preferred to unilateral. This will limit recurrence and additional reproductive tract–related abnormalities. In squamates, the right ovary is anatomically close to the vena cava and care must be taken not to damage this structure. Hemoclips are helpful, although suture material (e.g., 3/0 Polydioxanone) can also be used to ligate ovarian arterial vessels. Irrigate the coelomic cavity with warm saline before closure. Postoperative complications may include infection, hemorrhage, thromboembolism, paresis, or ovarian remnant. Complete removal of ovarian tissue is essential. A bacteriology swab of the coelomic cavity should be taken and culture and sensitivity performed, and then coelomic lavage with warm saline is advised before coeliotomy closure (see Chapter 105).

Husbandry should be optimized, and normal perioperative care should be followed, maintaining core body temperature and hydration, and a feeding plan should be established. Provide suitable postoperative analgesia (see Chapter 50) and monitor for urine and fecal production and evidence of straining, discomfort, or pain.[20]

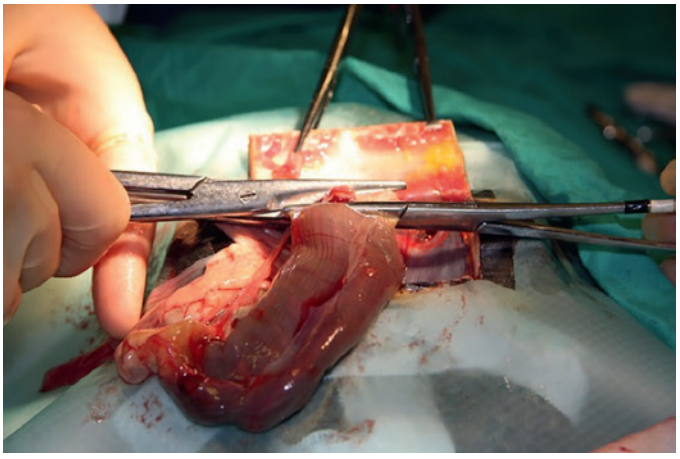

FIG 106.9 After returning the oviduct to the coelomic cavity via gentle traction, it is ligated and removed along with the associated ovary. (Courtesy of Stuart McArthur.)

LARGE INTESTINE (RECTAL/COLONIC) PROLAPSE

Intestinal prolapse has been reported in all reptile classes (Figs. 106.10 through 106.12). Animals may be male or female.[16–18] The main differential diagnosis of a prolapse of the colon in a female reptile is an oviductal prolapse.[16] In one UK study, prolapse of the colon represented one-sixth of the prolapses presented.[4] Chapter 75 contains a guide to prolapse identification and the conditions predisposing to intestinal tract prolapse.

The patient typically presents with a prolapse of a smooth linear structure. There is a lumen. Feces or gas may be present. Because the structure will generally be an intussusception, it may be rigid and inflexible.

Chronic prolapses often become severely swollen or strangulated, and tissues may be necrotic and traumatized, all of which complicate organ identification. Initial stabilization is described in Table 75.3 (see Chapter 75) and includes protection of the prolapsed organ, analgesia, rehydration, and placement in a warm environment. Suitable analgesia protocols are identified in Table 75.4 .

A coeliotomy (open reduction) with multimodal analgesia is advised as part of the overall management strategy of a colon prolapse.[1–3] There may be radiographic evidence of an additional dystocia or urinary calculus that can also be addressed during the coeliotomy. Surgical entry into the coelomic cavity and coelomic closure varies with species and is covered in detail in Chapters 97 through 101. For the patient to remain viable, it is necessary for all (or a significant amount) of the prolapsed colon to be preserved during treatment; therefore a closed amputation is not a realistic option. Euthanasia, or open salvage techniques, described later, may be considered in severe presentations (e.g., sepsis and collapse) or where there are economic constraints.

After lavage of the prolapse, removal of any necrotic tissue, and osmotic reduction as described earlier, coeliotomy (open reduction) allows traction to be applied to the proximal colon during reduction. Milking the intussusceptum slowly and gently out of the intussuscipiens is important. Sustain gentle manual pressure rather than pulling out the intussusceptum to avoid the risk of iatrogenic perforation.[23] After correct reduction, colopexy is performed in an area of healthy viable colon tissue to prevent recurrence. Sutures are placed between the colon

and the body wall by using a small atraumatic needle and monofilament absorbable suture material with partial-thickness sutures to minimize potential leakage of colon contents. Alternatively, the colon may be incorporated into the body wall closure. Where exposed tissue is devitalized, a resection and end-to-end anastomosis can be performed. This involves a combination of clean and dirty techniques where an intussusception is retracted back into the coelom during coeliotomy. Resection and anastomosis can be performed with standard soft-tissue techniques. A bacteriology swab of the coelomic cavity should be taken and culture and sensitivity performed, and then coelomic lavage with warm saline is advised before coeliotomy closure.

Provided there is no associated coelomic condition that requires coeliotomy, such as dystocia or urinary calculus, open salvage techniques can be attempted. A fresh nontraumatized prolapse may be hydrostatically reduced using warm water local irrigation after a period of osmotic reduction. Local anesthetic agents can be applied topically, via infiltration or as an intrathecal block and will aid reduction and retention. Contrast radiography, ultrasonography, and endoscopy may be necessary to confirm correct organ replacement. Retention is then achieved via transverse cloacal sutures or staples. However, it is unusual to reduce a colon prolapse without persistence of inversion or recurrence. A pexy between the colon and the body wall may not be necessary. However, if the prolapse remains unstable and recurs, or is likely to recur, then a pexy suture(s) will be required and a coeliotomy (open reduction) necessary to ensure correct reduction.

An anastomosis may also be performed in an unreduced prolapse without coeliotomy, after insertion of a smooth, tubular object (stent) into the lumen of the colon (e.g., a thermometer or clean syringe). The tissue is then transfixed with orthogonal needles, non-viable tissue is excised, and the two remaining layers are anastomosed with monofilament absorbable suture material in a simple interrupted pattern. Alternatively, the sutures can be placed and then the non-viable tissue can be removed.[6,15,16] When the exposed tissue is returned to the coelomic cavity, an inverting end-to-end intestinal anastomosis will have been created. It is essential to monitor these animals postreduction to confirm that they can urinate and defecate and to ensure that no recurrence infection or wound breakdown has occurred. The underlying conditions leading to the prolapse will also require identification and correction.

Systemic or regional postoperative complications should be considered and may include suture breakdown, infection, coelomitis, hemorrhage, thromboembolism, or paresis. Antibiotics in line with local antibiotic policy or based on culture and sensitivity should be considered. Husbandry should be optimized, and normal perioperative care should be followed; maintaining core body temperature, hydration, and a feeding plan should be established. Provide suitable postoperative analgesia (see Chapter 50), and monitor for urine and fecal production and evidence of straining, discomfort, or pain.[20]

BLADDER PROLAPSE

Chelonians and some lizards have bladders that may become prolapsed, and one UK study reported that bladder prolapse represented around 3% of prolapses encountered in a first opinion and referral setting. Chapter 75 contains a guide to prolapse identification and the conditions predisposing to bladder prolapse.

Bladder prolapses present as an amorphous translucent structure protruding from the cloaca, which may or may not contain fluid. There is no lumen. Because the ureters empty into the urodeum without a direct connection to the urinary bladder, it is unusual for them to become damaged during a bladder prolapse. However, their outflow may be temporarily obstructed. The bladder, when present, participates in water and electrolyte reabsorption, and therefore an attempt should be made to salvage as much of the viable tissue as possible.[8]

Initial stabilization is described in Table 75.3 (see Chapter 75) and includes protection of the prolapsed organ, analgesia, rehydration, and placement in a warm environment. A prolapsed bladder should be protected quickly because further trauma is likely due to the thin tissue nature of the organ. Suitable analgesia protocols are identified in Table 75.4. If the animal has been unable to urinate, it is prudent to assess blood potassium and azotemia levels at the start of treatment and take measures to address abnormalities.

When a small viable portion of the urinary bladder is prolapsed, closed reduction in the sedated patient via the cloaca using the hydrostatic pressure of a warm water enema can be attempted. However, if complicating issues such as the presence of urinary calculi or ectopic egg(s) exist a coeliotomy will likely be required. Multimodal analgesia should be used.[1–3] Hydrostatic reduction can be achieved by infusing both the bladder and cloaca with warm fluid via an endoscope sheath or suitably sized crop tube. An appropriate reduction may be confirmed endoscopically or by radiography following infusion of suitable media into the reduced bladder. The patient must be carefully monitored postoperatively for recurrence and ability to urinate and defecate.

Where exposed tissue is not viable, it must be surgically resected and nonviable tissue removed. Using a closed technique, a bowel clamp or set of intestinal forceps is lightly placed across the viable section of tissue, with minimal crushing. A double-layer inverting suture line (e.g., 3/0-5/0 poliglecaprone with triclosan) is placed proximal to the bowel clamp, sealing the urinary bladder.[6,15,16] The nonviable tissue is removed distal to this suture line. The clamp is removed, and the residual bladder is replaced through the cloaca and back into the coelomic cavity. A hydrostatic enema as described earlier can be used to reduce the bladder and return it to a coelomic location, and, if the sheath of a scope is used, endoscopy can confirm the bladder is relocated back where intended.

If a substantial portion of the bladder is damaged, coeliotomy (open reduction) with multimodal analgesia is advised to allow better exposure and excision of the diseased tissue. Local anesthetic agents can be applied topically via infiltration or as an intrathecal block. Surgical entry into the coelomic cavity and coelomic closure varies with species and is covered in detail in Chapters 97 to 101.

VetBooks.ir

During the coelomic exploration, salvage as much of the viable bladder tissue as possible and remove any urolith or ectopic egg. A double-layer inverting suture line (e.g., 3/0-5/0 poliglecaprone with triclosan) is used to close the bladder.[6,15] It will be difficult to avoid contamination of the coelomic cavity with bladder contents. A bacteriology swab of the coelomic cavity should be taken and culture and sensitivity performed, and then coelomic lavage with warm saline is advised before coeliotomy closure.

Husbandry should be optimized, and normal perioperative care should be followed, maintaining core body temperature and hydration, and a feeding plan should be established. Provide suitable postoperative analgesia (see Chapter 50) and monitor for urine and fecal production and evidence of straining, discomfort, or pain.[20] Specifically monitoring blood potassium levels and for azotemia in the postoperative period after this procedure is important.

Amphibian Soft Tissue Surgery

Brent R. Whitaker and Kevin M. Wright[†]

Amphibian surgery remains poorly documented in the veterinary literature; however, several good references exist.[1–3] Amphibians tolerate anesthesia well when properly used (see Chapter 52), and it is required for the majority of the procedures described here. Our experience is that amphibians make good surgical candidates and that the clinician should consider this therapeutic approach when it is required.

Soft tissue surgical intervention is commonly required to repair wounds and prolapses and perform biopsies, as well as to remove foreign bodies, masses, and damaged eyes. Coeliotomy may be necessary to obtain diagnostic biopsies or remove gastrointestinal foreign bodies, retained eggs, neoplastic masses, or uroliths (Fig. 107.1).

EQUIPMENT

The size of the patient and procedure to be performed must be considered when selecting surgical instruments. Ophthalmic or microsurgical instruments, including scissors, forceps, and hemostats, are often required for delicate surgeries. Ophthalmic knives, for example, come in a variety of sizes, shapes, and angles, making them very useful in smaller patients. Number 11 and 15 scalpel blades also work well. Nonabsorbent clear plastic drapes can be used to create a clean field and minimize desiccation of the patient. Eyelid retractors and plastic ring retractors with elastic stays (e.g., Lone Star retractor) work well to retract coelomic incisions, but care should be taken to ensure that only the minimal amount of pressure needed be applied in order to avoid damage to the skin. Radiosurgery, a laser, or a fine-tipped surgical spear can be used for hemostasis. Magnification and bright but cool illumination are recommended. Many different sutures have been used successfully, including polydioxanone and polyglactin 910; however, one study in the African clawed frog (*Xenopus laevis*) concluded that monofilament nylon showed the least histological reaction and was therefore recommended as the suture of choice in amphibian skin closure. Chromic gut and silk elicited the greatest histological reaction and resulted in a high rate of dehiscence and is not recommended for use in amphibian skin.[4] Polydioxanone, poliglecaprone 25, and polyglactin should be used internally and for muscle closure, although polyglactin is likely to cause greater inflammation.[1] Antibiotic-impregnated sutures may guard against bacterial translocation and are especially useful for GI, bladder closures, and skin closures. Tapered needles with wedged-on suture are least traumatic and work best.

Cyanoacrylate tissue glue can also be used in small quantities for skin closure. The glue not only creates a watertight physical barrier but has been shown to have antimicrobial properties, with greatest activity against gram-positive organisms.[5–7] A rigid telescope and carbon dioxide insufflator are useful for minimally invasive coelioscopic and endoscopic examinations (Fig. 107.2).[1,8]

[†]Deceased.

SURGICAL PREPARATION AND POSTOPERATIVE CARE

Maintaining physiological homeostasis for the patient preoperatively, perioperatively, and postoperatively is important for a successful outcome. Temperature of the amphibian's environment must be monitored and maintained within the preferred range. Hypothermia is not an acceptable means to provide surgical restraint or analgesia. Minimal preparation of the surgical site is desired, as amphibian mucus and skin contain antimicrobial peptides produced in granular glands that are protective.[9] Gently cleaning the incision site to ensure that it is free of debris using sterile cotton-tipped applicators dipped in sterile saline or a 2% povidone-iodine in sterile saline solution is all that is needed. The patient should be properly hydrated prior to, throughout, and following surgery. This can make maintaining sterility challenging. Several recipes for balanced solutions exist (see Chapter 89).[1,10,11] Fasting is not required prior to prevent aspiration but may be desirable due to the intended procedure. Gloves should be worn but must be powder free (or powdered gloves must be wiped with saline-moistened sterile gauze). Preioperatively, perioperatively, and postoperatively, the need for antibiotics and pain relief should be evaluated and provided, if necessary. Little information on the clinical effectiveness of analgesics is available; however, the administration of 38–46 mg/kg buprenorphine subcutaneously every

4 to 6 hours or dexmedetomidine injected into the dorsal lymph sac (0.6 mg/kg) every 8 hours appears to be effective.[10,11,12] Nutritional supplementation must be provided if the patient is not eating.

TOE CLIP

Toe clipping remains a standard research/institutional method of identification of anurans and urodeles; however, some salamanders will regenerate an amputated digit or limb, limiting the long-term effectiveness of toe clipping as a permanent means of identification in this order.[13] This procedure is not warranted for client-owned pets. For many amphibians, such as poison dart frogs, identification can be achieved using photographs to capture an individual's unique color pattern. Although some field biologists routinely perform this procedure without sedation under research license, ethical and humane concerns exist. Additionally, reports show that toe clipping may have associated complications such as infection, decreased mobility or dexterity, and subsequent increased susceptibility to predation. The rate of return also increases as more toes are removed.[14] When removing a toe from anurans, one should consider that the first three digits of the male's forelimb are important to mounting the female during breeding and that the fourth hind digit is used by both sexes to remove shed skin and should not be removed. Small anurans can have the toe clipped with iris scissors, and direct pressure is applied to the site until bleeding stops. A small drop of surgical glue adds an additional barrier and can aid in homeostasis. Instruments should be disinfected between individuals. Larger anurans can be toe clipped with stainless steel liga-clips, and the digit distal to the clamp is removed. The clip falls off in 7 to 28 days. Although the regenerated tissue is slightly different in appearance than the original tissue, this can vary.

IMPLANTATION OF TRANSPONDER

A highly successful method of permanent identification of amphibians is the implantation of a transponder chip within the amphibian's body.[15] The procedure is not without risk, as it can cause significant disruption to the skin's bacterial flora and proliferation of resident fungi.[16] Some debate exists about the preferred site of implantation. A subcutaneous site (e.g., underneath the parotid gland of a toad) has been advocated by some instead of an intracoelomic site. The subcutaneous site avoids the chance of abdominal adhesions forming and associated clinical problems arising from migration of the coelomic implant. A subcutaneously

placed transponder may be visible and therefore unacceptable for display animals. The intracoelomic implant avoids this problem. The intracoelomic implant may be administered via the paralumbar region or ventrally, lateral to the midline. Long-term studies comparing the advantages and disadvantages of the two site choices are lacking, and choice is currently a matter of clinician preference. Anecdotal reports are found of amphibians shedding their transponders several months after implantation. The transponder likely migrates and is expelled through the bladder, the intestine, or even transcutaneously. Implantation of a second transponder and routine monitoring to ensure both transponders are present and working is recommended for specimens that must have permanent identification.

CLOACAL PROLAPSE

Prolapse of tissue out of the cloaca is a common but life-threatening disorder of amphibians (see Fig. 89.21). Rectum and bladder are among the most commonly seen organ prolapses. Predisposing conditions include metabolic abnormalities such as dehydration, hypocalcemia, hypoglycemia, and malnutrition. Other differentials include gastrointestinal foreign bodies, cystic calculi, gastroenteritis, hyperthermia, trauma, and parasitism. Radiographs to exclude gastrointestinal foreign bodies and cystic calculi are suggested. If the prolapse is detected while the mucosa is viable, the prolapse can be gently replaced using a blunt tool such as the rounded end of an appropriately sized feeding tube. Glycerin gel may be applied to the rectal mucosa to moisten and shrink the tissue before placement. Alternatively, a hyperosmotic saline or sugar solution applied to the prolapsed tissue (not the entire patient) followed in 10 to 20 minutes by a water-soluble lubricant can be effective. If the prolapse appears devitalized, excision of the devitalized intestine and anastomosis of the healthy tissue may be attempted. An antibiotic pessary may be warranted in some cases, as may parenteral antibiotics. A nylon purse-string suture should be used to close the cloaca for 2 to 3 days, and the amphibian should not be fed until after the suture has been removed. Any predisposing conditions should be corrected. Prognosis is guarded, but many anurans respond favorably.

COELIOTOMY

Some of the larger carnivorous frogs, such as the popular Argentine horned frog *(Ceratophrys ornata)*, are well known for pica, or eating abnormal objects, especially rocks. An occasional rock can be manually extracted with long curved Kelly forceps if it is still located in the stomach; however, foreign bodies that have passed the pylorus and entered the small intestine require an enterotomy. Removal of cystic calculi is a common surgery for many phyllomedusine frogs[8,17] because of the number of species that produce uric acid as a nitrogenous waste. Where possible, a two-layer closure of the bladder is ideal, but a one-layer closure is often most practical and works well in our experience. Many of the same techniques used for reptile patients work well for amphibians (see Section 10). Exploratory celiotomy is a useful diagnostic tool and can be used to confirm celioscopic diagnoses, to obtain tissue samples, or for therapeutic procedures such as gastrotomy (Fig. 107.3). Partial ovariectomy is used to harvest ova by exteriorizing a portion of the egg mass through a 3- to 5-mm paramedial incision and excising a sample. Ligation, surgical clips, or radiosurgery of blood vessels may be required if performing a gonadectomy.[1] Closure of a celiotomy site may be problematic because the cutaneous sutures are prone to dehisce. The suture line should be under as little tension as possible. A 3-0 or 5-0 nylon (or antibiotic impregnanted absorbable monofilament) in an everting pattern is suggested, with further strength provided with a layer of tissue glue or with internal placement of absorbable sponge material. The patient should be confined in a small space and managed with a minimum of handling for at least 10 days after surgery.

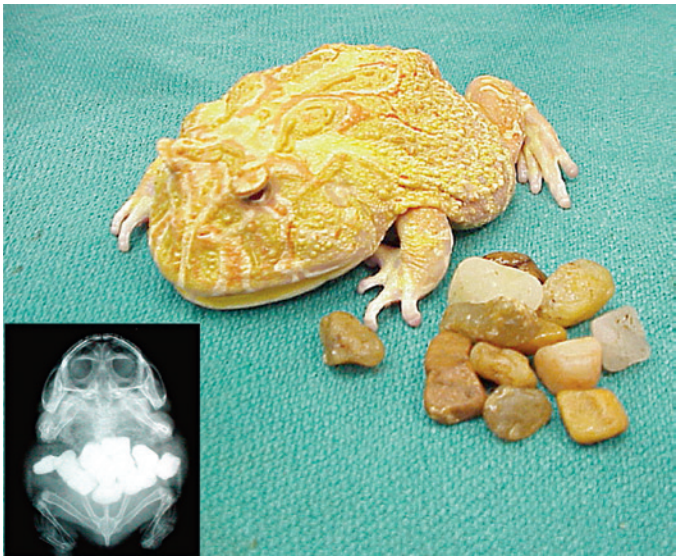

FIG 107.3 Postsurgical photograph of an ornate horned frog *(Ceratophrys ornata).* Gastrotomy/enterotomy is a common procedure in amphibians. Note the radiograph of the patient showing the multiple ingested rocks (*inset*). (Courtesy of Douglas R. Mader.)

OCULAR SURGERY

Corneal biopsies are rarely needed but can be taken. The removal of the lens that had luxated into the anterior chamber of a milk frog *Trachycephalus resinfictrix* was successfully removed using a Snellen loop after making a 180-degree incision at the limbus, decompressing the globe and injecting viscoelastic material into the anterior chamber. After irrigating the globe with saline, the incision was closed with 9-0 nylon suture.[1] Ocular tissue damaged beyond repair due to trauma, infection, or neoplasia can be painful and may require removal. Two critical issues must be managed by the surgeon when performing an enucleation of the eye. The first is that amphibians have a membranous orbit and poorly defined lacrimal bone; caution must therefore be taken not to damage the membrane that separates the globe from the buccal cavity. The second is to control bleeding that can be life threatening in small amphibians. This can be done by first applying pressure with fine-tipped surgical spears and then packing the cavity with an absorbable collagen hemostat or gelatin sponges. If infection is present, placing the patient on an appropriate antibiotic prior to surgery may be helpful.

CELIOSCOPY

Minimally invasive surgical procedures that reduce the size of incision and amount of tissue trauma are preferable. Celioscopy has been used to determine gender in monomorphic species such as giant salamanders (*Andrias* spp.) (Kramer et al. 1983, Proc Am Assoc Zoo Vet, pp 192–194) and goliath frogs *(Gigantorana conrauagoliath)* (Gillespie et al. 1988, Proc Joint Conf Am Assoc Zoo Vet and Am Assoc Wildl Vet, p 62), confirm granulomatous disease, biopsy organs, and biopsy tissue masses (see Fig. 107.2).[1,8,18] A 3-mm incision can be made in the paralumbar region or just lateral to the midline, depending on the purpose of the exam. After inserting the telescope-sheath system into the coelom, carbon dioxide is typically used for insufflation of the cavity.[1] Insufflation

VetBooks.ir

pressures of 0.5 to 2 mm Hg with a flow rate of less than 0.5 L/min is recommended.[18] Lateral recumbency may allow the internal organs to fall away from the hypaxial musculature and allow visualization of the testicle and kidneys. A paramedial midline incision allows best access to the liver, and care should be taken to avoid damaging the ventral midline vein. Tissue glue can be used to close the incision. Large incisions may be closed with 3-0 or 5-0 nylon sutures (or antibiotic impregnanted absorbable monofilament), which can be removed in 4 to 8 weeks.[4]

Orthopedic Principles and External Coaptation

S. Emi Knafo and W. Michael Karlin

Reptiles frequently suffer from fractured bones, either resulting from trauma or pathological processes. Traumatic fractures are most commonly due to inter- and intraspecific aggression, improper handling/restraint, and motor vehicles. Pathological fractures almost always result from any of the various metabolic bone diseases (MBD) that affect reptiles; however, neoplasia, osteomyelitis, or other metabolic diseases may play an underlying role. Many fractures are amenable to treatment with external coaptation, and pathological fractures from MBD are often unsuitable for internal fixation because the bones are unable to support hardware. These fractures are usually best treated with external coaptation (although exceptions exist). In other situations, such as the fracture configuration or size of the reptile, internal fixation may be indicated. In general, if the patient is healthy enough to undergo surgery, internal reduction and fracture fixation will provide superior alignment of fracture fragments, neutralization of fracture forces, and superior healing.[1] In patients with MBD, the underlying cause should be determined and corrected before or concurrent with fracture repair. This requires medical management while treating pathologic fractures. When severe tissue trauma, loss of vascular supply, uncontrolled infection, and inflammation exist, amputation may be required. Reptiles generally function well with partial or complete limb amputations (see Chapter 111).

Most fractures occur as a result of relatively low impact forces, which makes the incidence of comminuted fractures relatively low.[1] Reptiles also have tough inelastic skin, and fractures are often closed. However, open fractures do occur, and any resulting wounds should be thoroughly cleaned, debrided, and sampled for cytology and microbial culture and sensitivity.[2,3] Simple fractures usually carry a fair to good prognosis, whereas contaminated, comminuted fractures or fractures involving a joint can carry a guarded to poor prognosis.[4,5] Limited information is available regarding bone healing in reptiles, though this is discussed in more detail in Chapter 81. Factors that affect bone healing include fracture configuration, age of the animal, nutritional status, and environmental temperature. Bone healing in reptiles tends to occur at a slower rate when compared with birds and mammals, and no secondary cartilage has been demonstrated in the reptilian fracture callus.[6] Healing time for traumatic fractures is generally 6 to 18 months, compared with 4 to 8 weeks in most mammals and 2 to 6 weeks in most avian species.[7] Pathologic fractures that result from MBD seem to heal more rapidly (6 to 8 weeks) if the inciting problem is corrected.

General principles of mammalian fracture fixation apply to reptile patients. Anatomic alignment, stabilization, and neutralization of bending, rotation, compression, and shear forces with minimal disruption of callus and soft tissues should be achieved.[8] Generally, the more forces that must be neutralized by the fixation, the higher the incidence rate of complications and failure. Factors to be considered when deciding on the fixation method to be used include the patient's functional requirements, surgeon's level of experience, the cost of materials/procedure, ease (length of time) of application, and availability of equipment. The patient's size, general health, and metabolic status may preclude a surgical approach to orthopedic repair. Most closed fractures in reptiles may heal without immobilization but will have varying degrees of malunion. However, as the field of zoological medicine continues to advance, it is important to always strive to offer the best treatment options available for the given patient's condition. Even though a given fracture may heal on its own without intervention, it is important to offer hospitalization, (surgical) fracture fixation, multimodal analgesia, and supportive care as part of the initial treatment plan. If financial constraints prohibit such a plan, then modifications to fit the needs of the owner and patient can be made.

PREOPERATIVE AND POSTOPERATIVE CARE

A thorough history, including husbandry details and a physical examination, should be performed before any reptile patient is anesthetized for fracture repair. Anesthetic protocols will vary based on the health of the reptile, species, and size (see Chapter 49). During surgery, all reptiles should be provided thermal support to optimize their anesthetic induction and recovery.[7] The surgical site should be aseptically prepared using 2% to 4% chlorhexidine solution and saline.[9–11] Alcohol can be used, though it exacerbates thermal losses. Aseptic preparation of reptile skin is difficult due to keratinized scales therefore it is recommended to perform a "rough" preparation first. Toothbrushes or commercially available surgical scrub brushes can be used for this initial "rough" scrub to remove debris and clean in between scales. Following a "rough" preparation, an aseptic preparation with contact time of 3 to 5 minutes should be performed.[10,12,13]

EXTERNAL COAPTATION

External coaptation, which involves the use of bandages, splints, or slings to immobilize a fracture, has been successfully used in reptiles of many sizes, including very small lizards, snakes, and giant tortoises. Fractures that are minimally displaced may heal with simple external coaptation. When dealing with pathologic fractures, external coaptation is usually the treatment of choice for initial fracture stabilization. This is because medical management of MBD must be initiated before bone healing can occur, and it is possible for the bones to suffer repeated or additional trauma if not bandaged or splinted. Bone is dynamic, and, during prolonged hypocalcemia (as in MBD), the mineralization process lags behind the deposition of organic bone matrix, resulting in the formation of hypomineralized bone. Reptiles suffering from MBD typically have osteoporosis and weak, thin cortices. Such bones are usually unsuitable (too soft) to support plates, pins, or other orthopedic hardware. If Steinmann pins are inserted, they contact a cortex and then may penetrate rather than being diverted down the medullary canal. Cerclage, hemicerclage, and interfragmentary wires may collapse

VetBooks.ir

the soft bone. Bone screws have minimal pull-out resistance when placed in soft bone. Similarly, external skeletal fixation does not function well because the bone purchase of the fixation pins is minimal. In some cases, intramedullary pins can be carefully inserted to provide axial alignment and some bending stability; however, external coaptation should also be applied because cortical purchase may be minimal. Fortunately, once calcium homeostasis has been reestablished, fracture healing progresses rapidly, with a fibrous union providing stability as early as 3 to 4 weeks. Medical therapies for hypocalcemia are discussed in Chapter 122.

Many splinting and casting techniques have been used successfully,[7,14,15] and anesthesia is recommended during application of any external coaptation device. This is to prevent iatrogenic fractures or comminutions and to minimize patient stress and pain. All forms of external coaptation should be monitored closely for evidence of soiling, slippage, vascular compromise, or other problems that may require bandage or splint replacement. Splints and bandages should be changed at weekly intervals (or more frequently if wet/soiled) throughout the healing period to ensure no complications develop and allow the veterinarian to monitor patient progress.

Fractures of digits can be immobilized using ball bandages, in which roll cotton is placed in the palmar or plantar aspect of the foot. Digits are rested in a neutral position over the cotton and wrapped or taped into position. The bandage should include the entire foot and lower limb. If the bandage is at risk of becoming wet or soiled, cotton should be avoided and a nonabsorbent material can be used in its place.[15] Waterproof tape or plastic bags can be used to protect the outer surface of the bandage and reduce the risk of soiling. Owners or caretakers should be instructed to monitor bandages daily for moisture or soiling, which would necessitate a bandage change. Fractures of the forelimb should be bandaged directly to the body to achieve immobilization (Fig. 108.1). The pelvic limbs should be bandaged to the tail (Fig. 108.2). The affected limb should be bandaged to support and pad the fracture site, including joints proximal and distal to the fracture, and then strapped to the body or tail base. For improved rigidity, a small splint can be added between the limb and body or tail. Splints can be made from a piece of wooden tongue depressor covered in tape to protect sharp edges, paper clips, or commercial splint materials such as Hexcelite (Hexcel Medical, Dublin, CA) or other thermal polymer plastic cast material. These lightweight splint materials are ideal in small reptiles and are particularly useful in cases of metabolic bone disease, where the bones are not strong enough to carry a heavy bandage or splint. In cases of humeral or femoral fractures, similar techniques can be used. However, it is not always possible to adequately immobilize the scapulohumeral or coxofemoral joints, thus providing somewhat suboptimal reduction and immobilization. Depending on the body form of the reptile, some splints can be configured to adequately immobilize these joints by conforming to the affected limb and extending across the body or down the tail base.[15] In lizards, fractures of the humerus or femur can be stabilized with a modified spica splint that crosses over the pelvic or pectoral girdle to the opposite limb, thereby stabilizing the hip or shoulder joint and achieving the goal of immobilizing the joints proximal and distal to the fracture. Most lizards stand relatively low and use lateral abdominal undulation as an aid to locomotion, thus allowing them the ability to ambulate even with this type of device. With fractures of the pelvic limb, the splint should cross midline dorsally to allow normal voiding, and with fractures of the pectoral limb, the splint should cross ventrally (Fig. 108.3A and B). Juveniles that are still growing rapidly are at risk for joint deformity or loss of range of motion if the joints are immobilized for a prolonged period of time.[15]

A tube such as a syringe case of a diameter appropriate to the size of the patient's limb can be padded on one end (proximal end) and used as a splint. Tape stirrups are applied to the limb and secured to the syringe case/tube. Padding should be added to the limb to limit movement and avoid additional strain and fracture within the tube. The tape is then pulled through the tube so that the padded end of the tube is moved into the inguinal or axillary region, and the limb is maintained in traction. The tape is secured to the outside of the tube to maintain the leg in extension and traction.

In chelonians, fractures can be immobilized by restricting limb movement within the shell. The openings between the plastron and carapace (the cervicobrachial and prefemoral fossae) are physically blocked using sturdy tape or other adhesive material (Elastikon elastic tape [Johnson & Johnson], duct tape, etc) to prevent the limb from being extended out from the shell. This provides immobilization but unfortunately does not address fracture alignment and can result in greater fracture displacement. However, the resulting malunion may be acceptable for function (Fig. 108.4).

Snakes are occasionally evaluated because of spinal abnormalities. These spinal changes may be the result of osteoarthritis, osteoarthrosis, vertebral luxation (subluxation), or fracture.[16] In the case of spinal fractures, a body cast has been shown to be effective and easy to apply.[17]

FIG 108.1 Fractures of the humerus, radius, and ulna can be stabilized by pulling the leg caudally to apply traction to aid in reduction and securing forelimb to the body with adhesive tape. Pictured here is a veiled chameleon (*Chamaeleo calyptratus*) with a fractured radius and ulna, with carpus and elbow immobilized using a lightweight splint secured to the body caudally. (Courtesy of Stephen J. Divers.)

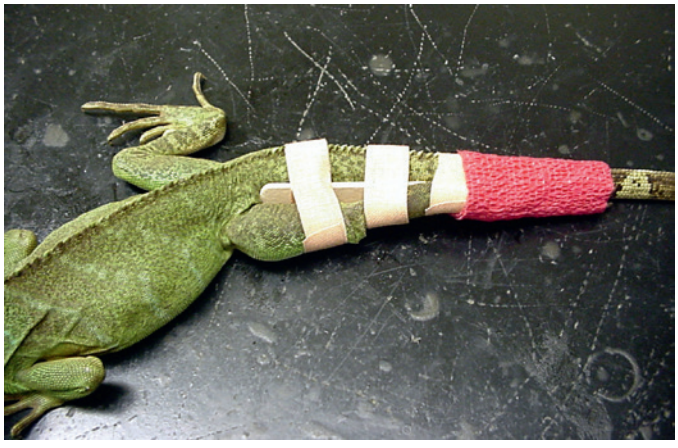

FIG 108.2 Immobilization of the pelvic limb secured to the tail base in a Chinese water dragon (*Physignathus cocincinus*). (Courtesy of Stephen J. Divers.)

The principles of application are to provide an even, continuous layer of cotton padding that conforms to the body and is just thick enough to allow a tube to fit snuggly over top. A lightweight, rigid tube (cardboard) is then placed over the affected area. Tube ends should be padded and the tube affixed to the snake using elastic adhesive bandage followed by waterproof tape (Fig. 108.5).[17] It is critical to not add extra cotton padding in areas of depression or to add less over elevated areas, because this will exacerbate the fragment displacement. Snakes in body casts should be fed small food items that will not cause distension of the body wall and can be easily passed.[17]

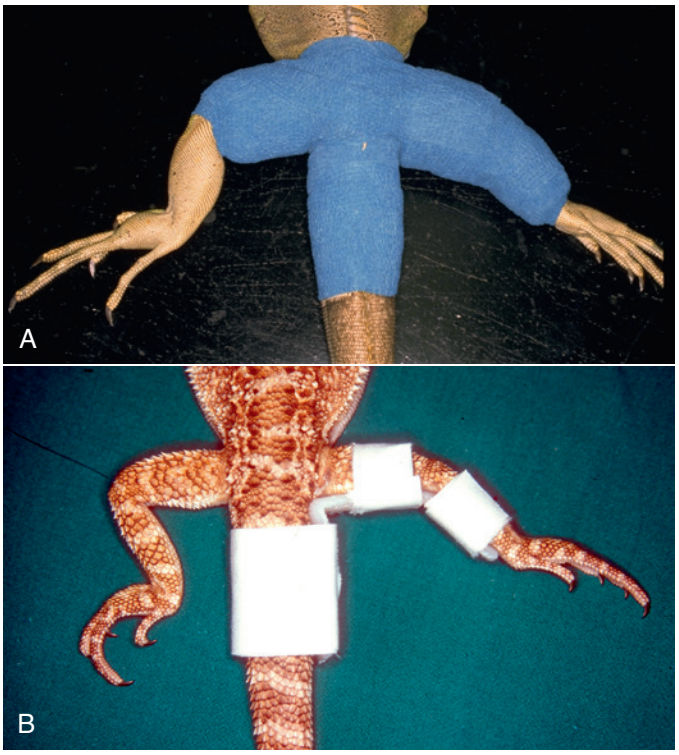

FIG 108.3 (A) A right femoral fracture immobilized using hexalite cast material covered with vetwrap in a green iguana *(Iguana iguana)*. The cast extends from the right tarsus, across the dorsal pelvis to the left stifle to immobilize the coxofemoral joints. (B) Fractured right femur in an inland bearded dragon (*Pogona vitticeps)*. The stifle and coxofemoral joints are immobilized using a lightweight thermal splint and tape, which extends down the tail base. (Courtesy of Stephen J. Divers.)

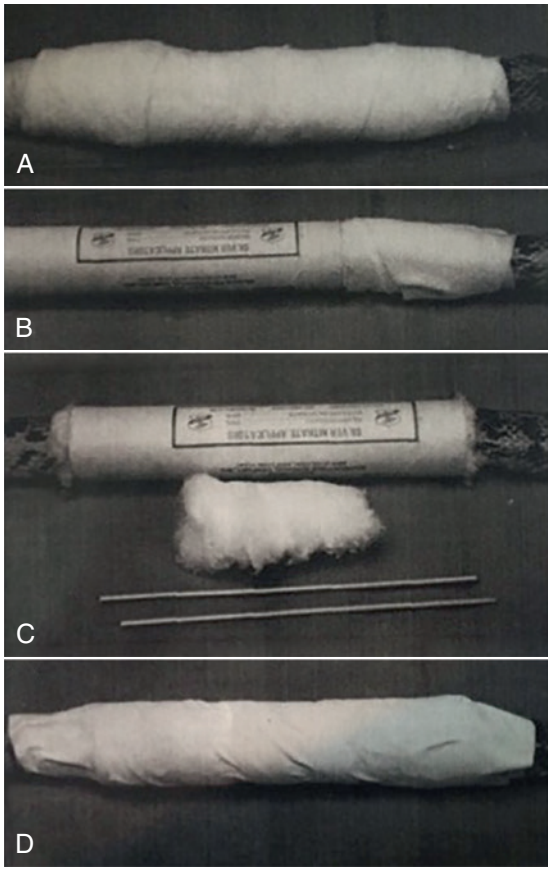

FIG 108.5 Application of a body cast in a snake. (A) Continuous layers of cotton bandage are applied to the affected area, taking care to apply cotton evenly and thick enough for a snug fit of the tube. (B) A rigid tube is fitted over the site. (C) Any openings are filled and padded with additional cotton. (D) The cast is then secured using adhesive bandage, including segments of the body proximal and distal to the tube. Water repellent tape is then applied over top.

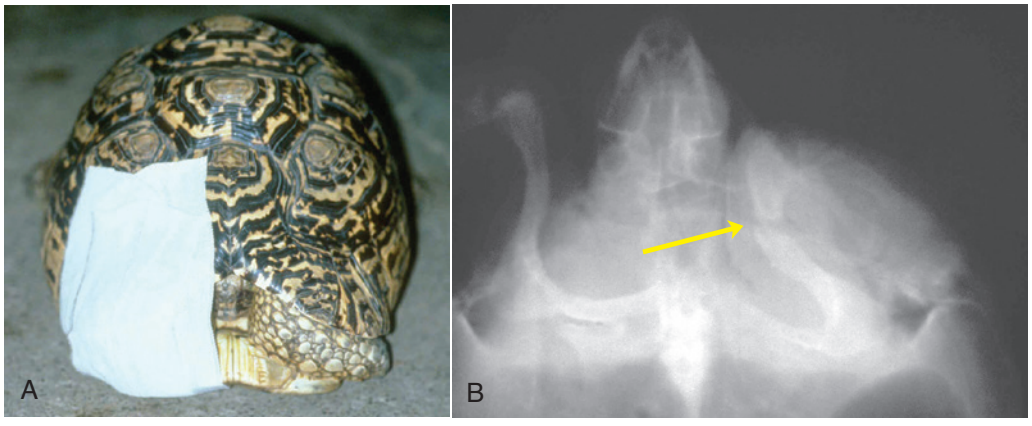

FIG 108.4 (A) In chelonians with a fractured humerus or femur, the limb can be folded into the cavity created between the plastron and the carapace and taped in place to prevent movement, as shown in this leopard tortoise (*Stigmochelys pardalis*). (B) It is recommended to radiograph the limb after it is secured in place to ensure adequate reduction (arrow).

VetBooks.ir

Orthoplast (Johnson & Johnson, New Brunswick, NJ), Hexcelite (Hexcel Medical, Dublin, CA), and veterinary thermoplastic (VTP; Imex Veterinary, Inc., Longview, TX) are rigid at room temperature but when heated in water become malleable. This allows the material to conform closely to the configuration of the limb. Orthoplast is a solid sheet, and Hexcelite is a webbed form available in a roll or sheet. Hexcelite is much easier to conform, but it is not as strong when cool and solid. Veterinary thermoplastic is available in various sizes and thicknesses. It is a solid sheet with a fibermesh reinforcement within the plastic. It is easy to cut to appropriate size, is more malleable than Orthoplast, and is more rigid than Hexcelite, thus making it ideally suited for use as a splint.

Radiography of the limb before and after placement of any bandage or splint is recommended to ensure adequate fracture alignment. If the fracture is not properly reduced, the splint or bandage should be removed, the limb set, and the splint or bandage then reapplied. Sedation or anesthesia is helpful when trying to align the fracture and also decreases patient pain and stress. Fractures splinted in this fashion may take several months to heal. Recheck the patient in approximately 1 to 2 weeks to assess the tolerance of any splints or bandages and the need for adaptations to the coaptation (as swelling reduces). This first recheck also permits assessment of potential complications earlier in the healing process. After the first recheck, the patient should be seen for examination and for radiographs every 4 to 6 weeks until union has occurred. Healing typically takes 6 to 12 weeks (even up to 18 months), and, unlike in mammals, initial healing will be made by fibrous union and may not be radiographically evident for many weeks. Owners should be clearly instructed to remove rocks, branches, or anything else upon which the animal may climb. As a result of enclosure redesign, the heat and light sources may also need to be repositioned to maintain the thermal mosaic within the preferred optimal temperature zone (POTZ) for the species.

Fracture Fixation and Arthrodesis

S. Emi Knafo and W. Michael Karlin

The majority of long bone fractures should ideally be repaired by internal fixation techniques. External coaptation may not be well tolerated by all reptile patients and is not feasible in aquatic and semiaquatic species. However, it is critical to perform a complete physical examination and assess the overall health of the patient, as bones affected by any metabolic bone disease (MBD) are not able to support internal fixation. Most surgical methods for fracture fixation, including bone plates, intramedullary pins, and cerclage wire, have been used successfully in reptiles.[1–7] The surgical approach to the long bones and the principles of application of internal fixation in reptiles are similar to those used in mammalian patients.

Intramedullary Steinmann Pins and orthopedic wires are inexpensive, provide axial alignment bending stability, and require minimal tissue exposure for insertion. Kirschner wires can be used as intramedullary pins and are available in sizes as small as 0.71 mm (0.028 inches). Spinal needles, which are available as small as 25 gauge (0.51 mm) x 8.9 cm (3.5 inches), can also be used as intramedullary pins in small patients.

External skeletal fixation (ESF) can be used for stabilizing a variety of fractures in reptiles. These fixation systems are especially well suited for open, contaminated fractures because they minimize the amount of hardware introduced into the bone through traumatized or contaminated tissues and can be placed without internal or permanent hardware in the surgical site. These devices provide good stability without interfering with joints and may be applied to small patients. ESF devices can include various-size Kirschner wires, Steinmann Pins, or hypodermic needles as fixation pins. Commercially available connecting bars and clamps are now more lightweight (carbon fiber) but can be substituted with acrylic polymer or a penrose drain or small hallow tube filled with acrylic (Table 109.1). In the past, polymethylmethacrylate has been used but presents some concerns for safety risks. Therefore products such as acrylic pin external fixation system (APEFS) or Acrylx from IMEX should be used. ESF is typically not possible in chelonian limbs, as the shell interferes with the external hardware. However, ESF techniques have been used successfully to repair mandibular fractures (see Chapter 110).[8]

In fracture management with ESF, pins must be cleaned daily with antiseptic disinfectant, as ascending infection can lead to pin loosening. It is common practice to provide intra-operative antimicrobial cover starting IV or IO 30 to 60 minutes prior to surgery. However, prevention of infection post-operatively relies heavily on aseptic preparation and appropriate pin management. The routine use of postoperative antibiotics following sterile surgery is inappropriate. Pin loosening is also commonly associated with unthreaded pins, and the components of the fixator should be inspected daily to identify problems early.[9] Highly active or fractious animals should be closely monitored for damage to the ESF or trauma to the affected limb. The success of the repair depends on the ability of the bone to heal before the fixation pins loosen and the device fails. Because reptile bones heal slowly, the pins are at risk of loosening before the fracture is stable. However, pin purchase can be maximized with positive-profile threaded pins (Fig. 109.1).[10–12] Radiographs should be repeated throughout convalescence to monitor healing. Typically radiographs are rechecked every 2 to 4 weeks, but frequency should be adjusted as needed based on patient progress.

The more heavy-bodied and active the animal is, the more rotational forces will impact fracture reduction and immobilization. Therefore in large patients, bone plating may be the most appropriate fixation technique. Bone plates provide excellent rigid fixation when angular forces may challenge the fixation.[13] However, application of bone plates often requires significant exposure for proper placement, though minimally invasive plate application techniques can be used to improve recovery and outcome.[14] In some instances, closure may be difficult, as reptile skin is less elastic than mammalian skin and may not accommodate the plate easily.[13] Veterinary cuttable plates (Synthes Ltd. USA, Paoli, PA) with screws as small as 1.5 mm in diameter (1.1 mm core diameter) permit plating of bones as small as 3 mm in diameter. Finger plates are also applicable to many long bone fractures in small reptiles. In some reptiles, the long bones are more dramatically curved, and plate contouring will be necessary. The 2.7-mm reconstruction plates may be used to allow the plate to be contoured to such bones. Bone plating requires specific expertise and equipment (Fig. 109.2). Locking plates have also been beneficial in providing a stable internal angle construct, which has the benefit of increased stability compared to traditional systems and is superior in soft bone (Table 109.2).

In most cases, removal of bone plates is not necessary or recommended. As is standard practice in domestic species, the decision to remove intramedullary pins or external skeletal fixators should be based on radiographic evidence of bone healing. However, in reptiles a fibrous union forms before radiographic evidence of healing occurs. This fibrous union may provide adequate stability, allowing fracture healing to proceed to completion if the implants fail or must be removed before the development of radiographic union.

BONE GRAFTING

Due to the nature of most reptilian fractures (e.g., trauma, MBD, hypomineralization, pathological fractures), rigid fixation is often not possible. Compression across the fracture site is paramount to ensure primary bone healing, but this may not always be possible in the reptile patient. Motion at the fracture site is a common reason for fracture repair failure. In many cases, external coaptation holds the limb steady with the fracture fragments in approximation but does not provide the same compression as properly applied bone plates. Incomplete fracture healing may still produce an acceptable outcome for small

terrestrial reptiles and those kept as pets. However, large reptiles, aquatic species, and wild individuals may not do well if their limbs are not completely functional.

As is commonly performed in mammalian patients with complicated fracture repairs, corticocancellous bone grafts may be necessary.[15] Bone grafts can be classified as osteogenic, osteoinductive, and osteoconductive. Osteogenic bone grafts supply and promote bone-forming cells. An osteoinductive bone graft has the ability to induce bone formation when placed into an area where no bone formation will occur. Osteoconductive grafts provide a scaffold for bone formation. In larger reptiles, bone grafts can be harvested from the proximal humerus or femur. A section of rib can be collected, morselized, and used as a corticocancellous graft. In smaller animals, the wing of the ilium is readily accessible. An incision is made over either wing, and a rongeur is used to harvest pieces of bone. These bone chips can be carefully crushed to increase the surface area of the graft and placed in a saline-soaked gauze until they can be packed within and around the fracture site prior to closure. There has been research that shows safety and benefit to the use of platelet-rich plasma in exotic species to promote healing, including a fracture model.[16,17]

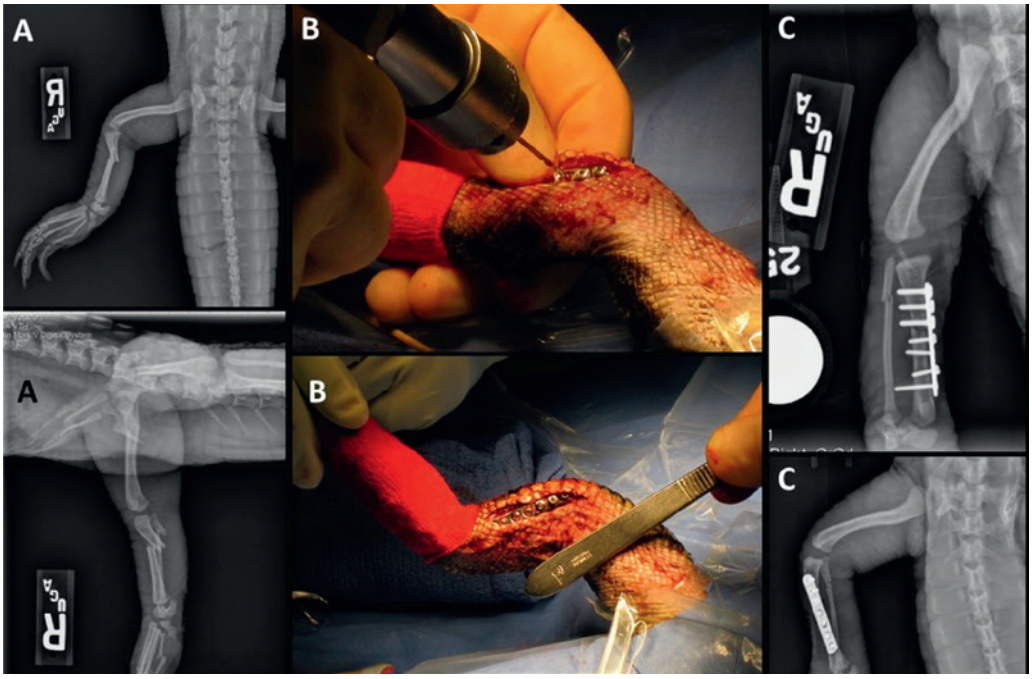

FIG 109.2 (A) Preoperative radiographs demonstrating complete, transverse, mid-diaphyseal right tibia/fibula fracture with moderate angulation (juvenile American alligator, *Alligator mississippiensis*). (B) Intraoperative photographs showing application of a locking bone plate. (C) Postoperative radiographs showing fracture fixation by plating. (Courtesy of Stephen J. Divers.)

Osteogenic bone stimulation can be used as an adjunct therapy to bone graft and external skeletal fixator. Successful use was reported in a Chinese water dragon (*Physignathus cocincinus*) to repair a nonunion fracture of the tibia.[18] A 1.5-volt (DC) battery source provided constant current output (20.5 ma), the IM pin served as the anode, and a subcutaneous implant over the nonunion site acted as the cathode. The fractured tibia was repaired using an IM pin and external skeletal fixator along with a bone graft harvested from the ilium. The osteogenic bone stimulator was left in place for 3 weeks, and the external fixator and IM pin were removed 3 weeks later. Radiographic evidence showed callus formation at the 6-week mark, and the animal recovered well.

COMPLICATIONS OF FRACTURE REPAIR

Implant loosening, migration, bending, and osteomyelitis are all potential complications. Failure of fracture repair should be approached similarly as in domestic mammals. Patient husbandry and nutrition must also be evaluated and optimized. Implants need to be removed from infected sites and cultured for pathogens. Antibiotics should be selected on the basis of culture and sensitivity results. Fistulae should be explored, sequestra removed, affected bone radically debrided, and abscesses treated. Once the patient is stabilized and the infection is controlled, attempts to repair the fracture can be pursued. If owner finances or compliance are concerns, or the limb is not salvageable, then amputation should be considered (see Chapter 111).

Osteomyelitis is a common disease in reptiles, often from hematogenous spread. However, osteomyelitis can also occur secondary to trauma, fractures, and implant infections. Diagnosis is made by hematology, palpation, fine-needle aspirate for cytology and culture, and radiography. Typical signs in mammals, such as swelling, heat, and pain, are not typically appreciated in reptiles.[19] Additionally, radiographically evident periosteal reactions expected in mammals may not be present in reptiles.[13] Implantation of antibiotic-impregnated methylmethacrylate beads has proven successful for the treatment of osteomyelitis. If beads have been placed in a joint, they must be removed once the infection is resolved. If the beads are placed in soft tissue or in or around bone, the beads do not need to be recovered.

ARTHRODESIS

Techniques used in mammalian orthopedics have been used in reptiles as treatment modalities with varying degrees of success. Coxofemoral luxations are seen frequently in chelonians and lizards. When presented early, these luxations are usually reasonably easy to reduce. Immobilization is achieved by bandaging the limb within the prefemoral fossa of chelonians and maintaining this for approximately 2 weeks. It is important to radiograph post bandaging to ensure that fracture displacement has not been aggravated. If coxofemoral luxations are presented in a chronic condition, reduction can be more challenging. In severe cases, femoral head (and neck) excision may be necessary. Successful use of this technique has been reported in chelonians,[2] but less favorable results have been reported in lizards.[20] Stifle luxation and cranial cruciate ligament rupture was successfully repaired using an over-the-top (with lateral vastus autograft) technique in a tortoise.[21]

In certain cases, arthrodesis may be necessary. Arthrodesis of the elbow was successfully performed in a green iguana (Mader D, unpublished data) with deep soft tissue injuries and osteomyelitis (Fig. 109.3). In this individual, the opposite forelimb had been previously amputated. Therefore amputation of the newly affected limb was not possible, though it likely would have been the treatment of choice. A cubital arthrotomy was performed, and the joint surface was debrided. The remaining space was packed with a cancellous bone graft, and a type II transarticular external fixator was applied (Fig. 109.4). Postoperative cage rest was instituted, and by 12 weeks sufficient callus was observed radiographically to remove the external skeletal fixator. The patient was mobile and was able to climb slightly inclined branches.

A desert tortoise required a carpal arthrodesis after repeated injections of enrofloxacin in the proximal limb resulted in radial nerve paralysis (Mader D, unpublished data). A mid-diaphyseal hole was drilled through the radius. A 20-guage orthopedic wire was then used to encircle ventral

VetBooks.ir

FIG 109.3 Osteomyelitis in the elbow of a green iguana (*Iguana iguana*). (Courtesy of Douglas R. Mader.)

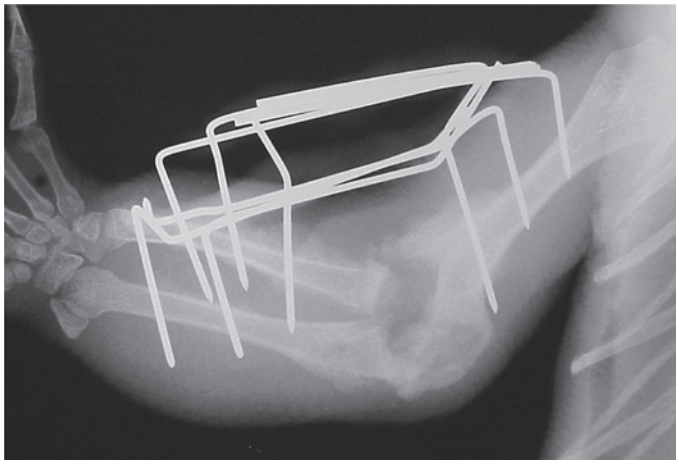

FIG 109.4 An arthrotomy was performed on the elbow joint of the patient in Fig. 109.3. The joint surface was curetted away, and the space was packed with a corticocancellous bone graft. A biplanar external fixator was applied across the joint for stability. Radiographs taken at 6 weeks postsurgery showed initial bridging and callus formation. (Courtesy of Douglas R. Mader.)

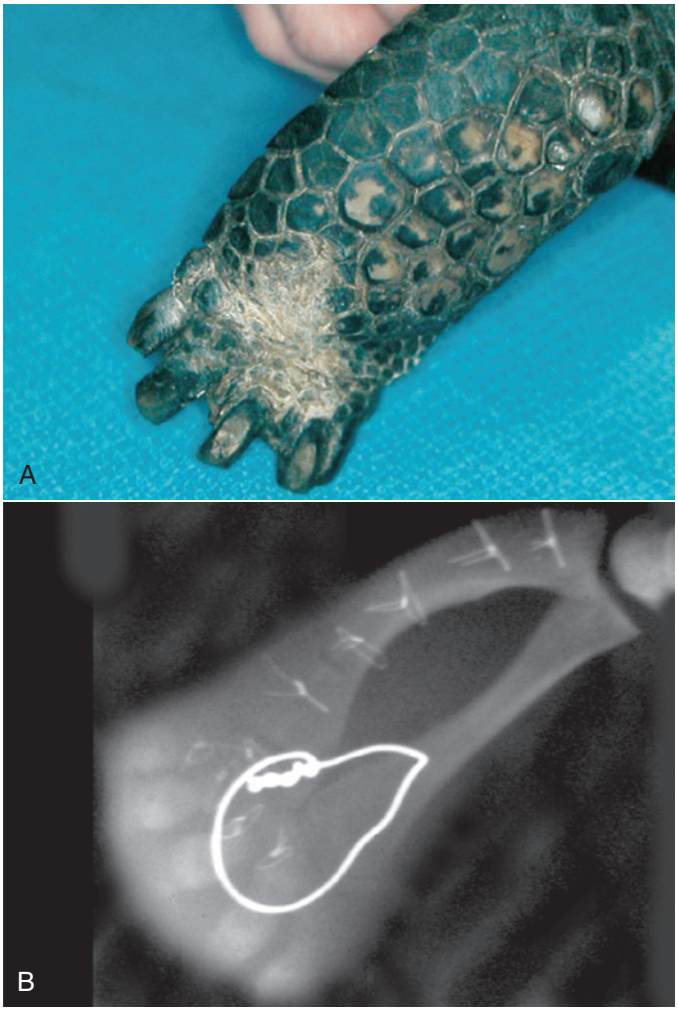

FIG 109.5 (A) Radial paralysis in a desert tortoise (*Gopherus agassizii* caused by multiple injections of enrofloxacin in the upper limb. (B) The carpus was arthrodesed in dorsiflexion using orthopedic wire. This permitted the animal to walk without dragging its foot. (Courtesy of Douglas R. Mader.)

to the digits and connect back to its origin in the radius (Fig. 109.5). With tension on the wire, the carpus was maintained in permanent extension.

PHYSICAL THERAPY

Physical therapy aims to restore full use of an injured body part through increasing blood and lymphatic flow through affected tissues. Such increased perfusion helps resolve inflammation, minimize muscle atrophy, and reduce the incidence of fracture callus entrapment of soft tissues. Range of motion (ROM) is preserved or regained through active and passive ROM exercises. Joint angles should be measured objectively at the start of PT and periodically throughout the course of treatment. Each joint should be moved through 10 flexions and extensions, and then the entire limb moved through full ROM.[22] Massage softens and lengthens tendons and muscles and improves circulation. It also serves to separate abnormally adhered, inflamed soft tissue structures. Other therapies include ultrasound, which produces deep physiological heat and is best used in cases of muscle spasm, adhesions, and tendon/ligament injury.[22] Application of heat or cold also has utility in the postoperative and convalescent periods. Cold is appropriate in the first 24 to 72 hours after surgery to induce vasoconstriction, and as a result reduces edema and inflammation and decreases pain perception by slowing nerve-conduction velocity. Heat produces vasodilation, which increases local perfusion and aids in drainage of edema. Pain relief is achieved by softening muscles and soft tissues that may be in spasm.[22] Please see Chapter 129 for additional information on low-level therapeutic laser therapy.

Physical therapy (PT) in reptiles is not well described in the literature. Several case reports describe the use of specific techniques in individual animals with varied success. However, postoperative PT is likely an important yet underappreciated tool in aiding recovery in reptile species (see Chapter 131).

A recent case report describes the use of the Wolfe Kinetic Technique to treat severe osteoarthritis in a 20-year-old Komodo dragon (*Varanus komodoensis*).[23] This animal had failed to respond significantly to oral analgesics and suffered from chronic, progressive lameness with decreased mobility. The Wolfe Kinetic Technique (WKT), which uses gentle manual manipulation, aims to change movement patterns to spread the workload

VetBooks.ir

of the body as the animal moves. The WKT focuses on the spine, ribs, and pelvis, because the central tenet is that spine and core must move normally in order for the extremities to function normally.[23] This Komodo dragon underwent weekly sessions with a physical therapist that focused on the thoracic spine, scapular stabilizers, lumbar spine, and pelvis. Within the first month, a noticeable improvement in mobility was reported. By 9 weeks, the animal was seen running, and by 12 weeks the animal was able to successfully negotiate a 12-inch step, which had not been witnessed in several years. The animal's gait, comfort, and mobility improved dramatically, and the sessions with the physical therapist were decreased to every other week. Eventually, the animal was taken off all but one oral analgesic, and the dose of that remaining medication was reduced with no adverse effects.[23]

Skull and Spinal Fracture Repair

S. Emi Knafo and W. Michael Karlin

Skull and spinal fractures can occur as a result of traumatic or metabolic causes. Skull fractures are more commonly seen in reptile species with rigid skulls. However, species with cranial kinesis, specifically snakes, still suffer from skull fractures in spite of their relatively malleable skulls. Fractures of the calvarium, mandible, and separation of the symphysis are the most common injuries seen.[1–3] Pathological fractures are associated with metabolic bone disease (MBD), and iatrogenic mandibular fractures (and dental trauma) can occur during attempts to open the mouth in an animal concurrently suffering from MBD or other pathology (especially osteomyelitis).

SKULL FRACTURES

Chinese water dragons (*Physignathus cocincinus*), sail-fin lizards (*Hydrosaurus pustulatus*), and other high-energy, nervous lizards may cause trauma to the mandible by repeated concussive force against enclosure walls. Similarly, snakes may strike glass enclosure walls while attempting to capture prey and injure their jaws. Because their skulls are normally distensible, fractures may initially go unnoticed; however, mandibular fractures are frequently open, which makes the traumatic event more evident to caretakers.[4] The open nature of mandibular fractures also increases the risk of secondary infection.[4–7] Symphyseal fractures in lizards can result in malalignment of dentition if not repaired.[4–7] Circumferential wiring of the mandibular symphysis (Fig. 110.1) creates a stable enough repair to allow healing, as long as the remainder of the jaw is intact. When oral fractures are more severe, interdental wiring with splinting, external fixator, or plating may be necessary.[4–7]

Diagnostic imaging should be performed to completely evaluate fracture configuration. Radiography should be performed before and after fixation. Alternatively, computed tomography or other advanced imaging can help yield greater detail and has been shown to aid in guiding diagnosis and repair in several species.[1,8] External fixation is commonly used to stabilize mandibular fractures in reptiles. Small pins or even hypodermic needles can be used as cross pins to create an external skeletal fixator. Intramedullary pins and cerclage wires can be used depending on the configuration of the fracture and size of the patient (see Fig. 110.1). The use of external or internal fixation

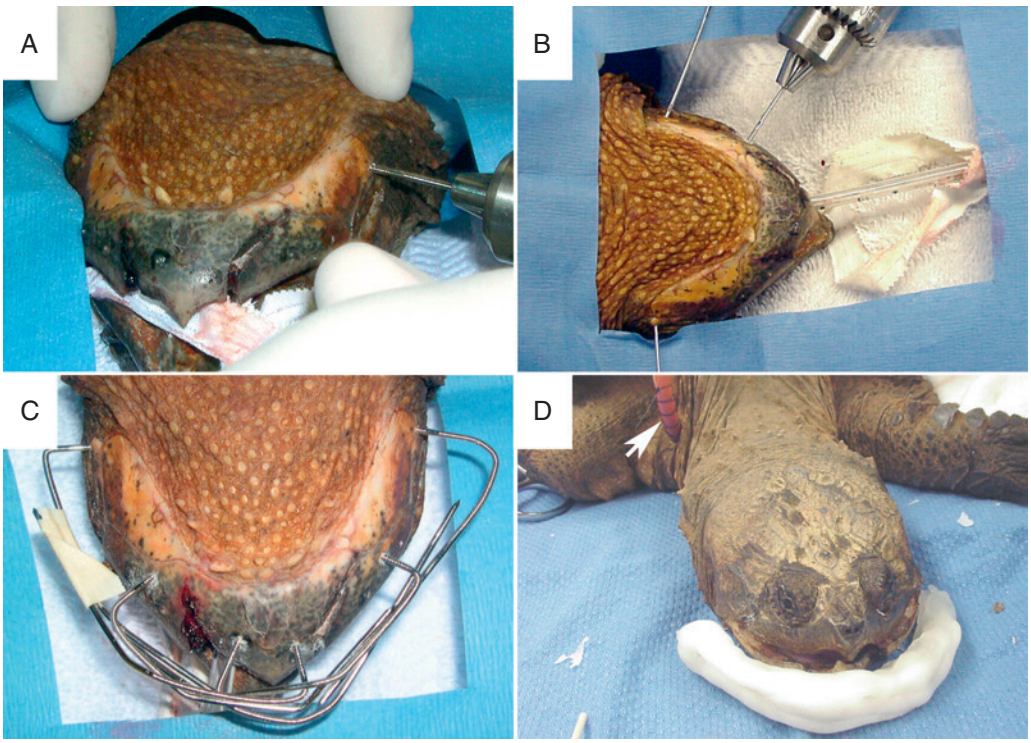

FIG 110.1 (A and B) Placement of cross pins using hand chuck in an anesthetized snapping turtle (*Chelydra serpentine*) with mandibular fractures. (C) Bent cross pins to form a tie-in external skeletal fixator connecting bar. (D) Application of polymethylmethacrylate to strengthen and cover connecting bar. VetBooks.ir

allows the animal to continue eating. However, external coaptation in the form of bandaging the mouth closed can also be used to stabilize jaw fractures.[4–7] In these cases, an esophagostomy tube must be placed to allow nutritional support during healing.[4] Typically, this technique is used in patients with suboptimal bone health, such as in cases of MBD. Traumatic, perforating fractures extending into the nasal cavities and paranasal sinuses in an alligator were successfully treated using methyl methacrylate to create an airtight seal over the perforations during healing.[3]

SPINAL FRACTURES

Pathological fractures of the spine are seen commonly in chelonians and lizards suffering from metabolic bone disease. Snakes have been reported to suffer from bacterial infection of the vertebrae manifesting as segmental, proliferative osteoarthritis and osteoarthrosis of the spine.[9] Most commonly, gram-negative bacteria are isolated, but gram-positive isolates have been reported.[9] Trauma from improper handling can also be a cause of spinal fracture in reptiles. When surgical stabilization of spinal column injury is pursued, it is important to focus on neutralizing the forces that result in bending, compression, shear, and torsion on the affected vertebra.[10–13] Severe injury can potentially occur to the spinal cord or nerve roots with fractures and luxation of the spinal column.[10–13] Stabilization of the spinal column and possible decompression of the cord or both should be explored to mitigate further damage.[10–13] It is important to perform a thorough physical and neurological examination to determine if any concurrent injury may be present. The decision on how to treat luxations and fractures of the spine depends largely on the fracture and the neurological status of the patient. Patients that have an unstable or compressive lesion should be surgically treated.[10–13] Radiographic or CT evaluation is important to determine displacement, but nondisplaced or minimally displaced injuries should be approached cautiously because they can be unstable.[13] Treatment of spinal fractures and luxations can be addressed with conservative or surgical management, used alone or in combination.

The application of a body cast for nonsurgical treatment of spinal fractures is described in Chapter 108. Given that most cases of spinal fracture in reptiles are due to pathological processes (MBD or bacterial infection), surgical repair may not be recommended in all cases. If there is concern for a possible pathological process, then the underlying disease should be addressed. Nonsurgical fracture management techniques may be applied until the patient is more stable and a better surgical candidate. If surgery is to be pursued, the same principles of spinal surgery in mammals apply. In cases where severe neurological deficits are present, the animal's quality of life should be evaluated and euthanasia considered.

Cervical spondylomyelopathy (CSM) is a disease often seen in large- and giant-breed dogs characterized by compression of the cervical spinal cord and/or nerve roots. This is a very complex disease and is not fully understood. Treatment is focused on stabilization and decompression of the cervical spinal cord. Pathophysiology of cervical spondylomyelopathy involves both static (cervical canal stenosis) and dynamic factors. A similar disease of compressive myelopathy of the cervical spine has been seen in four captive Komodo dragons (*Varanus komodoensis*), with three presumptively induced by trauma.[14] Clinical signs and disease progression were similar to what has been seen in small animals; however, the onset of clinical signs is not often associated with a known trauma (in small animals), as was the case in three of the four affected Komodo dragons.[14] The outcome in the case series of Komodo dragons resulted in all dragons being euthanized (range 4 days to 12 months). Komodo dragons have a single occipital condyle (as in all reptiles), single intervertebral articular surface, and ligamentous differences compared to mammals.[1] The difference in anatomy between the Komodo dragon and small animals may be a reason for the poor outcomes noted. Further investigation is needed to ascertain the best way to manage compressive myelopathy in Komodo dragons.

Limb Amputation

S. Emi Knafo and W. Michael Karlin

Digits and limbs frequently require amputation as a result of trauma or infection.[1,2] Chronic dysecdysis around a toe, or wire/string around a limb, can quickly result in ischemic injury. In cases where infection or pain is not sufficiently controlled, or if there is evidence of osteomyelitis, amputation is appropriate.[1,2] Highly comminuted fractures where blood supply is compromised and cases of nonunion and limb neoplasia may also necessitate amputation.[1,2] Lesions confined to the phalanges are typically amputated at the level of the metacarpus or metatarsus. When disease has progressed more proximally to include the carpus or tarsus, then partial or complete limb amputation is indicated.[1,2] Before amputation is pursued, it is important to assess the animal to determine if any other systemic, orthopedic, or neurological issues are present that may affect outcome once a limb is amputated. In some cases, slinging the affected leg can help determine how the animal will adapt to amputation and get them accustomed to ambulating without the limb. It is important to note that occasionally this can be misleading in dogs, where an individual dog will not adapt well to the sling but does well after amputation.[3] This could also be the case in some reptiles and should be kept in mind when assessing patients and advising owners.

In small animal limb amputations, there are several options for removal of the forelimb and hind limb. In forelimb amputations, techniques include disarticulation of the scapulohumeral joint or removal of the scapula. In hind limb amputations, techniques include osteotomy at the mid-diaphysis of the femur, disarticulation of the coxofemoral joint, and acetabulectomy. These different methods all have their proposed advantages and disadvantages depending on the disease process that is occurring to necessitate amputation.[4] Complications associated with amputations in small animals have been reported to include permanent gait changes, seroma formation, neuroma, phantom pain, and cervical disc herniation.[4]

Partial limb amputation will leave a stump that can be used to aid ambulation. However, such stumps can also become traumatized and (chronically) secondarily infected. The keratinized skin of most reptiles may reduce the risk of ulceration; however, as body weight increases, this complication becomes more common. Therefore partial limb amputation should be reserved for small lizards and chelonians.[1,2] When performing a partial limb amputation, the skin should be incised distal to the intended amputation site to preserve ample soft tissues to create tension-free closures. If possible, the incision should be oriented in

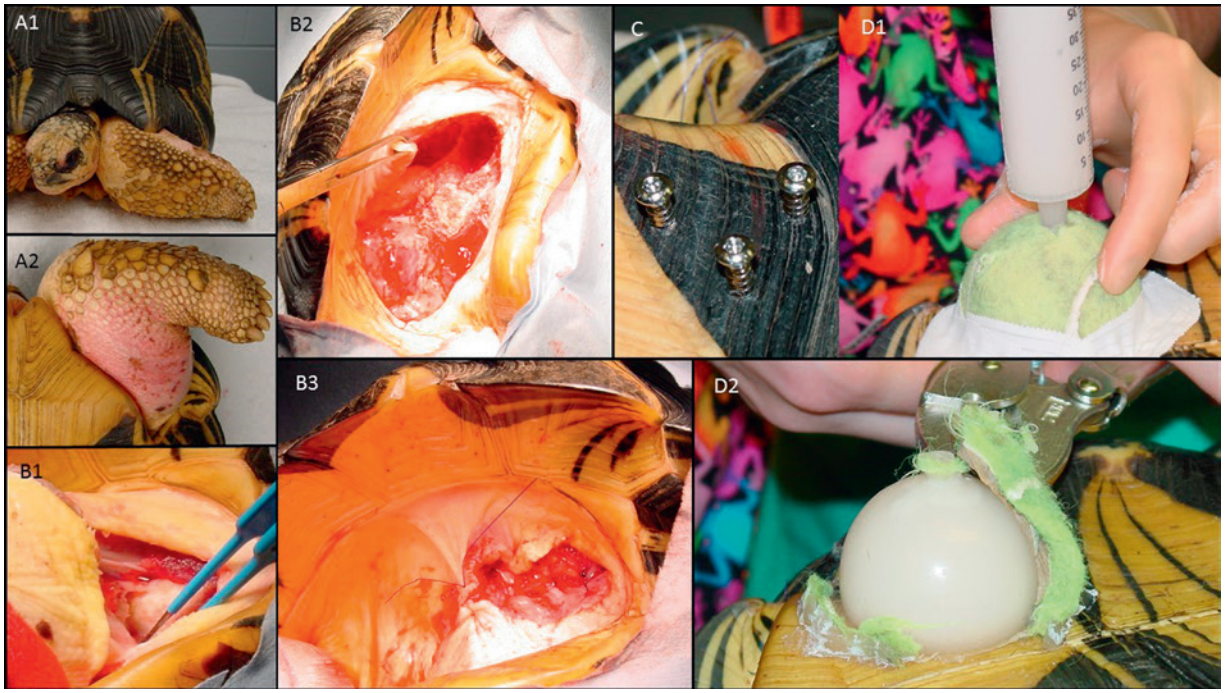

FIG 111.1 (A1 and A2) Sarcoma in the left forelimb of a radiated tortoise (*Astrochelys radiata*). (B1–B3) Amputation of the left forelimb at the scapulohumeral joint. (C) Three screws secured to the plastron. (D1–D2) Half a tennis ball placed over screws from panel (C), used as a mold for polymethylmethacrylate cement, with the tennis ball removed once set. (Courtesy of Stephen J. Divers.)

VetBooks.ir

order to create a flap from the dorsal surface that is placed over the end of the amputated bone and sutured ventrally. This places healthy, keratinized skin on the weight-bearing surface in contact with the substrate. Muscle bellies should be transected at their distal insertions (or as distally as possible) and dissected proximally to allow for adequate soft tissue coverage (padding) over the amputation site. Soft tissues should ideally be transected using radiosurgery or laser to reduce hemorrhage.[2] Major vessels should be identified and ligated with suture, a vessel-sealing device, or vascular clips. A proximal tourniquet may provide additional aid in reducing surgical hemorrhage.

In large lizards, small lizards with proximal lesions, crocodilians, and large chelonians, the entire limb should be removed. This requires disarticulation of the limb at the scapulohumeral or coxofemoral joint.[1,2] A similar surgical approach should be made in these cases, with attention paid to preservation of adequate skin and muscle to allow tension-free closure. The muscles should be elevated proximally from the periosteum until the articulation is exposed. Smooth transection of the nerves with a scalpel, laser, or radiosurgery is recommended. The nerves may be injected with lidocaine or bupivicaine to minimize postoperative pain and help decrease anesthetic requirements. Chelonians undergoing hind limb amputation may benefit from intrathecal anesthesia as described in Chapter 51. In chelonians, prostheses may be provided by securing a furniture caster, wheel, or other appropriate object (tennis or billiard ball cut in half, toy skateboard, etc.) on the plastron ventral to the shoulder or hip joint with an acrylic cement (Fig. 111.1).[2,5] This helps elevate the affected corner of the shell and aids mobility with the remaining limbs. Use of prostheses also prevents dragging and secondary erosion of the plastron. In general, wheeled devices work best on firm level ground, while half-balls work better on natural ground. Postoperatively, bandages should be placed to offer, at minimum, protection of the incision and often compression when indicated. Cage rest and modifications of the enclosure are important during convalescence as the patient adapts to ambulating with three limbs.

Tail Amputation

Richard S. Funk

It is sometimes necessary to amputate a reptile's tail. Damage to the tail from trauma, including bite wounds, infection, or neoplasia, may leave the tail compromised such that amputation becomes the best treatment. The surgeon should strive to perform the amputation proximally enough to ensure all affected tissue is removed but distally enough to leave as much functional tail as possible. In male snakes and lizards, it is advisable to appreciate the location of and avoid the hemipenes. Along with a thorough physical examination, radiography or CT may be useful to determine bone involvement and help define the best site for amputation.

There is considerable taxonomic variation in the ability of lizards to perform autotomy, and many exceptions exist.[1] Most, if not all, members of the Dibamidae, Anelytropsidae, Lacertidae, Cordylidae, Xantusiidae, Scincidae, Teiidae, Anguidae, and Anniellidae possess postpygal vertebrae and can perform autotomy along the length of the tail. Most members of the Gekkonidae (including Eublepharinae and Diplodactylinae) can perform autotomy, but functional autotomy planes are restricted to the most basal postpygal vertebrae close to the tail base. All agamids that have been examined lack autotomy planes in their caudal vertebrae, but intervertebral breakage takes place in many forms. Vertebral autotomy planes have been reported in many anolines. Vertebral autotomy planes are largely absent or reduced during ontogeny in the iguanids and basiliscines but present in all sceloporines and most tropidurines. No vertebral fracture planes or autotomy have been found in the Varanidae, Lanthanotidae, Helodermatidae, and Chameleonidae. Tail autotomy is rare in snakes but has been reported in some colubrids.[1]

With lizards that are capable of caudal autotomy through an anatomic autotomy plane, it is practical and simple to aseptically scrub the tail and hold the base of the tail with one hand, and then with the other hand bend the tail sharply laterally to effectively amputate through a natural autotomy site (Fig. 112.1). Alternatively, some clinicians may prefer to control the exact location of the amputation (a safe distance above the damage or pathology), and a scalpel blade can be used to completely sever the tail. In either case little hemorrhage occurs, but pressure and styptic powder or solution can be utilized to control bleeding. The tail tip is left unsutured, but a temporary bandage may be applied. The owner can remove the bandage in several days and await the regeneration of a new though modified and shorter tail tip. Sedation or anesthesia is required, and some clinicians prefer to administer a local or ring block using lidocaine or bupivacaine proximal to the projected autotomy site. If the site is closed with sutures, the lizard may not be able to regenerate its tail.[2]

In small lizards, with thin tails, utilizing either a ring block or sedation, the tail is aseptically prepared, and the tail tip may then be cut off with a scalpel blade or with surgical scissors. A styptic powder can be applied, and the exposed tip may be closed with surgical adhesive. Some clinicians may choose to place a small temporary bandage.

With larger lizards that naturally exhibit tail autotomy, such as the green iguana (*Iguana iguana*), once adults and depending on the location of the amputation (if a major portion of the tail is involved) the tail may no longer exhibit autotomy and often requires surgery and closure at the amputation site (Fig. 112.2). Amputation surgery will also be necessary for reptiles that cannot naturally autotomize the tail including some lizards (e.g., helodermatids, varanids) and snakes, chelonians and crocodilians.

The reptile is anesthetized, and local anesthesia can be helpful (e.g., ring block, intrathecal anesthesia) (see Section 6). Squamates and crocodilians are typically placed in ventral recumbency, but dorsal recumbency often affords better visualization around the posterior shell of chelonians. In larger animals a tourniquet may be placed proximal to the surgical site (see Fig. 112.2). It is best to visualize the completed surgical site as a curved stump, either closed dorsoventrally or laterally, before making any incisions. For example, with green iguanas, the author's preference is a laterally closed site, but with bearded dragons, a dorsoventrally closed site is more esthetic (Fig. 112.3). Symmetrical wedge incisons are then made on either side of the tail (or top and bottom). The muscle is then transected, and the tail amputation completed by dissecting between two caudal vertebrae proximal to the tip of the skin where the two wedge tips are, such that closure can be accomplished with minimal tension. If there is too much tension on the skin, additional soft tissue dissection and removal can help. The tail skin is not elastic as it is in mammals. In larger reptiles the individual muscle groups (caudal spinalis, caudal extensor medialis, caudal extensor lateralis, iliocaudalis, caudofemoralis longus, ischiocudalis, and inferior coccygeus) may be identifiable, and the caudal vein or variable vessels may require ligation before skin closure.[3] The muscles should be opposed to cover the exposed vertebrae using absorbable monofilament suture (e.g., polyiglecaprone 25). The skin is trimmed if necessary and closed with eversion utilizing horizontal mattress or simple interrupted sutures.

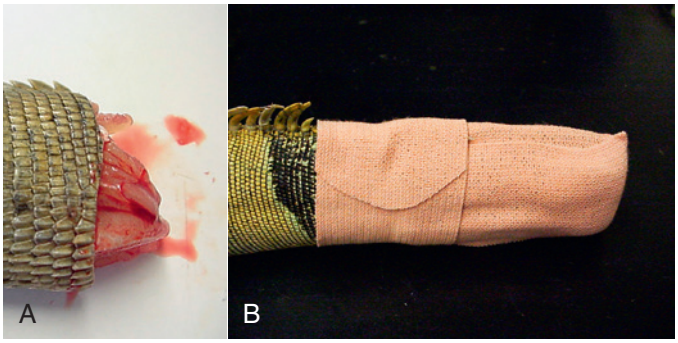

FIG 112.1 Simple tail amputation through a vertebral fracture plane in a green iguana (*Iguana iguana*). (A) Following the snap and twist, the tail separates and the muscle fibers can be trimmed. (B) The tail is not sutured but can be bandaged to prevent gross contamination. (Courtesy of Stephen J. Divers.)

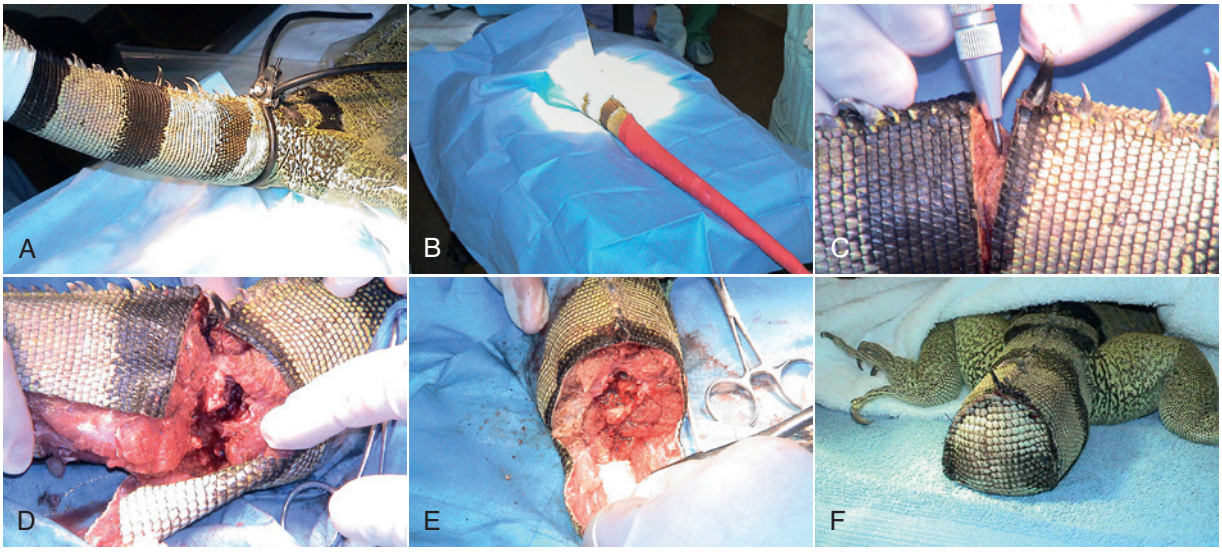

FIG 112.2 Major proximal tail amputation in a green iguana (*Iguana iguana)* by Heather Barron and Michael McBride. (A) Application of a tourniquet to reduce intraoperative hemorrhage. The tail has been suspended to facilitate aseptic preparation. (B) The tail has been placed through a sterile drape and wrapped with sterile bandaging distal to the planned surgical site. (C) Dissection through the dorsal skin and caudal spinalis, caudal extensor medialis, caudal extensor lateralis, and iliocaudalis muscles using a CO_2 laser. (D) Continued dissection through the lateral and ventral muscles, including the caudofemoralis longus, ischiocaudalis, and inferior coccygeus, followed by sharp vertebral separation. A large ventral skin flap is preserved for closure. (E) Following complete dissection of all muscles, ligamentous attachments, and the coccygeal spine, the muscles are sutured over the vertebral stump. (F) The large ventral skin flap is trimmed and sutured closed. (Courtesy of Stephen J. Divers.)

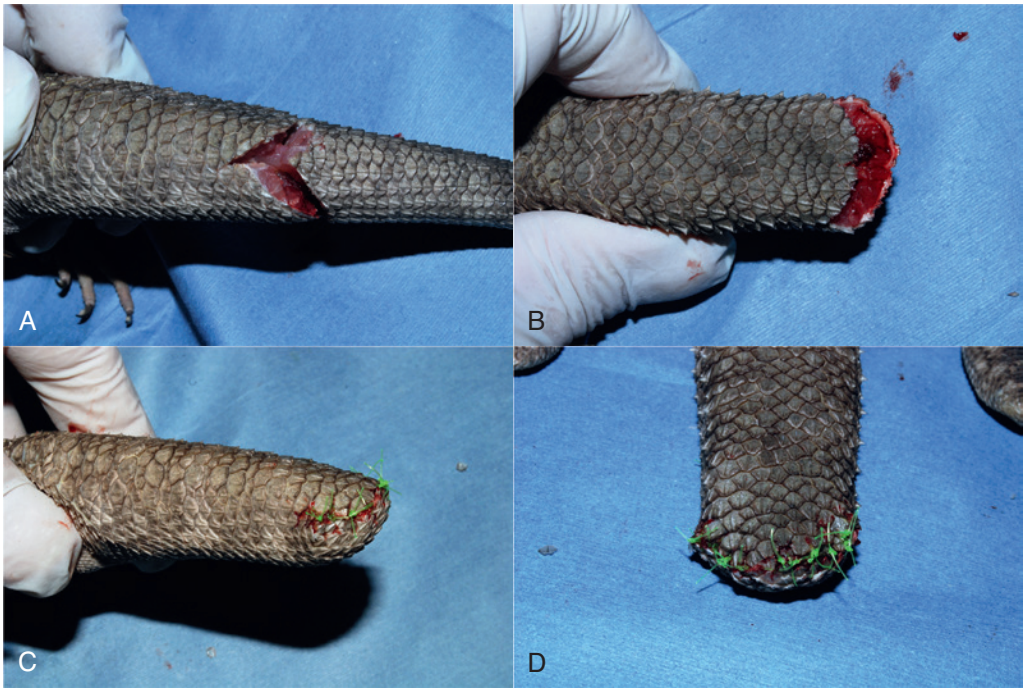

FIG 112.3 (A and B) Symmetrical wedge incisions are made in a top to bottom orientation to amputate the tail in this bearded dragon (*Pogona vitticeps*). (C and D) This wedge incision allows for a dorsoventral closure, which works well in this species. Note that the skin sutures are oriented dorsally to minimize substrate contact. (Courtesy of Richard S. Funk.)

