. Hines • Debra C. Sellon • Jill R. Johnson

Definition and Etiology Severe combined immunodeficiency (SCID) is a group of disorders in which both T- and B-cell functions are absent.[1-4] SCID has been recognized in several species, including humans, mice, dogs, and horses.[2-8] In horses, the condition primarily affects Arabians and part Arabians, although sporadic cases have been described in other breeds, such as Caspians and Appaloosas.[2,3,9,10] Affected foals are highly vulnerable to infections as a result of a stem cell defect that prevents maturation of T and B cells and leads to a complete inability to produce antigen-specific immune responses. In horses of Arabian breeding, the condition is transmitted as an autosomal recessive trait.[11]

Clinical Signs and Differential Diagnoses Foals clinically affected with SCID are typically normal at birth, but the absence of both specific humoral and cellular immunity renders them susceptible to infections once colostral protection wanes.[2,3] Typically, affected foals will develop infectious diseases between birth and 2 months of age and die before 5 months of age. The age of onset of infectious disease depends to some degree on the adequacy of passive transfer of maternal immunity and the degree of environmental challenge by organisms. Infections in affected individuals can be caused by a variety of bacterial, viral, parasitic, and fungal agents, some of which rarely affect animals that are not immunocompromised.[2,12-17] Many body systems may be involved, but pneumonia is particularly common. *P. jiroveci* (formerly called *P. carinii*) pneumonia and adenoviral pneumonia are often found in SCID foals as compared with other foals. Differential diagnoses include other immunodeficiencies in foals.

Foals of Arabian breeding that show clinical manifestations of SCID are homozygous for the defective SCID gene. Carriers of the gene are asymptomatic but can be detected by production of an affected offspring or genetic testing.[18,19] Recently, a correlation between heterozygosity for the SCID allele and the development of sarcoids has been demonstrated, suggesting that the gene may play a role in tumor suppression.[6]

Clinical Pathology A consistent finding on the hemogram is an absolute lymphopenia, which is less than 1000 lymphocytes/μL and often much lower.[20,21] Depending on the neutrophil response, the total white blood cell count may be low, normal, or elevated, making it essential that the absolute number of lymphocytes be determined. Infected and other compromised foals, as well as some normal foals, may have low lymphocyte counts during the first few days of life; therefore persistent lymphopenia should be established before considering a diagnosis of SCID.[22]

Concentrations of autologous serum immunoglobulin are low in foals affected with SCID.[20,23-25] The presence of colostral antibody may mask these low levels of autologous immunoglobulin and therefore the degree of colostral transfer and the age of the foal should be considered when interpreting the serum immunoglobulin values (see Table 53-7). In normal foals, IgM is produced in utero, and thus some IgM should be present in presuckle serum.[26] Although not pathognomonic, the absence of IgM in presuckle serum is a feature of SCID. Also, due to the relatively low concentrations of IgM in colostrum and the short half-life of IgM (see Table 53-8), maternally derived IgM is generally absent from the circulation by about 3 weeks of age. Thus the absence of serum IgM after 3 weeks of age, although also not pathognomonic, is consistent with SCID.

Foals affected with SCID do not respond to intradermal PHA by increasing skin thickness as do normal foals, nor do they respond to delayed-type hypersensitivity (DTH) stimulators, such as dinitrochlorobenzene.[27] In vitro tests such as blastogenesis are depressed with all mitogens.[20,21,24] The definitive diagnosis of SCID in foals of Arabian breeding is based on demonstrating that the foal is homozygous for the defective SCID gene.[18,28] Blood or cheek swabs may be submitted to VetGen (for complete address in Ann Arbor, Mich., visit www.vetgen.com) for deoxyribonucleic acid (DNA) testing to determine if a horse is clear, heterozygous, or homozygous for the gene defect. Before the advent of genetic testing, the criteria required to confirm a diagnosis of SCID included (1) persistent lymphopenia (<1000/μL), (2) absence of serum IgM in presuckle samples or samples collected after 3 weeks of age, and (3) thymic hypoplasia and characteristic histopathologic changes in lymphoid tissue.[25,29] These criteria were used to diagnose SCID in a Caspian filly with pneumonia that was negative for the defective gene of Arabians.[9] This suggests that a different mutation could be involved in some cases of SCID.

Pathophysiology Foals of Arabian breeding with SCID have a mutation in the gene encoding the catalytic subunit of DNA-dependent protein kinase (DNA-PK) and thus lack activity of this enzyme.[4,7,28,30,31] The mutation results in a five-base-pair deletion in the gene on equine chromosome 9. This results in a frameshift and a 967 amino acid deletion from DNA-PK, making the protein unstable. Without functional DNA-PK, lymphocyte precursors are unable to complete gene rearrangement events that lead to the expression of antigen-specific receptors on lymphocyte surfaces, namely T-cell receptor and immunoglobulin. As a result, there is an absence of mature, functional T and B lymphocytes. IFN-γ (EqIFN-γ), which is primarily produced by lymphocytes, is deficient.[32]

Neutrophils, monocytes, and NK cells appear to be fully functional and complement concentrations are normal.[2,33,34] Although these nonspecific protective mechanisms appear to be intact, the absence of both cell-mediated and antibody-mediated immunity leaves the foal vulnerable to even innocuous infectious agents.

Epidemiology SCID has been reported in Arabians in the United States, Canada, Australia, Morocco, and Great Britain.[2,3,35-37] It is believed that the trait originated in a horse in Great Britain and was subsequently imported into other countries. The distribution of this disease provides a significant example of the *founder effect* in population genetics.

The prevalence of SCID at one time was estimated to be 2% to 3% of Arabian foals born in the United States.[38] From this, it was predicted that the numbers of SCID carriers at that time could be as high as 25% of the U.S. Arabian horse population. The number of carriers appears to have decreased. Studies of Arabian horses in 1998 and 2002 found the frequency of SCID gene carriers to be approximately 8%, leading to the prediction that 0.18% of Arabian foals would be affected with SCID, assuming a random breeding population.[6,36]

Necropsy Findings Lymphoid tissues should be evaluated both grossly and histologically in cases of suspected immunodeficiencies. In SCID the thymus is small and has a fatty appearance on gross examination.[24,29,39] Because the thymus may be difficult to identify, mediastinal tissue often must be collected "blindly" for subsequent histologic evaluation and identification of thymic remnants. Histologically, the thymus is largely replaced with adipose tissue, with only islands of lymphoid cells and partially formed Hassall corpuscles present.

The spleen and lymph nodes may not be significantly abnormal on gross examination, but they generally have microscopic abnormalities, including an absence of germinal centers and periarteriolar lymphocytic sheaths in the spleen, as well as an absence of germinal centers with scarcity of lymphocytes in other areas of lymph nodes (Fig. 53-5, *A*).

Foals with SCID typically have evidence of infectious disease on necropsy, with bronchopneumonia being particularly common (see Fig. 53-5, *B*). Infectious lesions in other systems are also frequently found, including colitis and hepatitis.

Treatment and Prognosis Affected foals invariably die by about 5 months of age, despite intensive conventional therapy (e.g., antimicrobials, plasma, isolation).[40] There is no practical method of curing affected foals at this time. Successful bone marrow transplants

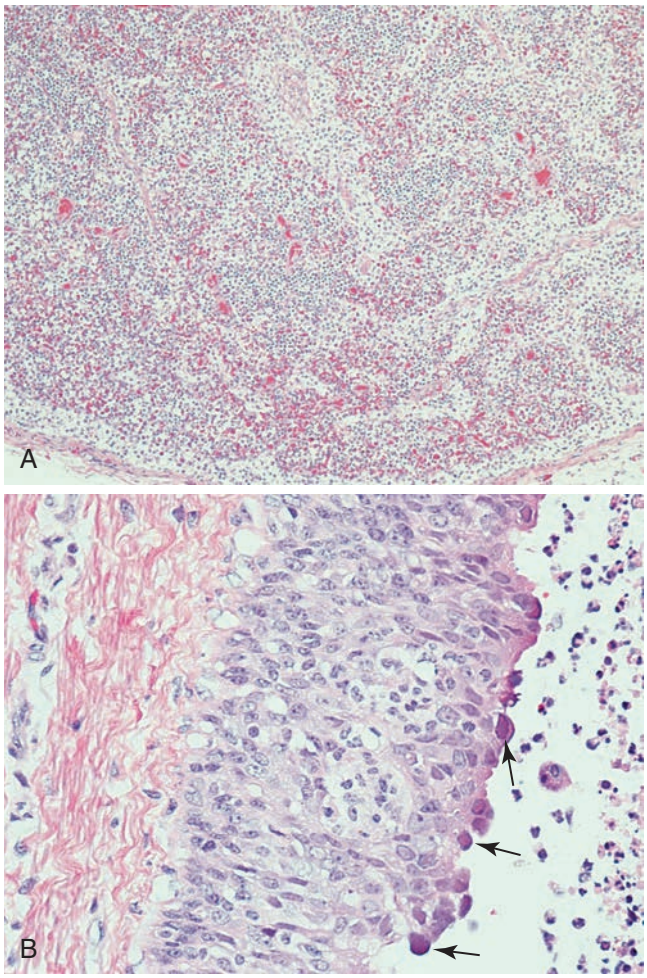

FIG. 53-5 Tissue from an Arabian foal with SCID. The foal presented at 1 month of age for evaluation of persistent pneumonia. **A,** 200× mediastinal lymph node with extensive lymphoid atrophy. The node is poorly populated with lymphocytes that fail to form lymphoid follicles, and active germinal centers are lacking. The node is predominantly composed of loosely scattered resorbed mononuclear cells and edema. **B,** 400× tracheal epithelium with adenovirus inclusion *(black arrows),* epithelial hyperplasia, and suppurative tracheitis. *(Photos courtesy Sushan Han.)*

have been performed between histocompatible full siblings in a research setting, but this option remains impractical.[41-43]

Prevention and Control SCID in horses of Arabian breeding is an autosomal recessive trait, and therefore production of an affected foal identifies both sire and dam as carriers of the SCID gene.[11] Mating of two carriers is expected to result in one in four foals affected with SCID, one in four completely normal and not a carrier, and two in four asymptomatic carriers of the SCID trait. Mating of a carrier and a normal (noncarrier) does not produce any affected foals, but half the offspring would be expected to be carriers.

The disease can be controlled in horses of Arabian breeding by avoiding the production of affected foals, which has been simplified now that carriers can be identified by genetic testing. Mares and stallions intended for breeding should be tested to determine whether they are free or heterozygous for the defective SCID gene. Under no circumstances should two heterozygotes be mated to each other. If an owner decides to continue breeding a heterozygote, the breeding partner should be confirmed homozygous normal. All foals from such matings should be tested to determine if they are clear of or heterozygous for the defective gene (50:50 probability). Homozygous normal foals may be selected for future breeding purposes, whereas heterozygous foals should be used for nonreproductive purposes.

Selective IgM Deficiency

Melissa T. Hines • Debra C. Sellon • Jill R. Johnson

Definition and Etiology Selective IgM deficiency is an immunologic disorder characterized by absent or decreased serum IgM levels with normal or elevated levels of other immunoglobulin classes. Three presentations of the disorder have been described in horses.[1-5] The most common involves foals that have severe infectious pneumonia, arthritis, or enteritis, resulting in death before 10 months of age. The second involves foals with a history of repeated episodes of infections that respond to antimicrobial therapy but recur when treatment is stopped. These foals tend to do poorly and are stunted, although they may survive for 1 to 2 years. The third involves older horses that are usually 2 to 5 years of age at initial diagnosis. These horses do not necessarily have problems with recurrent infections, but about half ultimately have lymphosarcoma.[5] Selective IgM deficiency has been most frequently reported in Arabians and American Quarter Horses, although it affects other breeds as well.

It is unclear whether the IgM deficiencies reported in foals are primary or secondary. The levels of IgM present before the onset of infections have not been measured. The occurrence of multiple cases within groups of related horses suggests a genetic basis. However, to date, breeding trials have been inconclusive with regard to the heritability of this condition. In people, both primary and secondary selective IgM deficiencies occur.[6-8] Secondary cases in human patients are often associated with neoplasia, immunologic diseases such as Wiskott-Aldrich syndrome, and gluten-sensitive enteropathies.

Clinical Signs and Differential Diagnoses Foals with selective IgM deficiency tend to have frequent respiratory infections, and *Klebsiella* is commonly isolated. Other infections, such as enteritis and septic arthritis, have also been reported. The age of onset of clinical signs may be slightly later than in foals with SCID and certainly later than in foals with FPT.

Older horses with IgM deficiency should be carefully evaluated for lymphoid neoplasia. The clinical signs and hematologic features of lymphoma in horses are often nonspecific (see Chapter 37). Although the signs can vary with the tumor location, weight loss, lethargy, edema, and pyrexia are common. Lymphadenopathy may be present. On blood work, affected horses are often anemic. Frank leukemia is uncommon. Although not a consistent finding, hypercalcemia of malignancy has been reported.

Clinical Pathology Selective IgM deficiency is defined by a persistently low or absent serum IgM, whereas other classes of immunoglobulin are normal or elevated for age. IgM levels are more than two standard deviations below the age-specific mean (see Table 53-7). Because IgM levels may transiently decrease, especially in critically ill foals, it is advisable to document that IgM levels are persistently low rather than to base a diagnosis on a single sample. Lymphocyte counts and other in vitro immunologic tests, such as lymphocyte proliferation to mitogens (including PHA, Con A, PWM, and LPS), are generally normal, and these features serve to differentiate selective IgM deficiency from other immunodeficiency conditions.[1,3,9] However, in one horse with selective IgM deficiency, lymphocytes failed to respond to the B-cell mitogen LPS, whereas responses to the T-cell mitogens ConA and PHA were normal.[4] The hemogram and biochemical profile may reflect infection or inflammation, depending on the underlying infectious process (e.g., neutrophilia, hyperfibrinogenemia, anemia) and the organ system involved, but no diagnostically specific changes occur.

Pathophysiology Whether IgM is low because of decreased production, hypercatabolism, or loss is not known. In one case with lymphosarcoma, suppressor activity was identified in the neoplastic cells, suggesting that the low IgM may be a result of suppression of B-cell function by neoplastic cells.[5,9]

VetBooks.ir

Necropsy Findings Lymphoid tissue in affected foals is grossly and histologically normal. Other findings reflect secondary infections. Pneumonia is frequently present and is often caused by *Klebsiella* infection.

Treatment and Prognosis Selective IgM deficiency has an unfavorable long-term prognosis. Most horses eventually succumb to infection despite appropriate antimicrobial therapy. However, the outcome of these cases seems less certain than with SCID foals, and a rare case recovers. Plasma therapy may provide some benefit, but because only small amounts of IgM are present in plasma and the half-life of transfused IgM is short, the effects are transient. No concentrated IgM preparations are commercially available for parenteral use. If persistently low IgM levels can be documented, a poor to grave prognosis can be expected.

Prevention and Control Some cases of selective IgM deficiency might be hereditary, and therefore it may be advisable to avoid repeating matings that produced an affected offspring. However, no firm recommendations can be made.

X-Linked Agammaglobulinemia

Melissa T. Hines • Debra C. Sellon • Jill R. Johnson

Definition and Etiology Agammaglobulinemia is a rare primary immunodeficiency disorder of horses characterized by complete B-cell dysfunction with an intact cell-mediated response. The disorder has been described in Thoroughbreds, Quarter Horses, and Standardbreds.[1-4] Thus far it has only been reported in males, suggesting the possibility of an X-linked disorder. The first report of an immunodeficiency in any species was agammaglobulinemia in a young boy, and the disorder has been shown to be inherited as an X-linked trait in people.[5,6]

Clinical Signs and Differential Diagnoses Clinical signs typically begin around 2 to 6 months of age and reflect the infections that develop. Pneumonia and septic arthritis, as well as dermatitis and enteritis, have been reported. Infections often respond poorly to therapy. The differential diagnosis list should include transient hypogammaglobulinemia and common variable immunodeficiency (CVID).

Clinical Pathology Total peripheral blood lymphocyte counts are within the normal range, but there is a lack of circulating B cells with normal numbers of T cells. Changes on routine laboratory evaluation are nonspecific and may reflect chronic infection. Depending on the response to infection, neutrophil counts may be normal, low, or high.

Serum levels of IgM, IgA, and all subisotypes of IgG are persistently low or absent. Depending on the age at evaluation, the assessment of antibody levels may be complicated by the presence of maternal antibody. Considering the half-life of IgG being longer than IgM, serial sampling will demonstrate a decline in antibody concentrations, with IgM and IgA typically decreasing first, followed by a decrease in all subisotypes of IgG. In some foals, low levels of immunoglobulin may persist, possibly due to either a prolonged catabolism of antibody or some residual B-cell activity, which has been identified in human patients with X-linked agammaglobulinemia.[1-5]

Horses affected with agammaglobulinemia do not produce specific antibody in response to immunization regardless of the antigen. Cell-mediated responses are essentially normal, including lymphocyte proliferation in response to T-cell mitogens (PHA and PWM) and DTH skin testing by intradermal (ID) injection of PHA. In contrast, lymphocyte proliferation and DTH skin testing by ID injection of ConA is blunted, but the reason for this response to ConA remains unclear.[4] Total hemolytic complement activity is also normal.

Pathophysiology The molecular basis of agammaglobulinemia in horses is unknown, but a defect at the stem cell level that blocks early B-cell differentiation is suspected because all classes of immunoglobulin are affected. In human patients a mutation in *Btk,* a gene encoding tyrosine kinase, accounts for the disease.[7,8] Assessment of the *Btk* gene in horses may help in understanding this disorder.

Necropsy Findings Gross and histologic changes in the lymph nodes, spleen, and thymus have been observed in horses with agammaglobulinemia.[1-4] Lymph nodes are small and microscopically they are devoid of germinal centers and follicles. Grossly, the spleen may be small and contracted and microscopically it lacks germinal centers, periarteriolar lymphocytic sheaths, and plasma cells. The thymus may be small and difficult to locate, making it necessary to blindly sample tissue from the mediastinal region in some cases. Histologically, the thymus does not show recognizable epithelial structure and lacks defined nodules. Why cell-mediated functions are normal while the architecture of the thymus is so abnormal remains unexplained.

Treatment and Prognosis In the absence of production of autologous antibody, affected horses develop recurrent infections. Although antimicrobial therapy and administration of plasma may temporarily control infections, the long-term prognosis is poor.

Horses with agammaglobulinemia illustrate that T cells make a significant contribution to immunity along with B cells. Horses with defects in both B- and T-cell functions (e.g., SCID) seldom survive to 5 months of age, whereas horses with a pure B-cell defect such as agammaglobulinemia may survive between 1 and 2 years. Agammaglobulinemia with a lack of circulating B cells was identified in a Pinto gelding that did not exhibit recurrent pyogenic infections until 3 years of age.[9] It is not certain whether this horse had agammaglobulinemia or a form of common variable immunodeficiency. Although it could not be established whether the immunodeficiency was primary or secondary, an underlying disease process was not identified.

Transient Hypogammaglobulinemia

Melissa T. Hines • Debra C. Sellon • Jill R. Johnson

Definition and Etiology Transient hypogammaglobulinemia is a rare disorder characterized by the delayed onset of immunoglobulin synthesis by the neonate.[1-4] Foals normally produce some IgM in utero and begin to produce significant amounts of immunoglobulins after birth following exposure to environmental antigens (see Fig. 53-4). Assuming adequate passive transfer, maternal antibody fills the void from birth until the foal has produced sufficient autologous antibody for protection (e.g., first 2 months). For unknown reasons, in transient hypogammaglobulinemia the onset of endogenous antibody production is delayed for as long as 3 to 5 months. As maternal immunoglobulins wane, the amount of endogenous antibody is transiently insufficient to be protective, making the foal highly susceptible to infections.

The disorder has been described in an Arabian foal and a Thoroughbred foal, but the low number of reported cases may not accurately reflect the prevalence. To make a diagnosis, serial samples may be required to document that autologous immunoglobulin is not increasing sufficiently as maternal immunoglobulin declines. Many cases that are not followed this closely probably occur.

Clinical Signs and Differential Diagnoses Clinical signs occur when passively acquired antibodies are catabolized to nonprotective levels. As with other immunoglobulin deficiencies, signs consistent with the acquired infections are seen in affected foals. The differential diagnosis list should include FPT and, if the affected animal is male, X-linked agammaglobulinemia.

VetBooks.ir

Clinical Pathology The cardinal feature is low immunoglobulin levels.[1,2] At approximately 2 to 4 months of age maternal antibody will have waned, but normal foals will have produced significant quantities of endogenous antibodies. In foals with transient hypogammaglobulinemia the concentrations of immunoglobulins, particularly all subisotypes of IgG, are substantially below the means when age-matched. Affected foals have normal cell-mediated responses in vitro and in vivo and appear to be able to respond to immunization to some antigens. Normal numbers of B and T lymphocytes are present in blood and lymph nodes. However, some foals may present CD4 T-cell lymphopenia and low CD4:CD8 ratio distribution (<2).[5] In addition, the age-dependent increase in the expression of MHC class II molecule on lymphocytes, but not on monocytes, is delayed.[5]

Differentiation between FPT and transient hypogammaglobulinemia is based on the age of the patient at evaluation. Transient hypogammaglobulinemia must be differentiated from agammaglobulinemia. Both disorders have normal lymphocyte counts and normal responses to PHA skin testing and show waning levels of maternal IgG and IgG(T) if followed serially. However, transient hypogammaglobulinemia cases usually have low but detectable levels of IgM and IgA, whereas agammaglobulinemia cases usually have no detectable levels of these immunoglobulins. Differentiation between the two may require serial sampling to show that immunoglobulin production does ultimately increase in the patient with transient hypogammaglobulinemia. Moreover, B lymphocyte count is absent in cases of agammaglobulinemia and normal in cases of transient hypogammaglobulinemia.

Pathophysiology The cause of this delayed development of the humoral immune response is currently unknown. A proposed mechanism is inadequate lymphoid tissue milieu to support B cell differentiation.[5] A syndrome of transient hypoglobulinemia of infancy has been described in children and is characterized by recurrent infections and one or more reduced serum immunoglobulin levels.[6-7] The pathophysiology of this disorder is also not completely understood.

Necropsy Findings No specific gross or microscopic lymphoid changes have been associated with transient hypogammaglobulinemia. Necropsy findings would reflect the secondary infectious processes that have affected the foal.

Treatment and Prognosis The goal of therapy is to minimize infections until the foal's immune system begins to function adequately. Treatment should include antimicrobial therapy and plasma transfusions. With appropriate support the prognosis is good, as the hypogammaglobulinemia resolves with time.

Foal Immunodeficiency Syndrome

M. Julia B. Felippe

Definition and Etiology Foal immunodeficiency syndrome (FIS), previously known as *Fell Pony syndrome* and also referred to as "anemia, immunodeficiency, and peripheral ganglionopathy," is an inheritable and fatal condition characterized by profound anemia and septicemia, the latter due to a primary immunodeficiency. A genomewide study identified a mutation in the gene *SLC5A3* on chromosome ECA26 associated with the syndrome.[1] The mechanistic implications of this mutation have not been fully resolved, and a causal relationship between the SLC5A3 mutation and FIS requires further studies to date. The presence of other mutations in that genomic region has not been ruled out as responsible for the phenotype of the immunodeficiency syndrome.

Clinical Findings/Clinical Signs and Differential Diagnoses FIS-affected foals are born apparently healthy but rapidly fail to thrive. The fatal illness becomes clinically apparent in foals within 1 month, and death occurs generally by 3 months of life due to a primary, profound, nonregenerative anemia and B cell lymphopenia, with increased susceptibility to opportunistic infections and septicemia.

The foals present with weight loss and dullness, pale mucous membranes, and signs of infection, including diarrhea and pneumonia.[2,3,4] Enterocolitis, bronchopneumonia, pancreatitis, and glossal hyperkeratosis are often caused by opportunistic infections (e.g., *Escherichia coli, Cryptosporidium* spp., adenovirus). The severe, progressive anemia results from lack of erythrocyte production in the bone marrow (nonregenerative), and it is not associated with hemorrhage or hemolysis.[2,3,5]

Clinical Pathology At birth, blood work may be normal, with normal or borderline low erythrocyte counts and hemoglobin values and normal distribution of neutrophils and lymphocytes.[5] When infections are present, abnormalities in the leukogram, including regenerative neutropenia or neutrophilia, toxic changes in neutrophils, and lymphopenia, may be present, and values vary depending on the type and phase of infection. Thrombocytes are often present in the blood in normal values unless disseminated intravascular coagulopathy secondary to septicemia is present.

Severe normocytic or macrocytic anemia develops rapidly. On the basis of bone marrow cytology, FIS-affected foals may be born with erythroid precursors but rapidly evolve to erythrocyte hypoplasia. At birth, hemoglobin and hematocrit values may be measured in the low end of the normal reference range, and peripheral blood B cell distribution may be equivalent to that of healthy unaffected foals. In a few weeks, profound anemia and B-cell lymphopenia develop. In time, cytologic evaluation of the marrow reveals differentiating myeloid precursors, megakaryocytes, and/or paucity of hematopoietic precursors. When present, proerythroblasts have been described to be binucleate.[4]

Immunologic Findings Absolute lymphopenia in FIS-affected foals likely reflects poor lymphocyte development in primary and secondary lymphoid tissues, as well as failure of lymphocyte population expansion with age.[6,7] B-cell distribution in blood may be within normal or low-normal values at birth but rapidly declines in the first few weeks of life.[5,8] Although $CD4^+$ and $CD8^+$ T-cell distribution has been reported normal in affected foals, T-cell dysfunction is suggested by the small thymus and opportunistic infections with cryptosporidia and adenovirus.[7,9] The expression of major histocompatibility complex class II (MHC class II) molecule in peripheral blood lymphocytes may be decreased and/or fail to increase with age in FIS-affected foals when compared with healthy foals, also supporting abnormal lymphocyte development.[10] Nevertheless, when stimulated in vitro, the peripheral blood lymphocytes of affected foals respond normally to mitogens PHA, Con A, and PWM.[4,7]

Although the B lymphopenia limits the ability of FIS-affected foals to produce immunoglobulins, serum IgG concentrations are often normal when clinical signs are detected due to the presence of circulating colostrum-derived antibodies during the time of diagnosis.[2,3,4,11] Nevertheless, serum IgM concentrations (a parameter not confounded by maternally derived antibodies at this age) are low in affected foals and strongly suggest impaired primary humoral immune response in FIS-affected foals.[5,11,12] FIS-affected foals develop septicemia despite normal (colostrum-derived) serum IgG concentrations, suggesting a broad lymphocytic dysfunction.[4,5]

The distribution and function of neutrophils have been reported normal, with the presence of bands and normal oxidative burst activity.[4]

Pathophysiology Bone marrow cytologic studies performed prospectively in affected foals immediately after birth and before clinical signs become evident in later age revealed evidence of initial erythroid hyperplasia with dysplasia, followed by a rapid and progressive hypoplasia and aplasia, as well as marked anemia.[5] In

VetBooks.ir

addition, a concomitant mild myeloid dysplasia could be observed, which questions the involvement of further types of cells.

The presence of erythrocytes and B cells in peripheral blood at birth suggests a limited hematopoiesis during fetal life. Nevertheless, this cell production is not sustained after birth, leading to a marked and progressive B lymphopenia and anemia in the perinatal phase, clinical signs, and death. B lymphocytes and erythrocytes are the most severely affected cell populations in FIS, and both undergo critical developmental stages in the bone marrow. The condition may be caused by independent or common genetic abnormalities that affect both cell lines. Most early B-cell differentiation essential genes and genes associated with erythropoiesis are expressed in the affected foals, and a potential common hematopoietic genetic defect is still under investigation.

Epidemiology Foal immunodeficiency syndrome is a genetic and inheritable fatal immunodeficiency condition that occurs in male and female young foals of the Fell and Dales breeds and, potentially, other breeds that include common ancestors.[13,14]

The Fell Pony breed experienced loss of genetic diversity due to the small numbers of animals and overuse of prominent stallions, which likely led to the spread of the genetic defect. Pedigree analysis of the Fell Pony breed suggests that FIS may have an autosomal recessive inheritance. Carriers are phenotypically normal. FIS was initially described in the United Kingdom and subsequently in Fell Pony foals of the United States, Czech Republic, and Netherlands.[2,4,15,16]

Necropsy Findings In the postmortem, abnormal gross findings include generalized tissue pallor, thymic hypoplasia, and inflammation and lymphadenopathy associated with infections of many organs (e.g., necrotizing enteritis, pyogranulomatous bronchopneumonia, pancreatitis, myocarditis). The medullary cavities of bones often do not contain marrow but instead pale, tan, fatty tissue, a striking finding in early age. Histopathology reveals severe erythroid hypoplasia, with small numbers or absent late erythroid precursors in the bone marrow, and high myeloid-to-erythroid ratio (ranging from 16 to 32:1, compared with the normal myeloid-to-erythroid ratio of 0.5 to 1.5:1).

Despite lymphadenopathy, there is severe lymphocytic hypoplasia and lack of secondary lymphoid follicles in the lymphoid organs; in addition, plasma cells are absent. Immunohistochemical staining detects no B lymphocytes in the bone marrow and rare or few B cells in the lymph nodes and spleen, dispersed in the tissues without forming germinal centers. In addition, peripheral ganglionopathy characterized by neuronal chromatolysis involving trigeminal, cranial mesenteric, and dorsal root ganglia has been reported.[2]

Treatment and Prognosis FIS is a fatal disease, and foals die or are submitted to euthanasia soon after the initial clinical signs. Management of infections and septicemia may be temporarily possible with antibiotic therapy; however, the combination of infectious organisms, commonly viruses and bacteria, prevents a sustained protection. The severe, progressive anemia is a major challenge for treatment.

Prevention and Control A DNA-based carrier test was developed by the Animal Health Trust (Newmarket, United Kingdom).[1,14] The genetic test offers powerful herd management planning to avoid the mating of two carriers with the genetic defect and, consequently, decrease the incidence of FIS, a fatal disease to date.

Common Variable Immunodeficiency

M. Julia B. Felippe

Definition and Etiology Common variable immunodeficiency (CVID) in the horse is a rare late-onset clinically relevant immunologic disorder of inadequate antibody production due to impaired B-cell differentiation in the bone marrow and consequent B-cell depletion from lymphoid tissues and blood. The cause of impaired B-cell development in the bone marrow is under investigation, and a primary or secondary cause has not been resolved.

Clinical Findings/Clinical Signs and Differential Diagnoses Most patients are reported to have had a healthy life until the signs of disease manifest as late-onset recurrent bacterial infections and fevers, hypogammaglobulinemia or agammaglobulinemia, progressive B-cell lymphopenia or depletion, and poor response to protein vaccination (e.g., tetanus toxoid).[1] Most common clinical signs include recurrent pneumonia, sinusitis, meningitis and/or neurologic disorders, abnormal gait (ataxia), peritonitis, gingivitis, hepatitis, diarrhea, susceptibility to gastrointestinal parasites, uveitis, conjunctivitis, and/or skin abscesses.[2,3,4] Meningitis may clinically present with marked depression, alternated by periods of normal appetite. Weight loss and/or muscle atrophy are common.

The humoral feature of this immunodeficiency predisposes to infections and disease caused by encapsulated bacteria, which requires opsonization with both antibody and complement for effective phagocytosis and bacterial killing. Therefore common pathogens involved in infections are *Staphylococcus* spp., *Streptococcus* spp., *Actinobacillus* spp., and *Klebsiella* spp. Occasionally fungal infections, such as *Aspergillus* spp., *Bipolaris* spp., *Pneumocystis jiroveci* (former *P. carinii*), or *Rhodococcus equi* infection have been diagnosed in a small number of CVID-affected horses that were treated with glucocorticoids or presented with a concomitant $CD4^+$ T-cell lymphopenia.[1,5]

A differential diagnosis is lymphoma because some forms of this type of cancer may alter lymphocyte distribution and function, including B-cell lymphopenia and hypogammaglobulinemia. If the disease manifests before the yearling phase, differential diagnoses would include transitory hypogammaglobulinemia of the young and X-linked agammaglobulinemia.

Clinical Pathology During bacterial infection, blood work reveals leukocytosis with neutrophilia, often mature, although a left shift and toxic changes may be present. Transient lymphopenia (<1200 cells/μL) is common. During the period when infections respond to antibiotic therapy, both neutrophil and lymphocyte counts may be within normal reference values.

Hyperfibrinogenemia is present accordingly to active infections. An important feature is the presence of low-normal or low globulin levels despite severe bacterial infections and hyperfibrinogenemia; the hypoglobulinemia results from the hypogammaglobulinemia. Abnormal liver enzymes may also be measured when there is septicemia.[3]

In the case of meningitis, spinal fluid analysis reveals increased protein values and pleocytosis, often with nondegenerate neutrophils, lymphocytes, and monocytes.[3] Blood culture has not been routinely performed in these patients but has resulted in bacterial growth in some cases; culture of spinal fluid may or may not result in bacterial growth.

Immunologic Findings Peripheral blood lymphocyte immunophenotyping reveals persistent, severe B-cell lymphopenia (<2%) in all patients. A relative increase in the percentage of circulating $CD8^+$ T cells and occasionally in $CD4^+$ T cells has been observed in most patients. The parameter that definitively indicates a humoral dysfunction is serum IgG concentration, which is markedly low (<800 mg/dL) in all affected horses. Serum IgM concentrations are markedly reduced (<25 mg/dL) in all patients, suggesting the inability to elaborate primary immune response. Serum IgA concentrations are often within low normal values (≈60 mg/dL) in early diagnosis in most patients despite severely low serum IgM and IgG concentrations, but levels reduce with progression of clinical disease, severity of clinical condition, and proximity to euthanasia. Affected horses do not respond to tetanus toxoid vaccination with an increase

VetBooks.ir

in serum antibody titers, and prevaccination values are often low or undetectable.

Lymphocyte proliferation assays reveal normal or subnormal responses to PWM, PHA, and Con A mitogens.[1] Upon stimulation with mitogens, the expression of IFN-γ and CD40-ligand in isolated lymphocytes of affected horses is comparable with control healthy horses, suggesting normal T-cell function and capacity for co-stimulation of B cells, which is required for B-cell differentiation and antibody production.

Besides the B-cell lymphopenia, a small number of CVID-affected horses may also present a concomitant $CD4^+$ T-cell lymphopenia, leading to a low CD4:CD8 ratio (<2). In these cases, infection with intracellular organisms that require cellular immunity may be observed, characterizing a clinical relevance for this finding.

The in vitro phagocytosis and oxidative burst activity are normal and often increased in these patients, reflecting in vivo activation.

Pathophysiology By the time of clinical diagnosis of CVID in horses, B cells are markedly rare in primary and secondary lymphoid tissues, leading to peripheral blood B-cell lymphopenia or depletion.[3,6] It is likely that B-cell production was sustained in the affected patients for a period of time before the diagnosis of CVID, and secondary lymphoid tissues were then populated with B cells, including memory cell development; however, a late-onset event impairs B-cell development in the bone marrow, and the continuous population of peripheral tissues could not be sustained.[7] B cells must be continuously generated over an individual's lifetime from hematopoietic stem cells in the bone marrow to maintain adequate population and humoral function in the lymphoid tissues.

B-cell differentiation and development is regulated by a network of transcription factors and demethylation of dinucleotides at promoter sites.[8] In the bone marrow of affected horses, the expression of key early B-cell commitment genes, including *E2A* and *PAX5,* is significantly decreased in comparison with healthy horses; in addition, *PAX5* downstream target genes are also significantly reduced in CVID-affected horses, including *CD19, IGHM,* and *IGHD*.[9] Immunohistochemical studies confirm the absence of PAX5-BSAP protein in the bone marrow of affected horses. Through a hierarchical dependence, *PAX5* directly promotes the expression of B lymphoid–specific genes while it represses the transcription of non–B lineage genes.[10] Hence, CVID in horses may be caused by impairment of B-cell development in the bone marrow at the transition between pre-pro-B cells and pro-B cells; current studies investigate epigenetic mechanisms that lead to gene silencing during the B-cell differentiation stage.

Epidemiology Affected patients are unrelated adult horses and ponies (average age 10 years, range 2 to 23 years) of both sexes and many different breeds (e.g., Thoroughbred, Quarter Horse, Arabian, Warmblood, Paint) living in distinct parts of the United States.[1] Cases elsewhere in the world have not been reported but are possible; their identification may be limited by the lack of knowledge of differential diagnosis for immunodeficiency diseases and availability of immunologic testing for the horse.

By the time the diagnosis of CVID is obtained, several months of recurrent infections and fevers may have been observed. The recurrent character of clinical signs is the most important factor that triggers the suspicion of an underlying immunodeficiency. Affected horses have been euthanized due to financial reasons or poor quality of life either soon after the diagnosis or after years of antimicrobial management.

Necropsy Findings Necropsy findings include organ lesions according to the infectious processes. In addition, histopathology confirms the lack of germinal cells, which affects the lymph node typical cortical-paracortical distribution and the primary and secondary follicles in the cortex.[1,3] In general, lymph nodes are small. In addition, there is absence of plasma cells in various lymphoid and mucosal tissues. Immunohistochemical analysis may identify occasional positive B cells dispersed or in small groups in the lymph nodes but absent B cells in the bone marrow and spleen (Fig. 53-6).

Treatment and Prognosis The majority of affected horses are subjected to euthanasia due to severe pneumonia, meningitis, and/or septicemia. When affordable, a few horses have been managed for 1 to 5 years on continuous or intermittent antibiotic and immunoglobulin therapies. Commercial equine plasma is the current available source of immunoglobulin for clinical use, and its low concentration prevents it from being a cost-effective treatment. Immunoglobulin replacement therapy in human patients is possible due to the availability of IgG concentrate products, which improves quality of life. Hematopoietic stem cell transplantation has been attempted in a horse with common variable immunodeficiency but no replacement of B-cell population, and function has been successful to date; the costs involved with the procedure discourage clinical application. When the mechanism of disease becomes revealed, gene therapy may be a more feasible treatment if appropriate.

Prevention and Control Current studies investigate the possibility of epigenetic mechanisms that lead to the impaired B-cell differentiation in the bone marrow. Epigenetic regulation can be affected by environmental or infectious elements, yet to date, common factors have not been identified in the horse patients. Therefore at this time, prevention and control measures are not known.

Drug-Induced Immunosuppression

M. Julia B. Felippe

Immunosuppressive therapy is required when an immune response causes excessive damage to tissues or autoimmunity develops. On the basis of their primary mechanism of action, immunosuppressants may be classified as inhibitors of gene expression or transcription (e.g., glucocorticoids); inhibitors of nucleotide synthesis (e.g., azathioprine); inhibitors of calcineurin phosphatase (e.g., cyclosporine, tacrolimus, rapamycin) and kinase (e.g., leflunomide); alkylating agents (e.g., cyclophosphamide, chlorambucil); and monoclonal antibodies (e.g., against T-cell receptor, IL-2R).[1-4] In the horse, only a few of these drugs have been studied and are used clinically.

Autoimmunity results from the production of self-reactive antibodies and/or T lymphocytes. The potential mechanisms involved include lack of central negative selection of autoreactive cells; molecular mimicry of microbes and self-epitopes; or the development of new epitopes on self-proteins secondary to tissue injury caused by viruses, bacterial exotoxins, chemicals, or tumors.

The type of mechanism involved in autoimmunity (e.g., antibody-mediated and/or cellular-mediated) may require immunosuppressive therapy with corresponding cellular metabolism targets. In addition, the combination of drugs may increase the success and decrease the necessary course of immunosuppressive therapy; nevertheless, this approach has been empirical in large animals and still lacks scientific evidence. Although the goal for immunosuppressive therapy is to decrease tissue damage caused by exacerbated immune response, systemic susceptibility to infections, particularly to fungal and viral organisms, is a risk in patients under therapy.[5,6]

Glucocorticoids are potent immunosuppressant drugs.[7] The lipophilic glucocorticoids pass freely through cell membranes and bind to a cytosolic glucocorticoid receptor (GR).[8,9] This interaction allows the GR transcription factor to translocate into the nucleus, bind to glucocorticoid-responsive elements, and regulate gene transcription that promotes or represses synthesis of cytokines, chemokines, inflammatory enzymes, and adhesion molecules. Frequently used glucocorticoids in horses include hydrocortisone, dexamethasone, prednisolone, methylprednisolone, isoflupredone, triamcinolone, beclomethasone, and fluticasone. Oral prednisolone has better bioavailability than prednisone in the horse.[10] In general, therapeutic doses are high and frequent in the initial phase of treatment, and dosage is subsequently tailored to the clinical condition.

VetBooks.ir

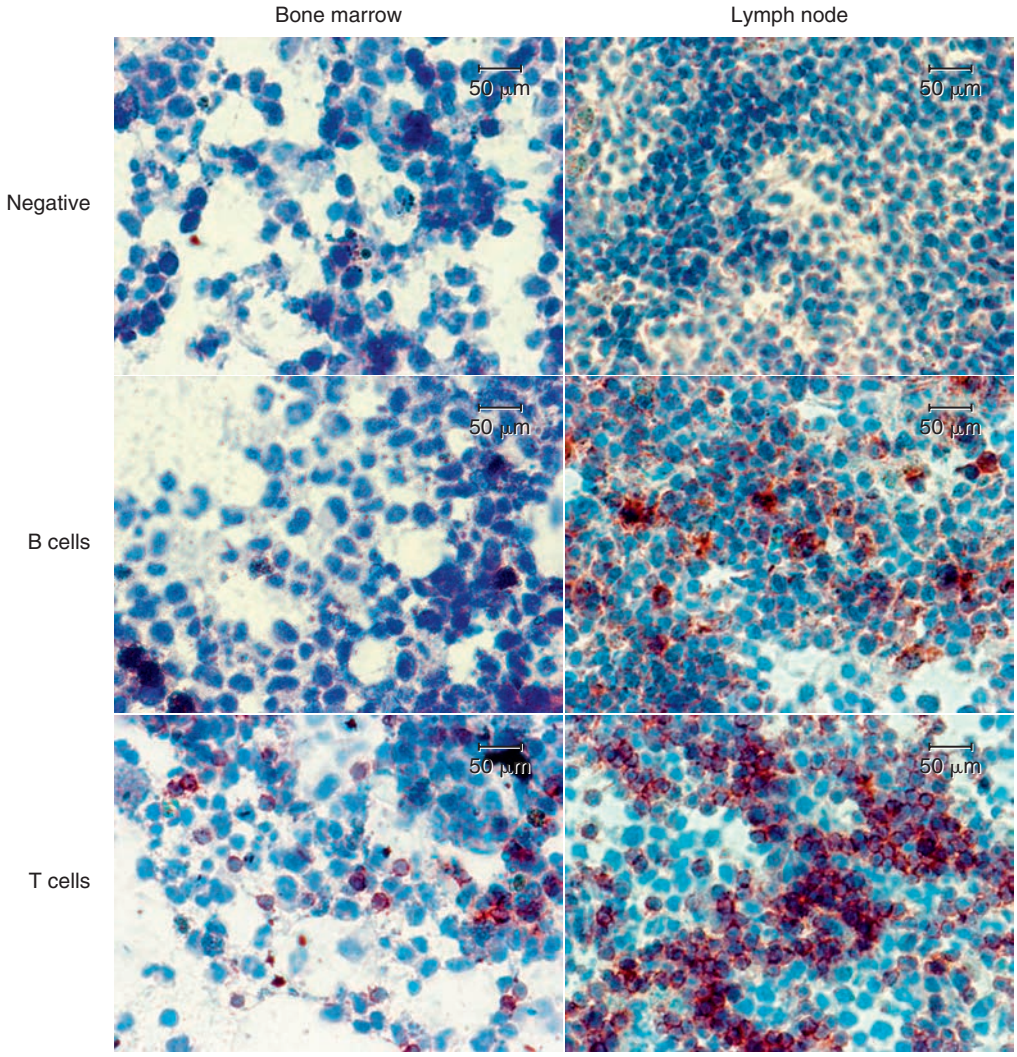

FIG. 53-6 Immunohistochemical analysis of bone marrow and lymph node microsections from a horse with common variable immunodeficiency. Bone marrow and mesenteric lymph node microsections from a horse with common variable immunodeficiency were stained using monoclonal antibodies against equine B-cell (CD19-like) and T-cell (CD3) markers, irrelevant control (negative), and 3-amino-9-ethylcarbazole (AEC) chromogen. Note the lack of germinal centers and paucity of lymphocytes in the lymph node. B cells are not detected in the bone marrow; numerous B cells are detected dispersed in the lymph node. T cells are present in the bone marrow and lymph nodes; however, the typical cortical-paracortical regions in the lymph node are lost with the lack of germinal centers.

Glucocorticoids in horses have been used for the treatment of a broad range of diseases that directly involve the immune system, including atopy or skin hypersensitivity reactions, contact dermatitis, immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, immune-mediated myositis, uveitis, purpura hemorrhagica, vasculopathy, pemphigus foliaceus, inflammatory airway disease, recurrent airway obstruction, and lymphomas or lymphosarcomas, many times with limited efficacy.[11-23]

Glucocorticoids cause immunosuppression mainly by sequestration of $CD4^+$ T lymphocytes in the reticuloendothelial system and by inhibiting the transcription of cytokines.[3] A single IV dose (any of 0.05, 0.1, or 0.2 mg/kg body weight) of dexamethasone has shown to induce neutrophilia and lymphopenia, a decrease in the peripheral blood $CD4^+$ T-cell population with a concomitant increase in the $CD8^+$ T cells, and a consequent decrease of CD4:CD8 ratio; these effects are observed at 4 hours and 12 hours after the drug administration and gradually decrease over time in the first 48 hours.[24] Chronic treatment with glucocorticoids may lead to susceptibility to infection, hyperglycemia, hypokalemia (particularly isoflupredone), gastrointestinal ulceration, delayed wound healing, osteoporosis, growth suppression, myopathy, and hypertension.[3,22] Parenteral, oral, and aerosolized corticoids reversibly suppress adrenocortical function, while the response to ACTH stimulation remains intact.[22,25]

Aerosolized glucocorticoids have been used for the prevention and treatment of recurrent airway obstruction in the horse, and they were shown to decrease neutrophilic pulmonary inflammation and the expression of IL-1β and IL-8 in isolated alveolar macrophages.[18,19,22,23,26] Aerosolized fluticasone proprionate may be detected in plasma for a minimum of 72 hours post administration.[27] The treatment of heaves-affected horses with inhaled fluticasone at therapeutic dosages for 11 months had no significant or detectable effect on innate and adaptive (both humoral and cell-mediated) immune function assays, including response to vaccinations.[28]

Azathioprine inhibits the de novo pathway of purine synthesis, essential for DNA and RNA production and, consequently, lymphocyte activation and proliferation. Azathioprine has been used in horse patients for the treatment of immune-mediated anemia, immune-mediated thrombocytopenia, vasculopathy, and pemphigus foliaceus.[29] The use of azathioprine allows reduction in glucocorticoid dose when the two are combined in therapy. Because proliferation of many cell types can also be inhibited, adverse effects associated with azathioprine treatment include leukopenia, alopecia, and hepatotoxicity. A single IV dose (1.5 mg/kg) of azathioprine resulted in a rapid

VetBooks.ir

decrease in plasma drug concentration with a half-life of 1.8 minutes.[30] Oral bioavailability at 3 mg/kg was low and varied from 1% to 7%. When given daily for 30 days, and subsequently every other day for another 30 days, that oral dose did not cause clinical adverse effects or abnormal hemogram, leukogram, and serum biochemical analysis in most horses. Lymphopenia and immunosuppression were observed in one horse during the experiment.

Cyclosporine is a cyclic polypeptide that binds to the cytoplasmic receptor cyclophilin and, subsequently, to the catalytic domain of the cytoplasmic phosphatase calcineurin.[31] This binding results in the inhibition of dephosphorylation of transcription factors, most importantly the nuclear factor of activated T lymphocyte (NFAT), which prevents their translocation to the nucleus. Therefore, the production of key elements of T-cell activation and proliferation (IL-2, IL-4, CD40L, TNF-α, IFN-γ, c-myc) is suppressed. Cyclosporine has been used in the horse for intravitreal treatment of recurrent uveitis and immune-mediated keratitis.[32] Potential adverse effects of cyclosporine include vasoconstriction, hypertension, nephrotoxicity, hepatotoxicity, and potential susceptibility to infectious organisms that require cell-mediated protection.

Rapamycin and tacrolimus are macrolide antibiotics that bind to the cytoplasmic FK-binding protein (FK-BP), and the resultant protein complex inhibits calcineurin. The effect includes cell-cycle arrest and decrease in the expression of inflammatory cytokines. Rapamycin ocular toxicity and distribution have been studied for potential clinical use in the horse.[33]

Cyclophosphamide (phosphoramide and acrolein) and chlorambucil (phenylacetic acid mustard) metabolizes alkylate DNA bases, resulting in mutagenic, cytotoxic, antiproliferative, and chemotherapeutic effects. Cyclophosphamide's effect on B cells promotes its application for the treatment of autoantibody-mediated diseases. In horses, these drugs have been used for the treatment of lymphosarcoma.[34] Adverse effects associated with cyclophosphamide and chlorambucil therapies include anemia, leukopenia, alopecia, and secondary malignancies.

Vincristine is a vinca alkaloid that binds to tubulin in the mitotic spindle and prevents purine synthesis. Consequently, it inhibits cell proliferation, resulting in antitumor and immunosuppressive effects. In horses, vincristine has been used for the treatment of immune-mediated thrombocytopenia, pemphigus foliaceus, and lymphosarcoma.[35] Mild neurologic adverse effects (proprioceptive deficits) and ileus may occur in the horse.

The development of species-specific monoclonal antibodies and the identification of appropriate antigenic targets have contributed to the advance of their use in medicine.[36] The great advantage of monoclonal antibodies is the specificity of response, which may minimize adverse effects. Examples of use include treatment of inflammation (targeting inflammatory cytokines) and cancer.[37]

Immunosuppression Associated with Leukoproliferative Disorders

Siddra Hines • Debra C. Sellon

Neoplastic disease can impair cell-mediated and humoral immune responses as a result of an abnormal bone marrow environment, altered patterns of cytokine production or release, or impaired proliferative responses (anergy). In horses, immunodeficiency has most often been described in association with lymphosarcoma or plasma cell myeloma.

Lymphosarcoma

Immunodeficiency has been identified in some horses with equine lymphosarcoma. The immunologic abnormality most often described is a decrease in the concentrations of serum immunoglobulins, especially IgM.[1-5] Recurrent or persistent infections may occur and complicate recognition of the underlying neoplastic disorder. Neoplastic cells were suggested to be T-suppressor cells in one horse, suggesting a possible mechanism for the IgM deficiency.[1] Diminished lymphocyte blastogenesis responses indicative of impaired T-cell function have been described in two horses with lymphosarcoma, one of which had concurrent IgM deficiency.[5] Some horses with lymphosarcoma have been diagnosed with concurrent bacterial infections, which may be related to immunosuppression.[4,5] A horse with myelomonocytic leukemia was found to have pulmonary aspergillosis.[6] Lymphosarcoma has been associated with bone marrow necrosis in people and horses, leading to pancytopenia and sepsis presumably due to profound neutropenia.[7] Similarly, myelophthisis (bone marrow suppression) secondary to tumor cell infiltration of bone marrow may lead to pancytopenia and immunosuppression in horses.[8,9]

Plasma Cell Myeloma

Plasma cell myeloma has been reported in horses of several breeds.[10] Although reports of the condition are limited, there appears to be no gender predilection. Horses have ranged in age from 3 months to 22 years (median, 11 years) at diagnosis. Common clinical signs include weight loss, anorexia, fever, pneumonia, and limb edema. Both equine and human patients with plasma cell myelomas have an increased susceptibility to bacterial infections, probably as a result of a secondary immunodeficiency.[10-12] Immune suppression in human patients with myeloma is well documented and can lead to severe infection.[13] Mechanisms include abnormal γ-globulin production, abnormal cytokine production, and dysfunctional natural killer and dendritic cell populations.[13] As a malignancy of plasma cells or lymphocytoid plasma cells, plasma cell myelomas typically produce large quantities of a homogeneous immunoglobulin or immunoglobulin fragment, resulting in a monoclonal gammopathy. In both equine and human cases of myeloma, the predominant serum globulins are generally subclasses of IgG.[10,11] Hyperglobulinemia is a characteristic but not invariable finding. Monoclonal gammopathies in the horse have also been reported with lymphoma and benign disorders.[14,15] The concentrations of normal polyclonal immunoglobulins are generally decreased in myeloma patients as a result of several mechanisms, including decreased synthesis and accelerated catabolism of antibody and suppressed clonal expansion of B cells.[10-12] Decreased numbers of neutrophils, which may also be dysfunctional, and defective complement activation may also contribute to the impaired immune function.