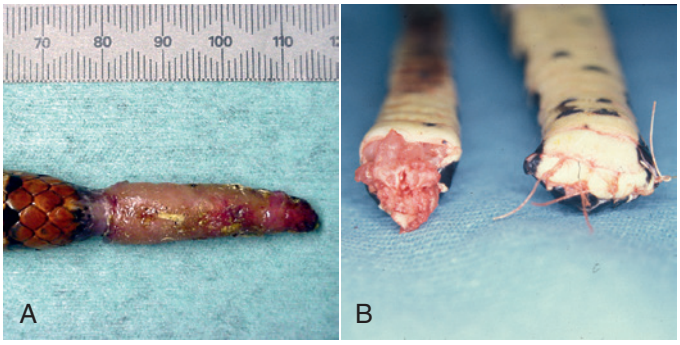

FIG 112.4 (A) Tail necrosis in a corn snake (*Pantherophis guttatus*). (B) View of the distal (amputated) and proximal (sutured) surgical sites following amputation. (Courtesy of Stephen J. Divers.)

Monofilament nonabsorbable (e.g., nylon) or absorbable (e.g., polydiaxanone) sutures may be utilized and removed 6 to 8 weeks later. Sometimes the sutures will be shed during ecdysis. With dorsoventrally flattened tails it is best to place the knots dorsally to minimize substrate contact (see Fig. 112.3).

Snake and chelonian tails may be similarly amputated under general anesthesia, but they tend to be more rounded in cross-section so the approach may be chosen based on esthetics (Fig. 112.4). Depending on access and severity, it may be necessary to resect parts of the posterior chelonian shell. Postoperative pain management is recommended with oral or injectable NSAID medications and/or opioids (see Chapter 50).

Shell Surgery and Repair

Terry M. Norton, Gregory J. Fleming,[†] and Jean Meyer

Automobile morbidity and mortality are among the most important conservation issues that affect turtles and other wildlife.[1] Shell trauma is the most common outcome of a turtle being hit by an automobile. These injuries vary in severity and often lead to death or require euthanasia. Other less common causes of shell trauma in turtles include boat strikes in aquatic turtles, lawn mowers and heavy equipment, human malicious behavior, and predation. Shell trauma in captive turtles occurs less frequently but may be caused by dog bites, thermal, crush, and fall injuries.

Although this chapter is focused on triage, repair, and follow-up of shell trauma in chelonians, it is important for veterinarians to be involved and take a lead role in the "bigger picture" mitigation efforts to help reduce the numbers being hit by automobiles. Mitigation efforts are typically applied to areas where large numbers of turtles are affected. Defining hot spots and temporal patterns to target mitigation strategies can be ascertained through active research.[2,3] Mitigation efforts may include placement of converts under roads to allow wildlife to move across the landscape without being hit,[4] static and flashing light signs on the road to alert drivers that turtles may be crossing,[5] active surveillance and moving turtles across road,[2,3,5] nest boxes with predator-proof caging,[6] fencing to prevent the turtle from crossing the road, awareness and education campaigns,[5] egg recovery from injured and dead females, egg incubation, and release of hatchlings or head-starting hatchlings.

With respect to wildlife rehabilitation, if a chelonian can be successfully treated and returned to the wild fully functional, then medical and surgical intervention should be considered. If the chelonian cannot be returned to the wild fully functional, in most cases humane euthanasia is recommended. Occasionally, a nonreleasable chelonian may be used for educational purposes if the appropriate facilities and programs are available and the turtle is comfortable despite its disabilities.

Determining which injuries are not treatable comes with experience, and triaging patients within the first few hours may determine which chelonians can be successfully treated and which cannot. In some situations, the turtle may need to be stabilized and given time to differentiate neurological deficits versus weakness and shock. These decisions are difficult, but with limited time and resources available, it is best to make this decision quickly to save months of work and emotional energy.

TRIAGE OF SHELL TRAUMA

Developing and following a triage system will assist the clinician in formulating a prognosis and implementing a successful treatment course. The following five categories of prognosis have been developed to assist the veterinarian in prognosis and treatment outcomes.[7]

The approximate age of the injury must also be considered when developing a prognosis (e.g., fresh < 6 hours, contaminated 6 to 24 hours, contaminated/infected > 24 hours). The same type of wound will have a very different prognosis depending on if it is recent trauma versus one that occurred a week ago and is now infected.

Excellent Prognosis

Turtles presenting with fresh shell injuries or fractures that are (1) uncontaminated, not infected (< 6 hours old); (2) singular, nondisplaced fracture that does not involve the spine; and (3) with only minor excoriations have the best prognosis for a full recovery. If there are no other associated medical issues, these wounds often heal quickly and may only need a few days to weeks of supportive care before the animal can be released.

Good Prognosis

Chelonians with multiple, unstable and/or open fractures, or dog bites with shallow shell puncture(s), usually have a good prognosis with treatment. Open fractures are characterized by malunion of a fracture with the bone exposed or missing pieces of the bony carapace or plastron. If large pieces of shell are missing or the coelomic membrane is damaged, the prognosis may only be fair to poor depending on the severity of the injury. Injuries in this category that are fresh carry a better prognosis. If the wounds occurred 24 hours or more prior to presentation, they are considered contaminated and are moved to a fair to guarded prognosis depending on the degree of contamination. These animals will usually need supportive care, surgical stabilization, and hospitalization for several months.

Fair Prognosis

Turtles with multiple fractures involving the pectoral or pelvic areas or penetrating punctures of the coelom have a fair prognosis. If the injury is greater than 24 hours, the prognosis becomes worse. Multiple fractures that destabilize the shoulder or pelvis may lead to ambulation difficulties. If the leg cannot be used at all, this would be a grave prognosis for release; the prognosis increases favorably as the ability to move the leg increases. Multiple fractures of the caudal shell narrowing the pelvic canal may lead to dystocia in females entailing a sterilization procedure for a captive animal or euthanasia if the turtle is not to be maintained in captivity.

Guarded Prognosis

Chelonians with open fractures with punctures to the viscera, like fractures of the plastron with concomitant disruption of liver parenchyma (which is lining up to 50% of the ventral coelomic surface, just above the cranial plastron) resulting in substantial blood loss, have a guarded to grave prognosis. In some cases, turtles may be seen with intestines or other organs trailing from the fracture or large amounts of debris,

[†]Deceased.

dirt, and fly larva in the fracture site or fractured limbs. These cases are difficult to treat successfully due to organ damage and infection. A group of high-risk patients are reproductively active females in which depressed fractures may lead to disruption of eggs or follicles, causing severe yolk coelomitis. Further investigation may be warranted, but more severe cases of this type of wound fall into the grave prognosis category, and euthanasia is the best option.

Grave Prognosis

This group includes chelonians with multiple fractures, internal injuries, and head and spinal injuries. Most spinal injuries in chelonians result in neurologic damage affecting the rear legs. In many cases, even though a fracture may proceed across the spine, it may be difficult to visualize this on radiographs. A neurologic examination, including assessment of sensation and deep pain, may assist in making this diagnosis; however, chelonians are capable of spinal walking, which masks spinal injury. Spinal walking consists of reflexive actions rather than conscious movement. Even if the entire spinal cord is severed, spinal walking is still possible. With spinal injuries, a variety of other problems, such as denervation of the bladder and lower gastrointestinal tract, are common. In a few of these cases, a turtle may continue to eat and drink while its urinary bladder and colon enlarges to the point of rupture. If a spinal injury is found, humane euthanasia is recommended. Pelvic fractures may narrow the pelvic canal, which has the potential to cause future dystocia in females. This should be accounted for when developing a prognosis.

Emergency Therapy and Initial Diagnostics

Once the chelonian enters the hospital, it should be evaluated immediately for prognosis, and a decision should be made as to whether to move forward with stabilization or not. An initial diagnostic investigation and emergency care can then be instituted. Emergency care typically includes fluid therapy and pain management.[8,9] If there is obvious infection (or major tissue compromise), broad-spectrum antimicrobials should be started following the collection of material for culture and sensitivity. Sea turtles can usually tolerate phlebotomy whereas most other species will need to wait until stabilized. Serial packed cell volume, total solids, blood glucose, blood gases, and electrolytes will help assess the status of the patient, target the most appropriate therapeutic regimen, and aid in prognostication and evaluation of response to therapy.[8] Radiography and/or CT/MRI, which in addition allow an assessment of internal organs,[10,11] are useful for assessing fractures of long bones, spine, and pectoral and pelvic girdles, and should be performed upon entry to allow for more accurate evaluation. The horizontal beam craniocaudal and lateral views are useful for the assessment of lung fields and can be used to determine carapace uniformity.[7,12] In cases of internal injury, the radiographs may assist in determining the extent of penetration or soft tissue injury.

INITIAL SHELL INJURY AND FRACTURE MANAGEMENT

Shell Wound Care

Wound management techniques used for chelonians are similar to humans and domestic animals. Initially the wound is cleaned and debris removed. Bony shell fragments adhering to the coelomic membrane should not be detached. Copious lavage with warm, sterile saline or lactated ringers, dilute chlorhexidine (0.05%), dilute betadine (0.1% to 1% depending on the degree of contamination and tissue being lavaged), or other commercially available antiseptic irrigation solutions (Octenisept, Schülke & Mayr, GmbH, Norderstedt, Germany; ProntoVet, B. Braun Medical AG, Sempach, Switzerland) is critical. Large quantities of the irrigating solution should be used under low to moderate pressure.[13] The recommended delivery method to generate the desired pressure (7–8 psi) is a 1-L fluid bag with a cuff pressurized to 300 mmHg with an 18-gauge needle.[13] SilvaKlenz (Molecular Therapeutics, Athens, GA) is a pH-balanced potentiated ionic silver solution that is showing promising results for wound cleansing and flushing in chelonians (Norton T, Ritchie B, unpublished information). Tricide-neomycin (Molecular Therapeutics, Athens, GA) is an antimicrobial that complements the effects of SilvaKlenz. The turtle should be positioned so the flushed solution drains from the fracture/wound site, especially if the coelomic cavity integrity is compromised. One person holds the chelonian and rotates it to direct the opening of the wound ventrally to prevent flushed debris from entering the coelom. Sterile saline or lactated ringers are the preferred solutions to use if the coelomic cavity is compromised. The surround tissue should be thoroughly disinfected prior to lavaging an open coelom.

Regular debridement of dead and infected tissue is critical, especially in the early stages of wound management. For major debridement in a stabilized patient, sedation and analgesia are typically required (see Chapters 48 through 51). Topical lidocaine placed directly on a wound after initial cleaning may provide additional pain relief in some situations. Dental instruments, rongeurs, periosteal elevators, and curettes can be very helpful in removing dead tissue and cleaning out pockets. Fractures of peripheral bones in the shell are often accompanied by soft tissue avulsions creating small defects or pockets. These are prone to infestation with maggots and secondary infection. Affected chelonians are best hospitalized indoors. If the medical management of these dead spaces fails, the overlying bone can be debrided to the point of viable attachment of the coelomic membrane. This enlarges the defect but promotes the healing process.

A variety of topical products for shell wound management are available. The choice of a particular product depends on the wound, stage of healing, and frequency of treatment. Rotating topical antimicrobial products is recommended to avoid resistance. The ultimate goal is to decrease wound-healing time. For relatively minor wounds on the shell, silver-containing products such as silver collasate postoperative dressing (PRN Pharmacal, Pensacola, FL) and silver sulfadiazine cream (SSD, Kings Pharmaceutical, Bristol, TX) mixed with ilex paste (Medcon Biolab Technologies, Grafton, MA) for waterproofing in aquatic species can be applied after cleaning and debridement.[14] Nanocrystalline silver dressings (NSD) are useful because of the extended duration of activity. NSDs have a slower release of silver ions into the wound compared with traditional silver dressings and creams, thus achieving longer bactericidal effects (approximately 3 days). Wound gels (e.g., ProntoVet Gel, B. Braun Medical AG, Sempach, Switzerland; Instrasite Gel, Smith & Nephew, Hamburg, Germany) maintain a moist and antiseptic environment. Commercially available medicinal honey products (Medihoney, Wound Central, Plainfield, IL) come in several forms (gel, liquid, sticky bandages, etc.) that may be used on a variety of wounds. Fresh honey is an alternative. Honeycomb has been used to pack deep wounds. Frequent wound management is usually necessary, and a waterproof bandage is often needed for aquatic species to keep the honey in place. Honey will attract ants, so if the patient is being managed outdoors, an alternative will be needed.

RediHeal (Avalon Medical LTD, St Albans, UK) is a borate-based biological glass wound management product containing factors that promote angiogenesis that can be applied to deep wounds with exposed bone and has proven to be very effective. For deep shell wounds, it can be placed within the wound and then covered with bone cement, impregnated or not with an antibiotic (Figs. 113.1A and 113.2). Doxirobe Gel (Zoetis, Parsippany, NJ) is a topical long-acting doxycycline that allows for very high concentrations at the site of application. Doxirobe

TABLE 113.1 Wound Care and Other Products Used for Chelonian Shell Fracture Repair

Topical Medication	Application
1% silver sulfadiazine cream (SSD cream, Kings Pharmaceutical, Bristol, TX) mixed with ilex paste (Medcon Biolab Technologies, Grafton, MA)	Good for most shell and skin wounds. Difficult to remove from some wounds so not the best choice for deep pockets or fractured shell edges. Can mix with Ilex cream (Medcon Biolab Technologies, Grafton, MA), which stays on in aquatic environments better.
SilvaSorb gel (product name: silver antimicrobial wound gel sustained release; Medline, Northfield, IL)	Similar use as SSD cream but does not stick to tissue and is more water soluble so easier to remove. Does not stay on wound long in aquatic environments unless waterproof bandage placed.
Silver collasate postoperative dressing (PRN Pharmacal, Pennsacola, FL)	Collagen-based product with silver. Stays on wound in the water fairly well.
Alginate/CMC dressings with antimicrobial silver (Maxorb Extra Ag+ ReliaMed, Medline, Ft. Worth, TX)	The material is saturated with sterile water and then placed on the wound. Used in a variety of situations from deep pockets to edges of shell fractures/wounds; 72 hrs of antimicrobial activity.
Silverlon Silver Mesh (Webster product name, Silverlon, Nich Marketers, Inc., Gulf Breeze, FL)	This product needs to be saturated with sterile water as well. Use on the surface of the wound for VAC therapy; 72 hours of activity.
SilvaKlenz (Molecular Therapeutics, Athens, GA)	pH-balanced potentiated ionic silver solution for wound cleansing.
Tricide-neomycin (Molecular Therapeutics, Athens, GA)	Antimicrobial used to complement the effects of SilvaKlenz.
Honey and honeycomb	Used on a variety of wounds. Honeycomb is great for packing into wounds and can be impregnated with honey. Honey and honeycomb can be obtained from local beekeepers.
MediHoney products with active leptospermum honey (Derma Sciences, MediHoney Company, Plainsboro, NJ, http://www.dermasciences.com)	Medihoney is expensive but can be cut up into pieces for smaller wounds. Reserve use for open coelomic cavity wounds and deep shell fractures. Comes in several forms (gel, liquid, sticky bandages, etc.).
Doxirobe Gel (Phizer Animal Health, Exton, PA)	Long-acting doxicycline at very high concentrations at the site of application. Useful in treating superficial and deep shell wounds and shell fractures. Provides protection to the wound and stays on very well in an aquatic environment. Does not heat up or smell when mixed.
Bone cement impregnated with gentomycin (Webster product: C-ment 1 J-912 bone cement medium viscosity; Jorgensen Laboratories Inc., Loveland, CO).	Similar benefits as doxirobe. Product heats up and has a strong odor when mixed. Water can get up under the material, so it is important to change weekly or place a waterproof epoxy on the edges.
Rediheal (Avalon Medical LTD, St. Albans, UK)	Borate-based biological glass wound management product containing factors that promote angiogenesis. It can be applied to deep wounds with exposed bone and has proven to be very effective. For deep shell wounds, it can be placed within the wound and then covered with bone cement.
Epoxy cement (Waterweld, J-B Weld Company, Sulphur Springs, TX; AquaStik Epoxy, Two Little Fishies Inc., Miami, FL)	Used to cover screws and wires used in repairing shell fractures. Waterproof and provides further stability.
Equi-Thane Super Fast (Vettec Care, Oxnard, CA)	Quick-drying equine hoof acrylic for attaching bra hooks and zip-tie bases to the shell.
Flexible human sports bandage (NUBandage, West Palm Beach, FL)	Used to cover wounds and hold products in place on shell or limb. Comes in a variety of sizes.

has been useful for treating exposed bone and stays on well in aquatic environments (Fig. 113.3). Cyanoacrylic glue can be used to lightly cover the Doxirobe or bone cement once it is dry to provide further waterproofing. Large carapacial defects may be temporarily covered with either daily adhesive dressings in conjunction with wound gels or a removable prosthesis allowing wound access. An adequate prosthesis can be formed with light curing dental tray material (Henry Schein Inc., Melville, NY) (Fig. 113.4) or generated by 3D printers. Adequately debrided and uninfected, sterile wounds or defects may be filled with glass ionomeres, odontoiatric human bone cement, or dental photo-polymerizable nano-hybrid composite.[15] Weekly wound management is usually adequate when using these products in aquatic species.

Shell fractures can be temporarily stabilized with a variety of bandaging materials, including Telfa nonadherent dressing (Medline Industries, Inc., Mundelein, IL) to cover the wound, self-adhering bandaging such as Vetrap (3M, St. Paul, Minnesota) or Elastikon (Johnson and Johnson, New Brunswick, NJ), and Steri-strips (3M, St. Paul, MN) can be used to temporarily hold unstable fractures in alignment or other similar bandaging products. Bone cement, cable ties, and bra hooks can be used to temporarily stabilize fractures and will be described later in this chapter (see Figs. 113.1B and 113.2).

A waterproof bandage for aquatic species consists of placement of petroleum-impregnated gauze over the topical product, Tegaderm (3M, St. Paul, MN) or similar sticky bandaging material with superglue placed around the edges, and finally waterproof tape placed over the entire area with another application of superglue. Dry-docking is an option for freshwater aquatic species that are less water dependent. Rotating between dry-docking and waterproof bandaging may also be an option in some situations. If the injuries are confined to the dorsal aspect of the carapace, the animals may be kept in shallow water after surgical treatment following the same principles as described previously. This allows the turtle to hydrate and feed. With plastral defects or cases of large missing shell areas, the turtle should be dry-docked on moist towels until a primary seal is visible. Another possibility of dry-docking is to place a high plastic grid in a shallow warm water bath, leaving a small freely accessible water surface at one side. This should be narrow enough to prevent the turtle from immerging but on the other hand allow free access to drink and feed. Feces will be passed through the grid, reducing the risk of contamination of plastral injuries. During long-term confinement, careful monitoring for the development of plastral pressure lesions is required. The use of plastic saddle clamps on plastral fractures lifts the animal off the ground, reducing the risk of secondary infections.[16] During the dry-docking period, nutrition and water uptake should be guaranteed by gavage or placement of an esophagostomy tube. A novel technique using a trimmed urine specimen cup, or similar containers with a water-tight lid, glued to the shell with

underwater epoxy (AquaStik, Two Little Fishies Inc., Miami, FL) can protect the wound from the aquatic environment and allow the turtle to be kept under natural conditions during the healing process[17] (Fig. 113.5). Before gluing the device onto the shell, loose scute material is removed to improve adhesion and guarantee waterproofing. Cleaning and debriding of the wound is achieved through the screw-top lid. After

FIG 113.3 Doxirobe applied to a wound post screw and wire removal in a diamondback terrapin (*Malaclemys terrapin*). (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

returning the turtle to the aquatic environment, good water quality has to be assured by frequent water change and high-quality filter systems.

Traumatic injuries that pull the skin away from the shell can be difficult to manage. The authors have used some innovative methods to repair these types of wounds. In an eastern box turtle (*Terrapene c. carolina*) with a severe caudal carapace fracture and skin separation from the shell, bra hooks were adhered to the shell using epoxy cement (WaterWeld, J-B Weld Company, Sulphur Springs, TX), and then the skin was sutured to the hooks (Fig. 113.6). In a green sea turtle (*Chelonia mydas*) with a severe shark-bite injury to the caudal carapace with inguinal fat exposure, plastic hooks were adhered using epoxy cement to the shell, while suture loops and zip ties allowed for a flexible human sports bandage (NUBandage, West Palm Beach, FL) to be attached and hold honey, honeycomb, and petroleum-impregnated gauze on the wound while the turtle was maintained in water (Fig. 113.7A and B).

If single fragments are missing, the prognosis is dependent on the extent of uncovered coelom. There is a reasonable chance that defects involving less than 25% of the shell surface will heal by metaplastic calcification of the coelomic membrane (see also Fig. 70.9A and B) or will be replaced by soft tissue if the defects are peripheral (Fig. 113.8A and B). Detached fragments may be cleaned and fixed in place. Sequestra formation is not uncommon, but they can serve as useful placeholders until new bone forms below.

Vacuum-assisted wound closure (VAC) has been very effective in treating a variety of wounds in chelonians (see Chapter 130 for more details). This technology is often used in patients that have had surgical repair to their shell, or it may be the primary wound-healing modality in some cases. Therapeutic laser therapy has been used for accelerating wound healing in a variety of chelonian species. This type of laser uses two wavelengths of laser light to stimulate cellular energy and increase blood flow (see Chapter 129).

NUTRITIONAL SUPPORT

Many chelonians will start to eat if housed in a semi-naturalistic setting with natural substrate, hide box, appropriate thermogradient, good water quality if aquatic, and outdoor access when appropriate. Short-term tube feeding with a nutritionally complete formula often stimulates the turtle to start eating. Some patients may require tube feeding for long-term oral medication and nutritional support, thus an esophagostomy tube should be placed. The stomach volume in most chelonian

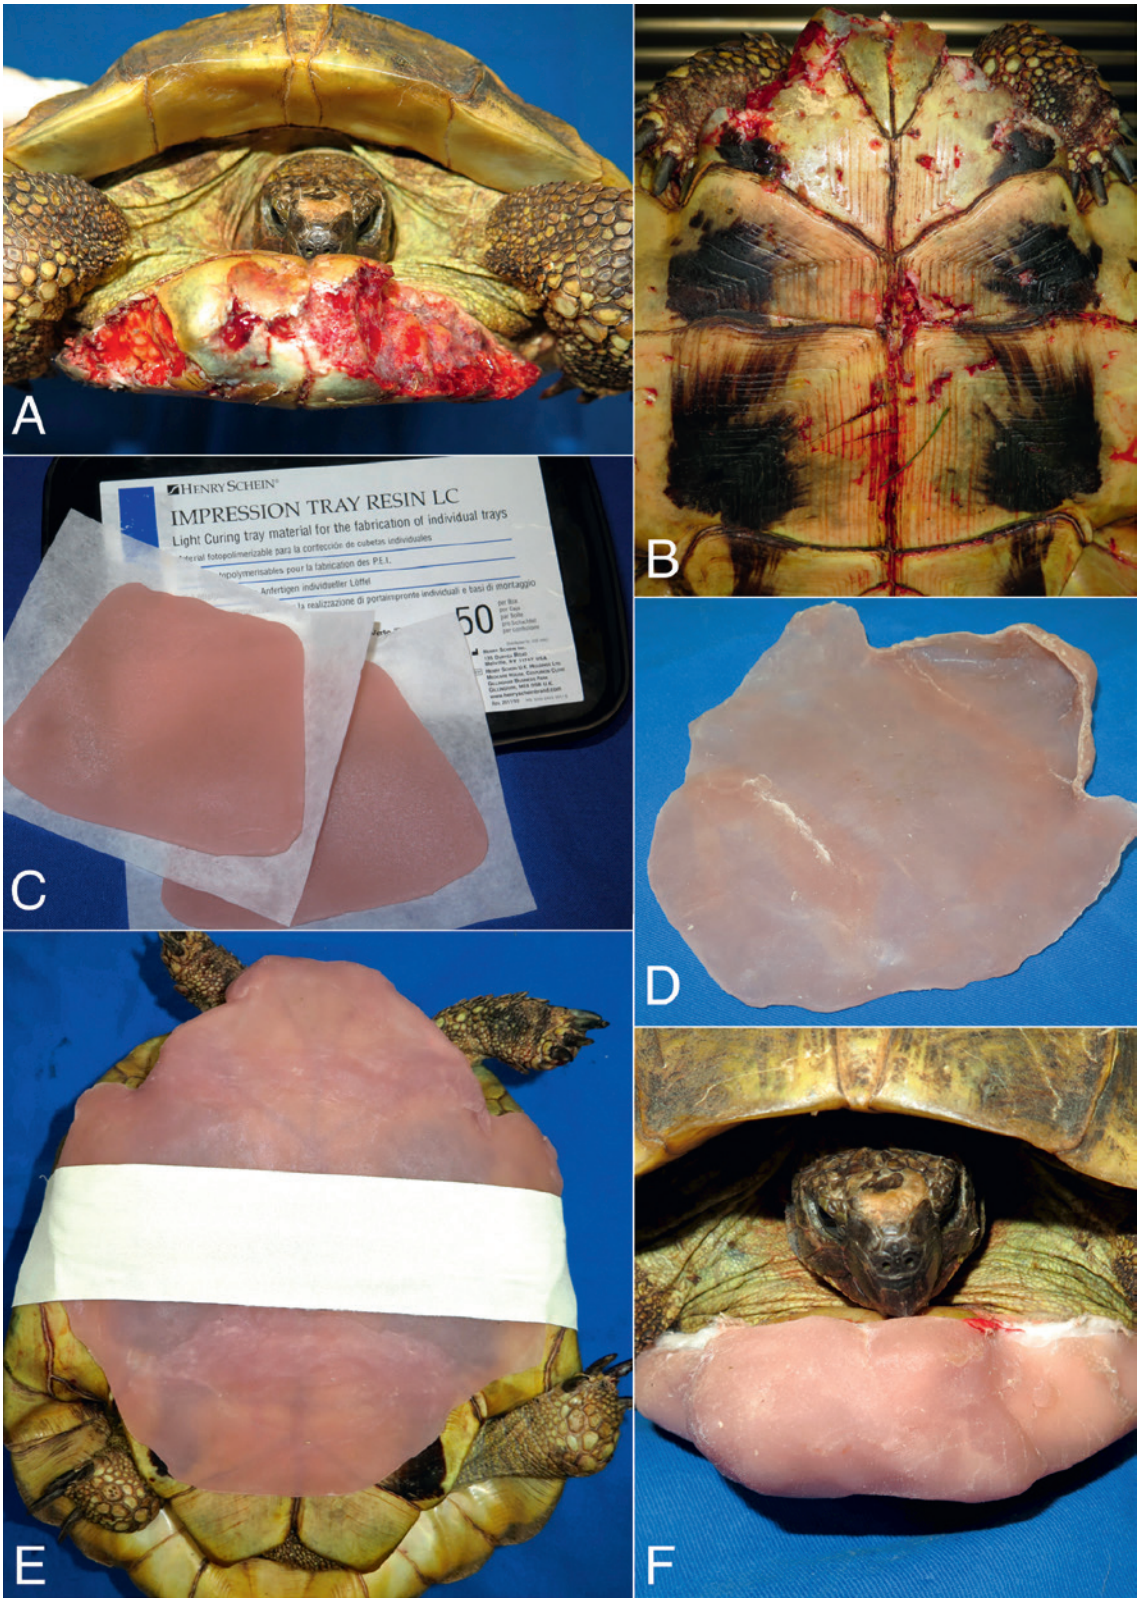

FIG 113.4 (A and B) Severe plastral bite injuries in a *Testudo hermanni*, inflicted by a fox. (C and D) A prosthesis is made out of light curing dental tray material. The tray material comes in plates that can be easily modeled on to the plastron or carapace. Due to the nonstick surface properties of the tray material, the mold can be simply removed after UV light curing. (E and F) The prosthesis is reattached to the shell with a piece of tape. It keeps wound dressings in place, prevents contamination of the wound surfaces by feces or urine, and allows easy changes of wound dressings. (Courtesy of Jean Meyer.)

FIG 113.5 Containers with a water-tight lid can be trimmed to size and fixed in place with AquaStik epoxy over perforating shell wounds, as seen in this slider (*Trachemys*) turtle. Wound management is achieved through the open lid. This allows a faster return of the animals into their aquatic environment. (Courtesy of Sypniewski LA, et al: Novel shell wound care in the aquatic turtle. *J Exot Pet Med*. 2016;25[2]:110-114.)

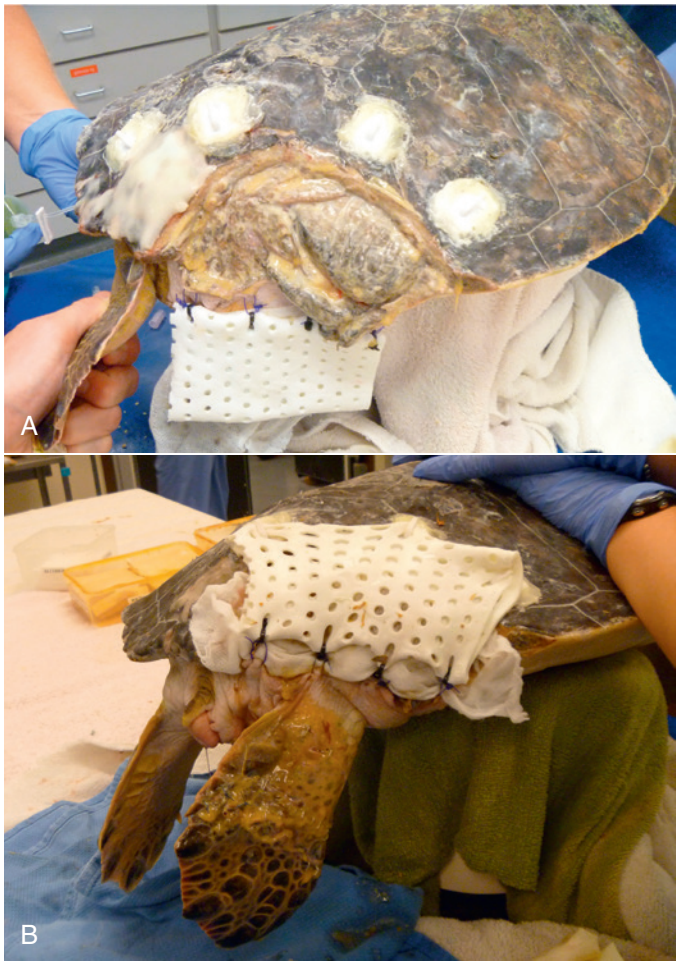

FIG 113.7 (A) Plastic hooks attached using epoxy to the carapace at the edge of the wound with a human sport bandage attached at the other end with suture loops and cable ties used to bandage the wound in a green sea turtle (*Chelonia mydas*) with a severe shark bite. (B) Medihoney gel, honeycomb, and petroleum-impregnated gauze held in place with the sport bandage attached dorsally to the hooks in the same green sea turtle. (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

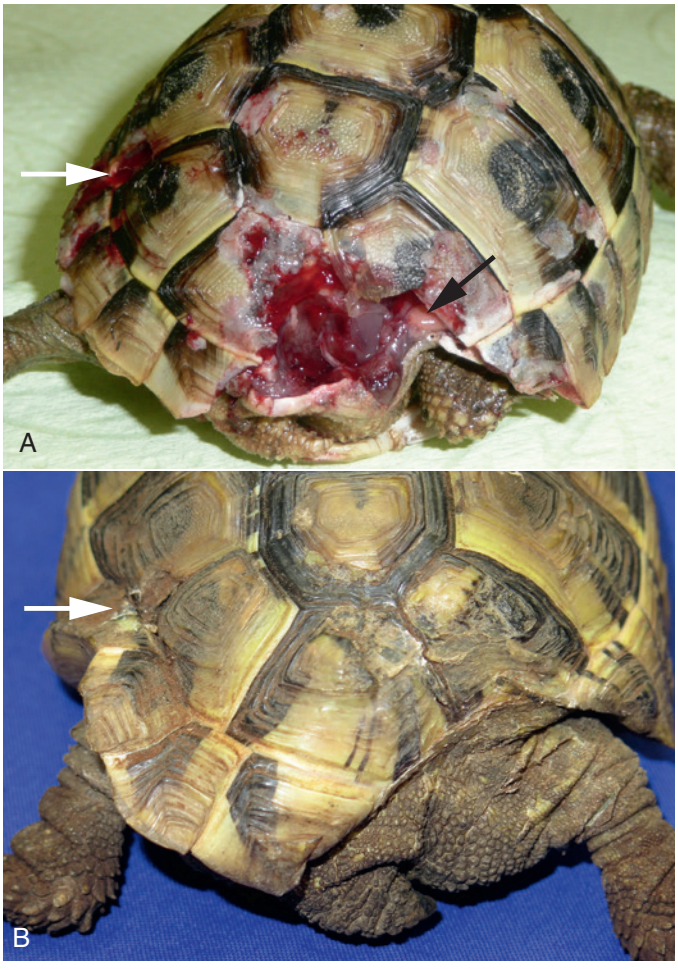

FIG 113.8 (A) Dog bite in a juvenile *Testudo hermanni* with substantial loss of bony carapace, opening of the coelomic cavity, and exposure of the right kidney (black arrow). Deep puncture wound from the canine tooth on the contralateral side (white arrow). (B) Three years after trauma. The skin filling the defect shows physiologic keratinization. The puncture wound on the left side (white arrow) lead to a premature ankylosis of the underlying bony suture with subsequent distorted growth. (Courtesy of Jean Meyer).

patients is about 2% of the body weight or 20 mL/kg.[8] Procedures for placement are described elsewhere in this book (see Chapter 45).[8]

SURGICAL MANAGEMENT

Anesthesia

Anesthetic and analgesic protocols should provide muscle relaxation and pain management when repairing shell injuries. Supplemental heat, consistent with the patient's POTZ, is necessary during an anesthetic procedure to allow normal metabolism of the anesthetics for both induction and recovery. Morphine, tramadol, and meloxicam are used most commonly by the authors for pre- and postoperative pain management. Dissociative anesthetic agents (e.g., ketamine), α-2 agonists (e.g., dexmedetomidine), propofol, alphaxalone, and inhalants, have been found to provide the most reliable results for shell fracture repair (see Chapters 48, 49, and 50 for more details).[18] A combination of injectable drugs are typically used to induce and may be the only anesthesia needed for some fracture repairs.

Fracture Repair and Fixation

Shell repair is a common reason for surgery in rehabilitated chelonians. The general principles for repair in reptiles are similar to other species: apply appropriate wound care principles preoperatively, utilize sterile technique, and provide stability in normal anatomic position for a sufficient time to allow bone healing. Bone healing for the chelonian shell may take 1 to 6 months or even longer depending on the complexity of the fracture repair. This will have an effect on long-term rehabilitation facility housing. The fracture(s) should be described based on the particular anatomical part of the shell that is affected (see Chapter 7, as well as Chapter 70, Fig. 70.3).

If the fracture is nondisplaced and stable, then external bandaging, bra hooks with suture material (see Fig. 113.1B), cable ties (see Fig. 113.2), RediHeal and bone cement with or without an antibiotic (see Fig. 113.2), or a combination of these methods (see Fig. 113.2) may be used as the primary repair. Bandaging should be nonadherent and securely affixed to the shell so as to prevent movement of bone fragments. Regular bandage changes and wound management are required in these situations. If a limb is fractured, then the bandage can splint the limb to the shell to prevent movement. Long bone fracture repair is another option in larger chelonian species and is discussed elsewhere (see Chapters 108 and 109).

Complete shell fractures in rehabilitated turtles should be considered open and typically contaminated, if not infected. Many chelonian shell fracture cases are presented in which where the duration of the injury may be unknown. When reducing shell fractures, strict asepsis should be maintained. Screws and cerclage wires for fracture repairs with regular wound management of the fracture lines and areas missing shell works well for a variety of species. Surgical plates may be used successfully in larger chelonians, such as sea turtles and giant tortoises (Fig. 113.9), and typical principles of repair should be followed.

Many different techniques can be used to repair shell fractures. A combination of techniques may be used initially and throughout the healing process. The use of removable hardware such as screws, bone plates, rods, and wire may be combined with techniques that employ epoxy, hooks, and cable ties. Fragments should be brought as close as possible back into their normal physiologic relationships. A perfect apposition is not mandatory or often even possible. Residual small cracks and voids will be undergrown by granulation tissue and ossifying coelomic membrane.

Adhesives and Epoxy. The use of epoxy and fiberglass for shell repair has been popular for many years. Epoxy resin with fiberglass is the preferred method of closure for plastronotomy. However, for traumatic and infected shell injuries, the use of epoxy and fiberglass is contraindicated, because sealing a contaminated wound will result in infection. Thus, fixation with an open system of wires and screws that allows for wound management is preferred. Epoxy putty, cyanoacrylate glue, and two-part epoxy resin have been used successfully in conjunction with bone plates and cable-tie attachments to stabilize plastron fractures (see Fig. 113.2).

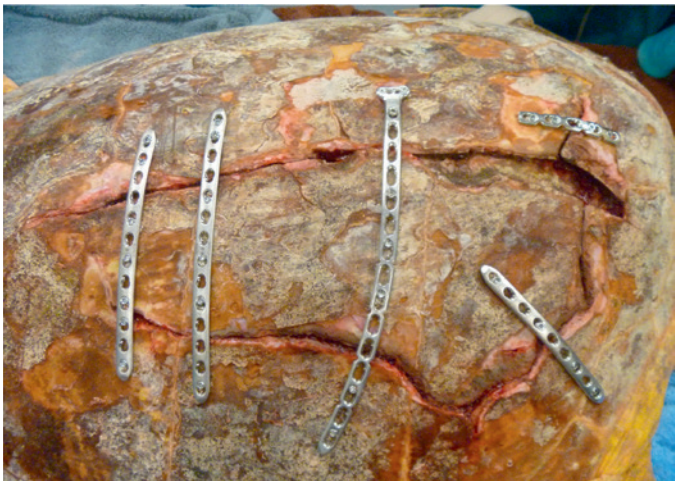

FIG 113.9 A large carapace fracture in a loggerhead sea turtle (*Caretta caretta*) was repaired with small fragment orthopedic plates that had combination holes so the fracture could be fixed in compression with 3.5 mm bicortical screws and also act like an external fixator by placing 3.5 mm locking screws. The plates were bent to fit the curvature of the carapace. The open areas between the plates were filled in with Rediheal and bone cement. The fracture eventually healed and the turtle was released. (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

Fixation With Hardware. For shell fractures that need stabilization, the use of external fixation has provided excellent results. For wildlife cases where finances are often limited, many of the supplies, such as screws, can be purchased from a home improvement store; however, they should be stainless steel because galvanized screws can release zinc systemically and are more likely to rust. If no financial constraints apply, surgical steel–grade implants should be favored. All fixation devices should be sterilized before use.

In most cases, an assistant will be needed to help position and hold the chelonian while the fixator is being placed. The shell and soft tissue around the fixation area should be surgically prepared, debrided, and lavaged. Once the area is prepared and dried, the fixation may take place. If there are missing pieces, the surgeon must try to piece the shell together, leaving an open space where the shell is missing. If the shell cannot be stabilized without the missing pieces, the prognosis is significantly worse. If the shell can be stabilized, applying VAC therapy to such cases may be very helpful.

Screw and Wire Fixation. The screw and wire method of shell fixation may provide the best stabilization in most shell fracture cases. The first step in fixation is to place sterile orthopedic or stainless steel screws where the fixation wire will be attached. There are two options available, depending on whether the case is client-owned (and approved veterinary orthopedic equipment should be recommended) or wildlife (where finances are limited and hardware supplies may be the only fiscal option available).

VetBooks.ir

Standard orthopedic equipment (plates, screws, and cerclage wire) and techniques can be applied (see Figs. 113.9 and 113.10A–C). A review of available supplies can be found in numerous places, including https://vetimplants.com and https://www.jorvet.com.

For wildlife or financially restricted cases where hardware supplies are utilized, first, select a drill bit that is slightly smaller than the screw. Sterilized, Phillips #6 1/4-inch machine stainless steel screws can be used. Smaller screws are also available. The machine head looks like a mushroom, and the flat aspect of the ventral screw head provides a secure purchase for holding the wire. Screw size needs will vary depending on the size of the turtle and the nature of the fracture to be repaired, thus it is good to have different sizes available.

When drilling into shell fragments, if possible, stay back at least 0.5 cm from the edge of the fracture to provide proper purchase for the screw and to minimize cracking of the shell. When drilling, be careful not to place too much pressure on the drill, as you may sink the bit several centimeters into the coelom and damage the internal organs. Placing a piece of tape around the drill bit at 0.20 cm (⅛ to ¼ inch) of depth will allow for a visual guide to drilling depth. The use of a drill sleeve aids in limiting penetration depth. Two hands on the drill with a slow steady force are recommended when using a power drill. One of the authors (TMN) uses a hand chuck with the appropriate-sized drill bit to make the initial hole (see Fig. 113.10A). Alternatively, the use of a finger clutch, slow-start, forward-reverse electric drill (e.g., Stryker Cordless Driver, https://www.stryker.com) also provides great control.

Fully penetrating the shell thickness should be avoided if possible but should not be a problem as long as trauma to internal organs does not occur. If drilling with a power drill is prolonged, heat may produce tissue necrosis. To avoid this, drip sterile saline on the drill bit when engaged or use a hand chuck to make the initial hole and a handheld screwdriver to place the screws. Once a few screws have been placed, it may be helpful to attach the wire. Each case is different, thus in some cases getting all the screws in place and attaching the wire loosely to start and then tightening to obtain good apposition may be the best option. Fractures of the caudal carapace can be difficult to get aligned, and care must be taken to avoid pulling the fragments upward with too much tension on the wire (see Fig. 113.10B).

To attach the wire, precut a few pieces of wire, 15 cm (6 inches) long (20- to 24-gauge stainless steel wire). It is recommended to have a few sizes of wire available for the different sizes of chelonians and type of fracture that might be encountered. Wrap the wire around one screw head, cross it over between the screws (see Fig. 113.9), wrap one end around the second screw head, and then wrap the two ends around each other. The knot should be between the two screw heads, which allows for the knot to be folded down against the wire but not directly on the shell. At this point, do not tighten the wire with cerclage wire twisters/shear cutters or pliers; only hand-tighten it for two to three twists. If a fractured shell fragment is attached to the underlying tissue but not to the rest of the shell, place screws and wires on all sides and then proceed to hand tighten. Tighten alternate sides to make even contact with the surrounding shell. Some small gaps may not close fully but will heal over time. With more severe cases, the entire shell may not stabilize until the last few wires have been tightened. Once tightened, some of the wires may have become loose and should be removed and retightened. When tightening the wire, the surgeon may need to place five to eight twists on the wire; however, do not over-twist for fear of breakage. In addition, if the wires are too tight, too much pressure may be placed on the tissue margins, causing pressure necrosis. Once the wires are tightened, use cerclage wire twisters/shear cutters or side cutters to remove the twisted knot to the level of four to five twists and use the wire benders or pliers to bend the twist down to be parallel with the wire and the shell. Epoxy putty is then placed on the screw head and wire, which allows for further stabilization and waterproofing (see Fig. 113.10C). In some situations, instead of using the wire, the epoxy putty can be used to bridge the screws. This will provide stability but will not put tension on the fracture. One of the authors (TMN) uses RediHeal and bone cement with antibiotics in it along the fracture line. This will need to be changed once a week along with wound cleaning and debridement. This is especially useful in aquatic species.

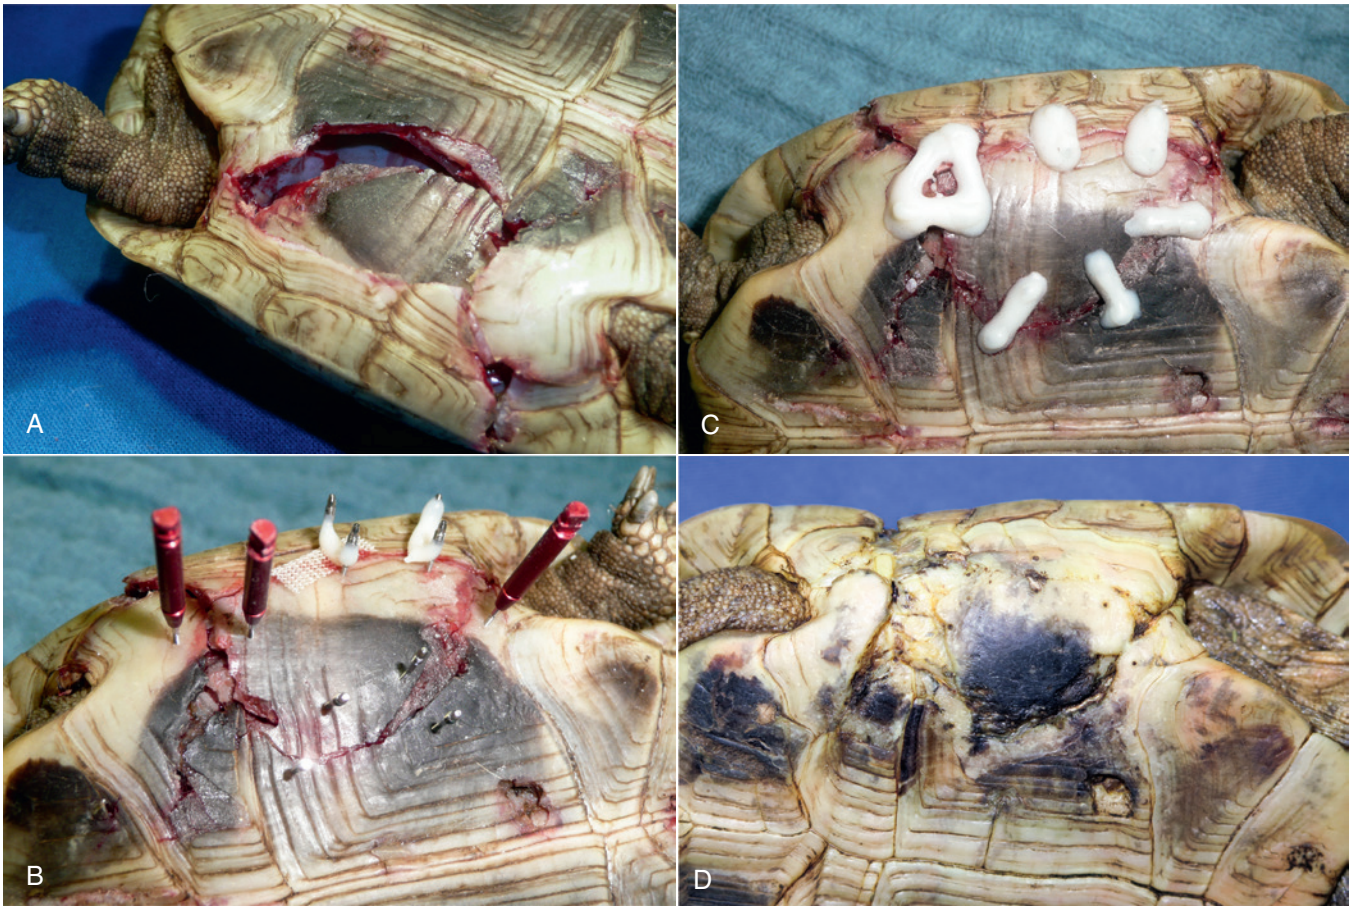

FIG 113.11 (A) An impression fracture of the plastron of a juvenile *Testudo hermanni*. (B) Repositioning of the fragment and fixation with self-threading dental pins in conjunction with UV-activated flowable composite. A small piece of gauze prevents the composite from entering the fracture site (later removed). (C) Finished fixation was left in place for 6 months. (D) Healed fracture 2 years later. (Courtesy of Jean Meyer.)

Fixation Techniques for Young or Small-Sized Chelonians. In small chelonians, self-threading dental pins in conjunction with UV-activated flowable composite (Natural Elegance, Henry Schein Inc., Melville, NY) can be used to bridge over the fracture line (Fig. 113.11A–D). Alternatively, Steri-Strips (3M St. Paul, MN) glued over the fracture site and fixed with a drop of epoxy at each end gives reliable, quick, and inexpensive support (Fig. 113.12). In young, fast-growing animals the time of fixation is kept as short as possible in order to prevent distortions of the shell skeleton during growth.

Cable Tie and Hook Fixation. In some cases of nondisplaced shell fractures where stabilization is needed, alternates to the screw and wire fixation are bra hooks with suture material (see Fig. 113.1B) and cable ties with bases (see Fig. 113.2 and Fig. 113.13). These techniques are less expensive and less invasive but, in general, do not provide as much stabilization as the screw and wire method. Bra hooks and cable tie bases are fastened to the shell with glue or epoxy. Suture material can be used to attach the bra hooks (see Fig. 113.1B) and cable ties are pushed through the bases as shown in Fig. 113.2. The use of a cable tie gun may aid in reducing the fracture. For minor fractures or when anesthesia is not available, this technique may be an option and will save time under anesthesia. These techniques can also be used for temporary fracture stabilization until the patient is more stable. One

FIG 113.12 Noninvasive fixation of a shell fracture in a juvenile *Testudo hermanni* using Steri-strips. The ends of the strips are secured with a drop of epoxy resin. They can easily be replaced and allow a ventral drainage of the fracture site. (Courtesy of Jean Meyer.)

FIG 113.13 Cable tie fracture fixation in a *Testudo* tortoise. Cable tie mounts are cut to size (white arrow) and fixed with epoxy putties (black arrow) to the shell. Putties have the advantage to cling well and smooth the irregularities of the shell surface. After setting, the mounts are connected via cable ties and tightened. This technique allows an open wound treatment. (Courtesy of Jean Meyer.)

FIG 113.14 Small, phalangeal plates adhered using epoxy to the carapacial and plastron marginal scutes to stabilize a plastrocarapacial bridge fracture in an eastern box turtle. (*Terrapene carolina carolina*). (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

of the authors (TMN) uses a quick-drying equine hoof acrylic (Equi-Thane Super Fast, Vettec Hoof Care, Oxnard, CA) for attaching bra hooks and cable tie bases. A tension relief system used in reconstructive surgery (TopClosure, IVT Medical Ltd., Ra'anana, Israel) has proven a durable and inexpensive noninvasive fixation device.[19] Alternatively, saddle clamps might be used to bridge the fracture site.[16] The use of these plastic saddle clamps on plastral fractures lifts the animals off the ground, reducing the risk of secondary infections.

Epoxy and Metal Fixation. Plastron fractures can be stabilized with bone plates, flat pieces of metal, small splints, cable ties, or just RediHeal and bone cement, or a combination thereof (see Figures. 113.2 and 113.5). In many chelonian species, the plastron is relatively flat, and epoxy can be used to attach a bone plate or metal strips across the fracture (Fig. 113.14). The low profile of the bone plate will allow for minimal drag when compared with screws and wire, which may become entangled on rough surfaces. Any open areas will need to be managed with regular wound care as described previously.

Monitoring and Healing Time

The fixation device should be monitored regularly. If the epoxy/screws/wire support becomes loose, they should be removed and replaced, if necessary. Healing time should be approximately 4 to 8 weeks, similar to bone in other species, but some cases may take much longer. This will depend on the severity of the fracture and the stability of the fixation. Simple closed fractures may achieve adequate stabilization in 4 to 8 weeks, whereas more severe cases may take 12 weeks or longer. In more complicated fractures, a staged removal of the screws and wires over 2 to 3 weeks is recommended. Open wound management may be required once the fixation devices have been removed. Radiographs may be helpful but often do not show callus formation. A better guide to a healed fracture is the stability of the fracture on palpation. If in doubt, leave the fixation device on longer.

A common sequel is mold formation on the exposed bony surfaces. Affected areas can be treated daily with terbinafine-containing ointments. Treatment is discontinued once the open bone surface seals or undergoes demarcation and is sloughed. Chelonians with injuries to the shell should not be hibernated before healing is complete because downregulation of the immune response may predispose to infection.

Removal of External Fixation

The area of the shell should be prepared just as it would for surgery. This procedure may cause some discomfort but does not require general anesthesia; however, analgesia such as meloxicam or tramadol should be used. Screws may be removed with a screwdriver, and then the holes should be lavaged and managed with a preferred topical as discussed earlier. Once screws have been removed, the timeframe to release could be as little as a week to a couple of months, depending on the injury.

MANAGEMENT OF DOG OR PREDATOR BITES

The clinical presentation may be diverse and range from scutal abrasions to cracks, compression fractures, or to the loss of entire parts of the shell. Evaluation and treatment of the injuries should follow the protocol described previously. Fresh bite wounds are generally highly contaminated and should be rinsed with copious amounts of antiseptic solutions and/or sterile saline. Older wounds are generally infected and need debridement and systemic antibiotic treatment based initially on gram stains and subsequently modified by sensitivity results. Dog bites often result in the loss of shell margins, exposing open bone surfaces and significant hemorrhage. The amount of blood loss should be evaluated and monitored by serial PCV measurements. Even if viscera are exposed, these wounds generally have a reasonable prognosis (see Fig. 113.6A–B). Treatment consists of thorough and repeated lavage and appropriate bandaging with local antibacterial ointments or wound gels. Radical debridement is contraindicated, as this may aggravate further hemorrhage. Hemostasis can be achieved by application of sterile surgical bone wax or porcine collagen–based hemostatic absorbable materials (Surgicoll, Medical Biomaterial Products, Germany) or radiosurgery/cautery. All superficial shell wounds will develop dry, yellowish granulation tissue, which should not be mistaken for purulent discharge and should not be debrided. These contaminated/infected wounds should never be simply covered by any kind of epoxy resin, as these materials are cytotoxic and infection is sealed in, leading to osteomyelitis, abscesses, and sequestra.

VetBooks.ir

CONCLUSION

Medical and surgical intervention of chelonian shell fractures can be prolonged but rewarding, because these reptiles often have life spans greater than 50 years. By rehabilitating an adult chelonian, you are assisting with conservation as well as helping individual animals that are often overlooked.

Therapeutic Overview and General Approach

Sean M. Perry and Mark A. Mitchell

The class Reptilia is comprised of more than 10,080 species divided into four orders: Squamata (Serpentes, 3567 species; Lacertilia, 6145 species), Chelonia (341 species), Crocodylia (25 species), and Sphenodontida (2 species).[1] Interestingly, since the last publication of this book in 2006, more than 2700 new species have been described. This increase in total species by more than 25% is the direct result of identifying new species and recharacterizing species based on new genotypic information. For the veterinary clinician, this species diversity is a reminder that reptiles presented are not necessarily the same morphologically or physiologically, and that these differences can impact how we manage a case. Veterinarians working with reptiles must develop an understanding of the species-specific requirements of these animals to ensure they make the most informed medical decisions regarding their care.

DEVELOPMENT OF A THERAPEUTIC PLAN

Any good therapeutic plan should focus on treating the underlying disease process while supporting other body systems and optimizing the immune system. Unlike higher vertebrates, reptiles are ectotherms and their metabolic rate and immune response can be impacted by environmental conditions. When considering therapeutic options for the reptile patient, the veterinarian must optimize the environmental conditions to ensure overall treatment success (e.g., drug and fluid absorption) (Fig. 114.1). In this section we will review specific aspects of therapy for reptile patients that may not be prioritized in other taxa.

ENVIRONMENTAL CONSIDERATIONS

Reptiles are ectotherms and depend on environmental temperatures to regulate core body temperature. A number of physiologic factors can be affected by the reptile's body temperature, including metabolic rate, heart rate, immune function, embryologic development, and reproductive activity.[2,3] Reptiles maintain a body temperature similar to their environment; however, exceptions do occur. Strel'nikov found *Lacerta agilis* in a montane environment (13,100 feet) to have body temperatures 29.2°C (84.6°F) above the ambient environmental temperature.[4] The thermal environment is extremely important when establishing a therapeutic plan in reptiles because of a high variability in physiological processes when reptiles are not at their appropriate physiologic state. Whereas the body temperature of a domestic pet mammal is not generally an important consideration in the selection and prescription of a therapeutic, it is an extremely important consideration for veterinarians working with reptiles.

Body temperatures for reptiles are highly variable. Brattsstrom reviewed the literature and published a report summarizing the cloacal and deep groin (chelonians) temperatures for 161 species of reptiles.[5] The range of body temperatures compiled for 13 species of chelonians was 8° to 37.8°C (46.4°–100°F), with a mean of 28.4°C (83°F). The temperature range compiled for 89 species of lizards was 11° to 46°C (51.8°–114.8°F) (mean, 29.1°C, 84.4°F). Overall, the lowest and highest body temperatures recorded were for the tuatara (*Sphenodon* sp.) (range, 6.2°–18°C, 43.2°–64.4°F; mean, 12.5°C, 54.5°F) and American alligator (*Alligator mississippiensis*) (range, 26°–37°C, 78.8°–98.6°F; mean, 32° to 35°C, 89.6°–95°F), respectively. This high degree of variability in body temperatures between reptilian groups and within species reinforces the dramatic physiologic changes that can occur in these animals on a daily basis and the need for an appropriate thermal gradient in captivity.

Veterinarians must be cautious because, despite reptiles' remarkable ability to undergo and survive large fluctuations in temperatures, exposure to excessive temperatures can lead to a fatal hyperthermia. Baldwin[6] showed that *Chrysemys picta* exposed to lethal environmental temperatures (42.2°C, 108°F) die suddenly. Once the animals achieved core temperatures greater than 27°C (80.6°F), they were found to be in

FIG 114.1 A neonatal sulcata tortoise (*Centrochelys sulcata*) set up in a plastic container with an inappropriate substrate (aquatic vs. terrestrial) and diet (carnivorous vs. herbivorous) for this species. Despite the best-developed therapeutic plan, this animal would not recover unless its environment and diet are changed. It is vital to understand each reptile's environmental and husbandry requirements to develop a successful therapeutic plan. (Courtesy of Jonathan Ho.)

VetBooks.ir

obvious discomfort, with tachypnea and frothing at the mouth.[6] A similar series of mortalities was reported in a control group of desert iguanas (*Dipsosaurus dorsalis*) exposed to prolonged elevated environmental temperatures.[7]

Reptiles lack the thermoregulatory function and endogenous thermal set point associated with the hypothalamus in higher vertebrates. In addition, reptiles have been found to self-regulate body temperature and behaviorally stimulate a fever response to control a pathogen. Vaughn found that when a reptile was provided a choice between two different environmental temperatures, the reptile chose the warmer temperature in an attempt to stimulate the immune system to eradicate pathogens. Desert iguanas experimentally inoculated with *Aeromonas hydrophila* sought warmer areas within their environment, whereas no alteration was observed in the behavior of desert iguanas that were given a saline placebo.[7,8]

In contrast to those studies that reported behavioral fever response in reptiles, Warwick has suggested that some reptiles in an advanced state of disease may select lower environmental temperatures rather than higher environmental temperatures. He theorized that these reptiles may undergo a "biological shut down" to reduce the activity level of an inciting pathogen.[9] The theory was based on anecdotal experience with diseased reptiles and was not rigorously tested. However, the authors have had similar experiences with reptiles in advanced disease. Bacterial pathogens are capable of activity at a wide range of temperatures. One of the authors (MAM) has successfully cultured *Salmonella* spp. from reptiles at a range of temperatures (22°–37°C, 71.6°–98.6°F). Although pathogens may remain active, other reasons may exist for why reptiles do not use optimal temperatures, such as general weakness. To ensure the greatest success with these cases, a thermal gradient must be provided that allows the reptile to self-regulate its body temperature. Veterinarians that can provide this specific information to their clients will have greater success with their cases, especially with follow-up to confirm compliance.

REPTILE IMMUNE RESPONSE

The immune system of the reptile is composed of innate, humoral, and cell-mediated arms of the immune system. Although the components of the reptile immune system are similar to those of higher vertebrates, the reptile immune system is more primitive than that described in higher vertebrates. Because reptiles are ectothermic, their immune system is also dependent on the ability to maintain an appropriate core body temperature. In the wild, diurnal species bask during the early morning hours and late afternoon to increase core body temperature. In captivity, reptiles that are not provided an appropriate environmental temperature range may become hypothermic, which can depress immune function.

The humoral component of the reptile immune system functions to produce both specific immunoglobulins (IgY) and nonspecific immunoglobulins (IgM) that interact with foreign antigens and stimulate the cell-mediated immune response. Macrophages phagocytize pathogens or foreign material, process it with a cascade of enzymatic pathways, and present specific antigens to the B-cell lymphocytes for globulin production. IgM is produced first and is a large nonspecific antibody; it is commonly produced in response to gram-negative bacteria and is a lytic antibody that has a half-life of about 10 days.[10] IgY is a smaller antigen-specific antibody that may appear weeks after the initial encounter; it has a longer half-life compared to IgM.[10] IgY is produced in greater quantities than IgM and provides the major defense against infections. It is also passed from the mother to the embryo via the yolk.[11] Recently, an IgA-like antibody has been found in the intestines of the leopard gecko (*Eublepharis macularius*).[12] It is hypothesized that this antibody originated from a recombination between IgM and IgY.[12] Evidence exists that reptiles may also produce the immunoglobulin IgD. The function of IgD is not entirely understood, but it is expressed on the surface of mature B-cells along with IgM and may play a role in modulating B-cell development.[13] Two IgD immunoglobulin genes, IgD and IgD2, have been sequenced in the leopard gecko.[14] IgD has been detected in tissues from the stomach, intestine, cloaca, liver, kidney, lung, spleen, and blood cells at the same concentrations as IgM. IgD2 was also found in these tissues but at low levels.[14] An IgD gene was also found in the anole lizard (*Anolis carolinensis*).[15] Relative to mammals, reptiles can have a prolonged IgM response before switching to IgY production.[16] Hyperglobulinemia is a common finding with an inflammatory leukogram. Antibody production can be influenced by temperature, antigen type and concentration, and route of inoculation.[13]

The cell-mediated component of the immune system uses T-cell lymphocytes to seek out and phagocytize foreign antigens. Killer T-cells probably have some influence on the destruction of viruses. Functional T-cells have been found in all reptiles tested, including snakes, lizards, turtles, and tuatara.[17] T-cell proliferation is strongly affected by the seasonal cycle in reptiles. Farag and El Ridi found that lymphocytes from the striped sand snake (*Psammophis sibilans*) had the highest proliferation in a mixed leukocyte reaction during the spring and autumn.[18]

Our current understanding of the reptilian immune system is in its infancy, and thus there is a need for us to invest additional resources into evidence-based research to unlock how we can use a reptile's functional immune system to help manage disease processes. For the time being, ensuring optimal environmental conditions is an important start.

NUTRITIONAL STATUS

The nutritional status of the reptile is an important consideration in the development of a therapeutic plan. Reptiles that are fed an inappropriate diet or provided insufficient calories may have multiple concurrent disease processes occurring. Dehydration, cachexia (muscle wasting), myopathies, gastrointestinal senescence, hepatic disease, and renal compromise may all be sequelae from an inappropriate diet. Alterations to hepatic and renal function due to nutritional stress can severely alter the pharmacokinetics of chemotherapeutics that are metabolized and excreted by the liver and kidney. Decreased hepatic function, decreased gastrointestinal function, and renal impairment can all lead to hypoproteinemia, which reduces oncotic pressure within the blood and can alter fluid balance between the intra- and extracellular spaces. This ultimately can affect the success of a fluid rehydration plan.

Reptiles in a negative energy balance can be expected to have physiological disturbances that can affect case management. In severe cases, nutritional deficiency can lead to refeeding syndrome, which is characterized by electrolyte disturbances such as hypophosphatemia and hypokalemia. These electrolyte imbalances can lead to hemolytic anemia or cardiac arrhythmias, and sudden death. Likewise, calcium deficiencies and metabolic alkalosis can lead to severe fluctuations in bound and ionized calcium concentrations, which can also be fatal.

Veterinarians should familiarize themselves with the specific dietary requirements for those species routinely in their care. Reptiles with a negative energy balance should be rehydrated and provided caloric replacement. However, reptiles should be gradually brought up to their resting energy (caloric) requirement over several days or weeks to prevent refeeding syndrome. See Chapter 122 for further discussion on the specific dietary needs of reptiles.

HYDRATION STATUS

Hydration status should always be considered in any reptile when developing a therapeutic plan and a basic understanding of fluid balance

VetBooks.ir

in reptiles is important. Reptile total body water content is generally similar to or slightly higher than that found in mammals.[19,20] The primary difference observed between these two groups is where the fluids are located, with higher intracellular (48%–80%) and lower extracellular (20%–52%) fluid volumes in reptiles compared with mammals.[20] In addition, terrestrial reptiles generally have a higher percentage of extracellular fluid compared with aquatic species.[20] Overall, plasma accounts for approximately 3.3% to 7% of the total body weight.[20,21] A high degree of variability exists in the electrolytes important to osmoregulation in reptiles, especially sodium, which represents the primary contributor to osmolality, and while it has been suggested that terrestrial species generally have higher sodium concentrations in the extracellular space than freshwater aquatic reptiles, this is not always true.[19] For example, sodium concentrations can be as low as 120 to 130 mEq/L in terrestrial chelonians.[22] This large variation in sodium, as much as 40%, suggests that osmolalities between species of reptiles may vary significantly, and thus the fluid balance between the extra- and intravascular spaces too. This difference in osmolality should be considered when selecting fluids for rehydration. Although limited, recent studies affirm the variability in plasma osmolalities in different reptiles, with healthy bearded dragons having a mean osmolality of 295 mEq/L and healthy male corn snakes of 344.5 mEq/L.[23,24] It is expected that in unhealthy animals these values would be different. Determining plasma osmolality is best done using freezing-point osmometry. Unfortunately, this is not always available, and thus the authors desired to determine if an algorithm could be used to estimate plasma osmolality. The calculations found to have the best level of agreement for the corn snakes and bearded dragons were 2(Na) and 1.85 (Na +K), respectively. These calculations may be used for these species and as a general rule for other reptiles, but variation dictates determining species-specific calculations, similar to those for cats and dogs. Additional information regarding fluid therapy in reptiles can be found in Chapter 87.

Routes of Administration

Sean M. Perry and Mark A. Mitchell

Reptiles possess significant diversity in their morphology, and these structural differences need to be taken into consideration when administering drugs or fluids. For example, venomous reptiles can be difficult to handle and present an increased risk to humans who must repeatedly treat them. In these cases, alternative drug delivery methods (e.g., osmotic pumps) can be used to minimize handling and personnel risks. This chapter will review the different methods and routes for administering drugs and fluids to reptile patients.

ROUTES OF DRUG AND FLUID ADMINISTRATION

Enteral Routes of Administration

Gastrointestinal (GI) tract anatomy and motility can affect the absorption and delivery of drugs and fluids in a reptile. Therefore it is important to ensure that every reptile patient is maintained at an appropriate environmental temperature so that the GI tract functions effectively and metabolism is maximized. Medicating per os (PO) can be challenging, especially in chelonians; thus, it is important to understand the different options available for delivering oral medications, including via the diet, directly PO, or through a feeding tube.

Medications can be easily hidden (injected) into food items, or gel diets can be prepared that are combined with the enteral medications. A gel diet can be offered as an exclusive diet during treatment or can be combined with the patient's primary diet. Target feeding or limiting the amount of food offered when treating a reptile with a medication will increase the likelihood of patient compliance; however, if there is any concern that the full dose is not received, then oral dosing must be done to ensure treatment success. Although reptiles have relatively few taste buds, they will avoid distasteful medications. If hidden in food, reptiles will often avoid the area in which the medication is present. To counter this, medications can be flavored too. Many compounding pharmacies can provide a variety of flavors, from fruit (e.g., cherry, grape) to meat flavors (e.g., liver), although any effects on bioavailability are often unknown. Although these different methods for enticing a reptile to eat can be successful, if there is any concern that the reptile is not receiving its full dose, direct oral dosing is recommended.

Fluid replacement should only be done PO for cases with mild dehydration (<5%) and when the GI tract is functioning normally (i.e., no vomiting or diarrhea). This route of administration is often underused in veterinary medicine because of our desire to administer fluids via the parenteral routes; however, since the GI tract is the natural physiological route of fluid absorption, it is appropriate to use when an animal needs mild replenishment. The advantages of administering fluids PO include non-invasiveness, stimulation of GI motility, and the relative ease by which non-veterinary professionals can be trained to perform. The PO route should not be used when the fluid type is a hypertonic fluid, as this can incite an osmotic diarrhea. Additionally, the PO route should not be used when large volumes of fluids are required, as this can lead to regurgitation or vomiting, and aspiration. The maximum fluid volume that the stomach can hold is 5% to 8% of the reptile's body weight. The authors do not recommend replacing more than 2% to 3% of the animal's body weight PO at a single time to prevent gastric atony and vomitting.

PO fluids or drugs can be administered either via a syringe directly into the mouth or with an esophageal or stomach tube (Fig. 115.1). The authors prefer to administer fluids via an esophageal or stomach tube, because a large bolus can be administered quickly. The tube should be premeasured from the mouth to the midpoint of the coelom, which is the approximate level of the stomach in most species.

Chelonians are more difficult to medicate PO. When a chelonian withdraws into its shell, gaining access to the oral cavity can be extremely difficult. Attempts to extract the head should be done with caution. The caudal cervical vertebrae of a chelonian are fused to the carapace, and aggressive manipulation of the head and neck can result in a cervical spinal injury. Sedation or anesthesia may be necessary to fully withdraw the head and neck. A soft pliable speculum, such as a rubber spatula, or a plastic-coated paper clip may be used to gently pry open the beak. Aggressive manipulation of the oral cavity can lead to fractures of the tomia. Either a soft pliable feeding tube or rigid stainless steel ball-tipped feeding tube can be used to deliver medication or fluids (Fig. 115.2). These tubes are preferred over direct placement of a drug or fluids into the back of the oral cavity because they decrease the likelihood of aspiration or drug loss. The dosing tube should be premeasured to deliver the drug directly into the stomach (approximately midbody to the left of center). When passing a stomach tube, the glottis must be avoided. The glottis is located at the base of the tongue. Passage of the stomach tube may be simplified with lubrication of the tube; however, care should be taken to avoid introducing lubricant into the glottis. Chelonians that need frequent oral treatments should have an esophagostomy tube placed to simplify treatment (see Chapter 45).

Parenteral Routes of Administration

Parenteral routes for administering drugs and fluids are preferred in those cases of severe dehydration and when the GI tract is not working appropriately. Because there are several different parenteral routes for delivering drugs, the patient's response to treatment route can vary. It is important to select the route that considers the size and health status of the patient, any known pharmacokinetic or pharmacodynamic data associated with a treatment, the ease of administration, and any potential adverse effects associated with the route of administration. Parenteral routes for fluid administration should also consider these factors, as well as the type of fluid used, any fluid additives that may be affected by route of administration (e.g., glucose concentration), and desired rate of absorption.

FIG 115.1 (A) Oral administration of medication can be performed utilizing a red rubber tube that is placed into the distal esophagus or stomach in snakes. Ensure that the tube is not passed into the glottis. (B) Tubes should be premeasured before administering medications as demonstrated in this ball python (*Python regius*). (C) In many snake species passing a red rubber tube ventral to the philtrum and between palatine and mandibular rows of teeth allows for easy placement of a distal esophageal or gastric tube, as seen in this green tree python (*Morelia viridis*). (D) Additional equipment may be needed when administering oral medications to venomous reptiles, such as restraint tubes and elongated forceps, as shown here with this Mangshan viper (*Protobothrops mangshanensis*) (A, C, and D, Courtesy of Sean M. Perry.)

FIG 115.2 A metal gavage tube can be used in assist feeding or administering medications in chelonian species.

Subcutaneous. In reptiles, the subcutaneous (SC) space is small and poorly vascularized compared with mammals. The limited blood supply to the SC space can lead to variable absorption rates, depending on the physiological status. In squamates, the preferred site for administering SC fluids or medications is over the lateral body wall (Fig. 115.3A). In chelonians, SC injections can be given in the axillary and inguinal regions (see Fig. 115.3B). Additionally, in some lizard species small volumes of medications can be administered in the axillary region (see Fig. 115.3C). SC injections in crocodilians are rarely employed but can be given over the lateral body wall. Drugs with pH <7 or >8 (e.g., enrofloxacin), or irritating adjuvants, should not be administered SC because they can cause localized inflammation, tissue necrosis, and skin discoloration or depigmentation (Fig. 115.4). Fluid replacement within the SC space can be used for reptiles but should be limited to those cases where the reptile is <6% dehydrated. Critically dehydrated reptiles should be rehydrated using the intracoelomic (ICo), intravenous (IV), or intraosseous (IO) routes. Hyperosmotic solutions, such as dextrose (concentrations greater than 5%), should be administered IV rather than SC, because there is a chance to induce sterile abscesses, skin necrosis, cellulitis, and sloughing, although in human medicine utilizing subcutaneous dextrose has shown comparable effects to administration IV.[1,2]

FIG 115.3 (A) The lateral body wall in snakes, such as this ball python (*Python regius*), provides an excellent location for administering subcutaneous fluids or medications; often a pocket at this location allows for subcutaneous fluid to track cranially and caudally. (B) Subcutaneous administration location in the inguinal region of a Burmese mountain tortoise (*Manouria emys emys*). (C) In lizards, small volumes of medications can be administered in subcutaneous space in the caudal axillary region, as in this Gila monster (*Heloderma suspectum*). (C, Courtesy of Sean M. Perry.)

FIG 115.4 Some species such as chameleons often will discolor their skin immediately after any type of injection; the site of subcutaneous injection is obvious in this veiled chameleon (*Chamaeleo calyptratus*). (Courtesy of Stephen J. Divers.)

Administering parenteral drugs via the SC route has become more common in reptile practice. This route of administration is thought to be a less painful route and likely causes less trauma to the surrounding tissue compared with intramuscular (IM) injections. Studies evaluating anesthetics and analgesics have demonstrated that utilizing the SC route was equally as efficacious as the IM route.[3,4,5] Ceftiofur crystaline free acid (CCFA) pharmacokinetics were evaluated utilizing both IM and SC routes in bearded dragons (*Pogona vitticepts*), and there was no observed benefit to the IM CCFA pharmacokinetic profile compared with the SC route of administration.[6] Similar pharmacokinetic profiles showed no clinical differences between these two routes of administration for danofloxacin in loggerhead sea turtles (*Caretta caretta*).[7] More research needs to be performed evaluating more medications and their absorption via the SC route.

Intracoelomic. The coelomic cavity is a large space that is lined with a highly absorptive coelomic membrane. In addition to the coelomic membrane, the serosal surfaces of the viscera are also highly absorptive. Squamates and chelonians do not have a diaphragm, whereas crocodilians only have a pseudodiaphragm. It is important to limit the quantity of fluids placed into the coelomic cavity, as excessive fluids can cause lung compression. Irritating and/or hyperosmolar compounds should not be administered ICo, as they can injure the viscera or lead to fluid accumulation in the coelomic cavity. Care is also required to avoid needle trauma to visceral structures, and some authors no longer recommend this route unless absolutely necessary. ICo fluids should be administered in the ventrocaudal third of the coelomic cavity to avoid the lungs or air sac. Lizard lungs are located dorsally and can extend the length of the coelomic cavity. Placement of the lizard in dorsal recumbency allows for gravity to pull the viscera away from the ventral injection site (Figure 115.5A). The injection site should be disinfected with a topical antiseptic. The hypodermic needle (22–25 gauge) or butterfly catheter (22–25 gauge) should be inserted paramedian at a <15 degree angle to avoid the ventral abdominal vein and viscera, respectively. Once inserted, the syringe should be aspirated to ensure that the needle was not inserted into lung, air sac, or bladder. If air or urine or blood is aspirated into the syringe, then the needle/catheter should be removed and replaced before reinsertion. The same technique can be used to administer fluids to a snake. In chelonians, the authors prefer to administer ICo fluids at the prefemoral fossa where the skin is attached to the shell at the ventral aspect of the bridge. With placement of the chelonian in lateral recumbency, gravity can be used to draw the viscera away from the needle (see Figure115.5B).

Intramuscular. IM injections are commonly used for administering drugs because of injection site access and rapid uptake and distribution. Physiologic status can have a significant influence on drug absorption via the IM route, as dehydration, hypothermia, and physiological shunting during times of illness or stress can affect muscle perfusion. Adequate hydration and body temperature are required before IM administration of any treatments. Fluids should never be administered via the IM route, because the infusion of a large volume can induce muscle damage and extreme pain. Common locations for IM injections include the triceps and epaxial muscles (Fig. 115.6). In some situations, repeated IM injections are not recommended, such as with irritating compounds or in reptiles with limited muscle mass. Multiple IM injections into a small muscle mass can cause myositis, myopathies, paresis, and changes in ambulation. Over an extended period of treatment, this could cause debilitation. SQ injections can be utilized as an alternative to IM injections for many non-irritating parenteral medications. The SC route is especially useful in small and debilitated reptiles to avoid trauma to muscles.

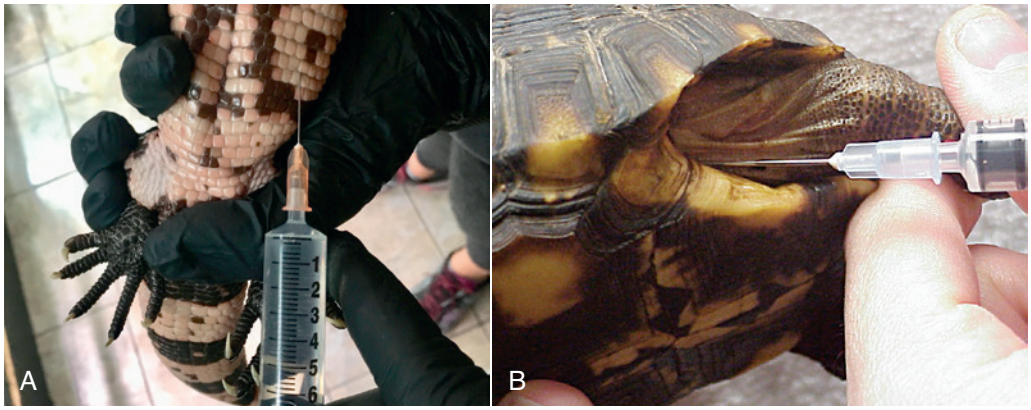

FIG 115.5 (A) Administration of intracoelomic fluids can performed with a lizard in dorsal recumbency and in the ventral third of the body as shown in this Gila monster (*Heloderma suspectum*). (B) Location of intracoelomic fluids within the ventral caudal coelomic cavity of the chelonian to avoid the lungs. This red-footed tortoise (*Chelonoidis carbonaria*) is placed in lateral recumbency. (A, Courtesy of Sean M. Perry.)

Intravenous. The IV route of administration is the most effective and rapid method for delivering drugs and fluids. Fortunately, IV administration has become more routine when performing surgery, providing intensive care, and administering certain therapeutics. Common sites for IV catheters or injections in squamates and chelonians are the jugular (Fig. 115.7A and B) and ventral coccygeal veins, and jugular and dorsal coccygeal veins, respectively (see Chapter 44). The cephalic vein can be used to obtain IV access in large lizards. Most IV catheters require surgical cut-down for placement (Fig. 115.8). The subcarapacial sinus of chelonians is also commonly used for delivering IV drugs; however, irritants or high volumes can lead to temporary or permanent paralysis or death due to presumed intrathecal administration (Fig. 115.9). Central venous catheterization has been recently reported in critical chelonians.[8–10] Arterial catheterization of the carotid artery has also been described in green iguanas for blood pressure monitoring; however, surgery is required to obtain access to this vessel.[11]

FIG 115.6 Cranial epaxial muscles, as shown in this Gila monster (*Heloderma suspectum*), can be utilized for intramuscular injections without influencing the muscles required for ambulation. (Courtesy of Sean M. Perry.)

Intraosseous. IO catheters can be used when rapid absorption of the fluids is required but IV access is limited or not (see Chapter 44). The proximal tibia is the preferred IO site for lizards. Because the catheter is placed through the periosteum, a local anesthetic and aseptic technique should be used. Spinal needles with a stylet are preferred to prevent bone coring; however, 18 to 25 gauge needles can be used too. The needle may need to be replaced with another if it is obstructed with a bone core, although the second needle must be reintroduced into the same IO site. The authors' preference for hypodermic needles is based on their shorter length. The tibial crest should be used as the primary landmark for insertion. The stifle should be flexed and the needle inserted on the tibial plateau anterior to the joint capsule (Fig. 115.10A). A gentle twisting force should be applied to the needle to ensure proper purchase into the medullary cavity. The catheter can be secured with suture or tape (see Fig. 115.10B). Radiography is recommended to confirm placement (see Fig. 115.10C). Large boluses of fluids are difficult to infuse through an IO catheter because of the small medullary cavity in the tibia. In chelonians, IO catheters can be placed in the distal femur or proximal tibia; however, they can be challenging to place in the femur because of the sigmoid shape of the femur. In addition, if the patient withdraws into its shell, the IO catheter may interfere or be displaced. The cranial and caudal limits of the bony bridge between the carapace and plastron of chelonians have also been suggested as a site for fluid administration (Fig. 115.11A–C). This site is considered analogous to the placement of an IO catheter in other species. However, this site can only be accessed via drilling a hole into the shell. It can also be technically difficult to place these catheters, because the size of the medullary cavity in these bridges varies from species to species. Because of the limited accessibility of this site and the invasiveness of the procedure, this site should only be used in rare instances in which other routes of parenteral fluid administration are not possible. In addition to the bridge, the authors have found the gular scute to serve as an acceptable site for IO catheterization in chelonians, especially juvenile animals. Placement of the catheter in these young animals is straightforward and does not require a drill, as the bone is softer. Delivery of fluids through this site

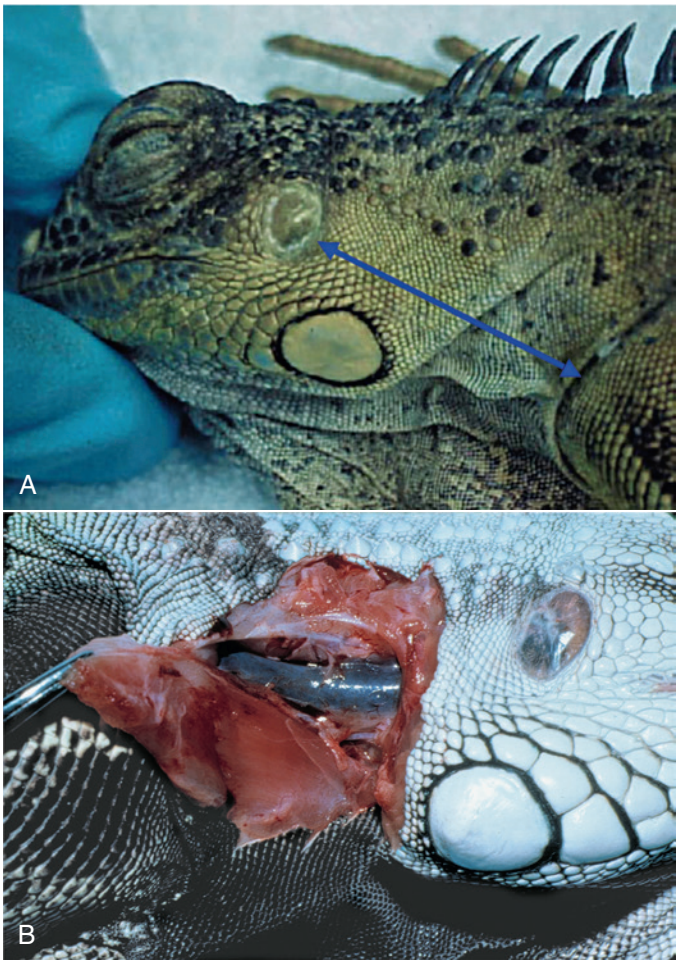

FIG 115.7 (A) The jugular vein in most species of lizards is located in the lateral cervical region. This figure shows the approximate location of the jugular vein in the green iguana (*Iguana iguana*). (B) Postmortem dissection of the jugular vein of an adult green iguana. The large jugular vein is located on the lateral neck caudal to and slightly below the tympanum. This site can be used for venipuncture or intravenous catheterization by drawing an imaginary line from the ear to the point of the shoulder, as seen in (A).

should be done with a syringe pump to limit any potential chance for pressure necrosis and damage to the scute.

Intrathecal Administration. Intrathecal injections have been demonstrated to be a viable option for parenterally administering drugs to chelonians, especially analgesics and anesthetics.[13] Intrathecal injections deliver the drug directly into the subarachnoid space, the location of cerebrospinal fluid (CSF) in reptiles. The dorsal tail of the chelonian should be aseptically prepared for the injection. Palpate the tail and, if possible, locate an intervertebral space as an insertion site. Insert a hypodermic needle (22–25 gauge, 1–1.5") fastened to a syringe into the intervertebral space. Adjustments to the insertion angle should be made to assist in correct placement. Begin insertion with a 45-degree angle once the neural arch is penetrated, then advance the needle into the spinal canal at a 20-degree angle. As the needle is advanced, maintain slight negative pressure. Upon penetration, clear to straw-colored CSF should enter the needle. If unsuccessful, the needle should be redirected

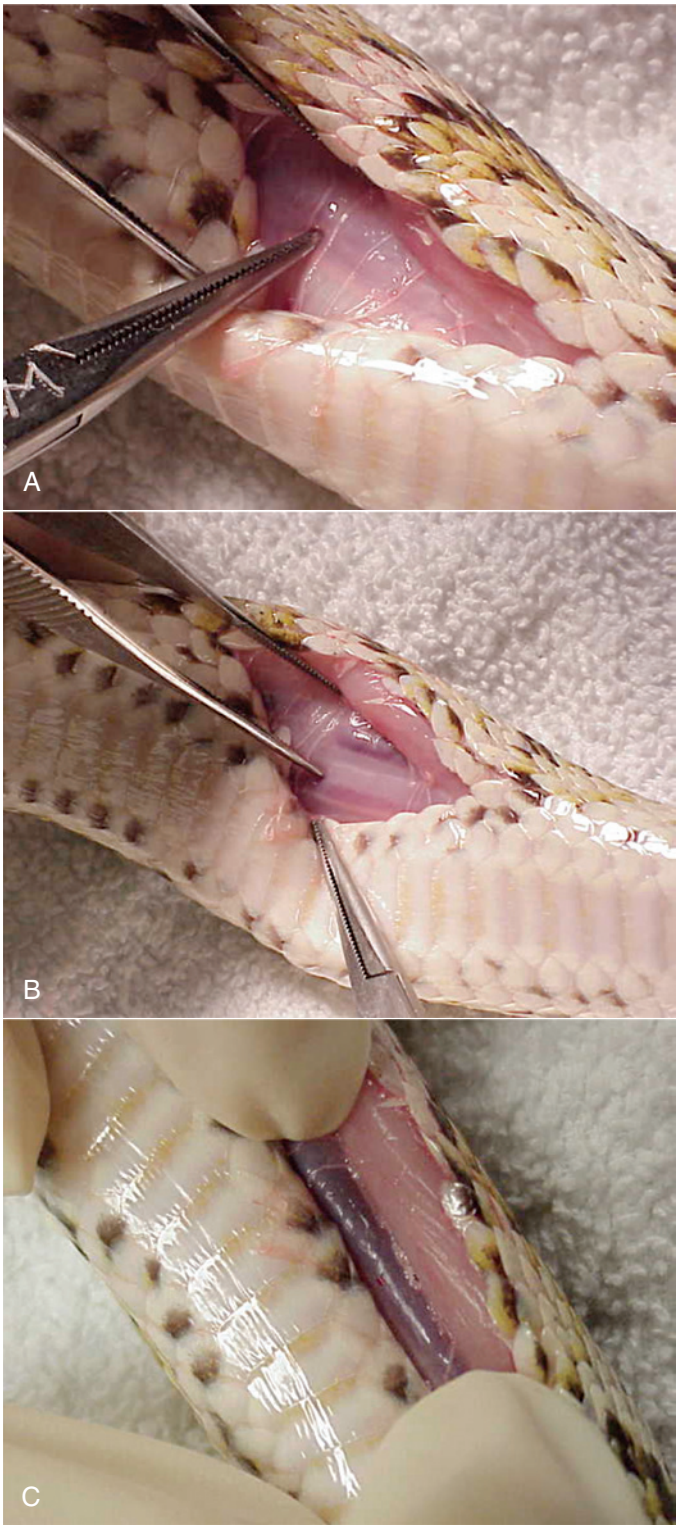

FIG 115.8 (A) The jugular vein of a snake can be located approximately nine scales cranial to the heart. The initial incision should be made between the first and second row of dorsal scales. (B) Blunt dissection of the rectus abdominius is necessary to identify the jugular vein. (C) The jugular vein is a sizable vessel in the snake. Here is an example of a right jugular vein in a reticulated python (*Malayopython reticulatus*).

until CSF is aspirated into the syringe. It is common to aspirate blood from the dorsal coccygeal vessel. If this happens, obtain a fresh needle and start again. Lidocaine (1 mg/kg) has been evaluated as an anesthetic for this procedure in the Galapagos tortoise (*Chelonoidis nigra*) and provides sufficient anesthesia for undergoing a phalectomy with minimal adverse effects.[12]

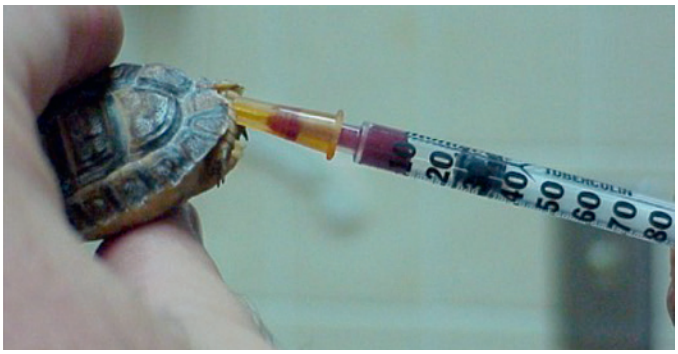

FIG 115.9 Subcarapacial sinus can be used to administer intravenous drugs in chelonians, even in the smallest patients; however, care is required as intrathecal injection is possible. (Courtesy of Mark A. Mitchell.)

Intracardiac Administration. Intracardiac venipuncture is routinely used to collect blood samples and deliver medications to snakes.[13,14] Recent studies in ball pythons *(Python regius)* found that serial cardiac venipuncture was not found to be associated with significant myocardial pathology, and propofol infusion directly into the heart showed minimal microscopic changes to the myocardium.[13,14] The authors have also administered radiographic contrast intracardially without obvious complications (Fig. 115.12). Injecting drugs into the heart is not without potential complications, including laceration of the great vessels or cardiac muscle, and arrhythmias. Although the likelihood of these complications appears to be low for experienced clinicians, they should be discussed with clients before hand.

Additional Routes of Administration

Nebulization. Reptiles have a primitive respiratory tract compared with mammals. Mammals have a well-developed ciliated epithelial lining and mucociliary escalator, whereas the reptile respiratory tract has very few epithelial cilia. Since reptiles lack this component of the immune system, they have a diminished ability to remove foreign material from this system; this can lead to the accumulation of mucous and microbes. Consequently, infections of the respiratory tract can be difficult to manage, and systemic antimicrobials may not be sufficient to control disease.

Nebulization therapy using antimicrobials is routinely done for mammals and birds with equivocal results. To date, only one study

FIG 115.10 (A) Placement of an intraosseous catheter in a green iguana (*Iguana iguana*) in the cranial tibia. (B) Intraosseous catheters can be placed temporarily with tape as shown here in emergency situations while they can be sutured in for long-term placement. (C) Radiographs should be performed after placement to confirm placement within the medullary cavity for appropriate fluid or medication administration. (A and B, Courtesy of Sean M. Perry.)

VetBooks.ir

exists evaluating the pharmacokinetics of an antifungal medication using nebulization therapy. Kane et al. reported that nebulization therapy using terbinafine in cottonmouths (*Agkistrodon piscivorus*) reached levels higher than in vitro susceptibility concentration (15 ng/mL) for *Ophidiomyces ophiodiicola*. The absorption of the terbinafine is thought to be both via the respiratory tract and cutaneous absorption[15](Fig. 115.13). Other drugs have been used successfully via nebulization by the authors, such as amikacin and gentamicin. Success with nebulization depends on the drug being used and the particle size of the vapor generated (<5 µm). Larger particles may not penetrate the distal lung and air sac spaces. The use of oxygen as a carrier gas can be associated with suppression of ventilation, and therefore air is recommended for reptiles. The duration of treatment is another important consideration to ensure sufficient penetration (see Chapter 76 for more details).

Reptiles can be nebulized with a variety of antibacterial or antifungal agents, sterile water, or a combination of these compounds. In addition, a mucolytic may be considered. Acetylcysteine 20% can be used to facilitate the breakdown of mucous, increasing the likelihood that the therapeutic is distributed throughout the respiratory tract and maximizing epithelial contact. When using acetylcysteine, exposure time should be limited to 30 minutes because it can be irritating to the tissues.

Intralesional Therapy. Intralesional therapy is a method of administering therapeutics directly to an area of concern either by direct injection of a chemotherapeutic or by implanting chemotherapeutic-impregnated beads. The beads then slowly release the drug into the local tissue to treat either infection or neoplasia for a period of time.

Antibiotic-impregnated polymethylmethacrylate beads can be used to treat osteomyelitis and local infections by providing long-acting, slow-release antibiotics to a specific area.[16] Only heat-stable antibiotics can be used to make the polymethylmethacrylate beads; the authors have had success with aminoglycoside agents (particularly gentamicin and amikacin) and clindamycin. The aminoglycoside antibiotics usually have good efficacy against gram-negative opportunistic pathogens, whereas clindamycin is often effective against anaerobic bacteria. Selecting the appropriate antibiotic-impregnated polymethylmethacrylate beads should be based on microbiologic culture and antibiotic sensitivity testing.

Intrapulmonary administration of amphotericin B has been used to successfully treat pulmonary candidiasis in a tortoise.[17] In reptiles, few case reports exist of intralesional therapy to administer adjuvant chemotherapy to control neoplasia. Squamous cell carcinoma was successfully treated in a yellow-belly slider (*Trachemys scripta scripta*) using a combination of surgery and electrochemotherapy with intratumoral injections of bleomycin.[18]

Transdermal Therapy. Transdermal therapy has become a common method for administering drugs in both human and veterinary medicine. This type of therapy is achieved by placing ointment or a patch delivery apparatus on the skin. In reptiles, the use of transdermal therapeutics is in its infancy. One study tested a loading dose of fentanyl in ethanol and cellulose gel that was enclosed by a plastic barrier with a permeable adhesive membrane on prehensile-tailed skinks (*Corucia zebrata*).[19] All of the animals within the study had measurable plasma concentrations of fentanyl within 24 hours of patch application and concentrations reached the human analgesic range within 36 hours. Another study evaluated the fentanyl transdermal therapeutic system in ball pythons.[20] In these snakes, a fentanyl transdermal patch (12 µg/h) was applied to the dorsum (cranial 1/3) of ball pythons with adhesive and staples. The investigators found detectable concentrations of fentanyl in the blood after 4 hours and human analgesic concentrations (1 ng/mL) starting at 8 hours and continuing for the remainder of the study (216 hours).[20] Both of these studies demonstrated that the scaled skin of a reptile does not present an insurmountable barrier to systemic absorption of fentanyl delivered by a transdermal patch and suggest that additional studies are needed in other species.[19,20]

FIG 115.12 Intracardiac administration of medications can be employed in snake species; butterfly catheters are utilized in these ball pythons (*Python regius*) to administer intravenous iohexol before contrast CT. Sedation or anesthesia is recommended to ensure safe venipuncture. (Courtesy of Sean M. Perry.)

FIG 115.13 Nebulization setup suitable for reptiles. The compressor (1) forces air through the drug reservoir (2), located on external rear wall, to form a fine mist, which is delivered through a port (arrow) into the nebulization chamber (3), which has rubber seals around the front access door to reduce drug vapor escape. (Courtesy of Stephen J. Divers.)

Osmotic Pumps. Alzet osmotic pumps (Durect Corp., Cupertino, CA) are implanted, miniature infusion pumps that provide continuous infusion of therapeutic agents to unrestrained animals. The "pumps" operate via an osmotic pressure difference between the tissue environment and a salt osmotic sleeve. The high osmotic pull of the salt within the pump causes water to diffuse into the pump across a semipermeable membrane and into the sleeve; this increases the pressure within the medication reservoir and initiates the release of the therapeutic agent via a flow moderator at a predetermined, continuous rate that is not dependent

on the therapeutic agent's chemical properties.[21] Variable dosing rates can be achieved by altering the concentration of the therapeutic loaded into the pump. In reptiles, osmotic pumps have been used in green iguanas (*Iguana iguana*), corn snakes (*Pantherophis guttatus*), and Mojave rattlesnakes (*Crotalus scutulatus*) to deliver gonadotropin-releasing hormone, amikacin, and florfenicol, respectively.[22–24]

Programmable Infusion Pumps. iPRECIO programmable infusion pumps (Durect Corp., Cupertino, CA) are implanted advanced infusion devices that are miniaturized, fully programmable pumps. These pumps provide the user the ability to program different dosing protocols while maintaining access to a reservoir that can be refilled percutaneously. These pumps utilize wireless data communication and management software that directs dosing and infusion rates. Battery life of these devices varies based on infusion type and model; however, they can last from 47 days to 6 months. There are no reports of these pumps being used in reptiles, although they could certainly have clinical value.[25]

Long-Acting (Depot) Formulations. There has been a movement in veterinary medicine to produce long-acting (depot) formulations to reduce patient stress associated with daily treatment and to increase owner compliance. These same depots would be welcome in herpetological medicine if they provided the same results. Examples of long-acting formulations that have been used to treat reptiles include leuprolide acetate, cefovecin, oxytetracycline, doxycycline, and ivermectin.[6,7,26–34] A pharmacokinetic study evaluating long-acting oxytetracycline in American alligators (*Alligator mississippiensis*) found it was useful for treating mycoplasmosis;[28] however, cefovecin has been thoroughly investigated and shows no efficacy in green iguanas because it is highly protein bound and has an extremely short half-life.[32–34] These results reinforce the importance of pursuing hypothesis-driven research to generate evidence-based information to ensure treatments will be optimized.

Vascular Access Ports. Vascular access ports are used to repeatedly collect blood samples or administer intravenous medications over time. They are useful in pharmacokinetic studies and for cancer chemotherapy. In a study evaluating these ports in tortoises, a sterile rubber stopper from an evacuated blood collection vial was inserted into a round plastrostomy site created at the location of the cardiac ventricle. This port was used to collect multiple blood samples over time; however, it is important to recognize that multiple injections into the heart can lead to myocardial fibrosis.[35,36] Vascular access ports have also been placed into the common carotid artery of green iguanas to evaluate serial blood gases. The ports remained functional in the green iguanas over several weeks.[37] In another case report, a vascular access port was placed into the ventral abdominal vein of a green iguana with lymphoma to deliver chemotherapy. This port needed to be replaced after 28 days due to dermal necrosis over the port; however, a second port was successfully placed and lasted 6 months without complications.[38]

Topical Administration. Many topical medications are used in reptiles to treat skin disease. Antiparasitics, disinfectants, ophthalmic solutions, creams, ointments, and lavage solutions can all be applied topically to reptiles. These types of drugs are intended to deliver local therapy to an affected area without unwanted systemic uptake and adverse effects.

Topical administration of antiparasitic agents has been evaluated in reptiles, because oral administration of antiparasitics can be challenging in some lizards and chelonians. In the United States the only USDA- and EPA-licensed topical antiparasitic medication for reptiles is Provent-a-Mite; its active ingredient is permethrin. This has been shown to be effective as an acaricide in Komodo dragons (*Varanus komodensis*) and leopard tortoises (*Stigmochelys pardalis*).[39,40] A commercially available topical treatment for intestinal parasites containing imidacloprid and moxidectin (Advantage multi/Advocate, Bayer, Shawnee Mission, KS) is available for companion animals. Frilled dragons (*Chlamydosurus kingii*) and bearded dragons (*Pogona vitticeps*) given a single topical dose of this drug were cleared of *Kalicephalus* sp. and oxyurid ova.[41] Another commercially available topical antiparasitic preparation containing emodepside and praziquantel (Profender, Bayer HealthCare, Shawnee Mission, KS) has been tested for absorption, elimination time, and efficacy in several lizards, snakes, and chelonians.[42–44] Both drugs were absorbed via the skin, except in one case; emodepside was not absorbed in a single red-eared slider (*Trachemys scripta elegans*) that was returned to the water within 1 hour of treatment.[42,43] Treatment with emodepside/praziquantel at doses higher than those used in mammals was followed by a significant decrease in the number of nematode ova in the feces within 48 hours. No adverse effects were observed, and fecal nematode egg counts decreased after treatment in a relatively large (n = 417), uncontrolled clinical trial of emodepside/praziquantel in species from four different reptilian families.[42] Despite these results, a clinical trial with the Texas tortoise *(Gopherus berlandieri)* showed no efficacy when using emodepside/praziquantel to treat pinworms; animals that were treated with topical emodepside/praziquantel had higher egg counts per gram of feces compared with the untreated groups (J. Jill Heatly: Pers. comm., 2016). Additionally, in four Hermann's tortoises (*Testudo hermani*), twenty-two spur thigh tortoises (*Testudo gracea*), two Russian tortoises (*Agrionemys horsfieldii*), and a leopard tortoise, after treatment with topical emodepside/praziquantel, the oxyurid egg count was slightly increased on day 14, although it declined significantly by day 33, which may have indicated a therapeutic effect and moderate efficacy 33 days posttreatment. Topical application of emodepside and praziquantel was well tolerated in our tortoise population.[44] The results of these studies reinforce the importance of pursuing hypothesis-driven research to evaluate species dosing, route of administration, location of treatment, and so on. When faced with a clinical case and no relevant evidence-based science, it is important to thoroughly document protocols used and share them with others to initiate a discussion and, hopefully, an interest in pursuing research.

Topical therapy to aid in wound healing has also been briefly explored in reptiles. Becaplermin, a topical platelet-derived growth factor, was investigated to determine whether it altered the rate of wound closure in bearded dragons. Becaplermin did not have a significant effect on wound closure rates in this species.[45]

Implications of the Renal Portal System and Administration Route

The renal portal system is a unique component of the circulatory system of lower vertebrates. Historically, parenteral drug administration into the tail or caudal extremities was not recommended because of the potential adverse effect (nephrotoxicosis) associated with drug passage through the renal portal system. Although reports exist of nephrotoxicosis associated with the administration of aminoglycosides in reptiles, a review of these cases suggests that the toxicosis was attributed to high doses of gentamicin rather than the route of administration.[46,47]

Research has suggested that parenteral administration of drugs into the caudal extremities may not pose as great a risk as once thought. Holz et al.[48] evaluated renal perfusion in red-eared sliders with radioangiography. The research suggested that intravenous injections of a radiopaque dye into the dorsal coccygeal vein or femoral vein do not necessarily perfuse the kidneys via the renal portal system. The renal portal system most likely serves to perfuse the kidneys, more specifically the tubules, during times of water conservation. During times of water conservation, arginine vasotocin increases water resorption at the level

VetBooks.ir

of the tubules while reducing glomerular filtration.[49] Prolactin is the antagonist for this system.[50] Holtz et al.[49] proposed that a valve located between the abdominal and femoral veins might regulate blood flow through the kidneys. At times of water conservation, a valve in the abdominal vein closes, redirecting blood through the iliac veins and into the kidneys. Holz et al.[51] tested the practicality of this concept by performing two antibiotic pharmacokinetic studies in the red-eared slider. Gentamicin and carbenicillin were selected for the study because they are excreted via glomerular filtration and tubular secretion, respectively. The bioavailability of gentamicin was not affected by injection site. However, this was not unexpected because the renal portal system provides blood to the tubules and should not affect glomerular filtration.[48] The area under the curve for carbenicillin plasma concentrations was significantly lower for the hind limb injections at 1, 4, and 8 hours after injection. Although the plasma concentrations were lower for the hind limb injections, the levels recorded remained above the minimum inhibitory concentration (MIC) required for susceptible bacterial pathogens.

The renal portal system of the iguana may behave differently than that described in chelonians. When three green iguanas were given a radiopaque dye intravenously into the ventral caudal vein, the contrast entered the caudal renal parenchyma and moved cranially into the caudal vena cava.[52] When the radiopaque dye was intraosseously delivered into the femur of three green iguanas, the dye entered the common iliac, pelvic, and ventral abdominal veins. The contrast eventually extended into the renal parenchyma. Variation, however, did exist in the movement of the dye in the iguanas, which may be attributed to individual variation or the small sample size.

To determine whether the renal portal system has any effect on drug pharmacokinetics in snakes, Holz et al.[53] evaluated the injection site on the pharmacokinetics of carbenicillin in carpet pythons (*Morelia spilotes variegata*). Seven carpet pythons were used for the study, and each received a 200 mg/kg intramuscular dose of carbenicillin in either the cranial or caudal epaxial musculature. Five months after the injection, the snakes again received a 200 mg/kg intramuscular injection of carbenicillin; however, the site of the injection was reversed from the previous example. No significant difference was seen in the pharmacokinetics between injection sites. Although the concentrations of drugs given in the cranial half of the snakes were higher over the first 6 to 8 hours, the difference was not significant. However, the range of concentrations was quite varied for each time point, suggesting variability within the sample population. A larger sample population may have led to different results. Regardless of the difference, Holz et al.[53] found that the plasma concentrations were sufficient to control susceptible bacterial pathogens.

Research to investigate the pharmacokinetics and the pathological effects of drugs given in the caudal extremities is limited to a few species, and generalization of these results to all 10,000+ species of reptiles could be dangerous. Additional research to elaborate the effects of different drugs on the renal portal system should be pursued.

Treatment of Eggs

In 1975, attempts to reduce or eliminate *Salmonella* in chelonians with antimicrobials led the US Food and Drug Administration (FDA) to ban the sale of turtle hatchlings. Treatment of the freshly laid eggs with oxytetracycline or chloramphenicol with a temperature differential egg dip method was successful at eliminating *Salmonella* in eggs less than 1 day old but did not clear eggs greater than 2 days old.[54,55] However, because of the development and persistence of antimicrobial-resistant strains of *Salmonella*, antibiotic treatment of reptiles or their eggs is not recommended.[56] Alternative techniques have been developed to suppress or eliminate *Salmonella* in red-eared slider eggs. Mitchell et al. demonstrated that two nonantibiotic microbicide compounds (sodium hypochlorite [NaOCl] and polyhexamethylene biguanide [PHMB]) could be used as a bath and pressure-differential dip to successfully suppress or eliminate *Salmonella*.[57]

Antibiotic Therapy

Sean M. Perry and Mark A. Mitchell

Historic recommendations for dosing and delivering (route of administration) antibiotics have been based on empirical suggestions derived from evidence gained through domestic mammal research or "positive results" derived from case reports. These historic limitations can be attributed to the lack of pharmacokinetic and pharmacodynamic studies specifically evaluating antibiotics in reptiles, although since the last publication of this text, some progress has been made.

ANTIBIOTIC SELECTION

Specific factors that should be considered when selecting an antibiotic for a case include the intrinsic antimicrobial spectrum of that drug (e.g., gram positive vs. gram negative, aerobic vs. anaerobic), acquired antimicrobial resistance, mechanism of action, tissue distribution, potential side effects, metabolic and excretory pathways, dose and volume required, and route and frequency of administration. The antibiotic with the narrowest spectrum of activity should be selected to treat the pathogen to limit collateral damage to the patient's microbiota.

An antibiotic should be administered after confirming the existence of an infection. Ideally, culture and sensitivity profile (or MIC testing) should be done to determine the preferred antibiotic. While pending microbiologic culture and sensitivity testing, the veterinarian must select an antibiotic based on gram stains, cytology, past experience, and best practices. Although limited in sensitivity, cytological examination of a lesion may be used to determine whether the microflora associated with a lesion is homogeneous or heterogeneous. If the bacteria appear homogeneous (all gram positive or all gram negative), then this information may be used to guide antibiotic selection. Most bacterial pathogens isolated from reptiles are gram negative, although gram-positive bacterial infections do occur. Of 141 bacterial cultures and sensitivity panels from clinical reptile cases that were evaluated by a large accredited laboratory, 28% were gram negative and 72% gram positive (Tang et al, Proc ExoticsCon, 2018, p 963).

INDISCRIMINANT ANTIBIOTIC USE IN HERPETOLOGICAL MEDICINE

In both human and veterinary medicine, our management of bacterial infections remains primitive. Currently, our process of isolating and treating a pathogen using an antibiotic suggests a specificity that does not exist. When a reptile, or any vertebrate, is given an antibiotic, the drug can have broad and impactful effects on the individual's microbiota and, more concerning, environmental and human health issues. *Salmonella*-positive green iguanas (*Iguana iguana*) treated with enrofloxacin were cleared of not only the enrofloxacin-sensitive *Salmonella* but *Pseudomonas aeruginosa* and *Citrobacter freundii* as well (Mitchell M, unpublished data). These latter two microbes were not isolated from cultures collected from the iguanas over 2 to 3 weeks posttreatment. Eventually, these organisms recolonized the gastrointestinal tract; the source was most likely the diet, which was always positive for these two organisms. However, a far greater concern with our current method of treating infections is that it creates a selection pressure that results in the emergence of antimicrobial resistance.[1] Until techniques are found to deliver a treatment that does not affect the commensal microbiota, the risk of creating antimicrobial-resistant organisms will exist, and continued efforts are required to minimize these risks.[2]

In herpetological medicine, it is not uncommon for veterinarians to have cases presented that have been treated empirically with antibiotics previously. Many veterinarians have the mentality that in exotic species, especially reptiles, enrofloxacin is a panacea. The routine use of advanced, broad spectrum antibiotics implies a low level of skill on the part of the clinician. It is our duty to develop appropriate antimicrobial stewardship. Widespread use of antibiotics has led to increases in the reports of antimicrobial-resistant pathogens. Veterinarians should limit antibiotic use to those cases in which their use is warranted. Antibiotic prescription should be limited to one of two reasons: (1) prevent infection (i.e., if an animal is immunocompromised, has severe trauma or wounds, or requires perioperative antibiotics) or (2) treatment of a documented bacterial infection.

MINIMIZING INDISCRIMINATE ANTIBIOTIC USE IN HERPETOLOGICAL MEDICINE

Not all animals that are ill have bacterial infections, and not all bacterial infections require treatment. Worsening of a disease state in critically ill animals does not always warrant escalation of antimicrobial treatments. Viral infections, immune-mediated conditions, and inflammatory conditions can cause signs that can often be attributed to bacterial infections. Early diagnostic testing rather than empirical antibiotic usage can help resolve if an animal needs antimicrobials. Even when bacterial infections are present, systemic antimicrobial therapy may not be optimal. Local therapy with biocidal or antimicrobial drugs may be equally or even more efficacious in some cases. Overall, there needs to be a reduction on the reliance of antimicrobials in veterinary medicine, not just in herpetological medicine. Unfortunately, despite clear efforts in this regard by some areas of the profession (especially small animal and agriculture), herpetological (and exotic pet) medicine is lagging behind. It behooves all of us to critically evaluate our prescribing practices and create appropriate antibiotic stewardship policies within our practices (Table 116.1). For further information on this specific topic we recommend reading the American College of Veterinary Internal Medicine consensus statement published in the *Journal of Veterinary Internal Medicine*.[2]

VetBooks.ir

TABLE 116.1 Zoological Medicine Service Antibiotic Policy From University of Georgia

Tier 1 drugs	Indications: 1. Infection prevention in severely compromised animals. 2. Intraoperative IO or IV administration to prevent infection (e.g., orthopedics). 3. First-line antimicrobial to treat infections, while awaiting culture and sensitivity or MIC results.	Trimethoprim, sulfonamides, or combinations Tetracyclines (e.g., oxytetracycline, doxycycline) Basic/potentiated penicillins (e.g., ampicillin, penicillin, amoxicillin/clavulanic acid) Metronidazole Basic macrolides and lincosamides (e.g., erythromycin, lincomycin, clindamycin) Aminoglycosides 1st- and 2nd-generation cephalosporins (incl intraop ceftiofur) 1st-generation quinolones (e.g., oxolinic acid, nalidixic acid)
Tier 2 drugs	Indications: 1. Only to be used if culture and sensitivity or MIC testing indicate tier 1 drugs are ineffective.	3rd-generation cephalosporins (ceftazidime, ceftiofur) Penicillinase-resistant penicillins (e.g., methicillin) Advanced penicillins (eg piperacillin, cerbenicillin, ticarcillin) Advanced macrolides (e.g., azithromycin, clarithromycin) 2nd-generation fluoroquinolones (e.g. enrofloxacin, orbifloxacin, ciprofloxacin, marbofloxacin) Florfenicol, Chloramphenicol
Tier 3 drugs	Indications: 1. Restricted or prohibited use antimicrobial agents for multidrug resistant infections. Generally, not to be used in veterinary medicine.	Glycopeptides (e.g., vancomycin) Carbapenems (e.g., imipenem) Oxazolidonones (e.g., linezolid) 4th generation and above cephalosporins (e.g., defepine) Ketolides (e.g., telithromycin) Lipopeptides (e.g., daptomycin) Ansamycins (e.g., geldanamycin) 3rd generation and above fluoroquinolones (e.g., levofloxacin)

ANTIBIOTIC DRUGS

Aminoglycosides

Aminoglycosides (Table 116.2) used in herpetological medicine include gentamicin, amikacin, kanamycin, neomycin, paromomycin, streptomycin, and tobramycin. These compounds irreversibly bind to one or more receptor protein of the 30S subunit of the bacterial ribosome, interfering with mRNA translation.[3–5] They are polycations that are minimally bound to protein and poorly absorbed from the gastrointestinal tract. Aminoglycosides are primarily excreted unchanged through the kidneys. This group of antibiotics has a narrow therapeutic index and should be used cautiously. The primary adverse effects associated with aminoglycosides in mammals are ototoxicity and nephrotoxicity. Aminoglycoside toxicity can vary with the specific drug, peak concentration, and hydration and renal status of the patient. Gentamicin is more nephrotoxic than amikacin.[3–5] Veterinarians should evaluate a reptile's renal function and hydration status before initiating treatment with an aminoglycoside. In reptiles, calcium, phosphorous, potassium, total solids, and nitrogenous waste (uric acid, urea, ammonia) concentrations can provide some insight into reptile renal function. An inverse calcium:phosphorous ratio is a strong indication of reduced renal function in lizards.

Aminoglycosides are considered standard of care for gram-negative sepsis and are generally indicated for gram-negative bacterial infections, including *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Pseudomonas* spp., *Proteus* spp., *Providencia* spp., *Salmonella* spp., and *Serratia* spp.[6] Aminoglycosides can be used in combination with penicillins to treat gram-positive infections. The MIC required to control gram-negative aerobes with aminoglycosides is dependent on the drug used, with gentamicin having lower MIC concentrations, 3 to 5 µm/mL, than amikacin, 5 to 10 µg/ml.[5] In general, up to three to five times the MIC may be needed to eradicate certain pathogens.[5] Aminoglycosides were one of the first antibiotics used to treat bacterial infections in reptiles. They were also the first class of antibiotics to have pharmacokinetic data that could be used to determine appropriate dosing intervals. Aminoglycosides should be considered a first-line antimicrobial drug choice.

Amikacin. The absorption, metabolism, and excretion of an antibiotic might be expected to differ when a reptile is maintained at different temperatures. However, no difference was reported in the absorption or elimination rates of amikacin in the gopher snakes *(Pituophis catenifer)* housed at different temperatures.[7] Snakes housed at the higher temperature did have an increased volume of distribution and body clearance compared with those housed at the cooler temperature. In addition, bacterial isolates were more susceptible to amikacin at higher temperatures.[6]

Johnson et al. performed a similar pharmacokinetic study with ball pythons (*Python regius*).[8] Whereas the drug half-lives were substantially higher than those reported in the gopher snakes, however, the dose used was also higher. The increased environmental temperature did not significantly affect the rate of elimination in these snakes. Drug bioavailability following intramuscular injection, which is rarely recorded in reptile pharmacokinetic studies, was substantially less (74%–77%) than that reported in mammals (>90%).[9]

The effect of environmental temperature on amikacin pharmacokinetics has also been evaluated in a chelonian species, the gopher tortoise (*Gopherus polyphemus*).[10] Clearance rates, mean residence times, and area under the curve were significantly different between the two treatment groups. The results of the study strongly suggested that environmental temperature could affect metabolic rate in this species, which in turn can affect drug pharmacokinetics.

Recently amikacin has been successfully delivered in snakes via an osmotic pump. Osmotic pumps were implanted in both corn snakes (*Pantherophis guttatus*) and a Taylor's cantil (*Agkistrodon bilineatus taylori*) to deliver amikacin as a constant rate infusion.[11,12] The results of the study suggested that the osmotic pump could be used for treating bacterial infections in snakes, because the pump delivered the drug at a predictable rate and plasma concentrations were found to reach

appropriate levels.[11] An osmotic pump has also been used in a clinical case to combat *Salmonella enterica houtenae* osteomyelitis in a Taylor's cantil. Progression of the osteomyelitis was controlled using amikacin (0.026 mg/kg/hour) via the subcutaneous osmotic pump for a total of 10 months. The pump was replaced every 4 weeks and no adverse effects were reported during the treatment period. Unfortunately, 5 months after therapy, the bony lesions progressed and abscesses were observed at the implant site. Euthanasia was elected for this animal.[12]

Gentamicin. Bush et al. was the first group to evaluate gentamicin in chelonians. The average biologic half-life for gentamicin was 32 hours ± 15 hours, with a range of 8 to 76 hours. The large variation in the half-lives can be attributed to the small sample size. Ultimately, the authors concluded that 10 mg/kg every 48 hours for less than 14 days was an appropriate dose (Bush, unpublished data).

Bush et al. were also the first to evaluate gentamicin in snakes, and the average biologic half-life of gentamicin was 82 hours.[13] The half-lives reported in chelonians and snakes were 10 to 40 times longer than those reported for mammalian species.[14] A second study was performed to evaluate serial doses of gentamicin over approximately 14 days. A stairstep increase in serum concentrations of gentamicin was recorded for all groups. The highest concentrations occurred in the groups receiving daily injections. The authors suggested that this might have occurred because the snakes could not excrete the drug in a timely manner. Although serum concentrations were not as high in the groups receiving the antibiotic every 72 hours, they did achieve therapeutic levels and are less likely to produce negative side effects.

Hilf et al. also evaluated gentamicin kinetics in two additional species of snakes, a Burmese python (*Python bivittatus*) and blood pythons (*Python curtus*).[15] The snakes received a single dose of gentamicin (2.5 mg/kg IM). On the basis of the results from the pilot study, and the authors' desire to achieve peak serum concentrations between 6 and 8 µg/mL, the blood pythons (n = 4) were given one of four dosing regimens: 2.5 mg/kg IM followed by 1.5 mg/kg after 72 hours, 2.5 mg/kg IM followed by 1.5 mg/kg after 96 hours, 3 mg/kg IM followed by 1.5 mg/kg after 72 hours, and 3 mg/kg IM followed by 1.5 mg/kg after 96 hours. Peak serum concentration was achieved within 10 hours; however, the biologic half-life varied between 32 and 110 hours. No apparent side effects were seen, although the author used blood uric acid levels to evaluate renal function. Uric acid is not a sensitive assay for renal function in reptiles, and GFR evaluation, renal biopsy, and histology would be more appropriate. Gentamicin accumulation was observed in these snakes, which suggests that multiple dosing could lead to negative side effects. To avoid these potential side effects, the authors suggested medicating pythons with a loading dose of 2.5 to 3 mg/kg and 1.5 mg/kg every 96 hours thereafter.

Raphael et al. also performed a study to determine the pharmacokinetics of gentamicin in red-eared sliders.[16] Differences in the pharmacokinetics of gentamicin between the turtles studied in the Raphael et al. and Bush et al.[13] papers may have been attributed to injection site or temperature variation. The turtles in Raphael et al. were housed at cooler temperatures than those in Bush et al. In addition, the red-eared sliders in Raphael et al. were given the injection in the musculature of the forelimb. This information was not provided by Bush et al., and injection site may have led to alterations in the disposition of gentamicin in these chelonians. On the basis of MIC values for susceptible species, the 6 mg/kg IM dose every 48 to 72 hours was considered appropriate for treatment of susceptible pathogens.

Beck et al. determined the pharmacokinetics for gentamicin in box turtles (*Terrapene carolina carolina*).[17] In addition, the authors also evaluated the role of injection site, forelimb versus hind limb, on the pharmacokinetics of the drug. No difference was seen in the plasma concentrations of gentamicin between the two treatment groups. Plasma concentrations remained above 2 µg/mL throughout the study, which should be adequate to achieve MIC for most pathogens, although it may be insufficient to achieve the levels suggested by Hoperich.[6] Because gentamicin is excreted via glomerular filtration, these findings were not unexpected. Evaluation of an antibiotic that is excreted via tubular secretion, such as a synthetic penicillin, may be more appropriate for evaluation of the role of the renal portal system in drug pharmacokinetics. Side effects associated with gentamicin have been well documented. The first report in a lizard was associated with the toxic effects on the basilar papilla of *Calotes versicolor.*[18] Gentamicin toxicity was also reported in two boid snakes that received 4.4 mg/kg (2 mg/lb) twice a day for 2 days, and then the same dose once a day for 5 additional days.[19] Both snakes had visceral gout develop, which was attributed to gentamicin-induced renal failure.

Many of the problems encountered with this class of antibiotics have been associated with the use of mammalian drug dosages. Montali et al. evaluated the pathological effects of giving a mammalian dose of gentamicin to two snakes.[20] In the study, two bull snakes (*Pituophis [melanoleucas] catenifer*) were given gentamicin at 5 mg/kg once every 72 hours, and another two bull snakes were given 5 mg/kg once a day for 14 days. Renal biopsy results from the second group of snakes revealed mild to moderate swelling in the proximal tubular cells. One snake from each of the two treatment groups was given an additional dose of 50 mg/kg once a day for 14 days. Again, swelling was noted in the proximal tubules; however, it advanced to tubular necrosis. Variability in the pharmacokinetics of aminoglycosides in reptiles suggests that veterinarians should be cautious and use lower doses when working with an untested species.

Jacobson et al. investigated the disposition kinetics of IM gentamicin and amikacin in juvenile American alligators (*Alligator mississippiensis*).[21] Gentamicin and amikacin were both rapidly absorbed in the alligators. The distribution of both compounds was biphasic. On the basis of MIC values for pathogenic microbes in crocodilians, such as *Aeromonas hydrophila,* 1.75 mg/kg gentamicin and 2.25 mg/kg amikacin were considered appropriate.[21]

Tobramyacin. A single case report of using tobramyacin in a reptile exists in the literature. One Kemp's ridley sea turtle (*Lepidocheyles kempii*) was treated with 5 mg/kg tobramycin (Tobramycin 40 mg/mL, Hospira Inc., Lake Forest, IL) IM every 3 days for 58 days. (Innis C, unpublished data).

β-Lactam Antibiotics

Penicillins. The primary action of the penicillins is against cell wall synthesis; however, this class of drug is susceptible to beta-lactamase. Variable amounts of the semisynthetic penicillins are bound to protein. Distribution of these drugs is greater via the parenteral route. The drugs are excreted primarily via tubular secretion and glomerular filtration. Semisynthetic penicillins cross the placenta in mammals but are not known to have teratogenic effects. Whether these drugs could affect embryos in reptiles is unknown.

There has been no pharmacokinetic investigations into the use of natural penicillins or aminopenicillins, with or without β-lactamase inhibitors. However, these drugs are often effective and are generally recommended as first-line antimicrobials. Of bacterial isolates from clinical reptile cases seen at the University of Georgia, all gram-positive isolates and 65% of gram-negative isolates were sensitive to ampicillin (Divers S, unpublished data).

Carbenicillin and piperacillin are semisynthetic penicillins with extended spectrum against gram-negative bacteria. These drugs were

originally found to have antipseudomonal activity; however, increased resistance is reported with increased usage. Lawrence et al. reported pseudomonal resistance to carbenicillin in multiple beta-lactamase-producing pseudomonal species in the early 1980s.[22] The semisynthetic penicillins also have some effect against anaerobes but are generally not recommended as a first-line antimicrobial, but rather when indicated by culture and sensitivity testing.

Studies evaluating the efficacy of the semisynthetic penicillins in reptiles are limited. Hilf et al. determined the pharmacokinetics of piperacillin in blood pythons. The half-life of piperacillin between the snakes used in the study was similar.[23] However, the distribution of the drug was variable after IM injection.

Lawrence et al. determined plasma concentrations of a single IM injection of carbenicillin in four different species of snakes.[22] Blood samples were collected on two different time schedules from the snake subjects, limiting the authors' ability to perform a pharmacokinetic study. Despite its limitations, this study demonstrated a C_{Max} ranging from 177 to 270 µg/mL was achieved 1 hour after injection. Therapeutic concentrations, 50 to 60 µg/mL, were maintained for 12 hours in three snakes. Although a full pharmacokinetic study was not performed, Lawrence et al. recommended 400 mg/kg IM every 24 hours would provide therapeutic levels of carbenicillin for snakes.[22] Holtz et al. reported that carbenicillin at 200 mg/kg IM every 24 hours was appropriate for carpet pythons (*Morelia spilota*).[24]

Lawrence et al. also evaluated the disposition kinetics of carbenicillin in two species of chelonians, *Testudo graeca* and *Testudo hermanni*.[25] A secondary drug peak was reported, which may represent secondary resorption of excreted drug across the bladder wall. Although limited by the numbers of tortoises used in this study, the authors did report that tortoises that evacuated urine during the study did have lower carbenicillin concentrations than those that did not micturate, suggesting that the bladder could serve in some capacity in the reabsorption of this antibiotic. The authors concluded that 400 mg/kg every 48 hours is likely sufficient to provide therapeutic concentrations in these tortoises. Manire et al. evaluated ticarcillin in three captive loggerhead sea turtles and concluded that 50 mg/kg every 24 hours or 100 mg/kg every 48 hours may be appropriate, but that liver enzymes should be monitored.[25a]

Cephalosporins

Cephalosporins were developed from a natural product of *Cephalosporium acreminium*. These antibacterials (Table 116.3) are related structurally to benzyl-penicillin and have a β-lactam ring. They act by inhibiting cell wall synthesis by preventing cross-linking of peptidoglycans. Cephalosporins are divided into five different generations. Unfortunately, there has been little research into the first-line, first- and second-generation cephalosporins, although they are frequently used intraoperatively.

In reptile medicine, third-generation cephalosporins have been evaluated most frequently, but their use should be restricted to infections resistant to more basic β-lactam drugs. Data from the University of Georgia demonstrates only marginally better sensitivity of third-generation (74%) compared with first- and second-generation drugs (57%) for gram-negative isolates, and no difference (75%) regarding gram-positive isolates (Tang et al, Proc ExoticsCon, 2018, p 963). Examples of third-generation cephalsporins used in reptile medicine include ceftiofur, ceftazidime, and cefoperazone.[26] Overall, third-generation cephalosporins have decreased gram-positive activity but increased gram-negative activity. Gram-negative bacteria typically found to be sensitive to these antibiotics include *Escherichia coli*, *Klebsiella* spp., *Pseudomonas* spp., *Proteus* spp., *Pasteurella* spp., *Haemophilus* spp., *Actinobacillus* spp., and *Salmonella* spp. Cephalosporins may be effective against some anaerobes, such as *Clostridium* spp. and *Fusobacterium* spp., but may be limited against others, such as *Bacteroides* spp.[26]

Ceftazidime. Ceftazidime is widely, and perhaps inappropriately, prescribed to numerous species of reptiles because it is broad spectrum, has a low-administration volume (when diluted to 100 mg/mL), and a prolonged dosing interval of 48 to 72 hours. However, clinicians should use caution in using this drug as a first-line antimicrobial to avoid creating resistant organisms and because dosing with ceftazidime has not been evaluated in boids, lizards, tortoises, or freshwater turtles. Lawrence et al. were the first to evaluate the effects of a ceftazidime in eight different snakes, representing five different species, maintained at 30°C.[27] Ceftazidime was selected because of its enhanced activity against gram-negative microbes. This compound also has excellent spectrum against *Pseudomonas aeruginosa*, although given the increased resistance with the continued use of this drug in veterinary medicine, culture and sensitivity testing is important. Peak plasma concentrations for ceftazidime were variable (26–70 µg/mL) and occurred between 1 and 8 hours. The high degree of variability in peak plasma drug levels (26–70 µg/mL between 1 and 8 hours) may have been associated with species differences but could not be evaluated further because of a limited sample size. The half-life of the drug was 24 hours, which is almost 12 times longer than that reported in humans.[28,29] No negative side effects were reported in any of the snakes. The dose administered might be expected to vary with a different environmental temperature. Studies have also been done to determine the pharmacokinetics of ceftazidime in loggerhead sea turtles (*Caretta caretta*), and there appears to be little difference in the plasma concentrations and half-lives following IV or IM routes.[29] In cold-stunned Kemp's ridley sea turtles (*Lepidochelys kempii*) the maximum concentration (C_{max}) was similar to that found in loggerheads, but the half-life in Kemp's ridley turtles was more than double that of loggerheads.[29,30] Further research is needed to determine appropriate dosing recommendations for more species.

Cefoperazone. Cefoperazone, another third-generation cephalosporin, has also been evaluated in reptiles. Although cephalosporins within the same generation typically have similar mechanisms of action, activity, and distribution within vertebrate hosts, some differences do exist. For instance, cefoperazome is more liposoluble than ceftazidime, which can increase its distribution to certain tissues. In addition, cefoperazome is excreted primarily via hepatic pathways, unlike most other cephalosporins, which are excreted via glomerular filtration or tubular secretion. Therefore excretion of this drug may be delayed or negative side effects might be expected in vertebrates with hepatic dysfunction. This may also make it a more appropriate antibiotic than ceftazidime when treating an animal with renal disease.

Cefoperazone pharmacokinetics have been evaluated in a single snake (*Hydrodynastes gigas*) and lizard (*Tupinambis teguixin*) (Speroni, unpublished data). Peak concentrations of cefoperazone were achieved much faster in the tegu (4 hours) than the false water cobra (8 hours). In addition, therapeutic concentrations remained higher in the snake for a longer period of time (96 hours) than in the lizard (<24 hours). From these results, the authors concluded that the snake should be given a dose of 100 mg/kg every 96 hours, and the lizard should be given a dose of 125 mg/kg every 24 hours. However, in the absence of additional animals, these recommendations should be interpreted with caution. The differences found in these animals could have been associated with individual and not species variations because of the limited sample size (n = 1); however, the stark differences between the lizard and snake for this antibiotic do warrant further study with larger numbers of study subjects.

Ceftiofur

Ceftiofur sodium. Pharmacokinetics have been evaluated in green iguanas after IM and SC injections. The mean maximum plasma concentration was significantly higher in iguanas receiving the antibiotic IM versus SC. There was no difference in the terminal half-life or area under the curve by route of administration. Ceftiour sodium maintained concentrations ≥2 µg/mL for more than 24 hours after both IM and SC injections. These results suggested that ceftiour sodium administered at 5 mg/kg IM or SC every 24 hours would be effective against bacteria susceptible at >2 µg/mL.[31]

Ceftiofur crystalline-free acid. Ceftiour is available as a long-acting, large-animal formulation: ceftiour crystalline free acid (CCFA) (Excede; Zoetis, Parsippany, NJ). Adkesson et al. determined the pharmacokinetics of CCFA in ball pythons and confirmed that at 15 mg/kg, the drug is well tolerated and could be effective for bacteria with MIC values of ≤0.1 µg/mL at a dosing interval of at least 5 days.[32] The authors noted that if the bacteria's MIC is ≥0.5 µg/mL, more frequent dosing or a higher dose of CCFA may be required.[32]

CCFA has only been evaluated in a single species of lizard, the bearded dragons (*Pogona vitticeps*).[33] An initial pilot study determined a preferred dose of 30 mg/kg. MIC concentrations ≥1 µg/mL were achieved within 4 hours and remained >1 µg/mL for 12 days via both IM and SC injections. The authors did note that there was less variability with the SC route, which was recommended because of ease of adminsitration.[33]

Cefovecin. Cefovecin is a relatively new third-generation cephalosporin that has been used extensively in small animal practice due to its long half-life and need for a single injection. However, the first-line use of this drug is discouraged.[34] Pharmacokinetics for this antibiotic have been determined in Hermann's tortoises and green iguanas after SC injection.[35,36] In the Hermann's tortoise, cefovecin at 8 mg/kg was rapidly absorbed, reaching maximum plasma concentrations between 35 minutes and 2 hours postinjection. The C_{max} of cefovecin was considerably lower than that reported in dogs and cats. Cefovecin was detectable at measurable concentrations for 3 days in some of the tortoises but below the level of quantification for all of the tortoises after 1 week. Compared with small animals, the $T_{1/2\lambda}$ mean was much shorter and was attributed to poor protein binding in the tortoises (41.3%–47.5%), compared with dogs and cats (99.5%–99.8%). The authors concluded that administration every 14 days, as with cats and dogs, would not be suitable for Hermann's tortoises.[35]

Green iguanas given a single dose of cefovecin 10 mg/kg SC were found to rapidly absorb the drug, but again, the authors concluded that the 14-day dosing interval used for dogs and cats was not suitable for iguanas. Instead, the authors suggested a dosing interval of 12 hours to 2 days would be more appropriate.[36]

Cefquinome. Cefquinome is a fourth-generation cephalosporin for use in veterinary medicine. Compared with other cephalosporins, cefquinome has a quaternary ammonium side chain that increases penicillin- binding proteins and penetration into the periplasmatic space of gram-negative bacilli. It has a high antibacterial activity against most gram-positive and gram-negative bacteria, including *Streptococcus spp.*, *Actinobacillus spp.,* Pasturellaceae, Enterobacteriaceae, and *Staphlococcus aureus.* In other species, cefquinome has good absorption, high bioavailability, and is eliminated by the renal system. See Table 116.3. for dosing and pharmokinectic data for cefquinome. This cephalosporin should be reserved for resistant infections following culture and sensitivity profiles.[37]

Carbapenems and Glycopeptides. The carbapenems and glycopeptides typically used in veterinary medicine include imipenem, meropenem, and vancomycin. However, the use of these antibiotics should be restricted to limit the likelihood of developing multidrug-resistant infections that can lead to issues in humans. Therefore, these drugs cannot be recommended for reptiles at this time.[2,3]

Tetracyclines. The tetracyclines represent one of the oldest classes of antibiotics available in human or veterinary medicine and a first-line drug choice (Table 116.4). Tetracyclines available to the clinician include doxycycline, chlortetracycline, minocycline, oxytetracycline, and tetracycline; however, limited, controlled studies exist that evaluate their specific use in reptile medicine. Tetracycline was originally isolated from *Streptomyces aureofaciens.* Tetracyclines are bacteriostatic and act by inhibiting protein synthesis by reversibly binding to the 30S ribosome. At high doses, these compounds can also affect eukaryotic cells. Although these compounds are generally reserved for aerobic bacteria, they have been found (in vitro) to be effective against anaerobes isolated from reptiles. Stewart found that 18 anaerobic isolates, representing 95% of the anaerobes isolated from clinical samples in snakes, were sensitive to tetracyclines.[39]

Tetracyclines are variably bound to protein and have good distribution to most tissues in the body. Tetracyclines are not metabolized but are excreted primarily through the gastrointestinal tract or kidneys. These compounds can be chelated by fecal material, thus reducing their effectiveness. In mammals, food can also diminish the absorption by chelating tetracyclines.[9] Because these compounds are excreted via glomerular filtration, reptiles with renal dysfunction may accumulate the compound over time. Although these compounds are generally broad spectrum, widespread use of these compounds in human and veterinary medicine has led to increased resistance. Of 34 gram-negative and 21 gram-positive isolates tested at a large accredited laboratory, 79% and 67% respectively were sensitive to tetracycline (Tang et al, Proc ExoticsCon, 2018, p 963). These compounds, especially doxycycline, have excellent spectrum against *Chlamydia* spp., *Mycoplasma* spp., and rickettsial organisms.[9,29]

No peer-reviewed studies of doxycycline exist in reptiles; however, one report determined a doxycycline therapeutic regimen to treat sensitive microbes in Hermann's tortoises. In the study, the authors isolated *Staphylococcus* sp. and *Klebsiella* sp. with MIC values of 8.9 µg/mL and 5.6 µg/mL, respectively. Other microbes, including *Salmonella* and *Pseudomonas aeruginosa,* were found to be resistant. The finding of resistance in these microbes should not be considered unusual, because they are highly adapted to the tetracyclines. The authors determined that a loading dose of 50 mg/kg IM once, followed by 25 mg/kg IM every 72 hours, was appropriate for managing sensitive pathogens in this species of chelonian (Sporle, unpublished data).

The emergence of mycoplasmosis in captive crocodilians has led to research to determine the pharmacokinetics of oxytetracycline in American alligators.[39a] The authors concluded that 10 mg/kg every 5 days should maintain appropriate plasma concentrations for susceptible organisms. Oxytetracyclines are also routinely used to manage infections in loggerhead and Kemp's ridley sea turtles. Harms et al. measured the pharmacokinetics of oxytetracycline in loggerhead sea turtles. Based on their data from 25 mg/kg pharmacokinetics and simulations they recommended IM doses of 41 mg/kg as a loading dose and 21 mg/kg every 72 hours to reach a plasma concentration of 1 µg/mL or 82 mg/kg as a loading dose and 42 mg/kg every 72 hours thereafter to reach a plasma concentration 2 µg/mL.[40]

Chloramphenicol. Chloramphenicol (Table 116.5) is a broad-spectrum bacteriostatic to bacteriocidal drug (depending on concentration and bacterial susceptibility) that was originally isolated from *Streptomyces venezuelae.*[9] This antibiotic has been found to have activity against

VetBooks.ir

aerobic and anaerobic gram-positive and gram-negative bacteria. Stewart found that 18 anaerobic isolates from reptiles, representing 95% of the anaerobes isolated from clinical samples, were sensitive to chloramphenicol.[38] In addition, 100% of gram-positive and 93% of gram-negative isolates evaluated at the University of Georgia were sensitive to chloramphenicol (Tang et al, Proc ExoticsCon, 2018, p 963).

Chloramphenicol inhibits protein synthesis by binding to the 50S ribosomal subunit of the bacteria and possibly mammalian cells. The binding to mammalian cells is the cause of the aplastic anemia reported in humans. Chloramphenicol is widely distributed throughout the tissues in mammals. The drug is primarily excreted via the liver, and a small quantity is excreted unchanged via the kidneys. Clients should be made aware of the potential side effects associated with handling chloramphenicol, and humans with hepatic disease and nonregenerative anemias should never handle the drug.[41]

Chloramphenicol, in combination with ampicillin, has been used to treat *Salmonella* spp. in both lizards and chelonians.[42] Although only 87% of the reptiles were considered *Salmonella*-free after a 5-day course of the two antibiotics, the remaining animals were "cleared" of *Salmonella* after an additional 5 days of treatment. However, one should be cautious with the interpretation of these results, because these animals could have become latent and not actively shed *Salmonella*, or the microbes were shed in such low numbers they were below the sensitivity threshold of the assay. Antibiotics should not be used in an attempt to control enteric *Salmonella* in reptiles.

Pharmacokinetic studies for chloramphenicol in reptiles is still limited to snakes. Bush determined the plasma concentrations of chloramphenicol sodium succinate in gopher snakes after a single 40 mg/kg SC dose. An oral dose of chloramphenicol palmitate (12 mg/kg) only achieved peak plasma levels of 10 µg/mL at approximately 12 hours and was not considered sufficient to provide therapeutic levels against reptilian pathogens. However, the oral dose was considerably less than that given parenterally (Bush, unpublished data).

Clark et al. determined the plasma concentrations of chloramphenicol in 16 different species of snakes.[43] Two different dosing regimens were evaluated, including 25 and 50 mg/kg SC. The 25 mg/kg SC dose was found to produce low plasma concentrations and was discontinued. The plasma concentrations from the 50 mg/kg dose were found to be highly variable between species. Differences in plasma concentrations were also observed between different injectable preparations, with Tevcocin (International Multifoods, Minneapolis, MN) maintaining higher concentrations than Mychel-Vet (Rachelle Laboratories, Long Beach, CA). This difference was attributed to an edematous reaction at the site of injection, which was more common with the Mychel-Vet preparation. One Midland water snake (*Nerodia sipedon*) developed anemia after receiving 6 injections of chloramphenicol every 72 hours; however, no further investigation, such as rib marrow evaluation, was pursued to determine whether the chloramphenicol had a direct effect on blood cell production. Because of the large variation in plasma concentration between species, the authors concluded that chloramphenicol could be given at 50 mg/kg SC every 12 to 72 hours depending on the species. The dosing frequency should also be based on the environmental temperature because it could affect drug metabolism.[43]

Florfenicol. Florfenicol, a fluorinated analog of thiamphenicol, is structurally similar to chloramphenicol, although it lacks the paranitro group that is associated with aplastic anemia in humans.[41] This compound is approved for cattle, poultry, and aquaculture and has also been used to treat other domestic and nontraditional species. Florfenicol is a broad-spectrum bacteriocidal antibiotic that acts against the 50S ribosome of bacteria. In cattle, the drug is moderately bioavailable (79%) after intramuscular injection.[9,41] The drug has good distribution into various tissues, including the central nervous system. Relatively few adverse effects have been reported in mammals and are primarily associated with the gastrointestinal tract. However, these side effects can be significant in horses, and the drug is not generally recommended for equids. Similar considerations may need to be taken into account for reptiles that use hindgut fermentation.

A single published study has been performed to determine the pharmacokinetics of florfenicol in a reptile.[44] In loggerhead sea turtles the plasma half-lives for both the IV and IM routes were short (2–7.8 hours), and florfenicol could not be measured in any of the turtles 12 hours postinjection. The plasma concentrations in both groups were lower than the acceptable MIC for most pathogens. From this study, the authors concluded that 30 mg/kg florfenicol either IM or IV in loggerhead sea turtles was insufficient to manage bacterial infections.[44]

Macrolides

Azithromycin. Azithromycin is an azalide, a subclass of macrolide antibiotics (Table 116.6) that are bacteriostatic and inhibit protein synthesis by binding to the 50S ribosome.[9,41,45] It concentrates in phagocytes and fibroblasts, which may increase its distribution to inflamed tissues. In human tissues, azithromycin is widely distributed but does not pass the blood-brain barrier. Its antimicrobial activity is pH-dependent and is reduced with decreasing pH. In humans, azithromycin is eliminated and excreted unchanged via the biliary and urinary tracts. Renal impairment has a minor effect on elimination. Drug-to-drug interactions are minor and not sufficient to warrant altered dosing. Its antimicrobial spectrum includes many gram-positive and gram-negative aerobes, including *Staphylococcus* spp., *Streptococcus* spp., *Haemophilus* spp., *Bordetella* spp., *Neisseria* spp., and *Moraxella* spp.; anaerobes, including *Peptostreptococcus* spp. and *Prevotella bivia;* and other notable bacteria, including *Legionella pneumophila, Chlamydia* spp., and *Mycoplasma* spp. Hepatotoxicity has been reported in humans, and azithromycin could cause reversible nonregenerative anemia in reptiles. It can contribute to dysbiosis and overgrowth of enteropathogens. Oral preparations should not be given concurrently with aluminum-containing or magnesium-containing antacids or phosphate binders.[45] Azithromycin is available as an oral suspension, tablet, or an intravenous injection and, as a dihydrate, is soluble in water.[45,46] In a single-dose pharmacokinetic study in ball pythons, the authors determined that azithromycin is distributed and excreted similar to humans.[47] The dose used in the study, 10 mg/kg PO, can be given at different frequencies based on the location of the infection. For skin infections, dosing should occur every 3 days, whereas for respiratory and liver/kidney infections, dosing should be every 5 or 7 days, respectively.[47]

Clarithromycin. Clarithromycin is a semisynthetic, bacteriostatic, macrolide antibiotic that inhibits protein synthesis by binding to the 50S ribosome.[48] It is soluble in acetone, slightly soluble in methanol, ethanol, and acetonitrile, and practically insoluble in water. It is available as immediate-release tablets, extended-release tablets, and granules for oral suspension. It is rapidly absorbed from the gastrointestinal tract in humans, with approximately 50% bioavailability, and it is metabolized by the liver into 14-hydroxy clarithromycin, which is also microbiologically active. Clarithromycin and the 14-hydroxy metabolite distribute readily into human tissues and fluids; intracellular concentrations were greater than serum concentrations, but cerebrospinal fluid was not tested.[48] Both clarithromycin and the 14-hydroxy metabolite are excreted primarily in urine. The antimicrobial spectrum of this antibiotic includes a variety of gram-positive and gram-negative bacteria as well as *Mycobacterium avium* complex bacteria, *Mycoplasma* spp., and *Chlamydia* spp. Adverse effects include hepatotoxicity. Hepatic enzymes should be tested before and monitored during therapy. This antibiotic should not be used in gravid or pregnant animals.

VetBooks.ir

Clarithromycin may be used to treat severe cases of mycoplasmosis in tortoises.[49,50] A recent long-term study showed that clarithromycin can be safe and effective (at resolving clinical signs but not eliminating the organism) in desert tortoises (*Gopherus agassizii*) when 15 mg/kg clarithromycin oral suspension (50 mg/mL Biaxin oral suspension, Abbott Labs, Abbott Park, IL) is administered by gavage every 3.5 days (every 84 hours).[50] The same study also showed that per rectum administration did not achieve target plasma levels.[50] Three Kemp's ridley sea turtles were treated with 15 to 20 mg/kg clarithromycin (Clarithromycin 250 mg tablets, Mylan Pharmaceuticals, Morgantown, WV) PO q72 hr (duration 59–62 days) as part of a treatment regimen. However, plasma levels were low to undetectable suggesting that clarithromycin may not be effective in this species (Innis, unpublished data).

Tulathromycin. Tulathromycin is a long-acting macrolide that has demonstrated efficacy against a variety of respiratory pathogens. A pharmacokinetic study was performed to evaluate the clinical applicability of tulathromycin in desert tortoises after a single IM dose of 5 mg/kg (resulted in a C_{max} of 36.2 ± 29.7 µg/mL and a long elimination half-life of 77.1 h).[51] This study represents a preliminary step in evaluating the utility of tulathromycin in chelonians and demonstrates that population modeling offers advantages for estimating pharmacokinetic parameters when sparse sampling occurs, and there is substantial variability in the data.

Lincosamides

Clindamycin. Clindamycin is a lincosamide (see Table 116.5) that is used to treat infections caused by gram-positive aerobic and anaerobic bacteria in multiple species.[41] One study determined the pharmacokinetics of this antibiotic in loggerhead sea turtles after a single IV, IM, and PO dose. Clearance was rapid and variable with IV dosing, and plasma concentrations persisted above 0.5 µg/mL for only 4 hours. Intramuscular administration revealed inconsistent absorption with a 1.0-hour median half-life and plasma concentrations above 0.5 µg/mL for <4 hours.[52] Oral clindamycin produced low concentrations that were insufficient to calculate pharmacokinetic values. The authors believed this could be attributed to the oral administration technique (in squid). The results of this study indicate that because of rapid clearance, clindamycin administration at 10 mg/kg q 24 hours did not achieve plasma concentrations needed for effective therapy in loggerhead sea turtles. More research is needed to determine whether higher doses and more frequent administration should be considered.[52]

Sulfonamides. The potentiated sulfas (e.g., trimethoprim sulfadimethoxine) are broad-spectrum antibiotics that are routinely used to treat bacterial and protozoal pathogens in reptiles. Sulfa drugs are generally bacteriostatic; however, the synergism with trimethoprim creates a bactericidal compound. These compounds affect folic acid synthesis. Oral doses are well absorbed in monogastric mammals. This compound has widespread tissue distribution, including the CNS when the meninges are inflamed. Potentiated sulfas are metabolized by the liver and excreted by the kidneys via both glomerular filtration and tubular secretion.[9,53] The primary adverse effects associated with this drug are attributed to hypersensitivity and the potential for crystallization in the urine. These compounds are generally delivered via an oral suspension, although compounding pharmacies can create parenteral forms. Of 141 clinical reptile cultures evaluated at the University of Georgia, 100% of gram-positive and 91% of gram-negative isolates were sensitive to trimethoprim-sulfas (Tang et al, Proc ExoticsCon, 2018, p 963), making these drugs a first-line antibacterial choice.

To date, there have been no pharmacokinetic studies done to evaluate these antibiotics in reptiles. However, Vree and Vree have determined that red-eared sliders can acetylate sulphamethoxazole.[54] Current dosing recommendations are varied, including 15 to 25 mg/kg every 24 hours, 20 to 30 mg/kg every 24 to 48 hours, and 30 mg/kg once a day for 2 days then 30 mg/kg every 48 hours. One should remember that these doses are anecdotal and to consider the general health status (e.g., hydration status) of the patient before selecting a dose. Given the in vitro efficacy against clinical reptile isolates, there is an obvious need for future pharmacokinetic research.

Fluoroquinolones. Fluoroquinolones (Table 116.7) are synthetic antibacterial agents derived from the 4-quinolone molecule that was first synthesized in the 1960s. Fluoroquinolones specifically inhibit topoisomerase II (DNA gyrase) that controls supercoiling of bacterial DNA. This is the major action of fluoroquinolones in gram-negative bacteria. This disruption of DNA gyrase results in rapid cell death. Their reduced effectiveness against gram-positives is poorly understood; however, it is thought to target topoisomerase IV. They are inactive against obligate anaerobic bacteria. The bactericidal action of fluoroquinolones is fast and concentration dependent. Fluoroquinolones are rapidly absorbed after oral administration in monogastric animals, although administration with food may delay the time to peak plasma concentration. Administration with compounds that contain metal ions will adversely affect plasma fluoroquinolone concentrations. Low protein binding, low ionization, and high lipid solubility result in large volumes of distribution and good penetration into CSF, bronchial secretions, bone, and cartilage. In mammals, concentrations achieved in respiratory and genitourinary tract secretions are higher than plasma concentrations. The major metabolite of enrofloxacin is ciprofloxacin, but the amount of ciprofloxacin produced varies with taxa. Depending on the drug, elimination may be renal, hepatic, or both. For example, enrofloxacin undergoes renal elimination, whereas difloxacin is fecal and marbofloxacin is excreted in both urine and feces. Fluoroquinolones, like enrofloxacin, can achieve a high concentration in the urine, because the kidneys are the primary route of excretion. Urinary drug concentrations are often in excess of MIC values for susceptible pathogens. Because the fluoroquinolones have low solubility in water, they crystallize in acidic urine.[55–57] Crystalluria could be a problem in carnivorous animals fed a high-protein diet. The adverse gastrointestinal effects associated with the fluoroquinolones include nausea, vomiting, and abdominal cramping.[55–57] The descriptions of adverse effects associated with the CNS have been documented in human patients.[57]

Enrofloxacin. Enrofloxacin has been largely abused in the treatment of bacterial infections in reptiles because it is active against most of the gram-positive and gram-negative bacteria that affect these species. Fluoroquinolones should not be considered first-line antimicrobials. At the University of Georgia, sensitivity to enrofloxacin was documented at 89% for gram-negatives and 38% for gram-positives (Tang et al, Proc ExoticsCon, 2018, p 963).

Enrofloxacin administered at a dose of 10 mg/kg IM or 5 mg/kg PO in savannah monitors (*Varanus exanthematicus*) resulted in minimal conversion to ciprofloxacin. The peak serum concentrations recorded in the monitor lizard are adequate to treat susceptible bacteria (Hungerford, unpublished data). Maxwell and Jacobson determined the pharmacokinetics of single-dose PO and IM enrofloxacin in green iguanas. A high degree of variability was found in the plasma concentrations in the iguanas receiving the oral dose, leading the authors to suggest the parenteral route for critical cases. Because ciprofloxacin was not readily detected, the authors suggested that it is not created in appreciable amounts from the metabolism of enrofloxacin in the green iguana (Maxwell, unpublished data).

Pharmacokinetic studies for fluoroquinolones in snakes are scarce. Young et al. were the first to determine the disposition of enrofloxacin in a snake.[58] Burmese pythons given a single dose of enrofloxacin resulted

BOX 116.1 Pharmacokinetically Derived Drug Doses and the Clinical Application of Minimum Inhibitory Concentration (MIC)

Patient Drug Dose (PDD)

1. Obtain cultured bacteria MIC for specific antibacterial medication
2. The host's MIC breakpoint
3. Drug volume of distribution (V_d) in species being treated*
4. Therapeutic factor†
5. Target tissue drug concentration = MIC × TF (therapeutic factor)
6. Patient drug dose = PDD × V_d × % bioavailability (unless given IV)

*Known V_d for some reptiles is presented in Tables 116.2–116.7. V_d is limited due to the number of drugs and reptile species numbers. Health status may alter true V_d.

†Therapeutic factor is often between 4 to 10; systemic infections: peak plasma levels 2 to 4x MIC (µg/mL); urinary tract (bladder levels): 10× MIC (µg/mL); biofilms 1000× to 1500× MIC (µg/mL).

Adapted from Visser M, Oster SC. The educated guess: determining drug doses in exotic animals using evidence-based medicine. *Vet Clin North Am Exotic Animal Practice*. 2018;21:183–194.

FIG 116.1 Burmese python (*Python bivittatus*) that received repeated injections of enrofloxacin (2.5%) every 3 days. Note the cutaneous necrotic lesions (arrows) at the injection sites. (Courtesy of Stephen J. Divers.)

in a significant conversion to ciprofloxacin; however, the half-life of ciprofloxacin could not be determined. The multiple-dose study revealed that the plasma half-life for ciprofloxacin might be longer than enrofloxacin as a result of the regular conversion of enrofloxacin to ciprofloxacin.

Recently pharmacokinetic parameters for 10 mg/kg enrofloxacin were investigated in seven urutu pit vipers (*Bothrops alternatus*).[59] The drug was slowly absorbed and had a long half-life during the terminal elimination phase, suggesting slow elimination and/or slow absorption in urutu pit vipers.[59]

The pharmacokinetics of enrofloxacin have been evaluated in several species of tortoises. Sporle et al. evaluated the drug in Hermann's tortoises. A dose of 10 mg/kg IM every 24 hours was sufficient to control susceptible bacterial pathogens (Sporle, unpublished data). Prezant et al. evaluated the drug in gopher tortoises (*Gopherus polyphemus*) at a lower dose, 5 mg/kg IM, and found it could be given every 24 to 48 hours to achieve MIC levels for common pathogens.[61] The terminal half-life for enrofloxacin in the gopher tortoise (23.1 hours) was significantly longer than other mammals, birds, and reptiles. Raphael et al. evaluated a similar dose of 5 mg/kg IM in Indian star tortoises (*Geochelone elegans*).[62] In the star tortoises, peak plasma concentrations were approximately 3.6 µg/mL, and the plasma half-life was 5.1 hours. Ciprofloxacin was identified after injection, suggesting that these tortoises can convert enrofloxacin to ciprofloxacin. Enrofloxacin pharmacokinetic studies have also been done with aquatic chelonians. In a study using red-eared sliders, both intramuscular (5 mg/kg) and oral (10 mg/kg) doses of enrofloxacin were evaluated.[63] Ciprofloxacin was measured in the turtles, confirming conversion to this metabolite. No negative side effects were detected in these turtles.

Intracoelomic administration of enrofloxacin was recently evaluated in yellow-bellied slider turtles (*Trachemys scripta scripta*) using a dose of 10 mg/kg and a 10 mg/mL solution.[64] Using the intracoelomic route, the authors were able to obtain therapeutic concentrations with a C_{max} of 10.3 µg/mL. Based on the data presented, 10 mg/kg every 6 days was recommended. The only adverse effects noted were that the animals demonstrated rapid, uncoordinated movements for several seconds postinjection suggestive of pain or discomfort; however, these reactions quickly subsided. Injection site histopathology was not performed in this study.[64] Intracoelomic administration of enrofloxacin has also recently been investigated in Herman's tortoises.[65] Plasma concentrations of enrofloxacin were detectable in all subjects for up to 240 hours, whereas ciprofloxacin was detectable in all subjects for up to 120 hours.[65]

The emergence of mycoplasmosis in alligators led Helmick et al. to evaluate the pharmacokinetics of 5 mg/kg (oral and IV) enrofloxacin in American alligators.[67] The peak plasma concentration of enrofloxacin (6 µg/mL) was much higher than the MIC (1 µg/mL) determined for the *Mycoplasma lacerti* isolated from the alligators. Additionally, the pharmacokinetics of enrofloxacin have been evaluated in the saltwater crocodile (*Crocodylus porosus*) at 5 mg/kg intravenously, intramuscularly, and orally.[68]

Although adverse effects have been associated with enrofloxacin in mammals, they are rare in reptiles. The most common side effects associated with this antibiotic are pain, inflammation, and necrosis at the injection site (Fig. 116.1). Affected reptiles may withdraw the limb where an injection is given, attempt to escape, or experience skin discoloration or twitching at the site of injection. One report of a more severe reaction was recorded in a Galapagos tortoise (*Chelonoidis nigra*). The tortoise was empirically treated with 1000 mg of enrofloxacin (Baytril, 10% solution, Bayer AG, Leverkusen, Germany) for a suspected pneumonia. The tortoise became hyperexcitable, uncoordinated, and had a profuse diarrhea develop approximately 1 hour after injection. A second, lower dose (500 mg, 5% solution) was given approximately 48 hours later. The tortoise again had a negative reaction postinjection. Because of the similarity in side effects recorded after the enrofloxacin injections, the authors concluded that the tortoise had a hypersensitivity reaction to the enrofloxacin. The adverse effects associated with this case may have been a direct hypersensitivity to the enrofloxacin or could have been the result of a reaction to the carrier associated with the antibiotic (Casares, unpublished data). The authors have used the 2.27% small animal injectable in a number of tortoises, including giant tortoises, without negative side effects. However, the manufacturers do not recommend more than a single IM injection, which should be followed by oral therapy. In addition, when dealing with large animals, the volume should not exceed 20 mL in any site.[69] Other adverse effects such as vomiting, regurgitation, and salivation have been observed in red-footed tortoises (*Chelonoidis carbonaria*) and yellow-footed tortoises (*Chelonoidis denticulata*) and may be seen in other reptiles after intramuscular or subcutaneous injections (Stahl S, unpublished data).

Marbofloxacin. Marbofloxacin is a synthetic, broad-spectrum, bactericidal fluoroquinolone approved by the FDA for skin and soft

VetBooks.ir

tissue infections in dogs and cats and for urinary tract infections in dogs.[70] It is available in the United States as an oral tablet and in Europe as both a tablet and injectable. Marbofloxacin is soluble in water, but its solubility decreases in alkaline conditions. This fluoroquinolone is rapidly and almost completely absorbed from the gastrointestinal tract after oral administration in fasted dogs and cats, with a bioavailability in dogs of 94%.[70] In dogs, a small percentage (10%–15%) is metabolized by the liver.[70] Approximately 40% of the oral dose is excreted unchanged in the urine of dogs, and 70% of the drug (85%) and its metabolites (15%) are excreted in the urine of cats.[70] The remainder is eliminated in feces via biliary excretion. Marbofloxacin is bactericidal against a broad range of gram-negative and gram-positive organisms. Marbofloxacin, like other quinolones, is contraindicated in immature animals because it can cause articular chondropathy, and it should be avoided in animals with known central nervous system disorders. Marbofloxacin pharmacokinetic studies have been performed in ball pythons, loggerhead sea turtles, red-eared sliders, and freshwater crocodiles (*Crocodylus siamensis*), and its metabolites have been studied in ball pythons[71–77] (see Table 116.7 for pharmacokinetic data and recommended doses).

Danofloxacin. Danofloxacin mesylate is a synthetic fluoroquinolone approved for SC injection in cattle.[78] The US Food and Drug Administration approved label dose is 8 mg/kg once or 6 mg/kg repeated in 48 hours for bovine respiratory disease associated with *Mannheimia* (*Pasteurella*) *haemolytica* and *Pasteurella multocida*.[78] It is rapidly absorbed, highly bioavailable, and widely distributed in tissues. Danofloxacin has a half-life in cattle of 3 to 6 hours, with negligible accumulation. It is active against gram-negative and gram-positive bacteria.[78,79] A single-dose danofloxacin pharmacokinetic study has been done to evaluate 6 mg/kg dosing via IM and SC routes in loggerhead sea turtles.[80] Danofloxacin has also been administered at 6 mg/kg SC every 48 hours for 30 days to treat chronic mycoplasmosis in *Gopherus* tortoises.[81]

Metronidazole. Metronidazole (see Table 116.5) is a synthetic, nitroimidazole antiprotozoal and antibacterial agent that comes in oral and injectable formulations. It is bactericidal against obligate anaerobes (MIC ranging from 0.25–8 μg/mL) and is protozoacidal against numerous protozoa with an in vitro MIC of ≤1 μg/mL.[82] Metronidazole's antimicrobial action targets DNA synthesis by acting as an electron acceptor in the phosphoroclastic reaction and causes breaks in the adenine–thymine base pairing.[83] Metronidazole is a basic compound with a pKa value of 2.62 and is moderately soluble in water (approximately 10 mg/mL at 25°C) at pH 2.5 to 8.0; the pH of the IV infusion is 5.8.[82–84] Metronidazole is available as an IV infusion (metronidazole HCl), oral tablet (metronidazole base), and oral suspension (Metronidazole benzoate) in many countries; however, the commercial oral suspension is not available in the United States.[85] Oral suspensions using pH-appropriate suspending agents can be procured from licensed compounding pharmacies, and although these are generally the most appropriate formulation for accurate dosing in reptile patients, bioavailability and pharmacokinetics may vary. Metronidazole is well-absorbed after oral administration and is widely distributed to most body tissues and fluids. The major route of elimination of metronidazole and its metabolites is via the urine (60%–80% in humans), and fecal excretion accounts for 6% to 15% of the dose.[82–84] Metabolism to the 2-hydroxymethyl metabolite occurs, and decreased plasma clearance occurs in patients with decreased liver function but not in patients with renal insufficiency. In humans, adverse effects are typically associated with the gastrointestinal, nervous, hepatic, and hematopoietic systems. Elevated plasma liver enzyme activities have been reported in reptiles after metronidazole treatment.[83] Serious toxic side effects in reptiles can occur at doses between 40 and 100 mg/kg.[19,83] The most common adverse effect observed in reptiles are associated with neurotoxicity, including ataxia, nystagmus, opisthotonos, tremors, seizures, and death. Gastrointestinal toxicity may also occur, including regurgitation and diarrhea. Reported deaths from metronidazole include indigo snakes (*Drymarchon corais couperi*), California mountain king snakes (*Lampropeltis zonata*), and Arizona mountain king snakes (*L. pyromelena*) when doses of more than 100 mg/kg are used (see Chapters 88 and 127). In addition, Jacobson has reported that side effects in Uracoan rattlesnakes may occur with doses >40 mg/kg.[19]

Metronidazole pharmacokinetic studies in red-eared sliders, colubrid snakes (*Pantherophis guttata* and *Pantherophis obsoleta*), and green iguanas have been published.[86–89] In red-eared sliders, side effects were noted, and the authors suggest caution.[86] In colubrid snakes, single doses of 20, 50, 100, and 150 mg/kg PO have been studied, and multiple 20 mg/kg doses have also been studied.[87] No clinically significant adverse behavioral, hematologic, or biochemical effects were observed other than mildly elevated plasma lactate dehydrogenase activity after the last 20 mg/kg dose and mildly decreased glucose after the 50 and 150 mg/kg single doses.[87,88] Taken together, the results support a dosage of 20 mg/kg every 48 hours in *Pantherophis* spp. Higher doses should be reserved for less sensitive infections so that the risk of adverse effects is avoided. A pharmacokinetic study of a single 20 mg/kg dose followed by 20 mg/kg every 24 hours for 10 days in green iguanas identified no adverse hematologic, biochemical, or behavioral changes.[89] The authors concluded that 20 mg/kg every 48 hours would be sufficient for "most" infections and that the dosing frequency could be increased to every 24 hours for more resistant strains.[89]

CONCLUSION

Despite the new information presented in this chapter since the last edition, more research is still needed to determine how we should be using these drugs in reptiles. As some of the results show, not only do we need to better understand how these drugs work across different orders of reptiles, but we also need to further clarify how these compounds affect closely related species and better characterize the effects of temperature and route of administration on these animals. In addition, concerns related to antimicrobial resistance have only increased, and the time has come to challenge the regular first-line use of advanced antimicrobial drugs in herpetological medicine.

Antifungal Therapy

Sean M. Perry and Mark A. Mitchell

Traditionally, fungal infections in reptiles have been thought of as secondary or opportunistic infections; however, there has been a recent emergence of obligate fungal infections (e.g., *Chrysosporium* spp., *Paranannziopsis* spp., *Ophidiomyces ophiodiicola*) being identified in both wild and captive reptiles. Ultimately, isolation, differentiation, and confirmation of pathogenicity using histopathological (or cytological) examination and culture are necessary to confirm fungal disease. Because fungal infections remain a common and growing concern in both wild and captive reptiles, it is important for clinician scientists to understand the different antifungal drugs available to them to manage these cases and to use evidence-based information when selecting from different antifungals.

Pharmacokinetic studies are most commonly done in healthy animals. Although we assume that the results of these studies can be directly transferred to our clinical patients, that may not be the case. Clinicians need to be cognizant of the physiological disturbances that occur in reptiles affected by disease; by relying on the results of pharmacokinetic studies, we may assume a treatment is working when it is not. The best way to ensure treatment success is to closely monitor our patients during treatment. Another important point to consider from these studies is that the results obtained for one species may not be directly applicable to another closely related species (e.g., two species of sea turtles).

In vitro sensitivity testing is not as routinely performed for fungal isolates as it is for bacteria; however, such testing is often of great value. Although disc sensitivity can be performed, MIC testing is preferred because it not only helps identify the antifungal drug choice but, in combination with pharmacokinetic data (e.g., volume of distribution), can be used to calculate the required patient dose.[1] Evaluation of therapy is important, and checking plasma drug levels should be considered given the lack of pharmacokinetic drug doses available. Just as with antibiotics, antifungal stewardship is often lacking, and the use of the broadest, most modern drugs implies a low level of skill on the part of the practitioner. Drug selection should be based on demonstration of a fungal disease and the use of basic first-tier medications, unless resistance indicates the need for therapeutic change.[2,3]

SYSTEMIC ANTIFUNGAL THERAPY

Amphotericin B

Amphotericin B is a polyene antifungal produced from a strain of *Streptomyces nodosus*.[4] This antifungal agent increases membrane permeability by binding to ergosterol in the fungal cell membrane, leading to depolarization and increased membrane permeability, leakage of the cell contents, and cell death. Amphotericin B has a much stronger affinity for ergosterol in the fungal cell membrane than other sterols, such as cholesterol; however, because it does bind to other sterols, it can cause some toxicity in animals and humans. In addition to fungicidal activity, there is evidence that amphotericin B has immunomodulatory effects. Several drugs are known to interact with amphotericin B when used concurrently. These include antineoplastic chemotherapeutics, corticosteroids, cyclosporin A, digitalis glycosides, flucytosine, imidazole antifungal agents (e.g., ketoconazole, clotrimazole, and fluconazole), other nephrotoxic agents, tubocurarine, and zidovudine.[4]

Amphotericin B is available in two forms: Amphotericin B deoxycholate (Fungizone) and Amphotericin B lipid complex (Albecet).[4] In mammals, the primary benefits associated with amphotericin B lipid complex are that it can reduce toxic side effects (e.g., nephrotoxicity) and improve organ-specific delivery when given intravenously. In addition to reduced toxicity, the lipid complex formulation also has an increased peak concentration, clearance time, volume of distribution, and terminal elimination half-life compared with amphotericin B desoxycholate.[4] It is important to monitor patients closely when using amphotericin B systemically because it can lead to increased concentrations of blood urea nitrogen, uric acid, aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, lactate dehydrogenase, and amylase. Amphotericin B can also lead to a reduction in phosphorus concentrations and an increase or decrease in blood glucose concentrations. One of the primary concerns when using amphotericin B is that it can be nephrotoxic, causing a reduction in the glomerular filtration rate and direct toxicity at the distal tubules.[4] Animals that are treated systemically with amphotericin B should be well hydrated to limit any potential side effects.[5] Amphotericin B should not be used in a reptile patient with renal disease. The toxicity of systemic amphotericin B is largely mitigated when the drug is used within the respiratory tract (e.g., nebulization, intrapulmonary injection), as it appears to be very poorly absorbed across the respiratory epithelium.[6,7] In addition, studies have demonstrated efficacy against mycotic pneumonia in a number of mammals, birds, and reptiles.[7–10]

In mammals, amphotericin B has been found to be active against *Aspergillus* spp., *Blastomyces* spp., *Candida* spp., *Coccidioides* spp., *Cryptococcus* spp., and *Histoplasma* spp. Antifungal resistance can occur with this drug, particularly with prolonged therapy; therefore treatment should be limited to cases with a confirmed diagnosis, and MIC testing should be considered, especially if clinical response is poor.

Evidence-based research specific to amphotericin B use in reptiles is limited. The minimum inhibitory concentration of amphotericin B against the *Chrysosporium* anamorph of *Nannizziopsis vriesii* (now reclassified, *Nannizziopsis* spp. and *Paranannziopsis* spp.) (Fig. 117.1) cultured from captive lizards was 2 µg/mL.[11] The only other reports of its use are clinical case reports testing nebulization, intratracheal, and intrapulmonary therapy in reptiles.[7–9] Amphotericin B should not be selected as a first-line systemic antifungal agent; instead it should

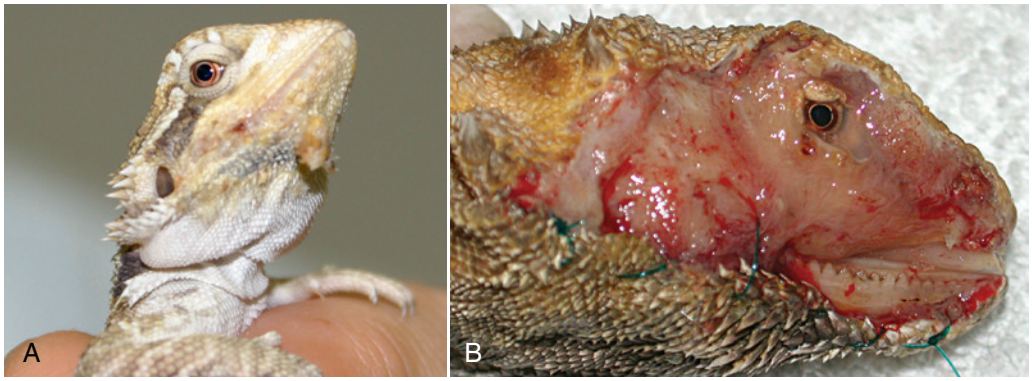

FIG 117.1 Chrysosporium anamorph of *Nannizziopsis vriesii* (CANV) (current characterization: *Nannizziopsis guarroi*) commonly effects bearded dragons (*Pogona vitticeps*) and can range in presentation from (A) small yellow plaques on the skin to (B) severe erosive dermatitis.

only be considered when treatment has failed with other antifungal agents. However, it should be considered as a first-line therapeutic for respiratory infections when administered directly to the respiratory tract.

Azole Antifungals

Azole antifungals are classified into two categories: imidazoles (e.g., miconazole, clotrimazole, and ketoconazole) and triazoles (e.g., fluconazole, itraconazole, and voriconazole). Azoles are often used as first-line systemic therapeutics to treat fungal infections, and a major advantage to azole antifungals is that there are many different oral formulations available. Azoles act by inhibiting ergosterol biosynthesis and thus interfere with fungal cell membrane function. Depletion of ergosterol, along with the accumulation of lanosterol and other 14-methylated sterols, results in destabilization of the cell membrane. This is accomplished by inhibiting P450-dependent 14 sterol demethylase.[5] In mammals, imidazoles are much more potent inhibitors of cell cytochrome P450 than triazoles; however, although largely unknown in reptiles, ketoconazole has been associated with elevated hepatocellular enzymes in a tortoise.[15] Additionally, azole antifungal drugs, such as ketoconazole and itraconazole, are potent immunosuppressive agents, with the ability to suppress T-lymphocyte proliferation in vitro.[5]

Imidazoles

Ketoconazole. The pharmacokinetics of a single oral dose of ketoconazole has been evaluated in gopher tortoises (*Gopherus polyphemus*), resulting in a suggested dose of 30 mg/kg once daily. The only adverse effects noted after a single oral dose of ketoconazole were elevated creatinine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LH) concentrations; however, the authors attributed the enzymatic changes to the anesthesia (succinylcholine) used to immobilize the tortoises for catheter placement and blood sampling.[12] The same authors performed a second study at different doses with peak plasma concentrations of 2.2 µg/mL and 4.4 µg/mL at 15 mg/kg and 30 mg/kg, respectively.[13] In mammals, plasma concentrations >1 µg/mL have been found to be effective at clearing approximately 80% of mycotic infections.[14] Based on the results, the authors suggested a single oral dose of 15 mg/kg/day was adequate to manage most mycoses encountered in chelonians. However, because the effectiveness of ketoconazole may be dose dependent, higher doses (30 mg/kg) may be necessary for more resilient fungal infections. Similar changes in the plasma enzymes, including elevated CK, AST, and LH, were reported in this study. The authors again suggested that the succinylcholine and frequent blood draws were responsible for the enzymatic changes.