Other Leukoproliferative Disorders

A wide variety of other leukoproliferative disorders have been described in horses, including acute and chronic granulocytic leukemia,[16-18] myeloblastic leukemia,[19] myelomonocytic leukemia,[20,21] monocytic leukemia,[22] eosinophilic myeloproliferative disorder,[23] and malignant histiocytosis.[24] Regardless of the primary cell line of origin, the end result is often myelophthisis and pancytopenia with the potential for significant immunosuppression.

Immunosuppression Associated with Infectious Agents/Processes

Debra C. Sellon[‡]

The interrelationship between infectious agents and the host immune system is complicated. Infection, regardless of etiology, initiates a cascade of complex reactions intended to assist the host in control and elimination of the infectious agent. When the immune system is compromised, infectious agents have an increased opportunity to become established and cause significant disease in the host. This may happen because external factors suppress immune function in the host before encountering a pathogen or the pathogen suppresses immune responses in the host.

[‡]Contributions to previous editions by Jill R. Johnson, Melissa T. Hines, and Debra C. Sellon are acknowledged.

VetBooks.ir

Common Infections in the Immunocompromised Host

Immunocompromised horses are incapable of developing a normal immune response, usually as a result of an immunodeficiency disorder, immunosuppressive therapy, underlying disease, or malnutrition. When an equine host has impaired immune responses for any reason, infectious agents have an increased opportunity to establish persistent infection or cause significant harm to the host. For many immunocompromised horses, the result is persistent or unusually severe disease secondary to infection with common equine pathogens. In some situations, however, the immune capabilities of the horse are so impaired as to enable normally nonpathogenic infectious agents to cause disease. Identification of such pathogens or patterns of infection in an equine patient should lead the clinician to suspect underlying immunodeficiency.

Undoubtedly, primary immunodeficiency disorders (including SCID, agammaglobulinemia, FIS, selective IgM deficiency), described in detail earlier in this chapter, represent the principal cause of immunocompromise in horses.[1-8] The most commonly described pathogens in horses with severe primary immunodeficiency include adenoviruses, *Cryptosporidium parvum, Candida* spp., *Pneumocystic jiroveci* (formerly called *P. carinii*), and *Rhodococcus equi* (in adult horses). These are generally considered to be pathogens of the respiratory and gastrointestinal tracts, and most affected horses present with persistent or severe clinical signs associated with these body systems. Horses with less severe primary or secondary immune deficiency (e.g., selective IgM deficiency) may present with recurrent respiratory tract infections associated with a variety of bacterial pathogens.[4] The most common secondary immunodeficiency disorder of horses is failure of passive transfer (FPT) of immunity.[9] Affected foals commonly develop bacterial septicemia with or without localized bacterial infections.

Some foals with FTP or other forms of immunosuppression develop localized or systemic candidiasis.[10,11] This disorder appears to be most common in foals with FPT that have been treated with broad-spectrum antimicrobial therapy for treatment of bacterial septicemia. This syndrome has some similarities to mucocutaneous candidiasis in people, which has been associated with several different subtle T-cell defects. Oral lesions range from discrete, focal, white, plaquelike lesions on the margins of the tongue to a generalized, thick, white, pseudomembranous coating covering the tongue and gingival mucosa. Most foals exhibit bruxism, ptyalism, fever, and depression. Other significant clinical problems include pneumonia, septic arthritis, and diarrhea. This syndrome should be distinguished from the glossitis caused by *Candida* infection seen in inappetent or debilitated neonatal foals, which is fairly common and generally resolves with amelioration of the primary disease.[12] Regardless of cause or underlying nature of the immunodeficiency, the prognosis for foals with oral candidiasis and associated bacterial septicemia is guarded to poor.

Immunosuppression may also occur secondary to corticosteroid administration, which is discussed in detail earlier in this chapter. Corticosteroid effects are mediated through binding to intracytoplasmic steroid receptors. The steroid-receptor complexes are transported to the cell nucleus, where they bind cellular DNA regulatory sequences and alter gene expression to enhance or inhibit production of specific proteins. The net result is lymphopenia, suppression of macrophage phagocytic function, impaired killing of ingested organisms, impaired secretion of monokines, and inhibited antigen processing and presentation.[13,14] Cell-mediated immunity is impaired through T-cell lymphopenia, altered cytokine production, and decreased antigen presentation, and it is reflected in the suppression of mitogen stimulation responses. Humoral immunity is impaired indirectly through altered T-cell responses, enhanced immunoglobulin catabolism, and decreased antigen presentation.[13] Horses receiving high or prolonged therapy with corticosteroids have been reported to experience exacerbations of preexisting infections or decreased resistance to newly encountered pathogens.[15,16] This may manifest as bacterial pneumonia or pleuropneumonia, candidiasis, equine protozoal myeloencephalitis, or a variety of other infectious disorders.[11,16]

Infections That Cause Immune Suppression

Some infectious agents have developed strategies to elude host defenses in hosts with otherwise normal, functioning immune systems. These strategies may downregulate immune responses to the extent that the host becomes vulnerable to secondary infection. Many viral, fungal, and bacterial infections transiently suppress specific and nonspecific immune responses, predisposing animals to secondary bacterial infections.[17] Severe endotoxemia or septicemia may suppress neutrophil numbers and bactericidal function, predisposing to secondary infection.

EQUINE INFLUENZA. Although there has been little work done to specifically examine the effects of equine influenza viruses on the equine immune system, it is widely acknowledged that this viral infection predisposes horses to secondary bacterial infection.[18,19] Proposed mechanisms for increased susceptibility to bacterial infection after influenza infection include disruption of the barrier function of alveolar epithelium, exposing bacterial adhesion molecules; desensitization of alveolar macrophages to bacterial Toll-like receptor ligands; and alteration of immune functions in the alveolar microenvironment.[20,21]

PERINATAL EQUINE HERPESVIRUS TYPE 1 INFECTION. Infection of the fetus with equine herpesvirus type 1 (EHV-1, rhinopneumonitis) late in gestation has been associated with postnatal development of interstitial pneumonia, lymphopenia, marked necrosis and atrophy of the thymus and splenic lymphoid tissue, and increased susceptibility to bacterial infections.[22] Affected foals may be either weak or normal at birth. Despite apparently adequate passive transfer of maternal antibody, affected foals contract a variety of infectious bacterial diseases, including colibacillosis, streptococcal septicemia, salmonellosis, and Tyzzer disease. EHV-1 is isolated from nasal passages in about 30% of the cases. The spleen and thymus are grossly small at necropsy. Bilateral adrenocortical hyperplasia is noted in most foals. Histologically, splenic periarteriolar lymphocytic sheaths are depleted of lymphocytes, and no lymphoid follicles are detectable. Thymic alterations vary from extreme diminutions of thymocyte numbers to complete necrosis of thymic lymphocytes with disappearance of Hassall corpuscles and disruption of the epithelial matrix. Lymph nodes also show lymphoid necrosis. An immunodeficiency secondary to the marked lymphoid damage induced by the virus is credited with allowing secondary bacterial infections to become established. Immunization of broodmares against EHV-1 would seem to be the most appropriate approach to prevention.

EQUINE HERPESVIRUS TYPE 5 INFECTION. Equine herpesvirus type 5 (EHV-5) is an emerging pathogen linked to equine multinodular pulmonary fibrosis (EMPF).[23-26] This γ-herpesvirus has been found in bone marrow of infected horses, contributing to speculation that the virus may be immunosuppressive.[25,26] Many affected horses are lymphopenic for undetermined reasons, most are anemic and thrombocytopenic, and at least one affected horse was profoundly pancytopenic, leading to speculation that immune-mediated or direct viral destruction of mature cells and/or hematopoietic precursors in the bone marrow may play a role in diminished cell counts in peripheral blood.[23-25] Transient improvement in cell counts after initiation of corticosteroid therapy supports the possibility of immune-mediated mechanisms for destruction of hematopoietic cells.[25] One case of EMPF presented with primary lymphocytic leukemia, generalized lymphadenopathy, and infiltration of neoplastic lymphocytes in bone marrow, lymph nodes, and spleen.[26] Infiltrating cells were almost exclusively T lymphocytes, whereas B lymphocytes could not be detected. Depletion of B-cell lines was accompanied by hypogammaglobulinemia.[26] EHV-5 infection was demonstrated in

VetBooks.ir

lung, bone marrow, and lymph nodes.[26] A link between the T-cell leukemia and infection by EHV-5 was suggested.

Immunosuppression Associated with Immune-Mediated Disorders

Siddra Hines • Debra C. Sellon

Immune-mediated disorders can result in immunosuppression and increased risk of secondary infection through a variety of mechanisms, including direct damage to immune components with subsequent immune dysfunction.

Penetration of the skin barrier resulting in an increased susceptibility to infection can occur with immune-mediated diseases such as cutaneous vasculitis, most commonly seen as purpura hemorrhagica. Immune complexes are deposited in the walls of small blood vessels and the resultant inflammation is manifested as severe edema, tissue necrosis, and ulceration. Secondary bacterial infection, particularly cellulitis and pneumonia, may occur. Therefore prophylactic antimicrobial therapy is often warranted in the treatment of purpura hemorrhagica.[1]

Reported occasionally in horses,[2] immune-mediated thrombocytopenia (ITP) has the potential to negatively impact immune responses.[3] Platelets can play both indirect and direct roles in protecting an animal from infection. They promote antiviral cytotoxic T lymphocyte–mediated responses and contain important antibacterial proteins that when released promote rapid microbial killing.[4] Diminished levels of platelet-derived cytokines may affect Th polarization and have a negative impact on bone marrow function.[5] Importantly, red blood cells from thrombocytopenic mice have demonstrated an increased susceptibility to hemoparasite infection, indicating that thrombocytopenia can have an important in vivo effect on immunocompetency.[4]

Alloimmune neonatal neutropenia causes moderate to severe neutropenia in neonatal foals and has been reported in conjunction with ulcerative dermatitis and thrombocytopenia.[6,7] The pathogenesis is similar to neonatal isoerythrolysis, with opsonization of neonatal neutrophils by colostrally derived antibodies resulting in enhanced clearance from circulation. The impaired immunity associated with profound neutropenia places these foals at significant risk for sepsis and other serious infections and must be identified early to allow successful intervention. Administration of exogenous granulocyte colony-stimulating factor (G-CSF) is usually necessary because affected foals often do not produce adequate levels of endogenous G-CSF.[6] Adult immune-mediated neutropenia has been reported in the dog, generally occurring concurrently with ITP and/or immune-mediated hemolytic anemia, but there have been no similar reports described in the horse.[8]

Immunosuppression Associated with Autoimmune Disorders

Siddra Hines • Debra C. Sellon

The etiology of most autoimmune diseases is uncertain but appears to be related to exposure to an environmental trigger in an individual animal or human that is genetically susceptible. Autoimmune disorders may lead to immunosuppression and secondary infection through a variety of mechanisms, including loss of primary infection barriers, loss of critical immune cellular elements, hormonal imbalances, and dysregulation of complex immune responses. Although these types of immunosuppressive syndromes have been infrequently described in horses, they are well documented in other species.

Autoimmune skin disorders causing lesions that impair the skin barrier can predispose affected areas to secondary infection.[1] This is primarily a concern with the large bullae and ulceration occurring in pemphigus vulgaris or bullous pemphigoid, but the risk exists for any skin disease that breaches this important physical barrier to infection. Pemphigus foliaceus, paraneoplastic pemphigus, cutaneous (discoid) lupus erythematosus, and systemic lupus erythematosus (SLE) can all cause lesions that may predispose to secondary infection. This risk may be amplified if the lesions are painful or pruritic, leading to excoriation or self-mutilation.

Systemic lupus erythematosus, rarely reported in horses,[2] may impair cutaneous defense to infection and compromise the adaptive immune system. In humans, SLE causes dysregulation of apoptosis that leads to premature death of peripheral blood mononuclear cells (PBMCs), resulting in leukopenia, particularly lymphopenia.[3] The functionality of T cells in patients with SLE is impaired, with decreased IL-2 secretion and other factors leading to weakened antiviral immunity.[3]

Aplastic anemia and myelodysplastic syndrome, both associated with autoimmune syndromes in humans,[4] have been reported rarely in the horse.[5,6] Severe panleukopenia is seen peripherally, whereas significant bone marrow hypocellularity and myeloid maturation arrest are seen in aplastic anemia and myelodysplastic syndrome, respectively. Profound immunosuppression would be expected to occur with such pathology because immune cells involved in all aspects of innate and adaptive immunity are affected.

Most reports of diabetes mellitus (DM) in the horse have described type 2 (noninsulin-dependent) DM secondary to pituitary pars intermedia dysfunction or equine metabolic syndrome. However, type 1 diabetes mellitus resulting from autoimmune destruction of pancreatic β-cells and subsequent decreased insulin production has been reported.[7] In humans, DM is associated with an increased risk of lower respiratory infections, urinary tract infections, and infections of the skin or mucous membranes.[8] Abnormal function has been documented in neutrophils, monocytes, and lymphocytes, including decreased adherence, chemotaxis, and intracellular killing, as well as impaired phagocytosis and diminished lymphocyte proliferative response.[9] These negative effects have largely been attributed to the impact of poor glycemic control, and it is therefore likely that similar effects could occur with equine DM.

Immunosenescence in Horses

Dianne McFarlane

Definition Immunosenescence is the term describing a multitude of changes in the immune system associated with aging. Reported age-associated changes in the immune system in people include alterations in cell population composition, as well as inadequate or inappropriate immune responses.[1] Immunosenescence is considered to be an important risk factor for the infectious, neoplastic, and inflammatory diseases that accompany aging. Although there are minimal available data, evidence suggests that horses experience similar age-related changes to immune function as people.

An important consideration when investigating age-related changes of immune function is how to define "aged." A study population that is too old may cause one to miss age-related immune defects because the selected population may have survived to extreme old age due to exceptional immune function. It is likely that aging biomarkers may differ between very old horse populations (e.g., horses older than 30 years of age) and less old horse populations, such as horses around 20 years of age. Risk of certain diseases, frailty, or other impairments differ along the spectrum of aging. Finally, it is also important that the comparisons are made between fully mature horses and aged horses.

Clinical Findings There are several important factors that must be considered when evaluating age-induced changes in the immune system. First, it is important to separate age-associated functional changes from disease-induced changes. In an aged population this can be difficult due to the high prevalence of comorbidities that contribute to chronic, low-grade, or occult inflammatory disease. Ideally strict evaluation criteria should be employed. In human

VetBooks.ir

immunologic research a screening procedure known as the SENIEUR protocol has been developed.[2] This protocol combines a clinical examination, medical and lifestyle history, diagnostic blood analyses, and urinalysis to identify healthy aged individuals for study inclusion. No such standardized protocols have been adopted in veterinary gerontology. In aged horse studies, important additional factors to consider would include endoparasite load and hormone profiles. The high prevalence of pituitary pars intermedia dysfunction (PPID) in the aged equine population, and the immunosuppressive effects of pars intermedia–derived pituitary hormones, make it absolutely critical that endocrine status be reported when evaluating immunosenescence in horses and ponies.[3,4] Other important considerations when assessing immune function in aged horses include diet, medications, nutritional supplements, exercise, season, and environmental conditions of the study participants.

Clinical Pathology Hematologic changes associated with aging in horses and ponies include a lower total white blood count due to a lower total lymphocyte count compared with younger counterparts.[5-8] In addition, there is a decrease in total monocyte and eosinophil counts in aged ponies.[6] The implications of these hematologic changes remain unclear.

Immunologic Findings Age-associated alterations in lymphocyte subset populations have been documented in several species, including people, dogs, and rodents, although inconsistencies in outcomes exist among the various studies.[9-12] Aging has been associated with alterations in subsets of circulating lymphocytes (i.e., $CD4^+$, $CD8^+$, and B cells) in horses and ponies.[5-8,13] The consistent decrease in total circulating lymphocyte populations in aged horses is due to a decrease in total number of $CD4^+$ and $CD8^+$ T cells and B cells,[5-7] although another study reported an increase in the percentage of $CD4^+$ lymphocyte population.[13] The CD4:CD8 ratio is an indicator of whether lymphocyte populations favor an inflammatory or immunosuppressive bias. The CD4:CD8 ratio has been reported to increase, decrease, or remain unchanged in geriatric human populations.[14-16] CD4:CD8 ratio has been reported to be increased in aged horses, suggesting a proinflammatory state, known as *inflammaging*.[7] A robust decrease in peripheral naive T cells has been a consistent finding in numerous studies in people and rodents.[17-20] Thymic involution is considered a likely major contributor to the failure to maintain a naive T-cell pool. In addition, it has been suggested the loss of naive T cells may be the result of lifelong infection by viruses, especially cytomegalovirus or other chronic antigenic stimulants.[21,22] The effect of age on naive T-cell populations has not been explored in the horse.

Serum cytokine profiles in the aged are typically those of a proinflammatory phenotype.[23,24] Aged horses show similar cytokine profiles with increased gene expression of TNF-α, IL-6, IL-1β, IL-8, IFN-γ, IL-15, and IL-18.[7,13] In addition, there are increased proinflammatory-to-antiinflammatory cytokine ratios such as IL6:IL10 and TNF-α:IL10.[25] Serum cytokine concentration of TNF-α was found to be increased in aged horses in one study but not another.[13,25] Confounding factors that might affect serum TNF-α concentration in these and other studies include concurrent illness, inflammation, or season of sample collection.

One of the most consistent findings in immunosenescence is a decrease in the ability of lymphocytes to proliferate. Studies in rodents and people have shown impaired lymphocyte proliferation possibly involving a decrease in serum IL-2 concentration or IL-2 receptor expression.[18,26,27] However, a decrease in lymphocyte proliferation has also been reported independent of these two factors, suggesting defects in intracellular signal transduction may also be a consequence of aging.[28] Horses also experience an age-associated decrease in lymphocyte proliferation, which is not responsive to IL-2 supplementation and not associated with a change in lymphocyte IL-2 receptor expression.[6,13,29] This suggests that similar to what has been observed in people, the age-associated defect in lymphocyte division in horses may be in intracellular signaling.

Several studies have assessed the ability of peripheral blood mononuclear cells (PBMCs) to respond to immune stimulation. Inflammatory response after stimulation of whole blood or PBMCs from healthy aged people results in a greater release of proinflammatory cytokines than that observed in nonaged adults.[30-32] Similar studies in aged horses have revealed an increase in TNF-α and IFN-γ production from PBMCs following stimulation.[13,25]

Although immunosenescence affects primarily adaptive immunity, changes in the innate immunity occur as well. Innate immunity includes the response of neutrophils and macrophages as a first-line defense against pathogens. Age-associated changes in neutrophil function that have been reported in people and rodents include decreases in phagocytosis, oxidative burst, chemokinesis, and chemotaxis, whereas neutrophil numbers appear to be maintained.[33-36] In healthy aged horses, neutrophil adhesion, oxidative burst, and phagocytosis were all found to be unchanged, whereas chemotaxis was increased compared with that observed in healthy adult horses.[37]

One of the major health concerns regarding immunosenescence in people is a failure of the geriatric population to develop an adequate protective titer following vaccination, particularly after influenza virus immunization.[38] As a result, morbidity and mortality due to influenza infection is greatest in the very old. The response of aged horses to influenza vaccines has also been reported to be less robust than that of young or adult horses in several studies.[6,39] Muirhead and colleagues[39] reported a decrease in immunoglobulin subisotypes IgG2 (former IgGa) and IgG4 (former IgGb) in aged horses, although single radial hemolysis titers suggested both adults and aged horses had adequate response that was protective. Using a different vaccine, Horohov and colleagues[6] reported a 10-fold decrease in resultant titers in aged ponies compared with nonaged adults, but it is not clear if adequate titers were achieved in either group. Response to naive antigenic challenge has also been examined in horses older than 20 years of age. Contrary to what has been reported in primates, the magnitude of a primary antibody response did not decline with age.[39-42] When a rabies vaccine was administered to aged horses naive to rabies vaccine, the antibody titer after both the initial and second immunization did not differ from that of nonaged adult horses. However, in this study 80% of both the control and aged population had low serum selenium concentrations, which could result in a suboptimal vaccine response in both groups. Further studies are necessary to clarify the ability of aged horses to respond to naive and anamnestic vaccinations and challenges and to assist in the development of ideal vaccination protocols for geriatric horses.

Diseases Caused by Allogeneic Incompatibilities (Horses and Ruminants)

Jill R. Johnson

The surfaces of cells are covered with molecular structures, the presence or absence of which are determined by genes. Some of these molecules have limited heterogeneity within a species, and all members of the species share identical forms (monomorphic). In other cases a spectrum of minor structural variations or polymorphisms of a particular molecule occur within the population, so some members of the species will have one form of the molecule, whereas others will have another. If the structural variations are such that the immune system of one individual can recognize the differences in the molecules from another individual, these are known as alloantigens. Antibodies produced against these antigens are alloantibodies. Examples of alloantigens include red blood cell antigens and lymphocyte antigens.

In nature, because there are few situations in which tissues are exchanged, there are relatively few naturally occurring diseases that involve allogeneic incompatibilities. Neonatal isoerythrolysis (NI), neonatal alloimmune thrombocytopenia (NAIT), and alloimmune

VetBooks.ir

neonatal neutropenia (ANN) are three examples of such naturally occurring diseases. Blood transfusion reactions and organ transplant rejection are examples of iatrogenic diseases associated with allogeneic incompatibilities.

The same alloantibodies that mediate disease are also useful in vitro as reagents for the detection of the presence of alloantigens and serve as the basis for blood typing.

Blood Typing and DNA Profiling

The blood type of an individual is actually a composite list of genetic markers that have been detected in the blood of an individual. Several kinds of genetic markers have been used in blood typing, including red blood cell alloantigens, electrophoretic markers, and lymphocyte alloantigens. Polymorphisms of the DNA itself have emerged as useful genetic markers and have essentially replaced other genetic tests for parentage verification.

Red Blood Cell Antigens

Seven independent red blood cell groups or systems have been internationally defined in horses under the auspices of the International Society for Animal Genetics.[1-4] (Tables 53-9 and 53-10). These systems are named A, C, D, K, P, Q, and U. Additional systems are recognized by individual laboratories. Each system corresponds to a particular gene for which two or more alleles exist. Some blood groups are relatively simple and contain only two alleles, whereas other systems may have more than two dozen different alleles.

*Most common factors involved in neonatal isoerythrolysis (NI).

†Previously reported to cause NI in at least one case.

The blood group genes produce surface molecules that contain antigenic sites known as *factors.* More than 30 different factors have been identified. Each factor is associated with only one system, although the same factor may be associated with more than one allele within the system. The factors are named with an uppercase letter to denote the system and a lowercase letter to designate the factor within that system. Groups of factors that are produced by a single allele are called *phenogroups.*

The presence of red blood cell antigens is detected primarily by either agglutination or complement–mediated lysis of test cells by antibodies directed against specific red blood cell alloantigens. Antigens in some systems are detected with antiglobulin tests.

Eleven blood groups have been identified in cattle [5] (see Tables 53-9 and 53-11). In cattle, groups B and J have the greatest clinical relevance. The B group is a complex system with more than 60 different antigens.[6] This complexity has been used to advantage for individual animal identification and parentage studies in the past, but it makes it difficult to closely match donor and recipient blood for transfusions.

The J antigen, a lipid found in body fluid, is adsorbed to erythrocytes; thus it is not a true erythrocyte antigen. Newborn calves do not have this antigen but usually acquire it during the first 6 months of life. After acquiring it, some groups of cattle have high amounts of J antigen both in the serum and adsorbed to erythrocytes, whereas other groups have small amounts found only on erythrocytes. These latter groups, often referred to as *J negative,* may actually have anti–J antibodies and develop transfusion reactions when transfused with blood from J-positive donors.[1]

Seven blood groups have been identified in sheep (see Table 53-9). The B system is analogous to the B system in cattle and is extremely polymorphic, with more than 52 different alleles. The R system is similar to the J system in cattle in that the antigens are soluble and are passively adsorbed to erythrocytes.[5] The M-L system is involved in the genetically determined red blood cell potassium polymorphism found in sheep.[7]

Blood groups of goats appear to be similar to those of sheep, and many of the reagents used for typing sheep blood have been used to type goats' blood. Reagents used to detect antigens of the J system of cattle have been used to detect differences in a similar system in goats.[8]

The biologic function of red blood cell antigens is not known for any system in any species with the exception of the M-L blood group system in sheep, which is involved in active potassium transport across red blood cell membranes.

Hemoglobin-a	HBA	Red cells
NADH diaphorase	DIA	Red cells

NADH, Reduced nicotinamide adenine dinucleotide.

Electrophoretic Markers

Many plasma and intracellular proteins have polymorphic forms. These variants have subtle biochemical differences, which for the most part do not alter the major characteristics of the molecules but which can be detected using electrophoretic methods. These are not technically alloantigens because the differences are not detected immunologically. The various forms of the molecules are detected on the basis of their different rates of migration in electrophoresis. The specific form(s) of any particular protein that an individual possesses are determined genetically, and those used in blood typing are usually expressed codominantly. Currently no diseases are clearly associated with the presence or absence of particular alleles of polymorphic proteins; however, they are useful genetic markers for identification and parentage studies and were commonly included in the blood type (Table 53-12).[3,8-10] Electrophoretic markers were used extensively in horses because red blood cell antigens did not provide the same degree of discrimination among individuals in this species as they do, for example, in cattle. The current application is limited to legacy parentage verification when parental DNA is not available for testing.

Lymphocyte Antigens

Three systems of equine lymphocyte alloantigens have been described: ELA, ELY 1, and ELY 2.[11-15] ELA is the major histocompatibility complex (MHC) of the horse. ELA is a complex system that includes several genes, each of which is polymorphic (e.g., has many different alleles). Because the MHC regulates the interactions of many cells in the immune response, a potential for the association of disease susceptibility or resistance with ELA exists. An association between a particular ELA allele and equine sarcoid has been described.[16,17] ELY I and ELY 2 have limited polymorphism and appear to be two allele systems.

The MHC of cattle is called BoLA, for bovine lymphocyte antigen. In sheep the MHC is called OLA for ovine lymphocyte antigen and is also known as SH-LA. In goats the comparable system is GLA.[18]

DNA Polymorphisms

A wide variety of approaches has been developed for detecting genetic variation using deoxyribonucleic acid (DNA). Certainly DNA sequencing is the most sensitive approach; however, this remains too costly for routine testing outside of research laboratories. Other approaches have been developed to detect DNA variants. Genetic variation of DNA can be detected among individuals on the basis of differences in length for a section of DNA or even for differences in base composition at specific sites. DNA length variants are usually referred to as *minisatellite* or *microsatellite markers.* Minisatellite DNA markers are based on sequences, often 15 to 100 bases long, that may be repeated hundreds of times on a chromosome. The number of repetitions can vary dramatically among individuals and can be readily detectable in Southern blotting assay. These tests were originally referred to as *DNA fingerprinting.* Although they are powerful, these tests are costly and time consuming. More recently, another type of DNA length variant has been discovered. Microsatellite DNA markers are short repetitions of nucleotides, usually ranging from one to nine bases long, which may be repeated 15 to 40 times. As with minisatellites, the number of repetitions may vary among chromosomes. The development of the polymerase chain reaction (PCR) has opened the door to easy, cheap detection of microsatellite and other types of markers. PCR is a method for amplifying short (fewer than 3000 bases, optimally 300 to 1000 bases) pieces of DNA, making it possible to easily study a particular gene. The amplification products can be separated by electrophoresis and length variants readily detected. More than 100,000 of these markers are thought to exist in each species. These markers form an important core for development of genetic maps in diverse species. These markers currently form the basis for most parentage analysis.

Variation recognizable as a change in a single base of DNA is more subtle but can be detected through a variety of techniques. DNA sequence variation is often detectable using restriction enzymes. Restriction enzymes are isolated from bacteria and will cleave DNA when the sequence is specific for the enzyme. For example, the method to detect the gene defect causing hyperkalemic periodic paralysis (HYPP) in horses is based on PCR amplification of the gene and then detection of sequence differences that occur between the normal and mutant gene using restriction enzyme digestion of the DNA. Other approaches to identifying DNA sequence differences include single-stranded conformational polymorphism (SSCP), allele-specific PCR amplification, and ligase chain reaction.

DNA-based testing has essentially replaced blood typing for purposes of parentage analysis. Furthermore, these techniques are also being used to develop gene maps for many species of domestic animals. These gene maps can be used to identify genes that play a role in performance, production, and disease.

Blood Typing and DNA Genotyping Applications

To determine an animal's blood type or DNA genotype, a battery of different tests is run on the blood or tissue to check for the presence or absence of each recognized allele in each of several genetic systems. Each system is controlled by a separate autosomal gene. These genes are inherited independently of one another.[4,15] Most genetic markers used in blood typing are expressed codominantly, which means that the alleles on both chromosomes are expressed. This often allows determination of genotype (the actual genes present) from the phenotype (the antigens actually detected). Some systems have null alleles with no detectable products that do not directly allow inference of genotype (e.g., C, K, and U blood group systems in horses). An individual can have only two of the possible different alleles for any given gene (one on each chromosome of a pair).

Blood typing based on red blood cell antigens and electrophoretic markers has been used for animal identification and pedigree analysis, but currently red cell typing is used primarily for prediction of potential for NI and crossmatching for blood transfusion.

The use of genetic markers for parentage verification is based on exclusion (i.e., markers are tested until a discrepancy is found). If no discrepancy is observed after a statistically acceptable amount of testing, the probability of a match is determined.

Because genetic testing is a composite mosaic of a large number of different, largely independent genetic markers, the odds of two individuals sharing exactly the same pattern of markers, whether red blood cell antigens, electrophoretic markers, or DNA polymorphisms, is remote. Thus once an animal's genetic type is on record, it can be a powerful identifier of an individual animal. In this sense it

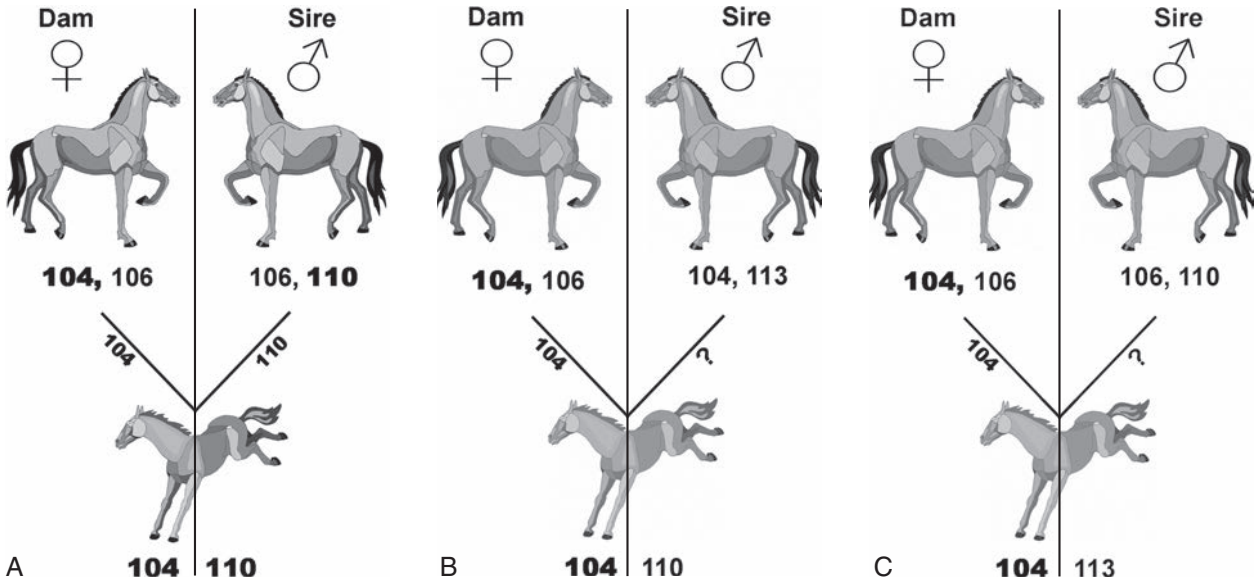

FIG. 53-7 **A,** The sire of this foal cannot be excluded as the sire of the foal on the basis of the results for the DNA marker VHL20. **B,** The sire of this foal is excluded by a type I exclusion. The foal possesses an allele for the DNA marker VHL20 not present on either parent. Assuming that the dam of the foal is known to be correct and therefore would have contributed the 104 allele to the foal, the sire must be incorrectly stated. **C,** The sire of this foal is excluded by both a type I and type II exclusion. The foal possesses an allele not present on either parent and also does not possess either allele expressed by the putative sire.

is an unalterable form of identification that is present from birth to death.

Because the presence or absence of markers is genetically determined and because the markers contributed by both parents are expressed in a codominant fashion (unless "blank" alleles exist), these markers can be used to support or refute parentage claims. Blood typing and DNA profiling cannot prove that one horse is the parent of another; however, in certain instances it can exclude with certainty a stated parent as the true parent. Two types of parentage exclusions can occur, type I and type II[19] (Fig. 53-7). With type I the foal possesses a dominant or codominant marker that is not present in either parent. This means that at least one of the stated parents is incorrect. If one parent (usually the dam) is known with certainty on the basis of circumstances other than genetic type, the error lies with the other stated parent. With type II exclusions, the foal does not possess either of the dominant or codominant markers of a stated parent. Because a foal must inherit one of the two markers expressed by each parent, exclusion can be made if neither of the two markers present on the stated parent is detected in the foal. In parentage cases, each genetic system is evaluated for type I and type II exclusions. A parent can be excluded on the basis of an inconsistency in even one system. For this reason, the more systems that are used the better genetic typing becomes as a tool for solution of parentage disputes. The calculated effectiveness of blood typing for detecting incorrect paternity using 20 internationally defined systems in horses is as high as 96%.[3,9,20] With DNA genotyping, effectiveness is as high as 99.998%.[21-23]

Laboratories that provide DNA genotyping in North America are listed in Box 53-1.

Neonatal Isoerythrolysis

Equine

Definition and Etiology Neonatal isoerythrolysis (NI) is a condition characterized by the destruction of red blood cells (RBCs) in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.[2,24,25]

Production of alloantibodies can be stimulated in mares several ways, including transfusion, exposure to blood from the foal during parturition, or as a result of placental pathology during gestation. Incompatibilities of at least some blood groups between the dam and foal are the rule rather than the exception, and yet the incidence of sensitization of the dam and occurrence of NI is relatively low. In Thoroughbreds the prevalence is about 1%, and in Standardbreds the incidence is about 2%.[26] The prevalence in mules (donkey sire, horse dam) has been reported to be as high as 10%.[2] Most blood groups are not strongly antigenic under the conditions of exposure via previous parturition or placental leakage. Several blood group factors, however, are particularly immunogenic, and antibodies against these antigens have been reported to cause nearly all cases of NI. These include factor Aa in the A system and factor Qa in the Q system. In mules a unique donkey RBC antigen named donkey factor has been associated with NI.[27] Antibodies to these antigens develop after the exposure of the mare to RBCs and are not naturally occurring antibodies. In humans the absence of certain RBC antigens results in the production of natural antibodies against that antigen, presumably because of exposure to cross-reacting antigens in the diet. This does not occur in horses with a few exceptions and has not been associated with NI. Ca-negative (Ca–) horses frequently make anti-Ca antibody of low titer without known RBC exposure. However, anti-Ca antibody is generally not associated with NI, and in fact mares with anti-Ca antibody actually appear less likely to develop certain antibodies responsible for NI.

For NI to occur, several things must happen (Figs. 53-8 and 53-9). First, the dam must be negative for the antigen in question. Because most cases of NI in horses are associated with either anti-Aa or anti-Qa antibodies, mares that are Aa–, Qa–, or both are considered at risk. All horses appear to lack donkey factor; thus all mule pregnancies are considered at risk. Second, the mare must become sensitized and produce antibody to the offending antigen. Sensitization can be caused by exposure during a previous pregnancy, blood transfusion, or transplacental contamination with fetal RBCs earlier in the current pregnancy (rare). Third, the foal from the current pregnancy must have inherited from its sire the antigen(s) to which the mare has been sensitized. When these conditions are met, there is a significant potential that maternal antibody directed against the foal's RBC antigens will appear in the colostrum and, if subsequently ingested and absorbed by the foal, could cause loss of RBCs. The higher the anti-RBC titer is at foaling, the higher the risk. The highest titers are likely to be produced in a previously sensitized mare that is reexposed to the same RBC antigens shortly before parturition.

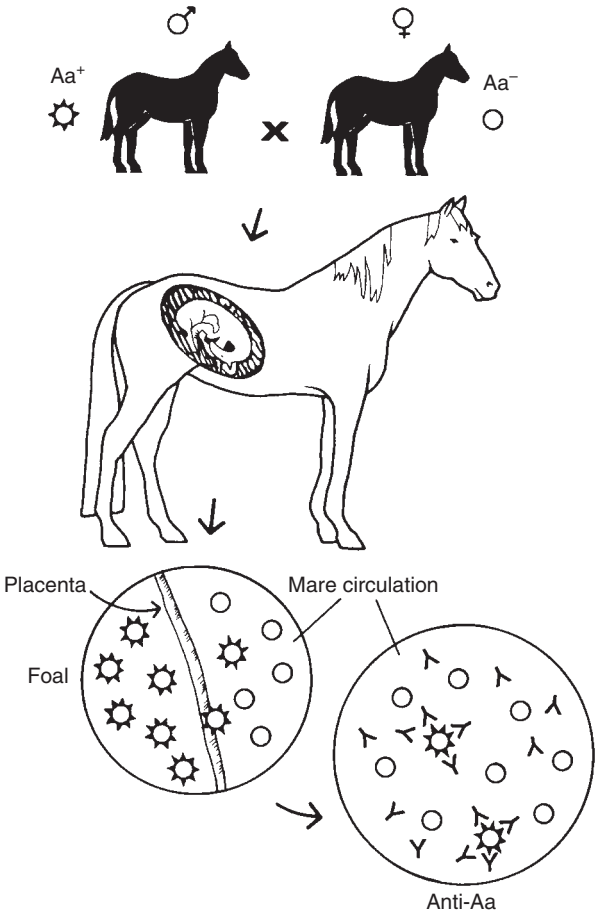

FIG. 53-8 Entrance of red blood cells of paternal antigen type into maternal circulation stimulates the production of alloantibody, and consequently the presence on alloantibodies in the mare's serum and in the colostrum.

Clinical Signs and Differential Diagnoses Foals are born healthy and usually begin to develop signs of NI at 24 to 36 hours of age, after suckling. Progressive lethargy and weakness are early signs. In acute cases, mucous membranes show initial pallor that is followed by icterus. In severe cases, hemoglobinemia and hemoglobinuria may be pronounced. In peracute cases, death may precede the development of icterus. Breathing becomes rapid and shallow, followed by labored breathing as the disease progresses. The foals may yawn repeatedly. Heart rate is elevated. Seizure-like activity may occur as the anemia becomes more severe.

Clinical Pathology Affected foals are anemic. All indicators of RBC concentration (packed cell volume [PCV] hemoglobin, RBC count) show significant decreases. PCV values often decline into the teens, and values as low as 5% have been observed. Hemoglobinemia and hemoglobinuria may be present. Bilirubin (mainly unconjugated) levels will be increased as a result of accelerated RBC destruction. Total bilirubin levels may be close to 20 mg/dL in severe cases. Affected foals, especially mule foals, may also be thrombocytopenic.[4]

Demonstration of significant amounts of alloantibodies in the colostrum (or serum from the mare) that are directed against the RBC antigens expressed by the foal provides a definitive diagnosis of NI. These antibodies are most commonly demonstrated by lytic and agglutinating tests. Lytic tests are believed to be more reliable indicators of the presence of offending antibody.[28] The presence of antibodies attached to the foal's RBCs can also be demonstrated with a direct antiglobulin test (Coombs test). The presence of antibodies in the mare's serum that attach to RBCs can be demonstrated with an indirect antiglobulin test.[2]

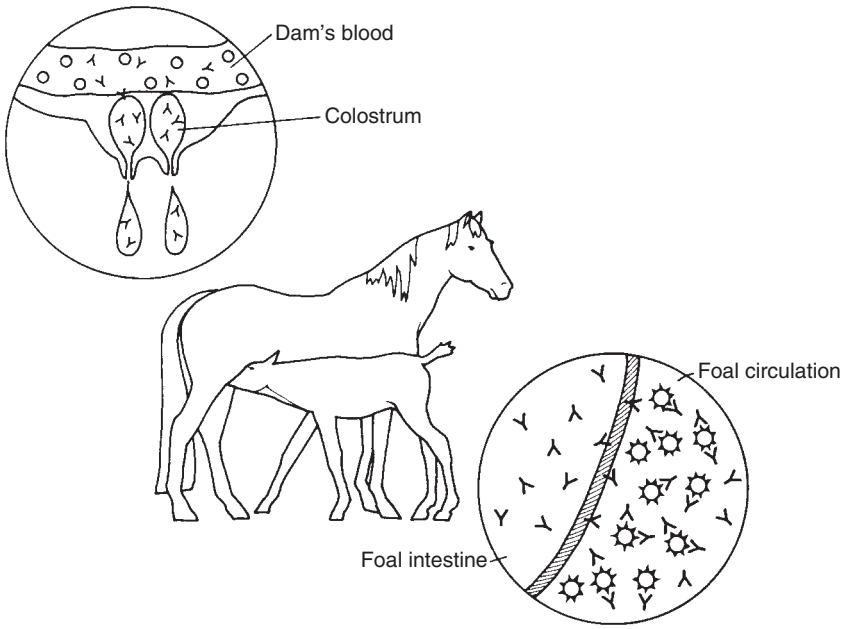

FIG. 53-9 Alloantibody in the mare's serum is concentrated in colostrum at the end of gestation. Through passive transfer, the foal absorbs immunoglobulins, including these alloantibodies. The antibodies attach to red blood cells and cause either premature removal from circulation or intravascular lysis.

Pathophysiology In mares sensitized to RBC antigens, most commonly Aa or Qa, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passed to the foal through passive transfer. If the foal's RBCs carry the antigen that the antibody recognizes, the cells become antibody coated. Subsequently they are removed prematurely by the reticuloendothelial system or lysed intravascularly by complement. A distinction has been made between antibodies that are lysins as opposed to agglutinins; however, this distinction is based on in vitro testing and may be somewhat artificial. Under appropriate laboratory conditions, offending antibodies may exhibit both abilities.[26] However, with conventional agglutination tests some alloantibodies capable of producing NI may go undetected.[10]

Epidemiology The percentages of mares at risk for sensitization against the common offending antigens (Aa and Qa) vary among breeds, depending on the frequency in the population of each gene involved (Table 53-13). Increased numbers of mares at risk in a breed do not necessarily translate into higher numbers of NI cases. A corresponding number of stallions lack the factors in question and are therefore unable to sire foals with the offending antigen.[25] Virtually all mule pregnancies are incompatible with regard to donkey factor.[27]

Although the disease is more common in multiparous mares, NI can occur with the first pregnancy.

Necropsy Findings Liver failure, kernicterus, and complications related to bacterial sepsis are the most important causes of death in foals dying from NI.[29] Pale tissues with or without icterus and splenomegaly are characteristic necropsy findings. Lesions associated with RBC destruction and anemia, such as nephrosis and centrilobular hepatic necrosis, may also be present.

Treatment and Prognosis In most cases, by the time the problem is recognized clinically (e.g., when the foal is about 24 hours of age), the bulk of colostral antibody will have been depleted from the mare's milk and the absorptive ability of the foal's gut will have diminished. Withholding milk at this point is of questionable benefit.

Stress should be minimized and exercise restricted. Affected foals have decreased exercise tolerance and can collapse and die if forced to follow their dams. Generalized supportive care should be administered as indicated by clinical parameters. Intravenous fluids are frequently indicated to promote diuresis to minimize the effects of the large hemoglobin load presented to the kidneys. Acid-base balance should be monitored and corrected if indicated.

If the anemia becomes severe (e.g., PCV = 10% to 15%), transfusions that provide RBCs should be considered. Unless the PCV drops below this level, transfusion may not be necessary if rest is enforced. The object of transfusion is to provide the affected foal with RBCs that will not be destroyed by the maternal alloantibodies that were absorbed from colostrum. The foal is immunologically naive and will not have autologous alloantibody directed against any RBCs that would have an immediate effect on transfused RBCs. Thus the key is to select an RBC donor whose cells will not be destroyed by the maternal antibody derived from colostrum. Crossmatching, with particular attention to the reaction of mare sera, colostrum, and foal sera (all contain the same antibody), with the donor RBCs, is important for selecting a cell that will not be destroyed by the maternal antibody.

Washed RBCs from the dam are obviously the perfect choice in terms of cells that will not react with the alloantibodies present in the foal. However, to avoid administering additional harmful antibody to the foal, the mare's sera (containing antibody against the foal's cells) must be removed by washing before administration. Up to 6 to 8 L of blood can be collected from the mare and anticoagulated with acid-citrate-dextrose (ACD) or sodium citrate (3.8% NaCitrate solution; 1 part NaCitrate/9 parts blood), although 3 to 4 L usually

TABLE 53-13

Estimate of the Percentage of Mares in Selected Breeds That Are "At Risk" for Producing a Foal with Neonatal Isoerythrolysis*[26]

Breed	At Risk for Aa	At Risk for Qa
Thoroughbred	2%	16%
Standardbred—pacer	22%	†
Standardbred—trotter	3%	†
American Saddlebred	25%	88%
Quarter Horse	25%	68%
Arabian	3%	72%

*Based on the lack of all alleles that include factors Aa or Qa.

†Mares all lack factor Qa and are technically "at risk," but all Standardbred stallions also lack the factor.

VetBooks.ir

provide sufficient RBCs. The preparation of large volumes of washed cells is aided by a large-volume centrifuge, but the procedure can be accomplished by serial sedimentations. Anticoagulated blood from the mare is allowed to settle for 1 to 2 hours. The plasma is aseptically drawn off, a similar or greater volume of sterile isotonic saline (0.9% NaCl) is added to the RBCs and mixed, and the RBCs are again allowed to settle. The saline is then drawn off and discarded. At this point the RBCs can be resuspended in an equal volume of isotonic saline for administration, or the washing procedure can be repeated. The sedimentation method is less desirable than centrifugation because it is slower and does not remove as much of the offending antibody. The aim is to dilute any harmful antibody to insignificant levels.

If it is not possible to use the dam's RBCs, alternative donors can be selected. The donor should lack the antigen to which the alloantibody is directed. Because it is generally not possible to blood type donors on short notice, a previously identified horse that has been determined by blood typing to be Aa–, Qa–, and free of alloantibody is a good choice for a donor because most cases of NI are associated with these two antigens. The odds of randomly selecting a donor that lacks the offending type (e g., Aa–, Qa–, or both) and would therefore be a suitable donor vary significantly with the breed and would mirror the percentage of the population of mares at risk. For example, the odds of finding an Aa– Thoroughbred to serve as an RBC donor would be about 1 in 50 (2%), whereas in Quarter Horses the odds would be about 1 in 4 (25%) (see Table 53-13). The sire of the foal is not the donor of choice. He shares the same RBC antigens as the foal, and his cells will react with the maternal alloantibody present, adding more of a load to the foal's reticuloendothelial system as they are destroyed.

In the case of mules the same considerations in the use of washed cells would be necessary if the dam's cells were used. However, because the offending antibody is generally directed against a unique donkey antigen, it appears that RBCs from any horse would be satisfactory. Horses do not appear to make naturally occurring antibodies against donkey factor; therefore in most cases it is not necessary to wash the cells from horses that would not be likely to have been immunized by pregnancy against donkey factor.

Transfusion of RBCs that will not react with maternal alloantibody means introducing an obviously incompatible cell into the foal, a cell that will probably not survive for long periods of time in the circulation. Such transfusions should be considered temporary stopgap measures. Transfused cells may also sensitize the foal to future transfusions, causing reactions (perhaps not within hours or a few days, but potentially within a week). This must be considered when weighing the potential good versus potential harm of such transfusions.

To produce clinical improvement, 1 to 4 L of washed RBCs or whole blood are usually adequate, although some cases may require repeated transfusion if the anemia progresses. Exchange transfusions can be done whereby blood is administered via one jugular and withdrawn simultaneously from the opposite jugular and discarded, allowing administration of large volumes of blood without overloading the vascular system. There is no good evidence to suggest that this is more effective than simply providing a source of RBCs that are unaffected by the maternal antibody.

Limited transfusion studies in adult horses have suggested that transfused RBCs do not survive long in circulation (e.g., 2 to 4 days), whereas in foals, cells survived slightly longer (e.g., 4 to 6 days).[30-31] PCVs in foals with NI commonly increase following transfusion and then gradually decline. This decline is probably not great cause for concern if it is gradual because the PCV of the foal generally levels off as the offending maternal antibody is metabolized. However, even short-term survival of cells may be of benefit in severely affected foals and may allow them to survive until the titer of maternal anti-RBC immunoglobulin has declined in the circulation. Hepatic failure in foals administered blood transfusions may be the result of iron intoxication. Administration of drugs that increase iron excretion, such as deferoxamine mesylate, are of potential value.[32]

The prognosis varies, depending on the quantity of antibody ingested, the rapidity of onset of signs, and the degree of anemia. Peracute cases may die before the problem is recognized, with no chance for administration of therapy. Foals that develop the condition more slowly may respond to supportive care or transfusion if the PCV continues to fall.

Prevention and Control Several strategies are available for prevention of NI.[33,34] First, identify broodmares at risk for development of NI by testing them for the presence of Aa and Qa. Mares negative for either antigen, which means they could potentially make antibodies against them, should be considered at risk. One subsequent strategy would be to breed at-risk mares to Aa/Qa-negative stallions, thus eliminating the possibility of the foal inheriting the offending antigens. However, in breeds in which a relatively small part of the population is negative for these antigens, identifying a stallion that is negative for these antigens and suitable on the basis of other criteria may be difficult. The percentage of at-risk females based on the presence or absence of Aa or Qa is somewhat balanced by the numbers of males able to transmit the offending antigen. For example, all Standardbred mares would be considered at risk because of the absence of Qa; however, because the antigen Qa is not present in the Standardbred population, no stallions have the Qa antigen to pass on to foals.

In the circumstance of unknown or incompatible matings, sera from at-risk mares should be screened for the presence of anti-RBC antibodies within 30 days before foaling. This can be done by submitting a serum sample and an anticoagulated sample to a screening laboratory. A panel of 10 to 12 different RBCs selected to represent all major blood groups is adequate to screen for anti-RBC antibody in the absence of blood from the sire. If results of serum testing are equivocal (e.g., low but positive titer, especially if there is anti-Aa or anti-Qa activity), the test should be repeated closer to the time of parturition because the levels of offending antibody can rise quickly late in gestation.

If anti-RBC antibody is detected in the mare before parturition, the colostrum should be checked for reactivity against the foal's RBCs before allowing the foal to ingest colostrum. An alternative source of colostrum should be provided to the foal. Most field screening tests of colostrum have not proved to be satisfactory for practical use; however, the jaundiced foal agglutination (JFA) test described in Box 53-2 has been shown to correlate well with the standard hemolytic assay, and it may detect antibody that does not react on the standard agglutination tests.[7]

Horses negative for Ca frequently make anti-Ca antibody; however, this antibody is not known to produce adverse effects in the foal. It has clouded the issue of field screening tests for NI because it commonly causes positive reactions in most screening tests at low dilutions. Because these tests do not differentiate between antibody to Aa, Qa, Ca, or any other blood group, anti-Ca antibody, when present in low dilutions, is responsible for many false-positive reactions. This antibody actually appears to play a protective role in the prevention of sensitization of mares to NI through a mechanism of antibody-mediated immune suppression. Aa–/Qa– mares that are also Ca– (and thus often produce anti-Ca antibody) become sensitized to Aa and Qa at a significantly lower rate than mares that are Ca+.[35] This is attributed to the fact that anti-Ca antibody is produced by Ca– mares. The anti-Ca antibody may more rapidly remove potentially sensitizing cells from the circulation before they stimulate production of antibody against Aa or Qa.