Oral ketoconazole (20 mg/kg) has been used in conjunction with topical chlorhexidine solution and terbinafine to successfully treat the fungus formerly characterized as *Chrysosporium* Anamorph of *Nannizziopsis vriesii* (CANV) (current characterization: *Nannizziopsis guarroi*) in a bearded dragon (*Pogona vitticeps*).[15] A similar treatment protocol was also used to successfully treat cutaneous hyalohyphomycosis in two green iguanas (*Iguana iguana*).[16]

Triazoles

Fluconazole. Pharmacokinetic studies evaluating fluconazole in reptiles have been done; however, they are limited to sea turtles.[17,18] A loading dose of 21 mg/kg, followed by additional 10 mg/kg doses every 5 days, were sufficient to treat mycotic infections in loggerhead sea turtles (*Caretta caretta*). In cold-stunned Kemp's ridley turtles (*Lepidochelys kempii*), subcutaneous fluconazole (21 mg/kg loading dose followed by 10 mg/kg every 5 days) failed to attain therapeutic targets for filamentous fungi.[18]

Itraconazole. Itraconazole has become an invaluable antifungal treatment in veterinary medicine and is the most studied antifungal in reptiles. In the spiny lizard (*Sceloporus* sp.), 23.5 mg/kg itraconazole once daily in food for 3 days was considered sufficient to control fungal pathogens for 6 days beyond the peak concentrations.[19]

Manire et al. determined steady-state plasma concentrations of itraconazole in cold-stunned Kemp's ridley sea turtles treated with itraconazole, and in some cases antibiotics, for a minimum of 30 days before having their plasma itraconazole concentrations measured.[20] The plasma concentrations of itraconazole and its primary metabolite, hydroxyl-itraconazole, were comparable, whereas in humans the metabolite concentrations are often twice that of the parent drug.[21] This difference may be attributed to the slower metabolism of reptiles. The itraconazole was well tolerated by these turtles, with no ill effects reported. Based on the study results, a dose of 5 mg/kg per os every 24 hours or 15 mg/kg per os every 72 hours should provide the steady-state concentrations required to kill susceptible fungal pathogens.[20]

Itraconazole is known to cause side effects in mammals and birds and has also been associated with side effects in reptiles too. Anorexia and weight loss are common sequellae in reptiles treated with

itraconazole. Additionally, a study evaluating itraconazole in bearded dragons found that an oral 5 mg/kg dose of a commercial suspension (Sporanox, Janssen-Cilag, Berchem, Belgium) was associated with the multiple deaths.[11,22,23] As is common with other species that suffer similar fates, there was no histopathologic evidence of hepatotoxicity in any of the dragons. Itraconazole has been found to accumulate over time in CANV-infected bearded dragons, reaching steady-state plasma concentrations of 4 to 8 µg/mL after 10 days.[11] In vitro MIC_{90} of itraconazole for CANV cultured from infected bearded dragons was 0.25 µg/mL.[11] Fungal organisms could no longer be cultured from CANV lesions after 4 weeks of treatment. In a different treatment trial, seven bearded dragons were successfully treated for CANV with itraconazole (and clotrimazole), but six were euthanized.[23] Although the authors have used itraconazole to treat fungal infections in many different bearded dragon cases, it is important to inform clients about the potential adverse effects, including death, associated with this treatment. Additional work is needed to determine the reason these animals can appear to be healing and die abruptly during treatment.

Itraconazole (10 mg/kg) has also been evaluated in green anacondas *(Eunectes murinus murinus)* infected with CANV.[24] Findings were similar to those reported in bearded dragons and should be therapeutic.[11] Additional work is needed to see if itraconazole produces similar results in other snake families.

Girling and Fraser evaluated the effectiveness of metabolically scaled itraconazole dosing in individual patients (two snake species and two lizard species).[25] These doses (0.5–1.7 mg/kg per os every 53–75 hours for 148–184 days) were found to be effective in treating *Aspergillus* spp. without adverse effects. Although limited in scope, this data does provide some insight into the use of itraconazole and raises the importance of considering the role of metabolic scaling in treating species with a potentially hepatotoxic drug.[25]

It is important to consider novel routes of treatment in cases where oral dosing is not possible or a safety issue. To minimize risk of injury, cloacal itraconazole administration (10 mg/kg) has been attempted in cottonmouths (*Agkistrodon piscivorus*), but plasma levels were low and not considered therapeutic.[26] Itraconazole appears to be well absorbed after oral administration in the few species in which it has been tested, but not after cloacal administration. Higher doses may be necessary, or additional considerations to improve absorption, such as clearing the cloaca and increasing mucous membrane contact time, should be considered.

Itraconazole is effective against fungal pathogens; however, its safety margin may be narrower than other antifungals. Further pharmacokinetic studies in normal healthy and debilitated animals are warranted.

Voriconazole. Voriconazole is a triazole antifungal agent that inhibits fungal cytochrome P450-mediated 14 alphalanosterol demethylation, which is necessary for ergosterol inhibition. Voriconazole has a much higher predilection for fungal cytochrome P450 enzymes than mammalian enzymes.[5,27] It is available as a lyophilized powder for intravenous infusion, film-coated tablets for oral administration, and as a powder for oral suspension.

In humans, the pharmacokinetics of voriconazole via oral and intravenous routes are similar, with maximum plasma concentrations being achieved 1 to 2 hours after dosing.[5,27] Voriconazole is widely distributed into tissues and is metabolized by cytochrome P450 enzymes into multiple metabolites, including N-oxide voriconazole; this metabolite has minimal antifungal activity but accounts for 72% of the circulating metabolites.[5,27] In humans, voriconazole is primarily eliminated via hepatic metabolism; however, more than 80% of the metabolites are recovered in the urine and <2% of the oral dose is excreted unchanged in the urine. Because voriconazole is excreted via the liver, doses in patients with liver disease should be adjusted according to drug plasma concentrations to minimize side effects. No dosing adjustment is necessary in patients with renal insufficiency after oral administration, but intravenous administration should be avoided because the vehicle (sulfobutyl ether beta-cyclodextrin sodium) in the intravenous form can accumulate. The terminal elimination half-life of voriconazole is dose dependent, because the pharmacokinetics are nonlinear. Serious drug interactions can occur with concomitantly administered agents that are also metabolized via the cytochrome P450 enzyme system. Side effects in humans include visual disturbances, gastrointestinal disturbances, hepatic toxicity, fetal toxicity in pregnant women, and electrocardiac disturbances. Voriconazole is effective against multiple genera of fungi, including *Aspergillus*, *Candida*, *Fusarium* (except *Fusarium solani*), and *Scedosporium.* Drug resistance has not been studied thoroughly, but strains that are resistant to fluconazole or itraconazole may also show reduced sensitivity to voriconazole.[5,27] In humans, voriconazole is not a first-line antifungal but is reserved for invasive aspergillosis, candidaemia, disseminated infections, and in patients with mycosis refractory to other antifungal therapy.[28] Consequently, it should not be considered a first-line antifungal in veterinary medicine but reserved for severe or resistant infections.

To date, there have been several studies evaluating the clinical and pharmacological responses of voriconazole in captive reptiles. In vitro voriconazole sensitivity (MIC_{90}) against CANV isolated from captive lizards was 0.0625 µg/mL.[11] When voriconazole was used to treat CANV in bearded dragons, only 1/7 (14%) animals died compared with 5/7 (71%) treated with itraconazole; in those that survived, the disease was cleared when treated with voriconazole (Vfend, Pfizer, Ixelles, Belgium) 10 mg/kg per os every 24 hours for 4 to 9 weeks.[11]

A giant girdled lizard (*Cordylus giganteus*) was treated for CANV with voriconazole tablets (Vfend, Pfizer, Ltd, Sandwich, England) suspended in water; the dosing schedule was 10 mg/kg per os every 24 hours for 10 weeks.[8] In vitro MIC of the cultured CANV was 0.25 µg/mL for voriconazole. Weekly fungal cultures from the skin wounds were negative during weeks 7 to 10 of treatment and for 3 weeks after treatment.[8]

Pharmacokinetics of voriconazole have been determined for single and multiple subcutaneous injections in red-eared sliders (*Trachemys scripta elegans*).[29] The results showed that 5 mg/kg achieved target therapeutic concentrations of 1 µg/mL for at most 8 hours, whereas single doses of 10 mg/kg and 20 mg/kg achieved this target for 24 hours. All peak concentrations were above the therapeutic target, whereas the trough concentrations were below the therapeutic target. Using voriconazole at 10 mg/kg subcutaneously twice daily for 7 days is likely to be an effective therapy for fungal infections when the MIC is ≤0.125 µg/mL.[29] Side effects noted in the study included hind-limb paraplegia in two turtles from the multidose study; however, the authors attributed this to repeated subcarapacial sinus venipuncture rather than adverse effects associated with the voriconazole.[29]

There is limited data available regarding voriconazole use in snakes, but preliminary results suggest side effects are common. A single subcutaneous voriconazole dose of 5 mg/kg administered to healthy cottonmouths resulted in the deaths of 3/4 (75%) of the animals within 12 hours of the injection. Necropsy results showed that these animals died from acute degenerative myopathy with a pigmentary nephropathy, suggestive of an acute rhabdomyolysis.[26] Additionally, voriconazole was administered to 2 massasaugas (*Sistrurus catenatus*) and a timber rattlesnake (*Crotalus horridus*) via an osmotically driven pump. Neither massasaugas snake achieved therapeutic voriconazole concentrations for *Ophidiomyces* sp., and one of the snakes died; however, this animal's death was attributed to a concurrent *Ophidiomyces* sp. infection.[26] The timber rattlesnake reached therapeutic concentrations and was able to suppress the infection; however, it was unable to clear the infection

based on PCR. This animal died after being released into the wild. Future studies are needed across different families of snakes to determine whether voriconazole can be used to treat susceptible fungal infections without negative side effects.

Posaconazole. To date, there are no clinical reports in the literature for its use in reptiles. In humans this drug is used for invasive or systemic mycosis refractory to itraconazole and/or fluconazole therapy and should not be considered a first-line antifungal.[30]

OTHER SYSTEMIC ANTIFUNGALS

Terbinafine

Terbinafine hydrochloride is an allylamine antifungal agent. In vitro testing suggests it can be fungicidal based on dose/concentration and fungal sensitivity.[5,31] Terbinafine exerts its antifungal action by inhibiting the biosynthesis of ergosterol via inhibition of the squalene epoxidase enzyme; fungi die as a result of the increased membrane permeability from high concentrations of squalene and not ergosterol deficiency.[5,31] It is freely soluble in methanol and methylene, soluble in ethanol, and slightly soluble in water. Oral pharmacokinetics of terbinafine have not been studied in reptiles, but it is well absorbed in mammals after oral administration; peak plasma concentrations generally occur within 2 hours of administration.[32] Terbinafine is lipophilic and rapidly concentrates in the stratum corneum. It has a terminal half-life of 200 to 400 hours in tissues such as adipose and skin, making it well suited for treating fungal dermatoses.[27] Terbinafine is metabolized in the liver via several CYP isoenzymes, not including cytochrome P450, but its metabolites have little antifungal activity.[5] It is primarily excreted in urine; therefore, dosing should be adjusted in patients with renal insufficiency. Terbinafine has been found to have activity against *Trichophyton* spp., *Candida* spp., *Epidermophyton* spp., and *Scopulariopsis* spp. CANV isolated from the skin of bearded dragons has also been found to be sensitive to terbinafine, with an MIC_{90} of 2 µg/mL.[11]

Pharmacokinetics of nebulized and implanted terbinafine has been evaluated in cottonmouths (Fig. 117.3).[33] Snakes provided terbinafine via nebulization were exposed to 0.47 mg/L (18 mg/animal in a 10-gallon tank using 2 mg/mL solution) for more than 30 minutes. Drug absorption was thought to occur by either skin absorption or through pulmonary absorption. Subcutaneous implants of terbinafine (Melatek Implants, MELATEK L.L.C., Middleton, WI) were dosed at 75 to 190 mg/kg. *Ophidiomyces* sp. (Fig. 117.2) from two infected massasaugas showed an in vitro MIC of 0.015 µg/mL, which was determined to be the target. Plasma concentrations from both the nebulization treatment and implants remained above MIC (15 ng/mL) for at least 12 hours in 4/7 (57%) nebulized snakes and for 7 weeks in implanted snakes. However, if conventional antibiotic predictive methods were used, the required therapeutic concentrations were not achieved with either approach. All of the animals in this study tolerated terbinafine well and showed no adverse effects to the medication.[33]

Terbinafine has been used to successfully treat *Exophiala oligosperma* phaeohyphomycosis on the carapace of an Aldabra giant tortoise (*Aldabrachelys gigantea*). Initially, it was used topically in combination with oral itraconazole; however, because the authors did not observe a clinical response, they initiated oral terbinafine (Lamisil, Norvartis Pharmaceuticals, East Hanover, NJ) 3.4 mg/kg per os every 24 hours for 15 months.[34] Plasma concentrations of terbinafine were not measured during treatment.

Terbinafine has also been used to treat veiled chameleons (*Chamaeleo calyptratus*) with systemic *Chamaeleomyces granulomatis.* Unfortunately, both individuals treated with terbinafine died 2 days after initiating therapy. The deaths of these animals were attributed to systemic mycosis rather than the terbinafine.[35]

FIG 117.2 Fungal dermatitis caused by *Ophidiomyces ophidiocola* in a Louisiana pine snake (*Pituophis ruthveni*); this animal had other cutaneous lesions that were successfully treated with terbinafine nebulization therapy. (Courtesy of Sean M. Perry.)

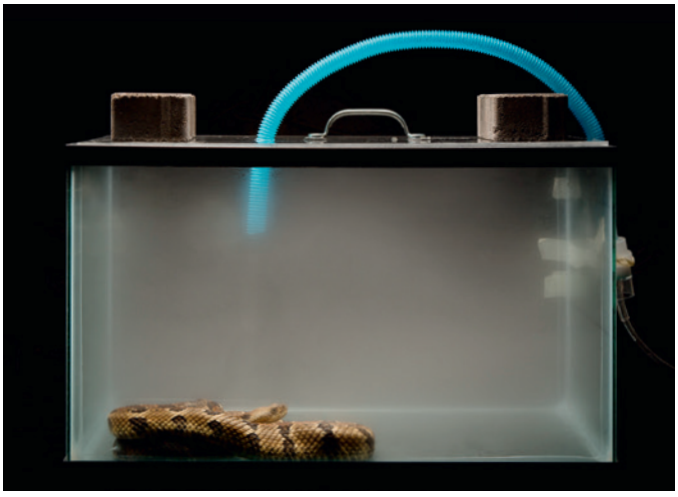

FIG 117.3 A timber rattlesnake undergoing nebulization therapy with terbinafine for snake fungal disease (*Ophidiomyces ophiodiicola*); the one study evaluating pharmacokinetic values of terbinafine used the nebulization setup pictured here in a 10-gallon aquarium. (Courtesy of L. Brian Stauffer and Matt Allender.)

TOPICAL ANTIFUNGAL THERAPY

Ketoconazole

A single case report exists in the literature detailing the use of topical ketoconazole for treating *Fusarium solani* in a loggerhead sea turtle (*Caretta caretta*). In this case the ketoconazole was used in conjunction with a 10% topical iodine solution; therefore its value as a standalone treatment cannot be determined.[36]

Miconazole

Topical miconazole therapy has been used as an adjunct therapy to systemic antifungals in cases of CANV with deep granulomatous dermatomycosis. Additionally, miconazole has been reported to successfully treat fungal keratitis in a gopher tortoise (*Gopherus polyphemus*).[37] However, no studies have evaluated miconazole's efficacy when applied topically to skin and the eye.

VetBooks.ir

Nystatin

Nystatin has been used as a topical adjunct therapy to treat fungal dermatitis; however, no controlled studies have been performed to evaluate its efficacy and absorption as a topical antifungal.[38] *Chamaeleomyces granulomatis* was determined to be sensitive to nystatin based on fungal culture and sensitivity testing from organisms isolated from veiled chameleons.[35]

Clotrimazole

Clotrimazole has been used topically in conjunction with itraconazole to treat necrotizing fungal dermatitis secondary to CANV in a group of 13 bearded dragons. A majority (7/13, or 54%) of the dragons were successfully treated with these topical drugs; however, the remaining 6 dragons (46%) were euthanized.[23]

Terbinafine

As mentioned previously, terbinafine nebulization is thought to act topically and may be absorbed through the skin (Fig. 117.3). Topical administration of terbinafine (Lamisil AT, Novatris Pharmaceuticals, East Hanover, NJ), in conjunction with nebulization therapy, has been used to successfully treat *Ophidomyces* sp. in a Louisiana pine snake (*Pituophis ruthveni*) (SMP and MAM, unpublished data). Topically applied terbinafine (Lamisil, Novartis Farmaceutica, S.A., Barcelona, Spain) has also been used in conjunction with topical chlorhexidine (Cristalmina solucion cutanea, Laboratorios Salvat A.A., Esplugues de Llobregat, Barcelona, Spain) and oral ketoconazole (Panfungol suspension, Doctor Esteve S.A., Barcelona, Spain) to treat CANV in a bearded dragon and two green iguanas.[15,16] Complete resolution of the disease was reported in these animals; however, it was unclear what role terbinafine played in the successful treatment because of the three-drug combination used.

Antiviral Therapy

Rachel E. Marschang

While the discovery of novel viruses in reptiles and the development of diagnostic methods have progressed rapidly in recent years, methods for treating viral infections have been slower to develop. Therefore, treatment options available to clinicians for managing viral diseases remain frustratingly limited. Many viral infections in reptiles appear to be able to persist for extended periods of time. Thus treatment of clinical disease caused by a viral pathogen may not lead to freedom from infection. Quarantine, barrier nursing, and disinfection are therefore all-important considerations for dealing with viral infections. In large collections, or if an animal is suffering, euthanasia may also be an important consideration. In many cases, viral disease develops because of multiple factors in addition to the virus, including husbandry issues and infections with other agents (e.g., other viruses, bacteria, fungi, and parasites). Optimization of husbandry and treatment of concurrent infections may therefore strongly affect outcome. Specific options for influencing the course of viral infections and the viruses against which each has been used are discussed.

ACYCLOVIR, VALACYCLOVIR, FAMCICLOVIR, AND CIDOFOVIR

Acyclovir, a synthetic nucleoside analogue, is probably the best known antiviral agent in reptile medicine, and it has been used mostly against herpesvirus (HV) infections in tortoises. This class of antiviral drugs competitively inhibits viral DNA polymerases, preventing further viral DNA synthesis. Acyclovir (and various related drugs) has been shown to inhibit the growth of a testudinid HV 3 (teHV3) in vitro with concentrations of 25 and 50 µg/mL inhibiting virus replication in cell culture.[1]

In marginated tortoises (*Testudo marginata*), the oral administration of 80 mg/kg acyclovir (Zovirax suspension, Glaxo Smithkline spa, Verona, Italy) led to a maximum serum concentration of 1.4 ± 0.45 µg/mL for up to 12 hours, with an elimination half-life of 8.85 ± 3.84 hours.[2] In box turtles (*Terrapene* sp.), oral administration of 40 and 80 mg/kg of acyclovir led to similarly low serum concentrations. Valacyclovir, a related substance with higher oral bioavailability, at 40 mg/kg PO, led to serum plasma concentrations similar to those measured for 80 mg/kg acyclovir, although anorexia and lethargy were observed in some treated animals.[3] Administration of higher dosages at more frequent intervals (2–3 times daily) has been suggested. Topical acyclovir on oral lesions of affected chelonians has also been associated with clinical improvement.[4]

Acyclovir and cidofovir have been shown to be ineffective against ranaviruses in vitro (Ferguson SD, Wellehan JFX, unpublished data). Cidofovir and related substances have been used for the treatment of adenovirus infections, although not in reptiles.[5] In a study on erythrocytic iridoviruses in Australian bearded dragons (*Pogona barbata*), an infected and anemic animal was treated with acyclovir (80 mg/kg PO SID) and died within 1 week. Other similarly affected animals that were treated with famciclovir (20 mg/kg PO q48h) had reduced numbers of intraerythrocytic inclusions and did not show overt signs of drug toxicity (Hyndman T, Personal communication, May 2016). Studies in mammals have shown that famciclovir can be a safer alternative to acyclovir.[6,7]

LYSINE

Lysine has been used to treat HV infections in humans and other mammals and has been suggested for use in tortoises with HV infections, although its efficacy in cats has been questioned.[8,9] In tortoises, a dose of approximately 250 mg/kg Viralyse (Vétoquinol, Fort Worth, TX) PO once daily has been described (Wright KM, unpublished observations), but controlled studies investigating the efficacy of this drug do not exist.

DISINFECTANTS

Local application of disinfectants on topical lesions has been suggested, especially for the treatment of stomatitis and glossitis in herpesvirus-infected tortoises (e.g., 0.5% chlorhexidine solution). This could theoretically also help with similar lesions caused by ranaviruses or nidoviruses in snakes, although this has not been investigated in controlled studies. The disinfectant F10 (containing benzalkonium chloride and polyhexanide) has been suggested for treating upper respiratory tract disease of bacterial and/or viral origin in reptiles. It has been used as a nasal wash and for nebulization at a recommended concentration of 0.22 mg benzalkonium chloride and 0.02 mg polyhexanide per ml solution. Although there are no controlled studies evaluating efficacy, this concentration appears to be safe in many species.[10]

MISCELLANEOUS DRUGS

There are a number of other substances that have been used to treat various viral infections in humans and other mammals, such as ribavirin for the treatment of infections with both DNA and RNA viruses, including paramyxo-, corona-, and arenaviruses.[11–13] A wide range of substances targeted against specific viruses, virus receptors, viral proteins, or viral genomes have been developed and tested;[12,14] however, cost and limited commercial interest has resulted in a lack of efficacy, pharmacokinetics, safety, and clinical trials in reptiles. Considering the poor prognoses associated with many reptilian viral infections, the clinician is encouraged to consider antiviral therapy in situations where the owner has provided informed consent, where intervention points and actions (e.g., euthanasia and/or analgesia) have been clearly defined, and where the health of in-contact animals will not be compromised. If therapy is pursued, these experiences, positive and negative, should be shared with the profession to facilitate progress.

VetBooks.ir

TEMPERATURE REGULATION

Adjustment of environmental temperatures has been shown to influence the course of viral infections, with anecdotal and in vitro evidence indicating that this may be true for a wide range of viruses. In most cases, viruses that are specific to reptiles, or to ectotherms in general, tend to replicate better at relatively low temperatures (below 30°C/86°F), and increasing ambient temperature may help slow viral replication. Conversely, reptiles kept at suboptimal temperatures may be more susceptible to viral infection and disease due to increased viral replication or immunosuppression. When adjusting a reptile's thermal environment, it is important to keep them within their preferred optimal temperature zone (POTZ) for that species because changes may affect welfare. Examples for viruses in which temperature has been demonstrated to play a role in the development of disease include gray patch disease (HV) in sea turtles, in which more rapid and severe disease was observed in animals when the water temperature was changed suddenly rather than gradually.[15] Viral replication and disease may also be reduced at higher temperatures for HVs of tortoises. Iridoviruses are temperature limited in cell culture and cannot grow at temperatures above 32°C/90°F. In transmission studies with ranaviruses, temperature has been found to play an important role in the development of disease, with higher mortality in red-eared sliders (*Trachemys scripta elegans*) kept at 22°C (71.6°F), compared with 28°C (82.4°F).[16] Transmission studies with another iridovirus, erythrocytic necrosis virus, in lizards (*Iberolacerta* [*Lacerta*] *monticola* and *Lacerta schreiberi*) showed that infection with these agents can become systemic and may lead to death if the animals are kept at suboptimal temperatures.[17] Temperature regulation may also be helpful in controlling other viral diseases, including ferlaviral, adenoviral, reoviral, and picornaviral disease.

In the case of viruses that can also infect mammals and/or birds (e.g., rhabdo-, bunya-, toga-, and flaviviruses), relatively high temperatures may not be helpful in combating disease development, and high temperatures in captive crocodilians may lead to increased disease and spread of West Nile virus.[18]

IMMUNOMODULATORS

The use of immunomodulators (e.g., Zylexis, which contains inactivated parapox ovis virus; Pfizer AG, Zurich, Switzerland) may be beneficial for treating viral disease in reptiles, particularly for HV-infected tortoises. This is largely speculative, and data on its efficacy are lacking. No adverse effects were reported following IM injection in a large group of mixed reptiles, and subjectively, injected animals appeared to have a higher survival rate than untreated animals (Brames H, unpublished observations).

TREATING SECONDARY INFECTIONS

The majority of viral diseases in reptiles are complicated by other agents, including other viruses, bacteria, fungi, and parasites, which likely play a role in disease progression and outcome. It is important to recognize and treat these concomitant infections appropriately. This has been well-documented for adeno- and reovirus infections in reptiles (see Chapter 30), and evidence suggests that the same is true for other viral infections (e.g., ferlaviruses).

VACCINATION

Vaccination has proven effective in treating poxvirus infections and in preventing West Nile virus infections in crocodilians. An autogenous poxvirus vaccine produced from skin lesions has shown some success in accelerating healing and reducing scarring.[19] West Nile virus can cause serious disease and death in infected crocodilians and is zoonotic. A commercial vaccine is available in the United States (Beohringer Ingelheim, St. Joseph, MO). It is an inactivated vaccine that has been conditionally licensed for use in alligators of age 1 month or older. Uninfected animals that have been vaccinated can be PCR-positive using certain PCR tests, which makes it difficult to differentiate them from infected animals that have not been vaccinated. Efficacy and safety trials are ongoing (Nevarez J, personal communication, 2016).

Vaccination of snakes against a ferlavirus has been attempted using an inactivated cell culture isolate. Western diamondback rattlesnakes (*Crotalus atrox*) were inoculated IM with the inactivated virus with and without the addition of an adjuvant. While no adverse effects of vaccination were noted in any of the snakes, antibody responses to vaccination were variable and transient,[20] and this vaccination method is not currently recommended for the prevention of ferlavirus infection and/or disease.

In the case of HV infections in chelonians, vaccination with an inactivated cell culture isolate has been attempted in a group of HV-infected Mediterranean tortoises (*Testudo* spp.). Inactivated virus with and without adjuvant was injected SC subcutaneously (s.c.) three times. Serology showed no increase in antibody titers against the homologous virus in the vaccinated animals.[21] Anecdotal reports exist on the use of autogenous vaccines made from inactivated material from fibropapillomas to vaccinate sea turtles infected with fibropapilloma-associated turtle HV (FPTHV), but no scientific reports on the effect of such vaccines are available.

Antiinflammatory Therapy

Kelly Rockwell and Mark A. Mitchell

Antiinflammatories represent one group of pharmaceuticals that are commonly used in veterinary medicine to treat a variety of maladies, and while it was once common to suggest that "no animal should perish without the benefits of steroids," a new mantra has been established that replaces steroids with nonsteroidal antiinflammatories (NSAIDs). Antiinflammatories can impact many different physiological functions in a patient, although much of the current focus on their usage is directed toward their "analgesic effects."

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Nonsteroidal Antiinflammatories are widely used in reptile clinical practice, even though their effects are still largely unknown. Although not as potent an analgesic as opioids, NSAIDs are commonly used to manage many chronic painful conditions in reptiles, such as pododermatitis, periodontal inflammation, arthritis, spondylitis, osteomyelitis, and articular gout, as well as cases of acute pain or trauma, including surgically induced pain (Fig. 119.1).[1]

The inhibition of the cyclooxygenase (COX) enzyme isoforms is the primary source of the analgesic and antiinflammatory effects seen with NSAID administration. In mammals, NSAIDs block the binding of arachidonic acid to COX, preventing the conversion of thromboxane A_2 to thromboxane B_2 and therefore preventing the formation of the prostaglandins (PG) that serve as potent mediators of inflammation.[2] Studies have shown that NSAIDs act on both peripheral tissue injury sites and at the level of the central nervous system due to the distribution of COX isomers. The COX-1 isomer is considered the constitutive form of COX and is thought to be part of normal homeostasis in many tissues of vertebrates. This isomer is found in tissues throughout the body, including the stomach, kidney, platelets, and reproductive tract. COX-2 is thought of as the induced isomer form, because it can be found at sites of inflammation and is upregulated in response to traumatic injury. However, in skin and muscle biopsies from ball pythons (*Python regius*), production of COX-1 rather than COX-2 was significantly greater at sites of inflammation.[3] In eastern box turtles (*Terrapene carolina carolina*), traumatized muscle also had significantly higher concentrations of COX-1 compared with grossly normal muscle, although both COX-1 and COX-2 were found in liver, kidney, normal muscle, and traumatized muscle samples.[4] As more research is published, it is becoming evident that complete COX-2 inhibition can be detrimental to many normal physiological functions, making COX selectivity an important consideration when prescribing NSAID therapies, as each NSAID may vary in its degree of specificity and subsequent side effects.[2,5]

Because of our limited understanding regarding the impact of long-term NSAID administration in reptiles, the same precautions used in small mammals should be implemented for these species. The primary NSAID side effects observed in mammals are associated with the excretory and gastrointestinal systems. Because most reptiles are uricotelic and their kidneys typically consist of only a few thousand nephrons, compared with the million nephrons found in mammalian kidneys, they are hypothetically more susceptible to nephrotoxic injury than mammals and less able to recover. Additionally, reptiles tend to eat less frequently than mammals and birds, increasing the likelihood that reptiles are receiving regular dosages of NSAIDs on an empty stomach. This can lead to adverse gastrointestinal effects, such of mucosal bleeding and gastrointestinal ulceration.[6] To limit these potential complications, NSAIDs should only be used in well-hydrated patients and preferably after the animal has eaten. Additionally, reptiles prescribed long-term NSAIDs should have their liver and kidney function monitored.

Meloxicam

Meloxicam preferentially inhibits COX-2 and spares COX-1, although at higher dosages its COX-2 specificity is diminished. It is often indicated in both acute and chronic musculoskeletal disorders and to reduce postoperative pain and inflammation following orthopedic and soft tissue surgeries. It is contraindicated in animals with hypotension and should be used with caution in patients with impaired hepatic, cardiac, or renal function, or those with hemorrhagic disorders.[7] In mammals, meloxicam is regarded as relatively safe, with gastrointestinal distress the most commonly reported side effect. Renal toxicity is relatively uncommon in animals with normal renal blood flow.

Carprofen

Carprofen is a COX-1-sparing NSAID, specifically inhibiting COX-2 activity and providing analgesic, antiinflammatory, and antipyretic

FIG 119.1 A bearded dragon (*Pogona vitticeps*) with swollen toes. A diagnosis of gout was confirmed in this case, and the pain and inflammation associated with this chronic condition were managed with NSAIDs. Monitoring renal function in these cases is valuable, because NSAIDs can contribute to renal disease. (Courtesy of Mark A. Mitchell.)

VetBooks.ir

effects. However, COX-2 specificity appears to be species, dose, and tissue dependent.[7] Carprofen is used to control postoperative pain and acute inflammation, as well as reduce chronic inflammation in cases of degenerative joint disease and osteoarthritis. It is also being investigated as an adjunct therapy for some types of cancer with COX-2 overexpression. Similar to other NSAIDs, it is contraindicated in patients with liver or renal impairment and bleeding disorders. Regular monitoring of hepatic and renal function should be done in patients being treated long term with this NSAID. Because the COX-2 inhibition activity of carprofen may adversely affect renal perfusion, periods of hypotension in patients may exacerbate this effect.[7] Mild gastrointestinal signs (e.g., melena) are the most common side effects in mammals but are very rare in occurrence. Carprofen is currently available in both injectable and oral tablet formulations.

The effects of repeated administration of carprofen for 10 days on blood parameters in green iguanas has been evaluated and showed that IM injections of 2.0 mg/kg had no significant impact on hematologic parameters compared with saline injections.[1] Hemoglobin and packed cell volumes were found to decrease, and the percentage of azurophils increase during the study, but these effects were found in both the carprofen-treated and saline-treated groups. Alanine aminotrasnferase was also found to be increased in the iguanas that received carprofen, but the elevated values were within the physiological reference range for green iguanas.[1]

Ketoprofen

Ketoprofen is a nonselective inhibitor of the COX enzymes, producing both analgesic and antiinflammatory effects. It is commonly used in reptiles for the treatment of musculoskeletal pain and to reduce inflammation. The adverse effects reported with the other NSAIDs have also been reported with ketoprofen, often in more frequency and severity, including surgical site bleeding, gastric ulceration, acute renal failure, and pruritis.[8] Ketoprofen is available in topical, oral, and injectable formulations.

Flunixin Meglumine

Flunixin meglumine is a potent inhibitor of COX enzymes; however, the direct mechanism of action for this NSAID is still unknown. This NSAID can provide analgesic, antiinflammatory, and antipyretic effects; however, its safety threshold is not as wide as the COX-2 inhibitors mentioned previously. For example, if an animal does not respond to an initial dose of flunixin meglumine, additional doses are unlikely to be effective and may increase the chance of toxicity. Adverse effects and contraindications are species specific, and there are currently no warnings regarding its use in reptiles due to lack of experimental studies.[7] It is important for clinicians to pay specific attention to dosing schedules due to the wide dosage range. Flunixin meglumine is available in both oral and injectable formulations.

Flurbiprofen

Flurbiprofen is a commonly used ophthalmic NSAID that nonselectively inhibits COX enzymes to produce both antiinflammatory and analgesic effects. It is indicated in patients before cataract surgery, as well as for anterior uveitis and ulcerative keratitis when topical corticosteroids are contraindicated. It has been known to cause local irritation and may delay epithelial healing. Flurbiprofen is currently available as a 0.3% ophthalmic solution. Reptiles with intact spectacles, such as snakes and certain geckos, may not gain any benefit from topical flurbiprofen.

GLUCOCORTICOIDS

Glucocorticoids have historically been used to treat a variety of disease processes and trauma-related injuries. They reduce neutrophil/heterophil migration by decreasing the expression of adhesion molecules for these cells in the vascular epithelium, thereby reducing their movement from the blood into tissues. Prostaglandin and leukotriene production is also reduced through the arachidonic acid pathway via inhibition of phospholipase A_2 and, possibly, COX-2 as well.[9]

Antiinflammatory dosages of corticosteroids are commonly administered for conditions such as atopy, angioedema, and urticaria in mammals.[9] Because no pharmacokinetic studies have been done to assess glucocorticoids in reptiles, dosages are empirical. Routine physical examinations and hematologic and biochemistry data should be collected to monitor reptile patients on long-term corticosteroid treatment to manage dosing regimens and screen patients for side effects.

Dexamethasone

In mammals, dexamethasone is 8 to 10 times more potent than prednisone and has a duration of effect that is 48 hours longer.[7] Dexamethasone is available as both an injectable and a 0.1% ophthalmic solution. Though often suggested as a treatment for CNS injury, corticosteroids have not proven to be effective in humans and may actually exacerbate injury. Again, because these drugs have not been fully evaluated in reptiles, they should be used with caution and the patient monitored closely.

Prednisolone

Prednisolone has approximately four times the antiinflammatory potency and half the relative mineralocorticoid potency of hydrocortisone.[7] Like methylprednisolone, it is considered to have an intermediate duration of activity and is suitable for alternate-day use. Prednisolone is available as an injectable, oral, topical, and 0.5% ophthalmic solution.

TABLE 119.1 Dosage Recommendations for Antiinflammatories Used for Reptiles

Class	Drug	Dosage	Source	Comments
Nonsteroidal antiinflammatories	Meloxicam	0.2–0.4 mg/kg IM, IV, PO q24–48 h	Experimental[6,10,11]	
	Carprofen	1–4 mg/kg IM, IV, PO, SC q24 h	Empirical[11–13]	Following initial dosage, decrease to half dose every 24–72 h[17]
	Ketoprofen	2 mg/kg IM, SC q24–48 h	Experimental[8,11]	
	Flunixin meglumine	0.1–2 mg/kg IM q24–48 h	Empirical[14]	
	Flurbiprofen	1 drop topically q6–12 h	Empirical[15]	
Glucocorticoids	Dexamethasone	0.2 mg/kg IM, IV q24 h for 3 days	Empirical[16]	
		2–4 mg/kg IM, IV q24 h for 3 days	Empirical[15]	
	Prednisolone	2–5 mg/kg PO q24–48 h	Empirical[15]	
		5–10 mg/kg IV as needed for shock	Empirical[17]	

VetBooks.ir

Methylprednisolone

Methylprednisolone is used as an antiinflammatory agent and is authorized for the management of shock in mammals. It has five times the antiinflammatory potency of hydrocortisone and is 20% more potent than prednisolone. In mammals, methylprednisolone has been associated with severe side effects, including thrombocytopenia, increased susceptibility to infections, and gastrointestinal signs. Because of the long-acting duration of this drug, and our limited understanding of its value in reptiles, the authors do not recommend treating reptiles with this drug currently.

CONCLUSION

Antiinflammatory drugs have been and will continue to be an important component of the treatment plans for reptiles. Currently, we do not have strong evidence to support the dosages, routes of administration, and dosing frequencies for these drugs in reptiles. It is important for all veterinarians to document and share their clinical experiences when using antiinflammatories so that we can develop some basic guidelines regarding these important drugs. Additionally, continued pursuit of experimental studies and research to further refine the use of these compounds in reptile species is important. Dosage recommendations for antiinflammatories currently used in reptiles can be found in Table 119.1.

Antiparasitic Therapy

Kelly Rockwell and Mark A. Mitchell

Parasites have spent eons creating niches in which to take advantage of their reptilian hosts. In the majority of these cases, the reptile and parasite are in balance; however, in captivity, reduced resources (nutritional, thermal, lighting), immunosuppression, and direct life cycles can often lead to clinical disease. Therefore antiparasitic medications are important tools to minimize the impact of parasitism on captive reptiles.

ENDOPARASITICIDES

Antiprotozoals

Ciliated and flagellated protozoans are common inhabitants of the intestinal tracts of reptiles, especially herbivores. It is important for veterinarians to recognize that most of these organisms are commensals or symbionts of the intestinal tract, and they play vital roles in the digestion of nutrients and the maintenance of the intestinal microbiome. Because of the importance of these organisms in the general health of the intestinal tract, treatment should only be initiated when clinical disease is present.

Metronidazole is the most common antiprotozoal agent used to treat reptiles, and one of the few antiparasitic drugs supported by evidence-based pharmacokinetic studies.[1–4] Metronidazole primarily acts as an amebicide against trophozoites, with limited activity against encysted forms of protozoa.[5] The pharmacokinetic studies performed in reptiles have shown that there is variability in the rate of absorption from the gastrointestinal tract between and within species, suggesting that patients should be monitored closely for a response to treatment as well as adverse reactions to the drug. One of the reasons clinical side effects are common relates to the wide dosing recommendations for this drug (Table 120.1). It is important to utilize evidence-based data first when selecting a dose. Side effects associated with metronidazole toxicity in vertebrates are typically associated with the central nervous system (CNS), including ataxia, an inability to locomote, nystagmus, opisthotonous, tremors of the lumbar muscles and hind limbs, seizures, and death, but may vary with different reptile species.[6] A corn snake (*Pantherophis guttatus*) treated with metronidazole at 250 mg/kg developed severe CNS signs within 24 hours but improved with supportive care over 72 hours (Mitchell M, personal observation). Plasma biochemistry testing showed elevated bile acids suggestive of hepatic dysfunction, whereas the CNS signs were presumably associated with hepatic encephalopathy. Several red-eared sliders (*Trachemys scripta elegans*) experimentally dosed with a single 20-mg/kg intracoelomic injection of metronidazole died 2 to 5 months after the completion of the study.[5] Although it was unclear whether their deaths were due to adverse effects, caution should be exercised when using intracoelomic administration. When using this antiparasitic medication, it is best to follow the guidelines established from the few pharmacokinetic studies reported (see Table 120.1).

Because metronidazole is ineffective at killing protozoal cyst stages, it is often used in combination with iodoquinol, paromomycin, and/or diloxamide furoate (not currently available in the United States) to effectively control both trophozoite and cyst stages in the gastrointestinal tract. The use of paromomycin alone in juvenile bearded dragons (*Pogona vitticeps*)[7] and Gila monsters (*Heloderma suspectum*) was found to be effective at higher doses and decreased dosing intervals, but in leopard geckos (*Eublepharis macularius*) an unknown dosage was only able to clear *Cryptosporidium* infections in two of four animals.[8] When using paromomycin in patients, caution should be used, because systemic absorption can occur in animals with ulcerative gastroenteritis, which can lead to nephrotoxicity, ototoxicity, and pancreatitis.

Other treatments, such as atovaquone-proguanil and halofuginone hydrobromide, were not effective at treating cryptosporidiosis in Boettger's lizards (*Gallotia caesaris*)[9] or snakes,[10] respectively. No adverse effects were reported in the lizards administered atovaquone-proguanil; however, snakes administered halofuginone had hepatotoxic and nephrotoxic changes, including severe, acute liver necrosis, liver hemosiderosis, and cortical and tubular necrosis with iron deposition. Postprandial regurgitation was also observed in several snakes treated with halofuginone and spiramycin.[10] In Boettger's lizard, 10 mg/kg of oral chloroquine for 7 days was also ineffective at decreasing *Plasmodium* sp., but no adverse effects were noted.

Coccidial infections are a common finding in captive reptiles, with most of these infections being perpetuated because of poor hygiene and biosecurity. Coccidial infections are typically self-limiting; however, autoinfection appears common in captive reptiles. Historically, sulfadimethoxine and trimethoprim-sulfamethoxazole (coccidiostats) have been recommended for treating coccidial infections in reptiles (see Table 120.1). Unfortunately, these recommendations were based on empirical data, although later research done by Walden and Mitchell did show that long-term treatment with sulfadimethoxine reduced *Isospora amphiboluri* in bearded dragons.[11] Attempts to control coccidia in reptiles using nutraceuticals (Oregano, *Origanum vulgare*), and probiotics have also been reported and found to be largely ineffective.[11,12] Ponazuril, an antiprotozoal commonly used to treat equine protozoal myeloencephalitis, is recommended for treatment, as it can impact all life stages of the coccidia. Walden[13] performed an experimental study testing the efficacy of ponazuril in bearded dragons and showed that doses of 15 to 40 mg/kg PO once daily for 21 days were effective against coccidia.

Anthelminthics

Nematodes. Nematodes are a common finding in captive reptiles, representing one of the most diverse groups of endoparasites found in these animals. They can travel subcutaneously and, if found in patients, should be surgically removed.[14] Anthelminthics are generally recommended for the treatment of disease, or strategically to control prevalence

VetBooks.ir

TABLE 120.1 Treatment Recommendations for Protozoal Infections in Reptiles

Treatment/Species	Dosage	Source	Comments
Metronidazole			
All reptiles	100–220 mg/kg PO repeated in 2 weeks	Empirical[5,26,41]	Caution with intracoelomic administration[5]
	50 mg/kg PO q 24 h for 3–5 days	Empirical[5]	
Red rat snakes	50 mg/kg PO q 48 h	Experimental[1]	
Yellow rat snakes	20 mg/kg PO q 48 h	Experimental[3]	
Green iguanas	20 mg/kg PO q 48 h	Experimental[3]	May dose at q 24 h if lack of response
Colubrid snakes	40–50 mg/kg PO	Empirical[26]	
Small chelonians	100–150 mg/kg PO every 10–14 days	Empirical[42]	
Larger chelonians	25 mg/kg PO q 24 h for 5 days, repeated in 10 days	Empirical[42]	
Metronidazole and Iodoquinol			
Aquatic and semiaquatic chelonians	Five days of metronidazole (25–50 mg/kg) and iodoquinol (25 mg/0.75–1 kg), followed by 5 days of iodoquinol alone, then 5 days of both, and a final 5 days of iodoquinol	Empirical[43]	
Terrestrial chelonians	Three days of metronidazole (25–50 mg/kg) and iodoquinol (25 mg/0.75–1 kg), followed by 14 days of iodoquinol alone, and a final 3 days of both	Empirical[43]	
Chelonians	Metronidazole (20 mg/kg) PO q 48 h and iodoquinol (50 mg/kg) PO q 24 h for 3 weeks	Empirical[43]	
Paromomycin			
All reptiles	300–800 mg/kg PO q 24–48 h for 7–14 days, or as needed	Empirical[1,43]	Caution with use—systemic absorption through damaged gastrointestinal tract may lead to nephrotoxicity, ototoxicity, or pancreatitis
Bearded dragons	100 mg/kg q 24 h for 7 days, then twice a week for 6 days, and 360 mg/kg q 48 h for a final 10 days	Experimental[7]	
Gila monsters	300–360 mg/kg q 2 days for 14 days	Experimental[44]	
Chloroquine			
All reptiles	50 mg/kg IM once weekly for three doses, in combination with iodoquinol and metronidazole	Empirical[43]	
Sulfadiazine, Sulfamerazine, and Sulfamethazine			
Lizards	25 mg/kg PO q 24 h for 21 days	Empirical[41]	
Sulfadimethoxine			
All reptiles	90 mg/kg PO once, then 45 mg/kg PO q 24 h for 5–7 days	Empirical[26]	
Bearded dragons	50 mg/kg PO q 24 h for 21 days	Experimental[11]	
Trimethoprim/Sulfamerazine			
Lizards	30 mg/kg PO combined q 24 h for two doses, then q 2 days PO for 21 days	Empirical[41]	
Ponazuril			
All reptiles	30 mg/kg PO q 48 h for two doses	Empirical[5]	
Bearded dragons	15–40 mg/kg PO q 24 h for 21 days	Experimental[13]	All treatments effective; no reinfection 40 days posttreatment

and burden, though caution should be used with these drugs because adverse effects have been reported. Most notably, ivermectin has been found to cause significant side effects in reptiles, especially chelonians, in numerous safety studies[15–19] because of its mechanism of action. Based on most of these reports, its use is contraindicated in chelonians. See Chapter 88 for more information. Ivermectin kills nematodes by causing paralysis with high-affinity binding to the glutamate-gated chloride channels in the invertebrate nerve and muscle cells. It has been used successfully in a variety of reptiles, with snakes apparently tolerating a higher dosage range than other groups without apparent side effects.[19] To date, there are no published pharmacokinetic studies assessing ivermectin in reptiles; however, other than chelonians, skinks, and indigo snakes (*Drymarchon couperi*), empirical dosing appears relatively safe. Current empirical dosing recommendations for ivermectin can be found in Table 120.2.

Milbemycin oxime analogs are insecticidal and provide anthelmintic activity at very low concentrations by opening glutamate-sensitive chloride channels in neurons and myocytes of invertebrates, leading to hyperpolarization of these cells and blocking of signal transfer. The efficacy and safety of this drug has been compared with ivermectin in several chelonian species using a suspended form of the commercial tablet in propylene glycol (2.5 mg/mL).[16] In the study, red-eared sliders, Gulf Coast box turtles (*Terrapene carolina major*), and ornate box turtles (*Terrapene ornata ornata*) showed no adverse effects to PO or SQ

VetBooks.ir

TABLE 120.2 Treatment Recommendations for Nematode Infections in Reptiles

Treatment/Species	Dosage	Source	Comments
Ivermectin			
Snakes and lizards	0.2 mg/kg PO or SQ repeated in 2 weeks	Empirical[41,45]	Caution in chelonians, skinks, and indigo snakes, fatal toxicity possible; mild side effects (anorexia, depression) in a Senegalese chameleon administered a single 0.2 mg/kg SQ dose[23]
	0.2 mg/kg PO, SQ, or IM repeated in 2 weeks	Empirical[1,46]	
	0.2–0.4 mg/kg SQ or IM	Empirical[26]	
Solomon island skink	0.2 mg/kg IM repeated in 14 days (up to six doses)	Empirical[23]	Fatality reported in one case 24 h after a dosage of 0.2 mg/kg PO
Corn snakes	0.4–1 mg/kg	Empirical[15]	
Dumeril's monitor	0.4 mg/kg	Empirical[15]	
Milbemycin Oxime			
Ornate box turtles	0.25 mg/kg SQ repeated in 8 days	Experimental[16]	
Fenbendazole			
All reptiles	50–100 mg/kg PO repeated in 2 weeks	Empirical[1,41,42,45]	
	50 mg/kg PO repeated in 3 weeks	Empirical[47]	
Snakes	100 mg/kg PO	Empirical[26]	For treatment of snake lungworms, *Rhabdias* and *Strongyloides*
Hermann's tortoise	Single administration of 100 mg/kg PO	Experimental[20]	
Boettger's lizard	Single administration of 0.4 mL/kg active ingredient	Experimental[9]	
Oxfendazole			
All reptiles	Single administration of 66 mg/kg PO	Empirical[20]	Does not require biotransformation and less toxic than fenbendazole
Hermann's tortoises	Single administration of 66 mg/kg PO	Experimental[20]	
Thiabendazole			
Rat snake	110 mg/kg PO repeated weekly for three dosages	Empirical[47]	
Praziquantel			
All reptiles	10 mg/kg PO	Empirical[26]	Caution for anaphylactic-like reactions in ball pythons
Levamisole			
Iguanas	10 mg/kg intracoelomically repeated in 2 weeks	Empirical[41]	
Vercom Paste (34 mg/mL Febantel and 3.4 mg/mL Praziquantel)			
Solomon island skink	0.5–1 mg/kg repeated in 2 weeks	Empirical[23]	
Emodepside + Praziquantel (*Profender*)			
All reptiles	4 drops/100 g body weight	Experimental[45,48,49]	

treatment. Ornate box turtles that received milbemycin SQ were found to have negative fecal screens, although acanthocephalans did pass throughout the course of the study.

The pharmacokinetics of fenbendazole has yet to be assessed in reptiles and, to date, few efficacy studies have been performed. In Hermann's tortoises (*Testudo hermanni*), oxfendazole was more effective at reducing oxyurid fecal egg counts.[20] Recent studies have indicated that a single dose of oxfendazole (25 mg/kg) was able to clear nematodes from green iguanas *(Iguana iguana)* (Kehoe, Divers, unpublished data). Oxfendazole is the active metabolite of fenbendazole responsible for most anthelminthic activity, and thus improved efficacy over fenbendazole is not surprising; oxfendazole has also been shown to be less toxic.[21] In Hermann's tortoises treated with oral fenbendazole, hematologic and plasma chemistry sampling showed marked changes associated with the treatment, although they remained clinically healthy. Their blood results indicated an extended heteropenia with transient hypoglycemia, hyperuricemia, hyperphosphatemia, and equivocal hyperproteinemia/hyperglobulinemia.[22] Such changes should be considered when treating ill tortoises with fenbendazole because these could have significant consequences on recovery. Current recommendations for these drugs are listed in Table 120.2.

Other therapies for the treatment of nematodes in reptiles include the empirical use of levamisole in iguanas, as well as vercom paste (Vercom Paste Anthelmintic, Miles Inc, Shawnee Mission, KS) (34 mg/mL febantel and 3.4 mg/mL praziquantel) in the Solomon island skink (*Corucia zebrata*); in the latter case there were no adverse effects and seemingly better results than ivermectin in eliminating fecal shedding of nematode ova.[23] An experimental application of a combination therapy of emodepside and praziquantel (Profender; Bayer HealthCare, Shawnee Mission, KS) in different reptile species found that both active ingredients penetrate the skin and can be found in serum when given topically, although effective doses may vary with the type and thickness of the integument.

Cestodes and Trematodes. Praziquantel is commonly used to treat cestodes and trematodes in reptiles. However, the few studies that have assessed the efficacy or pharmacokinetics of this drug have been limited

VetBooks.ir

TABLE 120.3 Treatment Recommendations for Cestode and Trematode Infections in Reptiles

Treatment/Species	Dosage	Source	Comments
Praziquantel			
All reptiles	10 mg/kg PO or IM, up to 30 mg/kg PO for trematodes	Empirical[26]	Caution for anaphylactic-like reactions in ball pythons
Green sea turtles	50 mg/kg PO three times over a 9h period for 1 day	Experimental[24]	
Loggerhead sea turtles	25 mg/kg PO three times at 3-hour intervals	Experimental[25]	
Emodepside + Praziquantel (*Profender*)			
All reptiles	4 drops/100 g body weight	Experimental[48,49]	

to sea turtles. Green sea turtles (*Chelonia mydas*) orally dosed were successfully cleared of trematode infections.[24] Although no adverse effects were reported in the turtles, treated animals did exhibit elevated alanine aminotransferase and aspartate aminotransferase levels after 3 days of treatment; no notable morphologic changes were noted in the livers of these animals at necropsy. This same finding is reported in humans and mice following praziquantel treatment and may be due to the movement of dead flukes from the mesenteric arteries and bile ducts into the liver, causing the release of hepatocellular enzymes into the plasma. In loggerhead sea turtles (*Caretta caretta*), plasma concentrations of praziquantel were found to be measurable in animals that received a multidose regimen compared with the nonquantifiable concentrations in those animals that received a single dose.[25] The multidose animals had concentrations that persisted for up to 48 hours, though there was some degree of individual variation. One of the turtles that received a single high dose also developed necrotizing skin lesions that resembled toxic epidermal necrolysis 48 hours after administration; the lesions resolved 11 days later. Although praziquantel appears relatively safe, it has been shown to cause anaphylactic-like reactions in ball pythons (*Python regius*) and should be used cautiously in this species.[26] Current recommendations for these drugs are listed in Table 120.3.

ECTOPARASITICIDES

Ticks

The need for tick control in reptiles has grown over the past several decades as more wild-caught animals have been imported with tick infestations. Ideally, external parasites should be removed manually whenever possible, but, with severe infestations, chemical intervention may be necessary for both the animal and the environment. Permethrin has become a common therapy for tick control in reptiles; however, several different commercial formulations contain ingredients that have been found to be toxic to reptiles. For example, piperonyl butoxide, which is added to some formulations as a synergist, has been associated with snake mortalities.[27] Currently, Provent-a-mite spray (Pro Products, Mahopac, NY), which contains 0.5% permethrin, is the only patented United States Environmental Protection Agency– and United States Department of Agriculture–approved acaricide product for use on reptiles and does not contain additives that pose a severe risk to most animals.

Juvenile African spurred tortoises (*Centrochelys sulcata*), juvenile green iguanas, and adult rosy boas (*Lichanura trivirgata*) given 6 applications of Provent-a-mite topically or on their substrate per label directions, but at 10 times the recommended dosage at each application, showed no signs of permethrin toxicosis.[28] One tortoise developed a thick, foamy covering over the skin, but no other signs of ill health were reported. Necropsy of 1 treated snake that had refused food before the study and then exhibited a kinked appearance showed no histologic evidence of an underlying disease process or toxicity. In leopard tortoises (*Stigmochelys pardalis*), permethrin and several other acaricides were assessed for toxic effects, as well as efficacy against the African tortoise tick (*Amblyomma marmoreum*).[29] Amitraz, cyfluthrin, and permethrin produced transient side effects, including decreased food consumption, reduced defecation frequency, diarrhea, and skin and eye irritation, that lasted for less than an hour after treatment, whereas carbaryl and chlorpyrifos produced prolonged effects lasting several hours. Chlorpyrifos, cyfluthrin, lindane, and permethrin treatment led to 100% mortality of ticks within 24 hours of application; cyfluthrin and permethrin continued to cause 100% mortality when diluted to as low as 1:10,000. Cyfluthrin and permethrin were therefore considered the safest and most effective acaricides for treating leopard tortoises. Comparatively, an additional study in leopard tortoises found that amitraz was successful in detaching and killing ticks without any adverse effects.[30]

A single injection of ivermectin was found to remove ticks on rat snakes, Indian cobras (*Naja naja*), and Indian pythons (*Python molurus*) without any side effects.[31] However, other studies have shown that ticks can recover from ivermectin-induced paralysis with time,[32] so good sanitation and concurrent use of acaricidal sprays may be necessary. Caution should always be used when administering ivermectin to reptiles, because fatal side effects can occur, especially in chelonians, skinks, and indigo snakes. See Chapter 139 for more discussion on treatment options. Current recommendations for these drugs are listed in Table 120.4.

Mites

Severe infestations of the snake mite (*Ophionyssus natricis*) can cause serious health problems for snakes, including skin damage, blood loss and severe anemia, and the spread of bacterial and viral pathogens. If a snake is infested, the parasite will also be present in its habitat, and environmental control, in and out of the enclosure, will be required. Current recommendations for medical therapies to control and eradicate snake mites (or other reptile mites) can be found in Table 120.5.

Currently, the only licensed product for treatment of mites in reptiles is Provent-a-mite spray (Pro Products, Mahopac, NY), though other therapies, such as natural pyrethrin and synthetic pyrethroid, have been empirically used. Pyrethroids tend to be more potent and have a longer half-life than pyrethrins. Both products are applied topically, therefore it is important to remove any residual product by thorough rinsing to prevent systemic absorption and toxicity.[33] Permectrin II (Bayer HealthCare, Shawnee Mission, KS), which contains 10% permethrin, was diluted to a 1% solution (0.1% active ingredient) and applied to several snake species and a blue-tongued skink (*Tiliqua scincoides*), as well as their enclosures topically via spray bottle over an 18-month period. Only one toxic reaction was observed in an adult green tree python (*Morelia viridis*); the animal exhibited convulsions, ataxia, and open-mouth breathing within 30 minutes of spraying but recovered with supportive care. The author suggested that the toxicity was most likely due to an exposure to 2% trichlorfon solution 10 days prior, prompting a recommendation that permethrin should not be used

VetBooks.ir

TABLE 120.4 Treatment Recommendations for Tick Infestations in Reptiles

Treatment/Species	Dosage	Source	Comments
Pyrethrin and Pyrethroids			
All reptiles	1% topically as a spray, remove excess; repeat in 10 days	Experimental[1,28,29]	Do not use with organophosphate insecticides—convulsions, ataxia, and dyspnea can occur. Rinse off as much as possible after application in snakes to prevent absorption and systemic toxicity
Cyfluthrin			
Leopard tortoises	As directed on label	Experimental[29]	Associated with toxicity in snakes and lizards at low doses
Ivermectin			
Rat snakes, Indian cobras, Indian pythons	Single 0.75 mg/kg injection SQ	Empirical[31]	Caution in chelonians, skinks, and indigo snakes; fatal toxicity possible
Lizards	Single dose of 0.2 mg/kg PO or SQ, repeat in 2 weeks	Empirical[41]	

TABLE 120.5 Treatment Recommendations for Mite Infestations in Reptiles

Treatment/Species	Dosage	Source	Comments
Pyrethroid			
Snakes and blue-tongued skink	1% topically as a spray, remove excess; repeat in 10 days	Empirical[33]	Do not use with organophosphate insecticides—convulsions, ataxia, and dyspnea can occur. Rinse off as much as possible after application in snakes to prevent absorption and systemic toxicity
Fipronil Spray			
All reptiles	0.29% topically, remove excess, allow to air dry; repeat weekly or every other week for 6–8 weeks	Empirical (Stahl S, personal communication, 2017)	Use caution when applying to smaller or juvenile reptiles
Ivermectin			
Snakes	5 mg (10 mg/mL) in 1 quart or liter water as a spray; shake vigorously before each use, maintain in an opaque container	Empirical[36]	Use with caution for chelonians, skinks, and indigo snakes; fatal toxicity possible
	0.2 mg/kg SQ once a week for three doses	Empirical[6,37]	
Lizards	Single dose of 0.2 mg/kg PO or SQ, repeat in 2 weeks	Empirical[41]	
Snakes and lizards	0.2 mg/kg IM once a week for up to 3 weeks	Empirical[37]	
	5 mg in 1 liter water sprayed topically once a week for up to 3 weeks	Empirical[33]	
Carbaryl Powder			
Lizards	5% powder topically once a week, rinse off with water after 1–5 minutes	Empirical[41]	Keep out of the lizard's mouth
Predatory Mites			
Stratiolaelaps scimitus mites	1 L, approximately 15,000 mites	Case report[39]	Controlled lizard mites in 5 days
Cheyletus eruditus (taurrus) mites	Predatory mites	Experimental[40]	

concurrently with an organophosphate insecticide.[34] In brown tree snakes (*Boiga irregularis*), pyrethrin applied topically produced mortalities, whereas permethrin showed no toxicity. Oral pyrethrin at both high and low dosages produced mortalities in reptiles too. Affected animals became disoriented and developed muscle tremors and mydriasis; death occurred within a few hours of administration.[35]

One important precaution with the use of natural pyrethrin and synthetic pyrethroid compounds is the increased toxicity associated with exposure to the fumes of the products. If applied directly to the reptile, it must not be placed in a bag or air-tight container directly afterward, as the product quickly becomes toxic with restricted air flow. If applied to the cage or substrate, they must be allowed to air out and dry before placing the reptile back in the enclosure. Removal of the water bowl for 24 hours to avoid the possibility of the reptile soaking in the bowl right after application and ingesting the water is an important precaution. Additionally, neonate and juvenile reptiles may be more sensitive to these

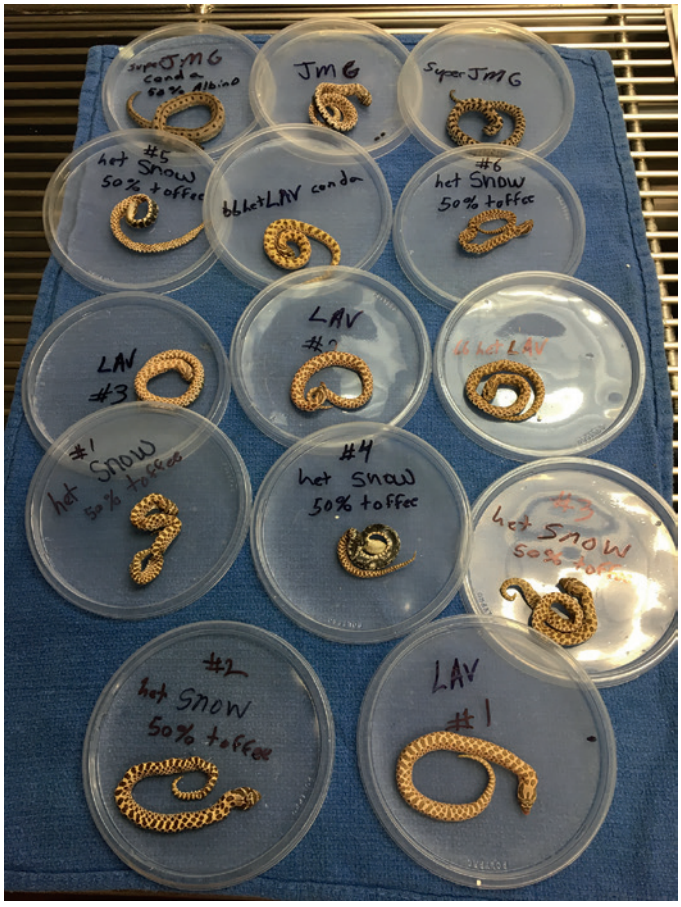

FIG 120.1 A group of juvenile western hognose snakes (*Heterodon nasicus*) that died shortly after being treated for snake mites using the same topical permethrin product and protocol that was used on adult hognose snakes with no adverse effects. Caution must be used in neonates, juveniles, and smaller species of snakes (many colubrids), as they seem more sensitive to these drugs. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

products than adult reptiles. Juvenile colubrids have died following the same directions safely used for adult animals (Fig. 120.1).

Fipronil spray 0.29% (Frontline Fipronil Spray Treatment, Merial, Duluth, GA) belongs to the phenylpyrazole chemical family and is an insect neurotoxin that has been successfully used to treat mites in reptiles. Because the spray is lipid based, it is not water-soluble and is thought to have a residual effect once applied. Stahl (personal communication, 2017) has used fipronil spray extensively to successfully treat snakes for mites. Larger snakes are sprayed directly, avoiding the eyes and mouth, or the spray is applied using latex gloves (spray gloves then rub gloves over reptile) to disperse. Once fipronil is applied, the snake is allowed to air dry before being placed back in its enclosure, or it can be wiped off after 5 to 10 minutes. Caution should be used with topical application of fipronil on smaller or juvenile snakes (apply with sprayed paper towel or cotton-tipped applicators) or use fipronil only in the environment for these more-sensitive reptiles. In these cases when the fipronil is not used directly on the animal, a warm water bath with a pinch of soap added to drown/remove mites from the reptile can be used in combination with environmental treatment with fipronil. Environmentally, fipronil can be liberally sprayed on all surfaces in the cage; however, it is important to allow the fipronil to fully dry before replacing the snake. During the treatment period any particulate substrate and wooden cage furnishings should be removed as they provide places for female mites to lay eggs and make treatment more challenging (this is true for all mite treatments discussed). The water bowl is removed during environment treatment and for 24 hours after fipronil spray has been applied to the snake. The snake and environment can be treated weekly or every other week for 6 to 8 weeks.

Ivermectin therapy has been used for mite treatment, both as an injection and a topical spray. Because ivermectin has a long half-life, it has been suggested that it may make treating the animal's environment unnecessary; however, not treating the environment can lead to reinfection. When using ivermectin spray follow a similar protocol described for fipronil spray, with treatment revolving around application to both the reptile and environment. Stahl (personal communication) has found weekly treatments (with a freshly made "batch" of ivermectin spray solution and by shaking the solution regularly to mix the oil-based ivermectin and water) to the reptile and liberally in the environment for 6 to 8 weeks may be necessary for successful eradication of mites. Recommended injectable doses of 0.2 mg/kg have been shown to be high enough to kill mites, but experimental work with fowl mites (*Dermanyssus gallinae*), which are closely related to the snake mite, require a dose of 0.4 to 0.5 mg/kg to be effective in mice.[4] Further work on ivermectin's effectiveness against *Ophionyssus natricis* and other reptile mites (e.g., lizard mites, *Hirstiella* spp.), as well as its safety in reptiles, needs to be done before dosages can be routinely recommended.[32,36,37] As previously mentioned, caution should always be used when administering ivermectin to reptiles, as fatal side effects can occur, especially in chelonians, skinks, and indigo snakes.

Dichlorvos-containing strips were once recommended for managing mites; however, due to their toxicity to both animals and humans, they should now be avoided. Formulations containing oils, synergistic compounds, or insect growth inhibitors should also be avoided as they can be toxic.[5] The organophosphate trichlorphon was shown to be highly effective against snake mites when applied as a 0.15% spray to both the animal and its cage for 24 hours.[38] It is recommended to remove the animal's water bowl before application and for 24 hours after treatment to prevent accidental ingestion and poisoning. Organophosphates should not be used concurrently with other cholinesterase-inhibiting insecticides, such as other organophosphates or carbamates. When used, animals should be closely monitored for signs of toxicity, including excessive salivation, abnormal posturing, or muscle twitching. Snakes exhibiting any of these signs should be thoroughly rinsed with water and promptly treated with atropine (0.4 mg/kg IM) and fluids.[5]

More recently, predatory mites have been investigated as a nonchemical, biological control method for snake and lizard mites. A recent report found that a 1-L culture of approximately 15,000 predatory soil mites (*Stratiolaelaps scimitus*) was sufficient to eliminate lizard mites (likely *Hirstiella* sp.) from bearded dragons and their enclosure in 5 days.[39] The mites, advertised as *Hypoaspis miles,* are commercially available. *Cheyletus eruditus,* another predatory mite, has also been evaluated as a biological control method for *O. natricis.*[40] When the two species of mites were placed in a tube together, only 6% of the snake mites survived for 48 hours in comparison to a 92% survival rate for snake mites housed alone in a control tube. A follow-up study using *O. natricis*–infested ball pythons found that after 15 days of treatment with the predatory mites, an average of two mites per snake remained, compared with 48 mites per snake in a control group. These predatory mites appear to be a promising nonchemical method of eliminating reptile mites without the potential side effects of some of the chemical treatments.

Mental Health Treatment (Psychopharmacology and Behavior Therapy)

Leticia Mattos de Souza Dantas and Teresa Bradley Bays

WELFARE AND PSYCHOLOGICAL WELL-BEING

Clinical Significance and Known Etiological Cause(s)

Similar to mammals and birds, reptiles have a wide range of sensory and cognitive abilities that facilitate awareness of their surroundings but can also experience distress related to aversive emotional states.[1] The ability to achieve different forms of learning, including recognition of visual, chemical, seismic, social cues, and special-object arrangement are a few examples of the wide range of cognitive capacities in reptiles.[2] The reptilian neuroendocrine system is comparable to other vertebrates, and many behavioral indicators of stress are often analogous to those of birds and mammals. However, it is important to keep in mind that reptiles not showing recognizable, physiological, or behavioral indicators of stress could still be experiencing distress.[3] Due to the evolutionary gap, some of the most reliable clinical signs in the diagnosis of fear- and anxiety-based problems in mammals, facial expressions and body language, are not always evident in reptiles.[1] Studies to investigate the correlation between behavioral change and the neuroendocrine processes related to distress and specific emotional states in reptiles and amphibians are still lacking.

Clinical Presentation and Diagnostic Confirmation

Behavioral pathologies are diagnoses of exclusion in veterinary medicine. A detailed history that includes behavioral and environmental information, an interview with the client for further clarification, a physical examination, and basic laboratory tests are all necessary to exclude medical causes not related to mental health. See various applicable chapters in this book for detailed information on disease diagnosis.

The most common behavioral symptoms presented by reptiles are aggression, stereotypical or repetitive behaviors (including self-injurious behaviors), and stress/fear-based behaviors.[1,4–6] All of these clinical presentations can be caused by several disease processes. Once a reptile becomes ill, regardless of the cause, it might become fearful or defensive, resistant, and even aggressive toward handling and being touched. Stressors that were previously tolerated will likely lead to distress as a consequence of lowered stress tolerance due to the patient experiencing discomfort.

Preferred Medical Therapy

Mental health treatment in veterinary medicine often includes a combination of recommendations and treatments, including environmental management and enrichment, behavior therapy, and medication. In mammals and birds, this multimodal approach has proven to lead to more effective and quicker results when compared to monotherapy. Studies in these areas are lacking for reptiles, and most interventions are based on environmental management and enrichment. Working with these patients, clinicians and caretakers must strive to avoid fear and aggression-inducing triggers.

When treating a patient that is experiencing psychological distress, all techniques used should target decreasing or avoiding the neuroendocrine stress response. In many cases, simply changing how the animal is handled and the setup of the cage (providing a sense of safety and control, e.g., multiple retreats or hide-outs) can be the most beneficial intervention.[4–6]

One of the most important pillars of behavioral medicine is client education. For any intervention to be effective, the caregiver must learn to recognize behavioral signs of stress for the particular species in hand. Then putting this knowledge into practice by providing safety and management instructions to clients will help them perceive signs of distress in their pet and be educated about what to do next. The same applies for the application of behavior therapy.

Behavior therapy, behavior modification, and cognitive behavior therapy are terms often used interchangeably; however, behavior modification generally refers to any procedure that modifies behavior (including brain surgery and shock therapy), and cognitive behavior therapy specifically applies to treatments that change cognitions. Therefore, behavior therapy (the systematic use of learning procedures to treat psychological problems and change behavior) is the more appropriate term to refer to the interventions prescribed in veterinary behavioral medicine.

Many behaviors develop, evolve, and are maintained through learning processes. The brain is molded by experience as every sensory and cognitive process impacts specific neural circuits, changing how future stimuli will be registered. Behavior therapy aims to affect neural plasticity and lead to behavioral change. Besides helping patients with aversive or distressing emotional states and dysfunctional behaviors, behavior therapy improves daily functioning and can decrease social stress. Data demonstrating the efficacy of specific techniques commonly used for birds and mammals is not available for reptiles. See Chapter 14 for examples of the use of operant conditioning–based therapy techniques to modify behavior.

Desensitization and Counterconditioning Therapy

Based on classical conditioning learning theory, human and nonhuman animals constantly learn through association between stimuli. In the classic example demonstrated by Pavlov, an unlearned response to a stimulus, such as drooling at the sight of food, is paired with a neutral stimulus, such as ringing a bell. Through repetition of ringing a bell every time food is offered, a dog will begin to associate the sound with the physiologic response of drooling in anticipation of a meal. Eventually one can ring a bell without the food present and the dog will begin to salivate. This principle of learning has many applications for veterinary patients, and detailed explanations of learning theory are available.[7]

Classical conditioning learning is commonly how fears are learned and how phobias develop. This process can lead to sustained distress

VetBooks.ir

or anxiety if the fear-inducing stimulus is constantly present or is presented repeatedly. A single experience can also be enough for some individuals prone to develop fear- and anxiety-based problems. However, learning via classical conditioning is also an effective therapeutic tool.

In desensitization therapy, the protocol should plan for gradual exposure of the patient to the fear-inducing stimulus. For example, the stimulus should be far enough away or in a reduced amount/time to not elicit the behavioral response. From there, it is slowly moved closer or increased incrementally so that the animal does not show signs of fear or other unwanted emotional or behavioral responses. Each incremental increase should only occur if the animal is showing no signs of stress (or the behavior that needs to be modified) at the current level. If the animal does begin to show signs of stress or aggression, they are becoming sensitized and the exercise must be stopped and restarted from the previous step.

Desensitization should be paired with counterconditioning therapy, which aims to create a positive or pleasant association with the stimulus. A naïve animal can also be *conditioned*, in other words, taught to tolerate and even enjoy a stimulus, interaction, individual, etc., by the same principle. Tools for counterconditioning or conditioning therapy can be as simple as the reptile's preferred foods. This principle is very effective in teaching an animal to tolerate handling and different medical procedures.[8]

Differential reinforcement of alternative behaviors is another type of therapy methodology that attempts to replace unwanted behaviors with actions that are more appropriate for a situation and less harmful for the individual. It is frequently used in conjunction with desensitization and counterconditioning therapy, especially when treating a problem that is a result of stress and fear.

In operant conditioning–based therapy, there are two paradigms: reinforcement (positive and negative) and punishment (positive and negative). Whereas both may lead to behavior change, punishment and negative reinforcement are counterproductive to mental health treatment since they will increase the animal's stress levels and cause fear and many times frustration. Treatments for animals should focus on removing the reinforcements for unwanted behaviors (when possible or applicable), teaching acceptable alternative behaviors in the same context, and using positive reinforcement to maintain these desired behaviors long term.[9] Similar to desensitization and counterconditioning, these principles can be applied to teach reptiles to feel safe and to accept different types of handling.[8]

Environmental Enrichment and Management

Environmental enrichment and management are covered in detail in other chapters of this textbook, but it is worth mentioning that enrichment and proper cage setup are crucial for captive reptile welfare. Most problem behaviors (not related to reproduction or other nonenvironmental-related physiological or endocrinologic changes) reported in the literature stem from a plethora of issues related to poor adaption to confinement, unacceptable physical environments, or inappropriate social interactions. It is also fundamental that the client is instructed to provide a home/cage environment that promotes predictability and consistency to the reptile, which significantly helps in decreasing stress levels.[4–6,10]

Pyschopharmacology and Endocrine Therapy

There are no safety or efficacy studies on the use of any psychoactive drugs for behavioral medicine treatments in reptiles. Most information published to date discusses the use of certain psychoactive drugs for chemical restraint, sedation, anesthesia, and pain management.[11]

A series of studies by Deckel,[12–14] Deckel and Jevitts,[15] and Deckel and Fuqua[16] evaluated behavioral changes in territorial behavior of *Anolis carolinensis* after injection of fluoxetine and other serotoninergic agents, injection of alcohol, and with exposure to mild stress. While these studies have started to shed a light into the interaction of antidepressants and the brain of *Anolis* lizards, controlled studies and clinical applications for veterinary practice are lacking.

Studies on the use of the antidepressant fluoxetine in newts[17] and fish[18] have been published, likewise with no follow-up controlled studies or clinical applications so far. In a study by Larson & Summers, setraline (dissolved in DMSO, resulting in a final sertraline concentration of 10 mg/kg and final DMSO concentration of 1%) was administered in *Anolis carolinensis* with the goal of decreasing aggressive behavior in five pairs of captive males. The animals were separated and treated with sertraline or placebo. Sertraline was given in food to both males or neither male in each pair for 1 week. The pairs were reintroduced, and behavior and social status was recorded. Latency to eyespot darkening was significantly retarded in "dominant" males treated with sertraline, and aggressive displays and attacks were reduced.[19] The role of monoamine neurotransmitters (among other neurotransmitters, neuropeptides, and hormones, such as the melanophore-stimulating hormone) in emotional processes and behavior responses is still unclear for reptiles, making it difficult to make a case for the use of psychoactive medication for the class Reptilia at this time.[20] The author recommends caution when extrapolating doses and treatment regimens from birds and mammals to reptiles because of the significant differences with regard to neurophysiology, neuroendocrinology, general metabolism, and the current lack of knowledge on how these drugs interact in the brain of different reptile species.

Hormone treatments may be used to treat problem behaviors related to the reproductive cycle or that are influenced by reproductive hormones. Castration might be effective in reducing territorial- and breeding-related aggression in some species,[21] but it has no effect on aggression caused by fear or pain. The use of hormones is beyond the scope of this chapter (see Chapters 79, 80 and 125).

Finally, a patient in pain will also be in psychological distress and is more prone to become aggressive and show behaviors that are consistent with distress.[4–6] However, pain management is also beyond the realm of this chapter (see Chapter 50), but it is worth noting that pain prevention and management are paramount for reptile mental health and welfare.[10]

Patient Follow-Up

After treatment is prescribed, close follow-up is advised until the problem behavior is resolved. The frequency of communications with clients may depend on the severity and welfare impact of the problem.

Nutritional Therapy

Thomas H. Boyer and Peter W. Scott

Warm reptiles to their preferred optimal temperature zone and ensure appropriate hydration before starting nutritional support. A dedicated room kept between 27°C to 29°C (80°F to 85°F) for reptiles with spot heating in cages helps and is better than providing just focal heat. Spot heat can be provided with under-tank heaters or overhead heat sources; be aware that both can burn reptiles. Overhead heat sources can be a fire hazard. Incubators are another excellent means of heat support, but can be too small for larger patients. Use indoor/outdoor thermometers to carefully monitor temperatures; overheating (>41°C, 105°F) kills reptiles quickly (see Chapter 46 for further details).

METABOLIC SCALING

Much has been written on metabolic scaling in reptiles, where metabolic rate (P_{met}) = mass constant × body mass $(M_b)^{mass\ exponent}$. Jacobson cautioned that when considering metabolic scaling for antibiotic dosing there are a host of variables to consider, and many of these apply equally to metabolic scaling of nutritional requirements.[1] For instance, the mass constant, typically quoted as 10 actually varies between reptiles (from 1–5 in snakes, 6–10 in lizards, and unknown for chelonians and crocodilians). The mass exponent also varies within groups (for instance, $P_{met} = 4.390\ M_b^{0.98}$ in colubrids, $P_{met} = 1.788\ M_b^{1.09}$ in boids, and $P_{met} = 3.102\ M_b^{0.86}$ for colubrids and boids combined) and both may be compromised if multiple taxa are combined.[1] In the previous example, mass constant is too low for colubrids, too high for boids, and the mass exponent is too low for both.[1] Furthermore, variable health status (healthy vs. sick will change mass constant), activity level (studies based on active, wild reptiles vs. sedentary captives), body temperature, and physiology of over 10,000 reptile species, makes it hard to derive any universal equation, as even extrapolation between species within groups can be inaccurate.[1] Equations based upon a single species that cover all ages and sizes from neonate to adult would provide the most biologic significance, but only for that species, and few of these complete equations exist.[1] Therefore the best advice is to consider any such equation as a guide and to adjust based on careful monitoring and individual patient response.

DEHYDRATION AND ORAL FLUID THERAPY

Most reptiles are capable of recovering from levels of dehydration that would kill most mammals. Dehydration is difficult to estimate visually in reptiles. Dehydration greater than 8% to 10% results in loss of moisture in the retro-orbital fat pads and sunken eyes. Reptiles have limited skin elasticity, thus skin turgor is of limited value. Hypertonic (hypernatremic, hyperosmolar) dehydration occurs when proportionally more water than sodium is lost from the body.[2–4] This results in an increased concentration of sodium in the extracellular fluid, which becomes hypertonic regarding the intracellular fluid, and therefore attracts water from the body cells. Hypertonic dehydration is common in reptiles that are not drinking or are hibernating, have end-stage renal disease, or heat stroke (hyperthermia). Isotonic (isonatremic, iso-osmolar) dehydration occurs when proportionally the same amount of water and sodium is lost from the body, so the sodium concentration of the extracellular fluid and hence its tonicity do not change.[2,3] Isotonic dehydration generally occurs as a result of hemorrhage, diarrhea, and short-term anorexia or vomiting. Hypotonic (hyponatremic, hypoosmolar) dehydration occurs when proportionally more sodium than water is lost from the body. This results in a decreased concentration of the extracellular fluid, which becomes hypotonic in comparison to intracellular fluid, which attracts water from the extracellular fluid. Hypotonic dehydration is common with prolonged anorexia and undernutrition.[2,3]

In green iguanas (*Iguana iguana*) subjected to water deprivation, elevations of sodium and potassium increased from baseline (118.5 mmol/L [mEq/L] and 4.2 mmol/L [mEq/l] respectively) to 135.5 mmoL and 4.9 mmol/L by day 3 and 150 mmol/L and 5.3 mmol/L by day 7, respectively. In addition, overt activity was almost nonexistent by day 5.[5] Other parameters that would be expected to elevate with hypertonic dehydration include packed cell volume, total protein, albumin, and chloride. Decreases in sodium and osmolality are good indicators of hypotonic dehydration but must be referenced to species normal or previously unremarkable panels from the same individual.

Maintenance fluid requirements have been determined for some species and range from 10 to 30 mL/kg/day. Daily water budgets for the waxy tree (*Phyllomedusa sauvagei*) and Mexican leaf frogs (*Pachymedusa dacnicolor*) have been documented as 8.6 mL/kg/day; Mojave fringe-toed lizard (*Uma scoparia*) as 11.3 mL/kg/day; diadem snakes (*Spalerosophis diadema*) as 16.7 mL/kg/day; African spurred tortoise (*Centrochelys sulcata*) as 27.6 mL/kg/day; common chuckwalla (*Sauromalus ater*) as 24.5 mL/kg/day; and desert iguana (*Dipsosaurus dorsalis*) as 30.5 mL/kg/day.[6,7] Rehydration typically involves giving maintenance (see Section 11) plus 25% to 33% of the fluid deficit/day. Fluid deficits should be made up over 72 to 96 hours, and rehydration rates of 3× maintenance or greater may be associated with fluid overload and should be avoided. Fluid type has been heavily debated in reptiles due to their larger intracellular fluid volume with presumed lower osmolality relative to mammals, but recent studies have shown reptiles' osmolality similar to mammals for freshwater turtles and crocodilians and sometimes higher than mammals in terrestrial and marine reptiles.[5,8,9] Formulas estimating osmolality in reptiles have been shown to be inaccurate in bearded dragons (*Pogona vitticeps*) and alligators (*Alligator mississippiensis*) but accurate

VetBooks.ir

in corn snakes (*Pantherophis guttatus*).[8–10] Recommended fluids include any warmed, balanced, isotonic crystalloid (see Chapter 87, Emergency and Critical Care, for further details). Lactated Ringer's solution, Normosol-R, and Plasmalyte-A are commonly used in reptiles.[11] Dextrose (5%) is isosmotic during administration, but metabolism of the sugar produces net water, which moves into the intracellular space. Consequently, dextrose is indicated where there is profound water deficiency with hypernatremia. Isotonic fluids will not have a severe negative impact on electrolyte imbalances and will benefit the patient until more specific fluid therapy can be determined from clinicopathologic results. LRS does not exacerbate lactic acidosis in mammals, even with liver disease, and reptiles are more tolerant of lactic acidosis than mammals.[12] Dextrose solutions should generally not be administered subcutaneously, but some (e.g., half-strength saline 5% glucose, 5% dextrose, and 4 g/L sodium chloride; two-thirds 5% glucose and one-third normal saline) have been successfully utilized by this route in humans.[12,13]

Fluids can be given by soaking, enterally via stomach tube (Fig. 122.1A–C), subcutaneously, intravenously, intraosseously, or coelomically (or by combination of routes). The authors no longer recommend coelomic fluid administration in reptiles because of the risks of visceral trauma and compression and other variables that may adversely affect absorption and assimilation (e.g., coelomitis, hypoalbuminemia, ascites, etc).[14] If the patient will drink, soaking is typically used for maintenance and mild dehydration. Use 24°C to 27°C (75°F–80°F) shallow, chin-deep water for several hours to overnight. All reptiles can drown in deep water; if they attempt to swim, the water is too deep. Accurately monitoring of body weight will determine whether they are taking in water. Enteral fluids can be given at 5 to 10 mL/kg every 8 to 24 hours via stomach tube with mild to moderate dehydration (<5%). Close monitoring of body weight, plasma osmolality, PCV, and urination helps evaluate response to hydration; however, monitoring PCV was considered inaccurate for evaluating hydration status in at least one species of avian reptile but has not been evaluated in nonavian reptiles.[15] For details on catheterization and parenteral fluid therapy, see Chapter 44 and Section 11.

NUTRITIONAL SUPPORT

Refeeding Syndrome

Refeeding syndrome is a syndrome consisting of metabolic disturbances that occur as a result of reinstitution of nutrition to patients who are starved, severely malnourished, or metabolically stressed due to severe, sometimes acute illness.[16,17] During prolonged fasting (>4–5 days in cats and >2–5 days in humans but unknown in reptiles), the body maintains extracellular electrolytes by depleting intracellular electrolytes, especially potassium (K), calcium, phosphate (P), and magnesium (Mg). Thiamine is also depleted.[18] Once refeeding starts, blood glucose rises and insulin secretion resumes and pumps glucose and K into cells, which may result in hypokalemia, accompanied by hypophosphatemia, hypomagnesemia, and thiamine deficiency. Electrolyte imbalances may

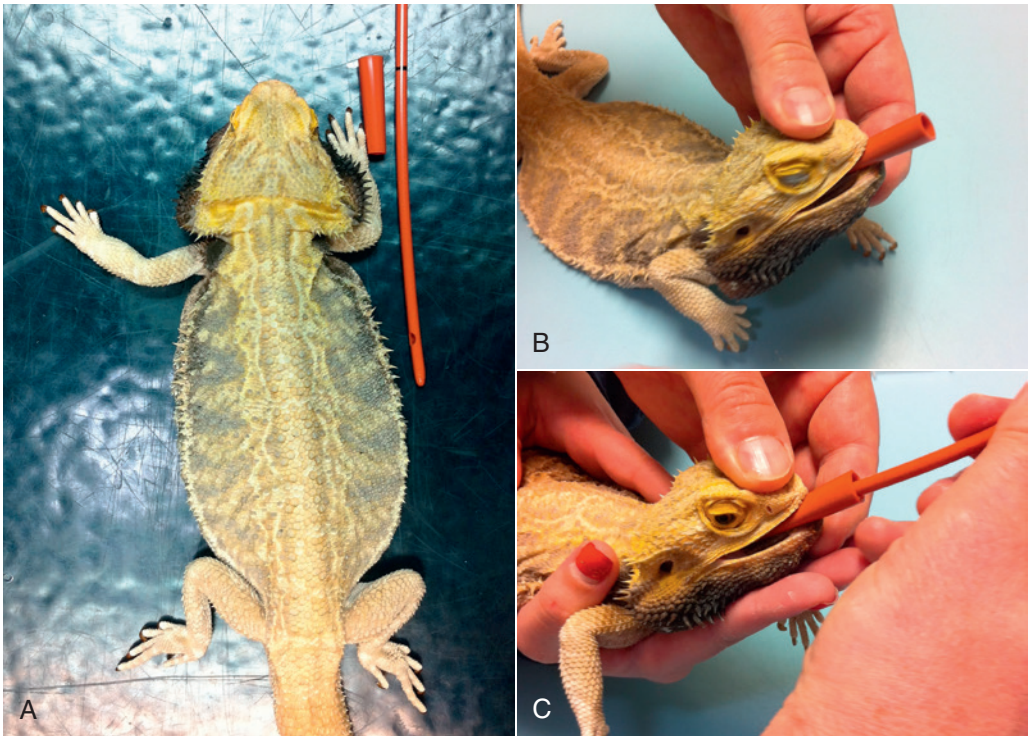

FIG 122.1 (A) To stomach-tube a lizard, here demonstrated in a bearded dragon (*Pogona vitticeps*), measure distal tube placement at one-third to one-half of the distance between front and rear legs. (B) Insert soft mouth speculum, and hold mouth shut on speculum. (C) Pass lubricated premeasured tube and give food slowly.

VetBooks.ir

lead to widespread cellular dysfunction, cardiac arrhythmias/arrest, hemolysis, pulmonary edema, convulsions, and coma.[18]

When nursing a reptile that has been anorectic for a long period, initially focus on rehydration for 2 to 5 days. Supplementation with water-soluble vitamins may be beneficial. When starting nutritional support, limit intake to 10% to 25% of calculated requirements and increase slowly over several days or even weeks. Monitor plasma levels of P, K, Mg (if normal values are available), and glucose as frequently as feasible (ideally every 1-2 days). Watch for the aforementioned worsening clinical signs, or increased lethargy, suggestive of refeeding syndrome and reduce nutritional support if present. Severe hypophosphatemia (≥30% drop from baseline), in particular, is an early warning sign of refeeding syndrome, so monitor closely.[18] Slow reintroduction of food over days to weeks may be required and additional oral supplementation of K, P, and Mg may be indicated if below normal. If the patient remains stable, increasing nutritional supplementation can commence after several days.

Stomach Tubing

Oral feeding of liquid products is generally poorly accepted by most reptiles, and aspiration pneumonia is a significant risk. Stomach tubing is faster, safer, and can be taught to almost all caregivers. Soft, pliable tubes and oral speculums are better than metal or hard plastic to avoid dental or mandibular trauma. For small lizards, use the flared, catheter tip connector end of a red rubber catheter as an oral speculum, and run the cut red rubber catheter through it. In larger lizards speculums can be improvised from 3 mL cut syringes, or syringe cases, generously wrapped with elastic adhesive tape (Elastikon Bandage Tape, Johnson & Johnson, or Veterinary Elastic Adhesive Tape, 3M). Have one person vertically restrain the lizard with one hand behind the head, and with their other hand they can pull down on the dewlap while the feeder holds the maxillae. As soon as the mouth is open, insert the mouth speculum, which the lizard will typically bite down on. Immediately the restrainer should hold the mouth firmly closed so the lizard does not push the speculum out with its tongue. The feeder can then insert the well-lubricated, premeasured feeding tube through the speculum, down the esophagus, and into the stomach, which lies on the left, in the first third to half of the coelom.

Snakes do not require a speculum for stomach tubing and can be fed in the stomach or as far distally in the esophagus as feasible. Stomach location is typically midbody. After feeding, keep the snake's head elevated and gently digitally occlude the esophagus as the kinked tube is withdrawn to prevent regurgitation. Milking food material deposited into the esophagus down to the stomach may help prevent regurgitation.

Chelonians can be stomach tubed, especially if small or weak, but repeated forceful head and neck extension can be traumatic and is not recommended. It is preferable to place an esophagostomy tube if multiple feedings are anticipated (see Chapter 45). For single feedings, it is easiest to pass a stomach tube with the head extended, although a flexible, well-lubricated, small-gauge tube can be passed with the head retracted. Sedation or anesthesia may be required to extract the head. Premeasure and mark the tube from the tip of the mouth, down the extended esophagus, to the mid left pectoral scute. Restrain the head from above, just behind the skull laterally, so that as the chelonian head retracts, the restrainer's thumb and forefinger stop at the cranial carapace (which may need to be padded). Do not let go, as subsequent attempts to extend the head and neck become more difficult. If the mouth opens, immediately block one side with a speculum, but do not place behind the rhamphotheca. If the mouth is not open, with the restrainer's other thumb and forefinger, apply slow, steady downward traction to the mandible until the mouth opens. If this is unsuccessful, the feeder can insert a dull right-angle dental probe into the mouth and direct it ventrally, gently, into the floor of the mouth, until the chelonian opens its mouth and a side speculum can be placed. Many aquatic species can deliver a powerful bite, and caution is required. The lubricated, premeasured stomach tube can be passed down the esophagus—slight resistance may be felt as it passes through the gastroesophageal sphincter—to the level of the left midpectoral scute. Administer liquid diet slowly over a minute, with the chelonian held vertical, and discontinue if any regurgitation is noted in the esophagus or mouth.

Stomach Volume

The maximum gastric volume of most reptiles has not been determined. One study in the viviparous lizard (*Zootoca vivipara*) determined a calculation for stomach volume, where $V = 0.048W^{0.99}$ (V is volume in mL, and W is weight in grams).[19] This equation would give stomach volume of 0.24 mL in a 5 g lacertid lizard (48 mL/kg), but its accuracy in other species has not been determined. In red-eared sliders (*Trachemys scripta elegans*), regurgitation was observed in 43% of the turtles following rapid administration into the stomach of 8 mL/kg of dilute barium, but not when administered slowly over 20 seconds.[20] A dose of 25 mL/kg dilute barium was associated with regurgitation in 22% (4/18) of ball pythons (*Python regius*) and 60% (3/5) of green iguanas (*Iguana iguana*).[21,22] In bearded dragons, a dose of 15 mL/kg dilute barium in the distal esophagus resulted in excellent distention of the stomach for the barium series, yet more than half the dragons showed barium in the cranial esophagus. It was unclear if this represented reflux or tracking of the contrast material as the tube was withdrawn from the caudal thoracic esophagus.[23] Given that reptiles needing nutritional support have often been anorexic for extended periods, stomach volume may be reduced, so the authors often start with 5 mL/kg/feeding and slowly increase the volume over several days or weeks. Too large a volume, or too rapid administration, especially early in treatment, will cause regurgitation, whereas overfeeding can overwhelm the alimentary tract and cause stasis. Multiple small feedings are better than a single large feeding. Regurgitation should be avoided, as it often leads to aspiration pneumonia, which can be fatal.

Esophagostomy Tubes

Esophagostomy tubes can be essential for managing chronic nutritional disease in chelonians and are covered in detail in Chapter 45 (Fig. 122.2A and B). Soft silicon tubes are better tolerated, especially for long-term use, than red rubber tubes. Typically 14 to 24 Fr are used, depending on the reptile's size, whereas intravenous tubing also works for smaller reptiles. Stylets are often needed for softer, more flexible tubes. It is wise to perform a radiographic tube check, flush tubes after each feeding with water, and keep capped when not in use. If the patient regurgitates, check tube placement with radiography or endoscopy, make sure environmental temperature is adequate, and reduce feeding for several days. Tubes can be unblocked by placing a small amount of carbonated cola in the tube until it dissolves the clog.

Critical Care Nutritional Foods

Several commercially available products have worked well for nutritional support of reptiles, including Emeraid Carnivore, Omnivore, or Herbivore (LaFeber Co., Cornell, IL); Critical Care, Critical Care Fine Grind, or Carnivore Care (Oxbow Animal Health, Murdock, NE); and Critical Care Formula (Vetark Professional, Winchester, UK) (Table 122.1 for nutritional information). Low-fat elemental or semielemental diets are typically used for the first week or two. Once the patient is stable, there should be a gradual transition to a more complete maintenance diet.

VetBooks.ir

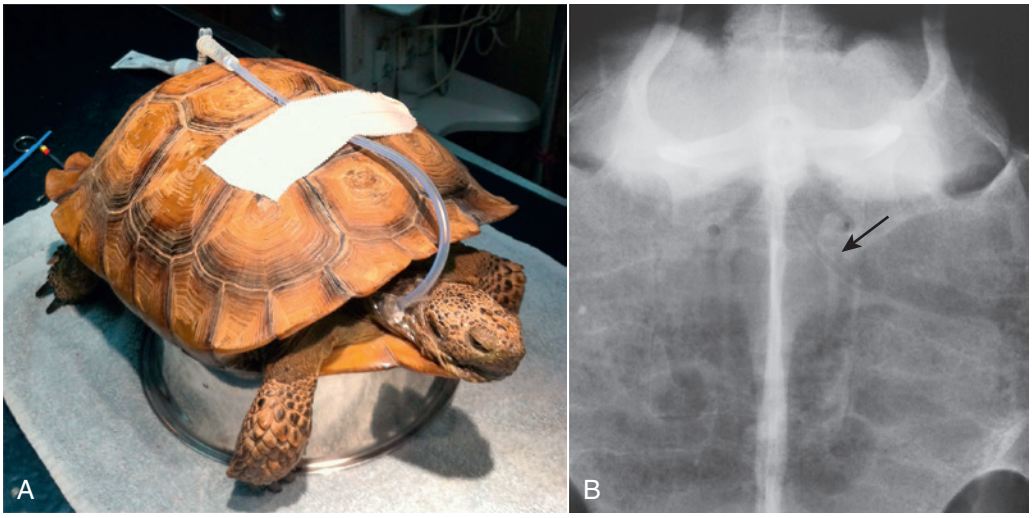

FIG 122.2 (A) Esophagostomy tubes are indicated for long-term administration of fluids, food, or medications to chelonians. (B) Always check tube placement (arrow) with radiography; distal tube should be located within the cranial left quadrant.

TABLE 122.1 Nutrient Profiles of Commercial Diets Used to Feed Reptiles (% of Dry Matter Basis)

Diet	Protein	Fat	Ash	CHO	Fiber	Ca	P	Ca:P
Emeraid Intensive Care Herbivore	19.0	9.5	5.3	63.0	32.0	1.00	0.39	2.5:1
Emeraid Intensive Care Omnivore	20.0	9.5	4.8	62.3	2.5	1.00	0.60	1.6:1
Emeraid Intensive Care Carnivore	37.8	33.9	5.9	14.6	4.5	1.00	0.67	1.5:1
Oxbow Critical Care, Normal or Fine Grind	16.0	3.0	10.0	26.1	21.0–26.0	0.40–0.60	0.20	2.0–3.0:1
Oxbow Carnivore Care	45.0	32.0	8.0	5.6	3.0	1.40–1.80	1.20	1.1–1.5:1
Vet Ark Critical Care Formula	14.5	0.3	6.2	79.0	0	0.41	0.22	1.9:1

Ca, Calcium; *CHO*, carbohydrate; *P*, phosphorus.
Thanks to Kelsey Carter for data collection.

Emeraid and Oxbow recommend various diet mixtures for different reptiles; see the manufacturer guidelines: Emeraid, Life Saving Nutrition, a Division of Lafeber, *Emeraid intensive care basic use guide for critically ill exotic animals,* https://emeraid.com/emeraid-intensive-care-basic-use-guide/; and Oxbow Animal Health website, http://www.oxbowanimalhealth.com/our-products/professional-line/. The goal is to maintain body weight and reverse the decline until the patient can eat on their own.

Cancer Chemotherapy

Antony S. Moore, Joerg Mayer, and Tara M. Harrison

Chemotherapy is the principal modality used to treat systemic cancers such as hematologic malignancies (lymphoma, leukemia) and metastatic carcinomas or sarcomas. In reptiles there is a high incidence of lymphoid neoplasia,[1] suggesting chemotherapy would have a role in the management of neoplasia. The main obstacles for the use of chemotherapy in reptile medicine are the lack of scientific literature from which to infer doses and scheduling, which may in turn exacerbate the preconceptions and misconceptions of owners and veterinarians regarding the toxicity of chemotherapeutic drugs. The goal of chemotherapy in human oncology is to cure the patient, while in veterinary medicine, palliation or remission is a more appropriate goal and, hence, drug dosages and schedules used are less likely to result in side effects. In palliative treatment the primary goal is to improve quality of life, which in veterinary medicine may result in prolonged survival because euthanasia is delayed. Just as quality of life for humans depends largely on preservation of body image as well as essential organ function, owners interpret their impressions of their pet's well-being in terms of their own expectations and beliefs, and this is likely true in reptiles as well. Therefore, communication between the veterinarian and the owner is essential. Options for treatment should never be limited by the veterinarian's interpretation of the owner's finances or preferences; rather, open and honest dialogue will allow an owner to make an informed decision and will ultimately create a "team" approach to chemotherapeutic treatment of the reptile's cancer.

Although it is tempting to think of chemotherapy protocols as a "recipe" for treating cancer, in fact they should be considered a guide. Just as every patient is an individual, their cancer is also individual, and the patient's metabolism and excretion of the drugs is individual. Complete evaluation of the cancer and the patient is therefore very important before administering the first dose of what are potentially toxic drugs.

In general, chemotherapy drugs are most active against cells that are actively dividing and in a particular phase of the cell cycle. Although most tumor cells are in an active phase of the cell cycle, only a small percentage of normal cells are actively dividing. Normal tissues can be classified as static (nerve, striated muscle) in which the capacity for mitosis is limited; expanding (organs, glands) in which mitosis can be induced; and renewing (hematopoietic cells, mucosa, epidermis, gametes, fetal tissues) in which the proliferating proportion approaches that of tumor tissue. In reptiles, proliferation may not be continuous but rather episodic, such as skin renewal (shedding), which could alter the risks for cutaneous toxicity of chemotherapy at that time. In addition, larger predators may induce mitosis in their gastrointestinal tract around feeding, altering the risk for gastrointestinal toxicity at such times. While it may not be practical to avoid chemotherapy at such times, awareness of these specific risk periods may allow for scheduling of drugs that do not target those organs. Toxicity from chemotherapy is most common in tissues that are renewing and is usually related to the dosage of the drug. This has implications for both the patient (toxicity and efficacy) and for the owner and veterinary staff's safety in handling the drugs during administration, husbandry, and follow-up care. Because of the slower metabolic rate of reptiles, side effects from any given chemotherapeutic agent might be significantly delayed when compared to the common expected time intervals we are familiar with from mammal oncology.

CALCULATING A DOSE OF CHEMOTHERAPY

By dosing chemotherapy on a metabolic basis, the risk of toxicity to the patient is decreased. Although imperfect, and somewhat controversial, current dosage recommendations for cats and dogs are based on body surface area (BSA, m^2). Many drugs used in chemotherapy are given as mg/M^2 (mg per body surface area) instead of as mg/kg. Not much is known about these formulas for reptiles, and systemic chemotherapy is often based on assumptions about drug metabolism and excretion. Although there are Meeh coefficients specifically for reptiles, the published literature uses mg/kg dosing, and that is what is recommended by the authors of this chapter.[2] Please see Chapter 126 for more details on how BSA relates to body weight.

Additionally, anatomic differences in reptiles may mean that drugs are metabolized or excreted prior to reaching therapeutic concentrations. For example, the "renal portal system" means that reptiles have the capability to bypass the systemic circulation by shunting blood from the caudal extremities directly to the peritubular (not the glomerular) renal circulation. This means that if a drug is excreted by tubular secretion it could experience a significant first-pass effect prior to entering the systemic circulation. For drugs such as cisplatin and its transformation products, renal excretion is a complex process involving glomerular filtration, tubular excretion, and tubular reabsorption. For that reason, pharmacokinetics may be altered in different reptilian patients treated with these drugs using the tail vein. Because of the uncertainty of how the renal portal system affects the pharmacokinetic in any given reptilian patient, the authors recommend to avoid injecting chemotherapeutic agents into the caudal portion of the body.

CHEMOTHERAPEUTIC STRATEGIES

Tumors grow most rapidly when they are small. As they grow larger, the growth rate decreases due to a decrease in the proportion of cells in active phases of the cell cycle, increased loss of cells, and cell death due to poor circulation, nutrition, and hypoxia. Larger tumors may also have a poor blood supply; thus chemotherapy drugs may not be delivered to cancer cells at cytotoxic levels. In addition, resistance to chemotherapy can occur through spontaneous mutations in the tumor cell. The likelihood that mutation has occurred is related to the number of cell divisions that have occurred, and therefore resistance to chemotherapy is more likely in large tumors. In general, therefore, chemotherapy

VetBooks.ir

will be most active against small tumors, either following early detection or following a cytoreductive ("debulking") procedure such as surgery or radiation therapy. Chemotherapy is rarely effective or curative for large bulky tumors. An exception to this rule is combination chemotherapy for lymphoid neoplasms (as discussed later).

Combination chemotherapy may overcome drug resistance by affecting different metabolic pathways in cells that are resistant to other drugs in the combination. While combination chemotherapy could potentially be more toxic to normal cells, patterns of toxicity vary between drugs, and judicious scheduling of chemotherapeutic agents so that their toxicities do not overlap appears to improve tumor kill without compounding toxicity. For example, drugs that do not produce significant bone marrow suppression (such as vincristine or L-asparaginase) may be scheduled to be given soon after a myelosuppressive agent (doxorubicin, cyclophosphamide), or even on the same day in combination.

BASIC CHEMOTHERAPY DRUG HANDLING

Most chemotherapeutic agents are both toxic and mutagenic. Alkylating agents have been associated with the highest risks to handlers. Organ damage and increased risk of fetal loss have been reported in persons handling and administering chemotherapy with inadequate attention to personal safety. Precautions should be taken when handling chemotherapy drugs during any phase of preparation, administration, and disposal of drugs or waste produced during reconstitution and administration. Personal protective equipment (PPE)[3] consisting of protective eyewear, a respirator mask, a disposable gown with closed-cuff sleeves, and latex (not vinyl) gloves should be worn during any and all phases of handling chemotherapy. A closed-system transfer device is highly recommended, as this reduces the risk for aerosolization and leakage during administration.

Cleaning of a reptile cage for animal waste after chemotherapy should be done by handling waste products with gloves for a minimum of 1 month after each treatment, but this time period could be longer depending on the medication used and in some reptiles where the gastrointestinal transit time is longer (several weeks in some species). Care should be taken to not have immunocompromised or pregnant women handle reptile waste products during the duration of the chemotherapy treatment.

TOXICITY FOLLOWING CHEMOTHERAPY

Myelosuppression is a general term applied to the toxic effects of chemotherapy on the bone marrow. The most chemosensitive cells in the bone marrow are the proliferating hematopoietic progenitors and precursors, which are starting to commit to a particular lineage but are still immature. The more differentiated cells form a nonproliferating pool of maturing hematopoietic cells that will be unaffected by chemotherapy and can continue to provide mature cells for a number of days. This means that the nadir (or low point) of peripheral cell counts occurs at some time after the treatment. The time at which the nadir occurs also depends on the lifespan of the hematopoietic cell. Neutrophils live only hours in both dogs and cats, and their nadir occurs first at 5 to 10 days postchemotherapy; platelets live for approximately 10 days, and their nadir occurs 1 to 2 weeks after chemotherapy; erythrocytes live for 120 days in the dog and 70 days in the cat, and although anemia may occur over a prolonged course of chemotherapy, it is rarely clinically significant. The survival of hematopoietic cells in reptiles is not as well known;[4,5] however, most veterinarians have assumed similar survival times when assessing the effects of chemotherapy on circulating numbers. Like the mature cells, hematopoietic stem cells are largely nonproliferating and so are relatively resistant to chemotherapy toxicity. However, they are stimulated to divide by the loss of proliferating precursor cells and rapidly replace the lost cells so that nadirs following chemotherapy rarely last more than several days. This also has implications for the interval between administrations of myelosuppressive drugs. If chemotherapy is given when the stem cell pool is dividing (i.e., soon after the previous administration), then severe prolonged myelosuppression due to stem cell destruction may occur. The usual interval between myelosuppressive drug administrations in mammalian species is every 2 to 3 weeks, and that is the interval used in the very few publications in reptile medicine.[6,7] Some drugs (such as lomustine and carboplatin) may have delayed or prolonged nadirs, and dosing intervals are longer for these drugs. EDTA may cause hemolysis in some species,[5] and so it may be advisable to use heparin as an anticoagulant when collecting samples from such species (especially chelonians). Also, veterinarians should be aware that the blood volume of reptiles is 5% to 8% of body weight, so no more than 0.5 ml/100 g should be collected.[5]

When administering chemotherapy, hematology should be performed at the expected heterophil nadir. While in mammalian species this is usually 7 to 10 days after treatment, in reptiles it may be delayed and hematology should be monitored for longer (2 weeks), at least when using a new chemotherapy drug for the first time in an individual patient. Due to lack of information known about the effect of chemotherapeutic drugs and because many apparently normal reptiles often have low leucocyte and heterophil counts, it is extremely important to compare serial hematology samples for each patient in order to try to establish a pattern. This pattern could then be traced back to a normal fluctuation (e.g., seasonal) or a nadir due to a drug reaction.

In one report, the authors recommended that hematology be performed prior to each chemotherapy, and if the heterophil count was 1.5×10^9 cells/L (1.5×10^{12} cells/µL), the treatment was delayed until the heterophil count exceeded 2×10^9 cells/L (2×10^{12} cells/µL).[6] The reason the heterophil count should be in normal range or above before the next dose of a myelosuppressive agent is administered is that treatment before bone marrow recovery may lead to stem-cell depletion and prolonged, occasionally irreversible myelosuppression. If the heterophil count is too low at the time myelosuppressive chemotherapy is due, it is best to delay administration by 1 week or until the heterophil count is more than 2.0×10^9 cells/L. The absolute heterophil count (not the percentage or the total leukocyte count) should be evaluated. Although many animals have a low heterophil count without clinical signs, a nadir count of less than 0.5×10^9/L is sufficient reason to reduce all subsequent dosages of that myelosuppressive drug. A dosage reduction of 25% is a good rule of thumb.

Thrombocytopenia is rarely severe enough to cause clinical bleeding, and normal ranges are difficult to obtain from the literature;[5] therefore, the authors cannot make firm recommendations about dosage adjustments based on thrombocytopenia in reptiles. Also complicating the issue is the finding that thrombocytopenia may be associated with severe inflammatory disease, which can occur as a concurrent response to the cancer. For drugs known to cause thrombocytopenia in mammals (lomustine [CCNU], carboplatin, cisplatin), the clinician is cautioned to assess trends in thrombocyte counts and discontinue if there is a continued downward trend.

The gastrointestinal mucosa is another site of renewing tissue, and toxicity may occur anywhere in the GI system. Some predatory reptiles increase the turnover of their mucosa during episodic feeding, which could increase the risk for gastrointestinal toxicity during such times.[8] While it may not be practical to avoid chemotherapy altogether, it may be prudent to schedule drugs that do not specifically affect the gastrointestinal tract during these times. Clinical signs include nausea, vomiting, inappetence, anorexia, ulceration, or diarrhea. The management of these toxicities will depend on the severity of signs. Vomiting is common in snakes and a terminal event in turtles and lizards; therefore,

VetBooks.ir

the clinician will need to evaluate each patient as to the likelihood that vomiting is caused by progression of the cancer, chemotherapy toxicity, or just normal behavior. Similarly, inappetence may be difficult to assess in patients that eat only intermittently. Diarrhea can increase the risk of subsequent sepsis due to breakdown of the protective mucosal barrier to gram-negative intestinal bacteria at a time when the animal is myelosuppressed. Antibiotics, preferably those that target gram-negative bacteria as the ones most commonly implicated in sepsis, should be administered to these animals (with heterophil counts $<1 \times 10^9$/L) in addition to supportive and symptomatic care.

In veterinary mammalian oncology, cardiotoxicity, nephrotoxicity, and urothelial toxicity (sterile hemorrhagic cystitis) have been associated with specific drugs and in specific species. These toxicities are not common to all species (for example, hemorrhagic cystitis after cyclophosphamide is seen in dogs and not cats; doxorubicin is a clinically relevant cardiotoxin in dogs and not in cats, but doxorubicin is renal toxic in cats and not dogs). The reader can see that predicting toxicities in reptiles generally, and particularly in different genera, is impossible, and careful observation is needed to build a body of knowledge around these treatments. Due to the significantly lower number of nephrons in the reptilian kidney, special attention has to be paid to nephrotoxicity, as this side effect may be more severe in the reptilian patient. Concurrent parenteral fluids may be supportive and renal-protective when administering any drug that could be nephrotoxic.

Extravasation of some chemotherapy agents may cause necrosis when they are administered outside the vein. While some drugs may cause temporary irritation, others are truly vesicant, and those are usually classified as DNA-binding and non-DNA-binding drugs. In general, for non-DNA-binding drugs (such as vinca alkaloids), there may be benefit to diluting the extravasated drug using saline and by application of warm compresses to increase blood flow to the area; also the addition of hyaluronidase to improve absorption of the drug has been shown to be beneficial after vinca alkaloid extravasation. In contrast, those that bind to DNA (such as doxorubicin) should be restricted after extravasation by using cold packs and by not flooding the area with saline. Specific antidotes are few, although the use of systemic dexrazoxane appears to reduce the severity of doxorubicin extravasation reactions in mammals. Especially after extravasation of DNA-binding drugs, the tissue necrosis may be severe and surgical debridement may be needed. Prevention is much preferred, and careful use of a "first-stick" intravenous catheter is always recommended. Vesicant drugs should never be administered subcutaneously, intralesionally, or intracoelomically.

Hypersensitivity reactions may occur due to histamine release. This effect usually occurs with rapid administration of some drugs and may be a consequence of the drug itself or due to the carrier solutions in these formulations (as opposed to the drugs themselves). True anaphylaxis rarely occurs in mammalian species following administration of L-asparaginase, an asparagine-specific enzyme, particularly by the intravenous or the intraperitoneal route. If anaphylaxis occurs, the patient should never receive further treatments with that drug. However, to date no published report of an anaphylactic reaction in a reptile exists in the scientific literature. It is possible that this side effect is not a significant concern in the reptilian patient; however, not enough data on reptiles that have been treated with chemotherapy has been collected.

CHEMOTHERAPY DRUG ADMINISTRATION

Systemic chemotherapy is the most common route used; oral or parenteral administration allows for systemic distribution of the active drug at therapeutic levels sufficient to allow damage to the neoplastic cells but at a level where significant or prolonged damage to normal cells is unlikely. Intralesional chemotherapy may be used under specific circumstances for local (rather than systemic) cancer control; more information follows at the end of this chapter.

As mentioned previously, the authors recommend against administering chemotherapy in the caudal half of a reptile's body due to the potential effect of the renal portal system. Ongoing venous access can be problematic, especially for small reptiles. A subcutaneously implanted vascular access port (VAP), placed surgically under anesthesia, may be suitable for larger reptiles, as they allow venous access with minimal restraint. The use of vascular access ports (VAP) in an (*Iguana iguana*) with lymphoma has been reported,[6] as has central line placement in tortoises.[9] As with mammalian species, where approximately 10% of patients experience complications (e.g., permanent loss of VAP patency, catheter breakage, suture breakage, infection, and incision dehiscence), in the iguana, reported difficulties included port disconnection, inability to aspirate blood after a few weeks, and infection.[10] Central lines have been successfully placed in a number of chelonians, which remained in place for many weeks and allowed repeated blood collection and intravenous medication without any complications (see Chapter 44 for instructions on how to place a central line).[10] Doxorubicin, which can cause severe tissue necrosis if administered extravascularly, was administered via a VAP to a corn snake (*Pantherophis* spp.) with a vertebral body osteosarcoma with no significant toxicities noted from either the port or the chemotherapy.[11] One iguana was treated over a 2-year period for lymphoma using three separate VAPs. The lizard experienced acute necrosis over the first VAP placed, and it was removed; the cause was uncertain, but possibly due to extravasation of vincristine. The second port was placed in the coelomic cavity and remained patent for 6 months, at which time the lizard had grown and a subcutaneous VAP was placed and used for an additional 18 months. Doxorubicin, vincristine, cyclophosphamide, and prednisone were all successfully administered to that patient.[6]

CHEMOTHERAPY DRUG DOSING

Dosing of chemotherapy is often based on metabolic rate, but assumptions used in mammals have been refined by multiple studies, including dosage escalation and pharmacokinetic studies; similar studies have been performed in some birds.[12] Unfortunately, chemotherapy dosages in reptiles remain empirical, usually based on dosages used in mammalian species, especially the dog (Table 123.1). Ideally, for each order and probably species, veterinarians will need to develop dosing strategies that maximize efficacy but result in an acceptable toxicity. One approach (at least for a starting dose) is allometric scaling from dog or human dosages, although that is also imperfect (see Chapter 126).

The difficulties are illustrated by one publication, where a dosage escalation for doxorubicin was performed in an iguana with lymphoma, increasing the dosage from the empirical start of 0.26 mg/kg (based on a dog dose reduced by one-third), to 0.75 mg/kg every 3 weeks.[6] During that escalation, the drug showed improved efficacy against the lymphoma but minimal increase in toxicity. Ideally, such a study could be performed in a number of patients from each species to determine the "maximally tolerated dose," which would allow optimum treatment of reptiles. The authors recognize this is difficult and would take a long time. Until those data are available, we will need to rely on case reports and anecdotal information, but if a general principle of dose escalation and scrupulous monitoring for toxicity is followed, eventually that data will be accumulated. It is not enough to say that a drug was nontoxic and not enough to say it was effective; it needs to be both effective and well tolerated.

VetBooks.ir

TABLE 123.1 Previously Reported Dosages of Chemotherapy Agents Used in Reptiles

Drug	Dose	Route	Potential Adverse Effects*
Prednisone[7,8,13]	0.2–2 mg/kg	PO, SC, IM, IV	Gastrointestinal ulceration, polyuria, polydypsia, weight gain
Cyclophosphamide[7]	10 mg/kg	IV, PO	Neutropenia, thrombocytopenia, gastrointestinal toxicity
Chlorambucil[8,13]	0.08–1 mg/kg, 2.0 mg/m^2	PO	Neutropenia, thrombocytopenia
Doxorubicin[7]	1 mg/kg	IV	Tissue vesicant if extravascular, hypersensitivity, myelosuppression, cardiotoxicity, gastrointestinal toxicity
Cisplatin[16]	0.5–1 mg/kg	IV, IC, IL	Cumulative renal toxicity, myelosuppression, hepatopathy, hypersensitivity reactions
Carboplatin[17]	2.5–5 mg/kg	IV, IC, IL	Myelosuppression
Cytosar[13,14]	6 mg/kg–30 mg/kg**	IV, SC	Myelosuppression and gastrointestinal disturbances
L-Asparaginase	400 U/kg	SC, IM, IC	Hypersensitivity reaction
Vincristine[7]	0.025 mg/kg	IV	Tissue vesicant if extravascular
Bleomycin[18]	1 u/cm^3	IV, IL	Pulmonary fibrosis

*Adverse effects primarily reported in domestic animals; not enough information in reptiles at this time.
**Too high and possibly fatal.
The reader is referred to other textbook sources on specific chemotherapy agents used in veterinary medicine.[20,21]

Other examples from the reptile literature follow. The chlorambucil dosage in the publications ranges from 0.08 mg/kg PO once (green tree monitor, *Varanus prasinus,* with chronic lymphoid leukemia, died 4 days later)[7] to 1 mg/kg every 7 days (diamondback terrapin, *Malaclemys terrapin,* with lymphoma,[13] was not apparently toxic but not effective either) to 2.0 mg/m^2 every day (King cobra, *Ophiophagus hannah,* with lymphoma [Willette et al, Proc AAZV, 2001, p 20]), which caused minimal hematologic toxicity and then the patient died 6 weeks after starting chlorambucil (but whether due to disease or drug was uncertain); in this latter case the technique for determining surface area was not reported.

Similarly, cytosine arabinoside varies in reported dosage from 6 mg/kg every 7 days (diamondback terrapin with lymphoma, peripheral decrease in abnormal cell counts but widespread systemic lymphoma),[13] to 30 mg/kg SC (24 hours after which the rhinoceros viper, *Bitis nasicornis,* with lymphoma was dead; presumably due to drug toxicity).[14] Even the prednisone dosage varies in reports from 0.2 mg/kg every 72 hours (sungazer lizard, *Smaug giganteus,* with acute lymphoid leukemia [Martin et al, Proc AAZV, 2003, p 6]), 0.6 mg/kg every 48 hours (terrapin),[13] 0.8 mg/kg every 48 hours (green tree monitor with chronic lymphoid leukemia [CLL]),[7] 40 mg/m^2 SC every 48 hours (cobra with lymphoma [Willette et al, Proc AAZV, 2001, p 20]), to 2 mg/kg daily for 2 weeks then every 48 hours (iguana with lymphoma).[6]

Currently for chemotherapy agents delivered systemically (see later discussion for intralesional administration), we recommend starting with established dog dosages reduced by one-third and at intervals as used in dogs. This may be a reasonable initial approach (at least in one report, there was efficacy and minimal toxicity with this approach).[6] Consultation with a veterinary oncologist is recommended, and if no toxicities are encountered after each treatment, consideration can be given to cautious escalation of dosages (by 10% for every treatment without toxicity) with careful and ongoing monitoring for hematologic and systemic visceral toxicities. All data should be made available for further studies, preferably in a published form, so that repetitive escalations are not performed.

The use of empirical dosing is often unsuccessful, even for tumor types such as lymphoma and leukemias that respond well in mammalian species. Cutaneous lymphoma in a king cobra was initially treated surgically, with recurrence 5 months later, and a second surgery allowed for another 2 months before a second recurrence (Willette et al, Proc AAZV, 2001, p 20). Chemotherapy with doses used for dogs and cats with L-asparaginase (10,000 IU/m^2 SC), vincristine (0.5 mg/m^2 IV), and prednisone caused a temporary partial response before progression after 4 weeks; chlorambucil caused stabilization for a further 4 weeks, at which time the masses progressed and treatment was ceased. Survival from diagnosis was 15 months (Willette et al, Proc AAZV, 2001, p 20). A diamondback terrapin with lymphoma treated with cytosine arabinoside, chlorambucil, and prednisone showed a decrease in peripheral abnormal cell counts, but widespread systemic lymphoma progressed with death 6 weeks after diagnosis.[13] Conversely, an iguana with lymphoma, treated with multiagent combination chemotherapy (doses discussed previously), was still in complete remission nearly 3 years after diagnosis.[6]

Partial response in chronic lymphoid leukemia was achieved in a green tree monitor for 7 months using chlorambucil and prednisone.[7] A sungazer lizard treated for acute lymphoid leukemia with whole-body radiation and prednisolone was in remission when it died 11 months after radiation (Martin et al, Proc AAZV, 2003, p 6) (see also Chapter 124). Clearly multimodality combinations of surgery, radiation, and chemotherapy should be considered when deemed appropriate to the individual situation.

In addition to systemic chemotherapy, localized (intralesional) chemotherapy is attractive for smaller reptiles. Intralesional chemotherapy is always administered as a suspension in oil or other vehicle, not as pure drug, and is considered a "local" therapy to treat tumors that have not metastasized. The mixture is injected into a tumor, providing a very high drug concentration to the tumor cells but minimal systemic drug levels, thereby avoiding the risk of systemic toxicity. These mixtures are prepared like any chemotherapy agent, but two Luer-lok syringes, one containing the cytotoxic agent and one containing the vehicle (e.g., sterile medical grade sesame oil),[15] should be prepared. The total dose of chemotherapy drug should not exceed the systemic dosage for that drug. Each agent should be placed into a syringe with sufficient capacity to contain both liquids when combined (i.e., 2.5 ml of drug and 2.5 ml of vehicle, each in a 5–6 ml syringe). The syringes are attached to a three-way stopcock, and the two liquids can then be rapidly mixed between the syringes to create an oily emulsion. PPE, as outlined previously, must be worn. It may be wise to mix inside a sealable plastic bag. The syringe that now contains all of the mixture should be detached after covering the attachment with an alcohol-moistened gauze swab to prevent aerosolization, and a 23-gauge needle should be attached. The remaining syringe and stopcock should be discarded as contaminated waste.

FIG 123.2 Intralesional chemotherapy for a cutaneous metastatic melanoma in a boa (*Boa constrictor* spp.). Note the use of personal protective equipment during administration. (Courtesy of Christine Swanson.)

It is preferable to mix multiple small volumes of drug in this way rather than a single large volume, because separation of drug from vehicle may occur rapidly, thereby reducing the efficacy of the treatment. Likewise, the drug-vehicle mixture should be administered soon after preparation. If a delay is encountered, the drug can be remixed with its vehicle using a new syringe and three-way stopcock. The needles on used syringes should not be recapped. Injection is performed in a grid-pattern to ensure highest possible intratumoral concentration of drug. It is important to use PPE for protection of staff and to watch the area carefully for any leakage of chemotherapeutic agent. If leakage occurs, the area should be swabbed and cleaned with soap and water, and the cleaning materials disposed of as hazardous waste. When removing the needle after intralesional therapy, there is often pressure on the syringe contents that will cause the mixture to leak out when the needle is withdrawn from the tumor. Negative pressure on the syringe when withdrawing will help reduce leakage. The patient should remain anaesthetized until oozing and bleeding stops (Figs. 123.1 and 123.2).

Note that some of the drugs reported for intralesional chemotherapy rely on reconstitution of the lyophilized drug to a higher concentration than would normally be administered systemically. Some of those drugs (e.g., cisplatin and carboplatin) are available as reconstituted drugs, which are too dilute for intralesional use. Drugs that can cause tissue necrosis (such as doxorubicin or vincristine) should never be delivered intralesionally.

The use of intralesional cisplatin has been reported in reptilian species without apparent adverse effect but with unknown efficacy.[16] A 10-year-old female boa constrictor (*Boa constrictor*) with a malignant subcutaneous fibrosarcoma of the body wall was successfully treated with 50 mg (total dose) of intralesional carboplatin in addition to radiation therapy, so the contribution of carboplatin is difficult to assess.[17] Electrochemotherapy uses electrical impulses to improve penetration of chemotherapy into cancer cells and may thereby increase efficacy. Following an incomplete surgical excision, intralesional bleomycin in combination with electrochemotherapy was used to treat squamous cell carcinoma in a yellow-bellied slider (*Trachemys scripta scripta*). The animal tolerated the treatment and had no evidence of neoplasia 12 months after treatment (Fig. 123.3).[18] Electrochemotherapy and intralesional bleomycin was also used to treat fibropapillomas in a green sea turtle (*Chelonia mydas*). The lesions resolved, and there was no evidence of local recurrence 12 months after treatment.[19]

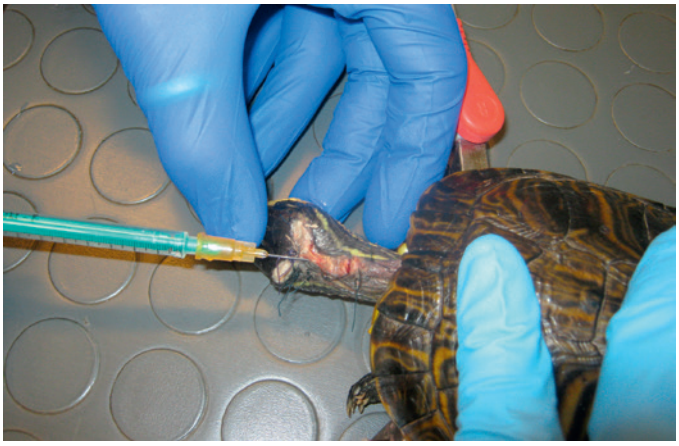

FIG 123.3 An aquatic slider with squamous cell carcinoma treated with electrochemotherapy. This involved intratumoral administration of bleomycin followed by trains of biphasic electric pulses. The treatment was well tolerated, and the turtle was disease-free after 12 months. (Courtesy of Enrico Spugnini.)

Radiation Therapy

Koichi Nagata and Joerg Mayer

Radiation therapy (RT) can be performed in several different ways. The most commonly used RT modality in veterinary medicine is a linear accelerator, which can produce highly penetrating x-rays. Gamma rays are emitted from Cobalt-60 sources or certain radioactive isotopes. X-rays and gamma rays kill the cell mainly by knocking out electrons from the exposed atoms' orbits.[1] The majority of the ejected electrons react with water molecules, which turn into free radicals that damage the DNA and cause double-strand breaks. This is often followed by lethal chromosomal aberrations during the cell division, which results in cell death (mitotic death). Although most cell types die mainly from mitotic death (i.e., cells do not die until they try to divide, which is why the effect or side effects of RT are usually not seen immediately after the treatment), some cells such as lymphocytes and lymphoma cells undergo significant apoptosis (instead of mitotic death), which often results in rapid reduction in tumor size within 24 to 48 hours after RT. Larger tumors are usually more resistant to radiation, partly because the center of the tumor is hypoxic, which makes tumor cells in this zone relatively resistant to the effects of radiation.

SIDE EFFECTS

Radiation side effects are classified into acute effects and late effects. Acute effects typically accompany inflammation and start within days to weeks after starting RT (at least in mammalian species). Late effects usually take months to years after finishing RT before they manifest. Most of the late effects are permanent and nonhealing. A well-known example is a permanent necrosis of the irradiated area.

The risk for radiation side effects may be reduced by careful planning of the radiation field to protect or by reducing the radiation dosage to radiation-sensitive structures. Computer tomography (CT) is the imaging modality of choice for planning, as it can be used directly for computer-based evaluation. In reptile species, achieving vascular access can be challenging, making it more difficult to perform contrast CT studies. In such patients, MRI may be helpful for RT planning in reptiles.[2]

LINEAR ACCELERATOR AND COBALT-60

The following is a summary of various case reports of reptile patients treated by x-ray or gamma-ray radiotherapy.

A 10-year-old Indian Rock python (*Python molurus molurus*) with postsurgical recurrent lymphoma of the ventral oral cavity (approximately $2 \times 2 \times 3$ cm) was treated with 15 Gray (Gy) using a cobalt-60 source.[3] Sixteen days later, tumor regression was observed, at which time the snake was irradiated again with 35 Gy. Approximately 6 months following the first RT, there was no evidence of tumor recurrence. However, the snake became lethargic and died 1 month later. Necropsy revealed lesions in the liver and gastrointestinal tract with the same lymphoma cell type. The only adverse event from RT was a permanent elimination of dentition at the irradiated site. This indicates that the threshold dose to cause an acute side effect in pythons may be significantly higher compared to the dose tolerated by mammals (in mammals, a single dose of 35 Gy is expected to result in severe acute effects followed by necrosis).

A 2-year-old green iguana (*Iguana iguana*) with a localized lymphoma in the cranial cervical area was treated with a single 10 Gy of radiation.[4] The tumor reduced in size by 90% the next day. Chemotherapy (modified CHOP protocol) was started at that time. The iguana was still in remission when it was rechecked 1008 days after the initiation of treatment. Lymphomas in mammals are known to be very sensitive to RT, and the significant response to RT observed in this iguana may indicate that lymphomas in reptiles also respond similarly to their mammalian counterparts.

It should be noted that when an entire snake is exposed to radiation, the LD50 dose is close to that of humans, which is approximately 300 to 400 Roentgen (2.6–3.6 Gy).[5] Similarly, irradiation of radiosensitive viscera such as lung should be undertaken with caution. A snake treated with 20 Gy to a field that included the lung developed pulmonary vasculitis and was euthanized because of dyspnea.[2] The LD50 in box turtles *(Terrapene* spp.) is reported to be approximately 850 Roentgen [7.5 Gy], indicating that LD50 may vary significantly between taxa. The relatively low LD50 for snakes is surprising, considering that whole body irradiation LD50 for lower vertebrates are higher in general (e.g., 800 Roentgen [7 Gy] in goldfish, 700 Roentgen [6.1 Gy] in frogs, and 1486 Roentgen [13 Gy] in newts) (Fig. 124.1).[5]

Low-dose, whole body radiation may be used for the treatment of lymphomas or lymphoblastic leukemias. An adult sungazer lizard (*Cordylus giganteus*) with acute lymphoblastic leukemia (ALL) and a total white blood cell count (WBC) of $3.1 \times 10^3/\mu L$ was initially treated with 0.2 mg/kg prednisone PO q72 hrs (Janet C. Martin, unpublished observations). However, 3 months after starting the treatment, WBC remained elevated at $34.3 \times 10^3/\mu L$. Two months later, prednisone was discontinued and a single whole body irradiation with 1 Gy was administered. Although WBC was still elevated at 1 month post-irradiation, it decreased at 3 months post-irradiation to $2.9 \times 10^3/\mu L$. Approximately 11 months after RT, the lizard died of femoral pore abscessation, which had been present before starting the treatment for ALL.

Radiation therapy for nonlymphoma tumors have been reported with less success. A 10-year-old boa constrictor (*Boa constrictor ortoni*) with a 4×15 cm subcutaneous fibrosarcoma located 10 cm caudal to the heart was incompletely excised.[6] Three weeks later, cobalt-60 RT (16×3 Gy fractions for a total dose of 48 Gy) was performed over a 21-day period. Hematology following the last radiation fraction revealed leukopenia (2.7×10^3 cells/μL) and severe lymphopenia (likely due to a combination of factors including the neoplasia, multiple coelomic

FIG 124.1 A sungazer lizard *(Cordylus giganteus)* receiving whole body irradiation by a linear accelerator. Tissue-equivalent bolus materials (Superflab and saline bags) are placed around the lizard, so that the entire body receives a homogeneous dose of radiation. (Courtesy of Joerg Mayer.)

surgeries, RT, and daily stress of handling). No physical changes to the scales in the radiation field were observed. However, the tumor increased in size during the course of RT. Twenty days after RT, the snake was further treated with intralesional chemotherapy (carboplatin), at which time debulking was also performed. A bacterial culture of the tumor, performed 32 days after RT, revealed *Mycobacterium chelonei*, and the snake was euthanized.

A 15-year-old Madagascar ground boa (*Boa madagascariensis*) with a squamous cell carcinoma was treated with two doses of x-ray radiation (10 Gy per fraction, total 20 Gy) 1 week apart.[2] The tumor increased in size after the first RT. The boa began open-mouth breathing, exhibited dysecdysis, and was euthanized 5 days after the second RT. MRI taken prior to euthanasia revealed streaky hyperintensities dissecting between facial planes surrounding the tumor, which were attributed to RT-induced edema and vasculitis. The electron beams produced by linear accelerators have a limited penetration depth of several (typically 1.5 to 5) centimeters from the skin surface, so electrons can be useful for treating superficial tumors when an underlying organ is to be spared (for example, a skin tumor over the thoracic cavity or the kidneys).

In one report, an adult yellow rat snake (*Pantherophis obsoleta quadrivittata*) with a subcutaneous malignant chromatophoroma in the middle of the body was treated with two surgical procedures.[7] Fifteen days after the second surgery, RT consisting of 4 fractions of 15 Gy (total 60 Gy) was given over 15 days by 6 MeV electron beams (the intervals between the RTs ranged from 3 to 6 days). Dry lackluster scales were noted in the irradiated area, which started 10 days after starting RT. The surgical site healed without a complication. The snake was irritable for several months following RT and anorexic for 20 weeks following the last RT. Ten months after the RT, the snake died with an abscess within the previous site of the tumor. In the caudal coelomic cavity, a lobulated mass was found, which appeared clinically identical to the irradiated subcutaneous tumor, although no histopathologic examination was performed on the new mass. Although the clinical signs exhibited by this snake could be a result of acute and late radiation side effects, the aggressive radiation protocol used would have resulted in more severe acute effects and necrosis in mammals.

One of the authors (KN) treated a 26-year-old male yellow anaconda (*Eunectes notaeus*) with a 3 × 4 cm squamous cell carcinoma with sebaceous differentiation next to the cloaca. The anaconda was irradiated with 6 weekly doses of 6 Gy of electron beams. By the last fraction of radiation, the lesion had regressed significantly, the patient was noticeably more comfortable, and he had gained weight. At the 6-week follow-up visit, acute radiation effects were noted, including edema and loss of scales. The cutaneous lesions were treated symptomatically with antibiotics and buprenorphine. Despite these treatments, the lesions persisted (but improved) over the next 6 weeks and had almost resolved 16 weeks after therapy. Five months after completion of radiation, a purulent pocket was noted near the vent, which progressed to a nonhealing wound causing pain and bleeding. Fourteen months after treatment, the anaconda was constipated, depressed, had lost weight, and was unable to pass feces. He was euthanized 2 weeks later. Postmortem findings indicated recurrent squamous cell carcinoma of the vent with extensive regional invasion. Although the exact onset of tumor recurrence was unknown, radiation side effects could have contributed to the pericloacal, necrotic lesion seen in this snake.

Stereotactic radiation therapy (SRT) is an emerging method of RT that involves a high dose of radiation (typically x-rays) per treatment (usually 6 to 17 Gy per fraction in mammalian species). The dose used for SRT is significantly higher than the doses usually used for definitive RT (2.5–4 Gy) or for palliative RT (4–8 Gy). SRT is typically delivered in 1, 3, or 5 fractions (instead of 18–20 daily treatments, which is typical for a definitive RT). SRT may be a promising treatment method for reptiles because daily anesthesia episodes may not be feasible in many cases. SRT can be performed by advanced linear accelerators that have an on-board imaging system, which allows a CT scan immediately before each radiation treatment (Fig. 124.2). This technology allows an accurate and conformal beam delivery with a technique called IMRT (intensity modulated radiation therapy), which results in minimal volume of normal tissue exposed to a high dose of radiation. However, the authors are unaware of any documented reports of SRT use in reptiles.

VetBooks.ir

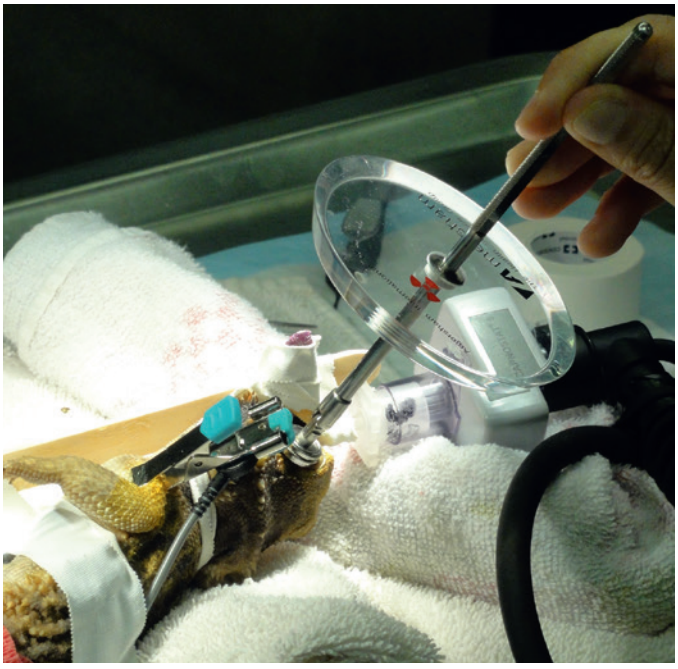

FIG 124.3 A lizard is receiving superficial radiation therapy from a strontium probe. The probe emits electrons that can only penetrate a few millimeters, which makes it suitable for the treatment of small, superficial tumors. (Courtesy of Joerg Mayer.)

STRONTIUM 90

Electrons emitted from a strontium-90 ophthalmic probe, which has an active source diameter of about 8 mm, has very limited penetration (the dose drops to <10% at 3 mm depth), and can deliver a high dose of radiation to the surface of the patient's body (100 Gy or higher) without causing significant side effects in mammals. In the authors' opinion, it should be used with caution if a tumor exceeds 3 to 4 mm in thickness, because the deeper portion of the tumor is likely to be underdosed. Strontium-90 radiation therapy may be an excellent treatment option for small superficial tumors (Fig. 124.3). In one case report, a bearded dragon (*Pogona vitticeps*) with a myxosarcoma on the medial canthus of the right eye was treated with a surgical debulking (all the gross disease was removed with the third eyelid) immediately followed by radiation therapy using strontium-90 ophthalmic probe with 100 Gy.[8] Tumor recurrence was noted 5 months later. Recurrence of the tumor may have been due to the locally infiltrative nature of the myxosarcoma, or the radiation probe may not have been accurately applied to the area of residual tumor tissue. Anecdotally, strontium-90 has resulted in successful treatments in other reptiles (according to the radiation oncologists' ACVR list serve).

RADIOACTIVE IMPLANTS

RT can also be performed by implanting radioactive "seeds" or "straws" directly into the tumor, although this type of RT is far less commonly performed in veterinary medicine. RT by using radioactive seeds was not successful for the treatment of melanoma in a common death adder (*Acanthophis antarcticus*) nor for the treatment of mast cell tumor in an eastern king snake (*Lampropeltis getulus getulus*).[9,10]

CONCLUSION

Given the body of evidence in the literature, radiation therapy may be a good option for some reptilian tumors. Based on some aforementioned case reports, some reptiles may tolerate radiation better than mammals. This may be due to the fact that reptiles are taxonomically closer to birds, which are known to tolerate radiation better than mammals. This may also indicate that radiation therapy should be more aggressively approached for reptiles compared to mammals. However, the greater radiation tolerance of reptiles is not consistently seen in all cases reported here. It is also possible that radiosensitivity may vary among different reptile taxa or even individual patients. Therefore, until more data become available, caution is advised when using aggressive radiation therapy in reptiles.

Miscellaneous Drug Therapy

Izidora Sladakovic and Rodney W. Schnellbacher

Many reptilian dosages are based on experience, case reports, or extrapolations from other species. Below is an overview of published reports on the use of miscellaneous drug therapies in reptiles for the support of various gastrointestinal, reproductive, renal, and hepatic diseases. Complete reptile and amphibian drug formularies can be found in Chapters 127 and 128.

GASTROINTESTINAL

The effects of cisapride (1 mg/kg PO SID) and metoclopramide (1 mg/kg PO SID) on the gastrointestinal transit time were investigated in desert tortoises (*Gopherus agassizii*) and compared with controls. Neither of these drugs significantly affected transit time.[1] Cisapride (1–4 mg/kg PO SID) has been recommended in bearded dragons (*Pogona vitticeps*) with constipation, in conjunction with correction of underlying conditions.[2] A green turtle (*Chelonia mydas*) received metoclopramide (0.05 mg/kg SC SID) for management of ileus following intestinal resection and anastomosis. After 7 days of therapy, no fecal production was observed. Following a change to cisapride (1 mg/kg PO SID), fecal production was observed after 5 days.[3] Sucralfate (1 g PO SID) was administered to a 23.5-kg loggerhead sea turtle (*Caretta caretta*) with melena, and normal feces were produced within a week.[4] Sucralfate, cimetidine, and activated charcoal suspension were administered to a South American red-footed tortoise (*Chelonoidis carbonaria*) with suspected ibuprofen toxicosis. The patient recovered, and no adverse effects associated with the treatment were observed.[5]

REPRODUCTIVE

A 4.7-mg deslorelin implant was used in a male bearded dragon for aggression. At reevaluation 2 months after implantation, there was significant reduction in aggression and a decline in serum testosterone level.[6] A study investigating the effect of leuprolide acetate on testosterone levels in male green iguanas for 35 days found no significant effect.[7]

In reptiles, arginine vasotocin is the endogenous hormone responsible for oviposition. However, the exogenous form is only available in a research setting; therefore oxytocin is used for nonobstructive dystocia. Oxytocin appears to be most effective in chelonians at relatively low doses and less effective in squamates. There are various treatment protocols and doses published. In general, if no oviposition has occurred after administration of two to three doses, it is unlikely to be effective, and ongoing administration can be detrimental. Concurrent use of prostaglandin $F_{2\alpha}$ or β-blockers may potentiate the effects of oxytocin.[8] See Chapter 80 for more details.

RENAL

Allopurinol (25 mg/kg PO SID) was administered to green iguanas with dietary-induced hyperuricemia, and uric acid concentrations were significantly lower compared with controls.[9] Allopurinol also reduced uric acid concentrations in European tortoises with hyperuricemia (Kolle, unpublished data). Lanthanum carbonate octahydrate reduced phosphorus levels in tortoises with renal disease (P. Kolle, unpublished data).

HEPATIC

Lactulose was used in a green iguana with pseudocarcinomatous biliary hyperplasia and was associated with a reduction in bile acid concentrations.[10]

Additional information on the management of diseases of the above-mentioned systems can be found elsewhere in this text. In conclusion, the use of miscellaneous therapies is in its infancy in reptiles and further studies are needed to evaluate the efficacy and safety of these agents.

Allometric Scaling

Joerg Mayer

The principles of scaling have been known and used by physiologists for many decades.[1–3] Kleiber first introduced the general formula used in allometric scaling as aM^b, with **a** being the scaling constant, **M** the body mass, and **b** the scaling exponent.[2] The scaling exponent b was considered to be 0.75 for physiological rates (e.g., metabolic rate) and –0.25 for physiological durations (e.g., gestation, elimination). However, a formula that applies to every physiological aspect of every species of reptile is unlikely when dealing in the life sciences. Applying equations to ectothermic animals also brings additional uncertainty with it in regard to providing a predictable outcome. Recently there is also concern expressed that there is no universal 3/4-power law for the body-mass scaling of metabolic rate globally, as the slopes of metabolic scaling vary substantially from approximately 2/3 to 1 depending on the taxonomic group and/or physiological (activity) states.[4] Some studies have shown that a 2/3-power scaling is more accurate within species of mammals and reptiles than is 3/4-power scaling.[5] Gillooly et al. showed that the metabolic rate (the transformation of energy and materials) is governed by two factors: the Boltzman factor (a factor used to describe the temperature dependence of biochemical processes) and the specific allometric relation, used to describe the change of biologic processes with the change in body size.[16] Because the body temperature in reptiles is environmentally dependent and therefore not constant, prediction of the metabolic rates have to be made with the specific temperature optimal for the species. Berner was able to show the significance of this by measuring the oxygen consumption of mitochondria in reptiles at different temperatures.[6] Mader and colleagues were able to show the importance of temperature for pharmacokinetics in the gopher snake (*Pituophis catenifer*) dosed with amikacin.[7] Caligiuri et al. also showed the same effect of temperature on pharmacokinetics in gopher tortoises (*Gopherus polyphemus*) given amikacin.[8] The route of drug excretion is also an important aspect, and this might also complicate calculations just based on bodyweight alone. This phenomenon was observed by authors who examined the allometric basis of enrofloxacin scaling in green iguanas, which showed that enrofloxacin clearance cannot be easily predicted using metabolic scaling.[9]

The advantages of familiarity with certain allometric equations are obvious when dealing with a complex situation such as drug clearance or pharmacokinetic studies. In spite of limitations, these formulas help summarize data and gain information about basic anatomical and physiological facts.

PHYSIOLOGICAL APPLICATION OF SCALING

The fundamental need to apply allometric scaling according to body size has been explicitly published by Kirkwood.[10] The author uses the example of a 1 gm tissue sample from a shrew and a blue whale, pointing out that the tissue sample of the shrew has a 100 times higher metabolic rate than the tissue sample of the whale. With allometric scaling, one has to keep in mind that all equations are merely descriptive in nature; they should NOT be considered biologic laws. Equations such as these are probably most useful when they are seen as tools to detect general patterns or used for estimations where data on physiological normals or pharmacokinetics are not available.

In the following list, a few reptile-specific formulas are compiled that might be of use to the reptile-oriented practitioner. Knowing physiological rules, such as maximum oxygen consumption (mL/min/kg) in reptiles with varying body temperature, can help monitor anesthetic procedures in controlled (surgery suite) or uncontrolled (field) environments. Growth rate and home range predictions can also be useful in the clinical setting.

Examples (Table 126.1), with **W** as bodyweight in kilograms and **L** as length in centimeters, include:

$13W^{0.8}$ = minimum energy (ME in kcal/d) requirements for free-living existence in lizards[11]
$6.5W^{0.75}$ = ME requirements for maintenance (kcal/d) in snakes[12]
$6W^{0.75}$ = ME requirements for maintenance (kcal/d) in chelonia[13]
$14.6W^{0.23}$ = life span in captivity (years) in reptiles[1]
$W = 0.0003L^{2.85}$ bodyweight in relation to carapace length in *Testudo greaca*[14]
$0.0012W^{0.61}$ = growth rate (g) of reptiles[1]
$4.8W^{0.95}$ = area (ha) home range of lizards[15]

Maximum oxygen consumption (mL/min/kg) in reptiles at varying body temperature[1]:

$3.1W^{0.81}$ lizards at 20°C	$3.3W^{0.83}$ reptiles at 20°C
$6.2W^{0.76}$ lizards at 30°C	$6.1W^{0.77}$ reptiles at 30°C
$9.5W^{0.76}$ lizards at 35°C	$8.1W^{0.71}$ reptiles at 35°C
$8.1W^{0.64}$ lizards at 40°C	$8.1W^{0.64}$ reptiles at 40°C

These calculations can be used to estimate the calorific requirements for hospitalized reptiles, and a calculation form is shown in Table 126.1. It must be remembered that such calculations are merely an estimation and should be modified based upon response and daily weight measurements. In addition there are often physiological variables that must be considered. For instance, when dealing with an emaciated, starving reptile, it is wise to start low (often 10%–20%) of calculated requirements to avoid refeeding syndrome or gastroinestinal overload.

PHARMACOLOGICAL APPLICATION OF SCALING

Allometric scaling can be extremely useful with calculation of a dose for a drug that has not been used in a reptile species before. Allometric data can provide additional information that may help better define and bring a greater level of rationality to the process of attempting to determine a dose that might be effective and not toxic. The formulas used may vary from species to species, between different aged animals

TABLE 126.1 Allometric Food Calculation Examples for Reptiles

Snakes

Species: Ball python — Weight: 0.546 kg
Daily minimum energy requirements = $6.5W^{0.75}$ = 4.13 KCal/day
Energy factor required: 1
Frequency of feeding: Every 4 days
Total energy requirement = 4.13 daily = 16.52 KCal every 4 days
Food make and manufacturer: Oxbow Carnivore Care
Food energy concentration: 1.6 KCal/mL (2 parts powder to 1 part warm water)
Total feed amount = 10.3 mL every 4 days*

Lizard

Species: Bearded dragon — Weight: 0.306 kg
Daily minimum energy requirements = $13W^{0.8}$ = 5.04 KCal/day
Energy factor required: 1
Frequency of feeding: daily
Total energy requirement = 5.04 KCal daily
Food make and manufacturer: Emeraid Omnivore Care
Food energy concentration: 2.39 KCal/mL (3 parts powder to 2 parts hot water)
Total feed amount = 2.1 mL every day*

Tortoise

Species: Leopard tortoise — Weight: 4.56 kg
Daily minimum energy requirements = $6W^{0.75}$ = 18.72 KCal/day
Energy factor required: 1
Frequency of feeding: Daily
Total energy requirement = 18.7 KCal daily
Food make and manufacturer: Oxbow Herbivore Care
Food energy concentration: 1.6 KCal/mL (2 parts powder to 1 part warm water)
Total feed amount = 11.7 mL every day*

*These figures are mere estimates and should be modified based upon clinical situation and patient response. In cachexic reptiles, initial feedings may need to be reduced by 90% to avoid refeeding syndrome or gastrointestinal overload.

TABLE 126.3 Allometric Scaling Formulary for Reptiles—cont'd

Drug	Model	Model Dose	Universal MEC Dose (yields mg/dose)	Frequency Coefficient (yields times/day)	Comments
Ceftazadime	Small snake[d]	20 mg/kg q 72 h	2.4	0.04	PK dose available for small snake; scaled dose recommended for large snakes
Cephalexin (Keflex)	Dog	22 mg/kg PO tid	0.665	0.091	
Cephalothin (Keflin)	Dog	15–35 mg/kg IM, SC, IV tid	0.453–1.0	0.091	
Chloramphenicol	Dog	25–50 mg/kg PO IM, IV tid	0.755–1.5	0.091	
	Snake[e] (1 kg)	50 mg/kg SC q 12–72 h	10.6	0.063–0.4	PK dose available for gopher snake, indigo snake, rat snake, and king snake, boas, rattlesnakes
Ciprofloxacin	Human	500 mg bid	0.3	0.08	PK dose available for chicken
Cisapride	Child	0.2 mg/kg qid-tid	0.006	0.1	Used successfully in tortoise (Kaufman, unpublished)
Clindamycin	Dog	10 mg/kg bid	0.271	0.054	
Colchicine	Macaw	0.01 mg/kg bid	0.00013	0.025	Anti-inflammatory for articular gout
Drontal PLUS Small (praziquantel/pyrantel pamoate/febantel)	Dog	1 tab (22.7/22.7/113.4 mg)	0.0064 tab/kcal (0.14/0.14/0.73)	Single treatment	Based on 3 kg dog; manufacturer's dose; successfully used in many herp species (Kaufman, unpublished)
Fenbendazole	Dog	50 mg/kg sid × 3 d	1.5	0.03	Toxicities reported in birds and reptiles; use with CAUTION; many empirical doses available
Fluconazole	Human	200 mg sid	0.12	0.04	
Flunixin meglumine	Horse	1.1 mg/kg sid	0.074	0.068	Used with good effect in reptiles (Kaufman, unpublished)
Gentamicin	Gophersnake[f]	2.5 mg/kg q 72 h	0.25	0.03	MEC dose recommended for large snakes; PK dose available for gopher snake, red-eared slider, alligator, many bird species
Itraconazole	Dog	2.5 mg/kg bid	0.076	0.06	
Ketoprofen	Horse	2.2 mg/kg sid	0.15	0.066	Used IM or IV, follow-up with oral carprofen for long-term therapy; successfully used in many reptile species (Flo Tseng, unpublished)
Metronidazole	Dog	7.5 mg/kg tid	0.2	0.08	Based on canine antibacterial dose;
	Iguana[g] (1.5 kg)	20 mg/kg PO q 24–48 h	2.2	0.055–0.1	PK dose available for Iguana
Praziquantel	Dog	5–10 mg/kg	0.3	Single dose	
Probenicid	Human	250–500 mg bid	0.148	0.08	
Rocuronium	Box turtle[h]	0.3–0.5 mg/kg IM	0.02–0.05	Single dose	For immobilization only, NOT ANALGESIC; reverse with gycopyrrolate/neostigmine
Trimethoprim-Sulfa	Dog	15 mg/kg bid	0.5	0.06	

To calculate a patient's dose:
1. Multiply the universal MEC dose by patient's MEC = mg/treatment
2. Multiply frequency coefficient by patient's SMEC = number of times/day

TABLE 126.4 Allometric Scaling Worksheet to Calculate the Universal Minimum Energy (MEC) Cost Dose From Published Dosages in the Literature

Required Data

Drug: _____

Source: _____

Model animal: _____

Body weight (BW; kg):_____

Dose: _____

Model animal MEC = K × $BW_{kg}^{0.75}$ = _____

Single dose: _____mg (mg/kg × kg)

Universal MEC Dose Calculation

Divide known single dose (mg) by model animal MEC universal MEC dose = _____

Frequency Coefficient Calculation

Divide frequency (per 24 hr) by (model animal MEC/BW [kg]) frequency coefficient = _____

FIG 126.1 Allometric scaling allows extrapolation of dosages between animals of different sizes and between individuals of different species. Here, a full-grown sharp-tailed snake (*Contia tenuis*) has a body mass one one-thousandth of that of an adult Burmese python (*Python bivittatus*). (Courtesy of Douglas R. Mader.)

of the same species, for individuals kept at different environmental temperatures, and between healthy and ill animals.[16] Use of formulas incorporating species-specific data, when available, may help decrease error in prediction, but development of such models is still in the earliest stages. The technique described for drug calculation depends on metabolic rate alone and does not take into account differences in metabolism that may affect the uptake, modification, distribution, elimination, and thus the activity of a drug in a particular individual. This level of uncertainty must be kept in perspective when proceeding with the technique.

Allometric scaling is also extremely useful, and appears to be reliable, when used to calculate a dose from a small to a large animal (and vice versa) within the same or closely related taxonomic group. If a pharmacokinetically derived dose is available for a small snake, this information might be used to extrapolate a more accurate dose for a large snake, instead of merely using the mg/kg dose (Fig. 126.1). This principle is illustrated subsequently with the use of ceftazidime in a large snake.

The practical use of metabolic scaling in large reptiles has recently been illustrated by medetomidine immobilization and atipamezole reversal in large estuarine crocodiles.[17] The authors concluded that medetomidine at a metabolically scaled dosage was effective for immobilizing large estuarine crocodiles. In addition, atipamezole administered at a dosage calculated as a function of surface area effectively reversed immobilization.[17]

REVIEW OF TECHNIQUE

Allometric scaling uses a simple ratio comparing established data from a well-known animal with the unknown patient to derive a logical dose. The energy formula is used as a point of comparison between two subjects to establish predictable data.

Minimum energy cost = K × $bodyweight_{kg}^{0.75}$

K = 10 reptiles

K = 49 marsupial mammals

K = 70 placental mammals

K = 78 nonpasserine birds

K = 129 passerine birds

With this formula, the minimum energy cost (MEC) can be predicted for both the well-known animal and the patient. With the addition of the drug dose information for the well-known animal, the drug dose can be predicted for the patient with a ratio:

$$\frac{\text{Well-known animal dose}}{\text{Well-known animal MEC}} = \frac{\text{Patient dose}}{\text{Patient MEC}}$$

The dose derived through this formula gives a suggested one-time or therapeutic dose for a particular drug in a novel patient. Sedgwick suggests a similar manipulation to calculate the periodicity, or frequency of dose administration.[18] This manipulation uses the mass specific minimum energy cost (SMEC).

$$\text{Specific minimum energy cost} = K \times bodyweight_{kg}^{-0.25} = \text{MEC/body weight}_{kg}$$

Again, the ratio is used to develop the frequency of administration on the basis of a well-known animal:

$$\frac{\text{Well-known animal frequency (times per day)}}{\text{Well-known animal SMEC}} = \frac{\text{Patient frequency (times per day)}}{\text{Patient SMEC}}$$

Following these two procedures results in a therapeutic dose and a frequency of administration. This dosage regimen may have to be adjusted for practical application. For example, a dose prediction of 4.2 mg to be given 0.4 times per day might be adjusted to 5 mg every 3 days. Adjustments should be made with safety, efficacy, and practicality in mind and must incorporate knowledge of the drug in question. In addition, maintaining careful and detailed records of outcomes after the use of allometrically scaled doses (e.g., measuring plasma drug levels) is prudent. Experience can help build confidence in the safety and efficacy of these estimated doses, which can be valuable in the future.

Choosing a Model

Attempts should be made to minimize metabolic and physiological differences between the well-known animal and the patient by basing comparisons on a pharmacokinetically derived dose of a closely related species as a model. For example, to determine a dose of ceftazidime for a 30 kg snake, an allometrically scaled dose based on the pharmacokinetically derived dose in a 2 kg snake is more accurate than a direct dose from a human or a dog or even the mg/kg dose established in the

VetBooks.ir

small snake. The 2 kg snake dose is 40 mg (20 mg/kg) every 3 days.[19] The 30 kg snake dose, based on allometric scaling from the smaller snake, is 307 mg (10.4 mg/kg) every 5 days.

Derivation of a Completely New Application

Considering the first time use of a new drug in a species is a complicated process. Drug discovery is currently moving at a dramatic pace, and newer and better therapies are continuingly being released for humans and domestic animals. Many of these novel antibiotics, antifungal agents, antiprotozoal drugs, and others are proving useful in reptile medicine.

Metabolic scaling continues to be useful in situations where pharmacokinetic information and empirical or experiential data are not available. This occurs most often with the application of new therapies, established in mammals or humans but not yet tried in reptiles. In these situations, a clinician must synthesize knowledge of the particular species involved, the medical condition at hand, and the various options for therapy used in other species with similar conditions.

A recent publication validated the idea of metabolic scaling and acknowledged the complexity of the concept, pointing out that no universal scaling exponent can be obtained for every case.[20] The authors conclude that individual extrapolation models should be built to obtain different scaling exponents specific to the species of interest.[20] At some point, a leap of faith is required to try a particular dosing regimen, hoping that safety is preserved and that efficacy is maintained.

CONCLUSION

Despite the controversies over the accuracy of allometric scaling in reptiles, the clinician dealing with reptiles finds that the methodology of scaling has distinct advantages in that it encourages us to think in detail about our patient's metabolism. As has been pointed out for humans and other mammals, some drugs appear to be scalable and others do not seem to be as predicable with current methods.

It must be restated that the method of allometric scaling should not be regarded as a substitute for pharmacology, but an addition to the problem-solving tool kit that clinicians must use when choosing the proper dosage for extra label pharmaceuticals. In human and veterinary medicine, one of the most common uses of allometric scaling is with the dosing of chemotherapeutic drugs, known to have a narrow margin of safety, by the use of body surface area to derive dosages instead of the standard mg/kg rate. Oncologists have long used body surface area (a rough approximation of metabolism) to derive dosages instead of the standard mg/kg rate.

Despite criticism, the need for allometric scaling is clear. It is of utmost importance when dosing a novel drug, for a novel species, to be conservative for safety reasons and aggressive for efficacy reasons.

The efficacy of antibiotic therapy will become more important as the number of resistant strains of bacteria continue to outstrip the introduction of novel antibiotics to the market. Which method would you use if you had to treat a 1 ton saltwater crocodile with a potentially nephrotoxic antibiotic?

ACKNOWLEDGMENT

The author thanks the coauthors of the previous version of this chapter for their significant contribution that provided the foundation for this updated edition.

Reptile Formulary

James W. Carpenter, Eric Klaphake, Paul M. Gibbons, and Kurt K. Sladky

This formulary is an updated version of the reptile formulary in the fifth edition of the *Exotic Animal Formulary* (James W. Carpenter, ed. St. Louis: Elsevier; 2018:81–116; 149–166), with permissions by the editor, contributors, and publisher.

For ease of use for the reptile chapter, drug dosages are first listed by "most species," followed by dosages in snakes, lizards, chelonians, and crocodilians; feed and water dosages are generally listed last. Some important considerations with the use of this formulary: Generic (nonproprietary) names of drugs are used in most instances.

Dosages are generally listed in ascending order (hence, dosages for a particular species may not always be listed together). For reptiles, dosages for drugs administered in the drinking water or food, nebulized or administered via nasal flush, are listed last.

Because most of the drugs mentioned in this text are not licensed for use in the species described, in some cases owner consent should be granted before their use. The superscript references include non-peer reviewed sources, including proceedings papers. Authors are encouraged to review the referenced sources and determine their reliability.

See the end of the chapter for a key to the abbreviations used in the formulary.

TABLE 127.1 Antimicrobial Agents[a]

Agent	Dosage	Species/Comments
Amikacin	—	Potentially nephrotoxic; maintain hydration; frequently used with a penicillin or cephalosporin
	26 µg/kg/hr via osmotic infusion pump implant[51,325]	Snakes/PD; consider loading dose at time of implant
	3.48 mg/kg IM once[155]	Pythons/PK (ball pythons)
	5 mg/kg IM, then 2.5 mg/kg q72h[199]	Gopher snakes/PD; house at high end of optimum temperature range during treatment
	5 mg/kg IM, then 2.5 mg/kg q72h[15,316]	Lizards
	5 mg/kg IM q48h[42]	Gopher tortoises/PK; 30°C (86°F)
	2.25 mg/kg IM q72h[146]	Alligators/PD
	50 mg/10 mL saline × 30 min nebulization q12h[99]	Most species/pneumonia; aminophylline at 25 mg/9 mL of sterile saline in nebulizer before antibiotics for bronchodilation[273]
Amoxicillin	22 mg/kg PO q12–24h[70,88]	Most species/use with an aminoglycoside
Ampicillin	—	May use with an aminoglycoside
	10–20 mg/kg SC, IM q12h[148]	Most species, including chameleons
	50 mg/kg SC, IM q12h[297]	Chelonians
	20 mg/kg IM q24h[99]	Tortoises
	50 mg/kg IM q12h[311]	Tortoises/PD
Azithromycin	10 mg/kg PO q2–7d[55]	Ball pythons/PK; single dose study; may cause nonregenerative anemia; *Mycoplasma*, *Cryptosporidium*, *Giardia*, and other susceptible organisms; location dictates dosage frequency: skin, q3d; respiratory tract, q5d; liver/kidneys, q7d
Carbenicillin	—	Discontinued; more stable than ampicillin; extended G-spectrum
	200 mg/kg IM q24h[134]	Carpet pythons/PK
	400 mg/kg IM q24h[181]	Snakes/PD; 30°C (86°F)
	400 mg/kg IM q48h[180]	Chelonians/PD (*Testudo* spp.)
Cefazolin	22 mg/kg IM q24h[264]	Chelonians
Cefoperazone (Cefobid, Pfizer)	100 mg/kg IM q96h[90]	Snakes/PD (false water cobras; 24°C [75°F])
	125 mg/kg IM q24h[90]	Lizards/PD (tegus; 24°C [75°F])
Cefotaxime	20–40 mg/kg IM q24h[99]	Most species/may use with an aminoglycoside
	100 mg/10 mL saline × 30 min nebulization q24h[238]	Most species/pneumonia

Continued

TABLE 127.1 Antimicrobial Agents—cont'd

Agent	Dosage	Species/Comments
Cefovecin	—	Short dosing interval is likely for most reptile species[240,329]
	10 mg/kg SC q12h[240]	Green iguanas/PD (25°C [77°F])
	10 mg/kg SC q24h[326]	Red-eared sliders/PK; long-acting cephalosporin; rapid decline in plasma concentrations; not recommended as a long-acting antibiotic; however, adequate to treat select bacteria q24h
Ceftazidime	20–40 mg/kg SC, IM, q48–72h[90,316,338]	Most species/chameleons use q24h
	20 mg/kg SC, IM, IV q72h[15,179]	Snakes/PD; 30°C (86°F); often effective against gram-negative aerobes (i.e., *Pseudomonas*)
	22 mg/kg IM, IV q72h[140,319]	Sea turtles
Ceftiofur	2.2 mg/kg IM q48h[70]	Snakes/ceftiofur sodium
	15 mg/kg IM q24–120h[1]	Snakes/PK; ceftiofur crystalline-free acid; ball pythons; 26.1°C (79°F); dosing interval based on MIC
	5 mg/kg SC, IM q24h[25]	Lizards/PK; ceftiofur sodium; (green iguanas)
	5 mg/kg IM q24h[285]	Green iguanas/PK; ceftiofur crystalline-free acid; no significant adverse affects noted
	30 mg/kg IM, SC[50]	Lizards/PK; ceftiofur crystalline-free acid; bearded dragons 30°C (86°F); interval may be q10–12d
	2.2 mg/kg IM q24h[70]	Turtles/ceftiofur sodium
	4 mg/kg IM q24h[70]	Tortoises/ceftiofur sodium; upper respiratory infection
Cefuroxime	100 mg/kg IM q24h[70]	Most species/30°C (86°F)
Cephalexin	20–40 mg/kg PO q12h[90]	Most species/unknown absorption
Cephalothin	20–40 mg/kg IM q12h[90]	Most species
Chloramphenicol	—	Most species/public health concern; reserve for meningitis or encephalitis caused by susceptible organisms
	40 mg/kg PO, SC, IM q24h, or 20 mg/kg PO, SC, IM q12h[90]	Most species/20 mg/kg may be given q24h in larger crocodilians
	40 mg/kg SC q24h[40]	Snakes/PD (gopher snakes, 29°C [84°F])
	50 mg/kg SC q12–72h[52]	Snakes/PD; q12h in indigo, rat, king snakes; q24h in boids, moccasin snakes; q48h in rattlesnakes; q72h in red-bellied water snakes
Chlorhexidine (Nolvasan 2%, Fort Dodge)	Topical 0.05% aqueous solution q24h[224]	All species/topical disinfection; dermatitis; infectious stomatitis; periodontal disease in lizards q24h
	Topical 0.07% (1 : 30 [solution:water])[34,237]	Most species/topical disinfection; infectious stomatitis; abscess lavage; middle ear infection flush in box turtles
Chlortetracycline	200 mg/kg PO q24h[90]	Most species
Ciprofloxacin	10 mg/kg PO q48h[70]	Most species
	11 mg/kg PO q48–72h[167]	Pythons/PD (reticulated pythons)
Ciprofloxacin ophthalmic ointment or drops (Ciloxan, Alcon)	Topical[99]	All species/infectious stomatitis; gingivitis
Clarithromycin	15 mg/kg PO q84h[344]	Tortoises/PD (desert tortoises); upper respiratory tract disease (mycoplasmosis)
Clindamycin	10 mg/kg PO, IM, IV q12h[115]	Loggerhead sea turtles/PK; 29.1–30.3°C (84.4–86.5°F) insufficient to be effective
Danofloxacin	6 mg/kg SC, IM[213]	Loggerhead sea turtles
	6 mg/kg SC q48h × 30 days[99]	Tortoises/upper respiratory tract disease
Dihydrostreptomycin	5 mg/kg IM q12–24h[88,99]	Most species/maintain hydration
Doxycycline (Vibramycin, Pfizer)	5–10 mg/kg PO q24h × 10–45 days[99]	Most species/respiratory infection (i.e., mycoplasmosis)
	50 mg/kg IM, then 25 mg/kg q72h[37,311]	Tortoises/Hermann's tortoise; 27°C (81°F)
Enrofloxacin	5–10 mg/kg q24h PO, SC, IM, ICe[99]	Most species/IM administration is painful and may result in tissue necrosis and sterile abscesses; may cause skin discoloration or tissue necrosis if given SC; to administer SC, dilute with sterile NaCl
	6.6 mg/kg IM q24h, or 11 mg/kg IM q48h[167]	Pythons/PD (reticulated pythons); *Pseudomonas*
	10 mg/kg IM q48h[338,339,351]	Snakes/PK (Burmese pythons, rattlesnakes, pit vipers)
	5 mg/kg PO, IM q24h[218]	Lizards/PD (green iguanas); marked pharmacokinetic variability with PO administration may make IM more suitable in critically ill animals
	10 mg/kg IM q5d[136]	Monitors/PK (savannah monitors); preliminary data
	5 mg/kg IM q24–48h[267]	Chelonians and most other reptiles/PD (gopher tortoises); hyperexcitation, incoordination, diarrhea reported in a Galapagos tortoise[47]

VetBooks.ir

TABLE 127.1 Antimicrobial Agents—cont'd

Agent	Dosage	Species/Comments
	5 mg/kg IM q12–24h[276]	Chelonians/PK (Indian star tortoises); q12h for *Pseudomonas* and *Citrobacter*, q24h for other bacteria
	5 mg/kg IV, IM q48h[176]	Sea turtles/PK (loggerhead sea turtles)
	10 mg/kg ICe q48h[104,286]	Chelonians/PD (Hermann's tortoises; yellow-bellied sliders) dilute with saline to 10 mg/mL
	10 mg/kg IM q24h[311]	Chelonians/PD (Hermann's tortoises)
	5 mg/kg IV q36–72h[125,215]	Crocodilians/PK; PO pharmacokinetics not fully determined; mycoplasmosis
	Nasal flush 50 mg/250 mL sterile water; 1–3 mL/naris q24–48h[99]	Tortoises/URT syndrome; use until no more discharge (5–10 days); may use concurrently with parenteral antibiotics
Gentamicin	—	Nephrotoxicity has been reported,[234] especially in snakes; maintain hydration; use with a penicillin or cephalosporin
	2.5 mg/kg IM q72h[40,41]	Snakes/PD (gopher snakes)
	2.5–3 mg/kg IM, then 1.5 mg/kg q96h[130]	Snakes/PK (blood pythons)
	3 mg/kg IM q > 96h[17]	Turtles/PD (eastern box turtles; 29°C [84°F]); lower dose may be more appropriate
	6 mg/kg IM q72–96h[274]	Turtles/PD (red-eared sliders; 24°C, [75°F])
	1.75–2.25 mg/kg IM q72–96h[146]	Crocodilians/PK (alligators); respiratory infection
Gentamicin ophthalmic ointment or drops	Topical[88]	Most species/superficial ocular infection; lesions in oral cavity
Gentamicin/betamethasone ophthalmic drops (Gentocin Durafilm, Merck)	1–2 drops to eye q12–24h[152]	Tortoises/upper respiratory infections; may also be given as a reverse nasal flush q48–72h or intranasal q12–24h
Kanamycin	10–15 mg/kg IM, IV q24h (or divided doses)[70,88]	Most species/24°C (75°F); give with fluid therapy; avoid in cases of dehydration or renal or hepatic dysfunction
Lincomycin	5 mg/kg IM q12–24h[70]	Most species/wound infection; potentially nephrotoxic; maintain hydration
	10 mg/kg PO q24h[70]	Most species
Marbofloxacin	10 mg/kg PO q48h[56]	Ball pythons/PD
Metronidazole	20 mg/kg PO q48h × ≥ 7 days[99]	Most species/anaerobes
	50 mg/kg PO q24h × 7–14 days[167]	Most species/may be administered concurrently with amikacin for broader spectrum; because of potential side effects at this dose, a lower dose may be prudent
	20 mg/kg PO q48h[31,172]	Snakes/PK (corn and rat snakes)
	20 mg/kg PO q24–48h[173]	Iguanas/PK; use q24h for resistant anaerobes
Oxytetracycline	6–10 mg/kg PO, IM, IV q24h[70,88]	Most species/may produce local inflammation at injection site
	10 mg/kg IM, IV q5d[124]	Crocodilians/PK (alligators; 27°C [81°F]); mycoplasmosis
Penicillin, benzathine	10,000–20,000 U/kg IM q48–96h[90]	Most species/may use with an aminoglycoside
Penicillin G	10,000–20,000 U/kg SC, IM, IV, ICe q8–12h[88]	Most species/infrequently used
Piperacillin	50–100 mg/kg IM q24h[70,88]	Most species/broad-spectrum bactericidal agent; maintain hydration; may use with an aminoglycoside
	50 mg/kg IM, then 25 mg/kg q24h[70,99]	Snakes
	100 mg/kg IM q48h[131]	Snakes/PK (blood pythons)
	100–200 mg/kg SC, IM q24–48h[148]	Chameleons
	100 mg/10 mL saline × 30 min nebulization q12h[238]	Most species/pneumonia
Polymyxin B sulfate, neomycin sulfate, bacitracin zinc ointment	Topical[99]	All species/rostral abrasions, dermal wounds
Povidone-iodine solution (0.05%) or ointment	Topical/lavage[88,256]	All species/fungal dermatitis; dermatophilosis; contaminated wound; can soak in 0.005% aqueous solution ≤ 1 hr q12–24h
Silver sulfadiazine cream (Silvadene, Marion)	Topical q24–72h[197]	All species/broad-spectrum antibacterial for skin (i.e., wounds, burns) or oral cavity; dressing is generally not necessary
Streptomycin	10 mg/kg IM q12–24h[88]	Most species/potentially nephrotoxic; maintain hydration; avoid in cases of dehydration or renal or hepatic dysfunction
Sulfadiazine	25 mg/kg PO q24h[99]	Most species/maintain hydration
Sulfadimethoxine	90 mg/kg IM, then 45 mg/kg q24h[88]	Most species/potentially nephrotoxic; maintain hydration

Continued

VetBooks.ir

TABLE 127.1 Antimicrobial Agents—cont'd

Agent	Dosage	Species/Comments
Ticarcillin (Ticar, SmithKline-Beecham)	50–100 mg/kg IM q24h[88]	Most species/maintain hydration
	50–100 mg/kg IM, IV q24–48h[203]	Loggerhead sea turtles/PK
Tobramycin	—	Potentially nephrotoxic; maintain hydration; potentiated by ß-lactams
	2.5 mg/kg IM q24–72h[70]	Most species
	10 mg/kg IM q24–48h[70]	Chelonians/can be given q48h in tortoises; fluid therapy recommended
Trimethoprim/sulfadiazine or sulfamethoxazole	—	Maintain hydration; parenteral form must be compounded
	10–30 mg/kg PO q24h[99]	Most species/maintain hydration
	30 mg/kg IM q24h × 2 days, then q48h[311]	Tortoises/PD
Tylosin	5 mg/kg IM q24h × 10–60 days[70]	Most species/mycoplasmosis

[a]Because reptiles are ectothermic, pharmacokinetics of drugs are influenced by ambient temperature. Antimicrobial therapy should be conducted at the upper end of the patient's preferred (selected) optimum temperature zone.