Uncommonly, other antigens have been associated with NI in foals. These include factors Db, Dc, Dg, Ua, Pa, Qc, and Ab.[2,4,35-39] Two other factors, R and S, have been described to be associated with NI, but they are not detected by routine hemolytic or agglutinating methods and are only detected using an antiglobulin test (direct Coombs test).[24] Because of the difficulty in testing for these antigens, there has never been sufficient agreement among laboratories to allow international designation. These antigens may not be detected using the JFA screening test.[25] Estimates are that 1 in 2000

VetBooks.ir

BOX 53-2

Jaundiced Foal Agglutination Test (JFA Test)[44,45]

Materials

1. Centrifuge capable of spinning 300 to 600× gravity
2. Test tube rack
3. Test tubes: 13 × 100 mm disposable or blood collection tubes
4. Pasteur pipettes and rubber bulbs or other pipette system to deliver 1-mL volumes
5. Isotonic (0.9%) saline at room temperature
6. Serum or colostrum from the mare; RBCs from mare and foal, preferable in EDTA anticoagulant

Methods

1. Collect colostrum from the mare.
2. Collect an EDTA-anticoagulated blood sample from the foal before nursing.
3. Set up six tubes and add 1 mL of saline to each tube. Label the tubes Control, 1:2, 1:4, 1:8, 1:16, and 1:32.
4. Make serial dilutions of the colostrum at 1:2, 1:4, 1:8, 1:16, and 1:32 in five of the tubes. Add 1 mL of colostrum (or serum) to the tube labeled 1:2 and mix. Then take 1 mL from that tube and add it to the second tube labeled 1:4 and mix. Take 1 mL from that tube and add it to the third tube labeled 1:8, and so on until all five dilution tubes have been filled. Discard 1 mL from the last tube labeled 1:32.
5. Add 1 drop of the foal's whole blood to each of the six tubes and mix.
6. Centrifuge the tubes for 2 to 3 minutes at a medium speed (300 to 500× gravity).
7. Invert each tube, pouring out the liquid contents; observe the status of the button of RBCs at the bottom of the tube. Complete agglutination causes the cells to remain tightly packed in the button; strong agglutination causes the cells to remain in large clumps; for weaker agglutination the cells are in smaller clumps as they run down the side of the tube. When there is no agglutination, the cells easily flow down the side of the tube. This should be the case in the control tube. If the cells in the control tube are clumped, they may be autoagglutinating and the results will have questionable validity.

   If there is a positive reaction with the foal's cells, the test should be run with the dam's own RBCs to be certain that neither the conditions of the test nor the viscosity of the colostrum is causing the agglutination.

   Positive reactions at 1:16 or greater are considered significant. At levels of 1:16 or greater, this test correlates well with the standard hemolytic assay. At dilutions of less than 1:16 the correlation is not as good, and more false-positive results will be recorded. Also, other factors such as the viscosity of colostrum make less diluted samples more difficult to read.

EDTA, Ethylenediamine tetraacetic acid; *RBCs,* red blood cells.

pregnancies may result in sensitization against some other antigen besides Aa or Qa. Because these cases occur so infrequently, it is not practical to consider mares without these antigens to be at risk for NI. A blood-type evaluation of mares with a history of production of foals with NI should be done to identify the offending antibody/antigen.

A list of laboratories providing NI screening tests (e.g., Aa, Qa, and Ca typing and screening of sera for alloantibody) is given in Box 53-3. Routine agglutinating crossmatch tests using mare serum or colostrum and foal or sire cells can be performed by most veterinary or human hematology laboratories.

Ruminants

NI is not a naturally occurring disease in cattle, sheep, or goats. Its occurrence in cattle has been associated with administration of vaccines derived from blood origin, such as certain anaplasmosis and babesiosis vaccines.[2] When these vaccines are used on breeding females, they may sensitize the dam to certain blood groups, most commonly in the A and F systems. Under chance circumstances, if the blood types of the sire and offspring reflect these systems and the dam has produced alloantibodies, an isoimmune hemolytic crisis may appear in the calf associated with successful passive transfer. Hemolytic crises are rare in sheep and are even difficult to induce experimentally.[2]

*Serum or colostrum from the suspect mare is required to screen for the presence of alloantibody. Acid-citrate-dextrose anticoagulated blood is generally preferred for screening for red blood cell antigens.

Neonatal Alloimmune Thrombocytopenia

Equine

Definition and Etiology Neonatal alloimmune thrombocytopenia (NAIT) is a condition characterized by the destruction of platelets in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.[40] The syndrome has been observed in horse and mule foals.[27,40,41] The prevalence of this condition is unknown. Some cases may be asymptomatic, and the condition may be self-limiting as alloantibody is metabolized.

Clinical Signs and Differential Diagnoses Few clinical signs may appear unless foals are traumatized. Affected foals may have prolonged bleeding from venipuncture sites. Petechial hemorrhages may not be present. Other conditions often associated with thrombocytopenia in neonates include sepsis, disseminated intravascular coagulation, equine infectious anemia, drug-induced thrombocytopenias, and angiopathies. The challenge is to determine whether the thrombocytopenia is primarily due to allogeneic antibodies or secondary to some other disease process.

Clinical Pathology Profound thrombocytopenia in the absence of other hematologic changes typifies uncomplicated NAIT. Evidence of successful passive transfer is present on the basis of quantification of serum IgG. Affected foals are thrombocytopenic. Thrombocyte counts less than 10,000/μL have been observed. Prolonged bleeding from venipunctures and petechia may be present.[40]

VetBooks.ir

Demonstration of significant amounts of antibody in the colostrum (or serum from the mare) that are directed against platelet antigens expressed by the foal provides a definitive diagnosis of NAIT; however, assays for equine platelet-bindable and platelet-associated immunoglobulins are not routinely available.

Pathophysiology The pathophysiology is believed to mirror that of NI. In mares sensitized to platelet antigens, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passed to the foal through passive transfer. If the foal's platelets carry the antigen that the antibody recognizes, the platelets become antibody coated. Subsequently they are removed prematurely by the reticuloendothelial system. Platelet antigens have not been characterized in horses, although platelet-associated antibodies have been recognized in affected foals. Circulating antibody is removed by attachment to platelets and rapid clearance by the reticuloendothelial system.

Treatment and Prognosis Circulating antibody is removed relatively quickly, and treatment may not be necessary. Platelet-rich plasma may be indicated in cases of severe thrombocytopenia accompanied by clinical signs of bleeding problems; however, as offending antibody is removed, the problem will tend to be self-limiting.

Prevention and Control Currently there are no screening tests to predict NAIT. Following production of an affected foal by a mare, it would be prudent to provide an alternate source of colostrum to foals born in subsequent pregnancies.

Alloimmune Neonatal Neutropenia

Equine

Definition and Etiology Alloimmune neonatal neutropenia (ANN) is a condition characterized by the destruction of neutrophils in the circulation of a foal by alloantibodies of maternal origin absorbed from colostrum.[42,43]

Clinical Signs and Differential Diagnoses In the absence of secondary bacterial infections, no clinical signs were observed. Diagnosis depends on the presence of persistent neutropenia in the absence of evidence of increased consumption or decreased production of neutrophils.

Clinical Pathology Persistent neutropenia in the face of normal clinical conditions has characterized reported cases.

Pathophysiology The pathophysiology is believed to mirror that of NI. In mares sensitized to granulocyte antigens, alloantibodies are concentrated in the colostrum late in gestation. These antibodies are passed to the foal through passive transfer. If the foal's neutrophils carry the antigen that the antibody recognizes, the neutrophils become antibody coated. Subsequently they are removed prematurely by the reticuloendothelial system. Neutrophil antigens have not been characterized in horses, but neutrophil-associated antibodies have been recognized in affected foals. Circulating antibody is removed by attachment to neutrophils and rapid clearance by the reticuloendothelial system.

Treatment and Prognosis ANN is self-limiting in infants and typically resolves over several weeks as maternal antibodies diminish. Administration of antimicrobial drugs may provide protection against bacterial infections. Corticosteroids are not currently recommended for treatment of the condition in human infants and have not been used in equine cases. Administration of recombinant human granulocyte colony-stimulating factor (rhG-CSF) was associated with increases in neutrophil counts in one affected foal.[42]

Prevention and Control Demonstration of agglutinating neutrophil antibodies or immunoglobulin coating of neutrophils from the foal may be used to confirm a diagnosis.[42] Following production of an affected foal by a mare, it would be prudent to provide an alternate source of colostrum to foals born in subsequent pregnancies.

Ruminant Immunodeficiency Diseases

George M. Barrington, *Consulting Editor*

Failure of Colostral Passive Immunity

Munashe Chigerwe • George M. Barrington

Definition and Etiology The process of ingesting and absorbing colostral immune components (immunoglobulins, immunoactive substances, and immune reactive cells) is termed *passive transfer of colostral immunity.* Such transfer is necessitated due to the structure of the domestic ruminant placenta, which largely restricts the transfer of immune components from the dam to the fetus.[1] Ruminants have a synepitheliochorial placenta possessing eight distinct membrane components separating fetal blood from maternal circulation, allowing low concentration of colostral components to cross the placenta.[2] Thus it is essential for ruminants to ingest and absorb colostral components to acquire passive immunity. Failure to acquire sufficient colostral components that confer passive immunity is termed *failure of passive immunity* (FPI).

Colostral Constituents and Synthesis Colostrum contains protein, fat, carbohydrates, water- and fat-soluble vitamins, growth factors, nucleotides,[3] cytokines,[4] complement,[5] and immunoreactive cells.[6-8] The major proteins in colostrum include immunoglobulins, lactoferrin, transferrin, α-lactalbumin, β-lactoglobulin, and albumin.[9] Immunoglobulins constitute approximately 95% of the total whey proteins in colostrum, and the major class (85% to 90%) of immunoglobulin in bovine colostrum is IgG.[10,11] While bovine IgG can be broadly separated onto two subclasses, IgG1 and IgG2, the predominant subclass in bovine colostrum is IgG1, constituting approximately 80% of total immunoglobulin.[12] Immunoglobulin G1 can fix complement, whereas IgG2 cannot.[13] Other immunoglobulins present in colostrum include IgM and IgA, which only make up approximately 7% and 3% of colostral immunoglobulin, respectively.[10]

The majority of studies in neonatal domestic ruminants concerning passive immunity have concentrated on immunoglobulins as the major component, whereas passively acquired cell-mediated immunity is poorly understood.[14] Clearly, assessment of immunoglobulins after ingestion of colostrum is technically much easier to quantitatively and qualitatively assess compared with assessment of colostral-derived cells.

Maternal cells found in mammary secretions include lymphocytes, neutrophils, macrophages, and epithelial cells.[15] The role of colostral lymphocytes is hypothesized to provide the neonate with transient local and systemic cell-mediated immunity that reflects antigenic exposure of the dam.[7] Studies reveal that transfer of live maternal cells from colostrum to the neonate enhances the neonate's response to antigens to which the dam has been previously exposed.[16] Other suggested roles of the cellular components from mammary secretions include development of local immunity and modulation of the active immunization of the neonatal intestine.[17] In calves, colostral-derived cells have been demonstrated to provide protective effects against enterotoxigenic *Escherichia coli* infections.[15]

Mechanism of Passive Immunity of Colostral Components The process of acquiring passive immunity involves two distinct processes. The first is colostral synthesis (colostrogenesis) whereby IgG1 is transferred into colostrum from maternal blood via

VetBooks.ir

an active, selective, receptor-mediated process.[18-22] Transfer of IgG1 begins approximately 5 to 6 weeks before parturition and ceases 1 to 3 days prior.[21,23] Colostrogenesis is largely controlled by lactogenic hormones.[24-26] Receptors responsible for the transfer of IgG1 into colostrum are located on the basilateral surface of mammary secretory epithelial cells. Colostral IgM and IgA are largely derived from local synthesis by plasmocytes in the mammary gland.[27]

The second process related to passive immunity involves absorption of colostral immunoglobulin and other colostral components by the calf. Absorption of colostral components occurs primarily in the small intestine during the first 24 to 36 hours of life via a nonselective, non-receptor-mediated, saturable process involving pinocytosis.[28] Intestinal absorption of colostral components steadily declines from the time of birth, terminating (termed "closure") at approximately 24 hours of age.[29] Absorption of colostral components may be extended to approximately 30 hours of age if feeding is delayed.[28] The efficiency of absorption of immunoglobulins decreases with increasing immunoglobulin concentration of the colostrum being fed.[30] As a result of all macromolecules competing for the same absorptive process, the mass of immunoglobulin absorbed by the calf is inversely proportional to the concentration of nonimmunoglobulin macromolecules present in the gut.

Epidemiology of Failure of Passive Immunity

Over the years, numerous studies have reported a wide variation in the prevalence of FPI in dairy and beef calves.[31,32] Recently, prevalence in U.S. dairy heifer calves has been estimated to be 19.2%.[33] In beef calves, prevalence rates range from 11% to 31%.[34-36] Regardless of use group (beef or dairy), the success or failure of passive immunity is largely a function of three general factors, including formation of colostrum with an adequate immunoglobulin concentration, ingestion of an adequate mass of immunoglobulin, and absorption of immunoglobulin in a timely manner.

FORMATION OF COLOSTRUM WITH ADEQUATE IgG1 CONCENTRATION. The mass of immunoglobulin presented to the neonate for absorption is dependent on the colostral immunoglobulin concentration and volume of colostrum available. The volume of colostrum produced by the cow is usually not a limiting factor.[37] However, large variations exist between colostrum with regard to immunoglobulin concentration. A tremendous difference in IgG1 concentration exists between beef and dairy cow colostrum. On average, the concentration of IgG1 in beef cow colostrum is approximately two to three times greater than that of dairy cow colostrum.[38-41] Significant differences exist not only between different breeds of cattle but between cattle within a specific breed.[42] Lactation number also influences the concentration of IgG1 in colostrum, though this variation is less than between individuals or breeds.

Low immunoglobulin concentration colostrum and the resultant ingestion of an inadequate mass of immunoglobulin are the primary causes of FPI in dairy calves.[40] In contrast, FPI in beef calves is unlikely to be due to low colostral IgG1 concentration.

INGESTION OF AN ADEQUATE MASS OF IgG1 (IgG). Depending on the environment and pathogen load to which they are exposed, calves must ingest an adequate mass of IgG1 to obtain protective immunity. Clearly, the mass of immunoglobulin needed for optimal protection is dependent on many factors. Older studies suggested that an average, 45-kg calf needed to consume approximately 100 g of IgG1 in the first hours of life to attain a serum IgG1 concentration greater than 10 mg/mL.[43] More recent studies suggest a total mass of 150 to 200 g IgG1 be fed for adequate transfer of colostral immunity.[44]

If one considers average dairy cow colostrum to contain approximately 35 mg/mL IgG1, volumes of 3 and 6 L of colostrum would be necessary to provide 100 g and 200 g, respectively. The recommendation to feed 3 to 4 L of dairy colostrum as soon as possible in the first hours of life is consistent with both older and newer studies.[43,45,46]

As previously mentioned, low IgG1 concentration colostrum is rarely a significant factor causing FPI in beef calves. Instead, factors such as mismothering, poor udder conformation, or environmental stresses are the more typical causes of beef calves failing to ingest adequate colostrum. Other factors that may affect passive transfer in beef calves have been reviewed.[36] Little evidence exists to suggest a direct effect on passive transfer when beef cows are fed protein- or energy-restricted diets. Dystocia does not appear to affect passive transfer of immunoglobulins as long as the calf receives an appropriate mass of immunoglobulin in a timely manner. Finally, young age of the dam is a risk factor for failure of passive immunity. This could be due to either lower colostral immunoglobulin concentration in heifer colostrum (beef and dairy), poorer mothering ability, or both.

TIMELY ABSORPTION OF IgG1 BY THE GUT. Cessation of absorption of colostral immunoglobulins (closure) occurs at approximately 24 hours of age.[47,48] If colostrum is completely withheld, closure will still occur by approximately 30 hours of age at the latest.[28,49] Closure is minimally affected by stresses such as dystocia or cold environmental temperatures, but the effect of extremely high environmental temperatures has been associated with reduced immunoglobulin absorption in calves.[50,51] In a study comparing three different feeding methods of colostrum to dairy calves, a higher prevalence of FPI was associated with sucking when compared with artificial feeding methods.[43] The higher prevalence of FPI in suckled dairy calves was thought to be due to an inadequate colostrum volume ingested. That is, dairy calves suckling low IgG1 concentration colostrum are less likely to consume an adequate volume of colostrum to obtain an appropriate mass of IgG1 in a timely manner. When artificial feeding methods are used, inadequate colostral immunoglobulin concentration is the most important factor resulting in FPI, even when calves are fed in a timely manner.

Finally, an effect of mothering has been associated with increased efficiency of absorption of colostral immunoglobulins. This may simply entail the presence of the dam or may be related to the effect of the neonate physically suckling the dam.[47]

PASTEURIZATION OF COLOSTRUM. Pasteurization of colostrum is used to prevent transmission of infectious pathogens through contaminated colostrum. Currently only 0.8% of dairy producers pasteurize colostrum before feeding it to calves.[52] Variable study results have been reported on the negative effects of pasteurization on colostral IgG concentration.[53,54] Practically, on-farm pasteurization most likely has minimal negative effect on colostral IgG concentration but is likely to destroy the colostral cellular components.

COLOSTRUM SUPPLEMENTS AND REPLACERS (see also Chapter 21). Colostrum supplements and replacers derived from bovine serum or colostrum have been formulated for use in calves. Effects of colostrum replacers on serum IgG concentration following ingestion indicate varying results depending on the type of product used and the differences in IgG concentration (or mass).[55-58] Fortunately, the quality of colostrum replacers has improved when considering their IgG concentration. However, processing during production largely destroys any cellular components from which the replacer or supplement was derived. For this reason, it is unlikely that colostrum replacers or supplements can provide cellular immunity to the newborn.

ECONOMIC IMPORTANCE OF FPI. Failure of passive immunity is responsible for approximately 50% of calf death losses on U.S. dairy farms.[59] Calves with FPI have increased mortality due to *E. coli* septicemia.[15] Inadequate ingestion of colostral immunoglobulins affects calf health and survival beyond the neonatal period; calves with FPI have increased rates of mortality until at least 10 weeks of age.[60] The effects of FPI on health and production can extend long beyond the neonatal period. Calves with FPI have been shown to possess double the odds of developing pneumonia when compared with calves with

VetBooks.ir

adequate passive immunity during the first 3 months of life.[61] Higher serum IgG concentrations (>1200 mg/dL) at 24 to 48 hours of age in heifer calves are associated with increased daily weight gain up to 180 days of life and higher weaning weights compared with calves with low serum IgG concentration.[62] Calves with FPI have lower milk production in their first lactation and are more likely to be culled for low production.[63]

ASSESSMENT OF IMMUNOGLOBULIN CONCENTRATION IN BOVINE COLOSTRUM. Differentiating between low IgG concentration and high IgG concentration colostrum is useful to ensure adequate passive transfer of colostral components. Several practical methods have been used to assess bovine colostral IgG concentration:

VISUAL APPEARANCE AND HYDROMETERS IN BOVINE COLOSTRUM. Visual appearance of colostrum and hydrometers are the two most commonly used methods to evaluate colostrum quality in the United States.[52] Although 41% of dairy operations in the United States use visual appearance to evaluate colostral quality,[52] studies have shown that visual evaluation of colostral characteristics are of little to no value in predicting colostral immunoglobulin concentration.[64]

A hydrometer (colostrometer) measures colostral-specific gravity as an estimation of protein concentration, and thus colostral IgG concentration.[65-67] Measurement of colostral-specific gravity can be affected by several factors, including colostral temperature, month of calving, and lactation number.[67-69] In the United States, 43.7% of dairy producers estimate colostral IgG concentrations using hydrometers. Although the hydrometer is a practical and inexpensive method of estimating colostral IgG concentration, it also tends to overestimate the actual IgG concentration.

WEIGHT OF FIRST MILKING COLOSTRUM. Weight of first milking colostrum is inversely related to colostral IgG1 concentration.[40] In a study by Pritchett and colleagues,[40] first milking colostrum weighing less than 8.5 kg was shown to have higher IgG concentration than first milking colostrum weighing greater than 8.5 kg. In a later study, colostral IgG1 concentration was found to be only weakly correlated with colostral volume.[70] The sensitivity of the weight of first milking colostrum was low (0.42) in detecting colostral samples with low IgG concentration (<50 g IgG/L).[71] In summary, weight of first milking colostrum as a screening test to identify low IgG concentration colostrum is less predictive compared with using it as a screening test to help select colostrum with a higher IgG concentration.[40,71]

OPTICAL AND BRIX REFRACTOMETERS IN BOVINE COLOSTRUM. Refractometers have been evaluated as cow-side tests for estimating colostral IgG concentration. The sensitivity of both types of refractometers in identifying adequate IgG concentration colostrum was acceptable when using a cutoff point of 22% Brix score.[71,72]

RADIAL IMMUNODIFFUSION (RID) AND QUANTITATIVE ELISA IN BOVINE COLOSTRUM. Both radial immunodiffusion and ELISA tests specifically quantify colostral immunoglobulins. The commercial availability of these tests for use in calves is limited because they are primarily used in research.

Clinical Signs and Laboratory Findings in Ruminants with Failure of Passive Immunity

Failure of passive immunity of colostral immunoglobulins is not a disease but simply a risk factor for increased morbidity and mortality from various diseases and conditions that commonly affect neonates, particularly diarrhea and respiratory diseases.[15,61] High prevalence of diarrhea and respiratory disease in neonates may prompt investigation of passive transfer of immunity in neonatal ruminants in addition to the investigation of management, the environment, or pathogen load.

Abnormal laboratory findings on hemograms or serum biochemical analysis are commonly a result of secondary changes involving diarrhea, septicemia, arthritis, and meningitis.

Laboratory assessment of passive transfer of immunity is important for the treatment, prognosis, and management of colostral feeding practices on farms. Several methods are available for assessment of FPI in ruminants and are performed in calves aged 24 to 48 hours.

Qualitative Methods for Assessing Failure of Passive Immunity

SERUM TOTAL PROTEIN USING REFRACTOMETRY. Serum total protein measurement is an indirect estimate of serum IgG1 because immunoglobulins make up approximately 90% of serum proteins in the neonatal calf. A total serum concentration of 5.2 g/L is consistent with 1000 mg/dL serum IgG1 level in clinically normal calves.[73] In clinically ill calves, a serum total protein end point of greater than or equal to 5.5 g/L is used to indicate adequate passive transfer to account for dehydration.[74] Refractometric measurement of serum total protein is the test recommended for herd monitoring of calves for adequate transfer of colostral immunoglobulins.[75] A serum total protein of greater than or equal to 5.3 g/L has been shown to be consistent with adequate passive immunity of colostral immunoglobulins in goat kids.[76]

SODIUM SULFITE PRECIPITATION OF SERUM. A mixture of serum and a sodium sulfite solution causes precipitation of proteins of high molecular weight, including immunoglobulins, and the result is recorded visually.[75] Three concentrations of the sodium sulfite (14%, 16%, and 18%) are commercially available (Bova-S, VMRD, Pullman, Wash.; ICN Immunologicals, Lisle, Ill.; Bethly Laboratories, Montgomery, Tex.). Turbidity in only the 18% solution indicates transfer of less than 500 mg/dL, turbidity in both the 16% and 18% solution indicates 500 to 1500 mg/dL of transfer, and turbidity in all three solutions indicates greater than 1500 mg/dL of transfer. The preferred test end point appears to be the 1+ test result. A 1+ test result equates to observing turbidity in the 18% solution with no turbidity in either the 16% or 14% solutions. Tyler and colleagues[73] demonstrated that the lowest serum IgG1 concentration (as determined by RID) observed in calves with a 1+ test result was 645 mg/dL, indicating at least partial successful passive transfer of immunoglobulins. Therefore it is recommended that the sodium sulfite test be used as a single-dilution assay procedure whereby calves with 1+ test result (precipitation in only the 18% test solution) are classified as adequate passive transfer of colostral immunoglobulins. Serum refractometry and sodium sulfite tests are the most practicable, inexpensive, and on-farm–adaptable methods for assessing passive immunity in calves.

ZINC SULFATE TEST OF SERUM. Specific concentrations of zinc sulfate precipitate immunoglobulins.[77,78] A volume of serum (0.1 mL) is added to a zinc sulfate solution (6 mL) containing 208 mg of $ZnSO_4\,7H_2O$ per liter, and the solution is allowed to incubate at room temperature for 1 hour. The turbidity of the solution is then evaluated visually or with spectrophotometric methods.[77] The zinc sulfate turbidity test is no longer widely used for assessing passive immunity in calves because the test is less accurate than serum total protein refractometry or the sodium sulfite test.[73] Other limitations of the zinc sulfate turbidity test include misclassification of samples in the presence of hemolysis and the instability of the solution when exposed to atmospheric carbon dioxide.[73,79,80] However, a follow-up study suggests that higher zinc sulfate concentrations in the test solution can provide a more accurate assessment of passive immunity. When the zinc sulfate concentration is increased from 200 to 400 mg/dL, sensitivity decreases from 100 to 82.6 and specificity increases from 25.5 to 90.6, respectively. The concentrations of which zinc sulfate test solution to choose therefore depends on the goal of the test. Choosing a test solution with higher sensitivity (e.g., 250 mg/L zinc sulfate) is likely warranted when testing individual calves with high economic

value. In herd monitoring programs, however, the choice of a test solution with higher specificity (e.g., 350 to 400 mg/L zinc sulfate) can maximize the proportion of calves correctly classified.

GLUTARALDEHYDE COAGULATION TEST IN WHOLE BLOOD. A whole-blood glutaraldehyde coagulation test used to estimate γ-globulins in cattle has low sensitivity (0.00 to 0.41) and specificity ranging from 0.85 to 1.[81] The performance of the test using whole blood is insufficient for routine diagnostic use; however, when the test is performed on serum it can be an accurate predictor of passive transfer status in calves.[81,82]

γ-GLUTAMYL TRANSFERASE ACTIVITY IN THE SERUM. Increase in serum γ-glutamyl transferase (GGT) activity, an enzyme synthesized in the mammary gland, is observed after ingestion of colostrum in calves.[83] Although increased activity of GGT confirms ingestion of colostrum, the association between the activity of the enzyme and serum IgG concentration is low.[83] Although a study by Parish and colleagues[84] suggested predicting passive transfer status on the basis of age and serum GGT levels, a study by Wilson and colleagues[85] determined that serum GGT activity was of little value in predicting passive transfer in calves. In summary, the use of increased serum GGT activity in calves is strongly discouraged as a method to assess passive transfer in calves, but it is an acceptable test for assessing passive immunity in lambs.[75,86]

Quantitative Laboratory Methods for Assessing Failure of Passive Immunity

TURBIDIMETRIC ASSAY IN SERUM. Recently, a portable, quantitative, automated turbidimetric serum immunoassay called the MBC QTII Kit (Midlands BioProducts, Boone, Iowa), specific for bovine IgG, was reported to be reliable in determining IgG concentrations in dairy calves.[87] However, a limiting factor of this assay was the relatively high cost per test ($7).

RADIAL IMMUNODIFFUSION IN SERUM. The RID is considered the reference method and measures serum IgG concentration directly. Different serum IgG concentrations for the RID end points have been used to define adequacy of passive transfer in dairy calves.[§] In beef calves, higher IgG concentration (2600 mg/dL) end points have been recommended.[90] Currently IgG concentrations of 1000 mg/dL or greater are considered indicative of adequate transfer of passive immunity in dairy calves.

QUANTITATIVE ELISA. Due to cost and availability, these types of tests are primarily only used in research settings.

Management of Ruminants with Failure of Passive Immunity

Neonatal morbidity and mortality is a result of several factors. These include passive immune status, environment, hygiene, and nutrition.[91,92] Thus it is important to partition mortality attributable to each of the risk factors when investigating calf morbidity and mortality on farms.[59] Consequently, intervention strategies should be focused on areas with the greatest impact on calf health. Calves with FPI can survive if housing, nutrition, and hygiene are optimal.[75] Decisions to treat calves with FPI should be based on the calf age, value, and presence of other risk factors for morbidity and mortality.[75] Treatment of FPI in clinically normal calves includes transfusion with plasma,[93] serum,[94] or whole blood intravenously or intraperitoneally. Plasma administered at 20 to 40 mL/kg intravenously or intraperitoneally has been recommended. Although treatment is empirical and no controlled studies have evaluated the efficacy of plasma, serum, or whole blood on morbidity and mortality in calves with FPI, clinical impressions indicate increase in serum IgG concentration following transfusions with all of these products.

[§]References 43, 61, 62, 74, 88, 89.

Prevention of Failure of Passive Immunity

Prevention of FPI is based on managing the previously mentioned factors that affect intake and absorption of colostral components in calves. Low IgG concentration colostrum is one of the primary concerns with FPI in dairy calves. Thus efforts to estimate the colostral IgG concentration before feeding colostrum, as well as feeding an appropriate volume of colostrum, is the most important management practice that needs to be addressed in dairy calves. Low IgG1 concentration colostrum is not generally the main cause of FPI in beef calves; rather, it is the failure to ingest and absorb colostral components in a timely manner. Hence in beef cattle, efforts to reduce FPI should be focused on ensuring timely ingestion and absorption of colostrum.

Lethal Trait A46

Steven M. Parish

Lethal trait A46 is a primary immunodeficiency that is found in black pied Danish cattle of Friesian descent.[1] It is an autosomal-recessive trait in which the calves appear normal at birth but develop skin disease at 2 to 8 weeks of age. Skin lesions are characterized by exanthema, alopecia, and hyperparakeratosis, with initial lesions occurring around the head, neck, and flexor surfaces of the legs and later involving the entire animal. Death within 4 months is often associated with bronchopneumonia and diarrhea. These animals do respond normally to humoral antigens but show deficits in cellular immunity. At necropsy the calves show marked lymphoid regression involving the thymus, spleen, lymph nodes, and gut-associated lymphoid tissues in the thymic-dependent regions. The condition is responsive to oral zinc oxide therapy, which suggests an underlying problem in zinc metabolism. Daily oral dosages of up to 1 g of zinc oxide have been used to establish normal function.[1] The primary immunologic defect is found in T lymphocytes. It appears that, because of a defect in a recessive gene, these animals have an unusually high metabolic requirement for zinc ions needed to sustain normal T lymphocyte development and function.

Selective IgG2 Deficiency

A primary IgG2 deficiency has been described in the red Danish milk breed in which there is a primary partial to complete deficit in IgG2.[2,3] These animals appear to be more susceptible to gangrenous mastitis and pyogenic infections such as bronchopneumonia, peritonitis, and abomasoenteritis.[4] A transient IgG2 deficiency has also been reported in neonatal lambs.[3] In lambs that ingested colostrum, there was a delay in the onset of synthesis of IgG2 until 5 to 6 weeks of age without any adverse consequences.

Chediak-Higashi Syndrome

Chediak-Higashi syndrome is an inherited disorder that affects neutrophil and monocyte function in Hereford cattle, mink, cats, mice, killer whales, and humans.[5,6] Clinically these patients are recognized by partial albinism that affects the skin and eyes, coagulation difficulties, and an increased susceptibility to bacterial infections. Large cytoplasmic granules are seen within neutrophils. The increased susceptibility to pyogenic infections is related to decreased neutrophil killing of ingested organisms caused by a defect in the hexose monophosphate shunt activity and defective degranulation.

Bovine Leukocyte Adhesion Deficiency

Bovine leukocyte adhesion deficiency (BLAD) is an autosomal recessive disorder of Holstein calves characterized clinically by chronic bacterial infections and premature death.[7-9] Leukocytes of affected calves lack surface glycoproteins, termed *β-2 integrins.* A mutation of the gene encoding bovine CD18 causes this disorder. The gene defect is termed the *D128G allele mutation.*

VetBooks.ir

VetBooks.ir

Heterozygous carriers are clinically normal; however, bulls and cows with this mutation may produce homozygous calves that manifest the deficiency. All calves with BLAD can be traced to a single male ancestor that must be present in both the sire and dam pedigree. In the United States, approximately 14% of sires and almost 6% of Holstein calves are affected with BLAD.

Homozygous calves have chronic, recurrent bacterial infections. Consistent clinical findings include fever, bronchopneumonia, stomatitis, gingivitis, recurrent or chronic diarrhea, peripheral lymphadenopathy, vasculitis, and dermatitis.[10,11] Calves appear normal at birth, but clinical signs are often present within the first few weeks of life. Affected calves usually die within the first year of life. Those surviving past 1 year of age have persistent ill-thrift. Hematologic abnormalities include mature neutrophilia (>40,000/L) without significant left shifts, lymphocytosis, and monocytosis. Abnormal serum biochemical findings include hypoalbuminemia; hyperglobulinemia; and low serum creatinine, urea nitrogen, and glucose concentrations.

Diagnostic tests are available to detect heterozygous carriers and identify homozygous clinically affected calves. Information regarding testing is available from the Holstein Association of America, Brattleboro, Vt.

Viral and Bacterial-Induced Immunodeficiency

Decreased B and T lymphocyte function has been reported associated with bovine virus diarrhea (BVD) infection in calves developing chronic BVD syndrome.[12] Depression of cellular, but not humoral, immunity is seen in cattle infected with Johne's disease *(Mycobacterium johnei),* with failure to develop, or DTH reactions in vivo and in vitro.[13] It is associated with a humoral-suppressive factor.

Combined Immunodeficiency

Genetic failure of development of both T- and B-cell lines results in a severely compromised immunodeficient animal. As passively acquired maternal antibody wanes, infections tend to develop. One possible case of combined immunodeficiency in a calf has been reported. It was recognized in a 6-week-old Angus that had an absence of serum IgM, low serum IgG, absolute lymphopenia, and an absence of lymphoid tissue at necropsy. The calf died of bronchopneumonia and disseminated fungal infection.[14]

Immunosuppression during Pregnancy and Postpartum Periods

James F. Evermann

Understanding

The immune response during pregnancy and immediately postpartum has been the focus of extensive research since the early reports by Hansen (1997) and Mallard and colleagues (1998).[1,2] There has been a remarkable surge in research reports over the past 5 years, which has allowed for increased knowledge regarding the mechanisms that affect the immune system during gestation.[3,4] With added data from the areas of reproductive immunology,[5,6] infectious disease ecology/epidemiology,[7] clinical medicine,[8,9] theriogenology,[10] and nutrition,[11] it has become apparent that what is observed clinically as outcomes of reproductive losses are indeed due to underlying immune suppressive states in the pregnant animal (Box 53-4). As the knowledge base expands, experts now recognize that, although transitory, the immunodeficient state extends into the postpartum period for at least 4 weeks.[12]

Mechanisms

T cells are an important population in the regulation and response of the immune system in general.[13] However, during pregnancy, the T cells are essential in the immunoregulation of the maternal immune system. Over the past 30 years it has become known that there is a maternal tolerance toward fetal alloantigens.[5] This has been partially explained by the interactions of the T-helper (Th) cells, which can be classified into various subgroups referred to as Th 1, Th 2, etc.[13] During pregnancy the Th 2–type (humoral) immunity overrules the Th 1–type (cell-mediated) immunity, therefore protecting the developing fetus from maternal Th 1–cell attack. In recent years, the Th-1/Th-2 paradigm has been expanded to include Th 17 and regulatory T cells (Treg).[3] The Th 17 cells produce the proinflammatory cytokine, IL-17, and play a vital role in the induction of inflammation. Treg cells are now recognized to inhibit proliferation and cytokine production in both $CD4^+$ (T helper) and $CD8^+$ (T cytotoxic) T cells, immunoglobulin production by B cells, cytotoxic activity of natural killers (NK) cells, and maturation of dendritic cells (DCs), resulting in the induction of tolerance, a form of immune regulation-suppression.[3] With the onset of pregnancy the hormonal factors cause macrophages to release predominately Th-2-stimulating cytokines that contribute to the overall dominance of humoral immunity during pregnancy and immediately postpartum.[12] The second key cell population affected during pregnancy and postpartum is the neutrophil.[14] The point of maximum immunosuppression occurs around the time when there is an acute elevation in glucocorticoids in the periparturient cow, as well as when there is a negative energy balance.[4,15]

BOX 53-4

Temporary Immune Suppression during Pregnancy Accounts for Both Direct and Indirect Effects on the Host Animal

Direct Effects

- Shift in T-cell population from Th 1 (CMI) to Th 2 (Humoral)
- Expansion of T-helper cells, such as Th 17, and T-regulatory cells
- Inhibition of T-cytotoxic cells
- Induction of maternal tolerance of the fetal alloantigens
- Inhibition of natural killer (NK) cells
- Inhibition of neutrophil function

Indirect Effects

- Increased risk of exacerbation of preexisting microbial infection
- Increased risk of systemic infections
- Increased susceptibility to environmental opportunistic pathogens
- Increased risk of metritis/endometritis
- Increased risk of mastitis

Outcome

The outcomes of the transitory immunodeficiency state that allow for fetal development also allow for exacerbation of preexisting microbial infections that were regulated by a potent Th 1–type immunity and for increased susceptibility to exterior environmental infections with bacteria, fungi, protozoa, and viruses.[12,13] The cell-mediated immune response relies primarily on the T-cytotoxic cells to control intracellular microbial infections, and when Th 1–type immunity is suppressed, these infections become systemic and affect the development of the fetus, by way of fetal loss, fetal congenital malformations, or birth of infected-weak neonates.[12] Concurrent with immunosuppression that accompanies pregnancy, there is an increase in shedding of infectious microorganisms (Fig. 53-10).[12] This is considered to be an extension of the impaired T-cytotoxic cell population, which follows systemic spread of the agents. Although the pregnant animal may appear clinically normal, her altered immune status results in the increased shedding of gastrointestinal viruses (coronavirus, rotavirus) and bacteria (*Mycobacterium paratuberculosis, Salmonella* spp., *Campylobacter* spp., etc.), usually during the periparturient period.[12]

The reduced neutrophil function and its association with periparturient immunosuppression has continued to be a major problem for dairy cattle, especially for the transition dairy cow.[10,14,15] This immune

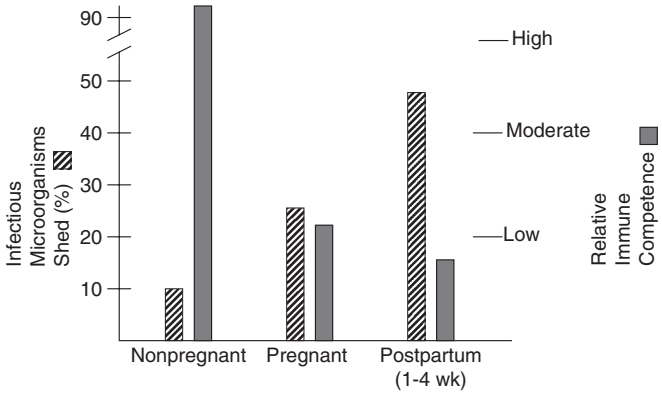

FIG. 53-10 Proposed relationships among shedding of infectious microorganisms during periods of nonpregnant, pregnant, postpartum, and relative immune competence. *(From Evermann JF. 2009. Pregnancy-associated immunodeficiency, pp 1681-1682. In Smith BP (ed), Large animal internal medicine, ed 4. Mosby, St Louis, MO.)*

suppression is directly related to increased cases of postpartum endometritis, metritis, and mastitis. As was noted with immune suppression during pregnancy, the periparturient period can be aggravated by preexisting subclinical infections, such as bovine herpesvirus type 4, and environmental bacterial pathogens, such as *Staphylococcus aureus* and *Klebsiella* spp.[12]

A more recent concern that accompanies the transitory immune suppression during pregnancy is the practice of using modified live-attenuated viral (MLV) vaccines during pregnancy. The controversy involves the ill effects of using MLV on naive animals and the potential effects on the pregnancy.[16] It has been a standard practice to vaccinate animals prebreeding and then booster during pregnancy to ensure fetal protection and enhance colostral immunity. The crucial data that are forthcoming are reporting ill effects in naive animals and should be interpreted with caution. As the report stated, "no conclusions can be made about adverse consequences (short-term or long-term) in using MLV vaccines at the appropriate time of breeding in vaccinated (prior immunity) animals."[16]

Management

Although the immunosuppressive periods during pregnancy and up to 4 weeks postpartum are well recognized, the exact mechanisms have not been fully revealed. However, one can proceed with control measures that accomplish two primary goals. These are to maximize reproductive performance and to ensure successful neonatal survival.[17,18] Over the years, the authors have emphasized the importance of effective vaccination programs prebreeding, use of licensed booster vaccine during pregnancy, clean birthing areas, and good hygiene for the lactating animals.[17,19] This, in conjunction with good colostral management, allows for us to compensate for the temporary immunosuppressive states encountered during pregnancy and immediately thereafter.

• CHAPTER 54

Disorders Caused by Toxicants

LYNN ROLLAND HOVDA, *Consulting Editor*

Poison cases in large animals occur less often than other species but are usually more time consuming and frustrating to manage. Generally, an animal is found dead in the stall or pasture or a sudden outbreak of illness occurs in a herd of animals. A rapid response is necessary, especially in herd cases, to eliminate the toxicant, treat affected animals appropriately, and prevent the development of further cases. The initial history is frequently limited, yet owners, trainers, barn managers, elevator owners, and others may demand an immediate answer. Emotions may run high, especially with the death of a beloved horse or when legal and media related issues arise. The veterinarian is left to provide answers to many complicated issues while attempting to undertake a diagnostic investigation.

Finding a toxicant does not necessarily mean it is the causative agent or that it is even related to the problem at hand. Concluding thus without further evidence could skew the investigation and result in an inaccurate diagnosis and further illness or death. A complete toxicologic investigation, including a thorough history, clinical signs, clinicopathologic testing (including necropsy if available), and analytic testing, should be undertaken in a careful and systemic manner. Internet websites can be used to provide accurate and rapid sources of toxicologic information to aid in the investigation and provide treatment options[1,2] (Table 54-1). An established working relationship with a diagnostic laboratory providing advanced testing and a board-certified toxicologist to help interpret results will increase the likelihood of a positive diagnosis.

History

An accurate history is the starting point of any toxicologic investigation and, done correctly, ensures that you have obtained the appropriate samples for further analysis. The investigation may vary from simple to complex but should always be done in a calm and ordered manner so that nothing is overlooked. The history should be used to provide information on circumstances surrounding the problem and may or may not identify the toxicant itself. Caution is advised in that the presence of a toxicant in the environment does not necessarily mean that it is the source of the problem. Finding a toxicant is simply a starting point. Many other factors, including the dose and degree of exposure, need to be considered because exposure to a nontoxic dose generally does not result in a worthwhile diagnosis.

Initial questions, however, often revolve around whether a known toxicant is present in the animals' environment. There are literally hundreds of toxicants, but many people, when questioned, often know which one may be playing a role. Common questions include whether or not medications, pesticides, herbicides, or fertilizers have recently been used or are present on the property. Is rodent control used in barns and outbuildings? Are there old junk piles on the property? What farm equipment/automotive products have been used recently? Have any old buildings been moved or torn down? Are there any known poisonous plants on the property?

Recent changes in animal management should be investigated in detail. Animal handlers should be questioned about the introduction of any new feeds, either new bags or fresh batches from a feed mill, or a complete change in feed. Feed should be examined closely for mold and the presence of any foreign bodies. Samples of feed, both as purchased and as fed, should be obtained and stored for further analysis. Hay and pasture should be examined for the presence of blister beetles, clippings from plants such as yew or oleander, other poisonous plants and weeds, foreign bodies, and mold. Again, samples should be taken and saved for analysis. Water samples from the original source and at the trough or stock tank should be taken and conserved in preserving jars for analysis if needed.

Species, breed, age, sex, body weight, and body condition are important pieces of information to be collected for all involved animals. Current and past medications used, vaccination history, reproductive status, and illnesses in other animals are other pieces of data that may be useful. Species identification is particularly important because some toxins are species specific or exhibit different toxicologic profiles. In addition, absorption of some toxins in ruminants, horses, and swine varies due to their specific gastrointestinal tracts. Some individual breeds may have different metabolic pathways resulting in delayed metabolism and excretion. The presence of a P-glycoprotein transporter in the *MRD-1* gene was recently identified in horses and in the future may play a role in the development of breed-related toxicosis.[3,4] Very young and very old animals are often at increased risk for developing signs of poisoning at much lower doses. Neonatal animals absorb some metals and chemicals more readily than adults, and nursing animals may receive toxic substances in the milk. Geriatric animals often have underlying deficiencies in liver metabolism and renal excretion that affect their ability to clear potential toxicants in a timely manner.

Clinical Signs

Live animals should have a complete physical examination performed and be closely examined for the presence of any unusual clinical signs. Ultimately, the conclusion of the physical examination may help narrow the list of toxicants. Both the nature of the signs and sequence of events should be documented. Specific abnormalities such as the color and consistency of mucous membranes, mouth lesions, blistering on pink skin areas, loss of hair around the eyes or tail, horizontal lines on hoof walls, and other abnormal findings may help determine whether the process is specific to an organ system or more generalized in nature. It is important to remember that in some instances this may not be an intoxication because other diseases and/or illnesses may result in similar generalized, nonspecific clinical signs.

The time frame from when the animal(s) was last noted to be normal to the onset of signs should be determined, as well as cessation, continuation, and/or duration of signs. Much of this

information may need to be obtained in a historical manner from the animal caregiver because the veterinarian is often examining the animal at a single time point in the progression of signs and may otherwise miss valuable information.

Clinicopathologic Testing

The results of clinicopathologic tests often shorten the list of potential toxicants and may point toward a specific organ system and/or toxicant. It is invaluable to obtain and either perform or store appropriate samples at the time of the physical examination or postmortem. Blood should be examined for electrolytes, complete blood cell count (CBC), liver enzymes, blood urine nitrogen, and creatinine. Urine should be examined for specific gravity and the presence of crystals, casts, red blood cells, hemoglobin, and methemoglobin. Other body fluids (ocular, cerebrospinal, etc.), hair, and ingesta should be obtained as needed. All samples except the blood and central nervous system (CNS) fluid can be frozen.[5,6] Blood should be centrifuged, the clot removed, and the sample stored in the refrigerator. It is important to remember that zinc and many of the trace minerals must be collected in a special tube for analysis.[5]

If at all possible, animals should be referred to the appropriate diagnostic laboratory for a postmortem completed by a board-certified pathologist. This is especially important if the animal is insured or legal issues are looming on the horizon. Animals sent to the diagnostic laboratory should be identified by tattoo, microchip, ear tag, or other means. Digital pictures taken before shipment can be used as a further source of identification. If a field necropsy is performed, extra samples should be taken because it is far wiser to take more samples than needed and discard them later rather than not have them at all. Often necropsy results will show specific lesions that may confirm a working diagnosis or point the veterinarian in another direction. Sometimes, the postmortem shows only generalized lesions or no lesions at all.

Analytic Testing

Analytic testing can be used to provide a definitive answer, but it must be used correctly and the results analyzed judiciously. Samples should not be sent to an analytic laboratory without some knowledge and forethought. The analytic laboratory will need guidance in terms of what they are testing for, as well as a history including the time since intoxication, dose of toxicant, and postmortem changes. Urine is the gold standard, especially for drug identification, but serum and plasma can also be used for analysis. Different forms of instrumentation/analyses are used for specific substances. For example, metals such as lead, zinc, arsenic, and others are analyzed with atomic absorption and spectrometry.[5] Enzyme-linked immunosorbent assay screens are generally sensitive, but the risk of cross-reaction with other substances may be large.[6] Drugs, many pesticides, and plant toxins are analyzed using gas or liquid chromatography/mass spectrometry, but unless specifically requested, the results are generally not quantitated and only demonstrate the presence of a toxicant.[5,6]

In summary, poisoning cases can vary from simple and direct to highly complex. It is important to investigate each one using a systematic approach, including history, clinical signs, clinicopathologic findings, and the results of analytic testing. As the veterinarian works through the investigation, each step may narrow the list of toxicants until a final answer is found. Alternatively, some investigations do not come to a final conclusion and the veterinarian is left to wonder what actually occurred. In many of these cases, environmental and management changes eliminated the toxicant before the investigation, leaving only the aftereffects.

Poisonous Plants

Julia H. Wilson

Poisonous plants pose significant dangers to all large animal species and should be weighted more highly on a differential list when the animal's or herd's history and location suggest potential access. A search for an incentive to have consumed a toxic plant should also occur, unless the toxic plant is palatable, was inadvertently harvested in hay, or its seeds contaminated grain stores. Observation that multiple animals on the premises are affected points to a common source for illness such as a toxicity, feed error, or infectious disease. Plant poisonings are most common in hungry animals at pasture that are driven to consume plants that are normally avoided. The need for forage and therefore risk of toxicosis in both ruminants and equidae is well established. Significant economic losses have been attributed to poisonous plants in regions and countries that rely on grasslands for raising livestock. Studies in the western United States suggest

VetBooks.ir

that plant poisonings adversely impact 3% to 5% of rangeland cattle, sheep, goats, and horses.[1] In China, poisonous grassland species of plants are responsible for an estimated $12.3 million of all livestock losses, including loss of performance and mortality from 2000-2006.[2] The estimated price of plant poisonings in Australia is $100 million (Australian) per year.[3] Deaths attributed to toxic plants are estimated to constitute 10% to 14% of all cattle mortality in the major cattle-raising region of Brazil.[4] Swine raised in confinement are least likely to be affected by plant poisoning; however, free-roaming swine may consume both garden and pasture species with known toxic potentials.

Circumstances that should stimulate investigation of possible plant poisoning on the affected premises include limited availability of forage as evidenced by animal observation and body condition scores; drought affecting plant growth, availability, and potentially high concentrations of toxins such as nitrates; recent storms that may have downed trees or fences; feed changes; inappropriate disposal of garden, shrub, or tree trimmings; and administration of herbal products for medicinal value. The level of toxins within a given plant species is often variable, even in samples from within the same pasture. Toxicity may be more pronounced in specific growth phases of the plant species, during times of stress or rapid growth, or after drying. Endophyte or fungal infections of the plant may be important as well, either as the sole or additional source of toxicity. These factors can be important in the timing and choice of plant specimens to identify, as well as assay for toxicity.

The distribution of clinical signs due to plant poisonings may be more difficult to decipher within a group of animals because individual factors play a role in both quantity consumed and expression of clinical signs. More than one type of toxic plant may have been ingested, which may lead to a wider variety of clinical signs. An individual animal may develop a taste for a plant that is avoided by others in their herd or flock or be forced to eat it due to feed competition and low social order. Herbicide application may also enhance the palatability of plant species such as water hemlock.[5] Recent fertilizer application may increase nitrate concentrations in both plants and water supplies. Some plants can create a wide range of clinical signs depending on the amount consumed acutely or chronically. Research done on specific toxins and plants, and applied to feeding trials, has demonstrated that differences in metabolism, gastrointestinal flora, and genetics may have a role in disease expression. Yet another variable is interaction between plant toxins and medications. Consumption of hay with two species of nightshade (*Solanum* spp.) has recently been identified as a factor in the development of clinical signs of ivermectin toxicosis in horses.[6]

Any suspicion of plant poisoning in an individual or group of individuals in a herd or flock should trigger a methodical investigation. The first step is a complete history of the affected individual(s), herd or flock, and farm. In addition to routine health questions, focus must be placed on current feed and any changes that have been instituted, weather factors that may have affected feed and water access or quality, fertilizer use on forage sources, differences between management of affected and unaffected animals, and the potential for any feeding errors or inadvertent exposure to garden refuse.[7] If the history yields evidence to strengthen the suspicion of plant poisoning, immediate removal of access to the suspected source of clinical problems should ensue. If multiple animals have been affected over time, establishment of a time line of events and cases may be a useful way to evaluate the history and determine the cause.