TABLE 127.2 Antiviral Agents

Agent	Dosage	Species/Comments
Acyclovir	40–80 mg/kg PO[4]	Box turtles/PK, low maximum plasma concentrations; uncertain efficacy
	≥ 80 mg/kg PO q24h[92]	Tortoises/PK; herpesvirus; poor oral absorption
	80 mg/kg PO q8h, or 240 mg/kg PO q24h[219]	Tortoises/herpesvirus; uncertain efficacy; unlikely to eliminate infection; combine with supportive care
	80 mg/kg PO q24h[255]	Mediterranean tortoises/decreased mortality in those infected with TeHV-3
	80 mg/kg PO q24h[58]	Australian Krefft's river turtles/herpesvirus; uncertain efficacy
	Topical (5% ointment) q12h[88]	All species/antiviral (i.e., herpesvirus-associated dermatitis)
Chlorhexidine solution	0.5% dilution, topical on oral lesions q24h[162]	Tortoises/herpesvirus
Famcyclovir	10–30 mg/kg PO q24h using allometric scaling[302]	Eastern box turtles/treated during outbreak of concurrent TeHV-1 and ranavirus (FV-3); uncertain efficacy
Valacyclovir	40 mg/kg PO q24h[4]	Box turtles/PK, effective plasma concentrations compared with humans; uncertain efficacy or toxicity

TABLE 127.3 Antifungal Agents

Agent	Dosage	Species/Comments
Amphotericin B	0.5 mg/kg IV q48–72h[89]	Most species/nephrotoxic; can use in combination with ketoconazole; administer slowly
	0.5–1 mg/kg IV, ICe q24–72h × 14–28 days[70]	Most species/aspergillosis
	1 mg/kg IT q24h × 14–28 days[147]	Most species/respiratory infection; dilute with water or saline
	0.1 mg/kg intrapulmonary q24h × 28 days[126]	Greek tortoises/pneumonia
	1 mg/kg q24h ICe × 2–4 wk[185]	Crocodilians
	5 mg/150 mL saline × 1 hr nebulization q12h × 7 days[143]	Most species/pneumonia
Chlorhexidine (Nolvasan 2%, Fort Dodge)	20 mL/g water bath[345]	Lizards/dermatophytosis
Clotrimazole (Veltrim, Haver-Lockhart; Otomax, with gentamicin and betamethasone, Schering-Plough)	Topical[281]	Most species/dermatitis; may bathe q12h with dilute organic iodine before use
F10 super concentrate disinfectant (Health and Hygiene, Roodeport, South Africa)	1:250 nasal flush, 0.1 mL each nare q24h[49]	Terrestrial chelonians/benzalkonium chloride/polyhexamethylene biguanide HCl
Fluconazole	5 mg/kg PO q24h[345]	Lizards/dermatophytosis
	21 mg/kg SC once, then 10 mg/kg SC 5 days later[116,201]	Loggerhead sea turtles/PK
Griseofulvin	15 mg/kg PO q72h[149–151]	Most species
	20–40 mg/kg PO q72h × 5 treatments[281]	Most species/dermatitis; limited success

VetBooks.ir

TABLE 127.3 Antifungal Agents—cont'd

Agent	Dosage	Species/Comments
Itraconazole	5 mg/kg PO q24h[214]	Most species/some hepatotoxicity noted when used for *Chrysosporium* anamorph of *Nannizziopsis vriesii*; can cause anorexia in bearded dragons without evidence of hepatotoxicity[97]
	5 mg/kg SC[184]	Cottonmouths/deaths in 3 out of 4 animals; not recommended
	10 mg/kg PO q24h[231]	Snakes
	5 mg/kg PO q24h[121]	Panther chameleons
	10 mg/kg PO q48h × 60 days[28]	Chameleons (Parson's)/osteomyelitis
	23.5 mg/kg PO q24h[94]	Lizards/PD (spiny lizards); following a 3-day treatment, a therapeutic plasma concentration persists for 6 days beyond peak concentration; treatment interval was not determined
	5 mg/kg PO q24h, or 15 mg/kg PO q72h[204]	Kemp's ridley sea turtles
Ketoconazole	—	May use antibiotics concomitantly to prevent bacterial overgrowth; may use concurrently with thiabendazole
	15 mg/kg q72h PO[149–151]	Most species
	25 mg/kg PO q24h × 21 days[144]	Snakes, turtles
	15–30 mg/kg PO q24h × 14–28 days[217,260]	Chelonians/PK (gopher tortoises); systemic infection
	50 mg/kg PO q24h × 14–28 days[99]	Crocodilians
Malachite green	0.15 mg/L water × 1 hr bath × 14 days[70]	Dermatitis
Miconazole (Monistat-Derm, Ortho)	Topical[281]	Most species/dermatitis; may bathe q12h with dilute organic iodine before use
Nystatin	100,000 U/kg PO q24h × 10 days[143]	Most species/enteric yeast infections; limited success
Terbinafine	3.4 mg/kg PO q24h × 15 mo[322]	Aldabra tortoises/severe phaeohyphomycosis of carapace; nonresponsive to itraconazole
	Topical[158]	Use in conjunction with oral azoles for *Chrysosporium* anamorph of *Nannizziopsis vriesii*; expect long treatment calendar
Tolnaftate 1% cream (Tinactin, Schering-Plough)	Topical q12h prn[3]	Most species/dermatitis; may bathe q12h with dilute organic iodine before use
Voriconazole	10 mg/kg per cloacal 3/wk × 4 wk[222]	Rattlesnakes/*Ophidiomyces ophiodiicola;* crushed in suspension (Ora-Plus, Paddock Laboratories)
	10 mg/kg PO × 47 days[301,333]	Bearded dragons for *Chrysosporium* anamorph of *Nannizziopsis vriesii*; possible hepatocellular injury
	5 mg/kg SC[138]	Red-eared sliders/exceeded MIC only until 4 hr postinjection; 26°C (78°F)
	10 mg/kg SC q12h × 7 days[142]	Red-eared sliders/resulted in trough concentrations considered subtherapeutic in humans but may reach MIC for some reptile fungal isolates; possible side effects seen
Voriconazole (V)/F10 super concentrate disinfectant (F10, Health and Hygiene, Roodeport, S Africa)	(V) 10 mg/kg PO q24h × 60 days + (F10) 1:250 dilution for 20 min bath q24h × 60 days[289]	Luthega skinks/systemic *Lecanicillium* sp. infection; nonresponsive to oral voriconazole and terbinafine ointment

TABLE 127.4 Antiparasitic Agents

Agent	Dosage	Species/Comments
Albendazole	50 mg/kg PO[99]	Most species/ascarids; most toxic of the benzimidazoles
Carbaryl powder (5%)	Lightly dust animal and environment; rinse after 1 hr; repeat in 7 days[79,90]	Lizards, snakes/mites
Chloroquine	125 mg/kg PO q48h × 3 treatments[99]	Tortoises/hemoprotozoa
Dichlorvos (Vapona No-Pest Strip; United Industries)	6 mm strip/10 ft^3 in cage × 3 hr q48h × 2–4 wk[88,347]	Most species/mites; toxicity occurs;[90] prevent contact with animals (e.g., place strip above cage or inside perforated container); avoid in cases of renal or hepatic dysfunction; remove water container; use is discouraged
Dimetridazole (Emtryl, Rhône-Poulenc)	—	Not available in the United States
	100 mg/kg PO once, repeat in 2 wk[99]	Most species/amoebae
	40 mg/kg PO q24h × 5–8 days[143]	Snakes (except milk and indigo)/amoebae; flagellates
	40 mg/kg PO, repeat in 14 days[99]	Milk and indigo snakes/amoebae; flagellates

Continued

VetBooks.ir

TABLE 127.4 Antiparasitic Agents—cont'd

Agent	Dosage	Species/Comments
Emodepside (1.98%) + praziquantel (7.94%) (Profender, Bayer)	1.12 mL/kg[225,291]	Many species/PD; nematodes; cestodes; aquatic turtles must be kept dry for 48 hr after application; appears to be safe but need more safety and efficacy data
Fenbendazole	—	Drug of choice for nematodes; least toxic of the benzimidazoles; may have an antiprotozoan effect; overdose may cause leukopenia, avoid in septicemic patients[242]
	25–100 mg/kg PO q14d for up to 4 treatments[37,143,166]	All species/nematodes
	100 mg/kg once[96]	Tortoises/nematodes; shedding of ova continues for 30 days
Fipronil (0.29%; Frontline Spray, Merial)	Wipe on then wash off in 5 min q7–10d prn[76,79]	Most species/mites, ticks; beware of reactions to alcohol carrier; needs safety evaluation[99]
Imidocloprid and moxidectin (Advantage Multi/Advocate, Bayer)	0.2 mg/kg topical q14d × 3 treatments[110]	Lizards/eliminated hookworms and pinworms; needs safety and pharmacokinetic evaluation
Ivermectin	—	Do not use in chelonians,[328] crocodilians, indigo snakes, or skinks[37,99,168]
	0.2 mg/kg PO, SC, IM, repeat in 14 days[80,99]	Snakes (except indigos), lizards (except skinks)[37]/nematodes (including lungworms),[190] mites; can dilute with propylene glycol for oral use; colored animals may have skin discoloration at injection site; rare adverse effects reported in chameleons, possibly associated with breakdown of parasites;[15] do not use within 10 days of diazepam or tiletamine/zolazepam; rare death and occasional nervous system signs, lethargy, or inappetence have been reported;[168] used for pentastomids in monitor lizards (with dexamethasone 0.2 mg/kg q2d)[80]
	5–10 mg/L water topical spray q3–5d up to 28 days[168]	Snakes (except indigos), lizards (except skinks)/mites; less effective than fipronil; spray on skin and in newly cleaned cage, then allow to dry before replacing water dish
Levamisole (Levasole 13.65%, Mallinckrodt)	5–10 mg/kg SC, ICe, repeat in 14 days[15,99,143]	Most species/lungworms; 5 mg/kg in chelonians; 10 mg/kg in lizards, snakes; very narrow range of safety; main advantage is that it can be administered parenterally; avoid concurrent use with chloramphenicol; avoid use in debilitated animals; low dose may stimulate depressed immune system; can be used IM, but less effective
Mebendazole	20–25 mg/kg PO, repeat in 14 days prn[143]	Most species/strongyles, ascarids, effective dosage of 400 mg/kg;[174] may be toxic
Metronidazole	—	Protozoan (i.e., flagellates, amoebae) overgrowth; may stimulate appetite; may cause severe neurological signs at doses > 200 mg/kg;[232] death occurred in indigo and mountain king snakes at 100 mg/kg;[143] injectable form can be administered PO; oral suspension is not available in the United States, but can be compounded
	40–100 mg/kg PO, repeat in 10–14 days[88]	Most species/flagellate overgrowth
	20 mg/kg PO q48h[31]	Corn snakes/PK; 28°C (82°F); protozoa
	40 mg/kg PO, repeat in 14 days[90,143]	Uracoan rattler, milk, tricolor king, and indigo snakes/flagellates
	40–60 mg/kg PO q7d × 2–3 doses[317]	Chameleons/flagellates; amoebae
	40–200 mg/kg PO, repeat in 14 days[228]	Geckos/ocular lesions (40 mg/kg) and subcutaneous lesions (200 mg/kg) caused by *Trichomonas*
	20 mg/kg ICe q48h[137]	Red-eared sliders/PK; ICe administration not recommended; needs further safety evaluation
	25 mg/kg PO q24h × 5 days[99]	Chelonians/amoebiasis
Milbemycin	0.25–0.5 mg/kg SC prn[30]	Chelonians/nematodes; parenteral form is not commercially available in United States; fenbendazole preferred
Nitrofurazone	25.5 mg/kg PO[340]	Most species/coccidia; seldom used
Olive oil	Coat skin q7d[15,79]	Most species, especially small, delicate lizards/mites; wash animal with mild soap (and rinse well) the next day; messy to use; environment must be treated with acaricide
Oxfendazole (Benzelmin, Fort Dodge)	66 mg/kg PO once[96]	Most species/nematodes; may be repeated after 28 days prn
Paromomycin (Humatin, Parke Davis)	35–100 mg/kg PO q24h × ≤ 28 days[88,143]	Most species/amoebae
	100 mg/kg PO q24h × 7 days, then 2×/wk × 3 mo[59]	Snakes/cryptosporidia; reduced clinical signs and oocyte shedding; does not eliminate the organism
	300–360 mg/kg PO q48h × 14 days[261]	Lizards (Gila monsters)/cryptosporidia
	300–800 mg/kg PO q24h prn[54]	Geckos/cryptosporidia; reduced clinical signs; does not eliminate the organism
	360 mg/kg PO q48h × 10 days[109]	Bearded dragons/intestinal cryptosporidia

VetBooks.ir

TABLE 127.4 Antiparasitic Agents—cont'd

Agent	Dosage	Species/Comments
Permethrin (Provent-a-Mite, Pro Products)	Environmental treatment, 1 sec of spray/ft^2; wait until dry before returning animal to enclosure[79]	Lizards, snakes/mites; ticks; FDA approved; safe and effective; wash immediately if accidentally applied to skin
	Topical[79]	Tortoises/ticks
Piperazine	40–60 mg/kg PO, repeat in 14 days[174]	Most species/strongyles, ascarids; poor efficacy at < 400 mg/kg[174]
	100–200 mg/kg PO[135]	Crocodilians
Ponazuril	30 mg/kg PO q48h × 2 treatments[32,233]	Bearded dragons/coccidiosis
Praziquantel	—	See also emodepside
	8 mg/kg PO, SC, IM, repeat in 14 days[15,99,148]	Most species/cestodes, trematodes; higher dosages have been administered[90]
Praziquantel (P) and emodepside (E) (Profender, Bayer)	(P) 5.5 mg/kg + (E) 21.5 mg (1 mL/kg) topical [327]	Tortoises/moderate efficacy against oxyurids in 2 of 4 species; efficacy against ascarids was not concluded; well-tolerated
	25–50 mg/kg PO q3h × 3 treatments[2,145]	Sea turtles (green, loggerhead)/PD; spirorchidiasis
Pyrantel pamoate	5 mg/kg PO, repeat in 14 days[168]	Most species/nematodes
	25 mg/kg PO q24h × 3 days; repeat in 3 wk[90]	Most species/ascarids, hookworms, pinworms
Pyrethrin spray (0.09%)	Topical q7d × 2–3 treatments[79]	Most species/use water-based sprays labeled for kittens and puppies; apply with cloth; can also spray cage, wash out after 30 min; use sparingly and with caution; pyrethroids are safer (see permethrin, resmethrin)
Quinacrine (Atabrine, Winthrop)	19–100 mg/kg PO q48h × 14–21 days[340]	Most species/some hematozoa
Quinine sulfate	75 mg/kg PO q48h × 14–28 days[340]	Most species/some hematozoa; toxic at > 100 mg/kg q24h; ineffective against exoerythrocytic forms
Spiramycin (Spirasol, May and Baker)	160 mg/kg PO q24h × 10 days, then 2×/wk × 3 mo[59]	Snakes/cryptosporidia; may reduce clinical signs and oocyte shedding; does not eliminate the organism
Sulfadiazine, sulfamerazine	—	Most species/coccidia; avoid sulfa drugs in cases of dehydration, urinary calculi, or renal dysfunction[232]
	75 mg/kg PO, then 45 mg/kg q24h × 5 days[88,340]	Most species/coccidia
	25 mg/kg PO q24h × 21 days[15,340]	Snakes, lizards/coccidia
Sulfadimethoxine	50 mg/kg PO q24h × 3–5 days, then q48h prn[168]	Most species/coccidia; ensure adequate hydration and renal function
	90 mg/kg PO, IM, IV, then 45 mg/kg q24h × 5–7 days[88,143,340]	Most species/coccidia
	50 mg/kg PO q24h × 21 days[334]	Bearded dragons/coccidia
Sulfadimidine (33% solution)	0.3–0.6 mL/kg PO q24h × 10 days[340]	Most species/coccidia; alternatively, 0.3–0.6 mL/kg, then 0.15–0.3 mL/kg q24h × 10 days
	1 oz/gal drinking water × 10 days[340]	Most species/coccidia
Sulfamethazine	25 mg/kg PO, IM q24h × 21 days[340]	Most species/coccidia
	50 mg/kg PO q24h × 3 days, off 3 days, on 3 days[99]	Most species/coccidia
	75 mg/kg PO, IM, IV, then 40 mg/kg q24h × 5–7 days[143]	Most species/coccidia; ensure adequate hydration and renal function
Sulfaquinoxaline	75 mg/kg PO, then 40 mg/kg q24h × 5–7 days[143]	Most species/coccidia
Thiabendazole	50–100 mg/kg PO, repeat in 14 days[89,143]	Most species/nematodes; fenbendazole preferred
Toltrazuril 5% (Baycox, Bayer)	5–15 mg/kg q24h × 3 days[73]	Bearded dragons/coccidiosis
	15 mg/kg q48h × 30 days[100]	Tortoises/coccidiosis; needs safety, efficacy, and pharmacokinetic study

TABLE 127.4 Antiparasitic Agents—cont'd

Agent	Dosage	Species/Comments
Trimethoprim/sulfa	—	Most species/coccidia; avoid potentiated sulfa drugs in cases of dehydration or renal dysfunction[232]
	30 mg/kg PO q24h × 2 days, then q48h × 21 days[15,340]	Most species/coccidia
	30 mg/kg IM q24h × 2 days, then 15 mg/kg IM q48h × 10–28 days[340]	Most species/coccidia
	30 mg/kg PO q24h × 14 days, then 1–3 ×/wk × 3–6 mo[59]	Most species/cryptosporidia; can reduce shedding but does not clear infection
Water	Bath × 30 min[79,194]	Snakes, lizards/mites; use lukewarm (29°C [85°F]) water; monitor to avoid drowning; not 100% effective; does not kill mites on head; must treat environment with acaricide

TABLE 127.5 Chemical Restraint/Anesthetic Agents

Agent	Dosage	Species/Comments
Acepromazine	0.05–0.25 mg/kg IM[99]	Most species/can be used as a preanesthetic with ketamine
	0.1–0.5 mg/kg IM[229,259]	Most species/preanesthetic; reduce by 50% if used with barbiturates
Acepromazine (A)/propofol (P)	(A) 0.5 mg/kg IM + (P) 5 mg/kg IV; (A) 0.5 mg/kg IM + (P) 10 mg/kg IV[5]	Giant Amazon pond turtles/sedation with both protocols, longer duration with higher propofol dosage
Alfaxalone(Alfaxan, Jurox)	6–9 mg/kg IV, or 9–15 mg/kg IM[182]	Most species/good muscle relaxation; variable results; drug requires more evaluation; may have violent recovery;[198] don't use within 10 days of DMSO treatment
	6–15 mg/kg IM, IV[298]	Most species
	9 mg/kg IV[290]	Snakes, lizards/induction; not effective for blotched blue-tongued skinks
	12 mg/kg IV[262]	Bearded dragons/effective for induction of anesthesia; respiratory depression noted
	15 mg/kg IM[229]	Lizards, chelonians/induction, 35–40 min; duration, 15–35 min; good muscle relaxation; variable results
	24 mg/kg ICe[111]	Chelonians (red-eared sliders)/surgical anesthesia with good relaxation
	5 mg/kg IV[170]	Turtles, tortoises/induction
	10–20 mg/kg IM[113,164,300]	Horsfield's tortoises (males only)/light to moderate sedation with no to minimal analgesia; red-eared slider turtles/light sedation of short duration; PD turtles administered 10 mg/kg at low temperature more relaxed than warm, and turtles administered 20 mg/kg at warm temperature were most relaxed
	20 mg/kg IM[141]	Red-eared slider turtles, Eastern painted turtles, yellow-spotted Amazon river turtles, other undocumented turtle species/anesthetic induction
	3 mg/kg IV[252]	Crocodilians/induction, but unpredictable results
Alfaxalone (Al)/medetomidine (Me)	(Al) 10 mg/kg + (Me) 0.10 mg/kg IM; (Al) 20 mg/kg + (Me) 0.05 mg/kg IM[113]	Horsfield's tortoises (males only)/deeper sedation than alfaxalone alone with analgesia
Atipamezole (Antisedan, Zoetis)	Give same volume SC, IV, ICe as medetomidine, or dexmedetomidine (5 × medetomidine, or 10 × dexmedetomidine dose in mg)[a,82,309]	Most species/medetomidine and dexmedetomidine reversal; causes severe hypotension in gopher tortoises when given IV[63]
	0.2–0.5 mg/kg IM[81]	Chelonians/shell repair 5–10 min before finished
	0.5–0.75 mg/kg IM,[275] 0.75 mg/kg SC[210]	Chelonians
Atropine	0.01–0.04 mg/kg SC, IM,[33] IV,[89] ICe[295]	Most species/preanesthetic; bradycardia; rarely indicated; generally use only in profound or prolonged bradycardia;[295] may help prevent intracardiac shunting;[149] ineffective at this dose in green iguanas[258]
	0.5 mg/kg IM, IV, IT, IO[232]	Most species/bradycardia, decrease secretions, CPR
Bupivicaine (0.5%)	1 mg/kg intrathecal[206]	Turtles and tortoises/spinal anesthesia
	0.1 mL/10 cm carapace[16]	Green sea turtles/spinal anesthesia
Butorphanol	—	Butorphanol combinations follow; see ketamine for combinations; inadequate for analgesia
	0.4–1 mg/kg SC, IM[295]	Most species/sedation; preanesthetic
	0.5–2 mg/kg IM, or 0.2–0.5 mg/kg IV, IO[23]	Most species/preanesthetic
	1–1.5 mg/kg SC, IM[295]	Lizards/administer 30 min before isoflurane for smoother, shorter induction
	0.2 mg/kg IM[118,275]	Chelonians/minimal sedation

VetBooks.ir

TABLE 127.5 Chemical Restraint/Anesthetic Agents—cont'd

Agent	Dosage	Species/Comments
Butorphanol (B)/medetomidine (Me)[a]	(B) 0.4 mg/kg + (Me) 0.08 mg/kg IM[95]	Green tree monitors/sedation
Butorphanol (B)/midazolam (Mi)	(B) 0.4 mg/kg + (Mi) 2 mg/kg IM[22]	Most species/preanesthetic; administer 20 min before induction
Dexmedetomidine[a] (Dexdomitor, Zoetis)	—	Dexmedetomidine combinations follow; α_2 agonist that has replaced medetomidine;[a] reverse with atipamezole
Dexmedetomidine (De)/ ketamine (K)	(De) 0.03 mg/kg + (K) 6 mg/kg IV[117]	Hatchling leatherback sea turtles/anesthesia; reversal with atipamezole (0.3 mg/kg IM, IV)
	(De) 0.2 mg/kg + (K) 10 mg/kg intracloacally[236]	Yellow-bellied sliders/adequate for light sedation or short clinical procedures
Dexmedetomidine (De)/ midazolam (Mi)/ketamine (K)	(De) 0.1 mg/kg + (Mi) 1 mg/kg + (K) 2 mg/kg SC[211]	Red-eared slider turtles/deep sedation
Dexmedetomidine (De)/ ketamine (K)/morphine (Mo)	(De) 0.075 mg/kg + (K) 8 mg/kg + (Mo) 1 mg/kg IM[223]	Gopher tortoises/anesthesia, reversed with atipamezole
Dextroketamine (DK)	10 mg/kg IV, ICe[132]	Spectacled caiman/mild sedation ICe; PK
Dextroketamine (DK)/ midazolam (Mi)	(Mi) 0.5 mg/kg + (DK) 10 mg/kg IV, ICe[132]	Spectacled caiman/deep sedation IV; PK; no analgesia
Diazepam	—	Diazepam has been replaced by the use of midazolam in many cases; see ketamine for combinations; muscle relaxation; give 20 min before anesthesia; potentially reversible with flumazenil; drug interaction with ivermectin
	0.5 mg/kg IM, IV[232]	All species/seizures
	2.5 mg/kg IM, IV[282]	Most species/seizures
	0.2–0.8 mg/kg IM[295]	Snakes/use in conjunction with ketamine for anesthesia with muscle relaxation
	0.2–2 mg/kg IM, IV[298]	Snakes, lizards
	2.5 mg/kg Po_2[95]	Iguanas/reduce anxiety, which often leads to aggression
	0.2–1 mg/kg IM[295,298]	Chelonians/use in conjunction with ketamine for anesthesia with muscle relaxation
Disoprofol	5–15 mg/kg IV to effect[36]	All species/anesthesia; similar characteristics to propofol; not available in United States
Doxapram	4–12 mg/kg IM, IV[295]	Most species/respiratory stimulant
	5 mg/kg IM, IV[22] q10min prn	Most species/respiratory stimulant; reduces recovery time; reported to partially "reverse" effects of dissociatives[183]
	20 mg/kg IM, IV, IO[232]	Most species/respiratory stimulant
	5–10 mg/kg IV[303]	American alligators/immediate dose-dependent increase in breathing frequency
Epinephrine (1 : 1000)	0.5–1 mg/kg IV, IO, IT[232]	Most species/CPR, cardiac arrest
	0.1 mg/kg IM[106]	Snapping turtles/reduction in time to spontaneous respiration after isoflurane anesthesia
Etorphine (M-99, Wildlife Pharmaceuticals)	0.3–0.5 mg/kg IM[229]0.3–2.75 mg/kg IM[182]	Crocodilians, chelonians/very potent narcotic; crocodilians: induction, 5–30 min; duration, 30–180 min; chelonians: induction, 10–20 min; duration, 40–120 min; not very effective in reptiles other than alligators;[259] poor relaxation; adequate for immobilization and minor procedures; requires an antagonist; limited use because of expense and legal restrictions
Flumazenil (Romazicon, Hoffman-LaRoche)	—	All species/reversal of benzodiazepines, including diazepam and midazolam; seldom indicated
	0.05 mg/kg IM, SC, IV[207]	All species/reversal of midazolam; extrapolated from mammals and birds
	1 mg/20 mg of zolazepam[187] IM, IV[275]	Crocodilians, chelonians/reversal of zolazepam
Fospropofol	25–50 mg/kg ICe[294]	Red-eared slider turtles/muscle relaxation and immobility especially at higher dosage, but prolonged recovery, and profound respiratory depression with resuscitation in 2/8 subjects; use with caution
Gallamine (Flaxedil, American Cyanamid)	0.4–1.25 mg/kg IM[19]0.6–4 mg/kg IM[288]	Crocodiles/results in flaccid paralysis, but no analgesia; larger animals require lower dosage; reverse with neostigmine;[188] use in alligators questionable; unsafe in alligators at ≥ 1 mg/kg,[259] deaths reported in American alligators and false gharials[185]
	0.7 mg/kg IM[235]	
	1.2–2 mg/kg IM[82]	
	0.5–2 mg/kg IM[177]	Crocodilians

Continued

VetBooks.ir

TABLE 127.5 Chemical Restraint/Anesthetic Agents—cont'd

Agent	Dosage	Species/Comments
Glycopyrrolate	0.01 mg/kg SC,[33] IM, IV[22]	Most species/preanesthetic; for excess oral or respiratory mucus; rarely indicated; generally use only in profound or prolonged bradycardia; may be preferable to atropine;[89] does not work at this dose in green iguanas[258]
Haloperidol	0.5–10 mg/kg IM q7–14d[320]	Boids/aggression management
Hyaluronidase (Wydase, Wyeth)	25 U/dose SC[187]	Crocodilians/combine with premedication, anesthetic, or reversal drugs to accelerate SC absorption
Isoflurane	3%–5% induction,[147] 1%–3% maintenance[37]	Most species/inhalation anesthetic of choice in reptiles; induction, 6–20 min; recovery, 30–60 min; not as smooth in reptiles compared with other animals; intubation and intermittent positive pressure ventilation advisable; may preanesthetize with low dose propofol, ketamine, etc.
	3% in 100% O_2 and 21% O_2[248]	Bearded dragons/trend toward shorter induction and recovery with 21% O_2 group compared with use of 100% O_2
	5% via chamber in 5 L/min O_2[129]	Green iguanas/15–35 min loss of righting reflex; mean MAC, 1.62%; pH 7.49
Ketamine	—	Ketamine combinations follow; muscle relaxation and analgesia may be marginal; prolonged recovery with higher doses; larger reptiles require lower dose; painful at injection site; safety is questionable in debilitated patients; avoid use in cases with renal dysfunction; snakes may be permanently aggressive after ketamine anesthesia;[18] generally recommend use only as a preanesthetic before isoflurane for surgical anesthesia
	10 mg/kg SC, IM q30min[33]	Most species/maintenance of anesthesia; recovery, 3–4 hr
	20–60 mg/kg IM, or 5–15 mg/kg IV[99]	Most species/muscle relaxation improved with midazolam or diazepam
	22–44 mg/kg SC, IM[18,19]	Most species/sedation
	55–88 mg/kg SC, IM[19]	Most species/surgical anesthesia; induction, 10–30 min; recovery, 24–96 hr
	10–20 mg/kg IM[231,232]	Snakes, chelonians/sedation
	20–60 mg/kg SC, IM[33,154]	Snakes/sedation; induction, 30 min; recovery, 2–48 hr
	60–80 mg/kg IM[37]	Snakes/light anesthesia; intermittent positive pressure ventilation may be needed at higher doses
	5–10 mg/kg[231,295]	Lizards, snakes/decreases the incidence of breath-holding during chamber induction
	20–30 mg/kg IM[78]	Iguanas/sedation (i.e., facilitates endotracheal intubation); preanesthetic; requires lower dose than other reptiles
	30–50 mg/kg SC, IM[33,154]	Lizards/sedation; variable results
	20–60 mg/kg IM[133,154,259]	Chelonians/sedation; induction, 30 min; recovery, ≥ 24 hr; potentially dangerous in dehydrated and debilitated tortoises
	25 mg/kg IM, IV[99]	Sea turtles/sedation; used at higher doses (50–70 mg/kg); recovery times may be excessively long and unpredictable; combination of ketamine and acepromazine gives a more rapid induction and recovery
	38–71 mg/kg ICe[346]	Green sea turtles/anesthesia; induction, 2–10 min; duration, 2–10 min; recovery, < 30 min
	60–90 mg/kg IM[154,229]	Chelonians/light anesthesia; induction, < 30 min; recovery, hours to days; requires higher doses than most other reptiles
	20–40 mg/kg SC, IM, ICe (sedation), to 40–80 mg/kg (anesthesia)[187]	Crocodilians/induction, < 30–60 min; recovery, hours to days; in larger animals, 12–15 mg/kg may permit tracheal intubation;[295] not recommended alone in Nile crocodiles[177]
	20–100 mg/kg IM[185]	Crocodilians/lower dose for sedation, higher for anesthesia (requires intermittent positive pressure ventilation for hours)
Ketamine (K)/butorphanol (B)	See (K) dosages + (B) ≤ 1.5 mg/kg IM[295]	Snakes/anesthesia with improved muscle relaxation
	(K) 10–30 mg/kg + (B) 0.5–1.5 mg/kg IM[295]	Chelonians/minor surgical procedures (i.e., shell repair)
Ketamine (K)/dexmedetomidine (De)	(K) 5–7 mg/kg + (De) 0.025–0.07 mg/kg IV[141]	Red-eared slider turtles, Eastern painted turtles, yellow-spotted Amazon river turtles, other undocumented turtle species/anesthetic induction
	(K) 10 mg/kg + (De) 0.05 mg/kg IM, IV[268,269]	Desert tortoises/premedication
Ketamine (K)/diazepam (D)	See (K) dosages + (D) 0.2–0.8 mg/kg IM[295]	Snakes/anesthesia with improved muscle relaxation
	(K) 60–80 mg/kg[229] + (D) 0.2–1 mg/kg IM[295]	Chelonians/anesthesia; muscle relaxation
Ketamine (K)/medetomidine (M)[a]	—	Medetomidine is no longer commercially available, but can be compounded;[a] reverse medetomidine with atipamezole
	(K) 10 mg/kg + (M) 0.1–0.3 mg/kg IM[71]	Most species
	(K) 5–10 mg/kg + (M) 0.1–0.15 mg/kg IM, IV[120]	Lizards (iguanas)
	(K) 3–8 mg/kg + (M) 0.025–0.08 mg/kg IV[189]	Giant tortoises (Aldabra)

VetBooks.ir

TABLE 127.5 Chemical Restraint/Anesthetic Agents—cont'd

Agent	Dosage	Species/Comments
	(K) 4 mg/kg + (M) 0.04 mg/kg IM[123]	Green sea turtles
	(K) 4–10 mg/kg + (M) 0.04–0.14 mg/kg IM[81]	Chelonians/sedation and muscle relaxation for shell repair
	(K) 5 mg/kg + (M) 0.05 mg/kg IV[48]	Loggerhead sea turtles/induction of anesthesia for intubation
	(K) 5 mg/kg + (M) 0.05 mg/kg IM[247]	Tortoises (gopher)/light anesthesia; tracheal intubation; inconsistent results
	(K) 5–10 mg/kg IM + (M) 0.1–0.15 mg/kg IM, IV[120]	Tortoises (small-medium)
	(K) 7.5 mg/kg + (M) 0.075 mg/kg IM[247]	Tortoises (gopher)/anesthesia; tracheal intubation
	(K) 10 mg/kg + (M) 0.1 mg/kg IM[169]	Hybrid Galapagos tortoises/sedation
	(K) 10–20 mg/kg IM + (M) 0.15–0.3 mg/kg IM, IV[120]	Turtles (fresh water)
	(K) 5–10 mg/kg + (M) 0.1–0.15 mg/kg IM[122]	Alligators/adults
	(K) 10–15 mg/kg + (M) 0.15–0.25 mg/kg IM[122]	Alligators/juveniles
Ketamine (K)/medetomidine (Me)/midazolam (Mi)	(K) 5 mg/kg + (Me) 0.15 mg/kg + (Mi) 1 mg/kg SC[209]	Leopard tortoises/deep sedation
Ketamine (K)/medetomidine (Me)/morphine (Mo)	(K) 2.5 mg/kg + (Me) 0.15 mg/kg + (Mo) 1 mg/kg SC[210]	African spurred tortoises/deep sedation and analgesia
Ketamine (K)/midazolam (Mi)	(K) 20 mg/kg + (Mi) 2 mg/kg IM, (K) 60 mg/kg + (Mi) 2 mg/kg IM[6]	Giant Amazon river turtles/sedation with both combinations; more rapid and prolonged sedation with higher K dosage
	(K) 20–40 mg/kg + (Mi) ≤ 2 mg/kg IM[29]	Chelonians/sedation; muscle relaxation
	(K) 60–80 mg/kg[229] + (Mi) ≤ 2 mg/kg IM[295]	Chelonians/anesthesia; muscle relaxation
Ketamine (K)/propofol (P)	(K) 25–30 mg/kg IM[229] + (P) 7 mg/kg IV[270]	Chelonians/administer propofol ≈ 70–80 min postketamine; see propofol
Ketamine (K)/xylazine (X)	(K) 30 mg/kg + (X) 1 mg/kg IM[45]	Broad-snouted caiman juveniles/provided mild sedation after either forelimb or hind limb administration
Lidocaine (0.5%–2%)	Local or topical[295]	Most species/local analgesia; infiltrate to effect (e.g., 0.01 mL 2% lidocaine used for local block for IO catheter placement in iguanas);[20] often used in conjunction with chemical immobilization
	0.158 mg/cm intrathecal (combined with epinephrine hemitartrate)[287]	Green iguana/spinal anesthesia
	2 mg/kg intrathecal (IT)[206]	Turtles and tortoises/surgical analgesia/anesthesia of caudal body
	0.038 mL/kg (1 mL/20–25 kg)[277]	Hybrid Galapagos tortoises/surgical analgesia/anesthesia for phallectomy
Medetomidine[a]	—	Medetomidine is no longer commercially available, but can be compounded;[a] reverse with atipamezole; produces poor immobilization alone; see ketamine and butorphanol for combinations
	0.1–0.15 mg/kg IM[22]	Most species
	0.06–0.15 mg/kg[296]	Lizards
	0.15 mg/kg IM[308,309]	Desert tortoises, crocodilians/sedation; incomplete immobilization; generally produces bradycardia and bradypnea
	0.04–0.15 mg/kg IM[185]	Crocodilians/need to reverse
	0.13–0.17 mg/kg IM[250,251]	Crocodilians/moderate sedation/atipamezole (0.1 mg/kg IM) for reversal
	0.5–0.75 mg/kg IM[250,251]	Crocodilians/sedation only when administered in thoracic limb (versus pelvic limb and tail), with atipamezole (2.5 mg/kg) reversal
Meperidine (Mp)/Midazolam (Mi)	(Mp) 1 mg/kg + (Mi) 1 mg/kg IM[16]	Green sea turtles/premedication
Methohexital (Brevital, Lilly)	—	Recovery time of red-sided garter snakes at 21°C (70°F), 125 min; 26°C (79°F), 86 min; 31°C (88°F), 64 min; thinner snakes had longer recovery times; if within 5 wk of parturition, mean recovery time 2 × as long as nongravid; time postfeeding had no effect at 1, 3, 10 days[266]
	5–20 mg/kg SC,[19] IV[89]	Most species/induction, 5–30 min; recovery, 1–5 hr; use at 0.125%–0.5% concentration; much species variability; decrease dose 20%–30% for young animals; avoid use in debilitated animals
	9–10 mg/kg SC,[243] ICe	Colubrids/induction, ≥ 22 min; recovery, 2–5 hr; does not produce soft-tissue irritation seen with other barbiturates; may need to adjust dosage in obese snakes
Metomidate	10 mg/kg IM[71,288]	Snakes/profound sedation; not available in the United States

Continued

VetBooks.ir

TABLE 127.5 Chemical Restraint/Anesthetic Agents—cont'd

Agent	Dosage	Species/Comments
Midazolam	—	See butorphanol, ketamine for combinations; can be reversed by flumazenil
	0.1–1 mg/kg[11]	Multiple species/mild to moderate sedation
	2 mg/kg IM[18,19]	Most species/preanesthetic; increases the efficacy of ketamine; effective in snapping turtles, not in painted turtles[19]
	0.5–2 mg/kg[296]	Lizards
	1.5 mg/kg IM[254]	Turtles (red-eared sliders)/sedation; onset, 5.5 min; duration, 82 min; recovery, 40 min; much individual variability
	2–3 mg/kg IV[117]	Hatchling leatherback sea turtles/sedation
Naloxone	0.04–2 mg/kg SC[304,305,307,309]	Corn snakes, bearded dragons, red-eared sliders/μ-opioid agonist reversal
	4 mg/kg IM[95]	Green tree monitors/reversal of butorphanol
Neostigmine	0.03–0.25 mg/kg IM[188]	Crocodiles/gallamine reversal; may cause emesis and lacrimation; fast 24–48 hr before use; effects enhanced if combined with 75 mg hyaluronidase per dose when administered SC, IM[188]
	0.063 mg/kg IV[188]	
	0.07–0.14 mg/kg IM[235]	
Pentobarbital	—	Rarely used as an anesthetic agent in reptiles
	15–30 mg/kg ICe[229]	Snakes/induction, 30–60 min; duration, ≥ 2 hr; prolonged recovery (risk of occasional fatalities); venomous snakes require twice as much as nonvenomous snakes;[18] avoid use in lizards
	10–18 mg/kg ICe[229]	Chelonians
	7.5–15 mg/kg ICe, or 8 mg/kg IM[18,229]	Crocodilians
Propofol	—	If administered in supravertebral sinus, be aware for potential submeningeal delivery;[271] see ketamine for combination; anesthesia; rapid, smooth induction; may give 15–25 min anesthesia and restraint in most species; rapid, excitement-free recovery; must be administered IV (slowly; no inflammation if goes perivascularly); may be administered IO; dosages may be reduced by as much as 50% in premedicated (e.g., ketamine) animals; may cause apnea and bradycardia; intubation and assisted ventilation generally required; considered by many to be parenteral agent of choice for inducing anesthesia
	0.3–0.5 mg/kg/min IV, IO constant rate infusion, or 0.5–1 mg/kg IV, IO periodic bolus[298]	Most species/maintenance anesthesia; must provide respiratory and thermal support
	5–10 mg/kg IV, intracardiac[9,288]	Snakes
	10 mg/kg intracardiac[222]	Ball pythons/anesthetic induction for isoflurane maintenance, but prolonged recovery; mild, resolving cardiac lesions
	15 mg/kg IV[27]	South American rattlesnakes/anesthetic induction
	3–5 mg/kg IV, IO[119,120]	Lizards (iguanas)/intubation and minor diagnostic procedures; may need to give an additional dose in 3–5 min; less cardiopulmonary depression than with higher doses
	5–10 mg/kg IV, IO[24]	Iguanas/higher dose is recommended for induction for short-duration procedures or intubation
	10 mg/kg IV, IO[24,71,242]	Lizards, snakes/0.25 mg/kg/min may be given for maintenance;[99] green iguanas/anesthetic induction[242]
	10 mg/kg IV[262]	Bearded dragons/effective for induction of anesthesia; respiratory depression noted; apnea in 2/8 animals
	2 mg/kg IV[22]	Giant tortoises
	3–5 mg/kg IV supravertebral sinus[81]	Chelonians/sedation (i.e., shell repair)
	5 mg/kg IV[106]	Snapping turtles/anesthetic induction
	10 mg/kg IV (supravertebral sinus)[350]	Red-eared sliders/40–85 min anesthesia
	12–15 mg/kg IV[68,318]	Chelonians/lower dosages (5–10 mg/kg IV[295]) may be used; 1 mg/kg/min may be given for maintenance[295]
	20 mg/kg IV (supravertebral sinus)[350]	Red-eared sliders/60–120 min anesthesia
	10–15 mg/kg IV[187]	Crocodilians/duration, 0.5–1.5 hr; maintain on gas anesthetics; experimental IM with hyaluronidase
Rocuronium (Zemuron, Organon)	0.25–0.5 mg/kg IM[157]	Box turtles/neuromuscular blocking agent; no analgesia; for intubation only and small, nonpainful procedures
Sevoflurane	To effect[15,279]	Most species/anesthesia; rapid induction and recovery when intubated

VetBooks.ir

TABLE 127.5 Chemical Restraint/Anesthetic Agents—cont'd

Agent	Dosage	Species/Comments
Succinylcholine	—	No analgesia; narrow margin of safety; generally not recommended, but included for completeness; intermittent positive pressure ventilation generally required; paralysis occurs in 5–30 min; avoid if exposed to organophosphate parasiticides within last 30 days; administer minimal amount required to perform procedure
	0.25–1 mg/kg IM[147]	Most species
	0.75–1 mg/kg IM[33]	Large lizards
	0.25–1.5 mg/kg IM[259]	Chelonians/induction, 15–30 min; recovery, 45–90 min; facilitates intubation
	0.5–1 mg/kg IM[34]	Box turtles/induction, 20–30 min
	0.25 mg/kg IM[177]	Crocodilians
	0.4–1 mg/kg IM[259]	Alligators/rapid onset; 3–5 mg/kg in smaller animals have been used
	0.5–5 mg/kg IM[19,185]	Crocodilians/variable induction and recovery periods
Thiopental	19–31 mg/kg IV[346]	Green sea turtles/anesthesia; induction, 5–10 min; recovery, < 6 hr; erratic anesthesia
Tiletamine/zolazepam (Telazol, Fort Dodge)	—	Sedation, anesthesia; severe respiratory depression possible (may need to ventilate);[37] variable results; may have prolonged recovery; use lower end of dose range in heavier species; good for muscle relaxation before intubation;[83,275] other anesthetic agents may be preferable
	4–5 mg/kg SC, IM[19]	Most species/sedation; induction, 9–15 min; recovery, 1–12 h; adequate for most noninvasive procedures
	5–10 mg/kg IM[22]	Most species
	3 mg/kg IM[120]	Snakes/facilitates handling and intubation of large snakes; induction, 30–45 min; prolongs recovery
	3–5 mg/kg IM[232]	Snakes, lizards/sedation
	10–30 mg/kg IM[229]–20–40 mg/kg IM[147,293]	Snakes, lizards/induction, 8–20 min; recovery, 2–10 hr; variable results; longer sedation and recovery times at 22°C (72°F) than at 30°C (86°F);[321] good sedation in boa constrictors at 25 mg/kg IM;[321] generally need to supplement with inhalation agents for surgical anesthesia; some snakes died at 55 mg/kg
	3.5–14 mg/kg IM[229] (generally 4–8 mg/kg)	Chelonians/sedation; induction, 8–20 min; does not produce satisfactory anesthesia even at 88 mg/kg[259]
	5–10 mg/kg IM, IV[295]	Large tortoises/facilitates intubation; if light, mask with isoflurane rather than redosing
	1–2 mg/kg IM[185]	Crocodilians/recovery takes several hours
	2–10 mg/kg IM[295]	Large crocodilians/may permit intubation
	5–10 mg/kg SC, IM, ICe (sedation), 10–40 mg/kg (anesthesia)[187]	Crocodilians
	15 mg/kg IM[53]	Alligators/induction, >20 min; adequate for minor procedures
Xylazine	—	Infrequently used; variable effects; potentially reversible with yohimbine; preanesthetic for ketamine; see ketamine for combination
	0.1–1.25 mg/kg IM, IV[89]	Most species
	0.1–1 mg/kg IM[185]	Crocodilians/atipamezole better reversal than yohimbine
	1–2 mg/kg IM[187,259]	Nile crocodiles
Yohimbine (Yobine, Lloyd)	—	Xylazine reversal; rarely indicated; atipameazole commonly used to reverse all α_2 agonists

[a]Medetomidine is no longer commercially available in North America, although it can be obtained from select compounding services; dosages are listed here as a guide for possible use with dexmedetomidine, an α_2 agonist that is the active optical enantiomer of racemic compound medetomidine; dexmedetomidine is generally used at half the dose of medetomidine but the same volume due to higher concentration; both compounds tend to have similar effects.

VetBooks.ir

TABLE 127.6 Analgesic Agents

Agent	Dosage	Species/Comments
Bupivacaine	1–2 mg/kg local q4–12h prn[298]	Most species/local anesthesia; 4 mg/kg maximum dose
	1 mg/kg intrathecal[206]	Turtles, tortoises/regional analgesia/anesthesia
Buprenorphine	0.2 mg/kg SC[212]	No evidence of analgesic efficacy in red-eared slider turtles or other reptile species
Butorphanol	—	Recent studies call into question use of particular doses or of this drug in general is providing analgesia in reptiles, including red-eared sliders, ball pythons, corn snakes, bearded dragons, and green iguanas; respiratory depression is a common side effect[292,306,307]
	0.4–1 mg/kg SC, IM[295]	Most species; sedation; preanesthetic; 0.2 mg/kg IM used experimentally in tortoises[98]
	1 mg/kg IM[84]	Green iguanas/ineffective for analgesia; presence of observer may affect iguana response
	20 mg/kg SC[161]	Red-eared slider turtles/ineffective for surgical analgesia
Carprofen	1–4 mg/kg PO, SC, IM, IV q24h,[183] follow with half the dose q24–72h[220]	Most species/nonsteroidal antiinflammatory; no efficacy data in any reptile species
Etodolac	5 mg/kg PO q72h × 30 days[257]	Komodo dragons
Fentanyl	12 μg/hr transdermal patch[61]	Ball pythons/therapeutic plasma concentrations, as defined in mammals, were sustained for the 7-day study, and higher than in mammals; however, efficacy was not determined
	12.5 μg/hr transdermal patch to cranial epaxial muscles[160]	Ball pythons/high plasma concentrations (above analgesic threshold in mammals); analgesic efficacy not proven in any snake species, but anecdotal evidence from certain snake clinical cases demonstrated improved condition after application of patch
	12.5 μg/hr transdermal patch to caudodorsal lumbar region[93]	Prehensile-tailed skinks/no side effects reported after 24 hr when skink blood levels reached human therapeutic levels; environmental temperature can significantly affect absorption
Flunixin meglumine	0.1–0.5 mg/kg IM q12–24h[183]	Most species/nonsteroidal antiinflammatory; use for maximum of 3 days; no evidence of efficacy
	0.5–2 mg/kg IM q12–24h[298]	Most species/nonsteroidal antiinflammatory; no evidence of efficacy
	1–2 mg/kg IM q24h × 2 treatments[36,313]	Lizards/postsurgical nonsteroidal antiinflammatory; no evidence of efficacy
Hydromorphone	0.5–1 mg/kg SC[212]	Red-eared sliders/analgesic efficacy
Ketoprofen	—	Nonsteroidal antiinflammatory
	2 mg/kg PO, SC, IM q24–48h[191,331]	Most species/green iguanas/PK study;[331] loggerhead sea turtles/frequently used due to historical evidence of safety;[191] no efficacy data
Lidocaine (0.5%–2%)	2–5 mg/kg local[298]	Most species/10 mg/kg maximum dosage
	Local or topical[295]	Most species/local analgesia; infiltrate to effect (e.g., 0.01 mL 2% lidocaine used for local block for IO catheter placement in iguanas);[20] often used in conjunction with chemical immobilization
	4 mg/kg intrathecal[206]	Turtles, tortoises/regional analgesia
Lidocaine (L)/morphine (Mo)	2 mg/kg (L) + 0.1 mg/kg (Mo) intrathecal[269]	Desert tortoises/orchiectomy analgesia
Meloxicam	0.1–0.5 mg/kg PO, SC q24–48h[149–151]	Most species
	0.3 mg/kg IM[249]	Ball pythons/physiological changes not consistent with analgesia
	0.2 mg/kg PO, IV q24h[72]	Green iguanas/PD; no evidence of efficacy
	0.1 mg/kg IM, IV[175]	Loggerhead sea turtles/PK; plasma concentrations not consistent with analgesia
	0.1–0.2 mg/kg PO, IM q24h × 4–10 days[81]	Chelonians; no evidence of efficacy
	0.2 mg/kg IM, IV;[332] SC[268,269]	Red-eared slider turtles/PK; plasma concentrations consistent with therapeutic efficacy for 48 hr by IM and IV administration routes;[332] Mojave desert tortoises, postsurgical nonsteroidal antiinflammatory[268,269]
	0.2–0.4 mg/kg IM[141]	Red-eared slider turtles, Eastern painted turtles, yellow-spotted Amazon river turtles, other undocumented turtle species/nonsteroidal antiinflammatory; no evidence of efficacy
	0.5 mg/kg PO, IM, or 0.22 mg/kg IV[278]	Red-eared sliders/PK; found better absorption IM vs PO;[278] after IV administration, plasma levels decreased rapidly and the elimination half-life was 7.57 hr
Meperidine	5–10 mg/kg IM q12–24h[118]	Most species/analgesia; no noticeable effect in snakes even at 200 mg/kg
	20 mg/kg IM q12–24h[183]	Most species/analgesia
	2–4 mg/kg ICe q6–8h[149]	Lizards
	1–5 mg/kg IM[156,306,335]	Turtles, crocodiles/analgesic efficacy of short duration
	2–4 mg/kg ICe[3]	Nile crocodiles/analgesia
Methadone	3–5 mg/kg SC, IM[58,306]	Aquatic turtles/analgesia

VetBooks.ir

TABLE 127.6 Analgesic Agents—cont'd

Agent	Dosage	Species/Comments
Morphine	—	No effective dose for analgesia documented in corn snakes[307]
	10 mg/kg IM[307,341]	Bearded dragons/analgesia; ball pythons/no analgesia
	1.5–6.5 mg/kg SC, IM (Sladky KK, unpublished data)[78,306–307]	Red-eared sliders (long lasting respiratory depression), freshwater crocodiles, *Anolis* lizards/may be effective thermal analgesia
	0.1–0.2 mg/kg intrathecal[206]	Turtles, tortoises/thermal analgesia for 48 hr; regional analgesia caudal body
	2 mg/kg SC[161]	Red-eared slider turtles/surgical analgesia
	1 mg/kg IM[141]	Red-eared slider turtles, Eastern painted turtle, yellow-spotted Amazon river turtle, other undocumented turtle species/analgesia
	0.5–4 mg/kg ICe[309]	Crocodilians/analgesia
Naloxone	0.04–2 mg/kg SC (Sladky KK, unpublished data)[304,307,309]	Red-eared sliders, bearded dragons, corn snakes/μ-opioid agonist reversal
Oxymorphone	0.025–0.1 mg/kg IV[89]	Anecdotal evidence of analgesia in some lizard and turtle species; no efficacy or PK/PD studies; avoid in cases with hepatic or renal dysfunction; no observable effects in snakes even at 1.5 mg/kg
	0.05–0.2 mg/kg SC, IM q12–48h[118]	
	0.5–1.5 mg/kg IM[89]	
Pethidine	—	See meperidine
Prednisolone	2–5 mg/kg PO, IM[183]	Most species/antiinflammatory
Proparacaine (0.5%)	Topical to eye[107,195,284,299]	Iguanas/desensitizes surface of eye; ineffective in animals with spectacles; bearded dragons/IOP by rebound tonometry;[299] Kemp's ridley sea turtles/one drop provided 45 min duration of action;[107] do not exceed toxic dose 2 mg/kg;[99] Yacare caiman/IOP by applanation tonometry[284]
Tapentadol	10 mg/kg IM[102,103]	Red-eared and yellow-bellied slider turtles/analgesia
Tramadol	11 mg/kg PO[108]	Bearded dragons
	5–10 mg/kg PO, SC[13]	Red-eared slider turtles, sea turtles/thermal analgesia, higher doses may affect ventilation
	5–10 mg/kg Po_2[245]	Loggerhead sea turtles/PK; plasma concentrations consistent with efficacy for 48 hr (5 mg/kg PO) or 72 hr (10 mg/kg PO)
	10 mg/kg PO[310]	Turtles, tortoises/analgesia
	10 mg/kg IM[105]	Yellow-bellied slider turtles/PK/PD comparing forelimb and hind limb administration; analgesia; plasma concentrations consistent with analgesia in both forelimb and hind limb

TABLE 127.7 Hormones and Steroids

Agent	Dosage	Species/Comments
Arginine vasotocin (AVT) (Sigma Chemical)	0.01–1 μg/kg IV (preferred), ICe[186] q12–24h × several treatments	Most species/dystocias; administer 30–60 min after Ca lactate/Ca glycerophosphate; more effective in reptiles than oxytocin but not commercially available for use in animals; higher doses have been reported; 0.5 μg/kg commonly recommended
Calcitonin	1.5 U/kg SC q8h × 14–21 days prn[89]	Most species (e.g., iguanas)/severe nutritional secondary hyperparathyroidism; administer after Ca supplementation; do not give if hypocalcemic
	50 U/kg IM, repeat in 14 days[21,99]	
	50 U/kg q7d × 2–3 doses[192,196]	Green iguanas/salmon calcitonin; do not give if hypocalcemic
Deslorelin acetate	—	No success with use in female reptile reproductive issues
	4.75 mg implant SC[283]	Bearded dragons/abnormal aggression in juveniles; decreased serum testosterone, behavior ceased
Dexamethasone	0.2 mg/kg IM, IV[297]	Most species/laryngeal or pharyngeal edema and inflammation
	0.6–1.25 mg/kg IM, 89	Most species/shock (septic/traumatic)
	0.3–1.5 mg/kg IM, IV, IO[151]	Chelonians/hyperthermia
Dexamethasone sodium phosphate	0.1–0.25 mg/kg SC, IM, IV[99]	Most species/shock (septic/traumatic)
Insulin	1–5 U/kg IM, ICe q24–72h[315]	Snakes, chelonians/doses are empirical and must be adjusted based on response to therapy and serial blood glucose; doses administered ICe may take 24–48 hr before a response is noted
	5–10 U/kg IM, ICe q24–72h[315]	Lizards, crocodilians/see previous
Leuprolide acetate (Lupron Depot 1.875 mg/mL, Abbott)	0.4 mg/kg IM[163]	Iguanas/did not suppress testosterone levels in males
Levothyroxine	0.02 mg/kg PO q48h[112]	Geckos/postthyroidectomy, lifetime management
	0.02 mg/kg PO q48h[246]	Tortoises/hypothyroidism; stimulates feeding in debilitated tortoises
	0.025 mg/kg q24h in AM[86]	Tortoises/monitor T_4 levels

Continued

VetBooks.ir

TABLE 127.7 Hormones and Steroids—cont'd

Agent	Dosage	Species/Comments
Methylprednisolone	1 mg/kg IV q24h[151]	Chelonians/ivermectin toxicity
Nandrolone (Deca-Durabolin, Orgamon)	0.5–5 mg/kg IM q7–28d[127]	Most species/hepatic lipidosis
	1 mg/kg IM q7–28d[69]	Lizards/anabolic steroid; reduces protein catabolism; may stimulate erythropoiesis
Oxytocin	—	Dystocias; results are variable; works well in chelonians, less so in snakes and lizards; generally administer 1 hr after Ca administration; use multiple doses with caution
	1–10 U/kg IM[78,99]	Most species/higher end of the range is commonly used; may be repeated up to 3 treatments at 90 min intervals with increasing dosage
	2 U/kg IM q4–6h × 1–3 treatments[10]	Most species
	1–5 U/kg IM,[67] repeat in 1 hr	Lizards/alternatively, 5 U/kg by slow IV or IO over 4–8 hr[67]
	1–2,[35] 2–20,[217] or 10–20[34] U/kg IM	Chelonians
	1–20 U/kg IM q90min × 3 treatments at increased doses, or 50%–100% first dose 1–12 hr later, or IO drip[324]	Chelonians
	2 U/kg IV q2h[65]	Red-eared sliders/faster onset vs IM; fewer animals required second or third doses vs IM route
Prednisolone	2–5 mg/kg PO, IM[183]	Most species/analgesia (chronic pain)
	0.5 mg/kg q24h × 14 days, then q48h until PCV stable[149]	Lizards/autoimmune hemolytic anemia
Prednisolone Na succinate (Solu-Delta Cortef, Pharmacia and Upjohn)	5–10 mg/kg IM, IV,[82] IO[69]	Most species/shock; brain swelling from hyperthermia; may help reduce nephrocalcinosis
Prednisone	0.5–1 mg/kg PO, SC, IM, IV[216]	Most species/lymphoma, leukemia, myeloproliferative disease
	0.8 mg/kg q48h[95]	Most species/chronic T-lymphocytic leukemia; may combine with chlorambucil, but need to monitor uric acid levels
Stanozolol (Winstrol-V, Winthrop)	5 mg/kg IM q7d prn[99]	Most species/anabolic steroid; management of catabolic disease states

TABLE 127.8 Nutritional/Mineral/Fluid Support

Agent	Dosage	Species/Comments
Calcium	PO prn[74]	Most species/dietary sources include crushed cuttlebone, oyster shell, egg shell, tablets of Ca salts, or other commercially available products
Calcium carbonate (Rep-Cal, Rep-Cal Labs; Repti Calcium, Zoo Med; Fluker's powdered or liquid forms of calcium)	PO prn[74]	Omnivores, herbivores, insectivores/dietary Ca supplement
Calcium glubionate (Neo-Calglucon, Sandoz; Calciquid, Breckenridge Pharmaceuticals; Calcionate, Rugby)	10 mg/kg PO q12–24h prn[91]	All species/nutritional secondary hyperparathyroidism
	25–50 mg/kg PO q24h prn[208]	All species/nutritional secondary hyperparathyroidism
	360 mg/kg (1 mL/kg) PO q12–24h prn[21,37]	Most species/nutritional secondary hyperparathyroidism; hypocalcemia; dystocia; ensure adequate UVB exposure and proper nutrition
Calcium gluconate	50–100 mg/kg SC, IM, IV[208]	Most species/hypocalcemia (low ionized Ca); hypocalcemic muscle tremors, seizures, dystocia, or flaccid paresis in lizards; when patient is stable, switch to oral Ca; should be diluted in fluids
	100 mg/kg SC, IM, ICe[200,220] q6–24h[21,37]	Most species/hypocalcemia (low ionized Ca); hypocalcemic muscle tremors, seizures, dystocia, or flaccid paresis in lizards; when patient is stable, switch to oral Ca
Calcium gluconate/borogluconate	10–50 mg/kg SC, IM[91]	Most species/hypocalcemia; hypocalcemic dystocia
Calcium glycerophosphate/calcium lactate (Calphosan, Glenwood)	1–5 mg/kg SC, IM[91]	Most species/hypocalcemia; hypocalcemic dystocia
	10 mg/kg SC, IM, ICe q24h × 1–7 days[15,21]	Lizards (iguanas)/hypocalcemia

VetBooks.ir

TABLE 127.8 Nutritional/Mineral/Fluid Support—cont'd

Agent	Dosage	Species/Comments
Carnivore Care (Oxbow Animal Health)	10–20 mL/kg PO or via gavage/esophagostomy q24–48h[98]	Carnivores/short-term nutritional support; anorexia; prepare according to directions; begin after rehydration and stable condition; more dilute in first feeding after anorexia, gradually increase concentration over 3–5 days
	30 mL/kg (3% of body weight) PO or via gavage/esophagostomy q24h;[64] range of 2%–10% body weight PO or via gavage/esophagostomy q24h[208]	Carnivores
Clinicare—feline and canine (Abbott Animal Health)	Gavage prn[348]	Most species/postomphalectomy; use canine formula for herbivores and omnivores, and feline formula for carnivores; initially dilute 1:1 with water and gradually increase to full strength over 48 hr; generally precede nutritional supplementation with 48–96 hr of water or electrolyte solution PO
Critical Care for Herbivores (Oxbow Animal Health)	10–20 mL/kg PO or via gavage/esophagostomy q24–48h[98]	Herbivores/long-term nutritional support; prepare according to directions; begin after rehydration and stable condition
	30 mL/kg (3% of body weight) PO or via gavage/esophagostomy q24h;[64] range of 2%–10% body weight PO or via gavage/esophagostomy q24h[208]	Herbivores
Dextrose in water (2.5%, 5%)	PO, SC, IV, IO, ICe, EpiCe, prn[162]	All species/hyperkalemia;[162] can mix with electrolye solutions
	Calculated water deficit IV, IO[198]	Most species/for intracellular rehydration when mentation is altered and plasma Na > 160 mEq/L; for acute Na toxicosis replace deficit in 12–24 hr; for chronic dehydration slowly replace deficit over 48–72 hr
Electrolyte solutions (Pedialyte, Abbott; Gatorade, S-VC, Inc.)	Voluntary drinking (whole body soak)[98]	All species/oral fluid therapy; early treatment of anorexia; dilute 1:1 with water; caution against drowning
	10–20 mL/kg via gavage or esophagostomy tube q24h[98]	All species/rehydration; when stable; first stage in supplemental nutrition
Emeraid Exotic Carnivore (Lafeber)	5–30 mL/kg gavage or esophagostomy tube q24–72h[99]	Carnivores/nutritional support, severely debilitated, cachectic patients; prepare according to directions; use when hydrated and stable condition; greater dilution in first few feedings
	3% body weight PO or via gavage/esophagostomy q24h;[64] range of 2%–10% body weight PO or via gavage/esophagostomy q24h[208]	Carnivores
Emeraid Herbivore (Lafeber)	5–20 mL/kg gavage or esophagostomy tube q12–48h[99]	Herbivores/nutritional support, severely debilitated, cachectic patients; prepare according to directions; use when hydrated and stable condition; greater dilution in first few feedings
	3% body weight PO or via gavage/esophagostomy q24h;[64] range of 2%–10% body weight PO or via gavage/esophagostomy q24h[208]	Herbivores
Emeraid Omnivore (Lafeber)	5–20 mL/kg gavage or esophagostomy tube q12–48h[98]	Most species/nutritional support, severely debilitated, cachectic patients; prepare according to directions; use when hydrated and stable condition; greater dilution in first few feedings
	3% body weight PO or via gavage/esophagostomy q24h;[64] range of 2%–10% body weight PO or via gavage/esophagostomy q24h[208]	Omnivores
Hydroxyethyl starch (Hetastarch, HES)	3–5 mL/kg slow IV or IO bolus prn[98,198]	All species/hypoalbuminemia; hypovolemic perfusion deficits; increased capillary permeability; use with crystalloids; reduce crystalloid volume 40%–60%; max volume 20 mL/kg[337]
Iodine	2–4 mg/kg PO q24h × 14–21 days, then q7d[99]	Herbivores/iodine deficiency (i.e., goiter); use in species fed a goitrogenic diet; can use a multivitamin-mineral mixture or iodized salt; suggested daily dietary iodine 0.03 mg/kg BW[74]
Iron dextran	12 mg/kg IM 1–2×/wk × 45 days[323]	Crocodilians/iron deficiency; in other species for anemia[99]

TABLE 127.8 Nutritional/Mineral/Fluid Support—cont'd

Agent	Dosage	Species/Comments
Lactated Ringer's solution (LRS)	15–40 mL/kg SC, IV, IO prn[198]	Land turtles/fluid replacement; use extracoelomically after warming the patient; avoid lactate if hepatic insufficiency
LRS + 0.9% saline (1 : 1 solution)	20 mL/kg/day ICe[44]	Loggerhead sea turtles/highest percentage of acid-base recovery and electrolyte balance compared with LRS, saline, or 5% dextrose in saline (1 : 1)
Maintenance crystalloid solution: 1/2-strength LRS and 2.5% dextrose	SC, IV, IO, ICe, EpiCe, prn[198]	All species/maintenance fluid therapy after losses have been replaced
Metronidazole	12.5–50 mg/kg PO[88]	Most species/appetite stimulant (anecdotal; presumably associated with antiprotozoal activity)
	50–100 mg/kg PO[148]	Chameleons/appetite stimulant (anecdotal; presumably associated with antiprotozoal activity)
Multivitamin products (ReptiVite, Zoo Med; Herptivite, RepCal; Repta-Vitamin, Fluker's; Exo-Terra; Nekton)	Dust on vegetables, fruits, or insects q84–168h[312]	Herbivores, omnivores, insectivores/preformed vitamin A; minerals; multivitamin
Polymerized bovine hemoglobin (Oxyglobin, OPK Biotech)	3–5 mL/kg slow IV or IO bolus prn[98,198]	All species/hemoglobin polymer; hypoalbuminemia; hemorrhage; severe anemia; hypovolemic perfusion deficits; increased capillary permeability; use with crystalloids; reduce crystalloid volume 40%–60%; max volume 20 mL/kg;[337] currently under FDA testing by a new manufacturer and unavailable
Replacement crystalloid solutions (Normosol-R, Ceva; Plasma-Lyte, Baxter)	15–25 mL/kg/d PO, SC, IV, IO, ICe, EpiCe prn[36]	All species/replacement fluid therapy; warm to 29°C (84°F)[198]
	10–30 mL/kg q24h, or divided into 2–3 boluses several hours apart[162]	All species/ongoing regurgitation or severe diarrhea
Ringer's solution for reptiles: 1 part Normosol-R + 2 Parts 2.5% dextrose in 0.45% saline [120] or, 1 part Normosol-R + 1 Part 5% dextrose + 1 Part 0.9% saline	10–20 mL/kg q24h[99]	All species/hypertonic dehydration or to prevent nephrotoxicity due to aminoglycosides
	15 (large reptiles) to 25 (small reptiles) mL/kg q24h, or divided into 2 doses per day[36]	All species/hypertonic dehydration; warm fluids to 28°C (82°F)
	20 mL/kg q12h[37]	Chelonians/severe dehydration
Selenium	0.028 mg/kg IM[15]	Lizards/deficiency; myopathy
Sodium chloride (0.45%)	PO, SC, IV, IO, ICe, EpiCe, prn[162]	All species/hypertonic dehydration; correct deficits over 3 days
Sodium chloride (0.9%)	SC, IV, IO, ICe, EpiCe, prn[162,198]	All species/hyperkalemia, hypercalcemia, hypochloremic metabolic alkalosis;[198] can mix with other crystalloid solutions, particularly 5% dextrose; use SC, ICe, EpiCe routes after patient is warm
Vitamin A	—	Overdose causes epidermal sloughing; greater risk with aqueous parenteral formulation; for less severe cases, commercial formulated diets or reptile multivitamin supplements may suffice;[74,230,312] may help infectious stomatitis
	2000 U/kg PO, SC, IM q7–14d × 2–4 treatments[34,37]	Most species/hypovitaminosis A
	2000 U/30 g BW PO once, repeat in 7 days[114,314]	Chameleons/eye swelling, respiratory disease, hemipenile plugs, dysecdysis
	200–300 U/kg[74] SC, IM	Turtles/hypovitaminosis A; give in conjunction with PO vitamin A (2–8 U/g feed DM)
Vitamins A, D_3, E (Vital E + A + D, Stuart Products)	0.15 mL/kg IM, repeat in 21 days[99]	Most species/hypovitaminosis A, D_3, or E; product contains alcohol and may sting when administered; a product without alcohol can be compounded commercially
	0.3 mL/kg PO, then 0.06 mL/kg q7d × 3–4 treatments[34]	Box turtles/hypovitaminosis A; parenteral use may result in hypervitaminosis A and D; given PO may enhance Ca uptake
Vitamin B complex	0.3 mL/kg SC, IM q24h[99]	Most species/anorexia; hypovitaminosis B; use with caution as B_6 toxicity may occur
	25 mg thiamine/kg PO q24h × 3–7 days[10]	Most species/appetite stimulant; hypovitaminosis B
Vitamin B_1 (thiamine)	50–100 mg/kg PO, SC, IM q24h[43]	Piscivores/thiamine deficiency from thawed fish
	30 g/kg feed fish PO[99]	Crocodilians/treat or prevent deficiency
Vitamin B_{12} (cyanocobalamin)	0.05 mg/kg SC, IM[99]	Snakes, lizards/appetite stimulant
Vitamin C	10–20 mg/kg SC, IM q24h[87,224]	All species/empirical for hypovitaminosis C; stomatitis; skin slough in snakes; supportive therapy for bacterial infections

VetBooks.ir

TABLE 127.8 Nutritional/Mineral/Fluid Support—cont'd

Agent	Dosage	Species/Comments
Vitamin D_3	—	Nutritional secondary hyperparathyroidism; hypocalcemia; deficiency and excess may result in soft-tissue calcification
	1000 U/kg IM, repeat in 1 wk[37]	Most species/deficiency; use with oral calcium glubionate and carbonate, general dietary management, and UVB irradiation
	200 U/kg PO, IM q7d[15,21]	Lizards/PO may be safer than IM, but absorption is poor in some species[26,253]
	400 U/kg IM q7d × 3 treatments[196]	Green iguanas/nutritional secondary hyperparathyroidism; use with calcitonin after normocalcemic; also supplement oral calcium
Vitamin E/selenium (L-Se, Schering)	1 U vitamin E/kg[74] IM	Piscivores/hypovitaminosis E; myopathy, anorexia, swollen subcutaneous nodule
	50 U vitamin E/kg + 0.025 mg selenium/kg IM[77]	Lizards/hypovitaminosis E (vitamin E/selenium)
Vitamin K_1	0.25–0.5 mg/kg IM[99]	Most species/hypovitaminosis K_1; coagulopathies

TABLE 127.9 Miscellaneous Agents

Agent	Dosage	Species/Comments
Activated charcoal-kaolin suspension (ToxiBan, Vet-a-Mix)	5–10 mL/kg PO q24h × 1–3 days[202]	Sea turtles/reduce exposure to brevitoxin
Allopurinol	—	Careful when giving with urine acidifiers and uricosuric drugs (probenecid)[60]
	10–20 mg/kg PO q24h[67,217,272]	Most species/gout; decreases production of uric acid;[193] long-term therapy; tortoises may respond best
	25 mg/kg PO q24h[128]	Green iguanas
	50 mg/kg PO q24h × 30 days, then q72h[171]	Chelonians/hyperuricemia
Aluminum hydroxide (Amphogel, Wyeth-Ayerst)	100 mg/kg PO q12–24h[193]	Most species/hyperphosphatemia (associated with renal disease); decreases intestinal absorption of P; use cautiously in patients with gastric outlet obstruction
Amidotrizoate (Gastrografin, Squibb)	5–7.7 mL/kg PO[205]	Gastrointestinal contrast agent; reported faster transit vs barium; no risk if regurgitation
	7.5 mL/kg PO[227]	Tortoises/gastrointestinal contrast agent; give via gavage; mean transit times: 2.6 hr at 87°F (30.6°C); 6.6 hr at 71°F (21.5°C)
Aminophylline	2–4 mg/kg IM[89]	Most species/bronchodilator
Atropine	0.01–0.04 mg/kg IM, IV q8–24h[226]	Most species/dries up excess mucous secretions with infectious stomatitis
	0.1–0.2 mg/kg IM prn[99]	Most species/organophosphate toxicity
	0.2 mg/kg SC, IM[282]	Most species/respiratory distress associated with excessive secretions
Barium sulfate	5–20 mL/kg PO[46]	Most species/gastrointestinal contrast studies
	25 mL/kg PO, 35% wt:vol concentration[14]	Ball pythons/best gastrointestinal image quality
Bleomycin with high voltage electrical pulses	1 U/cm^3 intralesional, repeat in 33 days[38]	Green sea turtles/fibropapillomas electrochemotherapy; use concurrent local anesthesia
	3.65 mg/kg (1 mg/mL) intralesional, repeat in 2 wk[178]	Yellow-bellied slider turtles/squamous cell carcinoma, postpartial surgical excision
Calcium EDTA	10–40 mg/kg IM q12h[244]	Most species/heavy metal chelation; ensure hydration
Carboplatin	2.5–5 mg/kg IV, intracardiac[216]	Most species/carcinoma, osteosarcoma, mesothelioma, carcinomatosis
Carboplatin 4.6 mg implantable bead (compounded, Wedgewood Pharmacy)	≤ 10 mg/kg total q3wk intralesional or surgical excision sites[153]	Chameleons/squamous cell carcinoma, carcinoma; cut bead into smaller pieces to avoid overdose
Chlorambucil (Leukeran, Glaxo SmithKline)	0.1–0.2 mg/kg PO[216]	Most species/lymphoma, leukemia, myeloproliferative tumors
CHOP Therapy (Modified)	See original paper for full protocol details[85]	Green iguanas/successful management of lymphoma postradiation therapy
Cimetidine	4 mg/kg PO, IM q8–12h[99]	Most species/gastric and duodenal ulceration; esophagitis; gastroesophageal reflux; may use in renal failure to increase phosphate secretion

Continued

TABLE 127.9 Miscellaneous Agents—cont'd

Agent	Dosage	Species/Comments
Cisapride (Propulsid, Janssen)	0.5–2 mg/kg PO q24h[99]	Most species/motility modifier; gastrointestinal stasis; not commercially available in the United States; may be compounded; ineffective in desert tortoises at 1 mg/kg[330]
	1–4 mg/kg PO q24h until defecates[336]	Bearded dragons/constipation
Cisplatin	0.5–1 mg/kg IV (prehydrate), intracardiac, intralesional (in oil)[216]	Most species/carcinoma, osteosarcoma, infiltrative sarcoma (intralesional), mesothelioma, carcinomatosis
Cyclophosphamide	10 mg/kg SC, IM, IV, intracardiac[216]	Most species/lymphoma, leukemia, myeloproliferative tumors
Dioctyl Na sulfosuccinate	1–5 mg/kg PO[101]	Most species/constipation; use 1:20 dilution
Diphenhydramine	2 mg/kg IM q24h[202]	Sea turtles/brevitoxicosis; rapidly reduced conjunctival edema, prevented corneal ulceration
Doxorubicin	1 mg/kg IV q7d × 2 treatments, then q14d × 2 treatments, then q21d × 2 treatments[280]	Snakes/chemotherapy for sarcoma (also lymphoma, carcinoma, etc.); treatment periods variable
Famotidine	0.5 mg/kg SC q3d[342]	Kemp's ridley sea turtles
Furosemide	2–5 mg/kg PO, IM, IV q12–24h[149–151]	Most species/diuretic for edema and pulmonary congestion; while lacking loop of Henle, may affect via other mechanisms
	5 mg/kg IM q24h × 1–3 days[202]	Sea turtles/intentional dehydration with brevitoxicosis, no concurrent fluids given
Hydrochlorothiazide	1 mg/kg q24–72h[69]	Lizards/promotes diuresis; monitor hydration status
Iodine compound (Conray 280, Mallinckrodt)	500 mg/kg IV, IO[69]	Lizards/IV urography; take radiographs 0, 5, 15, 30, and 60 min postinjection
Iohexol (240 mg I/mL; Omnipaque, Sanofi Winthrop)	5–20 mL/kg PO[99]	Most species/gastrointestinal contrast studies; nonionic, organic iodine solution; good alternative to barium;[36] faster transit time than barium; can be diluted 1:1 with water
	75 mg/kg IV[159]	Kemp's ridley turtles (juveniles)/GFR assessment
K-Y Jelly (Johnson & Johnson)	1–3 mL of 50% K-Y jelly and 50% warm water/100 g[8]	Most species/enema
Lactulose	0.5 mL/kg PO q24h[149,150,314]	Lizards, chelonians/hepatic lipidosis
L-asparaginase (Elspar, Merck)	400 U/kg SC, IM, intracardiac[216]	Most species/lymphoma, leukemia, myeloproliferative tumors
Maropitant citrate (Cerenia, Zoetis)	1 mg/kg PO, SC q24h (Klaphake E, personal observation.)	Antiemetic; antinausea; no adverse effects seen; Substance P conserved across classes
Melphalan (Alkeran, Celegene)	0.05–0.1 mg/kg Po[216]	Most species/lymphoma, leukemia, myeloproliferative tumors
Methimazole	2 mg/kg q24h × 30 days[114]	Snakes/excessive shedding from hyperthyroidism; limited effectiveness
Methotrexate	0.25 mg/kg PO, SC, IV[216]	Most species/lymphoma, leukemia, myeloproliferative tumors
Metoclopramide	0.06 mg/kg PO q24h × 7 days[66,99]	Most species/stimulates gastric motility
	0.05 mg/kg PO q24h × 7 days[202]	Sea turtles/intestinal motility stimulant
	0.5 mg/kg IM q24h[75]	Sea turtles/supportive care
	1–10 mg/kg PO q24h[349]	Tortoises/stimulates gastric motility; ineffective in desert tortoises at 1 mg/kg[330]
Milk thistle (*Silybum marianum*)	4–15 mg/kg PO q8–12h[149,151]	Lizards, chelonians/hepatoprotectant
Pentobarbital	60–100 mg/kg IV, ICe[7,39]	Euthanasia
Pimobendan	0.2 mg/kg PO q24h[149]	Lizards
Potassium chloride	2 mEq/kg IV, ICe[21]	Most species/euthanasia; cardioplegic; administer after a euthanasia solution
Probenecid	250 mg/kg PO q12h[265]	Most species/gout; increases uric acid excretion; can be increased prn
S-adenosylmethionine (Denosyl, Nutramax)	30 mg/kg PO q24h[239]	Savannah monitors/liver disease
Sodium bicarbonate	0.5–1 mg/kg IV[99]	Most species/hypoxic acidosis postanesthesia
Sucralfate	500–1000 mg/kg PO q6–8h[89]	Most species/oral, esophageal, gastric, and duodenal ulcers
	200 mg/kg PO q24h[343]	Green iguanas/postduodenoileal anastomosis
Tamoxifen 60-day time-release pellets (Innovative Research of America)	Pellets containing 5 mg tamoxifen implants ICe[62]	Leopard geckos/inhibition of follicular development for 60 days if implanted before vitellogenesis
Terbutaline	0.01–0.02 mg/kg IM[306]	Reduce bronchospasm
	Nebulization, 15–45 min/session q4–12h × 3 + days[263]	Lower respiratory tract particle size should be ≤ 0.5 μm, 2–10 μm for trachea; oxygen flow rates < 10 kg 1–2 L/min, 5 L/min for larger reptiles; use bubble humidifier; possible adverse cardiovascular effects
Tricaine methanesulfonate (MS-222)	250–500 mg/kg ICe 1% solution followed by 0.1–1 mL 50% solution ICe or intracardiac[12,57]	Fence lizards, desert iguanas, garter snakes, house geckos, anole species/euthanasia
Vincristine	0.025 mg/kg IV[216]	Most species/lymphoma, leukemia, myeloproliferative tumors

VetBooks.ir

Abbreviations Used in This Formulary

d	day	MIC	minimum inhibitory concentration
EpiCe	epicoelomic	min	minute
h	hour	mo	month
ICe	intracoelomic	mg	milligram
IM	intramuscular	mL	milliliter
IO	intraosseous	PD	pharmacodynamics/pharmacological data
IT	intratracheal	PK	pharmacokinetic data
IV	intravenous	PO	per os
U (IU)	international unit	prn	as needed
kg	kilogram	q	every
L	liter	SC	subcutaneous
LRS	lactated Ringer's solution	URT	upper respiratory tract
MAC	minimum alveolar concentration	wk	week

Amphibian Formulary

Brent R. Whitaker and Colin T. McDermott

TABLE 128.1 Antimicrobial Agents Used in Amphibians[a,b]

Agent	Dosage	Species/Comments
Amikacin	5 mg/kg IM q36h[52]	Bullfrogs/PK
	5–10 mg/kg SC, IM, ICe q24–48h[51]	Most species; may be used in combination with piperacillin
Carbenicillin	100 mg/kg SC, IM q72h[52]	
	200 mg/kg SC, IM, ICe q24h[52]	
Ceftazidime	20 mg/kg SC, IM q48–72h[52]	
Chloramphenicol	50 mg/kg SC, IM, ICe q12–24h[52]	Caution: even miniscule exposures carries risk of aplastic anemia in susceptible individuals; wear disposable gloves when handling; aplastic anemia-like findings in Bufo regularis exposed to 125 mg/kg PO q24h × 12 wk[13]
	20 mg/L bath[a] changed daily[52]	
Ciprofloxacin	10 mg/kg PO,[52] ICe[51] q24h	
	500–750 mg/75 L as 6–8 hr bath[a] q24h[52]	May be used for large numbers of animals
Doxycycline (Psittavet, Vetafarm)	50 mg/kg IM q7d[52]	Broad-spectrum antibiotic, part of 4-quadrant therapy; may have anti-inflammatory effect; chlamydiosis
Doxycycline (Vibramycin, Zoetis)	5–10 mg/kg PO q24h[52]	Chlamydiosis
	10–50 mg/kg PO q24h[52]	African clawed frogs/chlamydiosis
Doxycycline 1% topical gel, compounded	Apply topically q8–12h not to exceed 10 mg/kg per day[52]	Useful for localized lesions; may have antiinflammatory effect
Enrofloxacin	5–10 mg/kg PO, SC, IM q24h[52]	Most species/PK (bullfrogs);[52] ICe and topical routes also used but with limited PK data[52]
	10 mg/kg SC, IM[14]	African clawed frogs/PK; high kidney concentrations of enrofloxacin and ciprofloxacin;[14] no significant difference between routes[20]
	10 mg/kg topically[46]	Coqui frogs/detectable tissue concentration for >24 hr, no correlation to plasma concentration
	500 mg/L x 6–8 hr bath[a] q24h[52]	
Enrofloxacin and silver sulfadiazine solution (Baytril Otic, Bayer)	Apply topically to lesions q12h[52]	May have some antifungal effect, but does not appear effective against chytrid
Gentamicin	2–4 mg/kg IM q72h × 4 treatments[52]	
	2.5 mg/kg IM q72h[44]	Coldwater salamanders (i.e., Necturus)/ PD; more frequent dosing may be needed if temperature >4°C (39.2°F)
	3 mg/kg IM q24h at 22.2°C (72°F)[52]	Leopard frogs/PD; at higher temperatures, serum concentrations will be lower
	Topical to eyes[52]	All species/ocular infections; dilute to 2 mg/mL
	Intracameral injection once; not to exceed 4 mg/kg[52]	Panophthalmitis
Metronidazole	10 mg/kg PO q24h × 5–10 days[36]	For chronic diarrhea
	10 mg/kg IV q24h × 2 days[52]	Anaerobic infections
	12 mg/kg topically q24h × 5–10 days[52]	For chronic diarrhea
	20 mg/kg PO q48h × 20 days[52]	Anaerobic infections
	50 mg/kg PO q24h × 3 days[52]	Anaerobic infections
	60 mg/kg topically q24h × 3 days[52]	Anaerobic infections
	50 mg/L × 24 hr bath[a,52]	Anaerobic infections
Ofloxacin 0.3% ophthalmic solution	1 drop q2–4h × 10 days[51]	Keratitis; may also be applied topically to wounds

VetBooks.ir

TABLE 128.1 Antimicrobial Agents Used in Amphibians[a,b]—cont'd

Agent	Dosage	Species/Comments
Oxytetracycline	25 mg/kg SC, IM q24h[52]	Most species
	50 mg/kg PO q12–24h[52]	Most species
	50–100 mg/kg IM q48h[52]	Bullfrogs/PK; especially useful in cases of chlamydiosis (use up to 30 days)[52]
	100 mg/L × 1 hr bath[a,52]	Most species
	1 g/kg feed × 7 days[52]	Most useful with axolotls and Xenopus-fed compounded pelleted diet[52]
Piperacillin	100 mg/kg SC, IM q24h[52]	Anaerobes; may be used in combination with amikacin
Silver sulfadiazine (Silvadine Cream 1%, Marion)	Topical q24h[52]	Antibiotic/antifungal cream
Sulfadiazine	132 mg/kg PO q24h[52]	
Sulfamethazine	1 g/L bath[a] to effect[52]	Change daily
Tetracycline	50 mg/kg PO q12h[52]	
	150 mg/kg PO q24h × 5–7 days[52]	
	167 mg/kg (5 mg/30 g) PO q12h × 7 days[52]	
Trimethoprim/sulfa	3 mg/kg PO, SC, IM q24h[52]	Unspecified sulfa
Trimethoprim/sulfadiazine	15–20 mg/kg IM q48h[52]	Chronic diarrhea[52]
Trimethoprim/sulfamethoxazole	15 mg/kg PO q24h[52]	Chronic diarrhea

[a]Water baths containing antibiotics or topical applications may not provide as consistent distribution as parenteral administration.
[b]SC can be administered in the dorsal lymph sac of anurans.[52]

TABLE 128.2 Antifungal Agents Used in Amphibians[a]

Agent	Dosage	Species/Comments
Amphotericin B	1 mg/kg ICe q24h[52]	Internal mycoses; acutely toxic to *Alytes muletensis* tadpoles at 8 μg/mL bath[28]
Benzalkonium chloride	0.25 mg/L × 72 hr bath[52]	
	2 mg/L × 1 hr bath q24h[52]	Saprolegniasis
Chloramphenicol	20 mg/kg topically (applied as Chlorsig 1% ointment [Sigma], which also contains paraffin and wool fat)[4]	Chytridiomycosis; safe for larvae, recent metamorphs, and adults; confirm negative result by real-time PCR;[4,52] caution: even miniscule exposure carries risk of aplastic anemia in susceptible individuals; wear disposable gloves when handling; aplastic anemia-like findings in Bufo regularis exposed to 125 mg/kg PO q24h × 12 wk[13]
	10–30 mg/L (10–30 ppm) as continuous bath replaced fresh daily for up to 30 days[52]	
	20 mg/L by continuous shallow immersion × 14 days, changed daily[54]	Australian green frog (*Litoria caerulea*); severely ill frogs treated with combination of chloramphenicol, SC fluids q8–12h x 6 days, and temperature increased to 28°C × 14 days[54]
Florfenicol	10 μg/mL topical spray q24h × 14 days[33]	Experimentally infected *Alytes muletensis* adults/reduced zoosporangia numbers but did not eliminate infection; GI and renal toxicity to tadpoles at 100 μg/mL[33]
	30 ppm as continuous bath replaced fresh daily for up to 30 days[52]	Chytridiomycosis; safe for larvae, recent metamorphs, and adults; confirm negative result by realtime PCR[52]
Fluconazole	60 mg/kg PO q24h[52]	
Itraconazole	10 mg/kg PO q24h[52]	Topical route best choice to treat chytridiomycosis; caution with tadpoles[15,52]
	0.01% in 0.6% salt solution x 5 min bath q24h × 11 days[52]	
	0.01% in buffered solution x 5 min bath q24h × 11–14 days[16]	Multiple species/cleared chytridiomycosis by PCR 14 days posttreatment; 6–15 mo posttreatment follow-up yielded positive PCR in some individuals
	0.5–1.5 mg/L × 5 min bath q24h × 7 days[15]	*Alytes muletensis* tadpoles/safe at varying concentrations and duration of 7–28 days; confirmed negative PCR posttreatment; varying levels of depigmentation observed in all individuals[15]
	50 mg/L x 5 min bath q24h × 10 days[22]	Multiple species/cleared chytridiomycosis in subclinical animals; confirmed with PCR
	0.0025% × 5 min bath q24h × 6 days[7]	Australian green tree frog (*Litoria caerulea*), coastal plains toad (*Incillus nebulifer*)/cleared PCR positive juveniles with no clinically apparent side effects

Continued

VetBooks.ir

TABLE 128.2 Antifungal Agents Used in Amphibians[a]—cont'd

Agent	Dosage	Species/Comments
Ketoconazole	10–20 mg/kg PO q24h[52]	
	Topical cream[52]	
Methylene blue	2–4 mg/L bath to effect[52]	Tadpoles/may reduce mortality in newly hatched tadpoles
	4 mg/L × 1 hr bath q24h[52]	Saprolegniasis
Miconazole	5 mg/kg ICe q24h × 14–28 days[52]	Systemic mycoses
	Topical cream or solution[52]	Topical route best choice for chytridiomycosis; solutions containing alcohol may cause irritation; do not use with larvae[52]
Neomycin, polymixin B, bacitracin (Neosporin, Pfizer)	Apply topically to wound q24h[18]	Microsporidian infections; not recommended for bacterial infections, appears to inhibit reepithelialization[52]
Nystatin 1% cream	Topical[52]	Cutaneous mycoses
Potassium permanganate	1:5000 water × 5 min bath q24h[52]	Cutaneous mycoses
Sodium chlorite ($NaOCl_2$)	20 mg/L × 6–8 hr bath[52]	Cutaneous mycoses
Temperature elevation	30°C (86°F) × 10 days[10]	*Lithobates catesbeiana*, *Acris crepitans*/confirm negative result by realtime PCR[10]
	37°C (98.6°F) for 16 hr[49]	Chytridiomycosis, caution with temperature elevation in sensitive species
Terbinafine HCl (Lamisil AT, Novartis)	0.005%–0.01% in distilled water × 5 min bath q24h × 5 days, or q48h × 6 treatments[6]	Various species/no adverse clinical effects noted with treatment; pH 7.0; confirm negative result by realtime PCR[6]
Voriconazole	1.25 μg/mL q24h topically via spray × 7 days[28]	Poison dart frogs, Iberian midwife toad (*Alytes cisternasii*)/cleared chytridiomycosis in naturally infected individuals in vivo; performed poorly with in vitro assays[28]
Voriconazole (V) + polymixin E (P) + elevated temperature (T)	(V) 12.5 μg/mL q24h topically via spray + (P) 2000 IU/mL × 10 min bath q12h + (T) 20°C (68°F) continuous × 10 days[5]	Fire salamanders/treatment of *Batrachochytrium salamandrivorans*; no effect of medications at 15°C (59°F)[5]

[a]To control the spread of *Batrachochytrium dendrobatidis,* new gloves should be worn after handling each patient. Nitrile gloves are preferred for their ability to kill zoospores on contact. Bare hands are preferred over rinsing the same pair of gloves between patients.[30]

TABLE 128.3 Antiparasitic Agents Used in Amphibians[a]

Agent	Dosage	Species/Comments
Acriflavin	0.025% bath × 5 days[52]	Protozoa
	500 mg/L × 30 min bath[52]	Protozoa
Benzalkonium chloride	2 mg/L × 1 hr bath q24h to effect[52]	Protozoa
Distilled water	3 hr bath[52]	Protozoa
Febantel (in combination with pyrantel pamoate and praziquantel; Drontal Plus, Bayer)	0.01 mL/1 g (10 mL/kg) PO q2–3 wk[34]	Nematodes, cestodes, possibly trematodes
Fenbendazole	—	Fenbendazole combinations follow
	30–50 mg/kg PO[52]	Gastrointestinal nematodes
	50 mg/kg PO q24h × 3–5 days, repeat in 14–21 days[52]	Gastrointestinal nematodes
	50–100 mg/kg PO[36] repeat in 2–3 wk prn	Most species/gastrointestinal nematodes
	100 mg/kg PO,[52] repeat in 14 days	Gastrointestinal nematodes
Fenbendazole (F)/ivermectin (I)	(F) 100 mg/kg PO on day 1, then (I) 0.2 mg/kg PO on days 2,11[52]	Gastrointestinal nematodes
Fenbendazole (F)/metronidazole (M)	(F) 100 mg/kg PO, repeat in 10–14 days + (M) 10 mg/kg PO q24h for 5 days[52]	Concurrent gastrointestinal nematodes and protozoa
Formalin (10%)	—	Do not use if skin is ulcerated; may be toxic to some species
	1.5 mL/L × 10 min bath q48h to effect[52]	Protozoans; may be toxic in some species
	0.5% × 10 min bath once[52]	Monogenic trematodes; may be toxic to some species
Ivermectin	—	See fenbendazole for combination; caution: may cause flaccid paralysis with overdosage; caffeine or physostigmine may ameliorate effects[52]
	0.2–0.4 mg/kg PO, SC, repeat q14d as needed[52]	Nematodes, including lungworms; mites
	2 mg/kg topically, repeat in 2–3 wk[26]	Especially useful for small specimens[52] and Rana spp.[26]
	10 mg/L × 60 min bath, repeat q14d prn[52]	Mites

VetBooks.ir

TABLE 128.3 Antiparasitic Agents Used in Amphibians[a]—cont'd

Agent	Dosage	Species/Comments
Levamisole	—	May cause paralysis in some species at suggested dosages;[52] caffeine or physostigmine may ameliorate effects[52]
	6.5–13.5 mg/kg topically to pelvic patch, repeat in 10 days[3]	*Anaxyrus houstonensis*/reduced nematode egg counts
	10 mg/kg IM, ICe, topically,[52] repeat in 2 wk	Nematodes, including lungworms
	12 mg/L bath × 4 days[21]	African clawed frogs/cutaneous nematodes; use ≥4.2 L of tank water/frog
	100 mg/L × ≥72 hr bath[52]	Resistant nematodes
	100–300 mg/L × 24 hr bath, repeat in 1–2 wk[52]	Nematodes, including subcutaneous nematodes in aquatic amphibians; water soluble form is available through aquaculture supply companies
Metronidazole	—	See fenbendazole for combination; toxicity possible at high doses
	10 mg/kg PO q24h × 5–10 days[52]	Protozoa; for unfamiliar or sensitive species
	50 mg/kg PO q24h × 3–5 days[52]	Confirmed cases of amoebiasis and flagellate overload
	100 mg/kg PO q3d[52]	Protozoa
	100–150 mg/kg PO, repeat in 2–3 wk or prn[52]	Protozoa (i.e., Entamoeba, Hexamita, Opalina)
	50 mg/L × 24 hr bath[52]	Aquatic amphibians/protozoa
	500 mg/100 g feed × 3–4 treatments[52]	Ciliates
Moxidectin	200 µg/kg SC q4mo[38]	Nematodes
Oxfendazole	5 mg/kg PO[52]	Gastrointestinal nematodes
Oxytetracycline	25 mg/kg SC, IM q24h[52]	Protozoa
	50 mg/kg PO q12h[52]	Protozoa
	1 g/kg feed × 7 days[52]	Protozoa
Paromomycin	50–75 mg/kg PO q24h[52]	Gastrointestinal protozoa
Piperazine	50 mg/kg PO, repeat in 2 wk[52]	Gastrointestinal nematodes
Ponazuril	30 mg/kg PO q12h × 3 days, repeat in 3 wk; often more effective at 30 mg/kg PO q24h × 30 days; may work with less frequent treatments[52]	Coccidia but not Cryptosporidium; may have some effect on unidentified protozoan cysts
Potassium permanganate	7 mg/L × 5 min bath q24h to effect[52]	Ectoparasitic protozoa
Praziquantel	8–24 mg/kg PO, SC, ICe, topically,[52] repeat q14d	Trematodes, cestodes
	10 mg/L × 3 hr bath,[52] repeat q7–21d	Trematodes, cestodes
Pyrantel pamoate	5 mg/kg PO q14d[34]	Nematodes
Ronidazole	10 mg/kg PO q24h × 10 days[52]	Flagellated protozoa, amoebas
Salt (sodium chloride)	4–6 g/L continuous bath[52]	Ectoparasitic protozoa
	5 g/L bath up to 12h, 10 g/L bath up to 1h (Marcec et al, Proc ARAV, 2011, p 1)	Axolotls, immediate negative clinical effects in baths >20 g/L
	6 g/L × 5–10 min bath q24h × 3–5 days[52]	Ectoparasitic protozoa
	25 g/L × ≤10 min bath[52]	Ectoparasitic protozoa
Selamectin (Revolution, Zoetis)	6 mg/kg topically[11]	Bullfrogs/PK
Sulfadiazine	132 mg/kg PO q24h[52]	Coccidiosis
Sulfamethazine	1 g/L bath[52]	Coccidiosis; change daily to effect
Tetracycline	50 mg/kg PO q12h[52]	Protozoa
Thiabendazole	50–100 mg/kg PO,[52] repeat in 2 wk prn	Gastrointestinal nematodes
	100 mg/L bath, repeat in 2 wk[52]	Verminous dermatitis
Trimethoprim/sulfa	3 mg/kg PO, SC, IM q24h[52]	Coccidiosis; unspecified sulfa

[a]SC can be administered in the dorsal lymph sac of anurans.[52]

TABLE 128.4 Chemical Restraint/Anesthetic/Analgesic Agents Used in Amphibians[3]

Agent	Dosage	Species/Comments
Alfaxalone	5–25 mg/kg IM (Lennox, Proc ARAV, 2013, pp 66–68)	Most species/recommend starting at lower dose (5–10 mg/kg) and titrating up
	10–17.5 mg/kg IM[35]	Bullfrogs/immobilization, respiratory depression, still responsive to noxious stimuli; dose-dependent time to recumbency and time to recovery; no effect by immersion at 2 g/L for 30 min[35]
	18 mg/kg IM, IV, Ice (Hadzima et al, Proc ARAV, 2013, pp 60–64)	African clawed frogs/deep sedation for 1–3 hr (IM, IV), 10–60 min ICe; no effect via immersion at 18 mg/L
	20–30 mg/kg IM[40]	Australian tree frogs/initial effect within 10 min, respiratory depression; insufficient anesthesia as sole agent for painful procedures
	5 mg/L in fresh water bath[29]	Axolotls/single individual; induction of anesthesia, maintained continuous irrigation of gills and skin with additional 0.03 mL drops of alfaxalone for maintenance of anesthesia during surgery[29]
	200 mg/L in fresh water bath[2]	Fire-bellied toads/buffer with sodium bicarbonate to pH 7.2; anesthetic induction in 14 ± 4 min, variable duration of anesthesia up to 30 min; not sufficient for painful procedures
Alfaxalone (A)/morphine (M)	(A) 3 mg/100 mL + (M) 5 mg/100 mL as bath[1]	Fire-bellied toads/provided anesthetic induction and antinociception
Atipamezole (Antisedan, Zoetis)	Titrate to effect IM, IV[27]	Antagonist for dexmedetomidine[27]
Benzocaine (Sigma Chemical)	—	Anesthesia; not sold as fish anesthetic in United States; available from chemical supply companies; do not use topical anesthetic products marketed for mammals; prepare stock solution in ethanol (poorly soluble in water); store in dark bottle at room temperature
	50 mg/L bath to effect[52]	Larvae/dissolve in ethanol first
	200–300 mg/L bath to effect[52]	Frogs, salamanders/dissolve in ethanol first
	200–500 mg/L bath[52]	Dissolve in acetone first
Buprenorphine	38 mg/kg SC[27]	Analgesia & sedation;4 hr; ED_{50}[b] in leopard frogs[27]
	50 mg/kg ICe q24h[23]	Eastern red spotted newts/return to normal behavior after limb amputation; may take >1 hr for onset of clinical effects; postsurgical bath in 0.1% sulfamerazine (w/v; Sigma Chemical Company)[23]
Butorphanol	0.2–0.4 mg/kg IM[52]	Analgesia; efficacy uncertain[52]
	0.5 mg/L continuous immersion for 3 days[23]	Eastern red spotted newts/return to normal behavior after limb amputation; may take >4 hr for onset of clinical effects; postsurgical bath in 0.1% sulfamerazine (w/v; Sigma Chemical Company)[23]
Eugenol (clove oil, 100% eugenol; Aqui-S 20E 10% eugenol)	0.3 mL/L (~310–318 mg/L)[52]	Anesthesia; deep anesthesia after 15 min bath; caused reversible gastric prolapse in 50% of leopard frogs
	0.35 mL in 1 L purified water[17]	African clawed frogs/anesthetic plane for frogs <10 g after 5 min immersion, for frogs ~30 g after 10 min immersion
	0.45 mL/L (~473 mg/L)[32]	Anesthesia; deep anesthesia induced in 80% of tiger salamanders
Codeine	53 mg/kg SC[27]	Analgesia >4 hr; ED_{50}[b] in leopard frogs
Dexmedetomidine	40–120 mg/kg SC[27]	Analgesia >4 hr; ED_{50}[b] in leopard frogs
Diazepam	—	See ketamine for combination
Fentanyl	0.5 mg/kg SC[27]	Analgesia >4 hr; ED_{50}[b] in leopard frogs
Flunixin meglumine	25 mg/kg intralymphatic[9]	African clawed frogs
Isoeugenol (Aqui-S; 50% isoeugenol)	20–50 μL/L[41]	*Litoria ewingii* tadpoles/higher doses resulted in faster induction and longer recovery
Isoflurane	—	Anesthesia; induction chamber
	3%–5% induction, 1%–2% maintenance[52]	Terrestrial species
	5%[52]	Terrestrial species/euthanasia; induction chamber
	Topical application of liquid isoflurane[52]	Bufo spp. (0.015 mL/g BW), African clawed frogs (0.007 mL/g BW)/ induce in closed container; once induced, remove excess from animal
	Topical mixture of isoflurane (3 mL), KY jelly (3.5 mL), and water (1.5 mL)[52]	Bufo spp. (0.035 mL/g BW), African clawed frogs (0.025 mL/g BW)/ induce in closed container; once induced, remove excess from animal
	Topical mixture of 1.5 parts distilled water, 3.5 parts nonspermicidal jelly, and 1.8 parts isoflurane[55]	American tree frogs/induced in closed container; once induced remove excess from animal; erythematous lesions and signs of systemic illness noted after application[55]
	0.28 mL/100 mL bath[52]	Induce in closed container
	Bubbled into water to effect[52]	Aquatic species

VetBooks.ir

TABLE 128.4 Chemical Restraint/Anesthetic/Analgesic Agents Used in Amphibians[a]—cont'd

Agent	Dosage	Species/Comments
Ketamine	—	May have long induction and recovery times; does not provide good analgesia so may not be suited for major surgical procedures; other agents preferred; ketamine combination follows; see lidocaine
	50–150 mg/kg SC, IM[52]	Most species
Ketamine (K)/diazepam (D)	(K) 20–40 mg/kg + (D) 0.2–0.4 mg/kg IM[52]	Variable results
Lidocaine 1%–2%	Local infiltration[52]	All/local anesthesia; with or without epinephrine; 2% lidocaine in combination with ketamine has been used for minor surgeries;[52] use with caution
Meloxicam	0.1 mg/kg[31]	American bullfrogs/decreased circulating PGE2 levels measured 24 hr post muscle biopsy[31]
	0.4–1 mg/kg PO, SC, ICe q24h[51]	Antiinflammatory; presumptive analgesia; adjunct therapy for septicemia
	0.5% gel topically q24h; do not exceed 0.4 mg/kg[52]	Antiinflammatory for localized wounds
Metomidate hydrochloride	30 mg/L bath[12]	*Rana pipiens*/immersion for 60 min then transferred to amphibian ringer's solution; clinical sedation in 11/11 frogs; surgical anesthesia in 3/11; prolonged recovery; not recommended as sole anesthetic agent
Morphine	38–42 mg/kg SC[27]	Analgesia >4 hr
Nalorphine	122 mg/kg SC[27]	Analgesia >4 hr
Naloxone	10 mg/kg SC;[27] titrate to effect	Antagonist for buprenorphine, butorphanol, codeine, fentanyl, morphine
Naltrexone	1 mg/kg SC;[27] titrate to effect	Antagonist for buprenorphine, butorphanol, codeine, fentanyl, morphine
Pentobarbital sodium	60 mg/kg IV, ICe[52]	Euthanasia; can also be administered in lymph sacs in anurans
Pentobarbital sodium + sodium phenytoin	1100 mg/kg + 141 mg/kg ICe[45]	African clawed frogs/complete cardiac arrest within 3 hr
Propofol	10–30 mg/kg ICe[52]	White's tree frogs/pilot study; use the lower dosage for sedation or light anesthesia; induction within 30 min; recovery in 24 hr
	35 mg/kg ICe[32]	Deep anesthesia in 83% of tiger salamanders[32]
	35 mg/kg ICe[50]	Sonoran desert toads/sedation only; did not achieve surgical plane of anesthesia
	60–100 mg/kg ICe[52]	Euthanasia
	88 mg/L by immersion[19]	African clawed frogs/induced for 15 min, then rinsed; respiratory depression, darkened skin color; death at doses over 175 mg/L
	100–140 mg/kg topically[52]	Maroon-eyed tree frogs (Agalychnis litodryas)/unpublished data; 15–20 min to max effect at 100 mg/kg dose; 10–15 min to max effect at 140 mg/kg;[52] sedation to deep anesthesia; remove and rinse when desired level achieved; recommended only for animals <50 g
Sevoflurane	Topical application	Rapid recovery unless constant reapplication
	Topical mixture of 1.5 parts distilled water, 3.5 parts nonspermicidal jelly, and 3 parts sevoflurane[42,55]	American tree frogs/induced in closed container with 2 mL of sevoflurane jelly per individual; once induced, remove excess from animal; recovery 4.5 times faster than topical isoflurane jelly;[55] in cane toads, reliable loss of righting reflex when 37.5 μg/g sevoflurane in jelly was applied to dorsum[42]
Tiletamine/zolazepam (Telazol, Fort Dodge)	10–20 mg/kg IM[52]	Results variable between species; rapid recovery; not suitable as single anesthetic agent for anurans[25]

VetBooks.ir

TABLE 128.4 Chemical Restraint/Anesthetic/Analgesic Agents Used in Amphibians[a]—cont'd

Agent	Dosage	Species/Comments
Tricaine methanesulfonate (MS-222) (Finquel, Argent)	—	Anesthesia; buffer the acidity by adding sodium bicarbonate to buffer the solution to a pH of 7.0–7.1; aerate water to prevent hypoxemia; remove from bath on induction or overdosing can readily occur; after bath, place terrestrial amphibians on moist towel or in very shallow water to recovery; some species can be induced at much lower concentrations than listed here; in some cases, anesthesia can be maintained by dripping a dilute solution of this drug (100–200 mg/L) over the skin or by covering animal with a paper towel moistened with the anesthetic[52]
	50–200 mg/kg SC, IM, ICe[52]	Most species/may be irritating administered SC, IM (neutral solution is preferred)[52]
	100–200 mg/kg ICe[43]	Leopard frogs
	100–400 mg/kg ICe[43]	Bullfrogs
	100–200 mg/L bath to effect[52]	Larvae/induction
	200–500 mg/L bath to effect[52]	Tadpoles, newts/induction in 15–30 min
	0.5–2 g/L bath to effect[52]	Frogs, salamanders/induction in 15–30 min
	1 g/L bath to effect[52]	Most gill-less adult species (unless very large)/induction
	1 g/L by immersion, buffered with 1 g/L sodium bicarbonate[50]	Sonoran desert toads/surgical plane of anesthesia
	1–2 g/L by immersion[24]	African clawed frogs/buffered to pH of 7.0 +/- 0.4; 20 min induction then rinsed; respiratory depression; longer duration of surgical anesthesia with higher dosing
	2–3 g/L bath to effect[52]	Toads/induction in 15–30 min
	5 g/L immersion[45]	African clawed frogs/immersion for 1 hr; death within 3 hr
	10 g/L bath[52]	Euthanasia; can be administered ICe or in lymph sacs

[a]SC can be administered in dorsal lymph sac in anurans.[52]
[b]ED50, effective dose for 50% of the population.

TABLE 128.5 Hormones Used in Amphibians[a]

Agent	Dosage	Species/Comments
Gonadotropin-releasing hormone (GnRH)	10 μg SC to female followed by additional 20 μg after 18 hr; 5 μg SC to male[48]	Tomato frogs (Dyscophus guineti)/ovulation and spermiation
	0.1 mg/kg SC, IM, repeat prn[52]	Induction of ovulation in those nonresponsive to PMSG or hCG; administer to females 8–12 hr before males
Human chorionic gonadotropin (hCG)	50–300 U SC, IM[52]	For mating or release of sperm in males; follow with GnRH in 8–24 hr
	250–400 U SC, IM[52]	African clawed frogs, axolotls/induction of ovulation; may be used with PMSG and/or progesterone
Luteinizing hormone–releasing hormone (LHRH)	5 μg ICe per animal[47]	Salamanders (Desmognathus ochrophaeus)/induced oviposition in 94% of animals
	10 μg in 0.05 mL of 40% DMSO applied to ventral drink patch[37]	Bufo americanus, B. valliceps/induced spermiation in 70% of males
Pregnant mare serum gonadotropin (PMSG)	50–200 U SC, IM[52]	African clawed frogs, axolotls/induction of ovulation; administer 600 U hCG SC, IM 72 hr later[52]
Progesterone	1–5 mg SC, IM[52]	African clawed frogs, axolotls/use in addition to PMSG or hCG for induction of ovulation

[a]SC can be administered into the dorsal lymph sac of anurans.[52]

VetBooks.ir

TABLE 128.6 Miscellaneous Agents Used in Amphibians[a]

Agent	Dosage	Species/Comments
Amphibian Ringer's solution (ARS)	6.6 g NaCl, 0.15 g KCl, 0.15 g $CaCl_2$, and 0.2 g $NaHCO_3$ in 1 L water[52]	For treating hydrocoelom and subcutaneous edema; place animal in shallow ARS bath until stabilized (≈24 hr or more); replace with fresh solution daily; may need to wean animal off ARS by placing it in gradually more dilute solutions; hypertonic solution created by using 800–950 mL water instead of 1 L and may be more effective for some cases of hydrocoelom; up to 10 g of glucose may be added per L, but then solution must be made fresh daily[52]
Atropine	0.1 mg/animal SC, IM prn[52]	Organophosphate toxicosis
Caffeine	Use caffeinated tea bag; steep (soak) until solution is "weak tea"; place amphibian in shallow bath, replace q6h[52]	Stimulant; may help reverse ivermectin or levamisole toxicosis, or excessively deep anesthesia[52]
Calcium glubionate (Calcionate, 1.8g/5 mL, Rugby Laboratories)	1 mL/kg PO q24h[52]	Nutritional secondary hyperparathyroidism
Calcium gluconate	100–200 mg/kg SC[52]	Hypocalcemic tetany
	2.3% continuous bath (with 2–3 U/mL vitamin D_3)[52]	Nutritional secondary hyperparathyroidism
Critical care diets	—	Dosages are approximate; may be more appropriate to offer larger volume less frequently for easily stressed animals
• Carnivore Critical Care (Oxbow)	3% bodyweight PO q24–72h[52]	
• Emeraid for Carnivores (Lafeber)	3% body weight PO q24–48h[52]	
• Feline Clinical Care Liquid (Pet-Ag)	1–2 mL/50 g PO q24h[52] 3–6 mL/50 g PO q72h[52]	
• Hill's Feline a/d (Hill's Pet Nutrition)	PO[52]	Nutritional support; mix 1:1 with water; generally gavaged
Cyanoacrylate surgical adhesive (Vet Bond, 3M)	Topical on wounds[52]	Produces a seal for aquatic and semiaquatic species
Dexamethasone	1.5 mg/kg SC, IM[52]	Vascularizing keratitis
	1.5 mg/kg IM, IV[52]	Shock
Dextrose 5% solution	Bath[52]	For treating hydrocoelom and subcutaneous edema;[52] place animal in shallow bath until stabilized (≈24 hr or more); replace with fresh solution daily; may need to wean animal off dextrose by placing it in gradually more dilute solutions; 7.5–10% solutions may be more effective for some cases of hydrocoelom
	Topically to affected tissues (McDermott et al, Proc ARAV, 2015, p 477)	Small amount can be applied to edematous/inflamed tissue in cases of cloacal prolapse to aid in prolapse reduction
Doxycycline	1.25–2.5 mg/kg PO, SC, ICe q24h[52]	Antiinflammatory
	1% gel topically q12h[52]	Antiinflammatory
Hetastarch (6% in 0.9% saline)	Bath not to exceed 1 hr without reassessment[52]	May help with initial treatment of hydrocoelom
Hypertonic saline, 5% ophthalmic solution	Topically to affected tissues (McDermott et al, Proc ARAV, 2015, p 477)	Small amount can be applied to edematous/inflamed tissue in cases of cloacal prolapse to aid in prolapse reduction
Laxative (Laxatone, Evsco)	PO[52]	Laxative, especially for intestinal foreign bodies
Methylene blue	2 mg/mL bath to effect[52]	Nitrite and nitrate toxicoses
Oxygen	100% for up to 24 hr[52]	Adjunct treatment for septicemia, toxicoses
Physostigmine (ophthalmic drops)	1 drop/50 g topically q1–2h to effect[52]	May ameliorate flaccid paralysis from ivermectin or levamisole toxicosis
Prednisolone sodium succinate	5–10 mg/kg IM, IV[52]	Shock
Sodium thiosulfate	1% solution as continuous bath to effect[52]	Halogen toxicoses

TABLE 128.6 Miscellaneous Agents Used in Amphibians[a]—cont'd

Agent	Dosage	Species/Comments
Vitamin A (Aquasol A, 50,000 U/mL, Mayne Pharma)	Dilute 1:9 with sterile water; make fresh weekly; apply 1 drop from a tuberculin syringe with 27-g needle to amphibians under 5 g; 1 drop from tuberculin syringe w/out needle is about 200 U and useful for 15–30 g BW; >30 g, try 1 drop per 10 g BW; topically q24h × 14 days, then q4–7d[52]	Hypovitaminosis A; given the plethora of organ systems that hypovitaminosis A may affect, it is reasonable to institute vitamin A supplementation of any clinically ill amphibian, particularly ones with signs similar to "short tongue syndrome," swollen eyelids, evidence of infectious dermatitis, hydrocoelom, or simply "failing to thrive";[52] the use of mixed dietary carotenoids may also be effective in some species[8]
	Dilute 1:10 in sterile water; applied as one drop from 18-g needle; estimated as 50 U/frog q48h to q7d[39]	African foam–nesting frogs/weight range, 2–7 g; dosing q48h and once weekly significantly increased whole body vitamin A levels over control group and group treated with vitamin A fortified supplement dusted over crickets[39]
	1 U/g PO daily × 14 days[52]	
Vitamin A gel caps (10,000 U/cap)	Dilute 1:9 with corn oil to yield 1000 U/mL; give 1 U/g PO q24h × 14 days, then q7d[52]	Hypovitaminosis A; given the plethora of organ systems that hypovitaminosis A may affect, it is reasonable to institute vitamin A supplementation of any clinically ill amphibian, particularly ones with signs similar to "short tongue syndrome," swollen eyelids, evidence of infectious dermatitis, hydrocoelom, or simply "failing to thrive;"[52] the use of mixed dietary carotenoids may also be effective in some species[8]
Vitamin B_1	25 mg/kg PO[52]	Deficiency resulting from thiaminase-containing fish
	25–100 mg/kg IM, ICe[53]	
Vitamin D_3	2–3 U/mL continuous bath (with 2.3% calcium gluconate)[52]	Nutritional secondary hyperparathyroidism
	100–400 U/kg PO q24h[52]	
Vitamin E (alpha-tocopherol)	1 mg/kg PO, IM q7d[52]	
	200 U/kg feed[52]	Steatitis

[a]SC can be administered into the dorsal lymph sac of anurans.[52]

Abbreviations Used in This Formulary

d	day	MIC	minimum inhibitory concentration
EpiCe	epicoelomic	min	minute
h	hour	mo	month
ICe	intracoelomic	mg	milligram
IM	intramuscular	mL	milliliter
IO	intraosseous	PD	pharmacodynamics/pharmacological data
IT	intratracheal	PK	pharmacokinetic data
IV	intravenous	PO	per os
U (IU)	international unit	prn	as needed
kg	kilogram	q	every
L	liter	SC	subcutaneous
LRS	lactated Ringer's solution	URT	upper respiratory tract
MAC	minimum alveolar concentration	wk	week

Photobiomodulation (Low-Level Laser Therapy)

Lara M. Cusack and Stephen J. Divers

Low-level laser therapy (LLLT), or photobiomodulation (PBM), has been used in human and veterinary medicine for decades. More recently, zoological practitioners have begun to utilize LLLT for its anti-inflammatory, analgesic, and wound-healing effects. Though dissent in the level of effectiveness of laser therapy as a treatment modality remains, there exists a growing body of literature around its use as low-risk treatment with potential benefits for a variety of medical conditions. Improved rates of healing for epithelial trauma and musculoskeletal injuries, as well as improvements in chronic pain, have been documented in multiple species, including humans, rats, pigs, and rabbits.[1–7]

Laser light induces a photochemical reaction at the cellular level, which stimulates a biochemical response increasing the production of ATP and results in both local and systemic effects. Photoreceptor cells, such as hemoglobin, cytochrome c oxidase, and melanin, when hit by the laser, absorb the energy, which is stored and used to perform a variety of cellular activities that can have direct effects on healing, including fibroblast proliferation, angiogenesis, and cytokine synthesis.[8–10] An increase in fibroblast proliferation and migration, with subsequent increases in collagen production, contraction of granulation tissue, and improved wound tensile strength, has been attributed to laser therapy treatment and has been documented in multiple wound-healing studies in rats.[12–14] Additional effects, such as analgesia and reduction in edema, have also been documented.[6,7,15–17]

WOUND HEALING

The phases of wound healing in the reptile parallel those in mammals but occur at a slower rate, differ between species, and are affected by a variety of factors such as temperature and restraint-associated stress.[18–20] As infection remains one of the most common complications of wounds, promotion of epitheliogenesis is important both for the primary effects on wound retraction and due to the fact that the epithelial barrier is the primary method of preventing infection.[21] The use of LLLT may be an effective tool in promotion of healing in the reptile patient and may be used for promotion of epitheliogenesis and tissue healing, analgesia, and antiinflammatory effects.

EQUIPMENT AND TECHNIQUES

In a recent survey by *Veterinary Economics*, one in every five veterinarians were using or expanding the use of LLLT in their practices; this availability of equipment greatly increases practical application of this treatment modality for reptile patients.[22] There exists a variety of different veterinary laser units for purchase, each varying in terms of emission mode, power, wavelength, hand pieces, surgical options, and type of delivery system. The emission mode describes the method in which the energy is delivered and is usually described as continuous, chopped, or super-pulse. In general, increasing the pulse duration increases the level of peak power that can be delivered without tissue damage.[22]

The power of the laser is measured in watts (W), which describes the amount of energy (photons) transferred to tissue over time. Increasing wattage coincides with an increase in the number of photons arriving at the tissue. High- and low-power units can deliver an equal number of photons; however, higher-power units will be faster in their delivery.[23] This can be important in a clinical setting, in particular with zoological patients, where minimizing handling times is often desirable. The class of laser is determined by the level of average power, with anything above 500 mW classified as a class IV laser.[23] Due to their increased power, class IV lasers have the ability to damage eyesight and tissue, but they have the advantage of requiring decreased time for treatment.[23] A summary of some of the class IV lasers available for veterinary use is provided in Table 129.1.[22] The wavelength of the laser is measured in nanometers (nm) and is directly correlated to the capability of the laser to penetrate tissue.[22] Detailed information on delivery systems for individual units can be obtained from the specific laser companies.

Penetration of tissues requires the appropriate combination of power, wavelength, and treatment time. The World Association of Laser Therapy suggests that mammalian cells require 4 to 10 J/cm^2 in order to generate a positive photobiochemical response. Cells closer to the surface require a smaller dose, with deep tissue cells requiring an increased dose.[24] A number of variables of the reptile patient, including pigment, epithelial thickness, stage of ecdysis, and temperature, can make establishment of appropriate dose challenging for the reptile patient, and there are no currently established guidelines for the use of LLLT in any reptile. However, several of the available laser units offer preestablished settings for the exotic patient and for commonly treated conditions such as fractures and wounds, thereby increasing ease of use. The reliability of such presets is unknown, and these settings should be considered a guide at best. Individual animal and species variability can influence the effects of laser therapy, and it is recommended that practitioners maintain a log of settings used for individual patients, conditions, and results.

General recommendations for use of laser on wounds and other tissues involves gentle contact, if using a contact probe, and a continual, sweeping or painting motion of the tissues in order to distribute energy and prevent thermal or photodynamic tissue trauma. Consideration should be given to the level of pigmentation and thickness of the tissue being treated, as the degree of energy penetration will be increased with less pigmented and thinner tissues. Intermittent palpation of the treatment area (or use of a thermal imaging or temperature gun) will allow the operator to ensure that a targeted area is not becoming too warm. Continual visual assessment of the target area during treatment will allow for assessment of any additional signs of tissue trauma. The authors have used laser therapy for a variety of conditions in reptiles, including epithelial wounds, fractures of the carapace and plastron, and joint swelling, and have not noted any negative effects when using the preset

TABLE 129.1 A Summary of Some of the Commercially Available Class IV Laser Units

Company	Emission Mode	Min–Max Power	Wavelength	Handpieces/Probes	Surgery Option
Companion Therapy Laser (LiteCure)	Continuous, pulse	0.25 w–15 w (depending on model)	980, 810, 650 nm (depending on model)	2 deep tissue, 2 superficial treatment	Yes
Cutting Edge Laser Technologies	Continuous, frequenced continuous, super pulse, combined, synchronized	1.2 w (average)	650, 808, 905 nm	Small, large, acupuncture, and intraoral	No
Diowave Laser Systems	Continuous, pulse	1 w–10 w	980 nm, 808/810 nm, 810/980 nm (depending on model)	Multiple	Yes
K-Laser USA	Continuous, pulse, intense super pulse	0.1 w–20 w (depending on model)	660, 800, 905, 970 nm (depending on model)	Quick-release, adjustable for contact and noncontact, optional ear/nose/throat tip	Yes
Pegasus Therapy Lasers (LiteCure)	Continuous, pulse	0.25 w–15 w (depending on model)	980, 810, 650 nm (depending on model)	2 deep tissue, 2 superficial treatment	Yes
Respond Systems Inc.	Continuous, super pulse	1 mw–5 w (depending on model)	660, 810, 850 nm	Small profile with rounded tip, advantage tip, high-power, cluster, acupuncture tip	No

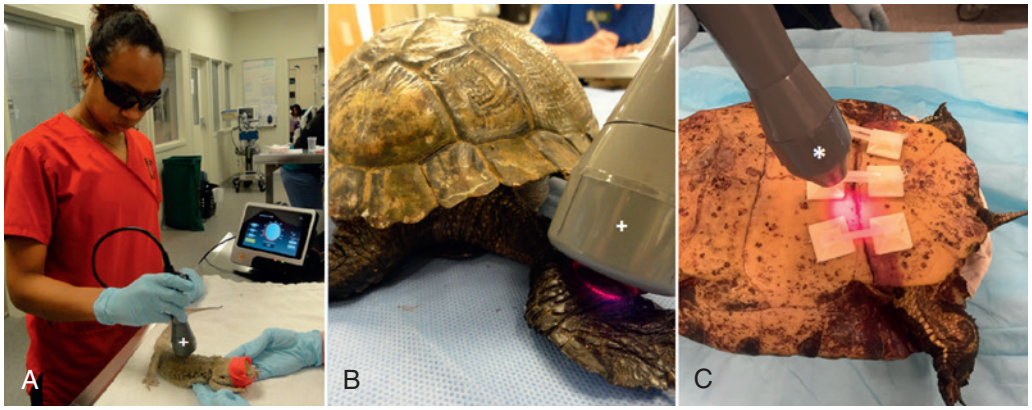

FIG 129.1 The use of different probes, or tissue applicators, can achieve different levels of tissue penetration. (A and B) Deep tissue applicators (+) can be directly applied to the tissue and are useful for deeper wounds and musculoskeletal injuries. (C) Superficial treatment applicators (*) may be used for shell fractures or for injuries where direct contact may be contraindicated. (Courtesy of Lara M. Cusack and Stephen J. Divers.)

reptile treatment protocols as a guideline for therapy. The use of different probes can increase or decrease tissue contact (Fig. 129.1).

Deep tissue applicators allow direct tissue contact and result in much less light being reflected from the skin. The use of such handpieces results in up to 90% more photons reaching the tissue compared to a noncontact hand piece. This may be of particular importance in the reptile patient, as there is a potential for increased reflectivity, or absorption, by the reptilian integument. Handpieces such as the superficial treatment applicators may be more appropriate for injuries such as shell fractures or suture lines, where direct contact may cause iatrogenic tissue trauma or damage to the probe tip.

Additional considerations for the use of laser therapy include the appropriate use of personal protective equipment for both the operator and the patient. Protective eyewear is essential, as high-power laser is known to have negative effects on the eye and should be specific for the wavelength being used (see Fig. 129.1A).

THERAPEUTIC EFFECTS

Despite the growing body of literature supporting the clinical effects of laser therapy in humans, some veterinary studies or reports fail to document an objective, therapeutic response when compared to controls. The effects of laser therapy vary greatly depending on wavelength, energy, energy density, duration, and the delivery system, and it is likely that the results of wound healing studies are related to these variables, making appropriate dosing important for safe clinical effect. Unfortunately, comparison between studies remains difficult due to variability between treatment protocols, and there is little information on effective and safe laser protocols, especially for exotic species. Therefore, although positive outcomes are possible, the use of nonspecific, unproven regimes may result in no objectively measurable, beneficial effects. Owners should be advised that there are likely no deleterious effects from appropriate LLLT, but clinicians should be cautious regarding unsubstantiated claims of proven efficacy.

Laser therapy has been used for the treatment of skin and shell ulceration in a soft-shelled turtle (*Pelodiscus sinensis*) and for skin wounds in two species of chelonians (*Testudo hermanni* and *Trachemys scripta*); subjective improvement of the lesions was noted in all cases, but results were not verified by histopathology.[25,26] A recent study looking at the effects of therapeutic laser on first-intention incisional wound healing in ball pythons (*Python reguis*) compared rate of healing and histologic wound reaction (reduced inflammation, necrosis, and edema) between

VetBooks.ir

wounds treated with therapeutic laser and untreated control incisions. Though there was no significant difference in overall wound healing between treatment groups at the end of the study, the grade of collagen maturity was significantly higher, and gross wound scores were lower for the laser-treated group than for the control group. Treatment in this study consisted of a power output of 0.5 W for 90 seconds once daily for 7 consecutive days, and the dose delivered to each incision was 5 J/cm^2 with a wavelength of 980 nm on a continuous wave sequence. The authors of the study acknowledge that the treatment protocol may have been insufficient because of possible greater reflection or absorption of photons by reptilian scales.[27] A more recent study by the authors investigated the use of laser therapy in the treatment of epithelial trauma in the green iguana (*Iguana iguana*). Epithelial wounds were created and received either topical wound care or laser therapy, at two different doses. The treatment protocol used by the authors in the iguana study used laser therapy at the same dose as the python study for one treatment group and a higher setting (10 J/cm^2), at double the dose, for a second treatment group. Wound measurements were obtained daily for 14 days, and the treatment sites were then evaluated microscopically for ulceration, inflammation, fibrosis, presence of bacteria, and collagen maturity. Subjectively, gross wound scores were less for the wounds treated with 10 J/cm^2 when compared to control wounds or those treated with topical medications or the lower level of laser therapy (5 J/cm^2) (Fig. 129.2). There was no significant difference in histologic evidence of healing between the laser treatment, topical treatment, and control wounds at completion of the study, at which time only 2.4% of wounds had complete epithelialization (Fig. 129.3). Though no significant improvement in histologic evaluation of overall healing was noted with this protocol in this species, there was no obvious damage or disadvantage caused by use of the laser. The low percentage of wounds showing complete epithelialization may support the need for an extended study period.

The effects of treatment with laser therapy have been shown to extend systemically to areas distant from the site of treatment, with one study in rats demonstrating increased healing of wounds that had direct treatment with laser as well as in standardized wounds distant from the site of application. Wounds in the intermediate position had the highest ranks or healing when compared to distant wounds and wounds treated directly.[28] Consideration of tissue characteristics and of the local tissue effects of laser treatment should play a role in the development of appropriate treatment protocols for the reptile patient. Additionally, regular clinical assessment should be performed throughout the course of treatment, allowing for modifications to the treatment protocol.

THERAPEUTIC PLAN

Laser therapy can be used in both acute and chronic conditions and is cumulative in effect. When initiating treatment, laser therapy should be applied in three phases, which include the initial or aggressive treatment phase, a transitional phase, and a maintenance phase. Objective criteria for these three phases in reptiles have not been established; the following are suggestions. During the initial treatment phase, therapy is provided daily or every other day, with clinical evaluation made daily.[29] Dose adjustments can be made during this time, and this period typically is recommended to last for approximately 7 days. Following the initial treatment phase, frequency of therapy is decreased; twice-weekly applications are often recommended (Riegel, 2011, Applications of therapeutic laser in everyday practice. *Veterinary Practice News.*

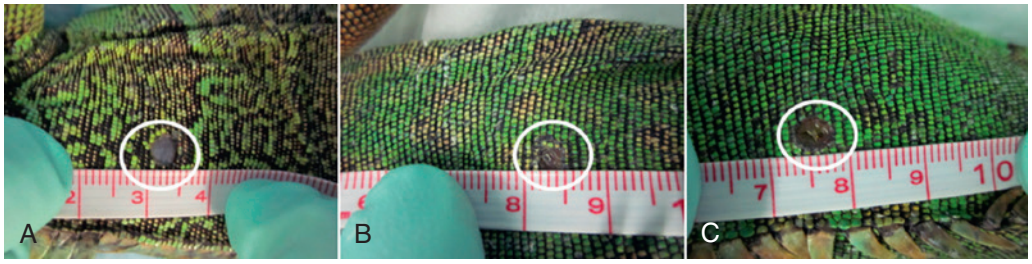

FIG 129.2 (A) Pre-treatment and (B and C) post-treatment epithelial wound in the green iguana (*Iguana iguana*). Post-treatment gross wound scores for (B) wounds treated once daily with laser therapy at 10 J/cm^2 were lower than for (C) control wounds, wounds treated with topical therapy, or wounds treated with laser therapy at 5 J/cm^2. (Courtesy of Lara M. Cusack and Stephen J. Divers.)

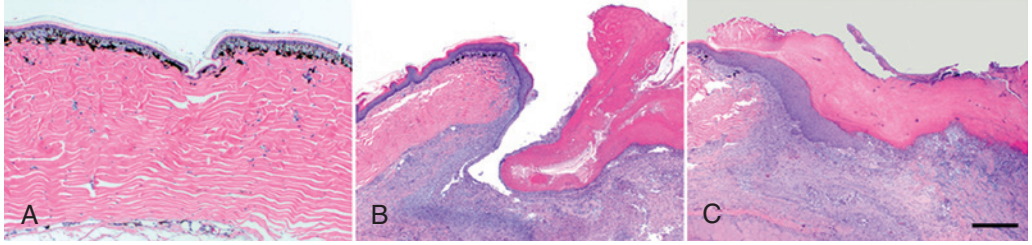

FIG 129.3 Micrograph of pre- and post-treatment epithelium of a green iguana (*Iguana iguana*). Normal, prestudy epidermis and dermis (A). Mild healing was noted when regular epithelial migration was present (B) and partial healing was noted when irregular epithelial migration was present (C). Complete epithelial migration was present in only 2.4% of wounds. Bar = 500 µm. (Reprinted with permission from Cusack LM, Mayer J, Cutler DC, et al. Gross and histologic evaluation of effects of photobiomodulation, silver sulfadiazine, and a topical antimicrobial product on experimentally induced full-thickness skin wounds in green iguanas [*Iguana iguana*]. *Am J Vet Res.* 2018;79[4]:465–473.)

VetBooks.ir

2011;23[8]:26-27). For acute clinical conditions, such as wounds and fractures, the transitional phase lasts until resolution of the condition, whereas in chronic conditions, such as arthritis, this phase often lasts until a clinical goal, such as improved joint mobility, is reached. The maintenance therapy phase can be utilized for ongoing or chronic conditions, and frequency is typically dictated by clinical response. Once- or twice-monthly treatments are often used for maintenance of chronic conditions. In general, the use of laser therapy in the treatment of neoplasia is contraindicated due to the potential for increased growth of tumor cells.

Wound Management

Maud L. Marin and Terry M. Norton

Reptiles are often presented with different types of wounds on their body. Although their ability to heal wounds is good overall, their healing rate is relatively slow, and significant wounds can take several months and even over a year to fully resolve. It is therefore important to use appropriate techniques in order to minimize healing times. Reptilian wound management follows the general techniques used in small animal and human medicine, but certain products and techniques work better than others in reptiles and will be described below. Wound management is an art, and treatment modalities need to be adapted to each animal, situation, and phase of healing. New products and techniques are constantly discovered, and their application will have to be tested in our reptilian patients.

Wounds commonly seen in reptiles include husbandry-related injuries (dysecdysis, burns, bacterial, fungal, and parasitic dermatitis and shell infections), conspecific- or prey-induced injuries (bites, lacerations, and abscesses), and trauma (fall from perches; lacerations from cage or furnishings; predator attacks; and car, boat or lawn mower accidents). Infected surgical incisions and tumors can also lead to skin wounds.

GENERAL WOUND MANAGEMENT

Husbandry and Management of the Patient

Irrespective of the cause for the wound, providing proper husbandry, nutrition, and a low-stress environment is paramount in optimizing wound healing.[1] The animal should be kept at its preferred optimal temperature zone, with appropriate substrate, excellent water quality (aquatic turtles and crocodilians), and hygiene (see Section 3). Providing nutritional support and a proper diet during the healing phase is also important. When needed, supplemental nutrition can be achieved by assist feeding, tube feeding (snake, lizards, and chelonians) or via an esophagostomy tube (chelonians, lizards, crocodilians). A surgically placed feeding tube also permits long-term administration of fluids and medications in a relatively low-stress manner (see Chapter 45).

Initial Wound Evaluation and Diagnostic Evaluation

Sedation with local analgesia or general anesthesia may be required for initial evaluation and management of serious wounds. It is beneficial to stabilize critical patients prior to anesthesia. Physical and neurologic examinations, and diagnostic investigation (e.g., clinicopathology, diagnostic imaging, and microbiology), are beneficial in establishing an accurate diagnosis and prognosis, which will direct the treatment plan.[2,3] Antimicrobials (following the collection of samples for culture and sensitivity testing) and pain management should be initiated if indicated. Local anesthetics can be injected around the wound prior to debridement to reduce perioperative pain (see Chapters 50, 51, 116, 117, and 119 for further information). Hemorrhage should be controlled and fractures immobilized.

Wound Lavage and Debridement

The initial lavage should be done using a warm, balanced electrolyte solution, sterile saline, 0.05% chlorhexidine solution, or 0.1% to 1.0% povidone-iodine.[4] Surgical debridement should follow if needed, carefully removing all nonviable tissue. Any tissue that has questionable viability can be left in place and reevaluated later or treated with autolytic or enzymatic debridement products (Granulex V, Bertek Pharmaceuticals, Research Triangle Park, NC).[4]

Snakes with generalized dermatitis may be treated with periodic soaking in a medicated water bath (after appropriate diagnostic tests have been performed) containing dilute chlorhexidine or povidone-iodine. It is often beneficial to bathe the snake in water first in case the snake wants to drink. After a 10- to 20-minute antiseptic bath, the animal may be dried off and a thin layer of antimicrobial ointment or cream may be administered topically.

Wound Closure

Reptiles tend to heal well from minor wounds with little intervention. After cleaning/lavage, they may be left to heal by second intention or can be sutured or stapled. Suture materials preferred for use in reptiles include nylon, polypropylene, polydioxanone, poliglecaprone 25, and polyglyconate.[5,6] Apposing and everting suture patterns have been used on reptilian skin, taking care to prevent inversion and subsequent dysecdysis. Although the literature suggests that sutures should be left in place for a minimum of 6 weeks in reptiles, clinically some wounds heal in 2 to 4 weeks with sutures able to be removed at that time.[2,5] Because of the low exudative nature of reptilian wounds, drains are not useful for these patients. The remainder of this chapter will focus on the more challenging wounds that require extensive treatment and bandaging.

Topical Products

Chronic and infected wounds may benefit from topical product application. A wide variety of topical antimicrobials and products that accelerate wound healing are currently available. New products are regularly introduced into the market. It is good to rotate topical antimicrobials over time in order to avoid resistance and to try different products when a wound fails to improve. Topical treatments commonly utilized include silver sulfadiazine cream (Silvadene, Hoeschst Marion Roussel, Kansas City, MO), antibiotic ointments (triple antibiotic ointment; gentamicin sulfate), doxycycline gel (Doxirobe Gel, Pharmacia & Upjohn Company, New York, NY), aluminum spray (AluSpray, Neogen, Lansing, MI), nitrofurazone (Fura-Zone, Squire, Revere, MA), aloe vera gel, sugar, and honey (MediHoney, DermaSciences, Princeton, NJ).[1,7,8] Other wound care products that may help support the healing process include growth factors (Regranex Gel, Ortho-McNeil Pharmaceutical, South Raritan,

VetBooks.ir

NJ), maltodextrin (Intracell, Macleod Pharmaceutical, Fort Collins, CO), chitosan, acemannan hydrogel or the freeze-dried form (CarraVet, Veterinary Products Labs, Phoenix, AZ; Carrasorb Carrington Labs, Irving, TX), and skin protectant cream (ilex Skin Protectant Paste, Medcon Biolab Technologies, Grafton, MA) mixed in with antimicrobial cream. These products can generally be used over an open wound, as well as within the primary layer of a dressing.

BASIC BANDAGING TECHNIQUES

Benefits from applying a bandage include protection from contamination and external mechanical forces, elimination of dead space, immobilization of the injured area, support and comfort, as well as provision of a moist environment.[1,4] Bandaging reptile wounds can be quite challenging. Creativity is required to provide a bandage that is sturdy yet light enough, stays in place, and does not limit the animal's mobility extensively. In aquatic species, some bandages need to be waterproof. Reptile wounds generally produce a thick to hard caseous material rather than a liquid exudate, so light dressings that keep the wound moist are preferred with this group of animals.

A bandage generally consists of three layers. The primary layer consists of a nonadherent dressing placed directly over the wound bed. The most commonly used types of dressings in reptiles are the semiocclusive and occlusive dressings, hydrogels, and hydrocolloids.[1] Examples of semiocclusive dressings include Telfa adhesive pads (Kendall, Mansfield, MA) and Adaptic (Johnson & Johnson nonstick dressings, Arlington, TX). Silver-impregnated dressings have the added benefit of providing a sustained antimicrobial effect on the wound bed (Acticoat burn dressing, Smith and Nephew, Largo, FL; Aquacell Ag hydrofiber dressing with ionic silver, ConvaTec, Greensboro, NC; Silverlon, Argentum Medical, Willowbrook, IL). An example of an occlusive dressing is the Op Site Spray Bandage (Smith and Nephew, Lachine, QC, Canada).[9] Hydrogels come in a flexible sheet or a gel that covers the wound bed and are useful to keep a wound moist. Certain hydrogel sheets also contain silver ions (SilvaSorb, Medline Industries, Mundelein, IL). Hydrocolloids such as DuoDERM (ConvaTec) interact with wound fluid to form a gel.

The secondary bandage layer holds the contact layer in place and can provide support as well as reduction of mobility. Materials commonly used include cast padding and rolled gauze. When needed, a splint can be added into this layer. This layer is not always necessary or useful in reptiles and is often omitted.

The tertiary layer is made with adhesive films (Steri-Drape and Tegaderm, 3M Animal Care Products, St. Paul, MN), bandage wraps (Vetrap, 3M), adhesive tapes (Elastikon, Johnson & Johnson Medical Inc., Arlington, TX) white porous tape or duct tape, and fabrics such as a stockinette. Dressing changes should be tailored to each animal and situation and will vary between daily to once a week. Depending on the patient and the nature of its wounds, the procedure may be performed under manual restraint only, while others will require sedation or general anesthesia.

In snakes, traditional bandages placed around the animal's body do not usually stay in place because of the unique undulating movement they use for locomotion. Adhesive tape and bandages on the skin of snakes can leave a sticky residue, peel off the scales, or even tear the skin. An excellent alternative technique for these wounds is the tie-over bandage technique, which is described later in this chapter.[3,10] Lizards tend to tolerate bandages quite well and are not prone to removing them. Fig. 130.1A through D shows a Komodo dragon (*Varanus komodoensis*) that suffered from severe burns on the ventral skin from a defective ventral heating pad. Wounds on the limbs of chelonians can be challenging to bandage. In certain cases, the affected limb can be kept in place by flexing it into the shell fossa and securing it in this location by placing tape around the shell.

Aquatic animals pose an extra challenge to the clinician when it comes to bandaging. Most conventional bandages are not waterproof and will allow contamination and potential maceration of the wound when they are submersed. Faced with this reality, clinicians may elect to leave the wound unbandaged and unprotected, or periodically dry-dock the animals for wound treatment (more stressful). An alternative is to apply a waterproof bandage. In aquatic chelonians with minor shell wounds, this can be achieved using antibiotic cream covered with an adhesive such as Tegaderm (Fig. 130.2A–C). For more extensive wounds, waterproof tape, Elastikon, silicone, and superglue may be needed to create an adequate water seal. See Chapter 113 for more details on shell bandage waterproofing.

SPECIALIZED BANDAGING TECHNIQUES

Tie-Over Bandage

The tie-over bandage offers an excellent alternative technique for wounds in areas that are mobile or difficult to cover. It is particularly useful in snakes but is also effective in lizards and turtles that have challenging wound locations. The technique has been previously described.[3,10] Briefly, after the wound has been debrided, nonabsorbable suture loops are placed around the wound. A topical medication can be placed over the wound and covered with Telfa pad, hydrogel, or hydrocolloid. Gauze is placed over the primary layer, and umbilical tape is threaded onto the suture loops with the help of a hemostat and tied over the bandage (Fig. 130.3A and B). Bandage changes may be done awake or under anesthesia if further debridement is needed, every 1 to 4 days initially. Later, the schedule should be tailored to the needs and evolution of the wound. In sea turtles, one of the authors (TN) has used a modified technique using metal skin staples instead of suture loops and suture material in lieu of the umbilical tape. In these aquatic animals, Telfa and gauze pads can be replaced with petrolatum gauze. Fig. 130.4A to D show a joint abscess in a Kemp's ridley sea turtle (*Lepidochelys kempi)* that is being treated with a tie-over bandage.

Vacuum-Assisted Closure Therapy

The vacuum-assisted closure therapy (VAC therapy) system (KCI, San Antonio, TX) is an excellent technique used for healing difficult wounds in humans, mammals, and reptiles.[8,11–22] VAC therapy is most beneficial in chelonians when a shell defect is present, usually because of trauma or infection. The reduction of healing time is striking, often saving many months of treatment and hospitalization. The technique is relatively simple to use and can be learned rapidly. The reader is referred to previous publications for a more detailed explanation of the technique.[8,19]

Negative pressure wound therapy (NPWT) promotes wound healing by promoting contraction of wound margins to facilitate closure, encouraging granulation tissue formation, increasing tissue perfusion, removing exudates, and reducing edema.[11–14] In chelonians with an open coelom, NPWT has the added benefit of bringing collapsed lung tissue back into its original location, favoring a more normal anatomic orientation and preservation of the coelomic space.

VAC therapy relies on open-cell foam that is placed into the wound bed, covered by an airtight plastic dressing, and attached to a suction machine by plastic tubing (Fig. 130.5). Additional materials have proven useful for the chelonian patient and are included in Table 130.1. Fig. 130.6A through D shows the use of VAC therapy in a gopher tortoise (*Gopherus polyphemus*), and Fig. 130.7 the use of a waterproof VAC dressing in a Florida cooter (*Pseudemis floridana*).

FIG 130.1 (A) Severe burn wounds on the ventral surface of a 4-year-old Komodo dragon (*Varanus komodoensis*) during debridement. This picture was taken 4 weeks after initial presentation. (B) After debridement was performed under anesthesia, primary dressings (Telfa) were placed over the wound. Rolled cotton and Vetrap were used as secondary and tertiary layers. (C) Stockinette was used as a body suit to complete the bandage. (D) Skin wounds 7 months after presentation. The wounds healed after 9 months of intensive therapy. Multiple therapeutic techniques and products were used on this animal, including skin graft, tie-over bandage, and laser therapy. (Courtesy of Maud L. Marin.)

A variety of nonadherent mesh materials (Adaptic, Acticoat, Silverlon) or sterile gauze can be placed on the wound bed with petroleum jelly, saline, or sterile water to keep it moist. Several types of open-cell foam can be used (VAC GranuFoam, GranuFoam Silver, VAC WhiteFoam). Alternatively, inexpensive open-cell foam can be found at home improvement stores (e.g., speaker foam or air conditioning foam with pore size of 400–600 μm) and can be gas sterilized. The open-cell foam is cut to size and placed into/on top of the defect. Multiple foam pieces can be used if needed.

Several types of occlusive plastic adhesive films can be used, including VAC adhesive drape (KCI), Steri-drape, and Tegaderm. If needed, grooves in the scutes can be covered with tape, adhesive materials, or filled in with epoxy. Orthopedic hardware can be covered with adherent bandage material (Elastikon) or epoxy putty before placing the adhesive drape.

Finally, an egress tube (VAC therapy-regulated accurate care [TRAC] pad or red rubber tubing) is placed through the adhesive drape and into the foam, after a quarter size hole is cut at the optimal location. The tube is then hooked to a suction pump. The VAC Freedom suction pump, a surgical suction pump, or a passive suction grenade can be used to generate negative pressure.

When suction is applied, the foam should take on a shrunken appearance beneath the adhesive film. Negative pressure between 100 mm Hg and 175 mm Hg is typically used in chelonians. Continuous suction is generally used, and leaving it on for 24 hours a day is ideal. If during the treatment the airtight seal is lost, it needs to be restored by applying more clear adhesive dressing. If it cannot be repaired within 2 hours, the whole dressing should be removed and the wound irrigated and left open until a new VAC bandage can be applied. Time off from treatment between bandage changes may be beneficial for the animal to relieve stress and give an opportunity for aquatic turtles to swim freely. Bandages can be changed without sedation or anesthesia, as humans report minimal pain during bandage change or therapy. It is important to monitor fluid loss and hydration status, especially in small patients weighing less than 10 kg. Initially the VAC treatment was used in dry-docked patients, but a waterproof technique was successfully used to treat sea turtles in a hospital treatment pool.[8] VAC treatment time for shell injuries in terrestrial chelonians has been reported to be from 3 to 43 days, whereas in sea turtles, treatment is generally a few weeks to months, depending on the severity of the wound.[19]

SUPPLEMENTAL THERAPIES

Skin grafts (allogenic and porcine small intestinal submucosa [VetBioSIST, Cook, West Lafayette, IN]) have been used successfully in reptiles, with the placement technique being similar to mammals.[5] Proper bandaging techniques, temporary immobilization of the graft, and other protective measures are often necessary for a successful outcome.

Alternative therapies that are suggested to promote wound healing in mammals include low-level cool laser (photomodulation) therapy, electroacupuncture, hyperbaric oxygen therapy, stem cell therapy, and

TABLE 130.1 Negative Pressure Therapy: Equipment Needed

Components	Best	Good	Adequate
Nonadherent barrier	Silver-impregnated mesh (Acticoat Silverlon) + saline or petroleum jelly	Adaptic+ saline or petroleum jelly	Telfa gauze + saline
Foam	VAC GranuFoam Standard, Silver, or WhiteFoam	Open-cell polyurethane foam (speaker foam at home improvement store)	Loosely placed gauze or laparotomy sponges
Adhesive drape	VAC sterile adhesive drape	Tegaderm, Steri-drape	Food-quality clear plastic wrap with silicone seal on margins
Tubing	Purpose-made pad and tubing (VAC TRAC pad)	Red rubber tube, fenestrated	Any plastic tubing, fenestrated + adaptor
Suction	VAC Freedom or Simplicity Therapy unit	Surgical suction unit	High-volume passive suction grenade

Acticoat burn dressing (Smith and Nephew, Largo, FL); Silverlon (Argentum Medical, Willowbrook, IL); Adaptic (Johnson & Johnson Nonstick dressings, Arlington, TX); VAC products (KCI Animal Health, San Antonio, TX); Steri-drape and Tegaderm (3M, St. Paul, MN).

FIG 130.6 (A) Gopher tortoise (*Gopherus polyphemus*) hit by a car with multiple cranial carapace fractures and an exposed coelom and lung on the right side. A set of screws, wires, and epoxy were used to stabilize the fracture. Regular wound management included lavage, debridement, RediHeal and bone cement, and VAC therapy. (B) RediHeal and bone cement were used to manage the wound, seal the coelom, and provide a surface for VAC placement. VAC therapy is being used on this tortoise. (C) The same tortoise in an outdoor pen with VAC unit in place. The tortoise is much more comfortable in an outdoor setting. The VAC unit is protected in a waterproof container. Ice packs are used to keep the VAC unit cool during warmer months of the year. (D) The wound 4 months post initial presentation. (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

VetBooks.ir

FIG 130.7 VAC therapy was used on this Florida cooter *(Pseudemys floridana)* with an exposed lung and spinal cord. This was alternated with RediHeal and bone cement application to the wound. The turtle continued to feed the entire treatment period and never showed any neurologic deficits. Eventually the turtle was released back to the wild. VAC therapy was critical for the success of this case.

platelet-rich plasma.[23–30] Although few research studies exist on their efficacy in treating reptiles and some refuted efficacy, many clinicians are using them in their reptilian patients with promising results.[28,31] More research is needed on their effects in reptiles.

In conclusion, multiple treatment options exist to treat reptile wounds. Extensive wounds are a challenge to treat, but with proper therapy, as well as husbandry and nutritional support, reptiles have a great ability to heal. Multiple modalities can be used simultaneously, for example, placing a skin graft within a tie-over bandage and using laser therapy on the wound during bandage changes. Finally, the treatment techniques should be reevaluated and modified as needed during the healing period and based on the wound appearance.

Physical Therapy and Rehabilitation

Albert Martínez-Silvestre and Samuel P. Franklin

The rehabilitation of reptiles encompasses two overlapping disciplines. One involves actual physical rehabilitation, which includes the diagnosis and physical treatment of reptiles with pathologic processes that may hinder their healing or recovery. Application of rehabilitation practices enables these injured reptiles to become as healthy, mobile, and functional as possible. Second, rehabilitation includes habituation of a reptile to a new environment, a new facility, or the preparation of an individual for release into the wild. This chapter describes both aspects of rehabilitation and their application in reptile medicine. Only the rehabilitation of inland reptiles is considered in this chapter. Specific rehabilitation of sea turtles can be found in Chapter 176.

PHYSICAL THERAPY

Response of Musculoskeletal Tissues to Disuse and Remobilization

Fortunately, reptiles spend much of their life in a relative state of inactivity, and their metabolism has a high capacity to adapt to such inactivity. Unlike many other vertebrates, they can quickly change to a state of high energy consumption and high activity such as when hunting, breeding, and avoiding predation, even after days or weeks of inactivity. Some reptiles, such as alligators or lizards, experience a sharp increase in tissue lactate in the pursuit and capture of prey after long periods of inactivity.[1] Resting reptiles have been shown to have blood lactate levels ranging from 4 to 20 mg/dL. Moderate activity results in lactate accumulations of 30 to 80 mg/dL, and prolonged or vigorous activity quickly produces levels exceeding 100 mg/dL. After experiencing such abrupt increases in lactate, reptiles are physiologically exhausted and often unable to appropriately respond to stimuli. Maximum or near-maximum levels of lactate can be produced in only 30 seconds of vigorous struggling in a number of lizard species.

In regard to kinematics and load resistance, generally a reptile's slow walking speed and robust limb bones result in low locomotor forces and limb bone stresses. However, their highly sprawled posture and perpendicular-to-axis femurs and humeri can produce high bending loads. This leads to high limb bone stresses similar to those of avian and mammalian species, as well as high torsion. Turtle limb bones seem considerably "overdesigned" for resisting the loads that they encounter. Additionally, comparisons of bone loading across tetrapod lineages are consistent with the hypothesis that low limb bone loads, elevated torsion, and high safety factors may be primitive features of limb bone design.[2]

Keeping these physiological characteristics in mind, negative side effects associated with extended hospital stays can be overcome by understanding and applying (or minimizing) physical activity specific to each reptile species. Prescribed rehabilitation exercise(s) in tame reptiles are better to be concentrated, not into one long session, but broken up into multiple shorter sessions distributed throughout the day. However, with highly stressed reptiles, it may be more stressful to handle them multiple times. In these cases, once a day rehabilitation is advisable to avoid disrupting their ability to acclimate and feed. Weekly rechecks are recommended to confirm positive progress in the recovery process. In some cases the degree of disuse atrophy can be cumulative and extreme. This is especially true for larger, heavy-bodied reptiles with chronic lameness, as they may be unable to lift their body weight off the ground to allow for normal locomotion. In such cases physical rehabilitation can be used to help them regain strength and enable controlled exercise.

Limb Paresis/Paralysis

Paresis/paralysis of the hind limbs is a common clinical presentation in lizards and turtles. Involvement of all four limbs is less common but may also be seen. Although spinal cord trauma is the most common cause of limb paresis/paralysis, a thorough historical evaluation and physical examination is required to exclude other causes of paresis such as coelomic pain, reproductive activity, neoplasia, renal disease, urolithiasis, neuromuscular disease, metabolic disturbances, and intoxication. A definitive diagnosis for the paretic patient is important, as therapy varies for each of these conditions. Table 131.1 shows the score and the decision-making process in cases of ataxia and postural immobilization.

To diagnose the possible causes of paresis/paralysis, a thorough physical, orthopedic, and neurologic examination are necessary. In cases where coelomic pain is suspected, a pharmacologic review of pain management and analgesia is discussed in Chapter 50. Table 131.1 provides an overview of differential diagnoses for reptile paresia/paralysis and ataxia, the associated etiologies for these conditions, and recommended diagnostic tests including hematology and biochemistry, radiology, cytology, and endoscopy. In cases of suspected vestibular syndrome or nerve injury, magnetic resonance imaging (MRI) is advised, as well as CT for possible vertebral damage.

In addition, we can test the animal's proprioception and mobility using proprioception exercises (see Chapter 77). Generally, land tortoises are scared of heights and they will not jump from a height greater than 30 cm. By placing the tortoise close to the edge of an elevated examination table, we can assess their capacity of vision, proprioception, and ability to escape from danger.

Physical Rehabilitation

Physical rehabilitation can include numerous different approaches to optimize patient function. Manual therapies include the use of mechanical touch, massage, stretching, and joint mobilizations. Physical modalities include treatments such as heat and cryotherapy, vibration therapy,

VetBooks.ir

TABLE 131.1 Functional Scoring System in Reptiles With Possible Spinal Cord Injuries

Five stages of spinal cord injury and related diseases. Each stage is subdivided based on recovery patterns and diagnostic procedures.

0. No pelvic limb movement and no deep pain sensation.
   a. In tortoises, rule out spinal cord trauma, nonspecific coelomic pain, and infection. (Rads, US) (Coe P) (PB) (CT, MRI) (EMG)
1. No pelvic limb movement but voluntary tail movement.
   a. In snakes rule out spinal cord trauma, nonspecific coelomic pain, and infection. (Rads, US) (Coe P) (PB) (CT, MRI) (EMG)
2. No pelvic limb movement with deep pain sensation. Behavioral changes.
   a. In general, rule out end-stage pregnancy, spinal cord trauma, and renal disease. (Rads) (Coe P) (PB) (CT, MRI)
3. Minimal protraction of the pelvic limb(s).
   a. Movement is generally limited to the forelimbs. (Rads) (EMG)
4. Protraction of pelvic limbs >50% of the time. Mild coelomic distension.
   a. Difficulty in urinating and retention of feces. In general, rule out renal disease, pregnancy, obstipation, spinal cord trauma, and metabolic disturbances. (Rads) (Clo T) (PB) (CT, MRI) (EMG)
   b. In the majority of reptiles, rule out ovulation and postovulation pain. (Rads)
5. Protraction of pelvic limbs >50% of the time. Coelomic enlargement.
   a. Chronic urinary retention, azotemia secondary to renal disease, or metabolic disturbances. (Rads, US) (Clo P) (Clo T) (PB)
   b. Rule out acute trauma, spinal cord injury. (Rads) (Clo T) (CT, MRI)

To diagnose all the described diseases in this table, these techniques may need to be performed: *Clo P*, cloacal palpation; *Clo T*, cloacal tone; *Coe P*, coelomic palpation; *CT*, computed tomography; *EMG*, electromyiography; *MRI*, magnetic resonance imaging; *PB*, plasma biochemistry; *Rads*, radiography; *US*, ultrasonography.

electrical stimulation, therapeutic ultrasound, and photobiomodulation. Therapeutic exercise can include aquatic therapy, neuroproprioceptive training, and strength and physical conditioning. Lastly, use of orthoses and prostheses are valuable aspects of physical rehabilitation. Many of the techniques described in the following sections have been assessed for their applicability to reptile rehabilitation in recent years.

Exercise and Joint Mobilization. Ultimately controlled exercise is the greatest tool in physical rehabilitation because it can achieve the objectives of building strength, improving range of motion, and facilitating neuroproprioceptive training. Trained exercises including target training and operant conditioning are widely used in captive crocodiles and large chelonians in zoologic collections and include performing exercises or movements associated with certain commands. Such training can help with completion of therapeutic exercises, improving posture, and allowing diagnostic sampling and feeding control.[3]

It is also important to consider environmental enrichment in physical rehabilitation as is commonly used with sea turtles**.** Enrichment includes providing food, toys, tactile stimulation, and keeper interaction. Husbandry training is a critical component of this therapy. It elicits the animal's cooperation during treatment, reducing the need for restraint, and provides mental and physical stimulation. Other techniques include conditioning reptiles to feed by tongs, acceptance of tactile manipulation, target training, the following of a trainer, responding to a recall stimulus, and providing a reward for allowing shell scrubbing. These techniques are particularly applicable to land tortoises (*Centrochelys sulcata*, *Stygmochelis pardalis*, and *Testudo hermanni*). Initial exercise sessions must be kept short because tortoises can become fatigued after only 10 to 15 minutes of walking, but the sessions can be repeated regularly. In other studies, the use of silhouettes of birds of prey (predators) by artificial models passing over terrariums have been used to induce exercise by encouraging an alert and escape reaction in captive lizards.[4]

In order to help improve muscle mass and strength, and facilitate physical therapy and exercise, anabolic steroids such as stanozolol (5 mg/kg intramuscularly every 7 days) can be used. This hormone also stimulates appetite and reduces protein catabolism and purine degradation and is expected to have a positive effect on erythropoiesis and cellular metabolism in addition to muscle development.[5]

Heat Therapy. Reptiles with chronic pain or old injuries may benefit from superficial heat provided by a hot pack. Indeed, as ectotherms, heat therapy is especially important for reptiles. Superficial heat therapy reduces pain by reducing sympathetic neurologic tone, promoting local circulation, increasing tissue oxygenation, speeding biochemical reactions, and reducing muscle spasms. Heat therapy applied across the coelomic wall can also improve gastrointestinal motility.[6]

If a patient reacts negatively to heat therapy (stops eating, moves less, or otherwise demonstrates results opposite to those expected), the treatment should be discontinued. Caution must be taken to avoid cutaneous burns by excessive contact with heat application in small or young reptiles. Therapeutic ultrasonography or photobiomodulation (low-level laser therapy) are other modalities used for energy application. These therapies may achieve heating of deeper tissues more efficiently and in a shorter period of time than use of heat packs, potentially making them safer and more readily tolerated. Additionally photobiomodulation can be used to promote granulation tissue proliferation, scar formation, and autolytic debridement of necrotic debris in wounds. See Chapters 129 and 130 for more details.

Electrical Stimulation. Use of electrical stimulation for improving strength and muscle mass has not been sufficiently studied in reptiles. However, electrical stimulators have been used in an effort to facilitate tissue regeneration in deep wounds. This treatment may provide advantages over other traditional methods for wound healing. The electrical stimulator device may induce tissue repair without causing severe stress to the patient and could be a potential option for hastening tissue healing in reptiles.[7]

Massage. Massage therapy can be beneficial in many species for pain relief, anxiety reduction, and promotion of the human-animal bond. Furthermore, in reptiles massage can generate an increase in temperature locally, making it a useful thermal therapy. Coelomic massage may be helpful in treating posterior paresis by decreasing pain. It can also be an important aid in intestinal transit. Additionally, it may be helpful in removing foreign objects that are in the large intestine or small urinary calculi, although you must use caution not to cause damage to the colon or bladder. Coelomic massage can be performed in lizards by exerting pressure with the thumb in a clockwise direction and at the same time applying digital pressure on the flanks in a dorsoventral and craniocaudal direction. Spinal column massage with pressure points in the cranial coelomic ("thoracic") area prompts inspiration and facilitates lymphatic drainage and blood flow, which allows recovery of spinal movements and improves movement in lizards and snakes. In the authors' experience massage of dorsal column points associated with the lungs, pericardium, and heart stimulates breathing in reptiles in the postanesthetic period and when the patient is suffering from shock. These points are the same that are used in saurian acupuncture (Fig. 131.1) (see Chapter 132).

VetBooks.ir

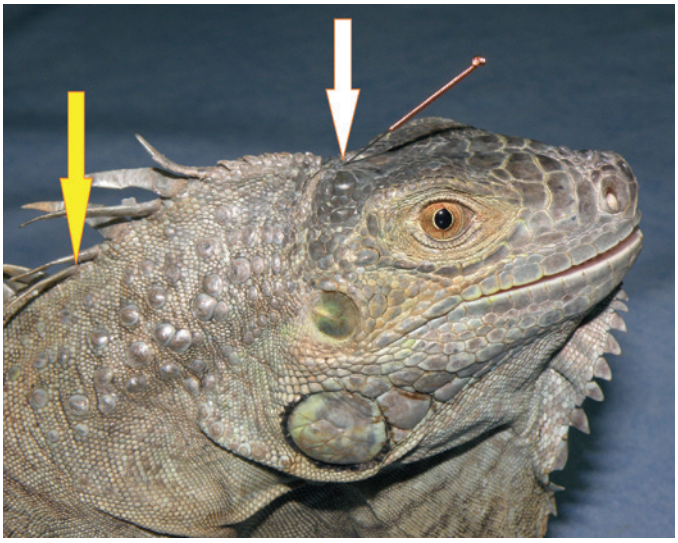

FIG 131.1 Acupuncture/pressure points to stimulate inspiration and breath (yellow arrow) and relax (white arrow) in a green iguana (*Iguana iguana*).

Vibrations. Vibration massagers may be beneficial in the alleviation of gut impactions in tortoises. The vibrator is adhered to the shell for vibrating sessions of several minutes. The vibrator is minimally invasive and well tolerated. A commercial vibrator was used to relieve intestinal constipation in a marginated tortoise (*Testudo marginata*).[8]

Orthopedics

Loss of Limbs. Wild reptiles can lose a limb and still survive; numerous field studies have identified reptiles with limbs that were amputated/removed by predators or other traumatic injuries. Wild turtles often survive the loss of one limb but may not be able to survive in the wild with the loss of multiple limbs. The loss of multiple limbs may affect foraging ability and thus growth in younger animals or reproductive success in mature turtles.

Similarly, in captivity turtles can survive with a loss of up to three limbs, but it is difficult to determine whether they have adequate quality of life. The most common causes of amputation are attacks by rodents (rats and mice), predatory carnivores (e.g., racoons, foxes, weasels, dogs), vehicular accidents, lawn mower damage, or falls from buildings. In cases of limb loss in chelonians, prostheses can be installed (Fig. 131.2).

Loss of forelimbs: Obviously the ability to apply traction using the forelimb is lost and the animal must depend on the propulsive ability of the rear limbs. In these cases the application of wheels or a support that can slide and elevates the plastron such as an acrylic ball cut in half may be useful. In male land tortoises the loss of a forelimb precludes successful mating; therefore, individuals missing a forelimb that are part of a rehabilitation project should not be released into the wild. The loss of a forelimb does not however preclude mating in aquatic turtles.

Loss of rear limbs: Mating is not hindered with the loss of hind limbs. However, in female turtles the loss of hind limbs makes digging a nest for laying eggs more difficult, and the female will need assistance during egg laying. Accordingly, female turtles that are part of rehabilitation projects should not be released into the wild, because they are unlikely to reproduce successfully.

Although wheels can commonly be used to improve mobility in individuals with loss of a limb, wheels are not always the best solution. They are beneficial and function well for tortoises living in terraces, floors, or tiled gardens. However, if wheels are small, or the turtle needs to move through an area of soil, sand, clay, or grass, the wheel may lose the ability to turn and become nonfunctional. In these cases adhering an artificial prosthesis to the plastron that is made of fiberglass, plastic, or wood is a better solution. The prosthesis should be smooth and blunt to allow sliding and minimize adherence of substrate, soil, or plant material (Fig. 131.3).

FIG 131.2 Female Herman's tortoise (*Testudo hermanni*) with prosthetic wheels after amputation of front limbs.

FIG 131.3 Male Russian tortoise (*Agrionemys horsfieldii*) with a nonwheel prosthesis after amputation of right front limb. Prosthesis is glued to the humeral-pectoral scales.

VetBooks.ir

In unusual cases prostheses are used even when there is no loss of a limb. A red-footed tortoise (*Chelonoidis carbonaria*) with secondary nutritional hyperparathyroidism and a deformed shell was treated with the use of a plastic prosthesis (nonwheel) to enable greater mobility, more involved rehabilitation, and the ability to interact with animals of the same species.[9] In a similar case a radiated tortoise (*Astrochelys radiata*) with a chronic limb lameness was provided with a kind of wheelchair that allowed the limb to move normally so that the animal could exercise and gain strength without having to bear full weight. The wheelchair consisted of an oval platform, made of ½-inch-thick recycled plastic lumber, cut to fit the plastron (Martin, et al. Proc ARAV, 2005, pp 25–26). Session times were gradually increased from 10 minutes to 1 hour daily. After the tortoise had regained sufficient strength, the original castors were replaced with a smaller set that allowed the tortoise to start supporting some of his own body weight. The total duration from initial presentation to complete resolution was approximately 1 year.

Aquatic Therapy. Swimming can be very useful in stimulating spinal movement and improving balance and proprioception. This is especially useful in species that use water periodically in their lives, such as iguanas, monitor lizards, or snakes. It is also useful in making terrestrial reptiles, including lizard species such as Agamidae (*Pogona, Uromastix*), Lacertidae (*Timon*, *Lacerta*), and Scincidae (skinks), attempt to escape a water bath. As they work to get out of the water they exercise joints and perform repetitive movements. Aquatic therapy in land tortoises consists of daily baths for 1 hour in shallow water to encourage limb movement. A leopard tortoise (*Stigmochelys pardalis*) with a transverse mid-shaft fracture of the right femur was treated with a modified tape bandage combined with aquatic therapy. After 60 days of this treatment and physical therapy the tortoise was ambulating normally (Raiti, Proc ARAV, 2008, pp 59–60).

For muscle building in aquatic turtles, it is necessary to increase the depth of water daily (1 cm daily), encouraging them to exercise to keep afloat. This is especially important in turtles that may lose fitness secondary to inactivity, such as in the softshell turtles (family Tryonichidae) or Fly river turtles (*Carettochelys insculpta*). These patients must be monitored closely to ensure they do not drown.

Rehabilitation Terrariums

The slow metabolism of reptiles necessitates more protracted rehabilitation efforts than generally required for mammal and avian patients. Although it depends on the species and disease, the rehabilitation process is generally no less than a month and can last up to a year or longer. Consequently, reptile rehabilitation facilities must meet certain specific requirements, which may differ from traditional veterinary hospitals. In general, environments and enclosures for rehabilitation should be able to confine the specimens and provide appropriate water, heat, light/photoperiod, temperature, substrate, humidity, ventilation, and visual security and should be easy to clean and disinfect. In many cases it may not be recommended to use elaborate and naturalistic vivaria during this time, as these environments may make it difficult to monitor the patient and eradicate possible contagious pathogens. Sometimes a balance may need to be met as some reptiles may be stressed with such a simplistic environment. In general, plastic, glass, acrylic, or fiberglass enclosures are most useful. For terrestrial species, enclosures can be simply lined with newspaper or paper towels. For aquatic and semiaquatic species, water may be added to the desired depth without substrate (Innis, Turtle and Tortoise Newsletter, 2001;4:14–16).

Reptiles destined for reintroduction to the wild are best maintained in outdoor enclosures. These facilities have to include running and stationary water (in different areas), living spaces consistent with the natural habitat, hibernaculums, surface hiding areas, basking areas, local climate, and predator control (Rossi, Proc ARAV, 1999, pp 59–60). To avoid infectious disease transmission, all tanks, tubs, tools, and other physical features that are used to rehabilitate native reptiles should never be used for exotic species.

Whether endangered species should be on display to the public is debatable. However, it is certainly advisable to prevent human contact or interaction with animals that are attempting to reproduce. However, public exhibition of some animals is essential to helping local human populations learn to value the species. Public education and outreach are important to support conservation efforts. Thus, there should be two types of facilities: those open to the public with educational and cultural themes and those closed to the public with primarily scientific or reproductive aims.

In those facilities in which animals will be displayed to the public, handling and display should be less than 10 minutes at a time to minimize stress. In the turtle (*Clemmys insculpta*), just 1 minute of handling resulted in an increase in heart rate from 28.39 beats/min to 40.2 beats/min (41% increase). This tachycardia persisted several minutes, then the heart rate returned to the baseline value in approximately 10 minutes.[10]

Nutrition During Rehabilitation

Dietary modification is an important aspect of reptile rehabilitation. Diets should be adjusted for age, rehabilitation goals, and disease processes. The diet should be tailored to meet the needs of four vulnerable conditions for the captive reptile: (i) hatchling and juvenile (musculoskeletal growth), (ii) maturity (gestation, ovulation), (iii) coexistence and overcrowding (parasitism, infectious bacterial, viral or fungal disease), and (iv) old age (hepatorenal dysfunction). Consequently, diets must be calculated to meet metabolic requirements, which should initially be based on calculated daily caloric needs (and then modified based upon response, especially accurate body weight). These data can also be used to calculate the total amount of food to be provided by tube feeding (see Chapters 45 and 122). An adequate supply of water is also important. Aquatic turtles absorb water when hunting and eating, and once they stop eating they dehydrate. Water is absorbed from the gut contents, and feces become dry, fluid flow stagnates, and the intestinal contents can produce a blockage. In an animal with gastrointestinal stasis, any new food will build up behind the blockage, and eventually the animal can die. So, solid food must always be mixed with the appropriate amount of water.[11]

In other rehabilitated reptiles, it is possible to produce a condition known as "refeeding syndrome" if too much nutrition is provided too rapidly. In this situation, the animal that has been chronically deprived of nutrition becomes metabolically deranged when calories are suddenly provided. To prevent this, rehydration should precede feeding. Initially, 10% to 20% of calculated caloric requirements should be provided and gradually increased over the first 1 to 3 weeks of rehabilitation (Innis, Turtle and Tortoise Newsletter, 2001;4:14–16) (see Chapter 87). Esophagostomy tube placement and nutritional support in turtles and other reptiles are discussed in Chapters 45 and 122.

Rehabilitation of Wild Reptiles

Successful reptile conservation requires the implementation of both in situ and ex situ programs. Given the current precarious conservation status of many endemic species around the world, it is clear that the captive breeding of reptiles, with the ultimate aim of their possible reintroduction in the wild, is insufficient to preserve a species. The ex situ strategies are needed to help bolster the number of individuals available for reintroduction and maximize genetic diversity. Conversely, the in situ strategies are needed to address the causes of species decline in the wild and focus on conservation of ecosystems that will support

VetBooks.ir

wild-born and reintroduced individuals. Both of these approaches are fundamental to preservation of endangered species.[12]

The release of reptiles into the wild must comply with local, national, and international laws (Cooper, et al. Proc iCARE, 2013, pp 242–243). In addition, selection of reptiles to be released should be subject to very strict criteria, including genetic, pathologic, ecological, and behavioral criteria.[13–16] Any individual not meeting these criteria should not be released. Consequently, some animals can never be reintroduced and should ultimately be removed from the rehabilitation program as "unrecoverable" or "unable to be rehabilitated."

Aid to Adaptation

It is important to promote adaptation of newcomers to facilities, including appropriate behavior training for healthy interaction with conspecifics. Reptiles can suffer maladaptation syndrome as a result of transport and changing maintenance conditions and may have difficulty when introduced into a new environment such as a rescue center. Animals that are already present and adapted to local conditions can help with the habituation of recently arrived animals. However, cohabitation of numerous individuals should be done cautiously and with concern for infectious disease transmission. Likewise, caution is required when mixing certain species renowned for intraspecific aggression (e.g., cobras, crocodiles, certain species of iguanas),[17] as well as intermixing of different species that may prey upon one another, such as king snakes due to their known ophiophagus diet and risk of preying upon other snakes and reptiles.

Unrecoverable Reptiles

There are numerous reasons why some reptiles cannot be released into the wild, including that they have spent excessive time in captivity, have suffered maladaptation, pose a risk of communicable diseases to wild individuals, have congenital anomalies or excessive disability (e.g., limb amputation), or are a species/subspecies not appropriate for a specific geographic release site. With this long list of preclusions for release, selection of individuals for release should be done carefully and in accordance with multidisciplinary teams, including ecologists, biologists, veterinarians, and environmentalists. Nonreleasable animals are often relocated to rescue centers or zoologic institutions. However, the role of such animals extends beyond display to the public, and their scientific value should be considered. Unfortunately, unreleasable individuals may need to be euthanized due to poor rehabilitation prognosis, fiscal limitations, or incompatibility within the overall program for species preservation.