The second step in the investigation should be thorough examination of affected animals to identify and characterize clinical abnormalities and lesions. Low body condition scores, particularly if accompanied by a strong appetite, should raise clinical suspicion of consumption of normally unpalatable plants. Pregnant animals should be evaluated for signs of potential abortion. Quick access to an animal poison control center or available online database where clinical signs are entered to yield potential diagnoses may help veterinarians quickly sort through potential differential diagnoses for the animal(s).[8] Symptomatic treatment is often the first line of medical response if the etiology has not been determined or a specific antidote is not available or approved for use in that species. Stress of treatment, particularly for ruminants, must be weighed against the benefits. Activated charcoal administration remains advisable for most acute toxicoses if the animal can withstand the stress of administration. In ruminants, rumenotomy for evacuation of contents and instillation of activated charcoal should be considered. In monogastrics, stomach lavage followed by instillation of a slurry of activated charcoal in water may be the best option for acute cases. A limited number of specific antidotes are described for a few plant poisonings, but their use may be restricted by cost and the need to avoid food residues. Enhanced excretion of toxins through the use of laxatives or manipulation of urine or rumen pH may be applicable in specific situations where the toxic plant or principle has been confirmed.

Postmortem examination of affected animals should take place as soon after death as possible to maximize the opportunities to identify lesions and an etiology. In some plant poisonings, a specific odor may be noted, such as a bitter almond smell in cyanide poisoning (e.g., *Prunus* spp.), acetone smell with white snakeroot poisoning, and a mousy aroma due to poison hemlock ingestion.[5] Samples should be taken of rumen or stomach contents to look grossly and microscopically for recognizable plant leaf fragments or seeds. An aliquot of the ingesta should be labeled and frozen as soon as possible if toxicologic analysis is anticipated. Depending on the history time line, more ingesta samples may be warranted from other segments of the digestive tract. Intact seeds may be identifiable in the distal intestinal tract or manure. Samples of aqueous humor, amniotic fluid, and fetal stomach fluid for nitrate concentrations should be considered if clinical signs are compatible with that etiology (see later). If the animal has died within a few hours, blood samples for hematologic, chemistry, and toxin profiling can be rewarding. Tissue samples are important for characterizing histologic lesions to confirm a plant toxicity or alternative etiology. All grossly affected tissues should be sampled and a piece of liver frozen for toxicologic analysis. If neurologic signs were observed, the brain should be removed with proper barrier precautions.[7]

Identification of the plants, feedstuffs, or water responsible for clinical signs or death(s) is important for guiding treatment and further control. This may entail feed inspection or walking the pastures and fence lines to look for not only feasible plants that fit the clinical signs but also evidence that it has been consumed. If blue-green algae poisoning is a potential etiology, this tour must include inspection of water sources, where a bloom of blue-green algae may be found to be responsible for sudden death (see next section on Blue-Green Algae). The veterinarian, farm manager, or owner should visually inspect feedstuffs, looking for not only noxious plant or seed contaminants but also for mycotoxins (see section on Mycotoxins). Unknown plants should be photographed and placed in plastic bags for later identification and potential toxin determination. If identification will be delayed, plant samples should be pressed between leaves of brown paper and weighted down with heavy books for several days; an aliquot should be frozen for later analysis if indicated. For identified plants known to have variable toxicity, such as larkspur (Color Plate 54-1) or selenium-accumulating plants, multiple samples should be taken of the same species, concentrating on areas where the plants have been visibly browsed or grazed.[9] Resources for plant identification include toxicology texts, the U.S. Department of Agriculture (USDA) plant identification website, the USDA Poisonous Plant Research Laboratory website and its publications, other country-specific websites, and university or extension service plant experts.[10-16] In the United States, plant samples can be sent to the USDA Poisonous Plant Research Laboratory or Texas A&M's Veterinary Diagnostic Laboratory.

Common plant poisonings often trigger a recognizable pattern of clinical signs and disease progression. These are reviewed below in more detail, with emphasis on diagnostic features, treatment options, and preventive measures. Less frequent causes of livestock morbidity and mortality are listed in tables, grouped by predominant

clinical signs. Highlights of newly described toxicities that have the potential to harm multiple animals are also presented in this chapter section.

Sudden Death

Poisonous plants, chemical toxins, lightning strikes, and infectious diseases are causes of sudden death that should be considered when investigating sudden death in multiple animals. Numerous plant species have the potential to kill multiple animals within minutes to hours (Table 54-2).

Several groups of plants warrant greater discussion because of the frequency with which they are incriminated in the death of livestock and horses. All produce a range of clinical signs, not just sudden death, because the spectrum is influenced by the amount consumed, time period of consumption, concentration of toxin(s), animal species, and in some instances, accommodation of ruminal microbes.

Larkspur (*Delphinium* spp.)

Larkspur is considered one of the most important plant poisonings of range animals in the United States, second only to locoweed in its impact.[10] Cattle are most susceptible but sheep and horses can also be affected. The toxicity varies with the specific plant, stage of growth, amount eaten, and the time period over which it is consumed. Numerous toxic diterpenoid alkaloids have been identified in the nine *Delphinium* spp. that most often cause poisoning in cattle. Tall larkspur *(Delphinium barbeyi)* is considered the most problematic.[1] The alkaloids cause a curare-like blockade of neuromuscular junctions, by reversibly binding to nicotinic acetylcholine receptors. Larkspur consumption may also enhance the toxicity of another range plant, death camas (*Zigadenus* spp.).[17]

Death may result in as little as 3 hours after consuming larkspur. Clinical signs include excitability, muscle tremors, stiffness, staggering, and a basewide stance.[10] Cattle may assume a kneeling position before collapsing. Bloat, regurgitation (ruminants), and constipation may also be seen. There are no pathognomonic postmortem changes. Mild gastrointestinal (GI) irritation, venous congestion, bloat, and aspiration pneumonia may be observed. A definitive diagnosis is usually reached by identifying pieces of larkspur in the upper GI tract.

If treatment is possible, bloat should be immediately addressed to relieve thoracic compression and reduce the chances of aspiration; however, the stress of treatment may hasten death. Intravenous physostigmine has been advocated at dosages of 0.04 to 0.08 mg/kg, repeated as needed over several hours.[10] Neostigmine at 0.04 mg/kg is slightly less effective. Neither drug is approved for use in food animals. An affected animal may be mistaken for a grass tetany case; however, treatment with magnesium exacerbates the effect of larkspur's toxins at the neuromuscular junction and should be avoided.

Prevention of larkspur toxicity in range cattle is challenging and requires knowledge of when the plants are most toxic and most palatable, particularly if other forage is limited. For example, early spring grazing of cattle in pastures with tall larkspur should be curtailed as soon as the flower stalks begin to elongate. Sheep are more tolerant and can be used to reduce the plant's density. Aversion to eating

larkspur has been created with lithium chloride administration, a strategy that may be worthwhile on some ranches.[22] Larkspur reduction may not be cost effective with herbicides, leading investigators to use insect control with the larkspur myrid *(Hoplomachus affiguratus)*.[10]

Cyanogenic Plants

Toxicity induced by consumption of cyanogenic plants is one of the most readily recognized syndromes in all species producing sudden death, along with the characteristic signs of cyanotic mucous membranes and bright red blood. Cyanide blocks molecular oxygen transfer in cytochrome oxidase systems in mitochondria, causing tissue anoxia.[23] Other signs include obvious respiratory distress, rapid breathing, bloat, salivation, muscle twitching, staggering, mydriasis, cardiac arrhythmias, and convulsions.[10] Ruminants are more susceptible than monogastrics because rumen microorganisms readily release cyanide from the cyanogenic glycosides. Acute, sublethal cases generally recover within an hour. In one report in cattle, however, the onset of signs was delayed until later in the day when cattle in an arid environment drank water, rehydrating the rumen. Toxicities have also been reported in alpacas.[24] Chronic cyanide toxicity has been associated with sorghum consumption in pregnant horses and cattle. The foals and calves are born with arthrogryposis. Animals may also develop neurologic damage to the brain and spinal cord resulting in weakness, ataxia, and urinary incontinence. Low doses of cyanogenic glycosides can be goitrogenic.[10]

Cherry red venous blood may be observed in fresh postmortem examinations. In ruminants, a bitter almond odor may be detected in rumen contents.[10] Tracheal, pulmonary, and muscle congestion may be observed, along with hemorrhages in multiple organs. Cyanide ion content may be measured in refrigerated samples of heart, brain, or skeletal muscle or rumen contents. Blood samples for analysis should be kept in airtight containers at 4° C until analyzed. A sensitive field test for use on forage samples or rumen content has been developed using alkaline picrate-treated filter paper strips.[11]

A number of plants have varying levels of cyanogenic glycosides, including trees, shrubs, crops, and grasses: acacia, African star grass, apple, arrow grass, Bahia grass, bamboo, Bermuda grass, birdsfoot trefoil, bracken fern (Color Plate 54-2), cassava, chokecherry, Christmas berry vetch, corn, elderberry, eucalyptus, flax, flowering quince, hydrangea, Indian grass, Johnson grass, lima bean, mountain mahogany, poison suckleya, reed canary grass, service berry, sorghum, South African daisy, star grass, Sudan grass, tall manna grass, Texas queen's delight, and white clover.[10,23] Seeds of apples and crabapples (*Malus* spp.) and the seeds, as well as leaves of the *Prunus* spp. (bitter almond, cherry, chokecherry, apricot, peach, nectarine, plum, mock orange), may have large amounts of cyanide. Drying as hay or incorporation into silage generally decreases the toxic potential of the forage plants; most are not routinely grazed or browsed. Early growth phases of the plants are the most toxic. Poisoning is most likely if animals eat a large quantity in a short period of time. Wilting, frost, or other damage to the plant enhances toxicity.[1] Toxicity is measured as cyanogenic potential. Plant material containing more than 20 mg per 100 g (200 ppm) cyanide potential is reason for concern, but this varies between species.[23] Cyanogenic potential is significantly reduced by properly curing forages for hay or ensilage.

If the diagnosis is rapidly made, some cattle and sheep may be saved by intravenous or intraperitoneal injection of 20 mL of a 10% solution of sodium thiosulfate mixed with 10 mL of a 10% solution of sodium nitrite.[1] This treatment, however, is not approved for use in food animals. An alternative treatment for ruminants with thiosulfate alone using a 30% to 40% solution intravenously (IV) at a dose of 25 to 50 g/100 kg of body weight has also been described.[11] Administration of a gallon of vinegar diluted in 3 to 5 gallons of water administered by stomach tube to help acidify the rumen has also been recommended.[10] Preventive measures are largely focused on limiting access to highly cyanogenic plants and trees, particularly during rapid early-growth phases, and planting varieties with lower cyanogenic potential.

Nitrate Toxicity

Many plants in addition to some water sources contain harmful concentrations of nitrates, which can cause a wide range of clinical signs from sudden death to congenital defects in ruminants, camelids, and monogastrics. Examples of plants known to accumulate nitrates are listed in Table 54-3. When photosynthesis is impaired by shade or prolonged cloudiness or excessive nitrogen is applied to plants (e.g., fertilizer), nitrate accumulation may reach dangerous levels. Other triggers for nitrate accumulation include drought, frost, hail, and herbicide application. Nitrates are water soluble and can leach from harvested forages, occasionally causing toxicosis by elevating concentrations in the lowest bales of a rained-on haystack.[25]

In ruminants, ingested nitrates are converted to nitrites and ammonium in the forestomachs. Nitrates can also cross the placenta. If excessive nitrates are ingested, absorbed nitrites can trigger oxidation of the ferrous iron in hemoglobin, producing methemoglobin. Chocolate brown mucous membranes and blood are characteristic findings. Vasodilation and hypotension may result, leading to hypoxia, dyspnea, exercise intolerance, death, fetal stress and subsequent abortion, stillbirths, and/or weak neonates.[27] In bulls, sperm abnormalities and degenerative changes within the testes have been reported.[28] If the animals are anemic or hypoxic for any other reason, methemoglobinemia will have even greater consequences. At

postmortem examination, a brownish cast of the tissues due to the methemoglobinemia may be apparent.

Congenital hypothyroidism in equine neonates is most often caused by insufficient iodine intake by the broodmare but can also be caused by excessive nitrate intake. Multiple animals in the herd may be affected.[29,30] Signs of high nitrate intake may not be observed in the broodmare. Abortion may result, or more commonly, a dysmature foal is produced after prolonged gestation. The affected neonates have varying degrees of signs but classically include mandibular prognathism, flexural deformities of the forelimbs, secondary rupture of the common digital extensor tendon just above the carpus, poorly ossified cuboidal bones, and poor immune function. If recognized at birth, these foals can survive to be useful animals if treated intensively with splints to address the flexural deformity, very limited weight bearing until the cuboidal bones ossify, and measures to reduce the likelihood of infection. If an affected foal is allowed to bear weight before full ossification of the cuboidal bones in the hocks and carpi, angular limb deformities will likely result. The syndrome can be prevented by avoiding high nitrate forage or water sources and ensuring that there is adequate iodine in the mare's diet. Confirmation of nitrate toxicity is based on demonstration of elevated levels in forages, weeds, water, or body fluids such as aqueous humor, fetal stomach fluid, and amniotic fluid.[1,10] In ruminants, plants containing more than 1.5% nitrates (measured as KNO3) dry weight may be lethal. Sublethal effects are seen from feed containing 0.5% to 1.5% nitrates. Seeds are usually unaffected by high nitrates in other plant parts. Ruminants can adapt to higher nitrate feeds if their introduction is gradual. Reproductive effects in ruminants are linked to forage concentrations greater than 5000 ppm on a dry matter basis.[27] In adult ruminants, signs of methemoglobinemia are seen with forages containing 2000 to 10,000 ppm nitrates on a dry matter basis. Water with greater than 200 ppm is excessive for pregnant ruminants, with 30 ppm the recommended limit for broodmares.[10,29,30] In nonpregnant animals, ranges from 445 to 1000 ppm in water are considered dangerous for livestock.[10,26]

Treatment of nitrate toxicity in ruminants is restricted by the paucity of approved drugs. Methylene blue administration is prohibited in food animals in the United States for at least 180 days before slaughter but, if permitted in other areas, may be given IV at a rate of 4 to 15 mg/kg body weight as a 2% to 4% solution.[10] Adjunct therapies that have been suggested in acute ruminant cases are administration of either cold water or vinegar to slow nitrate reduction, as well as mineral oil to hasten passage of the ingested source if the stress of intubation is warranted.[10] Identification of the nitrate source and prevention of animal access are the most effective management tools.

Forages known to have high nitrate potential should be tested before feeding them to livestock, particularly if fertilizer has been used. High nitrate forages can potentially be ensiled to reduce the nitrate content by as much as 30%.[26] Nitrate levels are highest at night and early morning, and this knowledge can be applied to the timing of pasture access and hay cutting. Gradual introduction of high nitrate forage into the ruminants' diet will permit rumen microflora to adapt, but this should preferentially begin with nonpregnant adult animals to minimize the reproductive effects. Monensin in the diet may lower the threshold for toxicity,[31] and probiotics containing *Propionibacteria* spp. reduce nitrates, which may also be useful.[10]

Neurologic Signs

Many plant ingestions result in neurologic signs exclusively or as part of an array of signs. Plants linked to neurologic deficits are listed in Table 54-4. Many other plants found in Australia and New Zealand are also capable of producing neurologic signs.[3] Abnormal behavior, seizures, coma, ataxia, weakness, and muscle tremors may be associated with ingestion of poisonous plants or other medical conditions such as rabies, encephalitis, and electrolyte disorders. Perennial ryegrass infected with an endophyte, *Neotyphodium lolii,* causes perennial ryegrass staggers in all herbivores. The syndrome, caused by lolitrem B, was recently reproduced in horses that demonstrated varying degrees of muscle fasciculations, tremors, truncal swaying, basewide stance, and limb edema.[35] Signs abate when the forage is changed.

Locoweed and Milkvetch

Locoweed and milkvetch (*Astragalus* spp. and *Oxytropis* spp.) (Color Plate 54-3) are the most important plant-related toxicoses in the western United States and significantly affect animals in other areas of the world.[10] A review of poisonous plants affecting livestock in China suggested locoweeds were responsible for an estimated 80% of all livestock losses due to plant toxicoses.[2] Many species in these genera can cause four different toxic syndromes: sudden death from methemoglobinemia due to nitro compounds in cattle and sheep (milkvetch [*Astragalus* spp.]); respiratory syndrome with emphysema-like signs, most often seen in sheep (milkvetch [*Astragalus* spp.]); neurologic signs (*Astragalus* spp. and *Oxytropis* spp.); and selenium toxicosis (*Astragalus* spp.). Recent investigations have shown that the toxin swainsonine, responsible for the signs of nervous system dysfunction, is produced by an endophyte *(Undilum oxytropis)* in the plant seeds rather than the plants themselves.[39] Swainsonine triggers clinical signs after chronic locoweed ingestion in horses and ruminants. This same toxin poisons horses and cattle that consume swainsona or darling pea (*Swainsona* spp.) in Australia.[3] The toxin creates a lysosomal storage disease in which α-mannosidase is inhibited, resulting in swelling of axonal hillocks and growth of new dendrites and synapses in severe locoweed cases, a nonreversible change.[36]

Clinical neurologic signs of locoweed intoxication begin with depression and incoordination, progressing to aberrant behavior including incoordination, aggression, circling, weight loss, and eventually death if locoweed consumption continues. In affected horses, this also leads to unpredictable behavior, endangering riders, so these animals are often euthanized or salvaged for breeding. Similar signs may be seen in horses forced to eat sagebrush.[10] Pregnant animals may abort or give birth to neonates with neurologic signs. In cattle and sheep, swainsonine-induced damage to the lungs and hearts may contribute to high mountain disease, characterized by right-sided heart failure.[10]

Nitro-toxins are the most common toxins found in the milkvetch species of *Astragalus* and are responsible for the greatest ruminant herd and flock problems. The toxic principles are β-D-glycosides converted to 3-nitro-1-propanol (miserotoxin) in the rumen and subsequently changed to the toxic compound 3-nitropropionic acid in the liver.[36] Signs of acute toxicosis include weakness, tachycardia, respiratory distress, coma, and death. Chronic consumption results in neurologic signs beginning with weakness, incoordination, fetlock knuckling, and goose stepping, progressing to paralysis and death. Respiratory emphysema, as well as incoordination and weakness, may be observed in both acute and chronic cases, particularly in sheep.

Chronic ill thrift is attributed to chronic locoweed consumption. Research in food animals has demonstrated a number of effects attributed to swainsonine, including reduced production of growth hormone and thyroxine, decreased intestinal absorption of nutrients, and reduced immune response to vaccinations. These can lead to poor weight gain and increased frequency of infections.[10]

Diagnosis of locoism is based on clinical signs and can be confirmed by measurement of swainsonine and/or α-mannosidase in serum. Vacuolation of peripheral lymphocytes may be evident in some cases. Vacuolation of many tissues, particularly brain and liver, may be seen histologically after finding little gross change at necropsy. Treatment is removal from locoweed forage.[10]

Locoweed is usually not palatable but will be eaten if more enticing forage is not available. For example, many locoweed species start growth early in the spring, attracting livestock less interested in dormant grasses. This period of preference is influenced by rainfall, so the impact of locoweed and milkvetch species will vary from year to year even within a region. Prevention is challenging if alternative forages are not available in the spring. One innovative approach is a

Plants Associated with Neurologic Signs*

Common Name	Scientific Name	Species Affected†	Toxin(s)	Plant Habitat	Clinical Signs	Specific Therapy
Blown grass, Pacific bent grass[3]	*Agrostis avenacea*	B, O	Corynetoxins in nematode	Australia, NZ, SW U.S.	Incoordination, weakness, muscle weakness, rocking stance, high stepping, collapse, seizures, abortion	
Bracken fern[10]	*Pteridium aquilinum*	E, P, B, O	Ptaquiloside	Worldwide	Weight loss, progressive incoordination, depression, tremors, crouching stance with arched neck (equine), blindness (sheep), aplastic anemia (ruminants), thrombocytopenia, bladder and gastrointestinal cancer	Thiamine
Buttercup[10]	*Ranunculus* spp.	B, E	Ranunculin	North America, Europe	Salivation, depression, blindness, hematuria, oral ulcers, diarrhea, colic	
Caltrop or carpetweed[10]	*Kallstroemia* spp.	B, O, C	Unknown	SW U.S.	Hindlimb weakness, knuckling, seizures, posterior paralysis	
Castor bean[19]	*Ricinus communis*	E, B, O, C, P	Ricin	Worldwide	Bloody diarrhea, tenesmus, colic, trembling, incoordination, seizures	
Coyotillo[10]	*Karwinskia humboldtiana*	B, O, C, E, P	Unknown	SW U.S.	Hypersensitivity, muscle tremors, abnormal high stepping gait, diminished reflexes, progressive paralysis	
Fitweed[10]	*Corydalis* spp.	B, E	Isoquinolone alkaloid	U.S., Canada	Tachypnea, seizures, staggering, snapping at objects, muscle tremors, depression	
Golden chain tree[10]	*Laburnum anagyroides*	E, B	Cystisine	Southern U.S.	Incoordination, muscle tremors, mydriasis, excitement, seizures, coma, vomiting, diarrhea, paralysis	
Hairy cat's ear, flatweed[32]	*Hypochaeris radicata*	E	Unknown	U.S., Europe, Australia	Bilateral stringhalt, depression, aggression	Phenytoin
Hairy vetch[10]	*Vicia villosa*	B, E	Unknown	U.S., Europe	Excitement, slobbering, oral ulcers, nasal discharge, cough, stiffness, anorexia, weakness, seizures, swelling of the head and neck, pruritic dermatitis, diarrhea, abortion, myocardial necrosis	
Halimium[33]	*Halimium brasiliense*	O	Unknown	Brazil, Uruguay	Transient seizures when excited, muscle tremors, ventroflexion of neck or opisthotonus, nystagmus, tetanic spasms, postictal ataxia	
Horse chestnut, buckeye[10]	*Aesculus hippocastanum*	B, O, C, E	Aesculin, fraxin, alkaloids	U.S., Europe	Muscle tremors, incoordination, depression or excitability, hopping gait, dorsomedial strabismus (ruminants), gastroenteritis (monogastrics)	
Horse nettle[10]	*Solanum carolinense*	B, E	Solanine	U.S., Canada	Falling when excited, incoordination, anorexia, emaciation, rough coat, constipation, mouth inflammation	Physostigmine
Horsetail or scouring rush[10]	*Equisetum* spp.	E, B, O	Aconitic acid, palustrine, thiaminase	Worldwide	Weight loss, staggering, muscle tremors or rigidity, paraparesis, tachycardia, diarrhea, coma	Thiamine
Jamaican nettle tree[34]	*Trema micrantha*	B, C, E	Trema toxin, ammonia	Americas	Apathy, blindness, recumbency, paddling, coma (hepatic encephalopathy)	
Jimmyweed[10]	*Haplopappus heterophyllus*	B, E	Tremetol	Western U.S., Mexico	Depression, trembling, weakness, knuckling, seizures, paralysis, congestive heart failure, acetone breath smell	
Jimsonweed, thornapple[35]	*Datura* spp.	E, P, B	Tropane alkaloids	Worldwide	Colic, ileus, diarrhea, mydriasis, tachycardia, anorexia, muscle spasms, seizures, polyuria	
Johnson grass[10]	*Sorghum halepense*	B, O, E	Hydrocyanide	Worldwide	Posterior ataxia, urinary incontinence, cystitis, weight loss	
Kochia[1]	*Kochia scoparia*	B, O E	Thiaminase, nitrates, oxalates	Worldwide	Ataxia, muscle spasms, depression, blindness, photosensitization	Thiamine

Sagebrush[10]	*Artemesia* spp.	E	Unknown	Western U.S., Mexico	Abnormal behavior, ataxia, sage aroma in breath and manure	
Sneezeweed[1]	*Hymenoxys* spp.	O, B, E	Sesquiterpene lactones	North America	Equine: weakness, incoordination, foaming at the mouth, seizures; ruminants: chronic vomiting, emaciation, stiffness	
Squirrel corn, Dutchman's breeches[10]	*Dicentra* spp.	B, E	Isoquinoline alkaloid	North America	Muscle tremors, seizures, extensor rigidity, dyspnea, pain	
Sudan grass[10]	*Sorghum sudanense*	B, O	Hydrocyanide, nitrates	Worldwide	Posterior ataxia, urinary incontinence, cystitis, weight loss	
Yellow jessamine[10]	*Gelsemium sempervirens*	E, B, O, C, P	Gelsemine, gelseminine	Eastern U.S., Mexico	Weakness, hypothermia, mydriasis, seizures, extensor rigidity, coma	
Yellow star thistle[1]	*Centaurea solstitialis*	E	Sesquiterpene lactones	U.S., Argentina, Australia	Twitching of lips, tongue flicking, involuntary chewing, weight loss, emaciation, poor prehension, incoordination, muscle tremors, facial paralysis	

*Plant names in bold are discussed in more detail in the text.

†Species listed in relative order of toxicity importance: *B,* Bovine; *C,* caprine; *E,* equine; *O,* ovine, *P,* porcine.

VetBooks.ir

conditioned food aversion model that combines feeding fresh-picked locoweed to naive animals with lithium chloride administration by stomach tube. The treated animals form a strong and lasting (>3 years) aversion to locoweed following a single dose but must be pastured separate from nonaverted animals on locoweed areas to prevent social facilitation from extinguishing the aversion.[22]

Musculoskeletal Disease Attributed to Plant Poisoning

Plant poisonings may affect the skeletal system, resulting in abnormal bone growth or remodeling. Day-blooming jasmine *(Cestrum diurnum)* induces calcinosis in horses and cattle by means of calcinogenic glycosides that may be converted to vitamin D–like compounds.[10,40] This plant is found in the southeastern United States and tropical countries. Other plants with this potential include *Solanum malacoxylon, S. sodomeum, S. linnaeanum, Trisetum flavescens,* and *Nierembergia veitchii*.[10] Those that affect the fetus are discussed in the reproductive section.

Signs of muscle dysfunction in livestock and horses have been attributed to ingestion of a number of plants, often as part of a larger panoply of signs. Muscle tremors may be manifestations of muscle or nervous system dysfunction, as well as electrolyte disturbances or pain. The toxin tremetol (tremetone and other compounds) affects all species of livestock and horses that consume it. The effects of the toxin are cumulative and affect both skeletal and cardiac muscle. Plants of importance include white snakeroot *(Eupatorium rugosum),* rayless goldenrod *(Haplopappus heterophyllus),* and burrow weed *(Isocoma pluriflora).*[10] Adult cattle are relatively unaffected by consumption of white snakeroot but pass the toxin through the milk, causing clinical signs in milk-fed calves. Rayless goldenrod produces myonecrosis and cardiomyopathy at higher doses in goats.[41] Horses, cattle, and pigs may also be affected by this plant. The effect of tremetol on myocardial tissue may lead to arrhythmias and congestive heart failure. Tremorgenic mycotoxins should also be considered in cases with muscle tremors, particularly in livestock grazing perennial ryegrass or paspalum species such as Dallisgrass or Bahiagrass.[42]

Cassia (Senna) species such as coffee weed (Color Plate 54-4) and sickle pod are an important source of skeletal and cardiac muscle degeneration and gastroenteritis in cattle, sheep, goats, horses, and pigs.[10] In severe cases, hepatic and renal failure may also be observed. Gossypol poisoning attributed to feeding cottonseed meal is a source of muscle degeneration and significant morbidity and mortality in livestock.[10]

Summer Pasture-Associated Myositis and Equine Atypical Myopathy

Recent research has defined ingestion of box elder seeds from female trees *(Acer negundo)* (Color Plate 54-5) as a cause of acute, nonexertional, severe, often fatal rhabdomyolysis in pastured horses and a donkey in the United States and Canada.[43] The syndrome of atypical myopathy seen in horses, donkeys, and zebras in Europe may also have this underlying cause because outbreaks have been linked to ingestion of maple leaves *(Acer pseudoplantanus)* covered with European tar spot *(Rhytisma acerinum).*[44] Box elder trees are also found in Europe. Additionally, European researchers have demonstrated a link between atypical myopathy and *Clostridium sordellii* toxin.[45] In both syndromes, one or multiple animals may be affected, typically on a premises that houses the equids for at least part of the day on a pasture surrounded by or with trees, sparse grass, and often after a storm or high winds in spring or autumn brings down tree branches or seeds.[43,46] The toxic principle identified in box elder seeds is hypoglycin A, a branched chain amino acid, which is metabolized to methylene cyclopropyl acetic acid (MCPA), a potent inhibitor of multiple acyl-CoA dehydrogenases (MADD). Lack of these enzymes damages mitochondria and impairs lipid metabolism within muscle cells, leading to lipid accumulation, thus limiting the muscle cell's energy supply and causing cell death.[43]

Clinical signs include muscle weakness, recumbency, and myoglobinuria.[43] Other signs that are reported include dysphagia, esophageal obstruction, or colic-like signs. In atypical myopathy, myocardial damage may be detected with electrocardiography (ventricular premature depolarizations, prolonged QT intervals); echocardiography (abnormal ventricular wall motion); and elevated serum troponin concentrations.[47] Histologically, the change in both diseases is marked myofibril degeneration with intramyofiber lipid accumulation in skeletal, respiratory, and cardiac muscles. Additional confirmation of this etiology for rhabdomyolysis can be obtained at specialized laboratories by demonstration of increased urinary organic acids (specifically ethylmalonic and methyl succinic acids and glycine conjugates) and abnormal patterns of serum acylcarnitines.[48] Other toxic etiologies for muscle disease to be considered are white snakeroot, rayless larkspur, and monensin toxicity.

Treatment of affected cases is symptomatic but should also include attention to establishing a positive energy balance. Case fatality rate is high despite treatment.[43] Preventive measures should focus on provision of sufficient forage to deter horses from consuming box elder seeds, rapid removal of downed box elder branches after high winds, and planting less toxic trees as windbreaks.

Cardiovascular and Hematologic Plant Toxicities

Ingestion of plants that contain toxins affecting myocardial function may result in a wide variety of signs including sudden death. Plants most noted for producing myocardial effects when consumed are those that contain cardiac glycosides; cattle are most frequently affected. These include the pasture plants milkweed (*Asclepias* spp.), dogbane or Indian hemp *(Apocynum cannabinum),* blue-eyed grasses (*Sisyrinchium* spp.), and a number of plants more likely to be found in gardens than pastures: foxglove (*Digitalis* spp.), hellebores (*Helleborus* spp.), hyacinth (*Hyacinthium* spp.), kalanchoe (*Bryophyllum* spp.), lily of the valley *(Convallaria majalis),* oleander (*Nerium* spp.), periwinkle *(Vinca major),* pheasant's eye *(Adonis microcarpa),* spindle tree (*Euonymus* spp.), squill (*Drimia* or *Urginea* spp.), and star of Bethlehem (*Ornithogalum* spp.). Digestive signs of hemorrhagic enteritis with colic may also be seen.[10] Gousiekte is a syndrome of heart failure and sudden death affecting sheep and cattle in South Africa 4 to 6 weeks after ingestion of Rubiaceae (coffee) family plants containing pavetamine. Six plants in the genera *Fadogia, Pavetta,* and *Vangueria* have been implicated in significant losses. New research suggests that toxin production in the plants may be linked to their infection by *Burkholderia* spp. of endophytic bacteria.[49] The toxin inhibits myocardial protein synthesis, resulting terminally in dilated cardiomyopathy and congestive heart failure.[50]

Four important plants with toxins that damage the myocardium and cause mortality in large animals are yew (*Taxus* spp.), avocado *(Persea americana),* death camas (*Zigodenus* spp.), and summer pheasant eye (*Adonis* spp.). Avocado poisoning in horses produces edematous swelling of the head and neck and subsequent respiratory distress, which may progress to congestive heart failure. Goats may also develop signs of heart failure. The udder is affected by avocados in female horses, cattle, and goats, creating a noninfectious mastitis.[10] Summer pheasant eye consumed in hay caused signs of colic and death in horses, and pigs have died after consuming a diet containing *Adonis* seeds.[51]

Signs of anemia and hemorrhage are linked to ingestion of several groups of plants that may cause methemoglobinemia, erythrolysis, or thrombocytopenia. Ingestion of wilted maple leaves or bark (*Acer* spp.) (Color Plate 54-6), most often red maple, results in oxidative damage to erythrocytes and acute Heinz body anemia with methemoglobinemia in horses and zebras. Weakness, tachycardia, tachypnea, icterus, and hemoglobinuria may occur. In severe cases, laminitis, colic, or abortion may result.[52] In ruminants, nitrate-accumulating plants that cause methemoglobinemia should be considered (see Table 54-3). Wild onions and garlic can also cause

VetBooks.ir

hemolytic anemia, most often observed as a clinical problem in cattle.[10]

Plants that contain coumarin, such as sweet clover (*Melilotus* spp.), have the potential for endogenous coumarin to be converted to dicoumarol if cut plants become moldy. Signs ranging from subtle to death may be observed, particularly in cattle, depending on the amount of dicoumarol ingested and trauma to the animal that may cause bleeding. Transfusion and vitamin K_1 administration may be necessary in moderate to severe cases.[10]

Thiaminase enzymes in bracken fern *(Pteridium aquilinum)* and horsetail (*Equisetum* spp.) produce thiamine deficiency most often in horses and pigs, resulting in anemia and hemoglobinuria. Other signs associated with bracken fern ingestion are due to alternate toxins, particularly ptaquiloside, a sesquiterpene glycoside responsible for detrimental effects on the bone marrow and neoplastic changes in the bladder and upper gastrointestinal tract. The cancerous changes in the urinary tract may be manifest as enzootic hematuria in cattle. Retinal changes resulting in blindness are reported in sheep. The toxins are transmitted through milk. Protamine sulfate administration may counteract the effects on blood coagulation. In horses, bracken fern may also produce neurologic signs and colic.[10,36]

Digestive and Hepatic Plant Poisonings

A plethora of plants have the potential to induce pathology in the digestive tract and liver. Plants that cause significant impact in large animals are listed in Table 54-5. The effects of a plant may be mechanical or chemical irritation, altered motility, or altered cell function. Depending on the toxin, plant species, animal species, and stage of intoxication, a single species of plant may produce a wide range of signs, even within the same animal. Clinical signs may include excessive salivation or slobbering, anorexia, dysphagia, colic, vomiting or regurgitation in ruminants, bloat, constipation, diarrhea, and melena. Excessive salivation may result from injury due to plant awns, irritant substances in the plant, mold infection of the plant (e.g., red clover and slaframine production), and inability to swallow. Sources of plant awns include grasses (e.g., foxtail, needle, squirrel tail, bristle, sandbur, medusahead rye, prairie three-awn, tanglehead, tickle grass); cacti (e.g., prickly pear); nettles; and many seed pods.[10,55] Substances irritating to mucous membranes are found in a number of plants and may also produce signs of diarrhea in the more distal digestive tract.

Bracken fern *(Pteridium aquilinum)* has long been recognized as a cause of enzootic hematuria and bladder cancer but more recently has been linked to upper digestive tract squamous cell carcinoma in cattle grazing pastures with high bracken content in conjunction with bovine papillomavirus type 4. In a study that reviewed 40 tumors in cattle, metastasis was common (56%), predominately to regional lymph nodes.[56]

Hepatic Disease

Absorption of toxins from the digestive tract results in subsequent exposure of liver tissue where further pathologic changes may be induced. Depending on the toxin and disease syndrome, signs of liver disease may be only subtle weight loss or failure to grow, but more often include icterus, photosensitization, and/or hepatic encephalopathy. For example, alsike clover in horses can produce two syndromes, either hepatic encephalopathy or photosensitization. (Plants causing primary photosensitization are listed in the later discussion of plant-induced skin lesions.) A variety of plants damage biliary cells leading to secondary photosensitization as the primary clinical sign, including agave *(Agave lecheguilla),* bear grass or sacahuista *(Nolina texana),* bog asphodel *(Narthecium ossifragum),* kleingrass and switchgrass (*Panicum* spp.), and puncture vine *(Tribulus terrestris).*[10] Mycotoxins can also produce biliary damage leading to photosensitization. Photosensitization is one of many systemic signs that may be seen with consumption of plants, such as black sage *(Artemesia nova)* consumed concurrently with horsebrush (*Tetradymia* spp.), *Brassica* spp., Dutchman's breeches *(Thamnosma texana),* hairy vetch *(Vicia villosa),* inkweed *(Phytolacca octandra), Kochia* spp., *Lantana* spp. (Color Plate 54-7), and yellow wood *(Terminalia oblongata).*[3,10,36,57] Plants containing pyrrolizidine alkaloids also produce photosensitization and are the most important source of widespread liver problems to both livestock and horses (see later).

Severe hepatic disease may lead to signs of liver failure, including hepatic encephalopathy and sudden death. The pyrrolizidine alkaloid

TABLE 54-6

Plants Containing Pyrrolizidine Alkaloids

Common Name	Scientific Name	Plant Habitat	Reference(s)
Groundsel	*Senecio* spp.	Western U.S., Australia	1, 3
Heliotrope	*Heliotropium* spp.	Worldwide	3
Houndstongue	*Cynoglossum officinale*	SW U.S.	1
Kochia	*Kochia scoparia*	Western U.S.	1
Paterson's curse	*Echium plantagineum*	Australia	3
Rattlebox, rattlepod	*Crotolaria* spp.	U.S., Australia	1, 3
Tansy ragwort	*Senecio jacobaea*	North America, Europe	10, 19
Tarweed, fiddleneck	*Amsinckia* spp.	U.S., Mexico, Australia	10
Viper's bugloss	*Echium vulgaris*	Australia, California	3

plants are the foremost plants associated with this. *Cassia* spp., in particular the seeds, are very toxic to multiple species. Sixty percent of a herd of broodmares died with signs of hepatic encephalopathy with histologic lesions of pericentrolobular necrosis after ingesting seeds of *Cassia occidentalis* in ground corn.[58] Cocklebur (*Xanthium* spp.) and blue-green algae should also be considered. Cocklebur most often produces signs in calves and cattle, but pigs and horses have also been affected.[10]

Pyrrolizidine Alkaloids

This large group of plants is a common source of adverse effects in livestock in many areas of the world, particularly in the southern United States. Plants in this category of toxins are listed in Table 54-6. Most often the clinical syndromes are chronic, with recognition of clinical signs of liver damage months after the plant is eaten. Cattle and horses are most susceptible. Poisoning typically occurs in overgrazed pastures but may also develop when plants such as houndstongue *(Cynoglosum officinale),* tansy ragwort *(Senecio jacobaea),* or rattlebox (*Crotolaria* spp.) (Color Plate 54-8) are incorporated in hay or accidentally harvested with small grains.[1] In cattle, chronic consumption usually occurs for an extended time before the onset of signs. Consumption of mature pyrrolizidine alkaloid forage at a rate of 5% or more of their total daily diet for more than 15 days usually results in death in 1 to 6 months.[1] Young plant growth tends to be even more toxic. Those animals that consume less may become chronic poor doers. Young animals are more easily affected. In horses, consumption of *Crotolaria* spp. causes liver failure and fibrosing pulmonary alveolitis.[10] There is some evidence that pyrrolizidine alkaloids pass through the placental membranes to affect the fetus. In humans, carcinogenicity is reported.[1] The pyrroles are powerful alkylating agents that react with cellular proteins, cross-link DNA, and cause cell necrosis and abnormal mitosis. Pigs are most prone to development of extrahepatic lesions.[36]

Clinical signs are variable but emanate from hepatic damage induced by the ingested pyrrolizidine alkaloids. Other stressors may trigger expression of clinical signs. Photosensitization of areas of white skin, particularly on the animal's dorsum and face, may be the first sign of illness. Crusting around the muzzle and eyes may be observed. In cattle, an unpleasant sweetish odor may be noted. Lethargy, loss of appetite, and weight loss are common. Weakness is observed when the animal tries to walk. In the terminal stages, signs of hepatic encephalopathy such as blindness and belligerent or compulsive behavior may be reported. Mucous membranes and sclera can be markedly icteric. Ascites, diarrhea, or constipation may be present as well.[1] Serum chemistry analysis confirms hepatocellular and biliary cell damage. The characteristic lesion on postmortem examination or biopsy is liver cirrhosis with necrosis and fibrosis, accompanied by bile duct proliferation. Varying degrees of hepatic megalocystosis may be observed in liver tissue.[36] Gastroenteritis may also be evident.

There is no specific treatment for pyrrolizidine alkaloid poisoning. Livestock may frequently graze these plants with seeming impunity if there is abundant high-quality forage available. If pastures with these plants are unavoidable, the use of herbicides should be considered. Biological control measures have been developed for some plants, such as tansy ragwort, and may also be considered as preventive measures.

Reproductive and Neonatal Effect of Poisonous Plants

Poisonous plants that affect fertility, pregnancy, fetal development, and lactation can have a large economic impact, as can plants infected with ergot or endophytes. Livestock at pasture or on a range are frequently affected, creating significant management challenges. The effects may be as subtle as reduced conception rates or as apparent as abortion storms and multiple neonates with congenital defects. Any severe plant poisoning in a pregnant animal has the potential to precipitate an abortion. Toxins from a few plants may pass into the udder in an active form, harming the neonate or human who drinks the milk.

Ponderosa pine *(Pinus ponderosa)* needles and bark, when consumed in the last trimester, are a significant cause of abortion and premature delivery in cattle in the western United States and Canada.[1] Junipers, lodgepole pine, and Monterey cypress evergreens may produce similar syndromes. A few cows or even the whole herd may be affected. Isocupressic acid, the abortifacient compound, is rapidly metabolized to agathic acid in the rumen, a process that is accelerated by conditioning of the cattle to pine needle consumption and thereby reducing its effect.[59] Other toxic compounds such as diterpene abietane acids are also present. A vasoconstrictive effect on uterine vessels leads to uterine inertia, abortion, and frequently, dystocia and/or retained placenta. Edematous swelling of the udder and vulva may be observed before abortion. Calves are typically weak, and lactation may be impaired.[1,10] Many other plants have been identified as sources of significant abortion in other parts of the world.[3,25,60]

Phytoestrogens may accumulate in a number of commonly consumed forages, adversely affecting reproductive performance. Examples include alfalfa and some types of clovers, which can produce coumestrol, and soybeans, which may contain isoflavones. Phytoestrogen concentrations may increase in stressed or diseased legumes. Fungal infections of feed may provide an additional source of xenoestrogens such as zearalenone. These phytoestrogens interact with endogenous estrogen receptors. In ruminants, this can create a syndrome of hyperestrogenism characterized by precocious sexual development in females and preputial swelling and testicular atrophy in immature males. Goats and sheep may be more susceptible than cattle. Disruption of cyclic estrogen changes in older animals has more subtle effects, with the end result of reducing fertility.[25]

A number of plants with significant reproductive effects are discussed earlier in this chapter, including locoweed and those that accumulate nitrate. Locoweed is particularly dangerous to range animals because it may contain excessive selenium and endophyte infection. Reduced fertility, abortion, fetal defects, abnormal placentas, hydrops, and weak neonates may be observed. Sperm quality is also affected.[10] Nitrate-accumulating plants (see Table 54-3) can be responsible for sudden death, abortions, stillbirths, congenital defects, and weak neonates.

VetBooks.ir

Congenital defects resulting from ingestion of specific plants during pregnancy may trigger abortion or result in nonviable neonates. Skeletal deformities such as arthryogryposis, kyphosis, scoliosis, torticollis, and cleft palate can be the result of lupine ingestion during early to midgestation in ruminants, a syndrome called "crooked calf disease," a significant problem in range cattle. The two specific teratogens that have been identified and studied are anagyrine, a quinolizidine alkaloid, and ammodendrine, a piperadine alkaloid, both of which reduce uterine motility. Toxin absorption and the likelihood of ingestion are affected by body condition score.[61] Anagyrine is also present in mountain thermopsis. Other plants with similar effects include locoweed, poison hemlock, and tobacco. The teratogenic effects of poison hemlock are greatest in cattle and pigs. In sheep, false hellebore and skunk cabbage (*Veratrum* spp.) ingestion in early gestation may result in abortion or birth of cyclopic lambs.[10] Cattle, goats, and llamas are also susceptible.

Congenital hypothyroidism in equine neonates can be caused by ingestion of high nitrate forages or plants with goitrogenic effect. Goitrogenic effects may be observed from plants that provide excessive iodine (e.g., seaweed) or compounds such as thiocyanates (white clover) or glucosinolates (*Brassica* spp., kale, turnips, and canola seeds) that interfere with iodine utilization. Horses are particularly susceptible to iodine excess, as well as iodine deficiency. Excessive iodine consumption in a seaweed-based supplement led to abortion in 27 of 39 mares, goiters, and signs of congenital hypothyroidism in many of the neonates, including pathologic changes in the long bones.[62] Diagnosis is most readily based on histologic evaluation of the thyroid gland or characteristic changes of the skeletal system characteristic of congenital hypothyroidism. More commonly, this syndrome is attributable to iodine deficiency or excessive nitrate in forages or water.

Milk-fed neonates may be affected by poisonous plants ingested by their dam, who may or may not show signs of toxicity, depending on the chemistry of the toxin and/or its metabolites. If plant poisoning is suspected in a sick dam, an alternative milk source for the neonate should be considered, particularly if the toxin is an alkaloid. Plants that affect milk flavor, such as onions, may diminish neonatal consumption. More significant toxic plants to consider in this category include those with pyrrolizidine alkaloids (see Table 54-6), white snakeroot, rayless goldenrod, locoweed, lupines, mountain thermopsis, poison hemlock, tobacco, *Cassia* spp., and lobelia. A number of plants in the Brassica family (mustards, kale, rape, turnips, horseradish, radish, and watercress) can adversely affect thyroid function, as well as impart a bitter flavor to the milk.[10]

Ergot Alkaloids and Endophytes

Clinical syndromes ascribed to plant infection with ergot and endophytes are often included in veterinarians' thought processes when considering poisonous plant etiologies. For this reason, plants with this potential are included in the charts of predominant clinical signs. Two categories primarily affecting reproductive functions are discussed here: ergot alkaloids (ergopeptines) from ergot and from endophyte infections. Neurologic signs and other syndromes associated with endophyte-infected locoweed are discussed in the neurologic section.

Ergot-infected forages and grains have much higher concentrations of ergot alkaloids than are found in endophyte-infected forages.[25] Ergot infection (*Claviceps* spp.) of many grasses and cereal grains produces dark fungal sclerotia (ergot bodies) shaped like seeds that are readily visible in the plant's seed head in pasture, hay, or contaminated grains.[63] Similarly, many grass species can be infected with endophytes, the most economically important of which is fescue (*Lolium* spp.) infected with *Neotyphodium coenophialum.* Ergovaline is the most prevalent ergopeptine in endophyte-infected tall fescue and considered responsible for the majority of signs associated with fescue toxicosis.[64] Infection provides fescue the advantages of increased resistance to drought, insects, parasitic nematodes, and herbivores. In contrast to ergot infections, endophyte infections are not visible to the naked eye and require microscopy for confirmation. The endophyte also infects the plant's seed, ensuring its survival to germination in subsequent seasons.[64] Tall fescue can be infected with both *Claviceps* spp. and the endophyte simultaneously.[25]

Ergot alkaloids affect all livestock and horses. Species susceptibility is highest in horses, followed by cattle, then sheep, goats, and finally camelids. Different disease syndromes may be seen, depending on the affected species and type of ergot alkaloids ingested. In ruminants and horses, ergot alkaloids, particularly ergovaline, have vasoconstrictive effects (α_2 adrenergic agonist) and/or depress secretion of prolactin via effects on lactotropic D_2-dopamine receptors in the adenohypophysis of the pituitary. There is a reduction in steroid genesis, including progesterone production by corpora lutea, and relaxin. Diminished relaxin production has less impact on readiness for parturition in ruminants because it is also produced by the placenta. Thermoregulatory centers are affected by diminutions in prolactin and dopamine receptor perturbation, leading to clinical problems in extreme temperatures.[64] *Claviceps cyperi* has produced signs of severe ergotism in dairy cows in the heat of South Africa.[65] In contrast, infection of grasses with another form of ergot, *Claviceps paspali,* produces predominately neurologic signs associated with γ-aminobutyric acid inhibition.[25]

Clinical abnormalities attributable to ergot and endophyte infections of grasses are most often detected in regions with warm, wet climates conducive to fungal infections, such as found in the southern portions of the United States (endophytes) and the cool wet springs of the northwestern United States (ergot).[66] Prevalence of toxicosis will vary by season and from year to year. Deciphering toxicity attributable to these fungal infections is complicated by the fact that some species of grasses can be simultaneously infected with both, as well as have dangerous levels of nitrates.[25] Additionally, concurrent copper deficiency may augment at least reproductive system clinical signs, as ergopeptine alkaloids impair copper homeostasis. Heavy parasitic loads may have a similar effect.[25]

Depending on environmental conditions, the vasoconstrictive effects of the ergot alkaloids can be costly to livestock. Cold weather can result in gangrene of the distal extremities and lameness. The tongue may also be affected in sheep. Lameness can lead to reduced feed consumption and diminished natural mating. In ruminants undergoing heat stress, hyperthermia can occur due to failure of heat dissipation through the skin. Sheep with full fleeces are particularly susceptible to this syndrome. Other signs include dull, rough hair coat and unthrifty condition. Nervousness, increased salivation, tachypnea, and delayed puberty may also be seen. In some regions, this condition is referred to as "summer slump." Ergot alkaloids should also be considered in alpacas and llamas that develop heat stroke.[64] Fat necrosis or lipomatosis in cattle and goats is associated with consumption of ergot alkaloids in fescue grasses. Masses of necrotic fat in the pelvic canal can lead to dystocia.[25] Because the ruminant placenta can produce a placental lactogen during pregnancy, the suppression of prolactin and hence milk production is minor in comparison with horses. Bulls grazing endophyte-infected pastures during the summer may have altered sperm motility parameters. Cows may have changes in ovarian follicular dynamics, as well as diminished embryo quality. Reduced fertility in both unshorn ewes and rams has been reported during the summer.[25] Diminished immune function may make animals more susceptible to infectious diseases and cases with dry gangrene more susceptible to wound infections. In swine, agalactia and abortion have been reported in association with ergot consumption.[63]

Ergot *(Claviceps purpurea)* and endophytes of forages such as fescue (*Lolium* infested with *Neotyphodium coenophialum*) have been extensively studied in horses. Broodmares eating ergot or endophyte-infected tall fescue pasture or hay may exhibit failure of udder development, agalactia, prolonged gestation, placental abnormalities, dystocia, decreased milk production, and subfertility.[66] Foals may show signs of dysmaturity despite prolonged gestation and frequently suffer failure of passive transfer and secondary septicemia due to the failure of udder and colostrum development. Early embryonic death and abortion are also possible, with a higher risk of abortion

VetBooks.ir

associated with ergot infections rather than endophyte.[67] Ergot alkaloids may stimulate the myometrium and probably impair placental circulation.[66] Gangrene of the extremities has been seen in horses exposed to ergot, as has a syndrome characterized by staggering following consumption of *Paspalum* grass seeds infected with *Claviceps paspali*.[68] A slightly different syndrome characterized by peripheral edema has been described in horses grazing Mediterranean tall fescue intentionally infected with a genetically modified, nontoxigenic form of endophyte, suggesting that other factors may also be involved and considered if reseeding of pastures is desired.[69]

Diagnosis of ergot alkaloid or endophyte-induced toxicity is based on recognition of clinical signs and consumption of infected feed. Diagnostic testing of suspect forages, hay, grain, or processed forages is based on observation of *Claviceps purpurea* sclerotia or intercellular endophyte infection via feed microscopy and testing of the forages. High-performance liquid chromatography (HPLC) can confirm the presence of ergopeptine alkaloid toxins: ergovaline, ergotamine, ergocristine, ergosine, ergocornine, and/or ergocryptine.[25,64] Adverse effects are linked to total dietary concentrations greater than 100 to 200 ppb. In affected broodmares, calcium concentrations in mammary secretions rarely exceed 50 ppm at parturition.[70]

Treatment is most effective if signs are recognized in the early stages and access to the implicated feed is removed. If pasture is the source, and alternative grazing is not available, mowing to remove seed heads and possible ergot bodies may be helpful. Foaling should be attended due to the risk of dystocia, placental problems, and likely dysmaturity of the neonate. Domperidone (1.1 mg/kg orally [PO] q24h) can be used successfully in pregnant mares suspected of ergot alkaloid toxicosis if use is begun 10 to 14 days before expected foaling. Reserpine (2.5 to 5 mg/450 kg PO q24h) may be helpful to induce lactation if administered postpartum.[66]

Prevention is focused on replacing contaminated feed sources with safer alternatives such as legumes or endophyte-free fescue grass. Ammoniation to degrade ergovaline in contaminated hay may be economically feasible on large cattle operations.[71] Pregnant broodmares should be removed from fescue pastures no later than day 300 of gestation. Domperidone can be used as described earlier in broodmares. Attention to mineral nutrition and other additive stressors is also advised.[66]

Respiratory Syndromes Following Poisonous Plant Ingestion

Few plants are associated with the development of predominately respiratory signs in large animals. Perilla mint *(Perilla frutescens)* (Color Plate 54-9) causes significant morbidity and mortality in ruminants. Perilla contains ketones and related furan compounds that are bioactivated in the lung and cause atypical interstitial pneumonia and acute respiratory distress. A similar syndrome may be seen in cattle following ingestion of sweet potatoes *(Ipomoea batatas)* damaged by *Fusarium* spp. molds.[72] Acute bovine pulmonary emphysema and edema may occur following ingestion of forages high in tryptophan, typically immature summer grasses. Rumen bacteria convert tryptophan to 3 methyl indole, a furan that is further metabolized to a lung toxicant. This syndrome can be prevented by gradually introducing cattle to these grasses or using monensin or tetracycline in the feed for a week before and 2 weeks after turnout on pasture. Peanut hay *(Arachis hypogaea)* has been linked to acute respiratory distress in beef cattle.[72]

Poisonous Plants Affecting Skin and Hooves

Skin and hooves may be adversely affected by plants causing physical trauma or those containing toxins or excessive selenium. Plants with awns or barbs that damage skin may also damage the digestive tract and adjacent tissues if migration occurs.

Photosensitization and laminitis are chief complaints that warrant further investigation. Photosensitization may be a primary effect of the ingested toxin or secondary to liver damage. Sunlight triggers an oxidative reaction with photoreactive, polyphenolic compounds absorbed from the digestive tract in areas of unpigmented skin, leading to inflammation, cellular necrosis, and sloughing of affected skin, particularly in horses and cattle. Lesions are typically most severe on the face and dorsum of the animal. Common plant sources of primary photosensitization are St. John's wort *(Hypericum perforatum),* buckwheat *(Fagopyrum esculentum),* Dutchman's breeches *(Thamnosma texana),* bishop's weed *(Ammi majus),* rain lily *(Cooperia pedunculata),* spring parsley *(Cymopterus watsonii),* giant hog weed *(Heracleum mentegazzianum),* and cow parsnip (*Heracleum* spp.).[10] Wild parsnips *(Pastinaca sativa)* contain furanocoumarins, which can result in contact blisters and photosensitization following ingestion.[55]

Hoary alyssum *(Berteroa incana)* (Color Plate 54-10) ingestion and black walnut *(Juglans nigra)* shavings used for bedding are known triggers of laminitis in horses.[10] Hoary alyssum, a weed often growing on the periphery of hayfields in Europe and North America, is usually avoided at pasture but remains toxic in hay for months. Clinical signs of toxicosis include limb edema, fever, and laminitis. In severe cases, intravascular hemolysis, endotoxemia, hypovolemic shock, diarrhea, abortion, and death may occur.[73,74] Black walnut shavings need not be ingested to cause limb swelling and laminitis in horses. Black walnut extracts containing the tree's heartwood and administered by nasogastric tube have been used to create a model for studying laminitis in horses. These studies suggest that oxidative stress to laminar tissues with subsequent inflammation is responsible for the predominant clinical sign, as well as a systemic inflammatory response.[75]

Selenium Toxicosis

Chronic excessive selenium ingestion produces skin and hoof abnormalities, known as "alkali disease." It is problematic for livestock in areas with seleniferous soils, such as the Great Plains of the United States and Canada, as well as many areas in Russia, Israel, and China.[76] Common seleniferous plant species with this potential include primary selenium accumulator plants, such as milkvetch (*Astragalus* spp.), woody aster *(Machaeranthera,* section *Xylorrhiza),* goldenweed *(Haplopappus*, section *Conopsis),* and prince's plume *(Stanleya pinnata).*[1,10] Selenium can reach levels of approximately 3000 ppm, remaining water soluble and not incorporated into plant protein. Secondary selenium accumulator plants may contain up to several hundred ppm and, rarely, several thousand ppm selenium. This group includes acacia, other asters (*Aster* spp.), beard tongue (*Penstemon* spp.), gumweed *(Grindelia),* Indian paintbrush *(Castilleja),* some milkvetch (*Astragulus* spp.), sage (*Artemesia* spp.), saltbush *(Atriplex patula),* snakeweed *(Gutierrezia),* stickleaf *(Mentselia),* and toadflax *(Comandra).*[1,10] A third group of plants that may endanger livestock do not accumulate selenium compounds but do incorporate it into readily absorbed plant proteins, rarely presenting with more than 50 ppm. This latter group is the most problematic because it includes grasses (e.g., Western wheat grass), small grains, and alfalfa.[1]

Toxicity is difficult to predict because palatability and tolerance vary with animal species, individual genotype, the form of selenium in the plant, duration of consumption, and amount consumed. Ruminants tend to be more tolerant of high selenium in the forage than horses. Water sources in seleniferous areas may also contribute to excessive selenium intake.[77]

Three syndromes are ascribed to excessive selenium intake: acute toxicosis, blind staggers, and chronic alkali disease. Signs of acute selenium toxicosis are most often described after iatrogenic overdosage of selenium and rarely occur from plant ingestion. In horses, the first signs of selenium toxicity may be vesicles on oral and nasal mucosa and a straw-colored exudate at mucocutaneous junctions, followed by coronary band separation from the hooves and hair loss in the mane and tail. In the tail, the hairs tend to break at the same level, leaving a "bob" tail.[10] In cattle, abnormal posture, unsteady gait, diarrhea, abdominal pain, and elevated pulse and respiratory rate are

VetBooks.ir

seen. Sheep do not show the typical signs of poisoning; rather, depression, increased respiration, and sudden death are observed.[10] At necropsy, in acute cases, endocardial petechial hemorrhage, acute congestion and hemorrhage of the lungs, enteritis, and passive congestion of the liver are reported.

Animals that chronically ingest high selenium forages show signs of emaciation, rough hair coat, lack of vitality, and lameness. Reproductive efficiency diminishes. Hooves may become overgrown or cracked (including swine), and long hair may fall out. At postmortem, cardiac atrophy, hepatic cirrhosis, anemia, and erosion of the long bones may be noted.[1,78]

Serum selenium provides an accurate reflection of the body's current selenium pool, whereas whole blood selenium (glutathione peroxidase) reflects a longer time period of selenium intake. Both can be useful in antemortem diagnosis. Hair and liver selenium are other options, particularly for more chronic cases and postmortem determination. Laboratories used for selenium determinations should provide ranges for normal values by species, and sample type, because these vary. Investigation of a herd or flock problem should ideally include samples from multiple animals to reduce the risk of misinterpretation on the basis of values of one or two individuals.

Once a selenium toxicosis is identified, producers and owners need to find alternative grazing and water sources for their animals, particularly breeding horses and cows. Consultation of soil maps may be useful, as well as looking for primary selenium accumulator species that serve as indicators. Animals that are relocated from high-selenium areas often recover when fed lower selenium rations. Producers should additionally check that diets contain sufficient copper and protein to avoid enhancement of selenium's toxic effects.[10]

Plant Toxicity in the Urinary System

Urinary system damage may be the result of direct toxin damage or secondary to the toxin's effects on other systems that lead to dehydration, pigmenturia, or hypoxia. Renal damage is an important determinant of case outcome for many intoxications, a fact that should focus clinical attention on hydration, urinary output, and other measures of renal function. Among common plant toxicities, renal dysfunction can be significant following consumption of bracken fern *(Pteridium aquilinum),* cocklebur (*Xanthium* spp.), inkweed *(Phytolacca octandra),* oak (*Quercus* spp.), pigweed *(Amaranthus retroflexus)* (Color Plate 54-11), jimsonweed (Color Plate 54-12), and all plants rich in oxalates.[36,57,72,79] Bracken fern's toxin, ptaquiloside, is carcinogenic to bladder epithelium and responsible for the syndrome of enzootic hematuria in cattle.[36] In oak poisoning, nephritis with necrosis and renal tubular casts is observed, which may lead to acute renal failure. Goats are relatively resistant to oak poisoning due to tannin-binding proteins in their saliva. Inkweed has caused acute renal tubular necrosis in calves, along with signs of photosensitization and cholangiohepatopathy.[57]

Oxalate Toxicity

Consumption of plants with high concentrations of sodium oxalate and/or potassium oxalate damages renal tissue if a large amount of plant is consumed over a short period. Additionally, some contain insoluble oxalate crystals in the form of complexes called *raphides,* which cause direct damage and irritation to the mucosal surfaces of the mouth and pharynx.[80]

Clinical manifestations of oxalate poisoning are variable and depend on factors such as the form of oxalate in the consumed plant, the animal species, and the rate of consumption. Plants that can cause oxalate toxicity are listed in Table 54-7. The balance between soluble (oxalic acid) and insoluble forms of oxalate in plants varies and is affected by gastrointestinal tract pH after ingestion. Binding of calcium can occur in the lumen. Once absorbed from the gastrointestinal tract, oxalates precipitate calcium from the blood, producing hypocalcemia, which may be most notable in lactating animals.[81] Oxalate crystals damage the microvasculature of the gastrointestinal tract and may also precipitate out on the wall of the rumen. Poorly soluble calcium oxalate crystals precipitate out in the renal tubules, causing acute nephrosis, tubular obstruction, and acute renal failure. At a cellular level, citric acid cycle of energy metabolism is inhibited,

VetBooks.ir

leading to cell death. In renal tubular cells, other pathways have been suggested, such as the production of phosphatidylserine, which promotes attachment of oxalates to the cell membrane, and phospholipase A_2 with subsequent mitochondrial damage and cell death.[82]

Oxalate poisoning in multiple animals is most often reported in sheep. Acute toxicosis is usually evident within 24 hours. The largest outbreaks are attributed to *Halogeton* spp. consumption. Other plants blamed for multiple deaths include slenderleaf ice plant *(Mesembryanthemum nodiflorum)* and golden bristlegrass *(Setaria sphacelata)* in Australia.[80] Muscle tetany or flaccid paralysis may be observed. These clinical signs pertain to hypocalcemia and hypomagnesemia, which result from sequestration of calcium and magnesium ions. Other reported signs include anorexia, ruminal stasis, mouth froth, weakness, stiffness, tachypnea, ataxia with jerky extensor rigidity, coma, and death. At necropsy, severe rumenitis may be evident. Kidneys are pale, edematous, and enlarged. Calcium oxalate crystals are readily identified in the rumen wall and kidneys. Less commonly, chronic toxicity has been reported with signs typical of chronic renal damage: anemia, weight loss, and poor appetite. Clinical signs of oxalate poisoning in cattle are similar to sheep but typically less acute and attributable to hypocalcemia. These include incoordination, belligerence, excessive salivation, bloat, recumbency, coma, and death. In calves, hypersensitivity to stimulation and seizures is possible.[11]

In horses, secondary nutritional hyperparathyroidism has been attributed to chronic high oxalate consumption, resulting in calcium binding in the hindgut and therefore deficiency. This leads to signs of osteodystrophia fibrosa.[80] Acute toxicosis with oxalate nephrosis failure is less common but associated with grass species with high oxalate content.

Treatment should be symptomatic with attention to electrolyte balance and renal function, but it may be insufficient in severely affected animals. Activated charcoal may help bind oxalates remaining in the gastrointestinal tract. Prevention requires recognition of the toxic potential of oxalate-bearing plants and management of livestock to avoid consumption of large amounts in a short period. Gradual introduction to the plants, ample alternative forage, and water are necessary to avoid deaths. In sheep, slow introduction (≈10 days) of sheep to grazing areas with high proportions of oxalate-bearing plants can result in better tolerance to the toxic effects. In contrast, a sheep acclimated to grazing other forage can be killed with as little as 12 oz (340 g) of halogeton.[1]

Blue-Green Algae

Birgit Puschner

Microcystis spp., *Nostoc* spp., *Anabaena* spp., *Planktothrix* spp.: cyanobacteria that produces hepatotoxic microcystins

Anabaena spp., *Oscillatoria* spp., *Phormidium* spp., *Planktothrix* spp.: cyanobacteria that produces neurotoxic anatoxin-a

Anabaena spp.: cyanobacteria that produces neurotoxic anatoxin-a_s

Aphanizomenon spp., *Anabaena* spp., *Lyngbya* spp., *Cylindrospermopsis* spp.: cyanobacteria that produces neurotoxic saxitoxins (paralytic shellfish poisoning toxins)

Blue-green algae blooms typically occur during warm months when water temperatures exceed 20° C and water is stagnant. High nutrient concentrations, especially phosphorus and nitrogen, increase the presence of cyanobacteria and cyanotoxins.[1] Algae can be suspended in the water column and easily visible, or attached to the surfaces of stones and sediments along the bottom of lakes or rivers.[2] Currently, of the 2000 species identified worldwide, more than 80 are categorized as toxigenic. It is well known that toxigenic and nontoxigenic species and strains coexist in water; thus, the potential toxicity of a given water source must be carefully evaluated not only by identification of the actual cyanobacteria population but also by measuring toxin concentrations.[3,4] George Francis first reported in *Nature* in 1878 a toxigenic bloom of a "poisonous Australian lake" with "a thick scum like green oil paint" and vividly described acute intoxications of sheep, horses, dogs, and pigs.[5] Since Francis's publication in 1878, numerous case reports describing animal morbidity and mortality exposed to cyanotoxins have been published.[6-12]

FIG. 54-1 Pond with *Microcystis* bloom in Petaluma, California. Pond water contained microcystin-LR and resulted in acute deaths and photosensitization of Holstein heifers.

The most commonly reported cyanotoxin poisoning in large animals is acute hepatotoxicosis subsequent to microcystin exposure. Microcystins are produced by multiple cyanobacteria and have been detected in fresh and coastal waters worldwide.[13] They present a realistic threat to pastured animals because of their presence in ponds and streams, and because animals readily consume algal-contaminated water (Fig. 54-1). Acute neurotoxicosis as a result of anatoxin-a or anatoxin-a_s can occur in large animals, but reports are rare.

The frequency of cyanotoxin poisoning in animals is likely underreported due to absent diagnostic workup of large animal mortalities and the current lack of well-established confirmatory methods in biological specimens. Diagnostic confirmation of suspect blue-green algae poisoning cases of humans and animals requires extensive efforts from both toxicologists and clinicians, and resources are often not readily available. New algal toxins are being discovered continuously, and oral bioavailability and toxicity data are often unavailable. It is probable that blue-green algae poisonings are more common in animals than humans due to increased dependence and contact with surface waters.

Hepatotoxic Microcystins

Microcystin-poisoned animals typically die within a few hours after exposure to contaminated water. Severe destruction of the hepatocytes leads to hypovolemia and shock secondary to blood loss into the disintegrated liver lobules and embolism of hepatocytes into the lung. Acutely poisoned animals develop signs of nervousness, reluctance to move, recumbency, diarrhea, and pale mucous membranes within 30 minutes to several hours of exposure.[14,15] Many die within hours to days, but animals exposed to nonlethal doses may survive and develop hepatogenous photosensitization (Fig. 54-2).

Clinical chemistry changes of animals with microcystin toxicosis include elevated serum gamma-glutamyl transpeptidase (GGT), aspartate aminotransferase (AST), bile acids, alkaline phosphatase (ALP), hypoglycemia, and hyperkalemia. Acute hepatic damage results in a grossly enlarged and friable liver from intrahepatic hemorrhage and, histopathologically, in hepatocyte dissociation, degeneration, and necrosis. Pathologic findings should quickly lead to an environmental assessment for possible microcystin-contaminated water.[16] Necrotic hepatocytes can also be seen in the pulmonary vasculature.

Microcystis, Anabaena, Planktothrix, Nostoc, Oscillatoria, and *Anabaenopsis* genera are among the known microcystin producers.[17] Toxins are retained inside the cyanobacteria and only released upon cell damage, lysis, and death; of note, destruction of algal mats (either naturally or through the application of herbicides) may result in a pulse of microcystin release following destruction of the individual cell walls. Microcystins are cyclic heptapeptides that inhibit protein

VetBooks.ir

FIG. 54-2 Holstein heifer with hepatogenous photosensitization from microcystin-LR toxicosis; Central Valley of California.

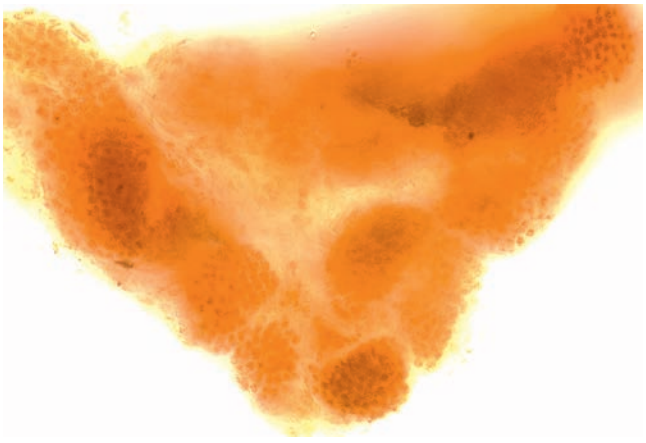

FIG. 54-3 Characteristic algal cell aggregates in rumen content of a heifer formed by *Microcystis* spp. Direct microscopic examination of rumen content in formalin (1 : 1; v/v). 60×. Rumen content was confirmed to contain microcystin-LR.

phosphatases; currently, more than 80 different structural variants have been identified. The most extensively studied congener, microcystin-LR, has been found worldwide and has caused acute, lethal hepatotoxicoses in farm animals.[2,15,18] Most natural outbreaks are a result of oral exposure through drinking water; microcystin-containing algae release microcystins in the acidic environment of the stomach. Recently, the risk of inhalation exposure to microcystins has been documented in humans recreationally using certain waters.[19,20] All animal species, including fish and reptiles, and humans are considered susceptible to the toxic effects.

Animals with acute microcystin poisoning may have algal material in the gastrointestinal tract (Fig. 54-3) or on the skin, especially the legs. Although identification of algae material in water and gastric contents is an important component of the diagnostic workup, it does not confirm intoxication. As mentioned previously, the toxicity of cyanobacteria is strain specific, and morphologic observations alone cannot predict the hazard level. Detection of microcystins in gastric contents is confirmatory, but these tests are not routinely available at diagnostic laboratories and are limited to a few structural variants.[21-23] Detection methods for microcystins in liver and other tissues are yet to be developed. Consumption of milk, meat, or liver is unlikely to pose a significant health risk to humans.[24,25] However, as a tumor promoter, microcystins may pose a cumulative health risk as they become more ubiquitous.

Neurotoxic Anatoxins

Anatoxins are produced by many cyanobacteria genera, such as *Anabaena, Aphanizomenon, Planktothrix, Oscillatoria, Microcystis, Cylindorspermum,* and *Phormidium.* Reports of anatoxin-a poisoning in livestock are extremely rare; most cases are documented in dogs. But all animals are considered susceptible. Anatoxin-a poisoning leads to muscle tremor, rigidity, respiratory failure, collapse, and death within minutes to a few hours.[26-28] This is a result of anatoxin-a being a potent cholinergic agonist at nicotinic receptors.[29] Animals poisoned with anatoxin-a_s develop acute signs of excessive salivation, lacrimation, diarrhea, and urination (SLUD) because anatoxin-a_s is a naturally occurring irreversible acetylcholinesterase inhibitor.[30] Animals often die of respiratory arrest within 30 minutes.

Because of the acute onset, CBC and chemistry profiles of animals with anatoxin poisoning are generally unremarkable. Furthermore, other than the possible presence of algae material in gastrointestinal contents, there are no specific gross or microscopic lesions. Confirmation of anatoxin-a poisoning is by analytic detection of the toxin in urine, bile, or gastrointestinal contents.[28] Diagnosis of anatoxin-a_s toxicosis is aided by the determination of blood acetylcholinesterase activity. In any suspect cases, environmental samples should undergo a toxicologic and phycological analysis.

Other Cyanotoxins

Other freshwater cyanotoxins of concern to livestock include neurotoxic saxitoxins, hepatotoxic nodularins, and cylindrospermopsin, which targets multiple organs (liver, kidneys, lung, heart, gastrointestinal tract).

Treatment for blue-green algae poisoning is supportive and often unsuccessful. No specific therapy has proven effective in laboratory animals, including decontamination with activated charcoal, and no data exist for adsorptive capacity in other animals.[31] Symptomatic and supportive care to treat hypovolemia and electrolyte imbalances, as well as antioxidants such as vitamin E and selenium, should be included in the therapeutic regimen for large animals poisoned with microcystins. Animals that develop photosensitization must be protected from sun exposure. Because of the rapid onset of clinical signs in animal with anatoxin-a poisoning, therapeutic options are often not possible, but artificial respiration may be of benefit along with general supportive care. Administration of activated charcoal has been recommended, but scientific evidence on its adsorptive capacity for anatoxin-a is lacking. Atropine should be considered in the treatment of animals poisoned with anatoxin-a_s. It is important to note that pralidoxime (2-PAM) is not recommended.[32]

The frequency and extent of harmful cyanobacterial blooms appears to increase with the addition of nutrients to surface fresh water ecosystems around the world. Steps must be taken to reduce fertilizer runoff and applications in fields surrounding ponds used for drinking water. Prevention of blooms is key to protecting animal and human health.

Mycotoxins

Timothy J. Evans • George E. Rottinghaus

Importance of Mycotoxins

Mycotoxins are secondary fungal metabolites, which, if consumed in sufficient amounts, cause adverse health effects in animal species including humans.[1] They can be detected in various matrices, including cereal grains and forage, and are a major concern to international agricultural production and a threat to food safety worldwide.[1-3] Individuals working within the United States swine and poultry industries are particularly cognizant of the potential for mycotoxin exposures, given the dietary dependency of those monogastric species on cultivated cereal grains. However, the globalization of agricultural commodities, climate change–related weather conditions favoring fungal growth and/or mycotoxin production,

VetBooks.ir

subsequent reductions in the availability of feedstuffs not contaminated by mycotoxins, and economic pressures from higher costs of better-quality feedstuffs all underscore the need for individuals participating in other aspects of animal agriculture in the United States to have a greater awareness of the potential for mycotoxin contamination.

Additionally, the increasing risk to human and animal health posed by mycotoxins means the veterinary profession must be vigilant in the surveillance of domesticated large animal populations as sentinels for mycotoxin contamination of agricultural products. Veterinary practitioners, regardless of whether their practices involve small companion animals or livestock, will need to be familiar with the "major" mycotoxins and the wide range of clinical signs, including subtle reductions in livestock production and food residues associated with these fungal toxins.[4] It is only through an increased awareness of these toxins that mycotoxin-related illness in food animals can be minimized, and companion animal and human exposure to mycotoxins limited or prevented.

General Principles of Mycotoxin Production and Detection

Many fungi are capable of producing toxins (i.e., are toxigenic), and a given mycotoxin could be synthesized by more than one fungal species.[3] Some fungi produce more than one toxin or even multiple classes of toxins.[1,3] Although many relatively common mycotoxins have already been identified, it is likely that several more potentially toxic, secondary fungal metabolites, such as those suspected in moldy hays, have yet to be isolated and characterized.[2,3,5] Fungal colonization does not necessarily mean that a given mycotoxin is being produced.[1,3] The substrate, moisture content, pH, ambient temperature, relative humidity, and other requirements for toxin synthesis are often more stringent than those for fungal growth.[1,2] The "ideal" toxigenic conditions for the production of specific mycotoxins have been characterized, and some mycotoxins are more likely to be produced in a "field" or "storage" setting.[1-3] The mere presence of fungal growth does not necessarily correlate with toxin production, and some mycotoxin-contaminated feedstuffs might not even be visibly moldy.[3]

From a clinical perspective, the inability to accurately predict whether mycotoxins will be present in a specific feedstuff means that fungal identification and spore counts are not adequate for identifying livestock diets contaminated with mycotoxins.[1-3] High-performance liquid chromatography (HPLC), liquid chromatography-tandem mass spectrometry (LC-MS/MS), and/or enzyme-linked immunosorbent assays (ELISA) are some of the more common analytic techniques used to directly measure mycotoxin concentrations in grains or processed feedstuffs. The use of an ultraviolet light to detect fluorescence associated with kojic acid, as an indirect indicator of aflatoxins, is outdated as the sole means of detection of these toxins.[1,6] Likewise, utilization of semiquantitative methods, such as thin layer chromatography (TLC), as stand-alone evidence of fungal toxin contamination, is also less than optimal. The consistent use of appropriate sampling techniques ensures the detection of suspected mycotoxins and guarantees that detected mycotoxin concentrations are representative of actual livestock exposure.[3,7,8] Grain "screenings" or "fines" are the grain by-products most likely to contain the highest concentrations of mycotoxins.[1,3]

One of the biggest challenges pertaining to mycotoxin contamination in livestock rations is the accurate interpretation of analytic results, especially now, when low concentrations of mycotoxins are detected by increasingly sensitive laboratory methods.[4] Table 54-8 shows "action levels" established by the U. S. Food and Drug Administration (FDA) for some mycotoxin-contaminated commodities fed to different species of livestock. These action levels were originally intended to be guidelines for "acceptable" concentrations of individual mycotoxins in common substrates being transported between states.[6,9] The mycotoxin concentrations have often been interpreted as the highest dietary concentrations of these mycotoxins considered "safe" in the denoted species. However, the definition of "safe" is a relative term that is dependent on the end point being measured. Some concern has recently been expressed as to whether these action levels are low enough to prevent adverse health effects, especially with respect to carcinogenesis in humans.[10]

Mycotoxicoses

In discussing mycotoxin-related diseases it is important to differentiate "mycosis" from "mycotoxicoses." The term "mycosis" refers to a disease caused by fungal growth, rather than by the adverse effects of any toxins produced by that fungi.[3] "Mycotoxicoses," on the other hand, are diseases caused by the adverse health effects of mycotoxins, which, in most cases, have been ingested.[1-3] For a specific mycotoxicosis to occur, growth conditions in substrates colonized by the appropriate fungal species must favor production of a specific toxin and sufficient amounts of that toxin-contaminated substrate must be consumed by a susceptible animal species.

The higher the dietary concentration of a given mycotoxin, the more likely and severe are the observed adverse effects.[1-3] Similarly, the duration of exposure to a mycotoxin impacts the likelihood and severity of the observed clinical signs, with longer exposures increasing the probability of more severe intoxications.[2,3] Peracute and acute intoxications generally occur over a short period of time (usually days) and involve one or several "large" doses (orders of magnitude greater than "allowable" quantities) of a specific mycotoxin. In these instances, the diagnosis is often fairly straightforward because contaminated feed is more than likely available for testing. However, clinically recognized mycotoxicoses, more often than not, involve subacute (weeks) to chronic (months) dietary exposures to fungal toxins.[1] Depending on the dietary concentration of a given mycotoxin, clinical signs in these types of exposures might be "classic" for a mycotoxin's typical target organ (e.g., moderate to severe hepatocellular damage with sufficient amounts of aflatoxins) or more subtle in nature (e.g., immunosuppression, suboptimal growth, reproductive inefficiency, and/or carcinogenesis), reflecting impaired hepatic function.[3,4] In subacute to chronic mycotoxin exposures, affected animals could still be ingesting specific toxins, with contaminated feedstuffs readily available for testing, or the consumption of specific mycotoxins might have already ceased, especially if the observed clinical signs are more subtle in nature and/or took some time to develop. Under these circumstances, analyses of representative samples of grains or forages harvested at the same time as the suspect feedstuffs or analyses of samples of prepared rations retained by the supplier or manufacturer might be the only way to establish the definitive cause of a suspected mycotoxicosis.

Another aspect of a potential mycotoxicosis, as illustrated in Fig. 54-4, using reproduction as an example of monitored animal performance, is the role that mycotoxins might play in diminished livestock performance, such as decreased feed consumption, growth rates, and fertility, where there is no single "cause" but, rather, an etiology that is multifactorial in nature. The mention of this type of diagnostic conundrum has the potential to increase the overdiagnosis or misdiagnosis of a mycotoxicosis and should not be misconstrued as an effort to indict trace amounts of some mycotoxins as the primary cause of clinical abnormalities in livestock.[4,6] However, although it is not practical or even possible to eliminate all measurable fungal toxins from livestock diets, one should recognize that there is no nutritional requirement or benefit related to dietary mycotoxins. It is important, therefore, when no clear-cut, single cause of diminished performance is evident, to take an integrated approach and objectively evaluate the relative contributions of a wide variety of enzootic variables or "stressors" to the clinical problems being observed.[4]

Major Mycotoxins of Veterinary Importance

AFLATOXINS. Aflatoxins arguably pose the most clinically relevant, mycotoxin-related threat to the worldwide health and well-being of humans and domestic animals. A number of fungal species, in particular *Aspergillus flavus* (*A+fla+* toxin) and *Aspergillus parasiticus,* can produce aflatoxins under appropriate growth conditions

in a variety of nuts and grains, including cottonseed, peanuts, and, especially, corn.[1-3] The major aflatoxins found in contaminated grains include aflatoxins B_1, B_2, G_1, and G_2 (B or G = fluorescence color), with aflatoxin B_1 (AB_1) generally being present in the highest concentrations.[3] Although aflatoxins are sometimes described as "storage" mycotoxins, there are certainly instances when they are produced under "field" conditions.[1,6] Drought and/or insect damage to corn or other susceptible plants, followed by warm (>25° C), humid (>70% humidity) ambient weather conditions, is the "classic" scenario that facilitates initial fungal invasion of compromised kernels/seeds and subsequent fungal growth with aflatoxin production.[1-3,6] In fact, drought conditions are often associated with increased scrutiny on the part of grain elevator operators, livestock producers, and regulators, with respect to possible aflatoxin contamination, particularly in corn and corn by-products.

Ingested AB_1 is metabolized by multiple cytochrome P_{450} subfamilies in the liver to produce several metabolites, including AB_1-8,9-epoxide and AB_1-dihydrodiol, which are toxic, and aflatoxin M_1 (AM_1), which can be found in meat as well as in milk.[1] AB_1-8,9-epoxide and other toxic metabolites bind to biologically important molecules, such as essential proteins, including enzymes involved in carbohydrate and lipid metabolism and protein synthesis.[1,3] These AB_1 metabolites also bind to macromolecular nucleic acids, inhibiting transcription and forming DNA adducts, which can be associated with carcinogenesis, especially hepatic tumors.[1-3,8] Additionally, toxic metabolites of AB_1 can also bind to subcellular organelles, such as mitochondria and ribosomes.[1]

Although excretion of violative AM_1 residues (>0.5 ppb or 0.0005 ppm) in the milk is the first observed "abnormality" associated with AB_1 exposure in lactating dairy animals, the liver is considered the major target organ of toxic AB_1 metabolites in all species.[1-3,6] Clinical signs of aflatoxicosis range from prolonged prothrombin time (PT), hemorrhage, bloody diarrhea, and rapid death in peracute and acute intoxication to anorexia, slow rumen motility, weakness, tremors, ataxia, reproductive failure (abortion), to hepatic failure with icterus, coma, and death in subacute aflatoxicoses.[1-3,6,8,11-16] Aflatoxin-induced hepatic insult and failure are usually accompanied by many of the typical clinical pathologic abnormalities expected with hepatocellular necrosis and/or hepatic failure, and elevations in the detected activities of liver-specific enzymes in serum often precede other clinical signs.[6] Suppression of immune function, particularly those aspects related to cell-mediated immunity, have also been reported in animals following repeated exposure to moderately high dietary concentrations of AB_1.[1,6,8,15] Chronic exposure to dietary aflatoxins can be associated with decreased growth rates and feed efficiency, roughened hair coats and ill thrift, impaired resistance to infectious disease, and hepatic fibrosis with regenerative nodules.[1,3,6,] Spermatogenesis can also be adversely

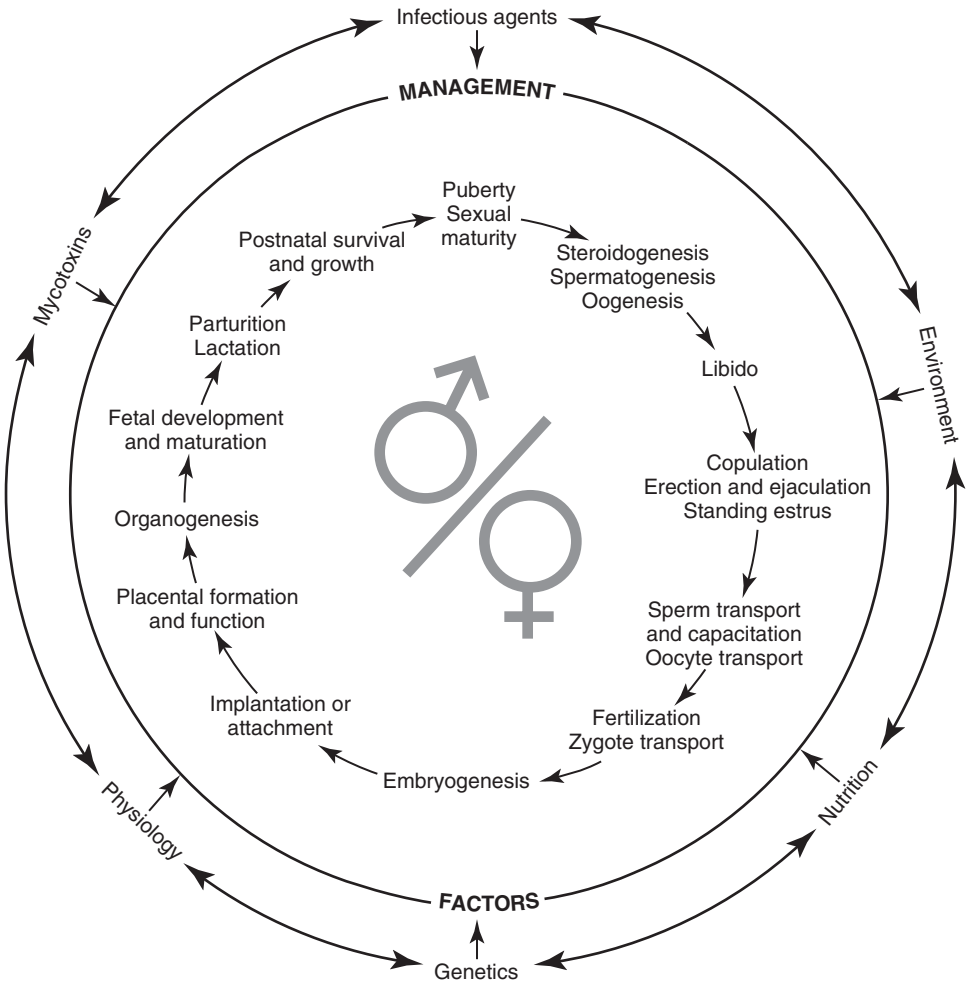

FIG. 54-4 The continuum of developmental stages and reproductive functions taking place in males and/or females, as well the embryo and fetus, are shown schematically and illustrate the complexity of reproduction in ruminant species. The possible influences of genetic and physiologic predispositions, as well as nutritional, environmental, infectious, and, especially, mycotoxin stressors, on decreased reproductive performance are also represented in Fig. 54-4, along with the role "management" can play in modulating those influences on reproductive function. *(Modified with permission from Evans TJ. 2011. Diminished reproductive performance and selected toxicants in forages and grains. Vet Clin North Am Food Anim Pract 27:345. Modifications and artwork courtesy Don Connor and Howard Wilson.)*

affected by chronic exposures of male animals to AB_1.[17] Low-level subacute to chronic exposures to AB_1 and its toxic metabolites also have the potential to be associated with teratogenesis, mutagenesis, and/or carcinogenesis, and, experimentally, AB_1 in grain dusts can be present in sufficient enough quantities to be converted to carcinogens by pulmonary cytochromes.[3,18]

Attempts to estimate the dosages or dietary concentrations of total aflatoxins likely to be "safe" or, conversely, those concentrations that will probably be associated with clinical disease can be challenging. Anecdotal evidence and reports of clinical cases of aflatoxicosis, which provide some dose-related data, might require additional scrutiny because some of the factors known to influence the toxicity of aflatoxins might be unaccounted for or unknown.[6] However, such reports are still of value because they represent "real" clinical situations. An animal's plane of nutrition, rate of hepatic metabolism, age, and species, as well as the level and duration of aflatoxin exposure, are all important determinants as to whether and what signs of aflatoxicosis are likely to be observed.[1,3,6,8] Animals fed a diet deficient in protein, selenium, and/or vitamin E and those with enhanced rates of hepatic metabolism are more likely to experience hepatic insult associated with dietary aflatoxin contamination.[6,8] Immature animals, particularly young swine, are the livestock populations considered most susceptible to adverse health effects associated with aflatoxins.[3,6] Weeks of exposure to total dietary aflatoxin concentrations of 200 ppb (0.2 ppm) have been associated with mild hepatic insult and suboptimal growth of piglets and decreased performance in calves.[3,6,8] Horses and more mature cattle and swine have experienced toxic insult to the liver following weeks to months of exposure to aflatoxin concentrations exceeding 400 and 600 ppb (0.4 and 0.6 ppm), respectively, and hepatic failure and death are possible in animals consuming feedstuffs that contain a flatoxin concentration exceeding 1000 ppb or 1 ppm.*

The "threshold" AB_1-induced "abnormality" usually first observed at the lowest dietary concentrations in livestock species is an actionable level of AM_1 detected in milk obtained from exposed lactating dairy animals.[3,6] The concentrations of AB_1 causing violative AM_1 residues in milk are much lower than those likely to cause liver-related adverse health effects, especially in ruminants.[3,6,8,11-16,19] The ratio of the concentration of AB_1 in the diet to the AM_1 concentration detected in the milk varies widely from less than 50:1 to almost 2000:1 (average of 300:1), and the proportion of dietary AB_1 excreted as AM_1 can range between 0% and 4% (average of 1%).[6] Excretion of AM_1 in the milk generally continues for 2 to 7 days following withdrawal from an AB_1-contaminated diet.[3,6]

The accurate diagnosis of clinical aflatoxicosis usually involves the detection of high AB_1 concentrations in the feed or, less optimally, the gastric contents of animals exhibiting appropriate clinical signs.[3,6,8]

VetBooks.ir

The detection of AB_1 and/or AM_1 in the liver and kidney, in particular, can also be indicative of recent AB_1 exposure (usually within 7 days) and might help establish the consumption of dietary AB_1 by a deceased animal, when feedstuffs are unavailable for analyses.[3,8]

Treatment of aflatoxicosis in large animals is often cost prohibitive, especially in food-producing animals, and limited to therapy for hepatic insult and/or failure; provision of a balanced, AB_1-free diet; possible supplementation with trace minerals and vitamins (selenium and vitamin E); and, most importantly, prevention of further exposure.[3,6,8] Growth conditions are not conducive to AB_1 production in *Aspergillus*-infected stored grains when the moisture content is reduced to less than 15%.[8] Ammoniation has been reported to prevent fungal colonization and growth and to facilitate detoxification of aflatoxins.[1,3,8] In "emergency" situations where it is difficult to find affordable, alternative feedstuffs free of AB_1 contamination, producers may consider dilution of feeds to "safe" concentrations of AB_1.[3] However, this approach has some attendant risk, including the species of animal involved, exposure to enzootic stressors other than aflatoxins (e.g., infectious disease, poor nutrition), level of animal management and husbandry skills, willingness of the producer to thoroughly "blend" the feeds and collect frequent representative samples for AB_1 analyses, and the targeted "safe" concentration of AB_1.[3,4] One approach to the dilemma of which targeted AB_1 concentrations are actually likely to be "safe" might be for producers to aim for total aflatoxin concentrations approximately one half of that shown in Table 54-8 for total dietary aflatoxin action levels, particularly in diets intended for lactating dairy cows, immature livestock, or animals used for breeding purposes.[4,9] This approach can also be used for other mycotoxins for which there are action levels.[4] Another, added consideration, especially for aflatoxins, might be the incorporation of clay binders in rations to prevent the absorption of fungal toxins.[3,4,6,8] Hydrated sodium calcium aluminosilicates (HSCAS) have been shown to effectively prevent violative AM_1 residues in milk and meat and reduce livestock production indices, especially those parameters (e.g., growth and reproductive performance) likely to be impacted by low-level chronic exposure to dietary aflatoxins.[3,4,6,8,20-24] Before using a given binder, there should be in vivo evidence that the binder in question is effective at reducing AB_1 absorption in live animals.[1,3,4,6]

DEOXYNIVALENOL (DON OR VOMITOXIN). Deoxynivalenol (DON or vomitoxin) is classified as a trichothecene mycotoxin and is produced in grains such as corn, wheat, and barley by toxigenic *Fusarium* species, especially *Fusarium graminearum* (formerly *roseum*). This species is also the conidial stage of *Gibberella zeae* and associated with "head blight" and "scab" in wheat and "Gibberella ear rot" in corn.[1-3,25] Although growth of this toxigenic fungal species occurs in the field when temperatures are warmer (20° to 25° C), DON production is favored under storage conditions when it is cooler (0° to 15° C).[1,3] Rising and falling (undulating) temperatures, especially when associated with a cool, wet fall and delayed harvest, facilitate production of DON.[1,3,26] Trichothecenes are stable compounds that persist much longer than the fungi producing them.[1] Deoxynivalenol can also be found in forages (such as corn stover and wheat straw) associated with the grains most frequently contaminated by this mycotoxin.[1,27] In addition, grains contaminated with vomitoxin are often contaminated with zearalenone (see later), which is also produced by *Fusarium graminearum* (see Table 54-8) under similar fungal growth conditions.[1,3,25]

Deoxynivalenol is an extremely important trichothecene mycotoxin, from an agricultural perspective, because of its impact on indices of animal performance and the frequency with which it is detected in livestock diets, especially those intended for consumption by swine and dairy cattle.[1-3,8,26] This particular fungal toxin inhibits protein synthesis and induces emesis by direct stimulation of the chemoreceptor trigger zone in the medulla oblongata, hence the alternative name of "vomitoxin."[3,25] Immunosuppression has been reported in some animal species, but feed refusal and gastroenteritis are the most common clinical signs, particularly in swine.[1-3,25] Clinical pathologic abnormalities include those associated with decreased feed intake, impaired absorption of nutrients, vomiting, and diarrhea.[8,25]

Table 54-8 shows the action levels for DON in various species of livestock. Clinical signs of dietary exposure to DON, such as feed refusal, generally begin within 1 day of ingestion.[3,25] Dietary concentrations of DON associated with clinical disease range from 1 ppm (feed refusal) to 5 to 10 ppm (vomiting and possible gastroenteritis) in swine; ruminants have been reported to refuse eating contaminated feedstuffs containing more than 10 to 20 ppm of DON.[8,25] One of the dilemmas often associated with DON occurs because of the low concentration frequently found in grains and their related forages. It is difficult to differentiate the direct adverse effects of the mycotoxin itself from clinical signs related primarily to reduced palatability and/or the decreased nutritional value of poorer quality feedstuffs, particularly when feed refusal and abnormalities arising from reduced feed intake are the only observed clinical signs.[4] Similarly, any deviations from optimal dairy cattle performance should not necessarily be attributed solely to low-level mycotoxin contamination (<0.5 ppm) without taking into account the reduced palatability and nutritional value of contaminated grains and forages. Evaluation of overall diet quality, rather than just the presence or absence of low concentrations of mycotoxins such as DON, remains an important aspect of the management of livestock production systems, even when experimental data indicate improvement following the addition of "binders."[28,29] Such products might have benefits related to nutrient uptake, which are completely independent of interactions with DON or any other mycotoxins.[30]

As with AB_1, appropriate clinical signs and analyses of feedstuffs and, less desirably, gastric contents can be used to determine whether there has been dietary exposure to DON.[3,8,25] However, unlike AB_1, consumption of DON is not associated with residues in milk or meat.[3,25] Treatment of DON intoxication is limited to supportive care and prevention of further exposure to feedstuffs contaminated by DON and related mycotoxins. There has been limited in vivo success in developing binders that are effective in preventing the absorption of DON in experiments involving susceptible species.[31,32]

ZEARALENONE. Like DON, zearalenone (ZEA) is produced in corn and other grains and their corresponding forages by *Fusarium graminearum* (formerly *roseum*), as well as other *Fusarium* species.[1-3,8,33] The synthesis of ZEA is facilitated by a drop in temperature to 12° to 14° C with greater than 23% relative humidity.[1,3,8,33] Under certain growth conditions, both DON and ZEA can be detected in some contaminated feedstuffs, and the diagnosis, treatment, and prevention of dietary exposures to ZEA is essentially the same as outlined for DON.[1,3,25,33]

Zearalenone is a naturally occurring xenoestrogen that binds to both the α and β estrogen receptors (ERα and ERβ). Swine, especially sexually immature, prepubertal gilts, and dairy heifers, at about the time they are being bred to produce their first calf and to enter their first lactation, represent the livestock populations most susceptible to the effects. Swine are more sensitive to ZEA because of its slow detoxification and enterohepatic recirculation in this species.[1,3,33] Unlike other livestock, dairy cattle are reported to metabolize ZEA to the more potent estrogenic metabolite, β-zearalenol, rather than α-zearalenol, which has less estrogenic activity than ZEA.[1,4]

Within a few days to a week after exposure to dietary concentrations of ZEA as low as 1 ppm, classic hyperestrogenism, as evidenced by vulvar swelling (one of the earliest and most dramatic signs), enlarged mammary glands, possibly prolapsed rectum, and increased size and weight of the tubular portions of the female reproductive tract, can be observed in prepubertal gilts.[1,3,8,33] Nymphomania in females and feminization and decreased testicular weights in males can also be observed, especially in gilts and young boars.[33] Dietary concentrations of 3 to 10 ppm of ZEA can be associated with anestrus and pseudopregnancy in postpubertal gilts and sexually mature sows, due to the unique luteotrophic effect of estrogens in swine.[8,34] Exposure of recently bred sows (7 to 10 days after breeding

VetBooks.ir

or insemination) to concentrations of ZEA, exceeding 15 ppm, can result in early embryonic death and prolonged interestrous intervals.[8,33]

Although it is clear that postpubertal dairy heifers are more susceptible than mature dairy cows (>10 ppm vs. >25 ppm ZEA, respectively) to adverse reproductive effects associated with ZEA, there still remains doubt as to how often ZEA-related problems are observed in dairy cattle in "real-world" situations.[4,8,33] There are reports that cattle are insensitive to ZEA, while others report a 25% lower pregnancy rate in postpubertal heifers fed 12.5 ppm of ZEA.[4,33,35,36] The disparity between these reports attests to the significance of the stage of sexual maturity, concurrent exposure to other enzootic stressors, and sensitivity of the criteria used to evaluate impaired reproductive performance in determining how ZEA affects dairy cattle fertility.[4]

FUMONISINS. Fumonisins, especially fumonisin B_1 and B_2 (FB_1 and FB_2), are produced primarily by the ubiquitous fungal species *Fusarium verticillioides* (formerly *moniliforme*).[1-3] *Fusarium verticillioides* grows primarily on corn, and the highest concentrations of FB_1, which is the most common and clinically important fumonisin, are most often found in association with corn "screenings" or "fines."[8,37,38] Although growth conditions facilitating FB_1 production are not as well defined as those for AB_1, DON, and ZEA, drought conditions during the growing season and subsequent cool, wet weather during ear development seem to correspond to higher FB_1 concentrations.[8,37]

Fumonisins structurally resemble sphingolipids, which are found in highest concentrations in the brain and liver, and are essential for cell growth and differentiation, as well as vascular integrity.[1,3,8,37] One primary toxic mechanism of action proposed for fumonisins, in particular FB_1, is inhibition of the conversion of sphinganine to sphingosine, resulting in a disruption of sphingolipid biosynthesis.[3,8,37,39] Horses and swine are the two livestock species most susceptible to fumonisin intoxication.[1,3,37] The brain is generally considered the major target organ in horses, especially following more chronic, low-level exposures, but centrilobular hepatocellular necrosis, with clinical pathologic changes in the serum typical of toxic hepatic insult, can be observed in the absence of brain lesions when horses are acutely exposed to high FB_1 concentrations.[1,3,37] Subacute to chronic consumption of dietary concentrations of FB_1 exceeding 8 to 10 ppm have been associated with the sudden onset of the clinical syndrome referred to as *equine leukoencephalomalacia* (ELEM) or "moldy corn poisoning."[1,3,8,37,40-42] Horses affected by ELEM (also see Chapter 35) exhibit altered mentation, ranging from depression to neuroexcitation, sometimes accompanied by head pressing; incoordination and apparent blindness; and, finally, recumbency and death, often within 5 to 7 days of the onset of clinical signs.[1,3,37,40-42] The pathognomonic lesion of ELEM is *leukoencephalomalacia* or degeneration of the white matter of the brain, which can be grossly visible involving one or both cerebral hemispheres, or subtle and difficult to detect in stained sections of brain.[1,3,37,40-42] Hepatosis of varying severity can also be observed in cases of ELEM, and transient increases in the activities of enzymes specific for hepatocellular damage might be observed under those circumstances.[37,41]

The primary clinical abnormalities associated with FB_1 exposure in swine include porcine pulmonary edema (PPE), which is thought to be secondary to left-sided heart failure, and toxic insult to the liver.[1,3,8,37] However, unlike ELEM, it is difficult to pinpoint any consistent "threshold" dietary concentrations of FB_1 likely to cause heart failure and the resulting PPE in swine or, alternatively, histopathologic changes restricted to only the liver.[8,37,38,43,44] Some authors have suggested that FB_1 concentrations in contaminated corn or especially in contaminated corn screenings, ranging from the dietary action level of 10 ppm of FB_1 (see Table 54-8), should be considered actionable. Conversely, it is interesting to note that swine have been chronically exposed to dietary FB_1 concentrations in excess of 100 ppm, without the development of signs consistent with PPE and with hepatic fibrosis being the only observed histopathologic finding.[44] It appears that if PPE is going to develop, it will almost certainly do so within the first week of consumption of FB_1-contaminated diets.[37,43] This consistent observation suggests a role of various stressors, such as recent transport, excessive animal handling, and/or the presence of respiratory pathogens.[44,45]

The diagnosis of ELEM and PPE involves the observation of the appropriate, species-specific clinical syndromes, as well as the detection of sufficiently high enough concentrations of FB_1 in corn-based rations, especially those diets prepared using screenings from homegrown corn.[3,37] An elevated sphinganine-to-sphingosine ratio (SA : SO ratio) in the serum, urine, or tissues of animals suspected of being exposed to FB_1 can also be an accurate indication of recent (<7 days) exposure to FB_1.[3,8,37] As with DON and ZEA, treatment of fumonisin intoxication is limited to stabilization and supportive care, withdrawal from FB_1-contaminated rations, and, most importantly, prevention.[47] Unless absolutely unavoidable and only if there is concurrent and vigilant FB_1 surveillance to ensure that FB_1 concentrations remain below 1 ppm (see Table 54-8), horses should not be fed diets containing homegrown corn and/or, especially, corn screenings. A similar approach could also be used to prevent FB_1-related PPE and hepatic disease in swine.[3]

ERGOT ALKALOIDS. Ergot alkaloids (EAs) are a complex class of mycotoxins that play a role in several financially devastating livestock diseases (i.e., "fescue toxicosis," "perennial ryegrass staggers," and "ergotism").[1,46,47] However, unlike the other "major" mycotoxins discussed in this chapter, EAs are not found in corn and the most commonly occurring intoxications involving EAs are restricted to forages (i.e., fescue toxicosis and perennial ryegrass staggers). Unfortunately, the economic impact of these two mycotoxicoses is thought by many to be restricted to certain geographic regions.[46,47] Ergotism, on the other hand, which can be associated with the ingestion of contaminated forages or grains, has mistakenly been relegated to history because of its sporadic occurrence and is almost exclusively limited to livestock species.[46-48] Although there are several separate systems of nomenclature for EA, an easy way to view these compounds is to divide them into clavine alkaloids; ergopeptine alkaloids (ergopeptines, ergopeptides, or EPs); and lysergic acid and its derivatives (LA+).[46,47] The LA+ have also been referred to as "ergoline alkaloids"; however, this terminology has the potential to be confused with the ergoline ring structure present in all EAs.[46-48,50,51] The most clinically relevant EA to livestock species are EPs, which include ergovaline, ergotamine, ergocristine, ergosine, ergocryptine, and ergocornine and LA+, such as lysergol, lysergic acid amide, and ergonovine (see Table 54-8).[46,47,51,52]

Most of the naturally occurring EAs have been isolated from fungal species within the *Neotyphodium* and *Claviceps* genera.[46-51] *Neotyphodium coenophialum* (formerly *Acremonium coenophialum* or *Epichlöe typhina*) is the endophyte that can grow, as part of a symbiotic grass/endophyte relationship, within the intercellular spaces of tall fescue grass, a long-lived perennial, cool-season grass most simply referred to as *Festuca arundinacea* or, more recently, *Lolium arundinaceum*. Toxigenic endophyte-infected (E+) tall fescue grass grows in humid temperate areas worldwide, including the upper southeastern and lower midwestern United States.[1,48-51] The EP present in highest concentrations in E+ tall fescue is ergovaline (≈0.2 to 0.6 ppm of ergovaline in the vegetative parts of the plant and >1 ppm ergovaline in the seed heads), and LA+ are also present in this grass.[50,51-53] The livestock species most likely to consume E+ forages are ruminants, especially cattle, and horses. The primary sources of the EP compounds, ergotamine, ergocristine, ergosine, ergocornine, and ergocryptine, are the dark-colored ergot bodies or sclerotia of *Claviceps purpurea*. Ergot sclerotia, unlike endophytic mycelia, are externally visible and replace the individual seeds of many common pasture grasses, including E+ tall fescue and small cereal grains, such as oats, barley, wheat, and especially rye and triticale, but NOT corn.[47,48,50] The cool, wet springs in the northwestern United States and the northern Great Plains facilitate the germination and growth of *Claviceps purpurea*.[47,48,50] Those animal species likely to consume E+ tall fescue will also be exposed to the EAs produced

VetBooks.ir

by *Claviceps purpurea*, if the E+ tall fescue or other nearby grasses are infected by this fungal species ("ergotized"). On the other hand, when small cereal grains are contaminated by ergot bodies, not only ruminants and horses but also swine, poultry, and even humans are likely to be exposed to EAs. The total concentration of EPs in *Claviceps purpurea* sclerotia are extremely high, generally ranging from 2000 to 10,000 ppm, with LA+ also likely to be present.[47,48,50,54-57]

Although there is some overlap, the pathogenesis of clinical signs associated with dietary exposures to EA can be explained in terms of vasoconstriction and/or hypoprolactinemia. Vasoconstriction involving interactions with dopaminergic, adrenergic, and serotonergic receptors is responsible for many of the clinical signs observed in ruminants, especially cattle, and possibly in South American camelids.[46,47,51] Hypoprolactinemia-induced agalactia in late gestational mares is the most sensitive indicator of dietary exposure to EA.[47,50,51] The stimulation of D_2-dopamine receptors by EAs dramatically reduces prolactin secretion by lactotropes in the adenohypophysis.[8,46-51,58] Abdominal fat necrosis in cattle is associated with chronic exposure to EAs in E+ tall fescue and arises from both vasoconstriction and the effects of hypoprolactinemia on lipid metabolism.[46,51] The higher the dietary concentrations of EA, the more likely horses are to exhibit vasoconstrictive effects and the more likely agalactia will be observed in ruminants, in which a placental lactogen helps prevent abnormal lactation from the amounts of EAs often present in E+ tall fescue.[1,34,47,51] Swine exhibit vasoconstrictive effects and suboptimal reproductive performance, including agalactia, when exposed to sufficient concentrations of EAs.[1,47]

When trying to define levels of exposure to EAs, the most readily available data pertain to concentrations of EPs measured using HPLC. If animals ingest total dietary concentrations of EPs between 0.1 and 1 ppm, regardless of the sources, this is equivalent to low-level exposures involving only E+ tall fescue without seed heads, plus or minus other grasses.[50,51,53] Low to moderately high total dietary concentrations of EPs between 1 and 5 ppm correspond to what would be expected in pastures consisting entirely of E+ tall fescue in the seed head stage.[51,53] Moderately high dietary concentrations of total EP ranging between 5 and 10 ppm and very high dietary EP concentrations, exceeding 10 ppm, would involve contamination of feedstuffs by ergotized grains.[47,54-57,59]

Due to vasoconstriction, the toxicity of EAs can be extremely dependent on ambient weather conditions (see Table 54-8), especially with lower dietary concentrations of EAs (0.1 to 1 ppm total concentration of EP), which are typical of E+ tall fescue.[51] When it is hot, a syndrome referred to as "summer slump" or "summer syndrome" is observed in ruminants, in particular cattle, grazing E+ tall fescue.[1,51] This condition is thought to arise from the limited peripheral dissipation of heat associated with vasoconstriction.[1,3,48,49,51] Regardless of the source of toxins, EA-related "heat stress" is characterized by hyperthermia, rapid breathing, lethargy, an unthrifty appearance, and reductions in feed intake and average daily gain, as well as suboptimal male and female reproductive performance.[†] When it is colder, peripheral vasoconstriction in ruminants impairs the circulation to the distal extremities, resulting in cow discomfort, lameness, and, eventually, dry gangrene with sloughing of ear tips, switches, and hooves referred to as "fescue foot" or "gangrenous ergotism," depending on the source of EA.[‡] Controlled experiments indicated that dietary concentrations of ergovaline between 0.4 and 0.8 ppm produced gangrenous effects in ruminants.[64] However, ambient temperatures in those experiments were not below freezing, so, with the impact of ambient temperature on the vasoconstrictive effects of EA, lower ergovaline concentrations would be expected to cause "fescue foot" at temperatures below freezing.[47,51,64] Given "average" ergovaline concentrations in E+ tall fescue and clinical signs in cattle eating other forages "free" of EA, along with E+ tall fescue, it appears that adverse effects on production parameters can be observed in cattle, when total dietary concentrations of EP exceed 0.1 to 0.2 ppm, especially under extreme weather conditions.[47,51,53,54]

Exposure to EAs during the last month of pregnancy is the most common cause of agalactia in mares.[47,50,51,58] Hypoprolactinemia, with minimal udder development, was consistently induced in pregnant ponies treated with a semisynthetic EP, and lactational abnormalities will invariably be the first signs observed in late gestational mares consuming EAs.[50,58] Anecdotal reports suggest that dietary concentrations of ergovaline as low as 0.05 ppm can cause agalactia in some susceptible late gestational mares.[50] Prolonged gestation, dystocia, and abortion, as well as fetal and placental abnormalities, are additional adverse effects observed in pregnant mares consuming higher dietary ergovaline concentrations (generally ≥0.1 ppm).[47,50,51] Pellets containing screenings of ergotized grains or grasses can also be associated with EA intoxication in pregnant mares.[50] The absence of normal changes in udder development ("waxing"), on which horse breeders and veterinarians are dependent to predict imminent parturition, results in unexpected and unsupervised parturition.[58]

The diagnosis of intoxications involving EA requires the observation of appropriate clinical signs, identification of a source of EA, and determination of EA concentrations in that source, as well as in the total diet.[1,3,46] The accurate interpretation of those analytic results necessitates a thorough understanding of the analyses being performed and the pathogenesis of EA intoxications in different species.[1,46] Using reproductive performance as an example of a monitored parameter, management factors and the stressors shown in Fig. 54-4, particularly those related to environment, should be considered when interpreting analytic results.[3]

The basic principles for the treatment and prevention of intoxications related to EA are no different than those outlined for other mycotoxicoses (i.e., removal from the source, stabilization, and supportive care). Incorporation of pasture management practices, including frequent mowing with removal of seed heads, careful use of nitrogen-containing fertilizers, dilution with legumes, and pasture replacement with genetically modified varieties of continental tall fescue free from EAs, can provide added benefits to cattle producers and horse breeders living in enzootic areas.[47,51] Drying and ammoniation of E+ tall fescue hay, manipulation of stocking rates, use of stockpiled E+ tall fescue during winter, and copper supplementation can also help to further minimize EA-induced effects and maximize performance parameters in cattle.[3,48,65,66] Veterinarians should be aware of "fescue-associated edema syndrome" recently observed in horses consuming a genetically modified Mediterranean tall fescue in Australia.[67]

Provision of ample shade (also, possibly pond access) and plenty of potable water to cattle consuming low concentrations of EAs during the summer can help prevent "summer slump" or clinical signs resembling this condition, when the source of EA is not E+ tall fescue.[47,49] Knowledge of mare breeding dates, confirmation of pregnancy, and withdrawal from any dietary sources of EAs at least 30 days before the anticipated foaling date are critical for the prevention of agalactia in pregnant mares.[3,47,49-51] Frequent evaluation of mammary development and, if deemed necessary, daily administration of the D_2-dopamine antagonist domperidone (1.1 mg/kg body weight; watch for leaking colostrum) are additional ways to facilitate adequate lactation and prevent failure of passive transfer in foals.[47,49-51] Domperidone can also be used to mitigate prolonged gestation, along with the attendant risk of dystocia.[47,50,51]

Grain or grass screenings or "fines," in general, and/or any grains containing visible ergot bodies should NOT be incorporated into feeds intended for consumption by pregnant mares or cattle maintained under extreme weather conditions.[47,50,51] The only current FDA action level pertaining to EA is expressed in terms of the percentage of ergot bodies (see Table 54-8), rather than concentrations of EPs.[9] On the basis of the average EP content of ergot sclerotia in barley, 0.1% ergot bodies translates into approximately 2.5 ppm, which, depending on the proportion of the diet represented by this ergotized grain, might not be very protective in many clinical instances.[47,53-57]

Rattlesnake Bites

C. Langdon Fielding

The majority of snakebites reported in horses and other large animal species are associated with rattlesnakes, which belong to a group of venomous snakes, the pit vipers. There are approximately 30 different species of rattlesnakes found globally and their venom contains various enzymes, proteins, and peptides. Mortality rates for horses envenomated by rattlesnakes may be as high as 10% to 20%, but this depends on the severity of the bite and the response to treatment.[1-3] Rattlesnake bites typically occur during the spring and summer and should only be suspected in regions where the snakes are known to exist.[2]

The muzzle is the most commonly described location for rattlesnake bites in horses, and rapid, severe swelling is common (Fig. 54-5).[2] As the nostrils become swollen and the airways narrowed, respiratory distress is common. In more severe cases, swelling may continue to spread up the head and down the neck. Epistaxis is observed in many horses following rattlesnake bite, and bleeding from the ocular tissues can be seen as the effects of the venom progress (Fig. 54-6). Arrhythmias have been described in horses following rattlesnake envenomation both acutely and chronically.[1,3,4] Diagnosis of rattlesnake bite is based on the characteristic swelling in a horse from an appropriate region during the typical time of year (spring and summer). The presence of fang marks, which are difficult to find in some cases, supports the diagnosis and helps to differentiate from other causes of acute head swelling.

Thrombocytopenia and prolongation of clotting times are described hematologic abnormalities but have not been consistent across various studies in horses.[1-3] Anemia can also be observed and is suspected to be due to both hemolysis and blood loss. Increases in cardiac troponin I (cTnI) have been described in a recent study, confirming myocardial damage in horses with envenomation.[1]

Treatment of horses with rattlesnake envenomation is largely dependent on the severity of clinical signs with many animals requiring only careful monitoring for respiratory distress. Maintenance of a patent airway is the single most important aspect of treatment, and a tracheostomy may be necessary in up to 50% of animals presented for veterinary care.[2] A nasal stent (plastic tubing placed up one or both nostrils) can be used but may be challenging to place and maintain in a distressed and painful horse.

Antivenin has recently been described for the treatment of horses with rattlesnake envenomation.[2] Although clinical trials in other species have suggested efficacy, the use in horses has only been retrospectively reported.[5,6] Polyvalent antivenin (Antivenin, Fort Dodge Animal Health, Fort Dodge, Iowa) was rehydrated according to the label directions, diluted in saline, and administered slowly to horses over 30 minutes.[2] Horses typically required 1 to 2 vials and beneficial effects were anecdotally observed even when given 24 hours after envenomation.[2] A newer polyvalent antivenin (Crofab, BTG International [formerly Protherics], West Conshohocken, Penn.) is used in other species, but the use has not been reported in horses.[5]

Wound care, particularly cleaning of the bite site, and tetanus prophylaxis are important components of treatment. Intravenous fluids are often necessary if the horse is unable to drink, but catheter placement should be performed carefully because affected animals may be prone to bleeding. Many horses may not be able to eat well immediately following a bite, but soaked pellets or mashes can often be hand fed as the swelling subsides. The use of broad-spectrum antibiotics is controversial and not recommended in other species but has been advocated by some authors due to concerns of aspiration pneumonia and infection at the bite site. Nonsteroidal antiinflammatory medications are frequently administered to horses and may help to decrease pain and inflammation. There is no evidence to support the use of corticosteroids or antihistamines for rattlesnake envenomation.

Blister Beetle

Cantharidin toxicosis in horses occurs following ingestion of alfalfa hay that is contaminated with blister beetles.[7] Affected animals are typically found in the midwestern United States due to the swarming of beetles in this region and subsequent incorporation into cut hay. In one study, cases were most likely to occur during the late summer and early fall.[8] Cantharidin causes irritation to the mucous membranes and interferes with a family of enzymes called the phosphoprotein phosphatases.[9]

Horses with cantharidin toxicosis develop signs of gastrointestinal disease (colic, diarrhea); urinary system disease (renal failures, cystitis); and cardiac disease (arrhythmias).[7,10] Affected horses may also exhibit a stiff gait.[10] With increased severity, horses may exhibit synchronous diaphragmatic flutter, hypovolemic shock, and death.[7,10] Laboratory data reflect abnormal renal function (azotemia), as well as hypocalcemia, hypomagnesemia, and hypoproteinemia.[7] Myocardial damage may be reflected in changes in myocardial enzymes; however, this has not been evaluated in horses.

VetBooks.ir

Presumptive diagnosis of cantharidin toxicosis in horses can be made following the identification of the beetles present in ingested hay. Testing of stomach contents and urine for cantharidin levels has been suggested as a common means for definitive diagnosis.[8,11] It has been shown that 450 µg/kg body weight of ingested cantharadin can cause clinical signs and even mortality.[10]

Treatment of cantharidin toxicosis is primarily supportive. Administration of activated charcoal to animals with recent exposure may be appropriate. Intravenous fluid therapy is important to correct hypovolemia and dehydration. If renal failure is present, therapy should be directed toward maintaining urine production. A balanced isotonic intravenous fluid can be used for resuscitation. Electrolyte and acid-base abnormalities should be corrected using additional supplements to intravenous fluids (e.g., calcium gluconate, magnesium sulfate). Gastrointestinal protectants are indicated, as well as pain medications to provide relief for the ulceration of the gastrointestinal and urinary systems. Hay that is suspected of contamination should be removed and not fed to animals.

Metals and Other Inorganic Compounds

Gary Osweiler

Metals have properties common to the science of toxicology. They are persistent in and move within the environment, change valence, or can be converted in nature or commerce to more or less toxic forms. Metals can accumulate in organs, milk, bone, or muscle and thus present a public health issue. Some metals are both essential and toxic (e.g., copper, iron), so diagnosis depends not only on presence of the metal but also on their concentration in organs or hair.

Arsenic

Forms and sources are widely variable. Arsenic occurs naturally in plants and soil at low levels (2 to 6 ppm), generally in a pentavalent form, but also as sulfides and less common forms.[1-4] These various forms of arsenic can undergo environmental change due to different plant bioavailabilities and solubilities, as well as methylation by microorganisms. Most poisoning, however, occurs from exposure to commercial products where the valence and solubility have been changed for pesticidal or other uses.[1] Poisoning has become less frequent in recent years due to replacement of arsenicals by other products with a lower toxicity and less environmental persistence.[5]

Inorganic arsenic compounds are more toxic[6] and more likely to cause toxicosis than the organic arsenic compounds used as feed additives.[1] Inorganic arsenic products for commercial use may be in a trivalent (arsenite) or pentavalent (arsenate) form. Arsenites are more soluble and 5 to 10 times more toxic than arsenates.[1,5-7] Past use of inorganic arsenic included rodenticides, insecticides, herbicides, fungicides, crop desiccants, antifouling paints, wood preservatives, and fire salts.[4-6] Present use of arsenicals is much reduced due to regulatory restrictions and the development of newer, more effective substitutes. A continuing risk occurs when livestock ingest ashes left from the burning of older arsenic-treated wood as the arsenic becomes concentrated and more available.[2]

Organic arsenic compounds can be either aliphatic or aromatic. *Aliphatic* arsenic compounds have been used as herbicides and tonics. *Aromatic* organic arsenic chemicals are trivalent (used for canine heartworm therapy) or pentavalent (phenylarsonic compounds occasionally used as feed additives for poultry and swine).[6,8,9]

The mechanism of action varies for different forms of arsenic. *Pentavalent* inorganic arsenicals (e.g., arsenates) replace phosphate in glycolysis, which uncouples oxidative phosphorylation and reduces available metabolic energy. These may be factors in the neural damage that follows excessive and prolonged exposure to pentavalent arsenicals.[3,6] *Trivalent* arsenicals block the citric acid cycle,[4,6] resulting in reduced energy metabolism, affecting metabolically active organs (e.g., liver, kidney, gastrointestinal [GI] epithelium, heart). Blocking of metabolic energy by inorganic and aliphatic organic compounds directly affects capillaries, resulting in transudation of plasma, diarrhea, decreased blood volume, dehydration, and shock. Phenylarsonic feed additives cause degeneration of myelin sheaths and axons in monogastric animals, causing neural degeneration, ataxia, paralysis, and blindness.[1,6]

Different forms of arsenicals exhibit different toxicities. Acute arsenite toxicity ranges from 1 to 25 mg/kg body weight (bw), while toxicity of arsenates is 30 to 100 mg/kg bw. Methanearsonate herbicides are toxic at 10 to 25 mg/kg bw over several days. The organic phenylarsonic feed additives are toxic on the basis of exposure concentration in feeds. Seven to 10 days' consumption of arsanilic acid at 500 mg/kg (ppm) of diet or 3 nitro, 4 hydroxy-phenylarsonic acid (roxarsone) at 250 mg/kg of diet will cause nonfatal but prolonged to permanent neurologic signs in swine.[8,9]

The clinical signs and lesions are similar for the trivalent inorganic arsenicals, while the organic phenylarsonic compounds used as feed additives cause peripheral nerve degeneration in monogastric animals. The inorganic arsenic compounds (arsenites, arsenates) cause dosage-related peracute, acute, or subacute toxicosis with cardiovascular collapse, sometimes presenting as sudden death.[1,5-7] Acute poisoning occurs 3 to 12 hours after ingestion. Clinical signs include ataxia, diarrhea ± blood, recumbency, and death with the most prominent clinical sign in acute and subacute cases being diarrhea that is frequently hemorrhagic.[5,7-9] Other clinical signs include anorexia, dehydration, weakness, colic, and agalactia.[1,6,8,10,11] Consistent necropsy lesions are present in the GI tract and may be hemorrhagic, edematous, necrotic, or eroded. The lesions may be confined to one region or spread throughout the GI tract.[1, 2,4-11] In ruminants, the abomasum is often the most severely affected area. The gut lumen is sometimes filled with necrotic material from the sloughed lining of the GI tract. Other lesions include pulmonary edema and hemorrhage of the cardiac serosa and peritoneum.[1,6,7] Histopathologic examinations may reveal multifocal necrosis of the liver and proximal tubules of the kidney.[4,10] Renal lesions are likely in animals that survive a subacute toxicosis. Peracute cases often have no abnormal gross findings.

The diagnosis of acute arsenic toxicosis is confirmed by elevated levels of arsenic in the liver, kidney, and GI contents.[4,6,8,11] In peracute death, the tissues may have normal concentrations of arsenic, but GI contents will have increased levels. In chronic toxicosis, arsenic deposition in hair begins 2 weeks after exposure, and hair or skin can be used as a retrospective diagnostic tool.[5,7-10] Gastrointestinal contents, urine, and whole blood are the best samples to collect from live animals for diagnostics.[7-10] Arsenic elevations in the GI tract may persist for only 1 to 2 days in surviving animals, and because arsenic is rapidly excreted from blood and urine, any delay in sampling may reduce the chances of confirmation.

Environmental exposure to livestock has been documented but is not consistent. Cattle tissues examined from areas with elevated arsenic in drinking water showed accumulation of arsenic in milk, feces, urine, and hair as compared with those from control areas. Straw from soil-contaminated sites has accumulated up to 10-fold higher residues than the soil.[12] In contrast, data in the United States showed little potential for low levels of arsenic to accumulate in milk of dairy cattle.[13] In the United States, areas of high environmental contamination have included mining waste, industrial contamination, and residue from livestock dipping vats.[14] Roxarsone arsenical feed additive that is present in swine waste effluent degrades to either organoarsenicals or pentavalent arsenic and several unidentified metabolites. The return of organic arsenicals as a source of pentavalent arsenic to the environment could pose issues for swine producers using such products.[15]

Treatment is dictated by the type and severity of clinical signs. Dimercaprol, also known as BAL (British antilewisite), can be used as a specific antidote for trivalent inorganic or an aliphatic organic arsenic. Recommendations vary, but a rigorous protocol is a loading dose of 3 mg/kg intramuscularly (IM) q4h for the first 2 days, q6h on the third day, and q12h for another 10 days.[16,17] Dimercaprol side

VetBooks.ir

effects inhibit metallic coenzymes needed for cellular respiration, and adverse side effects include hypertension, tremors, convulsions, and coma.[16] Early experimental work showed lipoic acid (LA) to be a superior chelating agent to dimercaprol when administered to calves in a 20% solution at 50 mg/kg IM (two or three injection sites) q8h. A combination of BAL with LA was most effective.[18] Sodium thiosulfate is a safe and readily available chelator in large animals but effective only if given before the onset of clinical signs. Dosage is 30 to 40 mg/kg IV or 60 to 80 mg/kg PO two or three times daily for 3 to 4 days.[9] Newer chelators, including 2, 3-dimercaptosuccinic acid (DMSA, succimer), have the benefit of chelating toxic metals such as arsenic, lead, and mercury while sparing iron, magnesium, and calcium.[16,17] DMSA is likely cost prohibitive for most large animals. D-Penicillamine is an effective arsenic chelator in humans but also may be too expensive in livestock.[16,17] Ethylenediamine tetraacetic acid (EDTA) is not effective for arsenic toxicosis.[2] Treatment plans should include supportive therapy for dehydration, shock, reduced renal function, and hemorrhage.[16,17]

Copper

Sources of copper used in livestock are widely available as sulfates, chlorides, and oxides. Concentrates of copper are found in feed premixes, fertilizers, copper footbaths, aquacides, and fungicides (Bordeaux mixture). Acute copper toxicosis has occurred in cattle given injections of copper disodium edetate as a therapy for copper deficiency.[19-21] Sheep are very susceptible to poisoning by chronic copper accumulation in feeds formulated with excessive copper and inadequate molybdenum and sulfur.

Copper poisoning can be acute or chronic. Acute toxicosis results from ingestion or administration of soluble copper salts in one of the sources listed earlier, usually from one to several large doses of copper regardless of sulfur or molybdenum status. Chronic copper toxicosis can be categorized as simple, hepatogenous, or phytogenous. *Simple* chronic toxicosis is caused by ingestion of excessive copper relative to molybdenum and/or sulfate in the diet. Sheep fed diets with a copper-to-molybdenum ratio greater than 10:1 are at high risk for developing clinical copper poisoning. Molybdenum and sulfate bind to dietary copper in the rumen and also form a copper-molybdenum complex post absorption, which decreases absorption and eventual accumulation of copper in the liver.[22] In addition, there is increased excretion of copper in bile and urine. Copper accumulates in sheep liver when the dietary copper-to-molybdenum ratio is greater than 10:1.[22] For cattle, dietary copper-to-molybdenum ratios above approximately 40:1 will allow chronic copper accumulation, and most clinical cases in cattle involve dietary copper in excess of 40 mg/kg of diet. Modest increases of dietary molybdenum in cattle can actually cause copper deficiency.[22,23]

Sheep are often poisoned when fed rations intended for cattle or horses,[24] and llamas have developed copper toxicosis when fed cattle feed.[25] Sheep have developed toxicosis on pastures fertilized with manure from swine or poultry fed copper.[26] Cattle develop copper toxicosis when supplemented with excessive copper,[27] when fields are contaminated by copper smelting,[26,28,29] or when they are fed litter from chickens supplemented with copper.[30] Excessive copper in calf milk replacers has been a source of toxicosis in both calves[31,32] and goat kids.[33] Copper-poisoned dairy cattle have elevated copper concentrations in blood, liver, and diet, but little information has been available about the relative amounts of molybdenum, sulfur, or zinc in the ration.[34-37]

Some cattle breeds display differences in their ability to concentrate copper in the liver. Angus steers had higher plasma copper concentrations than Simmentals on identical rations.[38] Jersey cows have maintained higher hepatic copper concentrations than Holsteins, but the toxicologic significance of these differences has not been determined.[39] Holsteins fed high dietary copper (40 mg/kg dry matter [DM]) had liver copper values twice that of cows fed 10 mg/kg DM, but the high copper group did not have overt signs of copper toxicosis.[40]

Hepatogenous copper toxicosis occurs when *Senecio* species and *Heliotropium europaeum* damage the liver and cause copper retention.[22] *Phytogenous* copper poisoning occurs from prolonged grazing on plants (e.g., subterranean clover *[Trifolium subterraneum]*) with elevated copper/molybdenum ratios. In general, mature pastures have lower copper/molybdenum ratios than young, rapidly growing plants.[41]

The pathogenesis of copper toxicosis involves absorption, binding to albumin and transcuprein proteins, and transport to the liver, where it binds with ceruloplasmin, a hepatic metalloprotein. Absorption in monogastric and young ruminants with a nonfunctional rumen is 75%, but only 1% to 10% in cattle and sheep with normal rumen function.[41]Dietary molybdenum at 2 to 5 mg/kg diet and dietary sulfur at 0.4% of diet substantially reduce ruminant copper accumulation. High dietary zinc (>200 mg/kg diet) and iron also limit copper absorption in ruminants.[23,41]

The concentration of copper in hepatic lysosomes increases over several weeks to months, leading to excess accumulation. When this occurs, there is necrosis of liver parenchymal cells and swelling of Kupffer cells, followed by sudden spontaneous or stress-related release of copper into the bloodstream.[22,23,41] This acute phase includes reduced blood glutathione, increased erythrocyte fragility, hemoglobin oxidation, and methemoglobin formation. The resulting *intravascular* hemolysis leads to anemia, icterus, and hemoglobinuric nephrosis.[22,23,41]

The clinical signs of copper poisoning are most prominent in sheep and include an abrupt onset of depression, anorexia, and weakness. Feces may be watery, dark, or blood tinged, especially in cattle. Evidence of a hemolytic crisis is apparent and signs include anemia, methemoglobinemia, and hemoglobinuria. Mucous membranes are icteric, muddy brown, or a combination of both.[22,23,34-37] Cattle with copper toxicosis after injection of copper disodium edetate have dyspnea, head pressing, ataxia, and circling.[19,21]

Gross lesions are present in the liver, kidneys, and spleen. The liver is yellow and friable and may be larger or smaller than normal. Hemoglobin casts in tubules cause the kidneys to appear dark red or blue-black. The spleen is enlarged and congested. Histopathologic changes in the liver include centrilobular necrosis, pigment-laden Kupffer cells, hepatic fibrosis, and bile duct hyperplasia.[22,23,27,30] Granules in the liver are positive for copper when stained with copper-specific rhodamine or rubeanic acid.[31]

The diagnosis of chronic copper toxicosis relies on measuring copper levels in serum, liver, and kidney as well as in serum hepatic enzymes.[22,23,27] Serum copper is not elevated until just before or during the hemolytic crisis. Animals with toxic copper levels in the liver may have normal or low serum copper values, so serum copper levels alone are not useful for judging copper status. For sheep and cattle there is typically a substantial increase in serum aspartate amino transferase (AST) and gamma glutamyl transpeptidase (GGT) released from damaged liver before the hemolytic crisis occurs and while the animals are still clinically normal.[41] Controlled studies of serum activities for AST and GGT are excellent predictive indicators of hepatic copper accumulation in sheep or cattle that are clinically normal.[42]

For dead animals, copper should be measured in *both* fresh liver and kidney; after the liver has released copper into the bloodstream, liver copper values may fall into a nontoxic range, but kidney copper values will remain in a toxic diagnostic range. The diagnosis should correlate with histopathologic lesions in formalin-fixed liver and kidney.[22,23] Acute toxicosis from copper disodium edetate does not consistently cause elevated copper levels in the liver or kidney.[19]

Several treatment options are currently available but are often unsuccessful once an animal is in acute hemolytic crisis. Ammonium molybdate (50 to 500 mg PO once daily) and sodium thiosulfate (300 to 1000 mg PO once daily) for 3 weeks have been used for many years as a treatment.[22,23,41] Liver copper levels begin to decrease within 4 days of beginning therapy.[22] A newer, but currently unapproved, treatment is ammonium tetrathiomolybdate at 3.4 mg/kg subcutaneously (SC) on alternate days for three treatments.[43] Either route of

VetBooks.ir

administration significantly decreases liver copper levels within 6 days. This change is accompanied by an increase of copper in the blood, bile, feces, and urine.[22] Most of this copper is bound with tetrathiomolybdate and albumin in an inert complex.[22,23] Xylazine given with tetrathiomolybdate is reported to double the amount of copper excreted in the urine as compared with tetrathiomolybdate alone.[44] D-Penicillamine (26 mg/kg PO twice daily for 6 days) results in a 10- to 20-fold increase in urinary copper excretion in sheep,[45] but this option is expensive and may not be cost effective for many livestock. Animals in the acute hemolytic phase of poisoning should be treated as needed for serious hemolytic anemia and potential methemoglobinemia from copper's oxidant effect.

Iodine

Iodine is used to prevent some infectious diseases and as a treatment for foot rot. Common sources of iodine include potassium iodide, sodium iodide, kelp, Chilean saltpeter nitrate deposits, and ethylenediamine dihydriodide (EDDI). Oilseed proteins or their concentrates incorporated into foodstuffs contain 0.1 to 0.3 mg iodine/kg. Estimated iodine requirements as mg/kg diet are beef cattle, 0.5; dairy cattle (lactating), 0.8 to 1; sheep, 0.2 to 0.5; swine, 0.3 to 2; and horses, 0.1 to 0.2.[46] Over-supplementation can result in toxicosis.

The toxicity of iodine in which large doses of iodine inhibit organic iodide formation and reduce active transport of iodine by the thyroid leading to goitrogenic effects has been documented. Iodine concentrations greater than 50 mg/kg of diet for calves caused reduced growth rate, and greater than 100 mg/kg resulted in coughing and nasal discharge, as well as reduced hemoglobin and serum calcium concentrations. Previous use of EDDI as an expectorant in feedlot cattle (400 to 500 mg/head/day) or swine (250 to 500 mg/head/day) sometimes resulted in signs of excessive expectorant activity.[47]

Elevated iodine intake (50 mg/day) in dairy cows will raise milk iodine to concentrations that may be unacceptable for public health reasons. One report of abortions in dairy cows was associated with excessive iodine consumption. Maximum tolerable levels (mg/kg diet) based on available literature are cattle, 50; sheep, 50; and swine, 400.[48]

The clinical signs of toxicosis include a nonproductive cough, lacrimation, serous nasal discharge, scaly hair coats, and hyperthermia. Other reported signs include decreased milk production, decreased gain and feed conversion, exopthalmia, nervousness, dermatitis, alopecia, and tachycardia. Young animals appear more susceptible than other age groups. Adults may not develop toxicosis unless stress, disease, or nutritional imbalances are also present.[49] Excess supplementation in mares is associated with goiter in foals.

Serum biochemical changes are inconclusive for iodine toxicosis. A diagnosis can be confirmed only with serum or milk analysis. Iodine concentrations in milk are directly related to levels of iodine in the diet.[49] Elevated serum iodine concentrations (1600 µg/mL) may be associated with mild clinical signs. Nonlactating cows have higher serum iodine concentrations than lactating cows that are eliminating iodine in milk.

Treatment is restricted to removal of the dietary source of iodine. Clinical signs associated with the respiratory tract disappear 1 to 4 weeks after the iodine source is removed.[46]

Iron

Iron toxicosis associated with excess oral or parenteral iron supplementation is distinguished from hemochromatosis (iron deposition in liver).[50,51] Normally, physiological mechanisms limit excessive iron absorption, but very high dietary concentrations or dosing with tonics or concentrates can impair the intestinal barrier to absorption and result in liver accumulation and possible toxicosis. Excess iron is stored in the liver as ferritin and hemosiderin.[50,52] When iron binding capacity is exceeded, free iron release can cause peroxidative damage to cell membranes, especially in the liver.

Toxicosis from iron overload has occurred in neonatal foals (normally born with high iron absorption and high serum iron levels) and adult horses given ferrous fumarate orally; calves injected with ferrous gluconate and ferric ammonium citrate; neonatal swine dosed with parenteral iron; pigs born from vitamin E– and selenium-deficient sows; and young bulls injected with ferric ammonium citrate.[53-57]

The clinical signs of iron toxicosis in neonatal foals include depression, icterus, head pressing, and disorientation.[53] Adult horses develop anorexia, icterus, and sometimes petechial hemorrhages.[52] Calves with iron toxicosis exhibit trembling, vocalizing, bruxism, colic, and convulsions.[54]

Clinicopathologic findings are related to cholestatic liver failure. Animals often have elevated serum levels of γ-glutamyl transferase (GGT), alkaline phosphatase (ALP), bile acids, and unconjugated bilirubin. Coagulopathies include abnormal coagulation profiles, thrombocytopenia, and elevated fibrinogen.[52-54]

The gross lesions are variable. The liver is discolored, pale tan, or mottled red-brown, and most are friable and swollen or shrunken. Hemorrhages may be present in the gastric mucosa, intestines, and urinary bladder. Microscopic lesions include perioral bile ductile proliferation, periportal necrosis, lobular necrosis, and fibrosis.[52-56]

Iron toxicosis is diagnosed on the basis of clinical signs and a history of recent iron exposure. When serum iron and total iron binding capacity (TIBC) are evaluated, serum iron often exceeds the TIBC. In dead animals, the liver iron is elevated to varying degrees in different species; iron may be above normal if the animal had hemolysis or blood congestion occurred within the liver.

The treatment of iron toxicosis is usually limited to supportive care. Repeated phlebotomy or chelation therapy with deferoxamine (40 mg/kg IM q4-8h) has been used to treat iron overload in humans and small animals.[57] The success rate and cost of these treatments in large animals has not been well documented.

Mercury

Mercury toxicosis has been caused by application or ingestion of an inorganic mercurial product used as a counterirritant or from ingestion of seeds treated with organic mercurial fungicides, which are no longer used in most of the world.[58] If blistering agents are used with dimethyl sulfoxide (DMSO), mercury absorption is enhanced.[59,60] The kidney is the primary target and storage organ of inorganic mercury, but mercury also localizes in the GI mucosa and is eventually excreted by the kidneys.[58-61]

Mercury causes two clinical syndromes: acute poisoning from inorganic mercury salts and chronic neurologic damage from organomercurials. Acute inorganic mercury causes ulceration of the mouth, esophagus, and the remainder of the GI tract followed by diarrhea and anorexia. If the animal survives, acute nephrosis develops. Anorexia, gastroenteritis, weight loss, nephritis, and alopecia occur in animals exposed to prolonged low doses of inorganic mercury.[60] Organic mercury fungicides cause brain damage, blindness, incoordination, and proprioceptive deficits. Most neurologic signs are long term or permanent.

The diagnosis of mercury toxicosis is supported by elevated serum creatinine and blood urea nitrogen levels, as well as proteinuria, glucosuria, and isosthenuria. Necropsy findings may include an ulcerated, necrotic, edematous, and hemorrhagic GI tract and pale, swollen kidneys. Confirmatory mercury concentrations may be found in liver, kidney, brain, whole blood, and urine.[58]

Therapy should include detoxification (oral sodium thiosulfate) for recent exposure and the appropriate antidotes. Sodium thiosulfate or BAL can be used for chelation therapy (refer to Arsenic earlier). Residual topical mercurial products (e.g., blisters) should be washed well from the animal's skin.[58-61] Supportive care should be provided for severe gastroenteritis and kidney failure. The success rate is low when poisoning is severe or progressive; the presence of oliguria indicates a poor prognosis.[58-61] Surviving food animals should be

VetBooks.ir

monitored closely for potential mercury residues, which may persist for extended periods in organs or muscle.[58]

Other Toxicants

Additional toxicants are covered in other chapters as follows:
Fluoride, Chapter 38
Lead, Chapter 35
Molybdenum, discussed under copper deficiency in Chapter 32
Selenium (see Toxic Plants, Chapter 54)
Sodium, discussed under salt poisoning in Chapter 35
Sulfate, discussed under copper deficiency in Chapter 32 and under polioencephalomalacia in Chapter 35
Zinc, discussed under osteochondrosis in Chapter 38

Medications and Therapeutic Agents

Lynn Rolland Hovda

Toxic and adverse drug reactions in large animals occur with some frequency but are not as routinely reported as small animal occurrences. Blurring of the lines between toxicity and adverse reactions exists in the literature and practice. Strictly speaking, toxic effects are dose related and do not occur at normal doses, whereas adverse reactions occur at normal, as well as elevated, doses.[1,2] The definition of an adverse drug reaction has not changed for 30 years and technically is "a response to a drug that is noxious and unintended and occurs at doses normally used in man for the prophylaxis, diagnosis or therapy of a disease, or for modification of physiological function."[2]

Adverse drug reactions can be classified in a variety of ways with six different presentations of the normal scheme.[2,3] A more simplified approach uses only two different types of reactions: dose related and idiosyncratic.[4] In dose-related reactions the signs move from physiologic to pharmacologic to toxic as the dose is increased. Often, simply stopping the medication and allowing the drug to clear the system results in cessation of the clinical signs. Anaphylactoid reactions are included in this group because they are not immune mediated and depend on mast cell degranulation to manifest effects. Idiosyncratic reactions are generally not related to a specific dose or concentration of the medication administered. Immune-mediated reactions are included in the group.

Finding accurate information on adverse or toxic medication reactions in large animals is difficult. Preclinical studies are generally small and include a limited number of animals when, in fact, the medication will be used to treat thousands of animals and reactions may not show up until these numbers are reached.[5] Clinical trials are often helpful, but again small numbers of animals may be involved. Useful information including preapproval medication data can often be found on the FDA's website. (http://www.fda.gov/AnimalVeterinary/Products/ApprovedAnimalDrugProducts/FOIADrugSummaries/default.htm).

Treatment of adverse or toxic reactions varies for each medication and route of exposure. Few antidotes exist for large animal medications, and for the most part treatment is symptomatic and supportive.[6] The use of an offending medication should be discontinued as soon as a reaction is recognized. Bathing for topical exposures, gastric lavage followed by activated charcoal for most recent oral exposures, mineral oil, and intravenous fluids are all useful tools for dealing with the clinical signs.

The most commonly reported adverse or toxic drug reactions in horses include antimicrobials (procaine benzylpenicillin), nonsteroidal antiinflammatory drugs, anesthetic agents, sedatives, and antiparasitic drugs.[7] Reports in cattle and swine primarily implicate antimicrobials.[7] Some of these drugs are covered in separate chapters (see the equine section on nonsteroidal antiinflammatory drug toxicity, in Chapter 32) or discussed more generally throughout the textbook.

Antimicrobial Drugs

It is not possible in the scope of this chapter to begin to review all the antimicrobial drug adverse or toxic reactions. Two antimicrobials, however, have specific known risk factors for large animals and are covered here.

Doxycycline

Doxycycline is a tetracycline used in large animal medicine to treat a variety of illnesses. The IV use of doxycycline in horses is not recommended and has been associated with supraventricular tachycardia, systemic arterial hypertension, discomfort, collapse, and death.[8] The cause is unknown but may be concentration or infusion-rate dependent. Treatment is symptomatic and supportive.

Sudden death has been reported in calves accidentally receiving 3 to 10 times the recommended daily dose (5 mg/kg bid) of doxycycline.[9,10] There is no known breed or genetic predisposition. Clinical signs included lethargy, dullness, loss of appetite, cough, dysphagia from paresis or paralysis of tongue, tachycardia, and tachypnea. Major problems included myopathies and necrosis (tongue, myocardial, other striated muscle), acute tubular necrosis, and hepatic fatty degeneration or congestion.[9] The tongue is affected before the myocardium. The cause of acute tubular necrosis remains unknown but may be a combination of a decreased cardiac output from myocardial issues and an increase in myoglobin from muscle necrosis. Death was reported to be from myocardial necrosis, although a recent clinical study in healthy calves dosed at 5 times the recommended daily dose for 5 days failed to support this.[10]

Enrofloxacin

Enrofloxacin is a second-generation quinolone metabolized in the liver to ciprofloxacin, an active metabolite. Ciprofloxacin, itself a quinolone antimicrobial, should not be used orally in horses because it causes mild diarrhea to severe colitis, laminitis, and endotoxemia.[11]

The most common adverse reactions in horses include mild diarrhea, neurologic signs, and orthopedic disorders in young animals. The neurologic signs are generally dose related (i.e., high dose, bolus route) and transient, resolving in 10 to 15 minutes after administration.[12] Diluting the drug and administering it at a slower rate prevents the development of neurologic signs. Juvenile arthropathies with associated cartilage damage have been reported in neonatal foals and other species.[13]

Several other adverse or toxic reactions have been reported. Intrauterine infusion in mares resulted in acute endometrial ulceration, necrosis, and hemorrhage, as well as fibrosis with inflammation.[14] Oral ulcers developed in animals treated with a gel compounded from the injectable cattle product.[15] Finally, in order to prevent toxicosis, the dose in neonatal calves needs to be lowered to accommodate their lower amounts of body fat and different metabolic capacities.[16]

β_2-Adrenergic Receptor Agonists (Clenbuterol, Ractopamine, Zilpaterol)

All three of these agents have been abused in horses for their known anabolic effects.[17,18] The use of clenbuterol in food-producing animals, once similarly abused, is now completely banned due to accumulation in meat.[19] Ractopamine and zilpaterol are still allowed as feed additives and discussed later in this chapter.

Clenbuterol is labeled for the management of acute and chronic respiratory disorders in horses. The normal dosage range is 0.8 to 1.6 µg/kg bid with a maximum recommended dosage of 3.2 µg/kg bid for 3 days.[19] The dose needed for muscle partitioning in food-producing animals is estimated to be 5 to 10 times the therapeutic dose, while the dosage needed for repartitioning in horses is much lower at 2.4 µg/kg bid.[20]

At normal doses clenbuterol is a moderately selective β_2-adrenergic receptor agonist; at high doses all beta adrenergic

VetBooks.ir

receptors are stimulated, and a wide variety of signs occur. Clinical signs are dose dependent with nervousness and mild agitation, sweating, and increased heart rate occurring in some horses 5 to 10 minutes after a therapeutic dose of 1.6 µg/kg.[19] Far larger overdoses, 10 µg/kg and 100 µg/kg, were used in three Quarter Horses treated with compounded, bootlegged products.[17] The horses showed excitation, profuse sweating, tachycardia, whole body muscle tremors, hypothermia, recumbency, and in two cases, death. Laboratory abnormalities associated with these large overdoses included azotemia, elevated creatine kinase, hypocalcemia, hypochloremia, hyperbilirubinemia, hyperphosphatemia, and severe hyperglycemia. Treatment included, among other things, multiple sedatives and analgesics, gastrointestinal protectants, intravenous fluids, propranolol (0.01 mg/kg IV diluted in 150 mL over 30 minutes), and insulin (0.22 U/kg IM).[17] It is important to note that propranolol is effective in treating tachycardia but will do little for other signs and that hyperglycemia, in these horses, did not resolve spontaneously and required multiple doses of insulin.

Long-Acting Tranquilizers

Fluphenazine Decanoate

Fluphenazine decanoate is a phenothiazine neuroleptic agent used as a powerful antipsychotic medication in human beings.[21,22] Although not approved or marketed for use in horses, it has been used for years off label to provide long-term sedation for anxious or nervous show and race horses and for uncontrollable horses needing stall rest for surgical procedures.[22]

The suggested equine dose is 0.05 to 0.08 mg/kg IM, but clinical signs have occurred in horses 12 to 36 hours after doses of 25 mg to 125 mg (roughly 0.06 to 0.26 mg/kg).[22,23] Signs are consistent with development of an extrapyramidal syndrome and include extreme agitation followed by a brief quiet period, hypermetria, profuse sweating, circling, rhythmic head tossing and neck arching, violent pawing, and self-mutilation.[22,23] These signs are nonresponsive to normal means of control. Hepatitis and urticaria (multiple, raised nodules; nonpruritic) occurred in one horse but may be due to other factors.[24]

Short-term sedation with xylazine, detomidine, or romifidine may control the animal long enough to perform a physical examination and place an intravenous catheter. Often they are ineffective and a barbiturate is necessary. Diphenhydramine (0.67 mg/kg to 1.5 mg/kg IV q12-24h) or benztropine mesylate (0.018 to 0.035 mg/kg PO q12h) has been used to control the extrapyramidal signs.[22,23] They are not always effective and a barbiturate (pentobarbital or phenobarbital) may need to be used for several days until the signs resolve.

Reserpine

Reserpine, a medication infrequently used in humans to control blood pressure, is used off label in horses to provide long-term sedation.[25] Clinical signs of an adverse reaction include profuse sweating, trembling, shaking, flatulence, watery diarrhea, marked miosis, upper eyelid ptosis, and paraphimosis ranging from mild to almost irreversible.[25-27] Treatment is similar to fluphenazine decanoate, although diphenhydramine and benztropine mesylate are not effective because reserpine's mechanism of action is different.

Blood-Doping Agents—Erythropoietin/Darbepoetin

Blood-doping agents such as erythropoietin (EPO) and darbepoetin have been abused in horses, in particular those horses in endurance events such as horse racing.[28] They increase aerobic capacity and endurance by increasing red blood cell (RBC) production and therefore oxygen transport.[29,30] The danger in using human products is the potential for an immune response with antibody development.[31] Clinical signs including depression, lethargy, and anemia can occur after a single dose or may not occur until many doses have been administered.[28,31,32] Two Standardbred racehorses developed severe anemia, elevated serum irons, and bone marrow specific hypoplasia after receiving at least two doses of EPO (4000 IU).[28] Treatment for these horses included stopping the EPO and administering oral dexamethasone (0.05 mg/kg once daily) with tapering of the dose as anemia resolved.

Miscellaneous Medications

Isopropyl Alcohol

Isopropyl alcohol is not a problem when used topically, but toxicosis has occurred when inadvertently given orally. A horse accidentally received 2 L via nasogastric tube instead of mineral oil. Shortly thereafter it became dull, depressed, and collapsed with no menace response and slow pupillary light reflexes.[33] Treatment included gastric lavage, activated charcoal, and IV fluids with recovery complicated by surgical correction of a cecal impaction.

Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO) when administered intravenously in concentrations greater than 50% results in severe hemolysis.[34] Few issues occur with topical and oral use of DMSO without additives. DMSO-associated toxicosis occurs when it is used in combination with other products, carrying them across membranes including the skin and the blood-brain barrier. In two instances, the application of a DMSO and mercury blister to limbs resulted in the development of mercury toxicosis.[35]

Dioctyl Sodium Succinate (or Docusate)

Dioctyl sodium succinate (DSS) is frequently used as a stool softener in horses with impactions. Single doses of 0.65 to 1 g/kg have resulted in agitation, abdominal pain, dehydration, watery diarrhea, intestinal mucosal damage, collapse, and death with signs occurring within 1 to 2 hours of administration.[36] Treatment is supportive and includes GI protectants, IV fluids, correction of electrolyte abnormalities, and pain relief.

Lidocaine

Lidocaine, when used as a continuous IV infusion for ileus, has caused muscle fasciculations, anxiety, sedation, and visual dysfunction. The targeted serum level associated with this use of lidocaine is 1 µg/mL (0.98 µg/mL) with signs occurring at levels of 1.85 to 4.53 µg/mL.[37,38] Geriatric and neonatal horses, as well as those with hypoproteinemia, may develop signs at much lower doses and serum levels. Treatment consists of stopping the infusion and waiting a short time for the signs to resolve.[38]

Menadione Sodium Bisulfide (Vitamin K3)

Menadione sodium bisulfide (vitamin K3) is an ineffective anticoagulant in large animal species and toxic in normal doses to horses.[39] When administered to horses, weakness, stiffness, colic, laminitis, and a depressed appetite occur within 4 to 48 hours.[39,40] Acute tubular necrosis with azotemia, proteinuria, hematuria, hyperkalemia, hypochloremia, and hyponatremia develop.[39] Treatment is focused primarily on the renal system with IV fluids and diuretics such as furosemide or mannitol recommended.

Propylene Glycol

Propylene glycol is used as antifreeze, a drug vehicle, and a treatment for bovine ketosis. A mature horse inadvertently received a gallon of propylene glycol instead of mineral oil and developed depression, ataxia, sweating, pain, and salivation in 10 to 25 minutes; some signs resolved. Cyanosis, respiratory distress, and sudden death occurred 24 hours later.[41] Although not effective in this case, sodium bicarbonate may be used to treat developing lactic acidosis. Cows receiving an overdose (median toxic dose of 2.6 g/kg BW) become ataxic, depressed, and recumbent 2 to 4 hours after administration; signs resolve in 24 hours with supportive care.[42]

Feed Additives

Robert H. Poppenga

Inclusion of a variety of chemicals in livestock feed is an efficient and cost-effective mechanism to improve animal performance and prevent disease. Livestock feed additives include growth promotants such as ionophores, partitioning agents such as ractopamine, antiparasiticides and larvicides such as tetrachlorvinphos, antibiotics, hormones such as melengesterol acetate, buffers, probiotics, nutritional agents, dietary supplements, and adsorbents such as sodium bentonite. Fortunately, the majority of feed additives are safe when used appropriately. The following discussion is limited to those feed additives that are most commonly associated with adverse effects.

Urea and Other Nonprotein Nitrogen Sources

Nonprotein nitrogen (NPN) is converted by ruminal bacteria to ammonia by the enzyme urease. Ammonia is subsequently used by the bacteria to form amino acids and, ultimately, protein. Utilization of ammonia for bacteria protein synthesis is dependent on the availability of a highly fermentable carbohydrate source.

NPN can replace a portion of more expensive natural protein in ruminant rations, providing up to 40% of their nitrogen requirement. Rumen bacteria can effectively utilize ammonia nitrogen in limited quantities. However, when ammonia is produced beyond the capacity of the bacteria to use it, it will accumulate in the rumen at potentially toxic concentrations. NPN is available in a granular form that is either incorporated into concentrates or range blocks or as a liquid that is incorporated into palatable vehicles such as molasses. The most commonly used form of NPN is urea, although other forms such as ammonium salts or ammoniated feed are also used.

Urea is typically recommended at a maximum rate of 3% of the grain ration or 1% of the total ration.[1]

The toxicity of NPN for ruminants is dependent to a certain extent on the adaptation of rumen bacteria to NPN; properly adapted animals can tolerate higher concentrations of NPN than naive individuals. Acclimation to NPN can be lost within 1 to 3 days, so maintaining a constant intake is important to prevent potential intoxication. In unacclimated cattle, a toxic dose of urea is approximately 0.45 g/kg body weight. In comparison, a lethal dose for acclimated cattle is approximately 1 to 1.5 g/kg body weight. Younger ruminants are more susceptible than older animals to intoxication.[1,2]

Ammonia not used by rumen bacteria is absorbed systemically and can result in hyperammonemia within ½ hour to 2 hours if it is not detoxified to urea by the liver for excretion. The amount of ammonia absorbed is dependent on the pH of the rumen. Normally, when rumen pH is below 7, the majority of ammonia is in the form of the charged ammonium ion (NH4+ vs. the uncharged NH3). As more ammonia is produced in the rumen, the pH of the rumen becomes more alkaline with a resultant dramatic shift in the relative amounts of NH4+ and NH3 in the rumen. Unionized NH3 readily crosses the rumen wall; in blood, ammonia is primarily in the form of ammonium ion.

NPN-induced ammonia toxicosis usually results from one of the following situations: (1) inadequate or improper feed mixing, (2) error in calculating the amount for inclusion in feed, (3) inadequate adaptation to NPN, (4) inclusion in carbohydrate-deficient rations, or (5) unrestricted consumption of palatable liquid NPN formulations.[2]

Clinical signs of ammonia toxicosis can occur within 30 minutes to several hours after consumption of excessive NPN. Signs include weakness; dyspnea; salivation; bruxism; bloat; excitation; belligerence; vocalizations; muscle tremors beginning with eyelids, lips, and neck and progressing posteriorly; and convulsions. Due to the rapid onset of clinical signs, it is common to find animals dead without signs being noted. There are no characteristic postmortem findings associated with intoxication. Gross or histopathologic lesions most often involve the lungs and brain and include generalized congestion, hemorrhages, and pulmonary and brain edema.

As evidenced by typical clinical signs, the central nervous system (CNS) is a primary target of NPN intoxication. Mechanistically, ammonium ion causes a number of changes in the CNS including amino acid disturbances, alterations in neurotransmission, cerebral energy deficits, and alteration of nitric oxide synthesis. Brain edema due to hyperammonemia is thought to occur through astrocyte swelling.[3]

A diagnosis of intoxication relies on a history of NPN supplementation, consistent clinical signs, and, ideally, measurement of elevated ammonia concentrations in rumen contents, whole blood, or ocular fluid. Unfortunately, ammonia is volatile, so appropriate sample handling and storage are critical for ammonia measurement. If urea is the NPN source, it can be measured in feed or, less usefully, in rumen contents. An antemortem rumen pH value greater than 8 is consistent with NPN intoxication. Postmortem pH values can be misleading depending on the time lag between death and necropsy.

Treatment is designed to decrease the amount of unionized ammonia absorbed from the rumen. Adult cattle should be given 20 to 30 L of cold water PO to reduce the ability of rumen bacteria to convert urea to ammonia by inhibiting and diluting urease. In addition, decreasing rumen pH shifts the form of ammonia to the unabsorbable ammonium ion; this is accomplished by administering 2 to 6 L vinegar.

A number of strategies can minimize the risk of intoxication. These include a gradual adaptation to NPN, feeding readily fermentable carbohydrate sources, ensuring uniform feed mixing, maintaining a regular feeding schedule, feeding liquid supplements with phosphoric acid to maintain an acidic rumen, coating urea with fat and extruding urea with concentrates such as grain, using urease inhibitors to decrease its hydrolysis, and ensuring that mineral nutrition is adequate.[2]

Ammoniated Feed

Ammoniated feed intoxication is a hyperexcitability syndrome called "bovine bonkers" and is reported in cattle and calves fed ammoniated molasses, hay, straw, and silage.[1] The ammoniation process improves the palatability and digestibility of otherwise poor-quality roughages. Ammoniation of high-quality roughages such as wheat, Sudan grass, alfalfa, orchard grass, Bermuda grass, fescue, and sorghum containing high concentrations of soluble sugars is most often associated with the syndrome. The putative toxicants are the imidazoles, 2- and 4-methylimidazole, which are formed during the ammoniation process. The mechanism causing CNS excitation is unknown.

Hyperexcitability, either spontaneous or induced, is a hallmark of the syndrome. Affected animals will suddenly stampede and run in circles or a straight line until they collide with other animals or buildings or fences. Other clinical signs include ear twitching, mydriasis, trembling, salivation, increased urination and defecation, and bellowing. The only postmortem lesions noted are secondary to trauma. The imidazoles can be excreted via milk, so nursing animals are at risk of intoxication.[4]

A diagnosis of intoxication depends on a history of feeding ammoniated forages and consistent clinical signs. Treatment is nonspecific and typically limited by difficulties in handling affected animals. Sedation can be tried; acepromazine has been suggested.[4] Animals often recover once exposure is halted.

Prevention involves restricting ammoniation to poor-quality roughages that contain low concentrations of soluble sugars. The amount of ammonia used should not exceed 3% of the dry weight of the forage. In addition, the processing temperature of the forage should not exceed 70° C (158° F).[1]

Ionophores

Ionophores are commonly added to cattle and poultry feed for their growth promotant and anticoccidial properties. A number of ionophores are commercially available including narasin, salinomycin, lasalocid, monensin, maduramycin, laidlomycin, and maduramycin.

VetBooks.ir

In cattle, ionophores result in more propionic acid production in the rumen, which improves feed efficiency. They are also used to prevent rumen acidosis and emphysema. Intoxication most often occurs due to errors in feed mixing that result in overdosing of target species (cattle and poultry) or accidental inclusion in feed of nontarget species (e.g., horses, camelids).

Ionophores are potentially toxic to a variety of mammalian and avian species, although sensitivities vary between species and among different ionophores.[5,6] Intoxications have been documented for horses, cattle, goats, pigs, camelids, chickens, turkeys, and quail. Ionophores bind and transport ions across cell and organelle membranes; the direction of movement depends on the concentration gradient of a particular ion. This results in disruption of multiple ion gradients as one or more ions move into or out of cells. Monovalent ionophores such as monensin, salinomycin, and narasin preferentially complex with either sodium (monensin) or potassium (salinomycin and narasin) ions. Divalent ionophores such as lasalocid and laidlomycin are capable of binding and transporting divalent cations such as calcium and magnesium across membranes. At a cellular level ionophores affect mitochondrial function and result in loss of aerobic energy production.

Horses Horses are the most sensitive livestock species with reported LD50s of 0.6 mg/kg for salinomycin, 2 to 3 mg/kg for monensin, and 21.5 mg/kg for lasalocid.[5]

Clinical signs in horses are similar irrespective of the ionophore ingested, although signs can vary among individuals within an affected group. Signs most commonly occur with 24 hours of exposure, but delayed onset can occur in some cases. Acute clinical signs are primarily due to effects on muscle cells and the nervous and digestive systems. Feed refusal is one of the earliest signs noted in horses. Other signs include weakness, ataxia or incoordination, tremors, stumbling, exaggerated stepping, hesitance to move or turn, tachycardia, congested mucous membranes, hypotension, dyspnea, hyperpnea, sweating, and recumbency. Death can occur without signs being observed. In individuals surviving acute intoxication, longer-term clinical signs result from myocardial damage and decreased cardiovascular function and include unthriftiness, poor performance, poor exercise tolerance, arrhythmias, pitting edema, and hyperpnea. Delayed sudden death can occur long after exposure.

A variety of clinicopathologic changes can occur including elevated ALP, AST, LDH, CPK, creatinine, indirect bilirubin, BUN, glucose, hematocrit, serum osmolality, and phosphorus. Decreased concentrations of serum Ca++ and K+ and urine osmolality occur. Myoglobinuria is often noted. Unfortunately, the usefulness of such changes is limited by significant variation among affected individuals and the timing of their occurrence. Measurement of serum cardiac troponin I has been suggested to help with the early identification of horses with cardiac damage.[7]

The most significant necropsy findings are due to direct or indirect myocardial damage. Acutely affected horses develop degeneration and necrosis of cardiac muscle, while horses dying later have marked cardiac myopathy and fibrosis. Lesions can be absent in horses dying peracutely.

A diagnosis of intoxication relies on a combination of consistent clinical signs, necropsy findings where death occurs, and analytic proof of ionophore exposure. Because medicolegal considerations are often encountered in cases involving horses, it is critical to try to quantify ionophore feed concentrations.[5] This is sometimes difficult if representative feed samples are not available or obtained. Testing several feed samples can be important to confirm nonuniform feed mixing. In the absence of feed testing, stomach contents and/or tissue testing can be done to confirm exposure, but not intoxication.

There is no specific treatment for ionophore poisoning.[8,9] It is critical to quickly remove access to suspect feed and initiate decontamination (e.g., gastric lavage and/or activated charcoal) as soon as possible. The efficacy of decontamination in most cases is questionable.

Supportive therapy is directed toward restoration and maintenance of cardiac output and tissue perfusion, stabilization of cell membranes, and treatment with antiarrhythmics if unstable, life-threatening arrhythmias are present.[8] Affected horses should be rested for up to 3 months after exposure, and echocardiograms (ECGs) and exercising ECGs performed to identify evidence of chronic cardiomyopathy. Reported mortality is 60% or greater.[8]

Cattle Cattle are less sensitive to ionophores than horses. At prescribed use levels, ionophores are safe. The LD50 for monensin in cattle is reported to be 26.4 mg/kg, and lethal doses of lasalocid range from 50 to 100 mg/kg.[6]

In cattle, signs of acute intoxication include early anorexia, rumen atony, CNS depression, muscle tremors, watery diarrhea, tachycardia, ataxia, recumbency, and death. Animals can be found dead without clinical signs being noted. Animals surviving acute intoxication can subsequently develop congestive heart failure characterized by brisket edema, prominent jugular pulses, ascites, fluid feces, dyspnea, and tachycardia. Deaths can occur weeks to months after exposure and be precipitated by exertion such as calving. In dairy cattle, decreases in milk production are likely with production requiring several days to a week to return to previous levels.

Clinical pathologic changes are similar to those described for horses. On necropsy, lesions include myocardiopathy, pulmonary edema, enlargement of the heart and liver, hydropericardium and hydrothorax, and ascites.

Elements necessary for a diagnosis in cattle are similar to those for horses. However, in contrast to cases involving horses in which confirming exposure is likely to be significant, in cattle it is important to confirm exposure to feed concentrations higher than expected concentrations. Treatment is similar to that for horses, although it is less likely to be as extensive in cases involving cattle.

Turkeys Both salinomycin and monensin intoxication have been reported in turkeys.[10] Sensitivity to salinomycin is age dependent with younger birds being less sensitive. Clinical signs in affected birds include dyspnea, drowsiness, sternal recumbency with rear legs extended posteriorly, inability to stand, stiffness, and weakness. Extensive fragmentation and necrosis of skeletal muscle fibers occurs and myocardial damage can also be noted.

β_2-Adrenergic Agonists

In livestock, β_2-agonists have been used as repartitioning agents (i.e., repartitioning nutrients away from fat in favor of muscle). This results in increased carcass weight and ratio of muscle to fat and improved feed efficiency. β_2-agonists approved in one or more countries for use in livestock feed include ractopamine (finishing beef cattle, swine, and turkeys) and zilpaterol (finishing beef cattle). Clenbuterol is approved for treating recurrent airway obstruction in horses but is not approved for use in food animals.[11] Due to the anabolic effects of β_2-agonists, there is the potential for their use as doping agents in racehorses. Horses appear to be more sensitive to adverse effects than cattle following exposure to zilpaterol. In a limited number of horses, adverse effects were noted soon after a single zilpaterol dosage of 0.17 mg/kg body weight PO; this is the recommended dosage for cattle.[12] Signs included nervous behavior, profuse sweating, muscle tremors, and tachycardia within 20 to 60 minutes post dosing. Clinical pathologic changes were consistent with muscle damage and included increased serum activity of LDH, CK, and AST. Myoglobin-induced nephropathy is possible in some individuals. The duration and severity of adverse effects were unanticipated, with some signs persisting for up to 2 weeks. Affected horses recovered completely without treatment.

On the basis of human data, clenbuterol is approximately 19 times more potent than zilpaterol and zilpaterol is approximately 125 times more potent than ractopamine. Dosages of ractopamine of up to 10 times the dose of zilpaterol given to horses have not been associated with adverse effects.[13]

VetBooks.ir

Antibiotics

The erroneous addition of antibiotics to feed is of particular concern in horses. Antibiotics such as lincomycin, clindamycin, tetracycline, and erythromycin have been associated with lethal colitis in horses.[5] Adverse effects are believed to be due to disruption of the normal microbial flora, resulting in overgrowth of pathogenic bacteria such as *Clostridium* spp., *Salmonella* spp., or *Escherichia coli*. Subsequent production of endotoxins or enterotoxins causes digestive tract damage and systemic clinical effects. Treatment primarily involves intravenous fluid therapy and correction of acid-base and electrolyte abnormalities.

Pesticides

Tetrachlorvinphos (TCVP) is an organophosphorus (OP) insecticide fed to horses, cattle, and swine as a pass-through fly larvicide. It is a cholinesterase inhibitor and intoxication is associated with overstimulation of muscarinic and nicotinic cholinergic receptors. Tetrachlorvinphos has low mammalian toxicity with an LD50 in laboratory animals of greater than 1 g/kg body weight. However, anecdotal evidence suggested that horses receiving TCVP at recommended levels were more likely to exhibit gastrointestinal problems and increased reactivity, leading to handling difficulties. In one study, six horses given the recommended dose of TCVP for 30 days were noted to have heightened reactivity to an external stimulus that correlated with a reduction in whole blood cholinesterase activity.[14] Another study demonstrated that TCVP at the recommended dose depressed plasma butyrylcholinesterase activity in horses but did not disrupt cholinergic neurotransmission in target tissues.[15] Although TCVP, at recommended doses, does not cause typical signs associated with OP overexposure, some clinicians have suggested that alternative methods for fly control be used for horses due to potential adverse effects on behavior.

Pesticides and Rodenticides

Michelle Mostrom

Pesticides

Pesticides comprise a wide variety of chemicals used to control insects and parasites in agriculture, animals, and public health, as well as to control weeds, fungi, and rodents or other animals determined as unwanted by man. The toxicology of pesticides covers a number of different chemical classes. This section focuses primarily on insecticides and rodenticides that are more commonly associated with toxicoses in large animals. Poisoning or toxicosis in large animals generally occurs due to misuse or overdosage with a pesticide, malicious use of pesticides or baits, or occasionally from accidental exposure (e.g., drift from aerial spraying, cleanup of buildings with old stored products).

All pesticides sold and distributed in the United States must be registered by the U.S. Environmental Protection Agency (EPA). Registration is based on scientific data demonstrating that the chemicals can be used without posing unreasonable risks to people or the environment. With advancement of science, all pesticides that were first registered before November 1, 1984 were required to be reregistered to meet the more stringent standards. The U.S. Code of Federal regulations established four acute toxicity categories for acute hazards of pesticide products (with Category I the most toxic and Category IV the least toxic or irritating) based on five types of exposure: oral, dermal, inhalation, ocular irritation, and skin irritation.[1] These categories can be used for regulatory purposes, precautionary statements, human hazards, and personal protection equipment statements. General scientific data on the toxicity of pesticides can be located on the Internet for the EPA (www.epa.gov) and in numerous databases supported by the U.S. National Library of Medicine such as ToxNet (http://toxnet.nlm.nih.gov) using search terms for the chemical, CAS number, trade name, or clinical sign. The product label can also provide data on potential toxicosis.

Unfortunately for large animals, there is a limited number of antidotes available for treatment of pesticide and rodenticide toxicoses.[2] For example, atropine sulfate, epinephrine, and vitamin K_1 do not have New Animal Drug Approval and are not formally approved by the Food and Drug Administration/Center for Veterinary Medicine (FDA/CVM), but the labels are reviewed and on file with the FDA/CVM.[3] These drugs may be used as antidotes in food animals, but the veterinarian should contact the Food Animal Residue Avoidance Databank (FARAD, www.farad.org or 888-873-2723) regarding withdrawal times if animals or milk will be put into the food chain. Regulatory considerations and information needed when using drugs not formally approved by the FDA in a toxicosis have been recently summarized for food practitioners and are not discussed here.[4] Because these toxicoses generally involve pesticides in nontarget species or at high concentrations, withdrawal intervals for these chemicals in food animals are often not readily available. A reasonable place to start locating this information is through contact with your state veterinarian, the District Office for the FDA in your region, and the U.S. Department of Agriculture Food Safety and Inspection Service (USDA FSIS, www.fsis.usda.gov). The state veterinarian may also assist with recommendations for proper disposal of chemically contaminated carcasses.

Organophosphates and Carbamates

Historically, inappropriate use or overdosage with these compounds was associated with a large number of toxicoses, particularly in herd situations. With the introduction of newer types of external parasiticides and chemical products, the incidence of these toxicoses has diminished significantly. Both organophosphate (OP) and carbamate insecticides inhibit acetylcholinesterase (AChE) at cholinergic nerve synapses and at neuromuscular junctions. They also inhibit other cholinesterases in the body (e.g., red blood cells, serum, liver, pancreas, nervous tissue). These insecticides lack species selectivity and may pose a hazard to domestic and companion animals, wildlife, and aquatic species. The anticholinesterase compounds may adversely affect the cardiovascular, respiratory, ocular, reproductive, endocrine, dermal, and immune systems but primarily act on the nervous system and skeletal muscles.[5] Death is usually the result of respiratory failure, often with cardiovascular involvement.

Approximately 200 OPs and several dozen carbamate compounds have been synthesized for numerous purposes. They are incorporated into a number of products including baits, dips, dusting powders, sprays, pour-ons, and oral anthelmintics. The OPs used as defoliants and herbicides, such as glyphosate and gluphosinate, have low acute mammalian toxicity but could induce delayed polyneuropathy.[5] Aldicarb, sold under the trade name Temik, was synthesized to mimic acetylcholine and is considered to have maximum potential for mammalian toxicity.[5]

Both OPs and carbamates inhibit the metabolism of acetylcholine at cholinergic sites. Acetylcholine is a neurotransmitter at postganglionic parasympathetic neurons in smooth muscles, cardiac muscles, or exocrine glands; at neuromuscular junctions of the somatic nervous system; at cholinergic synapses in the central nervous system (CNS); and between preganglionic and postganglionic neurons of the autonomic nervous system. The enzyme acetylcholinesterase (AChE) normally breaks down acetylcholine at these cholinergic sites, but when bound by OPs or carbamates it is inactive. During toxicity, acetylcholine maintains depolarization of the postsynaptic membrane, which is initially stimulatory but may progress to paralysis. The OPs have high affinity for the cholinesterase enzyme and are considered irreversible inhibitors of AChE. Organophosphates can undergo an "aging" process, which stabilizes the OP-acetylcholinesterase bond and cannot be broken. Carbamates do not undergo "aging" and can be dislodged from AChE, resulting in spontaneous enzyme regeneration. These insecticides also induce toxic effects through noncholinergic mechanisms that may involve glutamate release and activation of *N*-methyl-*D*-aspartate receptors

VetBooks.ir

and the γ-aminobutergic, adenosinergic, and monoaminergic systems that are involved in seizures, which are reviewed by Gupta and Milatovic.[5]

The toxicity of OPs and carbamates varies widely, from highly toxic compounds (OP nerve gases such as Sarin, Soman, VX, and carbamates such as aldicarb and carbofuran) to minimally toxic (e.g., malathion, tetrachlorvinphos). The very young, very old, and weakened animals are more susceptible to poisoning from these compounds. Following exposure, OPs and carbamates are rapidly distributed throughout the body and can undergo oxidation, hydrolysis, and conjugation. They are excreted in the urine and feces. The OPs tend to be more lipophilic than carbamates and are more likely to cross the blood-brain barrier; however, carbamates may cause marked CNS signs. Clinical signs can occur within minutes to hours of exposure depending on the dose, route of exposure, and toxicity of the insecticide. Death can occur within minutes with highly toxic chemicals or when large amounts are ingested. Repeated exposures can be clinically important. The insecticides may be metabolized and excreted within days of exposure, but the regeneration of AChE may require 2 weeks.[6] Clinical signs of acute toxicity due to OP and carbamate exposures result from overstimulation of muscarinic and nicotinic acetylcholine receptors because of the buildup of acetylcholine from inactivation of AChE. The clinical effect is excessive synaptic neurotransmitter activity and depolarization of effector organs.[7] Muscarinic signs include pytalism, excessive tracheobronchial secretions and sweating, bronchospasms and laryngospasms, lacrimation, nausea, diarrhea, miosis, and bradycardia. The muscarinic clinical signs are frequently described by the term "SLUD" or salivation, lacrimation, urination, and defecation. Nicotinic clinical signs include muscle fasciculations, tremors, weakness, ataxia, flaccid paralysis, vomiting, and paralysis of respiratory muscles. Muscarinic signs generally appear first, followed by nicotinic signs, and finally CNS effects (hyperactivity and seizures).

Not all clinical signs are observed in an OP or carbamate toxicosis. The clinical appearance of an anticholinesterase toxicosis may vary with the species exposed, toxic compound, dose, route of exposure, and time line in exposure-response. For example, the use of methiocarb as a snail bait in Australia uncommonly causes problems in horses but can result in AChE inhibition, clinical signs, and death. A 400-kg gelding developed clinical signs of profuse sweating, hypersalivation, lateral recumbency, paralysis of a distal hindlimb, and generalized muscle tremors within a few hours after consuming almost 20 g of methiocarb in bait form (1 kg of 2% weight/volume).[8] The horse had signs of colic, ileus, and a significant amount of nasogastric reflux (total reflux volume after presentation at a veterinary clinic was 55 L) but never developed diarrhea. Because of the large volume of nasogastric reflux, activated charcoal was not given nor was atropine administered due to the lack of gastrointestinal borborygmi. Gastric lavage had been performed about 6 hours post ingestion but was probably ineffective to recover ingested bait; the authors speculated that the worsening clinical signs were due to continued absorption of methiocarb, and the horse was euthanized about 54 hours post ingestion of the bait.

Delayed toxicosis has occurred with the use of chlorpyrifos, a chlorinated OP, as a pour-on in bulls and some exotic breeds of cattle. The toxicity appeared to be related to testosterone levels in cattle, with larger and older bulls affected. Clinical signs appeared 2 to 7 days post exposure and included weakness, muscle fasciculation, anorexia, rumen stasis and distention, and depression.[9] Decontamination of the skin and rumen, activated charcoal, and symptomatic treatment are recommended for treatment of chlorpyrifos poisoning in bulls.

Diagnosis of OP or carbamate toxicosis includes (1) history and clinical signs consistent with the toxicosis; (2) determining cholinesterase inhibition (whole blood, retina, brain), corresponding with adverse clinical effects; and (3) detection of the insecticide in biological tissues (gastrointestinal contents or tissues). The diagnosis can be challenging. Clinical pathologic changes are not consistent and postmortem lesions are nonspecific. Often pulmonary edema is evident on postmortem, along with tracheal fluid and diarrhea, but these changes are not unique to AChE toxicosis.

Measurement of cholinesterase activity in whole blood and brain is commonly used to establish an OP or carbamate diagnosis. Generally, AChE activity less than 50% of normal indicates exposure, and less than 25% of normal in an animal with compatible clinical signs indicates toxicosis from an OP and/or carbamate. Use of AChE activity alone is not always diagnostic. The use of OP anthelmintics in horses at therapeutic doses decreased AChE activity to less than 25% of normal, while no horses displayed clinical signs.[10] Interpretation of AChE activity is difficult in a carbamate toxicosis. Carbamates can spontaneously dislodge from the cholinesterase enzyme before or after sample collection; therefore, AChE activity may be in the normal range even though the animal is experiencing toxicity from a carbamate compound.

Check with your diagnostic laboratory for proper collection of specimens (whole blood, brain, plasma, serum, retina) for AChE activity. With an OP exposure, AChE activity in whole blood is fairly stable for about 7 days after collection if the blood is stored under refrigeration.[10] For determination of AChE activity in the brain, submit a chilled whole or half brain because cholinesterase activity varies with different regions of the brain and the laboratory may have a preference for the brain region tested.

Identification of the insecticide can often be made on postmortem specimens including rumen, gastrointestinal contents, liver, fat, brain, and perhaps kidney. Samples should also be taken of the suspect source (e.g., bait, feed, water) for identification and concentration. It is not unheard of to have acute death losses in animals, finding depression of AChE in brain, whole blood, and retina, detecting the insecticide in rumen contents, but locating no source of insecticide on the farm.[11] With suspect insecticide toxicosis, check with the diagnostic laboratory for proper collection and shipment of samples. Generally, the samples are kept chilled or frozen before analysis. Management of OP or carbamate toxicosis is dependent on the clinical signs and time from exposure. Treatment should be initiated quickly. If the animal is having seizures, stabilize the animal and attempt to control the seizures with diazepam, which may also need to be supplemented with methocarbamol, barbiturates, or general anesthesia. Oxygen therapy and ventilatory support may help with severe dyspnea. The noncompetitive antagonist for OPs and carbamate is atropine, which blocks excessive acetylcholine at synapses. It can control muscarinic signs and some CNS signs, but not nicotinic signs (e.g., muscle fasciculations, weakness, paralysis). The therapeutic range for atropine sulfate is between 0.25 and 1 mg/kg, with one quarter of the dose given intravenously and the remainder administered IM or SC.[6,7] It may be necessary to use the high end of the range in toxic situations. The dose should be repeated as needed (usually a lower dose and every 2 to 4 hours) to control bradycardia and secretions into the lungs. Avoid overtreatment with atropine, especially during prolonged treatment. Note that atropine has a low margin of safety in horses and causes gastrointestinal stasis, which should be carefully monitored during use. It is recommended not to exceed a total dose of 65 mg of atropine in the average horse.[6] When atropine is used in multiple doses as an antidote for a toxicosis, a 6-day milk withdrawal and a 28-day meat withdrawal have been recommended.[3] Note that veterinarians must also consider the residue/withdrawal interval for the insecticide in tissues.

Acetylcholinesterases can be reactivated with oximes, such as pralidoxime chloride (2-PAM), if aging has not occurred. The oxime attaches to the OP insecticide and dissociates the OP-cholinesterase bond. Response to oxime therapy is better when oximes are used within 24 hours after exposure to OP insecticides. Oximes ameliorate to some degree muscarinic, nicotinic, and CNS signs and work best with atropine. The dose, frequency, and route of administration of 2-PAM vary in the literature. A dose of 20 mg/kg IV q4-12h has been recommended in ruminants; the use should be stopped if no response occurs within 36 hours.[12] Excessive doses of oximes have the capability to inhibit cholinesterase.[5] The use of 2-PAM in treatment for a large animal OP toxicosis would be very expensive; in

VetBooks.ir

addition, 2-PAM is not approved for use in large animals and should be used with oversight under FDA/CVM guidance. Generally, 2-PAM is not used in carbamate toxicosis because the inhibition of AChE is spontaneously reversible by hydrolysis. In some cases the use of 2-PAM in carbaryl (carbamate) toxicity has been considered detrimental. However, in a murine model dosed with a lethal concentration of carbaryl, the use of a low dose of 2-PAM (25 mg/kg) with atropine improved survival to 24 hours.[13] The authors cautioned that the beneficial results of low-dose 2-PAM in a carbaryl toxicosis are based on a murine model (same sex, same age, same strain) using one carbamate with a small sample size.

Once the animal is stabilized, decontamination should be considered. Oral dosage of activated charcoal (1 to 2 lb/500 kg in a slurry) can bind the insecticides in the gastrointestinal tract and prevent absorption; this treatment may also be helpful with topical application of some insecticides. The use of activated charcoal is particularly recommended for ruminants, which have the capacity for large retention of gastrointestinal contents. With topical exposure to insecticides, animals should be washed with a liquid dishwashing detergent and rinsed off to reduce absorption. Gastric lavage with water may be indicated in high-dose exposures where only a few hours have passed since ingestion. Additional therapy may include fluids to treat dehydration and electrolyte imbalances.

Several drugs are contraindicated in OP and carbamate toxicosis (with cholinesterase inhibition) including opiates, physostigmine, phenothiazine tranquilizers, neostigmine, succinylcholine, levamisole, antihistamines, aminoglycoside antibiotics, and theophylline.

Pyrethroids

Pyrethroids are active synthetic derivatives of natural toxins in the plant *Chrysanthemum cinerariaefolium* and *Chrysanthemum cineum*. These chemicals are important insecticides used in crop protection, for controlling insect vectors carrying infectious diseases of animals and humans, and for controlling insects on premises. They are available as wettable powders, granules, and emulsifiable concentrates in sprays, dusts, dips, foggers, ear tags, pour-ons, and back rubbers. Pyrethrins are the naturally active insecticidal compounds from the plants; pyrethroids are synthetic analogs of the pyrethrin esters and tend to have more potent insecticidal activity, tend to be more stable in the environment, and tend to be more toxic. The pyrethroids are categorized as type I pyrethroids (a cyano group is absent) or type II pyrethroids (an alpha-cyano group is present that increases the insecticidal potency). Allethrin, bifenthrin, permethrin, resmethrin, and tefluthrin are examples of type I pyrethroids. Cyfluthin, cypermethrin, deltamethrin, and flumethrin are examples of type II pyrethroids. Often, synergists such as piperonyl butoxide, propyl ethers, and sesamin are combined with pyrethroids to inhibit mixed-function oxidase and esterase enzymes in the target species and reduce detoxification of the insecticide and prolong its action in insects. Synergists may also enhance toxicity in animals. Pyrethroids interfere with conductance of nerve membranes by binding to the membrane and prolonging the sodium current. The pyrethroids act on axons in the central and peripheral nervous systems. Gamma-aminobutyric acid-gated chloride channels may also be affected by high doses of type II pyrethroids. Compared with insect sodium channels, mammalian sodium channels are much less sensitive to pyrethroids and recover more quickly from depolarization.

Most pyrethroids are applied dermally, and there is limited absorption through this route. Pyrethroids are absorbed more efficiently across gastrointestinal and pulmonary membranes. Pyrethroids are lipophilic in nature and distribute into fat, central and peripheral nervous systems, milk, and other organs. Once absorbed, pyrethroids can undergo metabolism by nonspecific esterases and microsomal mixed-function oxidases. Pyrethroids and their metabolites are excreted in feces and urine, with a majority of pyrethroids excreted within 12 to 48 hours.[14]

Following application of pyrethroid pour-on products, cattle can exhibit a paresthesia-like syndrome, thought to result from direct action of pyrethroids on sensory nerve endings.[14] Cattle may be restless and uncomfortable, and twitch the skin on their backs. Young animals are more susceptible due to a lack of metabolism of pyrethroids; death can occur due to respiratory failure and convulsions leading to paralysis. No specific clinical pathologic or histopathologic changes have been reported with pyrethroid applications. In a toxicosis, check with the veterinary diagnostic laboratory regarding analytic testing on appropriate tissues. Pyrethroids concentrate more in nervous tissue than serum or plasma.

Pyrethroids have been implicated with disruption of the endocrine system, adversely affecting reproduction and sexual development, and interfering with the immune system. Pyrethroid treatment of laboratory animals and in vitro samples have induced a decrease in epididymal sperm count and sperm motility, as well as an increase in abnormal spermatozoa.[15,16] Pyrethroid treatments of mice and rats disrupt testosterone synthesis and downregulate 17 β-hydroxysteroid dehydrogenase (converts androstenedione to testosterone) and biosynthetic enzymes that have a critical role in the synthesis of testosterone in Leydig cells.[17,18] In addition, pyrethroid exposure has been shown to disrupt luteinizing hormone-responsible ovulatory genes in rats and prostaglandin synthesis in granulosa cells in vitro.[19]

Exposure of bulls in a bull stud to bifenthrin was associated with poor semen quality, including (1) decreased motility, (2) reduced ejaculate volume, and (3) spermatozoa abnormalities with a high percent of distal midpiece reflexes.[20] At 64 days post exposure, semen quality recovered to levels observed preexposure in these bulls. In this case, the use of bifenthin was apparently an excessive use of product in a building (bull stud) with the animals present so that excessive exposure was dermal, inhalation, and oral; additionally, these animals were being continually monitored for semen quality for cryopreservation and, therefore, clinical abnormalities in semen were easily detected.[21] Field cases of bulls exposed to pyrethroids and subsequently developing poor sperm quality and motility, with gradual recovery to normal after about 2 to 4 weeks, have been reported.[22,23] There is little scientific data, however, with controlled studies to support observations that use of pyrethroids will alter sperm quality in bulls.

Accidental pyrethroid exposure in bulls may result in inadequate semen quality (particularly for cryopreservation) but may not impair bull fertility when bulls are used in natural settings, such as pasture breeding where a number of males are available to breed female cows during a breeding season. The important considerations when using pyrethroids on pastured cattle are to exactly follow the application recommendations on the label, to use a product that the cattle producer has experience with for insect control, and to avoid using close to breeding if possible.[21] Another recommendation is to use only one method of insect control with pyrethroids on breeding cattle at a time (e.g., only spraying or only ear tags).[23]

With dermal exposure, wash and scrub the exposed area using liquid dishwashing soap and rinse well. Avoid using power washers because they may cause dermal trauma.[14] If seizures occur, the use of diazepam, methocarbamol, and barbiturates may be effective.

Neonicotiniamides

A relatively new and emerging class of insecticides are the neonicotinoids, which are heterocyclic nitromethylenes used primarily in crop protection against sucking and certain chewing pests. The neonicotinoids include imidacloprid, acetamiprid, dinotefuran, thiamethoxam, and clothianidin.

The neonicotinoids act on postsynaptic nicotinic receptors located in the CNS of insects. These insecticides initially increase the frequency of spontaneous discharge, which is followed by a complete block of nerve propagation. Neonicotinoids are considered relatively low risk for nontarget organisms and the environment.[24] The activity in vertebrates is much lower due to different binding properties to the nicotinic receptors, and they primarily act on the α_7 nicotinic receptor subtype.

Imidacloprid is used as an insecticide for dermal application on animals, as well as an insecticide for crop protection. Neonicotinoids do not readily pass the blood-brain barrier. Imidacloprid is primarily

VetBooks.ir

metabolized in the liver.[24] Metabolism of imidacloprid in mammals is by two routes: (1) oxidative cleavage and glutathione conjugation and (2) hydroxylation. Most of the imidacloprid is rapidly excreted in the urine. It is not carcinogenic nor a reproductive toxicant.

Adverse effects noted in laboratory animals dosed with imidacloprid were decreased activity and tremors, impaired pupillary function (dilated or pin point), and uncoordinated gait; higher doses were associated with hypothermia. The no observed effective level (NOEL) for chronic imidacloprid exposure in dogs was 15 mg/kg PO.[25]

Treatment for overdoses of imidacloprid is symptomatic. With dermal exposure wash the animal with soap and water, and with oral exposure use activated charcoal for adsorption and a cathartic. Generally, imidacloprid absorption and elimination are rapid and supportive care should provide recovery.

Organochlorines

Organochlorines are chlorinated hydrocarbons. These compounds include lindane, mirex, kepone, dichlorodiphenyltrichloroethane (DDT), aldrin, dieldrin, heptachlor, chlordane, toxaphene, and endosulfan. The persistence of some organochlorines in the environment and concern for neurotoxicity and endocrine disruption have terminated the use of most organochlorines. These compounds have limited to no distribution in the United States but may occasionally cause toxicoses when stored chemicals contaminate feed or premises. Organochlorines are available in other countries.

The organochlorines have several mechanisms of action. The DDT-type organochlorines affect the brain and peripheral nerves by slowing sodium influx and inhibiting potassium outflow, partially depolarizing the cell and increasing firing of the neuron.[26] Several organochlorines may act by inhibiting attachment of γ-aminobutyric acid to its receptor, which stimulates the neuron. The organochlorines are absorbed orally and dermally. These compounds are highly lipid soluble and distribute to adipose tissue, brain, liver, kidney, and milk. Metabolism of organochlorines can be through dechlorination and oxidation, glucuronidation, and sulfation. More toxic epoxides can be formed by the mixed-function oxidases. The organochlorines are excreted into bile and the gastrointestinal tract. They can undergo enterohepatic recycling, prolonging exposure for weeks. These compounds bioaccumulate in fatty tissue and persist in the environment. Organochlorines can act as endocrine disruptors.

Acute clinical signs include salivation, vomiting, and nervous system signs of agitation, hyperexcitability, incoordination, apprehension, nervousness, and tremors. As clinical signs progress, animals may display clonic-tonic seizures, opisthotonus, paddling, and clamping of the jaw. Cattle may walk backward, lick excessively, or have abnormal postures.[26] Seizures can persist for several days. Between seizures the animals may be depressed or normal in appearance. Clinical pathologic changes and histopathology are nonspecific.

Diagnosis is based on history, clinical signs, and analytic determination of organochlorines in blood, fat, liver, brain, or milk. Contact the veterinary diagnostic laboratory for sample submission instructions. Generally, samples for organochlorine analysis should not be submitted in plastic but wrapped in aluminum foil and/or placed in clean glass containers. Note that tissue levels of organochlorines do not correlate well with severity of clinical signs or prognosis.

Detoxification is an important step in treatment. Animals with topical exposure need to be washed with soap and water; animals with long hair should be clipped to reduce organochlorine exposure. Treating personnel should wear gloves and aprons to reduce exposure. With oral exposure, activated charcoal (1 to 2 g/kg body weight in a slurry) should be administered orally. Feeding activated charcoal, at 500 to 1000 g/day for a limited time, to large animals will reduce enterohepatic cycling.[26] General supportive care, such as the use of diazepam or barbiturates to control seizures, and placing the animal(s) in an environment to prevent trauma and keep comfortable are important. Organochlorines typically have a prolonged residue time in body tissue. Animals that are lactating or losing weight generally eliminate more organochlorines due to loss of milk fat or body fat, respectively.

The state veterinarian should be contacted regarding exposure of animals to organochlorines and proper disposal of contaminated tissue or materials. The long persistence of organochlorines in tissue prevents immediate placement of food animals or milk into the food chain; proper state or federal agencies will need to be contacted for withdrawal intervals.

Paraquat

Paraquat is a bipyridyl herbicide used as a desiccant on crops. Most questions regarding paraquat exposure in large animals deal with aerial spray drift onto animals and/or their pasture and application to forages that will be used for livestock. Paraquat absorbed onto soil particles is biologically inactive. Animals that have access to concentrated paraquat formulations or to wet forages following paraquat application are at risk for developing clinical signs.

Paraquat is poorly absorbed (5% to 10%) from the intestinal tract but has prolonged residual time in the digestive tract. Emulsifiers or other chemicals in paraquat formulations may enhance absorption and toxicity. Paraquat is concentrated in renal tissue and is eliminated in the urine.

Paraquat forms free radicals in the body and has special affinity for the lung. The production of superoxide radicals and hydrogen peroxide results in damaged cellular membranes and tissue necrosis.

Following ingestion, the initial signs reflect the irritating action of paraquat resulting in abdominal pain, vomiting, anorexia, and depression. By the second to third day post exposure, the onset of renal failure appears along with liver damage (hepatocellular necrosis), which is followed by delayed development of pulmonary fibrosis, respiratory dyspnea, cyanosis, and pneumomediastinum.[27] Death may occur several weeks after exposure. With topical exposure to paraquat, erythema, blistering of skin, and corneal irritation can occur and may resolve without additional complications.

Histopathologic changes from paraquat toxicosis include apoptosis or necrosis of alveolar epithelial cells, denuded alveolar basement membranes, and with a chronic response, hyperplasia of type II alveolar epithelial cells and pulmonary fibrosis.[28] Hepatic and renal lesions may be present. The diagnosis is based on history of exposure to paraquat and chemical analysis of paraquat in urine, plasma (up to 30 hours post exposure), and lung tissue (after 30 hours post exposure).

Treatment should be initiated as soon as possible (within 24 hours) using activated charcoal, bentonite, or fuller's earth. Supportive care includes monitoring vital signs frequently, using fluids to maintain renal perfusion, treating secondary infections, and employing pain management. If treatment is delayed, the prognosis is extremely poor.

Rodenticides

Zinc and Aluminum Phosphide

Zinc phosphide is a rodenticide used since the 1930s. Zinc phosphide is a gray, crystalline powder, which is relatively stable under dry conditions. Rodent formulations contain 2% to 5% zinc phosphide mixed with grains; therefore, the baits are attractive to most species. Under wet or acidic conditions, zinc phosphide degrades to phosphine gas. Phosphine gas has the odor of acetylene or rotten fish, and poisoning can occur in people at detectable concentrations of 2 ppm. Acute, oral lethal doses of zinc phosphide were recently reviewed in various species.[29] The lethal dose of zinc phosphide in ruminants was approximately 60 mg/kg body weight.

Aluminum phosphide is a fumigant used in stored agricultural products to control rodents and insects. It is classified in Category I by the EPA with high potential of acute toxicity with inhalation exposure.[1] After application of aluminum phosphide tablets to grain, phosphine gas is released for up to 5 days. A general recommendation

VetBooks.ir

is that grain treated with aluminum phosphide should not be handled or fed for at least 10 days after treatment.

Phosphine gas is readily released in acidic environments and can block cytochrome C oxidase, resulting in disruption of oxidative phosphorylation within mitochondria of cells.[30] Blocking energy-producing pathways leads to cell death and eventual multiple-organ failure. Brain, heart, liver, and kidney are most affected by phosphine gas due to high metabolic rates and high demands for oxygen. Because of the higher pH of the rumen, as compared with an acidic monogastric stomach, ruminants should be more resistant to phosphide toxicants.

The onset of clinical signs occurs within 15 minutes up to 12 to 18 hours, depending on the dose and stomach contents (the more acidic, the quicker release of phosphine gas). Death can occur within several hours after appearance of clinical signs. Ruminants show tympany and bloat, while horses can display signs of colic and abdominal pain. Horses fed a pelleted ration recently treated (within 14 hours) with aluminum phosphide showed rapidly developing clinical signs of profuse sweating, tachycardia, tachypnea, pyrexia, ataxia, seizures, and widespread tremors.[31] Clinicopathologic changes include hypoglycemia, high serum lactate and ammonia concentrations, and elevated activity of γ-glutamyl transpeptidase, aspartate aminotransferase, and alkaline phosphatase. Several horses in this case developed clinical signs consistent with hepatic encephalopathy, and eventually 27 out of 28 clinically affected horses died within 2 days after exposure. Postmortem changes were petechial and ecchymotic hemorrhages in numerous organs, widespread vascular congestion, hepatic lipidosis, pulmonary edema, and neuronal necrosis in the cerebral cortex.

Phosphine gas can be detected in gastric contents, vomitus, and possibly liver and kidney. The samples need to be packed in air-tight containers and frozen immediately to prevent phosphine gas dissipation. Check with the veterinary diagnostic laboratory for analytical capability to detect phosphine gas.

The progression of clinical signs often limits treatment options. Early decontamination of the animal by emesis (if the animal vomits), gastric lavage (especially with 5% sodium bicarbonate), and products to increase gastric pH for zinc phosphide exposure is critical. Activated charcoal may be beneficial when mixed with an antacid and a cathartic (e.g., aluminum or magnesium hydroxide). No specific antidote is available for phosphine gas. Supportive therapy should be aimed at correcting acidosis, treating shock and liver failure, and controlling seizures. Horses developing clinical signs after phosphine gas exposure were treated by gastric lavage followed by di-tri-octahedral smectite, atropine, fluids, 10% dextrose, flunixin meglumine, and sedatives.[31]

Metaldehyde

Metaldehyde is a molluscicide, usually sold in less than 5% concentrations as pelleted baits, granules, liquids, and wettable powders. Feed ingredients such as apples, molasses, rice, oats, and soybeans have been added to the baits to increase palatability to nontarget species. Most toxicoses occur in the coastal areas of the United States, where snail and slug populations can be high.

The mechanism of action of metaldehyde is unclear but may be related to alterations of neurotransmitters in the brain. Metaldehyde is toxic to all known animals. Oral ingestion is the most likely route of exposure. Acute, oral lethal doses of metaldehyde were recently reviewed in various species.[32] The lethal dose ranges for metaldehyde were from 200 to 300 mg/kg body weight in ruminants and 60 to 360 mg/kg body weight in horses. Young animals appear to be more susceptible than adults.

Clinical signs of toxicosis usually occur within several hours of exposure and include salivation, restlessness, anxiety, hyperpnea, tremors, colic, ataxia, nystagmus, and convulsions. Blindness and loss of a menace reflex have been reported in cattle with metaldehyde toxicosis.[33] No specific changes in clinical pathology or histologic lesions occurred in animals poisoned with metaldehyde. Gross lesions have included congestion in renal, hepatic, pulmonary, and gastrointestinal tissues and petechial and ecchymotic hemorrhages throughout the body. Demonstration of metaldehyde in gastrointestinal contents (possibly serum/plasma and urine) confirms exposure. Samples should be submitted frozen to the diagnostic laboratory.

Initial therapy may involve control of seizures and tremors with diazepam and barbiturates; xylazine and acepromazine have been used in horses.[32] Decontamination by gastric lavage and activated charcoal, orally at 1 to 2 g/kg body weight, followed by mineral oil has also been recommended. Supportive care with intravenous fluids and a quiet environment may be beneficial.

Anticoagulant Rodenticides

Cases of hemorrhagic disorders reported in cattle generally involve repeated exposure to moldy sweet clover hay or sweet vernal hay (dicoumarol) over a prolonged period of time. Accidental ingestion of anticoagulant baits over a short time period may result in potential toxicosis in large animals. The anticoagulant rodenticides are divided into first-generation coumarin derivatives (e.g., coumachlor, coumatetralyl, warfarin); second-generation coumarin derivatives (e.g., brodifacoum, bromadiolone, difenacoum, flocoumafen); and the indanedione derivatives (e.g., chlorophacinone, diphacinone, pindone). Generally, the second-generation coumarin compounds are more toxic than the first-generation products and can poison with one feeding.

All of the anticoagulant rodenticides interfere with vitamin-K epoxide reductase, which converts inactive vitamin K to the active vitamin. A depletion of active vitamin K may impact vitamin K-dependent clotting factors in the intrinsic, extrinsic, and common coagulation pathways. Anticoagulant rodenticides are well absorbed on oral exposure and are highly bound to plasma proteins. Oral availability of warfarin, chlorophacinone, and bromadiolone in sheep was estimated to be more than 79%.[34] Anticoagulants are metabolized in the liver, and some compounds may undergo enterohepatic recirculation. The half-life of anticoagulant rodenticides varies greatly with the compound and the species. The half-life of brodifacoum in horses was given as 1.22 ± 0.22 days, as compared with that of warfarin in horses at 16 hours.[34,35] The half-life of bromadiolone in cattle was reported to be approximately 20 hours.[34] As a general observation, the duration of action of anticoagulant rodenticides in large animals is about 14 days for warfarin, 21 days for bromadialone, and 30 days for brodifacoum and other second-generation coumarin derivatives. Ruminants are thought to have lower susceptibility to anticoagulants; however, a study in anticoagulant-dosed sheep revealed that the compounds were not degraded in the rumen and their bioavailabilities remained high after oral dosing.[34] The authors speculated that several factors may lower ruminant susceptibility, including the presence of a large forestomach (diluting the compound) and ruminal production of vitamin K_1, which may partially counteract the toxic effects.

Clinical signs may become apparent 2 to 10 days post exposure. Affected animals may display melena, epistaxis, hematuria, or excessive bleeding from a wound. If bleeding occurs within a body cavity, the animal may exhibit pallor, weakness, dyspnea, fever, and depression. Animals may die suddenly from excessive hemorrhage and shock. Generally, gross and histologic lesions are consistent with hemorrhage. Diagnosis is based on history, clinical signs, prolonged clotting times and anemia, and response to the antidote, which is vitamin K_1. Analytic detection of the anticoagulant rodenticide in whole blood, liver, and perhaps gastrointestinal contents can confirm exposure.

Vitamin K_1 is the antidote for anticoagulant rodenticides; the duration of therapy will vary with the specific compound causing the toxicosis and may vary from several days to several weeks. The dose of vitamin K_1 in the adult horse has been recommended at 300 to 500 mg SC q4-6h.[36] The prothrombin time should return to normal within 24 hours. Vitamin K_3, although less expensive to use, is not as effective as K_1, will cause renal disease in horses,[27] and is not recommended.

Packed cell volumes should be closely monitored during clinical signs, and whole blood transfusions may be required if the animal is

VetBooks.ir

anemic. Decontamination of the gastrointestinal tract with activated charcoal may lower absorption of the anticoagulant. After the animal has stabilized and the appropriate time has passed, vitamin K_1 should be discontinued for 48 hours and prothrombin time retested.

1080

Sodium monofluoroacetate, fluoroacetate, or 1080 is a nonselective rodenticide toxic to animals and humans. The compound 1080 has been available in the United States since the 1940s but now is restricted for use as a predacide in the United States. It is used in Australia and New Zealand to kill invasive, unwanted species. Fluoroacetate naturally occurs in several plants in Africa, Australia, South America, and perhaps southern Florida. Sodium monofluoroacetate also appears to be available over-the-counter in the United States as foreign rodenticides or "herbal" pesticides. This compound is colorless, odorless, and water soluble.

The mechanism of action of 1080 involves a critical cycle, the Krebs or tricarboxylic acid cycle, in cellular metabolism. Many of the effects of 1080 toxicosis result from impaired oxidative metabolism and reduced energy production.[37] The oral LD_{50} for monofluoroacetate in ruminants and equines ranges from 0.22 to 0.55 mg/kg body weight.[38] Sodium monofluoroacetate is quickly absorbed from the gastrointestinal and respiratory tracts and through mucous membranes but slowly absorbed through intact skin.

In general, herbivores have cardiotoxic effects, omnivores have cardiac and CNS effects, and carnivores have CNS effects. Clinical signs occur within 30 minutes to several hours post ingestion. Cattle may stagger, tremble, sweat, and display signs of gastrointestinal irritation; they may even die of heart failure.[39] Horses may display hyperesthesia to external stimuli and have marked cardiac arrhythmias and ventricular fibrillation. Sheep and pigs may show a combination of cardiac and CNS signs. Animals may have decreased ruminal movements, salivation, restlessness, apparent blindness, ataxia, frequent urination, muscular tremors, polypnea, and tachycardia. Pigs may have intermittent vomiting. Clinical pathology changes may include hyperglycemia, increased serum citrate, hypocalcemia (ionized), and acidosis. Electrocardiograms on 1080-poisoned sheep revealed S-T segment elevation and a marked increase in T-wave amplitude, suggesting cardiac ischemia.[40] Severely affected animals generally die within a few days post exposure. Postmortem lesions in ruminants may involve endocardial and epicardial petechiae, edema of the brain, and lymphocytic infiltration of perivascular tissue. A diagnosis of 1080 toxicosis is based on clinical signs, history of exposure, and detection of 1080 in the bait, vomitus/gastric contents, kidney, and liver. Few veterinary diagnostic laboratories in the United States analyze for 1080 in tissues. Generally the assay is by gas chromatography/mass spectrometry with a detection limit of 10 µg/kg (or parts per billion).

A recent case of 1080 toxicosis involved high, acute death loss in ewes and lambs following transfer of the flock to a new pasture over a municipal landfill site.[41] Clinical signs observed in affected animals were disoriented running and breaking through fences, apparent blindness, weakness, and ataxia. Gross lesions included pulmonary congestion and edema and epicardial petechiae and ecchymotic hemorrhages on the ventricles. Histologic changes were acute to subacute myocardial degeneration and necrosis with neutrophilic and lymphohistiocytic myocarditis. Compound 1080 was detected in several kidney samples, but the source of 1080 was not determined. No long-term effects on health or reproductive performance were observed in ewes that survived experimental dosing with a single, near-lethal amount of 1080.[40]

Compound 1080 has no known antidote, and the rapid onset of clinical signs may prevent effective, quick decontamination of the gastrointestinal tract with activated charcoal. A treatment protocol for 1080 toxicosis in dogs involves gastric lavage followed by activated charcoal, control of seizure and convulsions with barbiturates or gas anesthesia, fluid therapy including sodium bicarbonate, monitoring serum calcium and potassium, and use of acetamide if available.[42] The prognosis for most cases of 1080 toxicosis is poor.

Strychnine

Strychnine is a rodenticide often sold at 0.5% to 1% concentrations in a powder, pellets, or with grain bait for below-ground application. Strychnine-treated seeds are often dyed red or green. In several states, the use of strychnine is restricted. Storage of old containers of strychnine-laced grains can be sources of accidental toxicoses. Accidental and malicious toxicoses continue to occur fairly regularly.

Strychine is an alkaloid from the seeds of *Strychnos nux-vomica* and *ignatii*. Strychnine blocks inhibitory action of glycine at the inhibitory neurons, Renshaw cells, spinal cord, and medulla. The lack of inhibition leads to rigidity and tetanic convulsions. Strychnine is quickly absorbed from the gastrointestinal tract and widely distributed in the body. A small portion of the dose is excreted into urine. Hepatic enzymes can readily metabolize strychnine.

Clinical signs can appear within a few minutes to a few hours and include sweating, nervousness, incoordination, recumbency, and tonic-clonic seizures. The seizures can be induced by stimuli such as bright light, loud noises, and touch. No specific clinical pathology or histologic changes occur in strychnine toxicoses. Analytic determination of strychnine in gastric contents (and to a lesser extent in urine, serum/plasma, liver, and kidney) confirms a strychnine toxicosis.

Decontamination by gastric lavage followed by oral administration of activated charcoal (binds strychnine) is important; however, the degree of sensory stimulation may require initial treatment to control seizures and support respiration. The use of barbiturates along with diazepam and methocarbamol may control seizures. Severe respiratory dyspnea may require mechanical ventilation. Additionally, intravenous fluid therapy and a quiet environment may be beneficial. Prognosis for treatment of large animals with strychnine toxicosis is poor because of the difficulty of treating animals in the field. In one case report, several horses had access to an old bag of strychnine-contaminated barley. Clinical signs of CNS stimulation were observed in five out of six horses, with two horses dying. Treatment in the field consisted of activated charcoal and mineral oil to assist decontamination of the gut and xylazine, diazepam, and pentobarbital for CNS signs.[43]

A

Abdomen
  acute. *See* Acute abdomen
  contours of, 781-782, 782f, 791
  examination of, 801
  external palpation of, 297
  in neonates, 297
  ultrasound evaluation of, 16
Abdominal abscess
  illustration of, 482f
  Rhodococcus equi, 703f
Abdominal cavity, 5
Abdominal distention
  description of, 98-100, 99b
  in neonatal ruminants, 312-314, 312b
  in neonates, 297
  in ruminants, 312-314, 312b
Abdominal pain
  assessment of, 799-800
  cranial, 801
  Cryptosporidium parvum as cause of, 24f
  duodenitis–proximal jejunitis and, 697
  large colon impaction as cause of, 716
Abdominal paracentesis, 639
Abdominal pings, 5-6
Abdominal radiography
  in foals, 233
  traumatic reticuloperitonitis, 809
Abdominal sounds, 792
Abdominal splinting, 2-4
Abdominal ultrasonography
  abomasal ulcer evaluations, 816
  in foals, 233
  in ruminants, 767-777
Abdominal veins, 8
Abdominal wall distention, 791
Abdominocentesis
  abomasal ulcers, 816
  acute abdomen, 802
  caudal, 809f
  equipment for, 809f
  fever of unknown origin evaluations, 38t
  in foals, 233-234
  peritonitis evaluations, 724-725, 724t
  traumatic reticuloperitonitis, 806
  vomiting evaluations, 101
Abducent nerve
  dysfunction of, 127t
  examination of, 118-119
Abduction, 109t
Abnormal labial approximation, 1338
Abnormal offspring syndrome, 280
Abnormal peripheral pulse, 86-87, 86f, 87b
Abnormal respiratory noise. *See* Stridor
Abomasal bloat
  in lambs, 314
  in neonatal ruminants, 313-314
  sudden death caused by, 217
Abomasal dilation
  in calves, 790
  in Suffolk sheep, 817-818
Abomasal displacement
  etiology of, 812
  incidence of, 812
  left, 812-813, 812f
  in neonatal ruminants, 313
  pathophysiology of, 812
  prevalence of, 812
  right, 812f, 813-814
  surgery for, 812-813
  ultrasonography of, 774
Abomasal impaction, 818-820
Abomasal reflux, in calves, 789f
Abomasal ulcers
  blood transfusions for, 817
  in calves, 312-313
Abomasal ulcers *(Continued)*
  clinical pathology of, 816
  clinical signs of, 815-816
  control of, 817
  definition of, 815
  differential diagnosis of, 815-816
  epidemiology of, 817
  etiology of, 815
  necropsy findings, 817
  in neonatal ruminants, 312-313
  pathophysiology of, 816-817
  peritonitis and, 297, 816
  prevention of, 817
  prognosis for, 817
  sudden death caused by, 217
  treatment of, 817
  types of, 815-816, 816t
Abomasal volvulus
  acid-base imbalances in, 815
  clinical pathology of, 814
  clinical signs of, 814
  control of, 815
  differential diagnosis of, 814
  necropsy findings, 815
  pathophysiology of, 814-815
  prevention of, 815
  prognosis for, 815
  right-displaced abomasum versus, 814
  schematic view of, 812f
  signs and symptoms of, 5-6
  treatment of, 815
Abomasum
  displacement of, 5-6, 6f
  distention of, 774
  gas ping localization to, 5-6
  left displaced, 6, 6f
  right displaced, 6f
  in ruminants, 774, 774f
  torsion of, 5-6, 6f
  ultrasonography of, 774, 774f
Abortion
  bluetongue, 1352
  border disease, 1352
  bovine virus diarrhea virus as cause of, 755-756
  Brucella abortus, 1347-1348, 1481
  Brucella melitensis, 1353
  Brucella ovis, 1353
  in camelids, 1354
  Campylobacter fetus subsp. *fetus*, 1352-1353
  Campylobacter fetus subsp. *venerealis*, 1348
  causes of, 223b
  Chlamydia psittaci, 1345t, 1353-1354
  in cows
    bovine herpesvirus 1 as cause of, 1344, 1345t
    bovine virus diarrhea virus as cause of, 1345-1346
    causes of, 1345t
    epizootic bovine abortion, 1347
    leptospirosis as cause of, 1346-1347
  Coxiella burnetii as cause of, 1345t, 1352
  diagnostic approach to, 185-187, 187t
  endotoxemia as cause of, 1344
  enzootic, 1463t-1464t
  epizootic bovine, 1347
  fungal, 1340-1341, 1351-1352
  in goats, 1345t, 1352
  Histophilus somni as cause of, 1348
  in horses
    causes of, 1338t
    description of, 184-185, 223b
    endotoxemia as cause of, 1344
    equine herpesvirus-1 as cause of, 184, 1338t, 1341-1342
    equine viral arteritis as cause of, 1338t, 1342-1343
Abortion *(Continued)*
    insect-related, 1343-1344
    leptospirosis as cause of, 1343
    noninfectious causes of, 1339

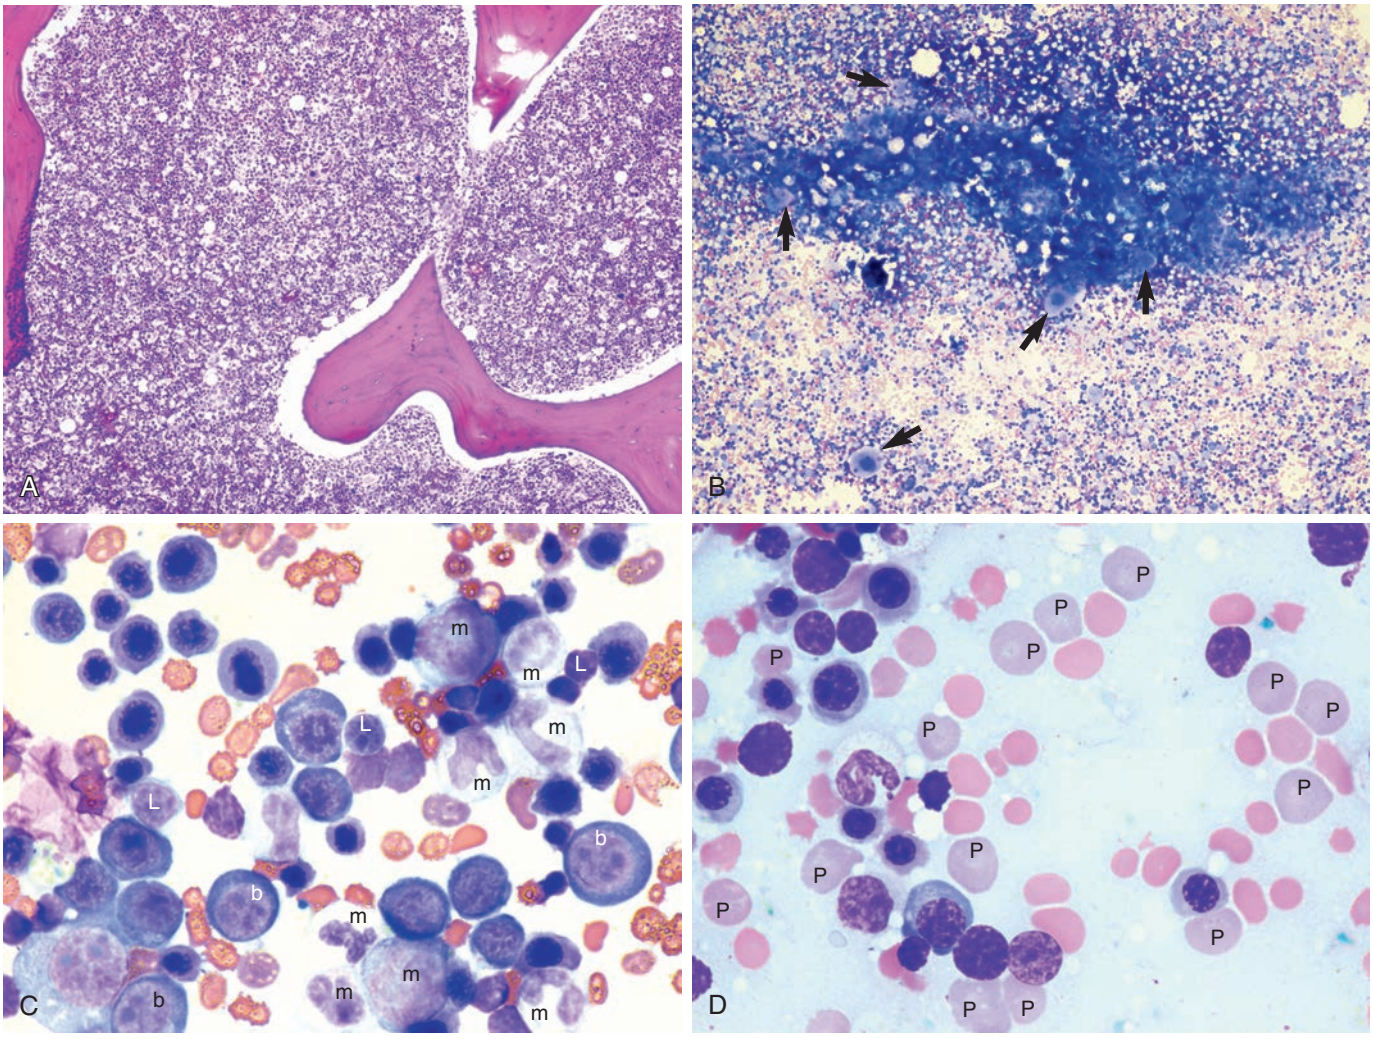

PLATE 28-1 Bone marrow biopsy and aspirate from a 5-year-old female Quarter Horse with marked anemia (PCV = 9%; 31% to 47%) and thrombocytopenia (42,000 platelets/µL; 125,000 to 300,000/µL). The bone marrow is highly cellular as seen in **A** (H&E) and **B** (Wright-Giemsa); arrows point to megakaryocytes, 10× objectives. The M:E ratio is decreased at 0.3, and polychromatophils comprise 30% of RBCs. **C** shows a large erythroid population (unmarked cells and b = erythroblast) with fewer myeloid cells (m) and lymphocytes (L); many polychromatophils (P) can be seen in **D** (Wright-Giemsa, 100× objective). This is representative of regeneration and consistent with either chronic blood loss or immune-mediated destruction of erythrocytes, which could both be occurring in this horse. The horse was diagnosed with intramuscular hemangiosarcoma.

VetBooks.ir

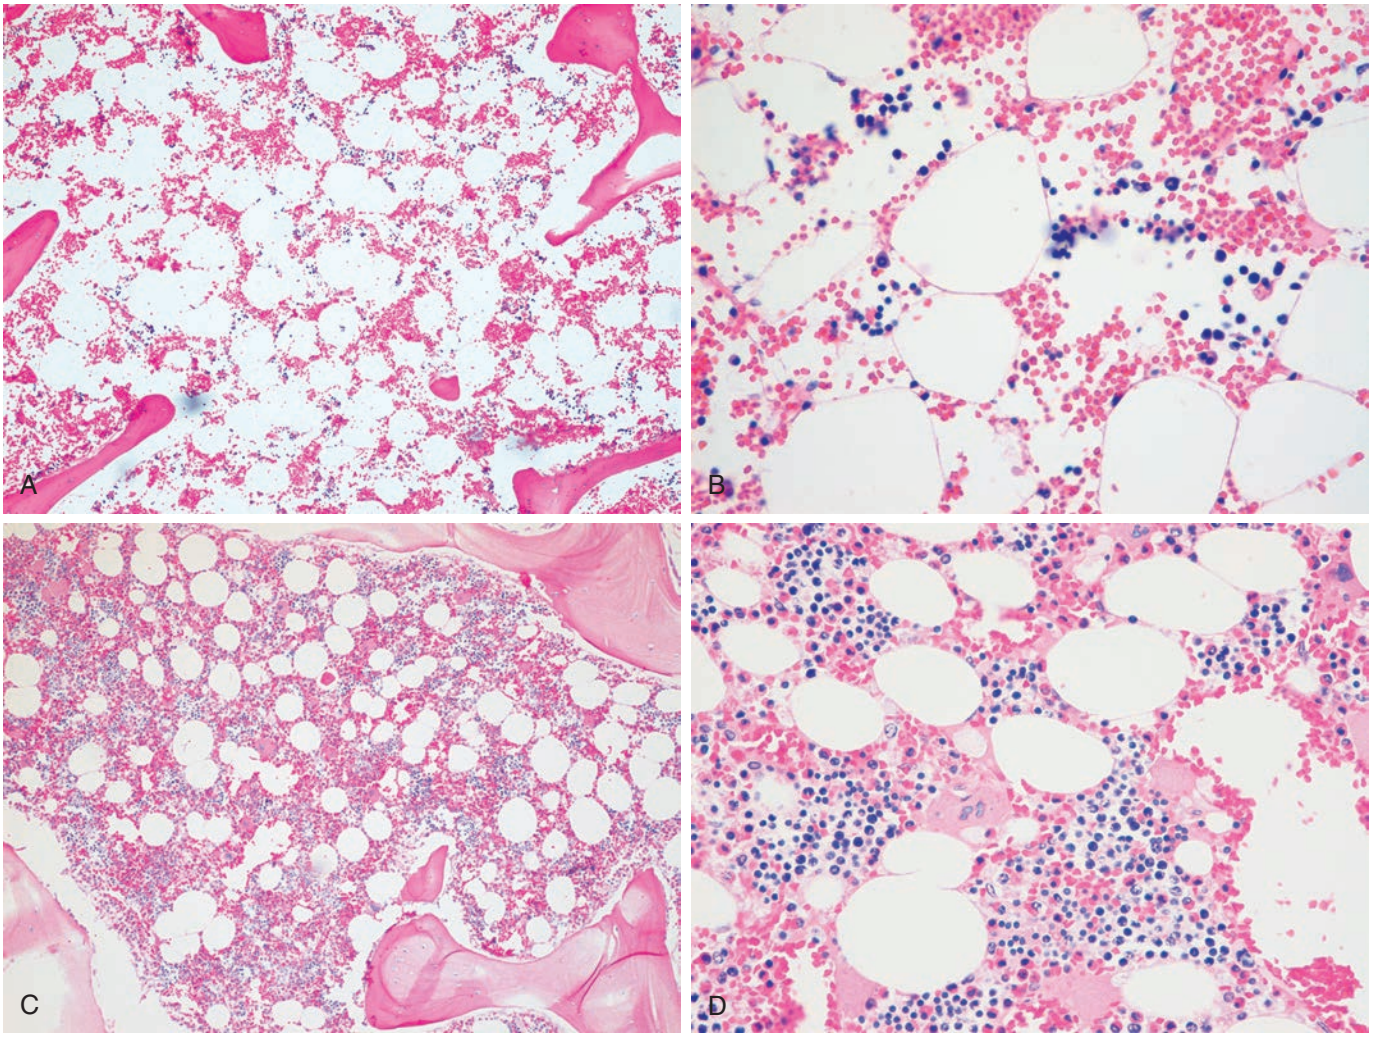

PLATE 28-2 Bone marrow biopsy from a 2-year-old mixed breed steer with mild anemia (PCV = 23%; 24% to 46%) and severe neutropenia (0/µL; 600 to 4000/µL) and thrombocytopenia (3000 platelets/µL; 100,000 to 800,000/µL) **(A, B),** compared with a normal age-matched control **(C, D).** Severe generalized bone marrow hypoplasia is apparent. The marked bone marrow suppression in this case is due to bracken fern toxicity. H&E; 10× **(A, C)** and 40× **(B, D)** objectives.

VetBooks.ir

PLATE 31-1 Postmortem photograph of tracheal edema syndrome. Note severe mucosal and submucosal thickening, which has obstructed the trachea by approximately 50%. *(Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.)*

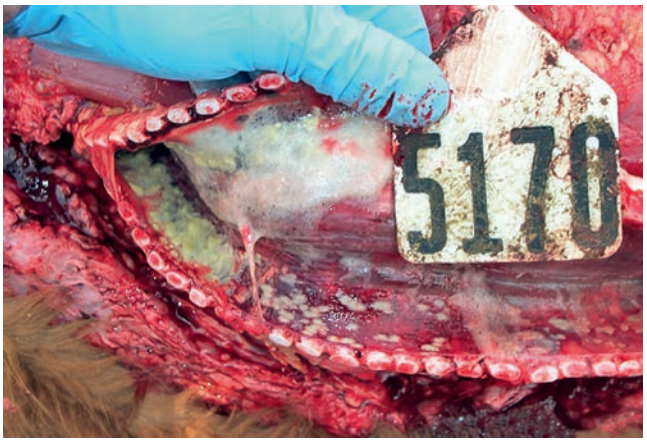

PLATE 31-2 Postmortem photograph of opened trachea from animal infected with bovine herpesvirus type 1 (BHV-1). Note multiple white fibrinonecrotic plaques and, distal to plaques, yellow fibrinopurulent material on dark red tracheal mucosa. *(Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.)*

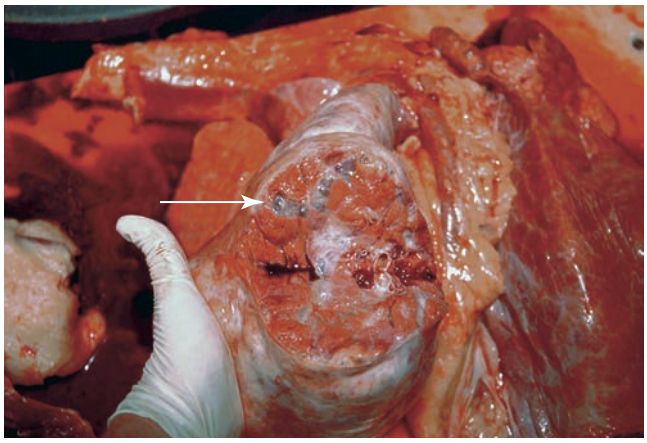

PLATE 31-3 Postmortem photograph of bovine lung with interstitial emphysema *(arrow)* often seen in severe bovine respiratory syncytial virus (BRSV) infection, as well as other causes of acute interstitial pneumonia (AIP). *(Photograph contributed by Dr. Amelia Woolums, University of Georgia, Athens, Ga.)*

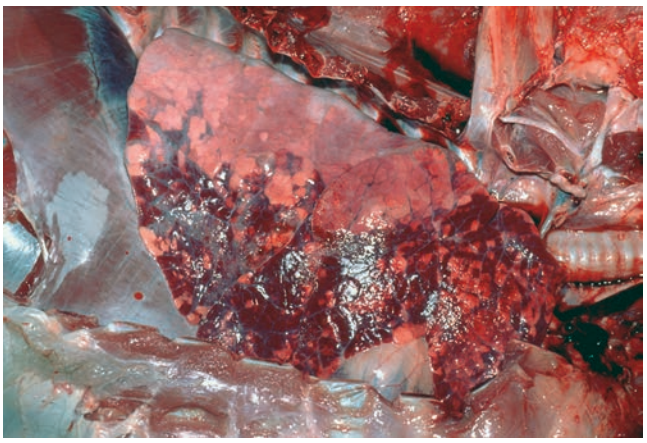

PLATE 31-4 Postmortem photograph of lungs from calf with severe BRSV infection. *(Photograph contributed by Dr. Laurel Gershwin, University of California, Davis, Calif.)*

PLATE 31-5 Postmortem photograph of fibrinopurulent pleuropneumonia caused by *Mannheimia haemolytica.* Note extensive dark red consolidated ventral lung, white fibrin on lung pleural surface, and red-tinged fluid in pleural space. *(Photograph contributed by Dr. Amelia Woolums, University of Georgia, Athens, Ga.)*

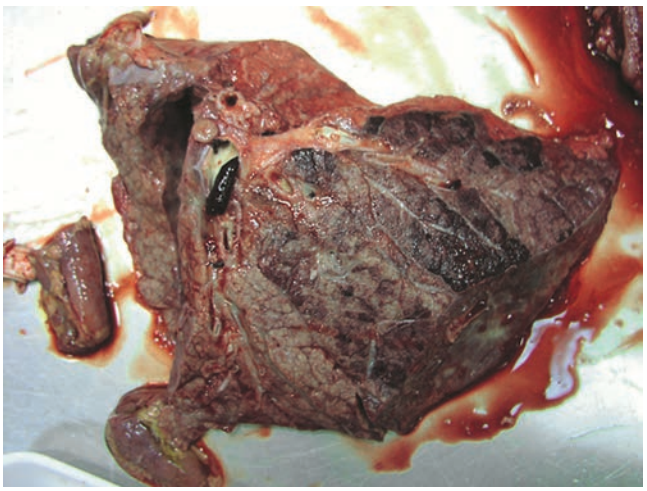

PLATE 31-6 Postmortem photograph of necrotizing bronchopneumonia caused by *Mannheimia haemolytica.* Abnormal lung is dark red to gray-brown in color. *(Photograph contributed by Dr. Amelia Woolums, University of Georgia, Athens, Ga.)*

VetBooks.ir

PLATE 31-7 Postmortem photograph of cross-section of lung tissue from feedlot steer with bronchopneumonia caused by *Histophilus somni.* Note interlobular space is expanded with fibrin and edema *(arrow). (Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.)*

PLATE 31-8 Postmortem photograph of lung from calf with bronchopneumonia caused by *Mycoplasma bovis.* Note extensive nodular abscessation of cranioventral lung. *(Photograph contributed by Dr. Tom Mullaney, Michigan State University, East Lansing, Mich.)*

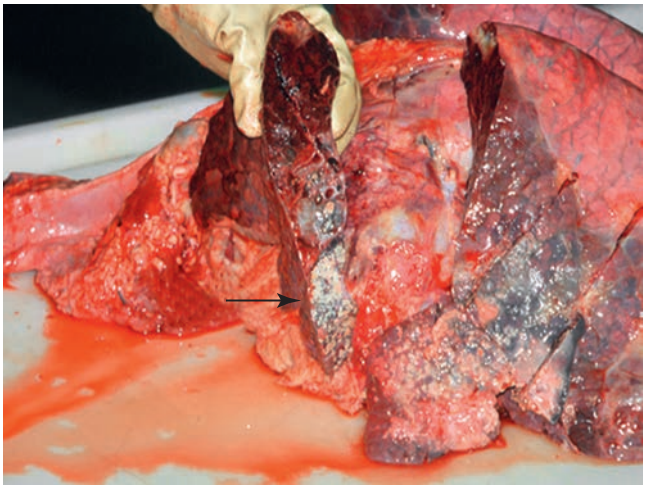

PLATE 31-9 Postmortem photograph of lung from calf with bronchopneumonia caused by *Mycoplasma bovis.* Note dark red consolidated ventral lung with white caseous material visible on cut surface *(arrow). (Photograph contributed by Dr. Ricardo Rosenbusch, Iowa State University, Ames, Iowa.)*

PLATE 31-10 Postmortem photograph of lung lesions typical of enzootic calf pneumonia. Note scattered collapsed, dark red lobules in the cranioventral lung. This type of lesion could be caused by bovine respiratory syncytial virus (BRSV), parainfluenza virus type 3 (PIV-3), *Pasteurella multocida,* or various mycoplasmas. *(Photograph contributed by Dr. Amelia Woolums, University of Georgia, Athens, Ga.)*

PLATE 31-11 Postmortem photograph of lungs from heifer with acute respiratory distress syndrome (ARDS) caused by feedlot acute interstitial pneumonia (AIP). Note expanded dorsocaudal lung and dark, collapsed lobules interspersed with pale, hyperinflated lobules. *(Photograph contributed by Dr. Amelia Woolums, University of Georgia, Athens, Ga.)*

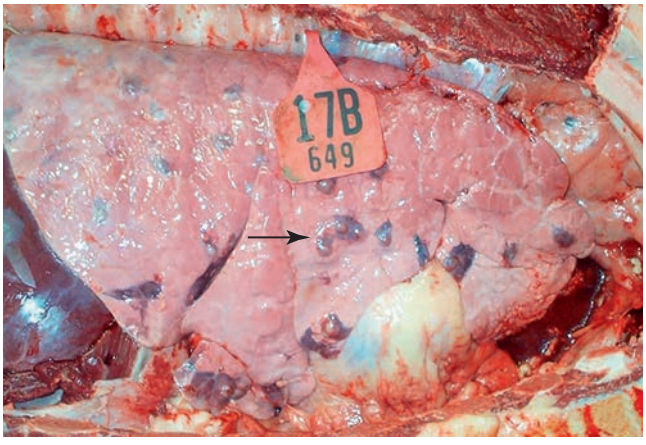

PLATE 31-12 Postmortem photograph of lung from feedlot steer with embolic pneumonia caused by caudal vena caval thrombosis. Note multiple dark red emboli *(arrow)* with raised abscesses scattered throughout lung. *(Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.)*

VetBooks.ir

PLATE 32-1 Endoscopic view of the esophagus of a 20-year-old gelding that presented with a history of 3 days of esophageal obstruction. The horse had recently been "rescued," and its previous history was unknown. After an obstruction consisting of grass was forcefully relieved by flushing water through a nasogastric tube, endoscopy revealed ulceration of the esophageal mucosa just orad to a stricture of the esophageal lumen. *(Courtesy Dr. M.J. Murray.)*

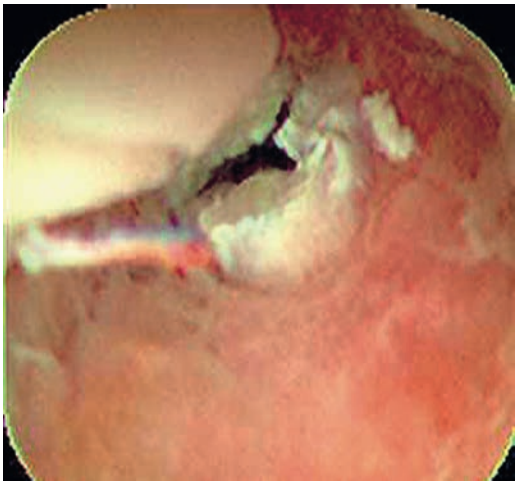

PLATE 32-2 Same horse as in Plate 32-1, 14 days later. The mucosa adjacent to the stricture remained ulcerated, and the diameter of the esophageal lumen had progressively diminished. At this point, it was not possible to advance the 10-mm-diameter endoscope through the stricture. *(Courtesy Dr. M.J. Murray.)*

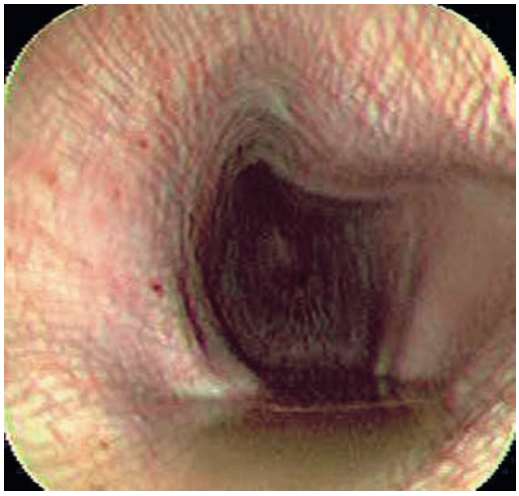

PLATE 32-3 Endoscopic view of megaesophagus in a 10-month-old foal, also shown in Fig. 32-45. The esophageal lumen is greatly distended, and the mucosa has multifocal erosion. *(Courtesy Dr. M.J. Murray.)*

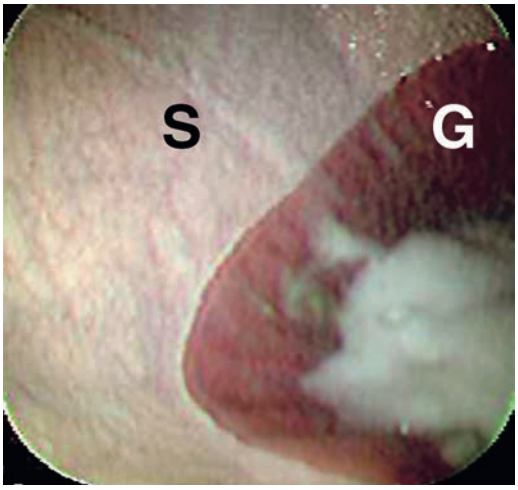

PLATE 32-4 Endoscopic view of the right side of a normal stomach, showing the pale squamous mucosa *(S)* and the red glandular mucosa *(G)*.

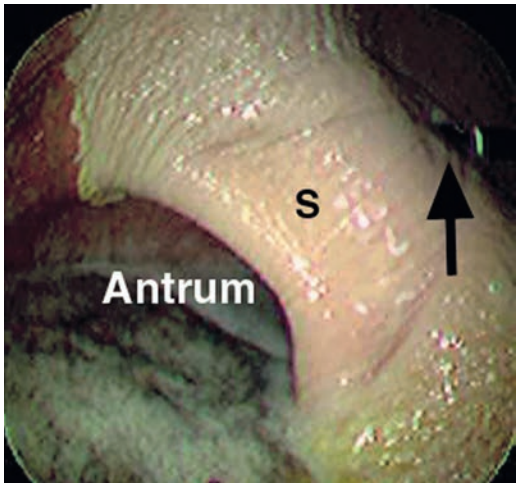

PLATE 32-5 Endoscopic view of the lesser curvature of a normal stomach, showing the pale squamous mucosa *(S)*. The antrum lies ventral to a fold formed by the squamous mucosa along the lesser curvature, and the pylorus is immediately ventral to the cardia, through which the endoscope *(arrow)* can be seen entering the stomach.

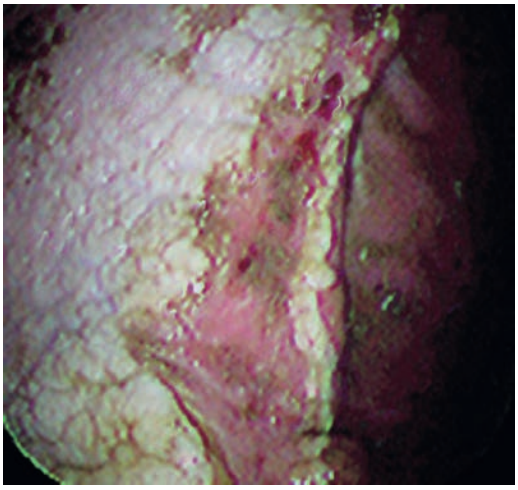

PLATE 32-6 Endoscopic view of a large area of ulceration of the squamous mucosa adjacent to the margo plicatus along the right side of the stomach.

VetBooks.ir

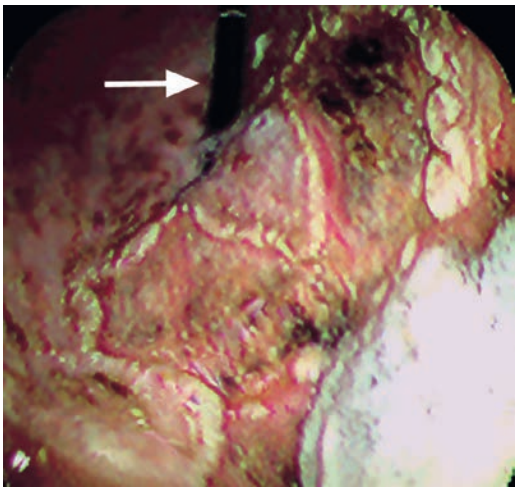

PLATE 32-7 Endoscopic view of a large area of ulceration of the squamous mucosa along the lesser curvature of the stomach. The ulceration has a "bufferfly" pattern, which is typical of ulcers at this site, and this pattern may reflect protection of the mucosa immediately ventral to the cardia by saliva entering the stomach from the esophagus. The *arrow* points at the endoscope entering the stomach through the cardia.

PLATE 32-8 Endoscopic view of an ulcer in the gastric glandular mucosa. The ulcer is in a rugal fold, which is a typical site of ulcers in the glandular portion of the stomach.

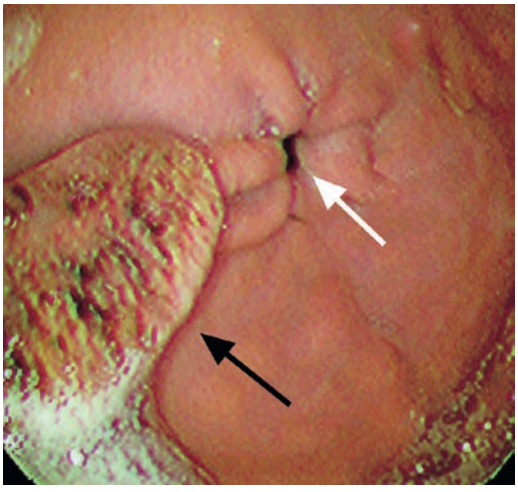

PLATE 32-9 Endoscopic view of the antrum of the stomach. The *white arrow* points at the pylorus. The *black arrow* points at an area of ulceration and thickening of a rugal fold leading to the pylorus. This is a severe example of a frequent finding in the stomach of adult horses: thickening of a rugal fold in the antrum with associated erosion or ulceration of the mucosa. The cause of these lesions is undetermined.

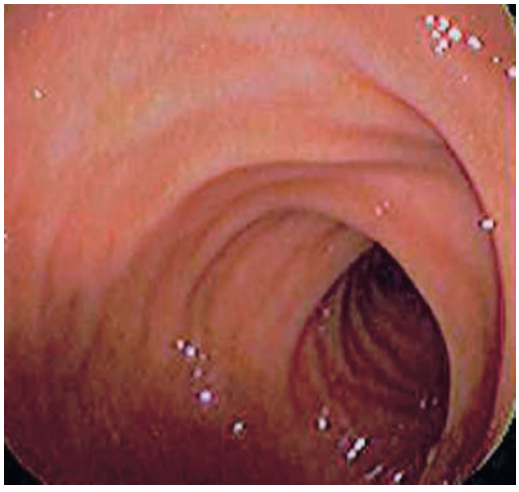

PLATE 32-10 Endoscopic view of normal duodenal mucosa. In this photograph, the endoscope has advanced aborad to the major duodenal papilla, which in most foals and horses is difficult and unusual to accomplish because of the anatomic configuration of duodenum with respect to the stomach.

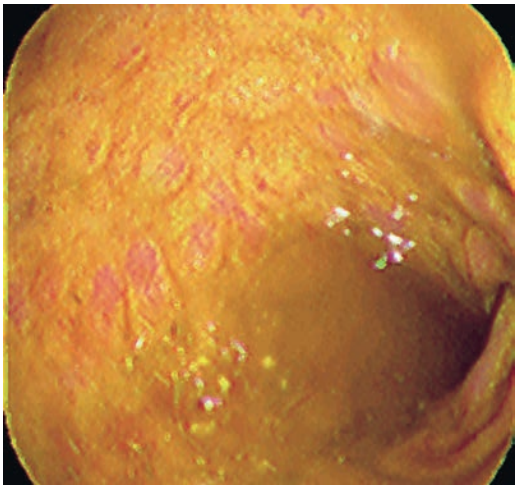

PLATE 32-11 Duodenum of a foal that presented with fever, depression, leukocytosis, and hyperfibrinogenemia. This endoscopic view is orad to the major duodenal papilla. The mucosa is inflamed and there is a yellow-orange fibrinous exudate adhered to the mucosal surface.

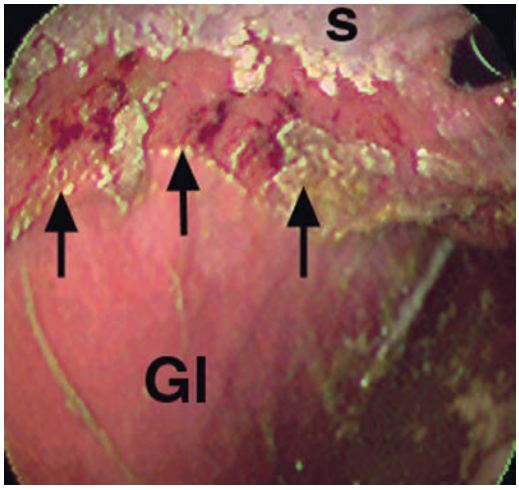

PLATE 32-12 Endoscopic view of the stomach of the foal in Plate 32-11. There is severe ulceration of the squamous mucosa *(S)* adjacent to the margo plicatus *(arrows),* because of delayed gastric emptying secondary to the severe duodenitis. Many foals with duodenitis present with classic gastric ulcer signs, because of delayed stomach emptying, accumulation of acidic peptic secretions in the stomach and often gastroesophageal reflux. *GI,* Glandular mucosa.

VetBooks.ir

PLATE 39-1 Marked asymmetry present when standing in front of this equine patient. Left eye is buphthalmic, with elevated lashes and diffuse corneal edema secondary to glaucoma. Right eye is developing phthisis bulbi, evident by increased scleral show and decreased lash height secondary to reduced orbital tissue volume.

PLATE 39-2 Entropion in a bovine patient; note the trichiasis present. Patient presented with blepharospasm and epiphora.

PLATE 39-3 Large third eyelid mass resulting in marked mucopurulent ocular discharge and enophthalmos.

PLATE 39-4 Caseous material obstructing the inferior puncta in a horse presented for epiphora. *(Photo courtesy Dr. Eric Storey.)*

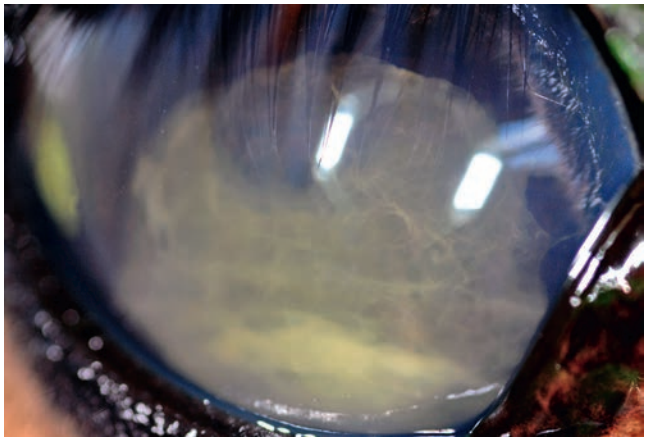

PLATE 39-5 Fibrin in the anterior chamber of a patient with anterior uveitis. Opacity is blocking the fundic reflex. Opacities in the cornea or anterior chamber will also obscure visualization of iris.

PLATE 39-6 Diffuse corneal edema in an equine patient. Diffuse patterns of edema, which are fluorescein negative, indicate endothelial dysfunction. *(Photo courtesy Dr. Lais Costa.)*

VetBooks.ir

PLATE 39-7 Corneal stromal abscess presenting as an area of off-white corneal infiltrate with secondary hypopyon and dense corneal vascularization (ciliary flush).

PLATE 39-8 Haab's striae in an equine patient with glaucoma.

PLATE 39-9 Light directed across the eye at a 45-degree angle is used to highlight anterior chamber abnormalities in this equine patient, including dyscoria secondary to synechia and a hypermature cataract.

PLATE 39-10 Iris atrophy in an equine patient.

PLATE 39-11 Dyscoric pupil secondary to posterior synechia and corneal scarring with a hypermature cataract in an equine patient with equine recurrent uveitis.

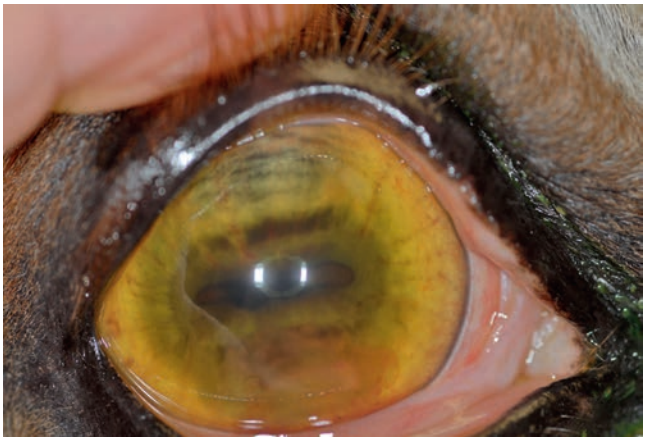

PLATE 39-12 Iridal color change, swelling, and miosis with blood (hyphema) and fibrin in the anterior chamber of a patient with anterior uveitis.

VetBooks.ir

PLATE 39-13 Phthisis bulbi secondary to chronic equine recurrent uveitis.

PLATE 39-14 Congenital cataract in a Thoroughbred colt.

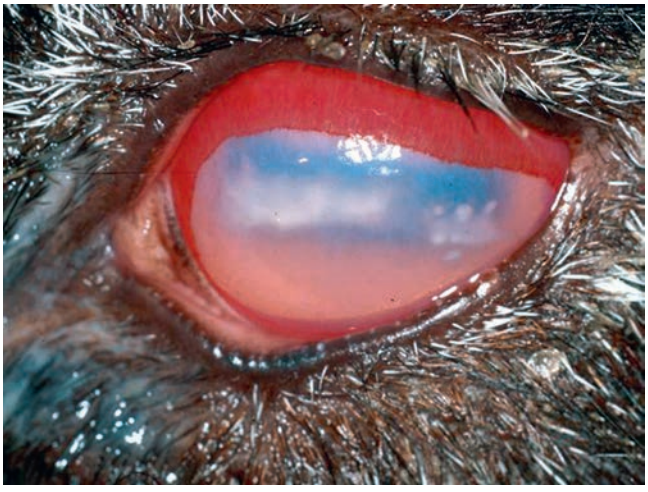

PLATE 39-15 Mycoplasmal keratoconjunctivitis in a goat. Note 360-degree superficial corneal vessels, diffuse corneal edema, a linear accumulation of white cellular infiltrates of the axial cornea, and miosis.

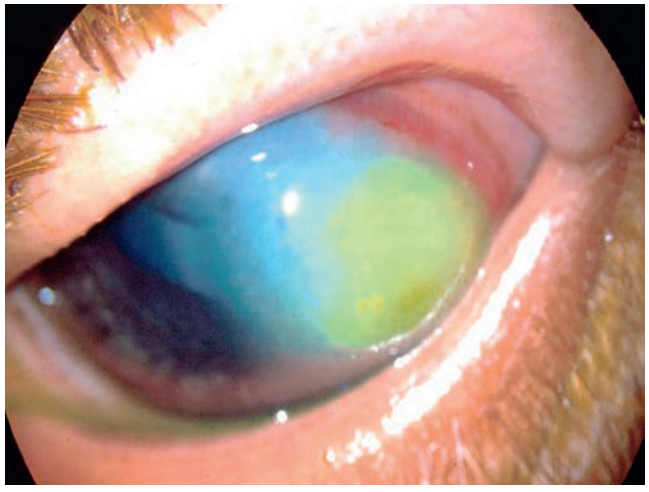

PLATE 39-16 Mycoplasmal keratoconjunctivitis in a sheep. Note miosis, focal corneal edema, and superonasal corneal vessels extending to the margins of a superficial corneal ulcer that has been stained with fluorescein dye.

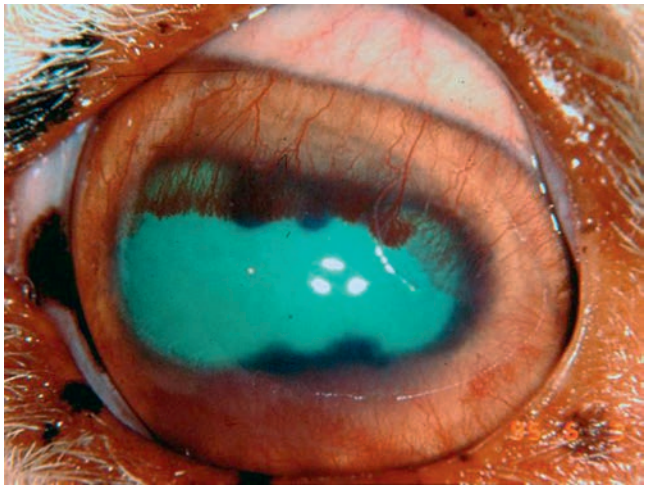

PLATE 39-17 *Chlamydophila* keratoconjunctivitis in a sheep. Note mild diffuse corneal edema, miosis, and 360-degree superficial branching corneal vessels.

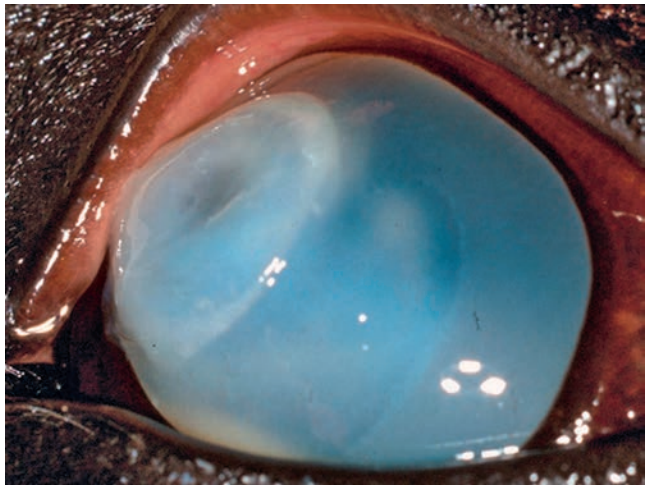

PLATE 39-18 Melting corneal ulcer, *Pseudomonas* infection. Note diffuse corneal edema, hypopyon, and a large superonasal ulcer with cellular infiltrate around margins and malacic corneal tissue protruding from surface.

VetBooks.ir

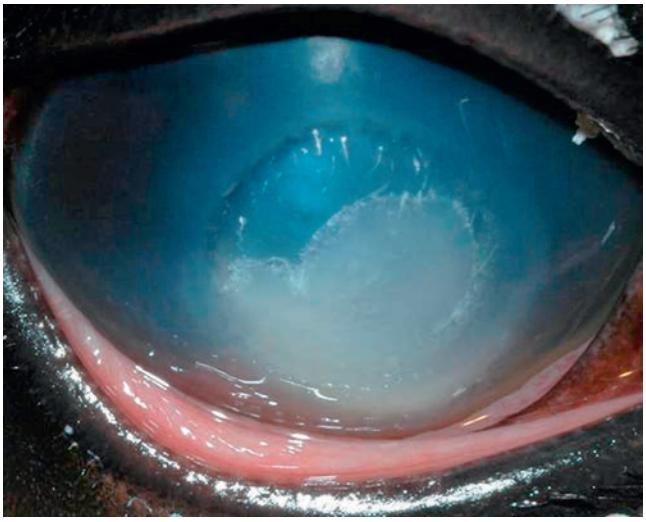

PLATE 39-19 Fungal keratitis with a granular white cellular infiltrate and a surrounding groove or gutter. Note corneal vascularization inferiorly.

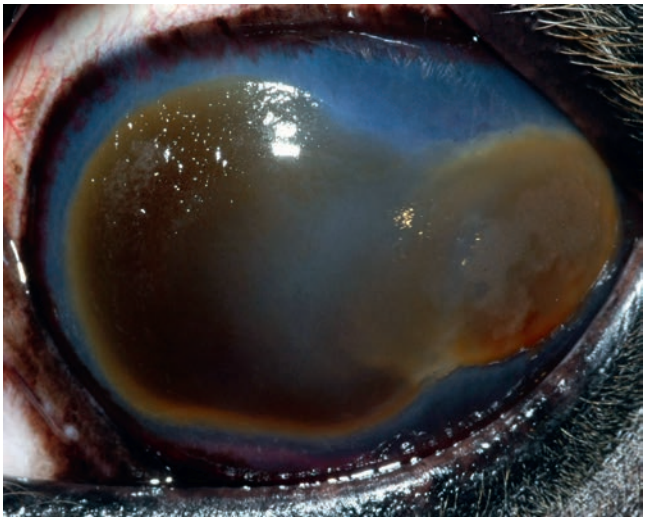

PLATE 39-20 Fungal keratitis with a pigmented necrotic axial plaque surrounded by active dense corneal vascularization.

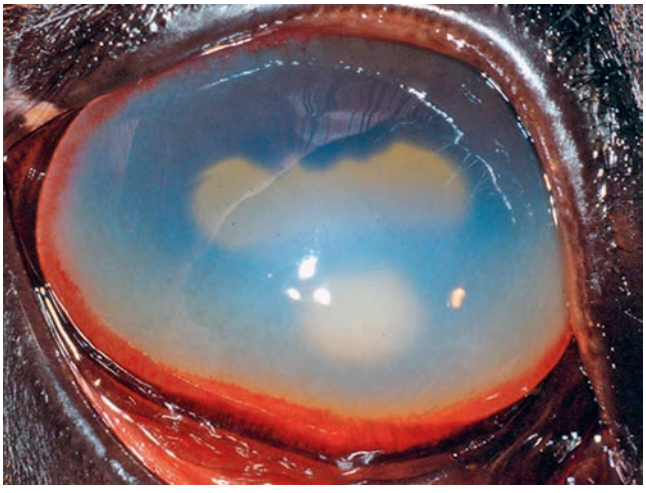

PLATE 39-21 Fungal corneal stromal abscess. Note 360-degree deep stromal corneal vessels, diffuse corneal edema, yellow cellular infiltrate of the inferior cornea, a paracentral foci of white deep stromal cellular infiltrate, and miosis.

PLATE 39-22 Bovine squamous cell carcinoma of lower eyelid and medial canthus, with secondary corneal ulcer.

PLATE 39-23 Large equine limbal (corneoscleral junction) squamous cell carcinoma extending into cornea.

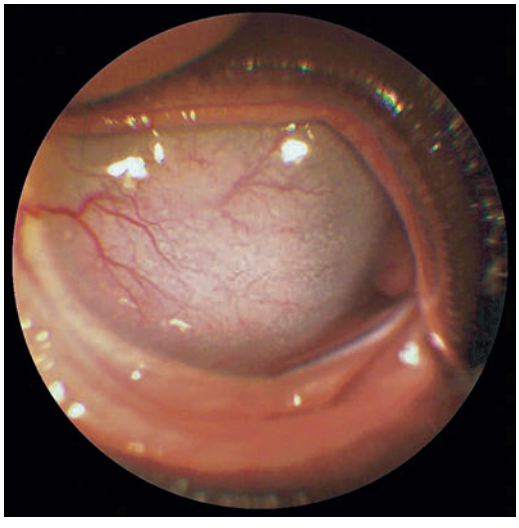

PLATE 39-24 Equine corneal stromal invasive squamous cell carcinoma. Note the vascularized infiltrative mass with smooth epithelial surface.

VetBooks.ir

PLATE 40-1 Pemphigus foliaceus in a goat.

PLATE 40-2 Alopecia areata on a horse's face.

PLATE 40-3 Vasculitis with ulceration on a horse's leg.

PLATE 40-4 Dermatophilosis on a goat's face.

PLATE 40-5 Dermatophilosis on a calf's head.

PLATE 40-6 *Corynebacterium pseudotuberculosis* abscess on a horse's neck.

VetBooks.ir

PLATE 40-7 Dermatophytosis on trunk of a Holstein cow. Lesions occurred after abdominal surgery.

PLATE 40-8 Scale and crust on a sheep's ear from biting flies, leading to eosinophilic dermatitis.

PLATE 40-9 Widespread squamous cell carcinoma on a goat's dorsum.

PLATE 40-10 Linear keratosis in a horse's jugular furrow.

PLATE 40-11 Vitiligo in a 5-year-old Quarter Horse.

PLATE 40-12 Chronic progressive lymphedema in a Gypsy Vanner horse.

everything but textbook

If you've never considered ebooks before, now may be the time. More than just words on a screen, Pageburst comes with an arsenal of interactive functionality and time-saving study tools that allow you to:

- access your entire course load from one portable device
- instantly swap notes with your instructors and classmates
- quickly search for topics and key terms
- watch videos and animations
- get the same Elsevier content for a lot less money

Discover more at **pageburst.com**.