Value of Nonreleasable Animals

Blood donors: Blood transfusions are increasingly used in reptile medicine. Hemorrhage secondary to fractures, falls or collisions, severe burns, or hematologic diseases are some of the causes of hemorrhage that warrant a blood transfusion. The possession of healthy nonreleasable animals allows an available pool of blood donors (assuming that appropriate scientific or animal use permits allow such use). When performing a transfusion it is important to perform a matched (homologous) transfusion whenever possible (see Chapter 87).

Mothership effect: Females of some species such as *Python molurus* incubate eggs, provide parental care, or provide protection to offspring other than their own. Eggs of different species of pythons (sick or dead during egg laying, for example) can be incubated by other females in zoos and breeding centers.

Serum bank: It is important for centers that handle endangered species to have a serum bank. This allows for screening of individuals for certain diseases. The ability to detect certain antibodies to disease, and to track trends through time, is important.

FIG 131.4 Collecting research data including femoral secretions (top), ECG readings (middle), and hematology (bottom) in some nonreleasable El Hierro giant lizards (*Gallotia simonyi*).

Sample size: Nonreleasable animals can help to achieve the ideal number of animals for research, assuming that appropriate scientific animal use permits have been approved.

Physiology research: For all species it is necessary to have established reference values for analytical, diagnostic imaging, or other diagnostic assays.[18] To avoid the risk of extrapolations between species or groups, nonreleasable animals can, with appropriate scientific permit or license, be used to establish reference values for their species (Fig. 131.4).

Semen banks: Nonreleasable reptiles can serve as useful breeders, and their offspring could be released. The collection of semen for artificial insemination is a technique that is beginning to be developed in reptiles[19] (see Chapter 80).

VetBooks.ir

Genome banks: Recent data indicate that within turtle species there is wide geographic variation in genetic variability (not only species but also subspecies, forms, populations, or ecotypes). The safeguarding of some populations may depend on animals that have been maintained in a recovery center. Nonreleasable animals contribute to the protection of viable genes belonging to populations on the brink of extinction.

Environmental education: Education is perhaps one of the most important tools of rehabilitation centers. Showing nonreleasable reptiles is an excellent method to teach visitors. Community education offers a potential to mitigate the impact of human activities that contribute to reptile population decline. Education may also limit the number of healthy animals that are unnecessarily relocated.[20]

Releasable vs Nonreleasable Decision Making

Before the release of any reptile, several factors must be considered, including, but not limited to, structural abnormalities of the animal; infectious disease risks; genetic factors; and national, state, and local laws (Innis, Proc ARAV, 2004, pp 6–8).

Chelonians with repaired shells can be released as long as the repair is inconspicuous to predators. Applying fiberglass and modeling, or 3D-printed shells and subsequent painting, allows released turtles with esthetic prostheses to have high survival rates (Fig. 131.5). However, when considering sealing of shell fractures in turtles, prostheses should only be applied to clean, uninfected wounds that have been managed appropriately. Animals should not be released if infection is present. Many different types of wound sealants and repair materials have been used, including calcium hydroxide pastes, bone cements, and epoxy resins. (For more information, see Chapter 113.)

With regard to hematology, the relative paucity of species-specific reference intervals and use of automated hemacytometers not validated for reptile species mandates a thorough visual examination of blood parameters including smears rather than merely relying upon automated or calculated results. Furthermore, researchers must interpret hematologic results with caution, utilizing the overall picture of an ecological or study population for wildlife monitoring and health assessment.[21] Blood analyses have great potential in ecology, ecotoxicology, and veterinary science, including comparisons between prerelease and postrelease. The major caveat for field researchers, however, is that the established reference intervals derived from captive reptiles may be less appropriate for free-ranging animals. Differences in certain parameters, such as glucose, total proteins, uric acid, and eosinophils may vary in the same animals before and after their release (Martínez-Silvestre, Proc *Congress Mediterraneend' Herpetologie Marrakesh*. 2007, pp 59–60).

It is important to avoid disruption to wild populations. Reptile translocation can result in a viable increase in the local population. However, augmentation may disrupt existing resident disease or parasitic dynamics and initiate an infectious disease outbreak that could effectively offset any advantages the translocation may have achieved.[15,22] The prevalence of parasites in wild reptiles is often an indicator of the immune status of these animals. In most countries, recovery centers shelter hundreds of animals originating from illegal trade or captive breeding. There are studies that investigate the presence of helminth eggs and worms in feces from free-ranging and captive tortoises and relate the findings to different environmental and host variables. Results show that ascarid infections affect mostly captive animals. Likewise, other diseases such as upper respiratory tract disease are more commonly associated with captive animals. Conversely, in free-ranging populations, oxyurid infections do not appear to be associated with poor health, and their prevalence increases with age. Moreover, in free-living tortoises, the distribution of some ascaris species varies according to habitat and can change significantly with location.[23] Treatment for parasites is recommended; however, in reptiles scheduled for release the goal should be control, not complete elimination, to ensure continued immune recognition.

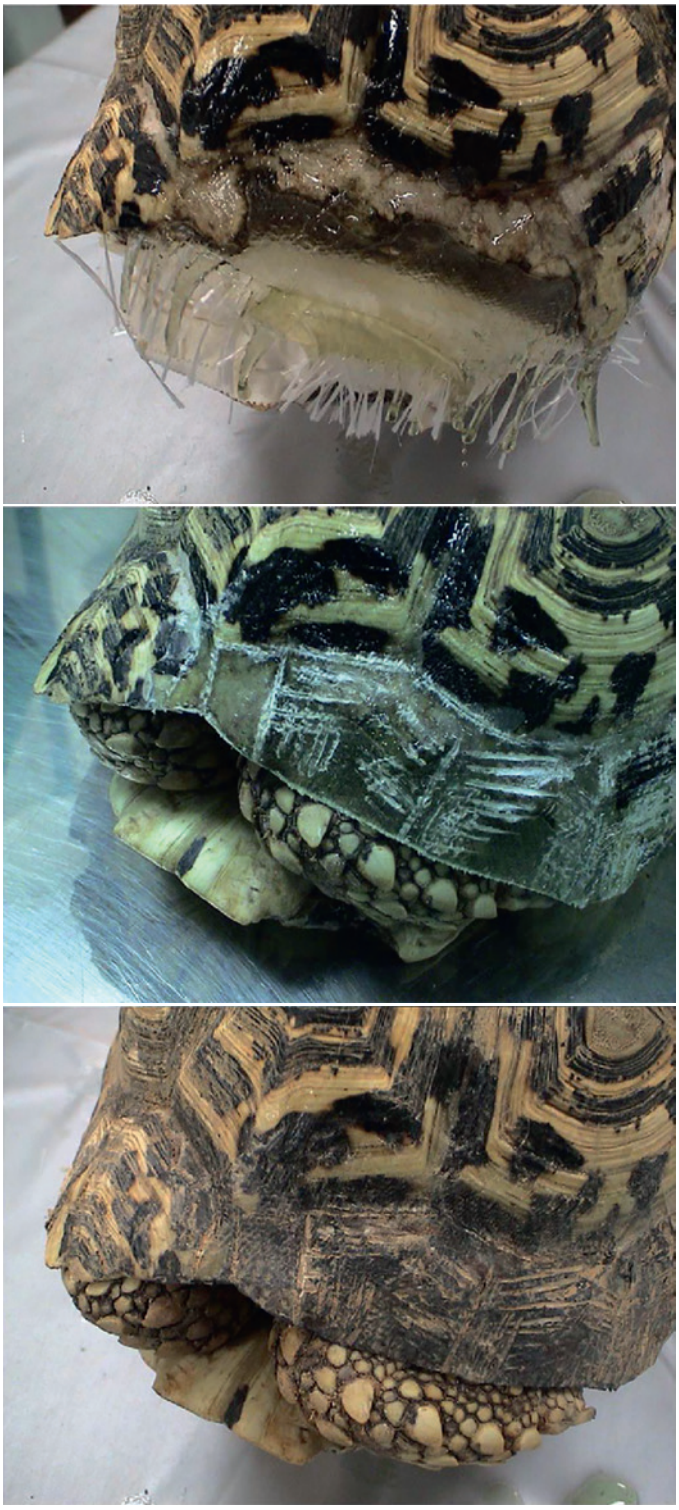

FIG 131.5 Esthetic prosthesis using painted fiber glass in a leopard tortoise (*Stygmochelys pardalis*) bitten by a dog.

There is always the concern that asymptomatic carriers of infectious agents released into the wild may spread disease in the environment and to free-ranging populations. There are reports of exposure of wild populations to Ranavirus and Batrachochytrium from released amphibians and herpesviruses and mycoplasmas from released reptiles.

VetBooks.ir

Although mycoplasmas do not usually survive long outside the host unless protected in organic material, numerous other pathogens, viruses in particular, can persist for extended periods in the environment. Rehabilitated animals that are exposed to such infectious diseases in captivity pose a serious threat to wild populations of tortoises (and potentially other reptiles) when they are released. The release of animals with antibiotic-resistant flora is also a concern that should remind the clinician of the importance of appropriate antimicrobial use.

Stress and immune status may affect the presence of pathogens in rehabilitated reptiles. Under stressful conditions, shedding of pathogens, including zoonotic agents, may be enhanced. Occasionally opportunistic pathogens are observed only in hospital conditions such as *Enterococcus* spp. in snakes.[24] In addition, the transmission of *Salmonella* can occur between animals at rehabilitation centers.[25,26] Exotic serotypes of *Salmonella* can be released into the environment with the reintroduction of these rehabilitated animals.[27,28]

Applying diagnostic techniques for isolation or detection of specific microorganisms is important and useful before considering release. These may include bacterial and fungal cultures, polymerase chain reaction (PCR) testing, and antibody testing for chelonian pathogens such as *Mycoplasma* and herpesviruses (Innis, Turtle and Tortoise Newsletter, 2001;4:14–16). Tortoise mycoplasmosis was first reported in desert tortoises from the southwestern United States and California, and has been associated with dramatic population declines. The etiologic agent is *Mycoplasma agassizii,* which has also been isolated from gopher tortoises from Florida. Recently a novel but related *Mycoplasma* species was identified using a PCR assay in box turtles (*Terrapene* sp.) displaying clinical signs consistent with mycoplasmosis. Herpesvirus and *Mycoplasma* have also been isolated from captive and wild moorish tortoises (*Testudo graeca*) in various European and North African countries (Mathes, et al. Proc ARAV 2001, pp 97–99).[29] Infection is usually chronic and can often be subclinical. Clinical signs are often intermittent or cyclical and may be associated with stress. Animals may be chronically infected and should not be released into the wild.

RELEASE STRATEGY

Reptiles can be either "soft released," where acclimation is provided with in situ enclosures, or "hard released" without acclimation, directly into the habitat. Usually, soft releases have resulted in greater survival and site fidelity than hard releases. However, the success of both techniques depends on the species and release habitat (Livoreil, et al. Proc Int Congress on Testudo Genus, 2001, p 32).

Most relocation, repatriation, and translocation projects involving amphibians and reptiles do not have demonstrable benefits for conservation and should not be advocated as acceptable management and mitigation practices.[30] Many reptile translocations fail because the animals are placed in low-quality habitat at the recipient site or dispersed from the release site. Overall success of translocation can be judged by species population viability. For example, the Florida sand skink (*Plestiodon reynoldsi*) is a resilient species that exploits heterogeneous habitats to find suitable microhabitats. Successful translocation of this skink can only be achieved with suitable habitat for this species.[31]

"Head-starting" is a conservation technique for improving survival of individuals from species with high juvenile mortality. This technique is designed to accelerate growth rate and increase body size of captive-born young. Head-started individuals are often kept active year-round to achieve body-size goals and increase survival, omitting or modifying overwintering (brumation). As brumation is part of the life cycle of reptiles, there may be tradeoffs related to temperature response postrelease.[32] This technique has proven useful for the conservation of the West Indian rock iguana (*Cyclura* sp.) (Raphael, Proc ARAV, 2006, pp 32–33).

FIG 131.6 Secondary shell infection after marginal scute notching in a reintroduced European pond turtle (*Emys orbicularis*).

There are seldom instances when reinforcement of stable populations with reintroduced animals is recommended. Territoriality of the species and the establishment of hierarchies, especially in turtles, should be considered. Modifications of resident populations may cause stress and compromise their reproductive future. It is important to avoid introducing reptiles in areas where there are already stable and consolidated populations. Instead, the best option is to release individuals into areas previously inhabited by the species, but where the species is currently extinct.[33]

The release of rehabilitated individuals must undergo a detailed sex ratio analysis. Behavioral anomalies have been described in wild Herman's tortoises (*Testudo hermanni*), including the "prison effect," in which the proportion of males and females is highly skewed. In these populations, tortoises exhibit extravagant sexual behaviors, showing homosexual behavior and attempting to copulate with dead conspecifics, empty shells, and stones.[34] The veterinarian plays an important part in reproduction control in both the selection of individuals to breed in captivity and also in postliberation management. In some cases, reptiles have been sterilized to avoid proliferation or genetic contamination in areas in need of sentinel release.[35]

Individual identification techniques in nonmarine reptiles are varied, including microchip (PIT), notches in marginal scutes of chelonian shells, notches in the neck scales or tail of crocodilians and lizards, and colored beads, as well as intracoelomic, subcutaneous, or external transmitters. Peripheral shell/scute notches can become infected and jeopardize the success of the reintroduction (Fig. 131.6). Appropriate technique and prevention of infection is necessary. Techniques that increase animal stress or affect metabolism and/or reproduction should be avoided.[36] A review of marking and tracking techniques in wild and released reptiles can be found in Chapter 175.

When and Where to Release

A conservative approach, maintaining the reptile in captivity for months to allow complete healing, is often preferred before release. Some other authors prefer to release reptiles within weeks of the time of injury if at all possible (Innis, Proc ARAV, 2004, pp 6–8). This philosophy is based on the premise that the patient will heal faster in its native habitat than it will in captivity. As a general rule, reptiles should be released in the evening, avoiding hours of maximum insolation, and in shadowed areas, with water and refuge easily available. Release should also occur during a season of activity for that species (i.e., not during winter) but not during the peak reproductive season (to avoid fights or disturbances). Reptiles may take several days to find refuge and water. When released,

VetBooks.ir

reptiles may stay in the same refuge for days or weeks until they feel secure and start to explore their new environment. The habitat chosen should have minimal predators.

Rewilding Programs

Reptile rewilding techniques are mainly restricted to islands. One example includes the rewilding of tortoises on Round and Rodrigues Islands of Mauritius. These islands used to be home to at least two species of giant land tortoises. These endemic species of tortoises were lost from the island ecosystem some 200 years ago due to human hunting. The reestablishment of land tortoises was necessary for restoring ecological function and included extant conspecifics and related taxa. In this case the conspecifics/analogous species chosen for rewilding were Aldabra tortoises (*Dipsochelys elephantina*) from the Aldabra Atoll and Radiated tortoises (*Astrochelys radiata*) from South West Madagascar. In only 5 years, 388 Aldabra and 898 radiated tortoises were naturally hatched in the reserve. Their interaction with vegetation seems to be having the desired ecological effect.[37] The project is transforming these degraded islands of the Indian Ocean into a successful mix of natural biodiversity, along with a popular and sustainable economic and social enterprise (Fig. 131.7). A similar rewilding technique was undertaken using sterilized Galapagos tortoises to engineer a more balanced ecological recovery of Pinta Island in the Galapagos. In this case the released subadult to adult animals were sterilized to avoid interbreeding with future high genetic stock.[35] Animals used in rewilding programs must pass strict health assessments as their role as potential vectors of diseases to the ecosystem must be considered (Martínez-Silvestre, Proc iCARE, 2013, pp 152–155).[38]

FIG 131.7 Physical examination of Aldabra tortoises introduced in Rodrigues Island (Mauritius).

Complementary and Integrative Veterinary Therapies

Cynthia L. West and Bruce Ferguson

A number of medical and surgical advances continue to be made in reptile and amphibian health care. Still, many diseases and conditions exist for which conventional medicine is inadequate, impractical, unsafe, or simply not efficacious. In addition, some clients are reluctant to subject their pets to the perceived or real risks of unapproved drugs, anesthesia, and surgery. There may be other methods that we can use to help these animals.

Complementary therapies may be referred to as alternative therapy (or complementary and alternative veterinary medicine [CAVM]) or, less accurately, holistic medicine. They are not generally taught in mainstream veterinary education. Some of these methods have a few thousand years of documented empirical evidence and clinical trials. Others have been developed more recently and have only limited empirical or anecdotal evidence of efficacy with few strictly controlled clinical trials. Traditional Chinese veterinary medicine (TCVM), for example, which incorporates several different disciplines, including acupuncture, herbal medicine, nutrition, massage, and meditation, dates back at least 2500 years, whereas homeopathy has a history of about 200 years.[1] What almost all complementary therapies have in common is that they are targeted to work with the individual animal's natural healing capabilities. They treat the whole individual (thus the term holistic) and support the individual body's healing processes. Much criticism has been aimed at these therapies as being nonscientific and lacking in research, controlled, double-blind studies or other perceived scientific validation. Clinical work is being undertaken worldwide and empirical results are accumulating. The National Institutes of Health's (NIH) website reveals a tremendous amount of ongoing research and has already proven the benefits of CAM for many human diseases.

Available conventional medical treatments can carry serious side effects and can suppress clinical signs while a disease or condition progresses. This is particularly true of chronic diseases like arthritis, asthma, allergies, and dermatologic conditions. In addition, there are few approved pharmaceuticals for use in reptiles and amphibians, and some are potentially harmful. Integrating complementary and alternative therapies into the treatment plan for these species may reduce, eliminate, or shorten the duration of treatment with potentially harmful medications.

Complementary therapies can be used to major benefit in wellness or preventive therapy, particularly for geriatric pets (though also beneficial to young and healthy adult animals) that are more prone to deficiencies, imbalances, and chronic degenerative conditions.

Incorporating these complementary therapies into the treatment plan is not meant to usurp the benefit of proper conventional medical diagnostics. A thorough investigation, including a physical examination, clinicopathology, diagnostic imaging, histopathology and microbiology, and so forth, are still recommended before treatment, along with a detailed history of clinical signs, behavior, husbandry, and nutrition. This will allow for the most effective integration of conventional and complementary medicine for treatment. However, due to the observational and noninvasive diagnostic tools available to trained practitioners of CAVM disciplines, it is possible to establish a treatment plan for those patients whose caretakers decline to pursue conventional medical testing or for whom invasive diagnostic techniques may prove hazardous or otherwise inadvisable.

Because of the pervasive constraints of time and funding, few of these technologies have been explicitly studied in reptile or amphibian patients. Consequently, little data are available for the use of such methods in these species. Therefore most of the following extrapolates from mammalian data or uses clinical cases from practicing veterinarians.

This chapter is meant to stimulate thought in these emerging therapeutic areas rather than answer all questions. It is a short introduction to some of the integrative and complementary therapies, which may be useful adjuncts in herpetological medicine. Our hope is that the ensuing discussion leads to future applications of the following methods with attendant clinical research. In this fashion, as with all incipient medical systems, a database will begin to accumulate that will enlighten us and benefit our reptile and amphibian patients.

In this section we will briefly introduce some of the more common complementary and alternative therapies found useful by clinical veterinarians, with the primary focus being on traditional Chinese veterinary medicine (TCVM). As stated previously, of the available complementary therapies TCVM is backed by the most clinical and scientific research evidence as well as a 5000-year tradition and approximately 2500-year written history. Many useful and worthwhile complementary therapies, including but not limited to homeopathy, chiropractic, bach flower therapy, aromatherapy, magnetic field therapy and other bioenergetic medicines, Tellington touch, and physical therapy, are omitted from this chapter due to lack of space and the lack of data, especially regarding the multitude of reptile and amphibian species.

Some of these therapies are immediately applicable to most practicing veterinarians (nutraceuticals and some herbs), whereas others require more specialized training (acupuncture, sophisticated herbal medicine, chiropractic, and homeopathy). Readers will find a list of resources for further information, organizations, and, most importantly, further education and training at the end of the chapter. We want the reader to view this introduction to CAVM with the knowledge that this area of herpetologic medicine is in its infancy.

TRADITIONAL CHINESE VETERINARY MEDICINE

TCVM incorporates the disciplines of acupuncture, herbal medicine, nutrition, massage, and meditation. Although some form of meditation is routinely incorporated into the treatment of human beings with traditional Chinese medicine, as veterinarians we normally utilize the

VetBooks.ir

first four categories in caring for our animal patients. For the fifth category, we may substitute "lifestyle" changes or improvement in husbandry to complete the balance of holistic care for our patients.

As advocates for our patients, we need to educate owners, to the best of our current knowledge and ability, concerning proper nutrition, housing, environmental enrichment, socialization, and stress reduction. This may be one of the most important aspects for restoring and maintaining health in reptiles and amphibians. Without such knowledge, our ability to offer veterinary care is only sufficient for the acute crisis.

ACUPUNCTURE

The basis and usage of acupuncture may be viewed in either a conventional scientific or TCVM framework. The placement of small needles (usually 30-gauge to 36-gauge) into exact locations in a subject's body may have a number of positive benefits. Western scientific analyses indicate local, immunologic, neuroreflexive, and central nervous system responses to acupuncture.[2] These effects may include shortened healing time in injured tissues and nervous system activation in neurologic trauma. Increased immune surveillance and heightened immune system function along with reflexive changes in organ system function and pain control are also reported as effects of acupuncture. Studies have shown acupuncture results in an increase in endogenous substances such as enkephalins and endorphins, and the analgesic effects of acupuncture can be reversed with naloxone.[3]

Analgesia is not the only measurable effect of acupuncture. Both parasympathetic and sympathetic components of visceral nerves may be stimulated,[4] as well as local changes in cells, nerves, and vessels where the needles are inserted, including mast cell release, vasodilation, and stimulation of neural terminals.[5] Acupuncture can enhance immunity by increasing levels of white blood cells, interferons, antibodies, and immunoglobulins.[6] Hormonal changes, including the release of growth hormone, luteinizing hormone, and thyroid hormones, have also been measured.[7]

In TCVM, health is defined as a state of harmony or balance between the body and its internal and external environment. Illness occurs when the homeostatic mechanisms of the body malfunction, and the resulting imbalance creates a disease condition of excess or deficiency.

Qi is the life force. It is energy and involves the energetic functions of the body, which is the focus of acupuncture. Qi flows through the body and can be accessed through a system of channels or meridians on which we find our acupuncture points. In TCVM, when Qi flows freely, there is balance, health, and the absence of pain. When Qi becomes trapped, obstructed, or stagnant, there is pain; if Qi is decreased, there may be weakness and disease. Acupuncture restores the free flow of Qi and in TCVM may be used to tonify, strengthen, and balance the body's systems.

One using acupuncture for therapy from a strictly western viewpoint would likely choose to treat pain (from trauma, for example) based on local points near the injured area along with a-shi points (Fig. 132.1). A-shi points are points of pain or sensitivity and do not necessarily correspond to known meridian points.[8]

Conversely, a TCVM practitioner might treat an internal medicine case, for example, chronic renal disease, by acupuncturing points that tonify, energize or nourish, and replenish kidney Qi. The TCVM practitioner would also likely use herbs and nutrition to hydrate the body, control and replenish electrolyte problems, and treat clinical signs related to the underlying imbalance. In TCVM, chronic renal disease is not a diagnosis but may present as several different patterns, each with its distinct acupuncture protocol, herbal medicine, and nutritional recommendations.

Most importantly, in modern veterinary medicine, the 2 forms of medical treatment can be successfully and effectively integrated. Chronic renal disease is a common problem in reptiles. An integrated approach might include fluids or diuresis and correction of electrolyte imbalances via conventional medications, along with nutritional and husbandry adjustments. Adding acupuncture to strengthen the kidneys, stimulate appetite, and treat associated problems like constipation and arthritis enhances overall patient support and well-being.

The use of acupuncture on animals transposes traditional Chinese points for humans along 12 major bilaterally distributed meridians, each linked to a specific internal organ, and along 8 extra channels that are not specifically linked to visceral organs. Anatomic differences in species (in comparison with humans), along with uncertain meridian pathways for animals, creates problems with the application of the meridian numbering system. Several studies comparing major points between humans and dogs with various electro point finders, or low skin resistant points (LSR), have revealed a moderately high (79% in one study) correlation between human and canine acupuncture points.[5]

Applying acupuncture to reptiles and amphibians must therefore take anatomic and functional differences into consideration. Meridian points on lizards are easily transposed from canine acupoints, but snakes and turtles are more challenging (Fig. 132.2). Meridians found primarily on the extremities are impossible to directly transpose on a limbless animal. It is likely that many of the points found on legs and digits do exist in some area of the snake's body but have not been discovered or described. Many of the points on the Bladder, Gallbladder Spleen, Liver, Kidney, and Stomach meridians are inaccessible in chelonians (Fig. 132.3). Some species, particularly amphibians and delicate lizards like geckos, may have easily identifiable or accessible points, but handling and stress must be considered when attempting to needle these species. Many of the benefits of acupuncture rely on the release of humoral substances like serotonins and endorphins. Therefore, because corticosteroid and epinephrine release may antagonize many of its positive effects, a highly stressed animal may not receive as much benefit from acupuncture as a calmer, more receptive patient.

Amphibian skin is very delicate and easily subject to damage. Using techniques such as dry needle acupuncture without retention or using the blunt end of the needle handle or moistened, cotton-tipped applicator to briefly stimulate an acupoint may be more appropriate methods for applying acupuncture to delicate amphibian skin.

FIG 132.1 For this green iguana *(Iguana iguana)*, a-shi acupuncture points are used to treat pain based on local points near the injured area. A-shi points are points of pain or sensitivity and do not necessarily correspond to known meridian points. (Courtesy of Douglas R. Mader.)

VetBooks.ir

Numerous animal patients have been successfully treated with acupuncture for a wide range of maladies, including, but not limited to, anorexia, constipation, decreased intestinal motility, diarrhea, dystocia, cloacal prolapse, renal failure, respiratory infections, oral inflammation and infection, behavior problems (aggression/anxiety), and musculoskeletal problems such as intervertebral disk disease and resulting neuropathies.

Figs. 132.4 and 132.5 show typical acupuncture points used in lizard and turtle patients. Fig. 132.6 illustrates acupuncture points on an argentine horned frog (*Ceratophrys ornata*). Table 132.1 lists some commonly used acupuncture points, their approximate locations, and a brief description of their primary actions and indications. Specialized techniques such as aqua-acupuncture (Fig. 132.7) and electroacupuncture (Fig. 132.8) can be readily utilized with proper training. To be used safely and effectively, acupuncture requires appropriate training, and we strongly recommend interested veterinarians take a formal course before applying acupuncture to patients.

HERBAL MEDICINE

Herbal medicine encompasses a broad category of uses and applications from various cultures, including traditional Chinese medicine; western herbal medicine, which includes Native American plants; and Ayurveda medicine from India. The components of formulas used in these disciplines may include whole plants or parts of plants, minerals, and even animal parts (Chinese medicine may use all three in their herbal formulas).[9] A practitioner may prescribe a single herb or a combination of herbs (an herbal formula) when treating a patient and has several options for the form used. Herbs can be ordered from professional suppliers as bulk herbs, dried extracts, and liquid extracts (usually extracted in alcohol) and therefore can be administered in several ways, including capsules, powders, drops, teas, and soups. Many Chinese herbal formulas come conveniently concentrated into a pill

FIG 132.2 Meridian points on lizards (shown here, a bearded dragon [*Pogona vitticeps*]) are easily transposed from canine acupoints; snakes and turtles are more challenging. (Courtesy of Douglas R. Mader.)

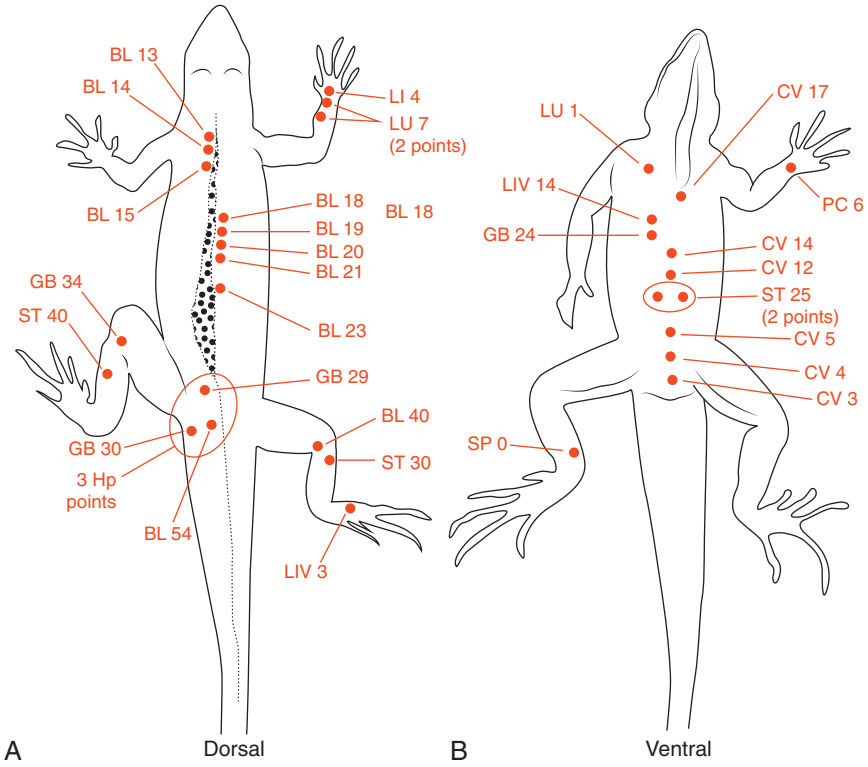

FIG 132.3 Most of the bladder and gallbladder meridians and points on spleen, liver, kidney, and stomach meridians are inaccessible on the turtle. Acupuncture (as demonstrated here for a red-eared slider [*Trachemys scripta elegans*]) is limited to the skin of the legs and neck. (Courtesy of Douglas R. Mader.)

TABLE 132.1 Commonly Used Acupuncture Points for Reptiles and Amphibians

Acupuncture Point	Actions/Indications	Location
GV 26	Resuscitation	In the philtrum at the level of the ventral limit of the nostrils
GV 1	Diarrhea, constipation, food stasis	On the midline halfway between the vent and the ventral base of the tail
Shan-gen	Appetite stimulation, anorexia	On the dorsal midline on a line just caudal to the caudal aspect of the nostrils
GV 14	Fever, any infection, immune regulation	On the dorsal midline at the space between the last cervical and first thoracic vertebrae
Wei-jian (Tail tip)	Fever, disc injury, spinal injury	At the tip of the tail
ST 36	General weakness and gastrointestinal disorders	On the craniolateral rear limb about 1/5th the distance from the stifle to the hock
LI 10	General weakness and gastrointestinal disorders	On the craniolateral forearm 1/6th the distance from the elbow to the carpus
LIV 3	General pain management, liver disorders, conjunctivitis, and intraocular inflammation	On the dorsum of the rear foot between the first and second metatarsals proximal to the metatarsophalangeal joint
LI 4	General pain management, immune regulation	On the dorsum of the front foot between the first and second metacarpals proximal to the metacarpophalangeal joint
GV 20	Calming, relieves anxiety	On the dorsal midline on top of the head on a line level with the caudal aspects of the orbits
GB 34	Tendon/ligament problems, liver disorders, seizures	On the mid lateral aspect of the rear leg just cranial and distal to the head of the fibula
PC 8	Paresis and paralysis	On the palmar surface of the front foot between metacarpals II and III
KID 1	Paresis and paralysis	On the plantar surface of the rear foot between metatarsals II and III
ST 1	Conjunctivitis, any ocular problem	Just over the orbital rim directly below the center of the pupil

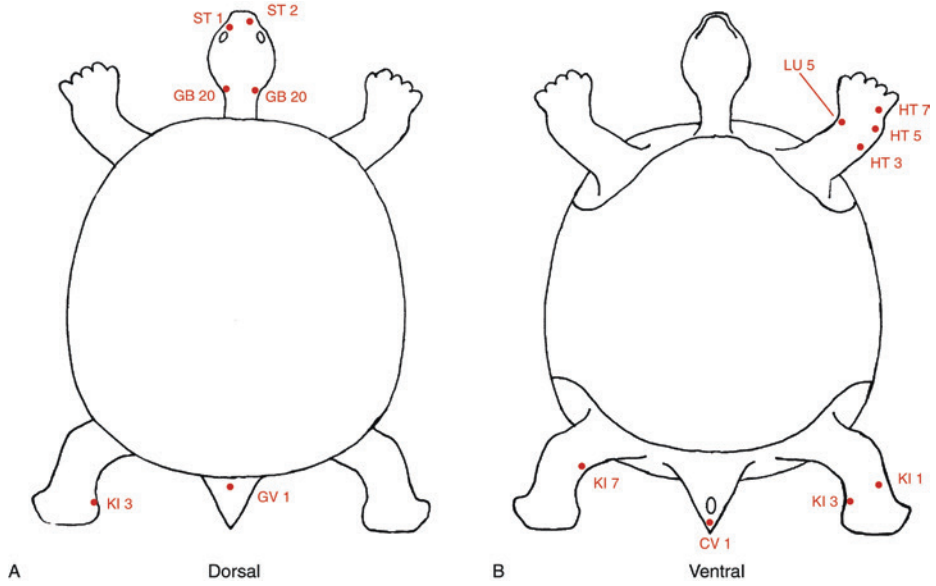
Lizard Acupuncture (Dorsal View)

Acupuncture Point	Association Point for	Anatomic Location (Bilaterally—1½ Rib Widths Lateral to the Dorsal Midline at the Level of the Intervertebral Space)
BL 13	Lung	3rd intercostal space
BL14	Pericardium	4th intercostal space
BL 15	Heart	5th intercostal space
BL 18	Liver	10th intercostal space
BL 19	Gallbladder	11th intercostal space
BL 20	Spleen	12th intercostal space
BL 21	Stomach	13th intercostal space
BL 23	Kidney	15th intercostal apace

Master Point	Affects
LI 4	Face and mouth
LU 7	Head and neck
BL 40	Back and hips
ST 36	Abdomen and gastrointestinal system

Other Useful Point	Affects/Actions/Indications
LIV 3	Gastrointestinal system, urogenital system, liver, gallbladder, general pain management, conjunctivitis, and intraocular inflammation
GB 34	Tendons
ST 40	Phlegm, ascites, accumulation of damp
GB 29, GB 30, BL 54	Hips, arthritis, paralysis
LU 7	Arteries and respiratory system

Master Point	Affects
PC 6	Chest and cranial abdomen
SP 6	Caudal abdomen and urogenital system



Lizard Acupuncture (Ventral View)

Point	Alarm Point[a] for
LU 1	Lung
CV 17	Pericardium
LIV 14	Liver
GB 24	Gallbladder
CV 14	Heart
CV 12	Stomach
ST 25	Large intestine
CV 5	Triple heater
CV 4	Small intestine
CV 3	Urinary bladder

[a]Pain in these points indicates pain in the corresponding organ.

FIG 132.4 (A and B) Typical acupuncture points for a lizard patient.

VetBooks.ir

Useful Point	Affects/Actions/Indications	Anatomic Location
GV 1	Diarrhea and rectal/cloacal prolapse	Ventral to tail base and dorsal to vent
CV 1	Constipation and prolapse	Ventral cloacal midline between anus and urinary pore
ST 1	Eye disorders, conjunctivitis	Just over the orbital rim directly below the center of the pupil
ST 2	Eye disorders, conjunctivitis	In the infraorbital foramen rostroventral to ST 1
GB 20	Neurologic disorders and cervical problems	In the shallow depression between the cervicalis and sterno-occipitalis muscles, 1 rib width lateral to the dorsal midline
LU 5	Respiratory disorders and infections	At the elbow immediately lateral to the biceps tendon
HT 7	Sedation, calming, anxiety, and behavioral effects	Immediately proximal to the carpal bone at the lateral carpus
HT 5	Sedation, calming, anxiety, and behavioral effects	Along the same groove as HT 7 but more proximal
KI 1	Revival point, paralysis	Plantar surface of the rear foot between metatarsals II and III
KI 3	Urogenital, cystitis, chronic renal disease	Medial tarsus, caudal to and at the level of the medial malleolus
KI 7	Diarrhea, cystitis, urogenital disorders	Medial rear limb 1/6 of the distance proximal from the medial malleolus to the tibial plateau just cranial to the Achilles tendon

FIG 132.5 (A and B) Typical acupuncture points for a turtle patient. Note: The same points used on the iguana can be used on the turtle *if* accessible. For instance, you cannot access many of the association or alarm points due to the shell.

form as well. When prescribing an herb compared with a conventional western drug, one prescribes a whole plant, substance, or formula where the active constituents may be tempered or enhanced by other parts of the herb or herbal formula. Thus what may be toxic when isolated becomes safer, or absorption may be increased, or effects may otherwise be altered.

Active Constituents and Actions

Some 25% or more of the pharmaceuticals used today are derived from specific substances found in medicinal herbs (Griffith, personal communication). Pharmacognosy has revealed many important biologically active compounds in plants, and one can use this knowledge in prescribing herbal products and incorporating historic uses for dispensing herbal medicines. Some of the more common chemical constituents of herbs and their actions are described in Table 132.2. So, with some understanding of its active constituents and actions, one might prescribe a soothing demulcent such as marshmallow root (*Althea officinalis*) for such diverse conditions as enteritis, colitis, cystitis, and urethritis.

Herbal Energetics

Most indigenous herbal medical systems, including TCVM, are based on the belief that herbs have specific energies or broad therapeutic categories based on their effects in the body. Empirical evidence supports specific effects of herbs, including those that "clear Heat," "drain Damp," "warm," "cool," or "nourish Blood."

For example, a hot pepper is considered to be "warming" and is used to "dispel Cold and clear the exterior." When consumed the pepper elicits sweating, facial redness, and a general warming sensation in the body. Detailed experiments have suggested that these physiological changes are from peripheral vasodilation and increased tissue perfusion and that the flavonoids in the pepper increase neutrophil-killing function and generally increase immune system function.[10] Sweating itself has been shown to have a positive influence on the body's ability to deal with pathogens.

In general, Chinese herbal medicine is heteropathic in nature. Warming herbs are used to treat cold diseases, and cooling herbs treat

Point	Actions/Indications	Anatomic Location
GV 14	Fever, any infection, immune regulation	On the dorsal midline at the space between the last cervical and first thoracic vertebrae
GV 20	Calming, relieves anxiety	On the dorsal midline on top of the head on a line level with the caudal aspects of the orbits
GV 26	Resuscitation	In the philtrum at the level of the ventral limit of the nostrils
LU 5	Respiratory disorders and infection	At the elbow immediately lateral to the biceps tendon
LI 4	Face and mouth, general pain management, immune regulation	On the dorsum of the front foot between the first and second metacarpals proximal to the metacarpophalangeal joint
LI 10	General weakness and gastrointestinal disorders	On the craniolateral forearm 1/6th the distance from the elbow to the carpus
LI 11	Skin inflammation, diarrhea, constipation, any traumatic injury	At the lateral end of the cubital crease at the lateral elbow
ST 1	Eye disorders, conjunctivitis	Just over the orbital rim directly below the center of the pupil
ST 4	Stomatitis, oral lesions	Just caudal to the mucocutaneous junction at the lateral commissure of the mouth
ST 36	General weakness and gastrointestinal disorders	On the craniolateral rear limb about 1/5th the distance from the stifle to the hock
SP 10	Blood loss, skin inflammation	1½ rib widths proximal and cranial to the medial femoral condyle
BL 60	Back and neck pain, general pain relief	Lateral tarsus, caudal to and at the level of the lateral malleolus
LIV 3	General pain management, liver disorders, conjunctivitis, and intraocular inflammation	On the dorsum of the rear foot between the first and second metatarsals proximal to the metatarsophalangeal joint

FIG 132.6 Acupuncture points of the Argentine horned frog (*Ceratophrys ornata*).

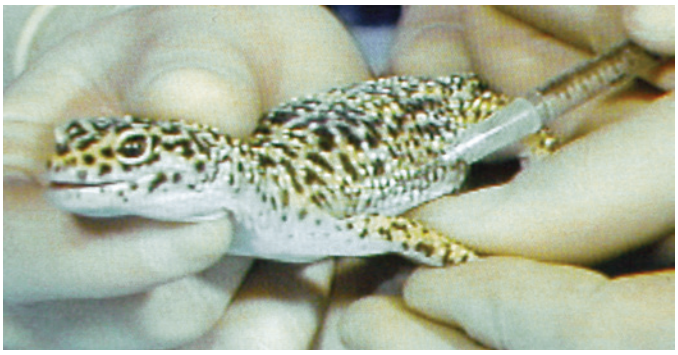


FIG 132.7 Small (such as this leopard gecko [*Eublepharis macularius*]) or easily agitated lizards that do not tolerate needling may benefit from aqua-acupuncture. Aqua-acupuncture is a variance from dry needling where, in this case, vitamin B_{12}, diluted with sterile 0.9% saline, is injected into acupoints instead of using needles. Exercise caution to avoid the renal portal system with any injection into the caudal half of the body (including rear limbs and tail) of reptile and amphibian patients. (Courtesy of Douglas R. Mader.)

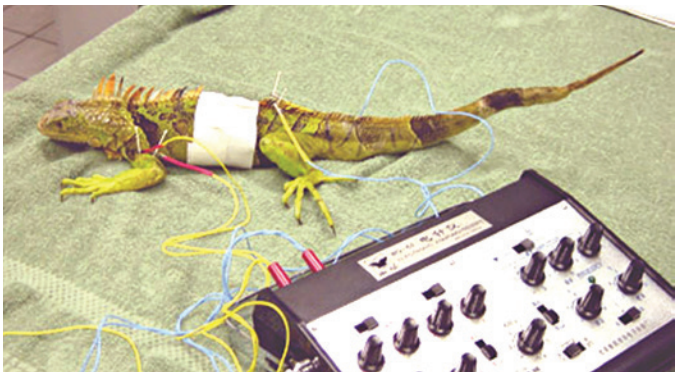

FIG 132.8 As demonstrated in this green iguana (*Iguana iguana*), electroacupuncture, in which dry needles are inserted into specific points and electrical current is applied via an electronic control panel, is a valuable tool for recovery of neural damage. (Courtesy of Douglas R. Mader.)

VetBooks.ir

TABLE 132.2 Common Chemical Constituents of Herbs and Their Actions

Constituent	Actions
Mucilage	Hydrophilic and soothing polysaccharides
Phenols	Broad group of aromatic compounds, astringents (eg, salicylic acid)
Tannins	Coagulate proteins
Coumarins	Anticoagulants, muscle relaxants
Anthraquinones	Irritant or cathartic laxatives
Flavonoids	Complex anti-inflammatory, antioxidant, aromatics
Anthocyanins	Plant pigments that benefit connective tissue
Volatile oils	Ketones, esters, and aldehydes with many effects
Saponins	Steroidal and triterpenoidal compounds
Cardiac glycosides	Digitalis, positive inotrope
Vitamins	Benefit most metabolic processes in body
Bitters	Broad class, stimulates digestion and bile flow
Alkaloids	Broad class (e.g., vincristine, atropine)
Minerals	Support normal metabolic processes (e.g., potassium)

warm or hot diseases. In Chinese medicine, herbs are prescribed based on the individual's TCVM pattern diagnosis and not the specific clinical signs. For example, two patients are seen with chronic diarrhea. One patient has "cow patty" type stools once a day, weak pulses, fatigue, and cool limbs and lower back. The other has bloody, foul-smelling diarrhea; fast, pounding pulses; and hot ears, feet, and groin. The first patient has a deficient and cold-type pattern, and the second has an excess and heat-type condition. The herbal prescriptions for these patients are quite different.

General Use of Herbs in Veterinary Practice

Frequently, the conditions we treat with complementary therapies are chronic problems for which conventional medicine has not been successful, including degenerative joint disease, autoimmune disorders, psychological disturbances, and seizures. Herbal medicine can provide effective treatment choices for these patients when conventional medicines are not adequate or have adverse side effects.

One of the more controversial areas of veterinary medicine is treating behavior disorders with psychotropic drugs. Many perceived "behavior" problems are unacceptable in our homes but natural for the animal in its own habitat. Marking and aggression are frequently seen, and treatment is often sought and administered despite undesirable side effects. Herbal medicine may offer an effective option for calming anxiety while avoiding the adverse consequences of pharmaceuticals such as Depo-Provera, Amitriptyline, Buspirone HCL, and others. An example of this may be incorporating herbal calming preparations for the treatment of farm-raised alligators to reduce skin trauma from heightened agitation when moving the animals to new enclosures. This would not only benefit the animals themselves but also reduce economic loss due to damage to the future harvested hides.

Dosing and Administration of Herbal Medicines

Herbal medicines generally work at a rate somewhere between nutritional therapy and conventional drug therapy. Their actions are generally slower to effect than a pharmaceutical but much faster than nutritional changes or therapies alone.

Metabolic studies conclude that smaller animals generally have a need for relatively higher amounts of herbs than larger individuals due to their higher basal metabolic rates. Herbal components are absorbed, used, and excreted more rapidly, on average, by animals of smaller body size. Our broad recommendation is to calculate herb amounts based on mathematic reduction due to smaller body size and increase that amount to account for increased metabolic rates using metabolic scaling. For example, if an adult 68 kg (150-lb) human dosage of peppermint in an infusion (tea) is 14.8 mL (1 US tablespoon) of herb in 473 mL (US pint) of water, then the dosage for a 34-kg (75-lb) dog is the same, because one increases the amount of peppermint to offset for carnivore inefficiency in using herbal constituents. In other words, a 34-kg (75-lb) dog should take one half of the adult human dose by weight, but this is then increased (doubled) because of the canine gut inefficiency. Note that this increase attempts to consider both body size and natural dietary predilection. These differences may be significant when dealing with herbivorous, omnivorous, or carnivorous herpetological patients.

That said, our reptile and amphibian patients differ drastically in metabolism compared with the small mammalian and avian patients we treat. Dosing should take these species' slower metabolic rate into consideration. As is often the case with conventional pharmaceuticals, this can generally be accomplished by less frequent dosing (q 24 hours vs q 12 hours) for many herbal medicines.

A broad, general dosing recommendation for reptiles and amphibians using oral Chinese herbal medicine is 0.1 to 0.4 g/kg of body weight q 24 to q 12 hours depending on species and herb or formula used. It is best to start with a low dosage of any new substance. If vomiting, diarrhea, or other adverse side effects are seen, discontinue use immediately and restart at a lower dosage or frequency. If the patient has no problems, gradually increase the dosage and monitor efficacy over time. The exact doses of each herb to use in assorted species of animals of dissimilar sizes and metabolism is unknown. Fortunately, however, most herbal medicines lack the dangerous potencies of derived pharmaceutical agents and serious side effects are rare.

Administering herbal medications to animals can be challenging. Many herbs and herbal supplements are given over periods of weeks or months. A significant number of herbal medicines are not particularly palatable for many species. Encapsulating powders and concentrated extracts can provide a more effective means of administration. For some larger species the medicine can be disguised in whole animal foods such as mice or chicks. Some reptiles and amphibians will accept treats such as black soldier fly larvae dusted with herbal powders. Another effective delivery system for herbal medicine is small balls of highly palatable foods. Extracts are generally easy to administer and are believed to have the most rapid gastrointestinal absorption rate (Wynn, personal communication). Alcohol extracts are not very palatable to animal patients, but usually only small amounts are needed. Glycerin extracts are also available and may be more readily accepted but are usually not as concentrated, necessitating a larger volume to be administered. Milk thistle, for example, is available in health food stores in pill, capsule, and both alcohol and glycerin extract forms. We commonly use it for avian hepatic lipidosis, hepatitis, and feline liver diseases and have used it in a green iguana (*Iguana iguana*) with chronic hepatitis.

Topical herbal preparations, such as Yunnan Bai Yao or Coptis powder can be used to good effect for some mild local conditions such as small traumatic wounds and mild local inflammation or infection. It is important, particularly with amphibian patients due to their highly permeable skin, to only choose those preparations that are safe for ingestion to avoid toxicity in these sensitive species. Start with low concentrations and monitor closely for distress or skin irritation. The author has used Yunnan Bai Yao in a free-ranging Southern toad (*Anaxyrus terrestris*) injured by a lawn string trimmer to effectively stop bleeding, prevent infection, and resolve the skin wounds.

In general, herbal medicine is best undertaken by a trained herbalist. Formal training and certification in both western and Chinese veterinary herbal medicine are available both on line and on site from several

providers worldwide. However, by careful extrapolation and species consideration, it is possible for new herbal practitioners to provide relief to some patients for chronic and acute conditions when conventional therapies fail or are unavailable.

NUTRITION AND NUTRACEUTICALS

Many chronic health problems in captive reptiles and amphibians are likely secondary to long-term errors in nutrition, husbandry, and the increased stress of confinement. Prior authors have implicated malnutrition in poor performance, disease, and high mortality (see Chapter 27). Micronutrient imbalances are more difficult to discover and are generally inferred from clinical signs or response to treatment. Rarely are all of the important antioxidants, including vitamins C, E, and A, added to manufactured diets for captive reptiles and amphibians. In TCVM, nutritional therapy is based on a heteropathic system of medicine incorporating the ideas of feeding cooling foods for "hot" conditions, warming foods for "cold" conditions, "nourishing" foods to tonify deficiencies, and "clearing" foods to sedate excess conditions. However, to reasonably implement such therapy, we must first understand the nutritional requirements of the particular species being treated. It will do no good to suggest a dietary modification for an animal that incorporates foods inappropriate for that species. Because we are commonly uncertain or unable to reproduce the biologically appropriate diet for each species, investigation of either diverse fresh foods or food additives with nutraceuticals may be prudent.

Many ingested foods have both nutritional and pharmacological effects on the body. Sometimes these two cannot be separated. For example, the US Food and Drug Administration (FDA) defines a food as a substance that provides nutrition, taste, or aroma. By FDA definition, a drug is a substance that is a food or nonfood substance that is used to treat, cure, mitigate, or prevent disease.[11] Nutraceuticals are mostly foods or food derivatives that have known pharmacologic effects. The North American Veterinary Nutraceutical Council defines a nutraceutical as a nondrug substance that is produced in a purified or extracted form and administered orally to provide agents required for normal body structure and function with the intent of improving the health and well-being of animals.[12]

Most veterinarians have some experience with nutraceuticals in the form of supplements for the hair and coat, multivitamin supplements, and joint supplements such as chondroitin sulfate and glycosaminoglycans. Geriatric animals in particular may benefit from these substances because of their decreasing ability to absorb and use nutrients. In these patients nutraceuticals may be used to treat more obvious clinical signs like arthritis, a dry and/or thin skin and coat, and impaired vision.

Nutraceuticals range from macromolecules to simple fatty acids and may act both locally and systemically. For example, numerous species have both quantitative and qualitative fatty acid requirements.[13] Most fats, depending on the natural history and metabolic limits of each reptile, can meet calorific requirements. Some fatty acids may, however, promote inflammation in the body and possibly interfere with normal cytokine production.[14] Furthermore, each bowel segment has an ability to either digest or microbiologically alter fats. Fatty acids that are not biologically appropriate for each species could possibly lead to local bowel inflammation, disharmony, and unbalanced cytokine production and yield less than optimal nutrition to the animal.[15]

Unfortunately, in the still-emerging area of reptile and amphibian complementary medicine we are often left with many uncertainties in the use of nutraceuticals. How to use? When to use? How much to use? Table 132.3 lists some supplements, doses, and possible side effects. We have used joint supplements as recommended on the label but metabolically scaled where warranted.

TABLE 132.3 Common Supplements, Doses, and Possible Side Effects

Supplement	Daily Dose	Possible Adverse Effects
B-complex: B_1, B_2, B_6	5–40 mg	Nontoxic
Folic acid, B_{12}	5–100 mg	Nontoxic
Vitamin C[a]	50–1000 mg	Considered nontoxic
Vitamin E	10–100 IU	Anorexia, increased clotting time
Vitamin A	500–5000 IU	Anorexia, weight loss
Selenium	5–50 μg	Anorexia, ataxia, weakness
Zinc	5–20 mg	Causes calcium/copper deficiency
Omega-3 fatty	25–250 mg	Dyspepsia, diarrhea[b]

[a]Should have mixed bioflavonoids in C:bioflavonoid of 1:1 to 1:2.
[b]Omega-3 fatty acids should be mostly from fish for carnivore supplementation; alpha-lanoline acid from seeds is converted more efficiently to helpful prostaglandins and leukotrienes or eicosanoids in herbivores.

TUI-NA

Our best historic records of the origin of massage as a component of an intact medical system come from China. There, the indigenous manual therapy system Tui-na (literally push-pull) was recorded by the physician Bian Que as being used in 2500 BCE. Regardless of its cultural origin, massage therapy has many proponents and styles.

Known effects of massage therapy include both physiological and psychological changes.[16] Lymphatic drainage and local vascular function are both benefitted by gentle massage and can often be beneficial for reptiles recovering from general anesthesia. Muscle relaxation with attendant reduction in myofascial pain and quicker recovery after exercise are facilitated by massage.

Traumatic fibrosis and sprain or strain injuries respond to deep friction massage techniques and range of motion exercises better than to steroids or surgery. Pain relief is probably the most universally reported effect of massage. Contraindications to massage therapy include avoiding direct massage of cancerous lesions, sites of recent trauma, inflammation, infection, or fracture.

Body work is a superb adjunct to many types of surgery, particularly orthopedic. Physiotherapy technologies in human medicine are advanced compared with veterinary medicine, although a number of universities and referral practices now offer physical therapy and rehabilitation services. For example, after cranial cruciate ligament surgery, the surgical leg should be manipulated daily. In the field of reptile medicine, we may find that soft tissue manipulation techniques can shorten the course of recovery from surgery and trauma.

In some instances, massage may be used instead of surgery. An animal may be a poor surgical candidate, or the owner may not want to pursue surgical options. Massage may contribute to tissue changes that completely relieve the original problem. In an article by Speciale and Fingeroth, the authors conclude, "Persistent use of physical treatment for paralysis that results from conditions affecting the cervical spinal cord may be useful even without concurrent surgical or pharmacologic treatments."[17]

Massage is a valuable addition to acupuncture therapy. Many acupuncture points can be stimulated to good effect with firm finger pressure (acupressure). With proper instruction and the use of selected, gentle techniques, it is possible for clients to extend the effects of acupuncture treatments. Additionally, recalcitrant animals may be treated calmly at home rather than stressfully in the office. Manual therapy courses are available to teach veterinarians Tui-na and massage techniques

VetBooks.ir

that they can both apply in their office and show to companion animal caretakers so that the client may treat the animal at home. This empowers and directly includes the caretaker in promoting the healing process for their animal companion. Although unknown, it is likely that such techniques may be of benefit to captive reptiles.

We insert here a word of caution concerning amphibians and all manual therapies. Because of the delicate, sensitive, and highly glandular nature of amphibian skin, all manual therapies must be administered with extreme caution to avoid significant damage and injury to the patient.

Some techniques frequently used with many mammalian species, such as pulling on the tail to relieve pain and stagnation (energy blockage) in the spine, are inappropriate in many lizard species because they may result in inadvertent caudal autotomy.

CHIROPRACTIC

Chiropractic is a separate form of complementary medicine and applies manual spinal manipulation based on the interactions between neurologic mechanisms and the biomechanics of the spine. Treatment is directed at "adjusting" the spine and correcting abnormal positional relationships in the contiguous vertebrae, which, in humans, result in symptoms such as soreness, muscle spasm, tingling, or hard hyperirritable nodular structures called trigger points.[18]

Chiropractic manipulations should only be undertaken by veterinarians with proper training. Great caution must be exercised to avoid further injury when treating small reptiles, where disks are fragile, small, or thin, and when bone integrity is compromised, as with cases of nutritional secondary hyperparathyroidism and osteomyelitis. It is highly questionable whether these techniques are appropriate at all in amphibians because of their delicate and easily damaged skin.

HOMEOPATHY

Homeopathy, a separate discipline from TCVM, is emerging in the field of complementary and integrated veterinary medicine. Homeopathic medicine predates modern medicine by a century or more. Samuel Hahnemann, a German physician, first explored homeopathy in the late 1700s and based his theories and practice on the observation of the body's attempts to heal itself.[19] Homeopathy is said to treat the patient, not the disease, and works on what is called "the law of similars," that is, "like treats like."

Homeopathic practitioners believe that symptoms in humans are an inherent part of the body's defense mechanisms and eliminating them without addressing the source of the problem may suppress the body's ability to heal.[20] In that light, instead of suppressing clinical signs, therapies that augment the body's own defenses may be more appropriate. The homeopathic medicines or remedies used are extremely dilute, so much that there should be no original material left in the solution. Many theories are put forth for the mechanisms of action, including an immunologic basis similar to vaccines. Although research is in its infancy, controlled clinical studies have proven that some homeopathic remedies do work, though mechanisms of action are not yet understood.[19–21]

RESOURCES FOR FURTHER INFORMATION AND STUDY

For those who are interested, the following resources will provide you with opportunities for further education, investigation, and inspiration in applying an integrative approach in your own practices. Organizations and training opportunities in CAVM are listed below.

Academy of Veterinary Homeopathy. James Schacht, DVM, Corresponding Secretary; 6400 E. Independence Boulevard; Charlotte, NC 28212; phone: 704-535-6688.

Differential Diagnoses by Clinical Signs—Snakes

Richard S. Funk and Rodney W. Schnellbacher

The intent of this chapter is to familiarize veterinary clinicians with a brief overview of common clinical signs and differential causes observed in serpents. It is important to be familiar with proper husbandry because many of these clinical signs are related to a poor environment, improper temperature, lack of quarantine, and improper nutrition.

Correct identification of an individual snake is critical to understanding its biology, captive care, and veterinary care. A good reference library therefore is essential. Clients will expect you to be able to identify not only the common pet trade species, but also the snakes native to your area. An individual snake can be identified by photography and the images stored digitally, by making a photocopy of its distinctive pattern or by placing a pit-tag or microchip into the snake.

BEHAVIORAL SIGNS

An increase in activity can be related to a variety of causes, including high environmental temperature, insufficient hiding places, mate-seeking behavior, searching for a nesting site, hunger, thirst, ectoparasites including mites, improper substrate or cage furniture (e.g., no tree branch for an arboreal snake or no burrowing medium for a fossorial snake), odors in the room (e.g., rodents, the family mammalian pets, air fresheners, or incense), or an improper photoperiod (lighting on an irregular cycle or on 24 hours a day).[1] A snake may exhibit defensive behavior if it is a new captive or startled. The authors have observed defensive behavior in an otherwise calm snake in the clinic examination room when a king snake had been the previous patient.

Animals that exhibit signs of lethargy may be ill, gravid, digesting food, being kept too cool, getting ready to shed, or undergoing or preparing for brumation. A snake that is spending increasing amounts of time in its water bowl may be too dry, too warm, nearing ecdysis, have mites, or the water bowl may have been allowed to dry out by the keeper or overturned by the snake.

CARDIOVASCULAR SIGNS

Anemia may originate from blood loss, from neoplasia such as lymphosarcoma, laboratory or clinician error (mishandling or lymph dilution), or possibly hemic parasites, although the latter are generally asymptomatic incidental findings (see Chapter 32). Oral mucus membranes tend to be paler than those of mammals. Oral petechiation is rare but can be associated with stomatitis, septicemia, diffuse intravascular coagulopathy, hyperthermia, intoxication, and only rarely with anemia.

Avascular necrosis of the tail tip has been seen with parasitism, including *Alaria* flukes and microfilariae, or after trauma to the tail. Ischemic tail tip necrosis has been documented in breeding female Burmese pythons *(Python bivittatus)* in association with thromboembolic disease.

Hypovolemic circulatory shock, anemia, or dehydration may cause bradycardia and a weak heartbeat. Snakes that are inactive or at cooler temperatures may naturally have slower heart rates. Infectious diseases have been associated with cardiovascular disease in snakes. Salmonella, Arizona, and *Corynebacterium* sp. have been isolated from a Burmese python with endocarditis.[2] Chlamydiosis also has been associated with myocarditis in snakes.[3] Cardiomegaly has been reported in a variety of captive snakes. Apparent enlargement in the region of the heart (or radiographically the cardiac silhouette) may be caused by cardiomyopathy or pericardial effusion (cardiac tamponade) (Fig. 133.1). Cardiomyopathy has been described in two species of snakes. A mole king snake (*Lampropeltis calligaster rhombomaculata*) presented with lesions characterized by fibroblast proliferation and the replacement of myocardial fibrils with fibrocollagen.[4] A Deckert's rat snake

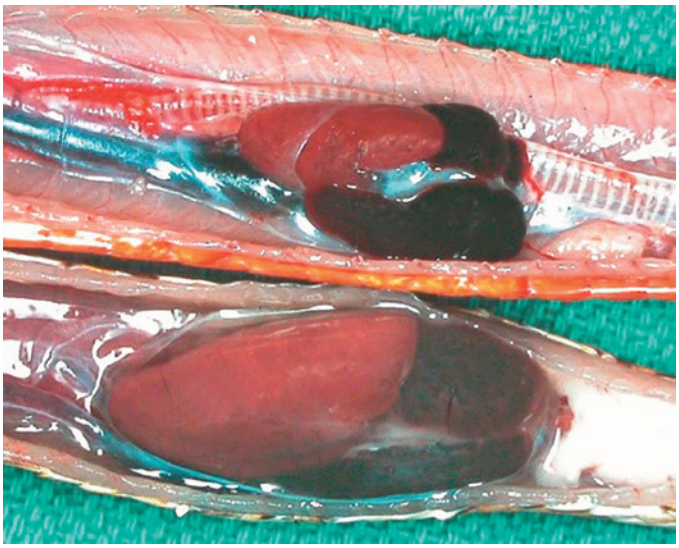

FIG 133.1 Heart comparison of two similar-sized adult corn snakes (*Pantherophis guttatus*). The heart on the bottom shows significant cardiomegaly from an unidentified cause. (Courtesy of Richard S. Funk.)

VetBooks.ir

(*Elaphe obsoleta deckerti*) presented with necrosis of the myocardial fibers.[5] In both cases, the pathologic changes led to congestive heart failure. Congenital cardiac disease has also been reported (incomplete atrioventricular valve in a neonatal boa constrictor that presented with cardiomegaly).[6] Noncardiac soft tissue mass effects include abscess, granuloma, or tumor.

The presence of mitotic figures in peripheral blood is a normal finding in snakes, although unusually high numbers are suspicious of a disease condition such as lymphosarcoma. Other clinical pathology abnormalities are addressed in the hematology chapter (see Chapter 33).

GASTROINTESTINAL SIGNS

Emesis (Vomiting and Regurgitation)

Emesis is a nonspecific sign and not a discrete disease entity. Vomiting (forceful ejection of the stomach contents) and regurgitation (backflow of undigested food) are difficult to distinguish in reptiles. Snakes possess a poorly developed cardiac sphincter, thus permitting what can appear to be almost effortless regurgitation.[7] Common causes include too large or too many food items, suboptimal temperatures, inappropriate postprandial handling, stress (e.g., no hiding place), or intraspecific interactions. Differential diagnoses must also include gastrointestinal obstruction, functional stasis, gastritis/sepsis (bacterial, fungal, or viral), parasitism (such as *Cryptosporidium*), intramural or extramural masses such as neoplasia, granulomas or abscesses, and exposure to commercial toxins. In a case report of a population of emerald tree boas (*Corallus caninus*), chronic regurgitation was associated with an infection of *Chlamydophila*.[8] Vomitus can be confused with diarrhea when the behavior is not directly observed. Concurrent respiratory disease can be present with any gastrointestinal sign.

Diarrhea

Diarrhea is another nonspecific gastrointestinal sign. First, one must ascertain that the feces is actually abnormal, some species have softer or more liquid stools than others, and in some stools, the quality can vary with prey type. Captive king snakes and rat snakes that are commonly fed rodents may have soft or diarrheic stools after a meal of day-old chicks. The most common causes of diarrhea in captive snakes are inappropriate temperatures (especially too low, inhibiting proper digestion) and gastrointestinal parasites. Foreign bodies, too large a meal, and inappropriate diets (such as dairy products) are also common causes. Bacterial, fungal, or viral intestinal infections can also cause diarrhea (see Chapter 145).

Oral Cavity

A good oral examination should always be performed and may reveal necrotic stomatitis (layterm "mouth rot"), abscessation, foreign objects (e.g., substrate), increased mucus or discharges, respiratory signs, petechiation, tongue abnormalities, icterus, parasites, masses (abscesses, neoplasia), edema, or other problems (see Chapter 167). A mass, broken jaw, or stomatitis can cause a deviation in the opening of the mouth, exposing the gums and leading to an exposure gingivitis.

An inactive tongue can result from a tongue sheath abscess or injury, or rarely the tongue may have been removed by trauma or necrosis. Oral petechiation can be associated with stomatitis, sepsis, hyperthermia, intoxication (as from cedar or organophosphates), or possibly a disseminated intravascular coagulopathy. The oral tissues may also be inflamed from infection, usually bacterial. Edema of the oral membranes has been seen with bacterial cellulitis and uremia secondary to renal failure. Head or intermandibular cellulitis may be bacterial (Fig. 133.2), whereas head edema can result from trauma associated with getting stuck in a hole of a cage or snake bag. Oral discharge or excessive mucus may be the result of stomatitis, esophagitis, gastritis, tracheitis, or pneumonia. Dental disease including loose teeth may be seen with stomatitis and osteomyelitis.

FIG 133.2 Submandibular or pharyngeal edema in a boa constrictor (*Boa constrictor*). (Courtesy of Richard S. Funk.)

Stomatitis (or necrotic stomatitis) is commonly seen in captive snakes and often associated with aerobic and anaerobic bacterial infections. Substandard husbandry and poor hygiene are often predisposing factors. An affected mouth exhibits swelling, exudative material that can be confined to a small area or affect the entire mouth, and increased mucus and may not be able to close properly (Fig. 133.3A and B). Secondary respiratory infection is common due to aspiration of caseous material (see Chapter 167).

Esophagus and Stomach

Emesis or anorexia can occur with stomatitis, which can extend posteriorly down into the esophagus and the stomach. This may not be obvious without endoscopy or being identified at necropsy. Esophageal tonsils may enlarge in boas and pythons with inclusion body (arenavirus) disease. A mass in the precardiac region of the snake could be within the esophagus but might otherwise involve the respiratory system or the rib cage. Cryptosporidiosis can cause marked gastric hypertrophy and is often characterized by a midbody swelling.

Intestines

A mass in the coelomic cavity could be an intestinal granuloma, abscess, neoplasm, foreign body, meal, or cryptosporidiosis, or may be extraintestinal. The snake could be a reproductively active female with enlarged ovaries, retained fetus(es), or eggs that could be mistaken for an intestinal issue. Constipation can be caused by meals that are too large, too frequent, or too heavily furred, or in addition, low environmental temperatures or extraintestinal mass effects (e.g., retained reproductive products, neoplasia, abscess, or granuloma) (see Chapter 145). Such a mass is often palpable but not identifiable as intramural or extramural without contrast radiography or ultrasonography. Advanced imaging, endoscopy, or an exploratory celiotomy may be required for definitive diagnosis. In neonate snakes, a firm midbody intracoelomic mass at the umbilicus may represent a poorly absorbed or infected fetal yolk mass. A prolapse that protrudes from the cloaca may be cloacal, oviductal, hemipenial, or colonic (see Chapter 75).

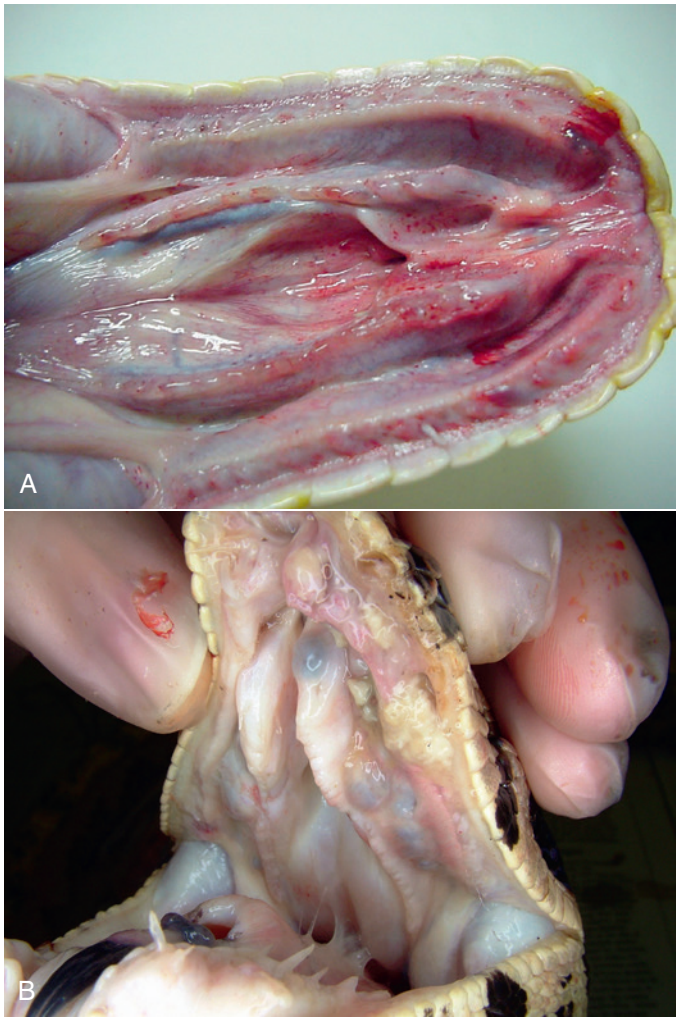

FIG 133.3 Infectious stomatitis, is a common cause of anorexia. Patients that exhibit signs need a thorough physical evaluation, including a discussion of husbandry and management. (A) An acute case of stomatitis with areas of oral petechiation, erythema, and inflammation in a ball python (*Python regius*). (B) A chronic case of stomatitis in common boa constrictor (*Boa constrictor*) with severe inflammation, abscessation, and mucopurulent discharge. (A, Courtesy of Stephen J. Divers; B, courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

OCULAR SIGNS

Retention of spectacles may be caused by dysecdysis (often associated with improper humidity), mites in the periorbital space, trauma to the spectacle (and perhaps to the eye as well), ocular abscessation, and husbandry issues including lack of cage furniture to facilitate shedding. Occasionally a normal spectacle may be misidentified as retained, and attempted removal may lead to exposure keratitis of the cornea and often ocular infection (see Chapter 71).

Eyes and periorbital areas may also be infected with the fungus *Ophidiomyces ophiodiicola*, which may cause swelling, cloudiness, and dermatitis. This has been found in wild and captive snakes (see Chapter 31).

Exophthalmia may be the result of an intraocular mass, such as an abscess or granuloma, a retrobulbar mass, subspectacular abscessation, or increased subspectacular fluid due to a blockage of the lacrimal duct.

FIG 133.4 Comparison of two similar-sized adult corn snakes (*Pantherophis guttatus*). A mature cataract can be observed in the lower snake. (Courtesy of Richard S. Funk.)

An association with stomatitis and/or respiratory infection must be considered (see Chapter 71).

Microphthalmia may be the result of an infected eye that is becoming phthisical, congenital aplasia, or reduced palpebral fissure partially covering a normal-sized globe. Anophthalmia may occur as a congenital abnormality either unilaterally or bilaterally. Scolecophidians, blind or thread snakes, normally have reduced eyes covered by a head scale.

Cloudy eyes may be normal and indicative of impending ecdysis or associated with a retained/missing spectacle, subspectacular abscess, inflammation of the subspectacular space or cornea, panophthalmitis, or a penetrating wound from a bite or foreign object. The presence of a subspectacular abscess makes examination of the globe very difficult. Occasionally a postbrumation vitreal haziness may develop, which is usually temporary.

Cataracts are occasionally seen in geriatric snakes and as a rare sequela to excessively low brumation temperatures (Fig. 133.4). Any association of cataracts with hyperglycemia, renal disease, hypertension, or increased intraocular pressure as seen in mammals is currently unknown. Blindness can develop with age and cataract formation. Uveitis and hyphemia may also cause a temporary blindness, as can retained spectacles, particularly if more than one is present.

DERMATOLOGICAL SIGNS

Masses and swellings are often abscesses, which are usually bacterial infections and can be fungal or mixed, but granulomas and neoplasms also occur. Myiasis is rare but acariasis is common. Sparganosis may appear as subcutaneous masses, particularly in tropical snakes. A generalized cellulitis may accompany dermatitis or septicemia.

Snout-rubbing abrasions may occur in snakes that need a more secure hiding refuge; are hormonal, especially males trying to escape to breed females; or those kept in cages with a rough edge, or screened top, or that rub and push against a weak or loose area of a cage. Abrasions can become infected, leading to abscessation and or stomatitis. If the inciting cause is eliminated, and the abscess and wounds are properly treated, lesions can heal well after several sheds, although a permanent scar can remain (Fig. 133.5A and B).

Acanthocephalans may also exit the skin and leave small ulcerated wounds.

VetBooks.ir

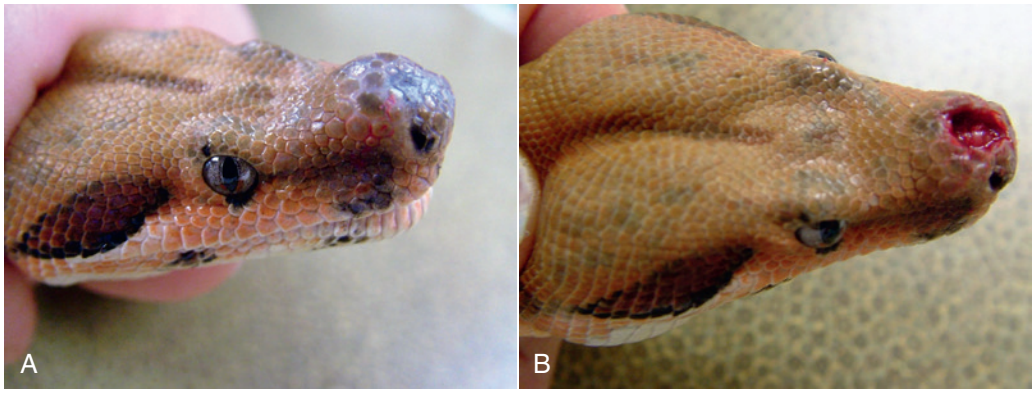

FIG 133.5 (A) This male boa constrictor (*Boa constrictor*) presented with obvious swelling and secondary trauma to the rostrum from attempts to "push out" of its enclosure, as a mature female boa was housed nearby. (B) The same snake after debridement surgery was performed. Note the extent of the abscess and need for aggressive removal of all infected material. In these cases, resolving the underlying condition causing this behavior, such as proximity of female snakes to mature males or the style and type of caging, is critical for success. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

Chemical and thermal burns may result in skin lesions of varying severity, often with fluid-filled vesicles ("blister disease") that may become infected. Poor cage hygiene is a predisposing factor for the development of skin lesions and dermatitis.

Petechiation in the skin may be associated with thermal burns or septicemia. Wrinkling of the skin can be seen with inanition, dehydration, acariasis, dysecdysis, or in postpartum females. Skin damage and bruising can occur secondary to trauma (e.g., tape removal, stuck under a door). A syndrome of skin rupture with separation of the epidermal-dermal layers has been attributed to cachexia and hypovitaminosis C; affected snakes have reduced collagen, but the exact etiology remains obscure. A fungal disease syndrome of the skin of snakes caused by *Ophidiomyces ophiodiicola* has been documented in wild and captive snakes in North America, Europe, and Australia. It can appear as dermal granulomas and crusting dermatitis and can be disfiguring and even fatal (see Chapter 31).

Ectoparasites may be found and are usually *Ophionyssus* mites but occasionally also ticks. Manual removal of ticks is usually possible, but treatments for both, including the use of ivermectin, permethrin, and various acaricides, are discussed in Chapter 32.[9] With mites, the cage and room environments must also be treated. The presence of mites may be suspected if there is dyecdysis, a fine whitish powder on the snake's skin, or if the snake is soaking excessively in its water bowl.

Rodent bite trauma may occur when a snake is offered a live rodent and does not feed immediately, leaving the rodent alive in the snake's vivarium. In addition to any legal and welfare issues, the rodent may cause minor bites to serious wounds that need major surgical repair or even euthanasia (see Chapter 142).

Dysecdysis may occur for numerous reasons, including ectoparasites, malnutrition, dehydration, improper humidity, improper substrate or cage furniture, systemic disease, debilitation, or rough handling during the immediate preshedding phase (Fig. 133.6). The spectacles should normally be shed with the skin as a single piece, but if not, check for mites or husbandry-related problems (see Chapter 149). Snakes with skin wounds, including surgical incisions, may increase their shedding frequency to facilitate healing. Juveniles shed more frequently than adults. A reduction in shedding frequency may accompany reduced feeding and growth.

When wounds heal by second or third intention, scars form and may be depigmented or hyperpigmented, or the scales may be malformed. Pigment-forming neoplasms of the skin, chromatophoromas, appear to be more common in diurnal species.

FIG 133.6 Scale dermatitis and necrosis of a rhinoceros rat snake (*Rhynchophis boulengeri*). Cytology and biopsy of scales revealed that dermatitis was caused by a fungal agent. (Courtesy of Rodney W. Schnellbacher.)

A wide variety of captive-bred "morphs" or phenotypes (cultivars) are now available in the commercial pet trade for a growing number of snake species. These include many with patterns and colorations that may differ widely from the wild phenotypes, for example, lacking melanocytes (amelanistic partial albinos), lacking reds and yellows (anerythristic partial albinos), homozygous recessive for both alleles ("snows" and "blizzards"), leucistics (white with blue eyes), piebalds, etc. Occasionally scaleless snakes are seen where the epidermis is keratinized, but scales may be limited to the head and ventrum and/or where mutant scales are rotated.

Subcutaneous and Cutaneous Masses

Masses are usually abscesses until proven otherwise, but granulomas, including those of bacterial or fungal etiology, and tumors may occur. Blisters or vesicles on the skin form from integumentary infections and may (or may not) progress to small abscesses; causes include unsuitably high humidity, excessive moisture, poor hygiene, prey bites, parasitism, and thermal burns. Rib fractures can present as small lumps, as can rib or spinal osteomyelitis and rarely congenital skeletal deformities. Internal

FIG 133.7 Impacted and abscessed scent gland of a king snake *Lampropeltis mexicana leonis*. Abscess was cultured and flushed with saline, and appropriate topical antibiotics were used. (Courtesy of Richard S. Funk.)

FIG 133.8 A boa constrictor (*Boa constrictor* spp.) presented with an abnormal conformation and limited regional mobility. Radiographs confirmed ossifying spondylosis and areas of scoliosis. (Courtesy of Stephen J. Divers.)

abscesses or granulomas, neoplasia, and organomegaly can cause the appearance of an internal mass. Unabsorbed fetal yolk at the umbilicus may also appear as midbody swelling in neonates. Fecal impactions, fecoliths, and uroliths can appear as caudal coelomic masses. Some snakes nearing shedding may hold feces and urates until ecdysis has been completed. Multiple intracoelomic masses, either visible or palpable, may be present in a reproductively active, gravid, or dystocic female. Unilateral or bilateral impacted or abscessed anal glands or hemipenes in the base of the tail may cause a mass effect (Fig. 133.7) (see Chapter 144). Some, primarily older female snakes, especially corn snakes (*Pantherophis guttatus*), may also develop lipomas on the dorsolateral posterior body.

MUSCULOSKELETAL SIGNS

Musculoskeletal deformities in snakes fed whole prey are rare. Exceptions may be found among snakes that are fed nonsupplemented invertebrates.

Fractures are frequently caused by bites, cage door or lid closures, falling from a perch or branch, unstable cage furniture, and rough handling. Osteomyelitis can weaken a boney area and contribute to a fracture. Rib fractures are common incidental findings on radiographs and, unless they are protruding or penetrating another organ, require no action. One should palpate and look for asymmetry, swelling, and evidence of pain and carefully evaluate skull radiographs or CT scans. Overzealous head-pinning of snakes with snake hooks or tongs may cause iatrogenic head or rib fractures.

Spondylosis, kyphosis, and lordosis, as well as swellings, may be the result of musculoskeletal problems such as abscessation, ossifying spondylosis, osteomyelitis, trauma, fractures, congenital defects, or neurologic disorders (Fig. 133.8).

Many deformities are seen in captive-bred snakes, including shortened jaws or snouts, restricted orbits, domed skulls, arched necks or spines, as well as spondylosis, kyphosis, and lordosis, with some of these conditions attributable to improper incubation or gestation temperatures. A possible role of inbreeding is often invoked but rarely proven. One category of congenital defect that elicits interest from private collectors, including high prices, is two-headed snakes (axial bifurcation).[10]

Tail tips may be damaged by parasites (such as flukes or ticks), prey (e.g., rodent bites) or predators, or accidental trauma (e.g., tail shut or caught in the cage lid or door, or mistakenly tied in the knot of the collecting or transport bag). Thromboembolic disease in Burmese pythons has been shown to cause avascular necrosis of the tail tip.

Paresis and paralysis can occur from musculoskeletal or neurologic abnormalities (see Chapter 77). Spinal lesions are the likely cause of paralysis or paresis in a snake, especially from trauma to the vertebral column but also from spinal infection and abscessation, ossifying spondylosis, or even spinal neoplasia. Affected areas of spine become rigid, and affected snakes have difficulty with locomotion, coiling, and constricting prey. Neurologically related postural abnormalities may be mistaken for musculoskeletal signs.

NEUROLOGICAL SIGNS

Lethargy and depression can be difficult to appreciate and evaluate in snakes. A client may state that a snake is lethargic, and this may not be obvious in the examination room. One should attempt to exclude nonneural causes such as gravidity, ecdysis, low environmental temperature, postprandial behavior, malnutrition, dehydration, or illness (e.g., respiratory or gastrointestinal disease, renal disease, sepsis). In fact, a wide variety of illnesses can cause a snake to be lethargic.

Depression can be the result of head trauma, inappropriately low environmental temperatures, drug reaction, systemic illness, or intoxication (e.g., organophosphates). Some boas and pythons appear to recognize their individual owners and may appear less inactive while their owners are away, only to resume normal activity upon their return.

Paresis and paralysis must be differentiated from musculoskeletal system problems (see Chapter 77). Ataxia may occur from exposure to toxins such as cedar shavings or phenolic cleansers, acaricides and insecticides, over-the-counter medications with questionable ingredients, head or body trauma, hypothermia, spinal osteomyelitis, boid inclusion body disease (arenavirus), meningitis, encephalitis, and thiamine deficiency due to certain fish diets. Ataxia and incoordination may be attributed to hypoglycemia, starvation, general debilitation, hepatic encephalopathy, renal disease, trauma, meningitis, neoplasia, drug intoxication (such as ivermectin), paramyxoviral infection, or boid inclusion body disease (arenavirus).

Inclusion body disease (arenavirus), mostly known to occur in boas and pythons, has now been confirmed in a few colubrid snakes (including *Lampropeltis*), can cause a head tilt, opisthotonos, flaccid paralysis, disorientation, loss of the righting reflex, an inability to prehense or ingest food, and death (Fig. 133.9) (see Chapter 30).

Nutritional deficiencies rarely contribute to neurologic problems in snakes, because most are fed rodents or other whole prey vertebrates. Snakes that are fed invertebrates might be more susceptible to hypocalcemia if the prey are not properly enriched or supplemented. Thiamine and biotin deficiencies have been linked to tremors and convulsions.

Dehydration or aminoglycoside administration can lead to renal disease and gout, which can cause lethargy, incoordination, and death.

VetBooks.ir

FIG 133.10 Western rat snake (*Pantherophis obsoletus*) with coelomic distension due to egg retention and dystocia. (Courtesy of Stephen J. Divers.)

Hyperactivity may be the result of insecurity (inadequate hiding places), inappropriately high environmental temperature, thirst or hunger, crowding, or mate-seeking behavior, or it may be a naturally active species. None of these are true neurologic disorders.

Central nervous system tumors are quite rare but can cause reduced activity, incoordination, ataxia, convulsions, anorexia, and death. Hepatic encephalopathy, although rarely documented, can be associated with lethargy, inappetence, ataxia, and weakness, and more rarely with opisthotonos. Head tilts are uncommonly seen in snakes but can be the result of head trauma, metabolic disease, unilateral ocular disease, and even sepsis. Central etiologies include encephalitis (due to a variety of infectious agents), abscess, granuloma, or neoplasia. Head trauma can occur from accidents involving cage doors, automobiles, falls, loose cage furniture, or other blunt objects.

Seizures and convulsions can occur from such varied causes as septicemia, including central nervous system abscessation, bacterial encephalitis, viral encephalitis (including paramyxovirus and inclusion body disease), protozoal encephalitis and helminth migration, head trauma, intoxication (including cedar, organophosphates [dichlorvos strips], insecticides, ivermectin over dosage, and paint solvents), heat stroke, metabolic disturbances (e.g., hepatic encephalopathy, uremia), neoplasia, and nutritional deficiencies (e.g., thiamine deficiency).

Unfortunately, many neurologic cases remain undiagnosed following a gross necropsy, and therefore, in addition to submitting tissues in formalin for histopathology, a second set of tissues should be kept frozen for potential toxicology or viral investigations.

REPRODUCTIVE SIGNS

True infertility is difficult to confirm. The failure of a snake to breed necessitates a physical examination to ascertain that the snake's sex has been accurately determined. If the snake was inadequately nourished or improperly cycled, it may not breed. Even if the keeper places the snakes together if not observing them continuously, it can be difficult to know whether courtship and mating has occurred. Infertile eggs may indicate a failure of copulation or sperm transportation, whereas an infection or blockage of the female reproductive tract could lead to failure to produce eggs or offspring.

Snake dystocia occurs when a gravid female does not deliver her brood or clutch or retains a portion of it (Fig. 133.10). This can result from many factors, including obesity, nutrition, dehydration, primipara, "power-feeding" for fast growth but marginal size to carry and deliver a normal clutch, large or abnormal eggs, improper gestation temperatures, inactivity (restricted cage size), lack of security, lack of a suitable laying or birthing site, oviductal infection or death of a fetus, mass impinging on the oviduct blocking egg/fetus transport, an oviductal torsion or constriction, ectopic egg or fetus, or prolapse of the oviduct. Some snakes will lay their clutch of eggs even without a suitable laying box or substrate, but others will not (for example, female smooth green snakes will die egg bound if no moist site is available for oviposition). Dystocia should always be suspected if a gravid female suddenly becomes anorectic and lethargic, or if there is evidence that the clutch has been retained. Radiography, ultrasonography, and advance imaging may be useful diagnostic tools in assessing reproductive tract, cloaca, and egg and follicle architecture. Medical and surgical treatments for dystocia are addressed in Chapters 80 and 105.

Stillbirth may result from early fetal death or almost any of the factors that contribute to dystocia. Large viviparous snakes that are kept confined to relatively small cages may have a normal delivery but accidentally crush or suffocate neonates because of a lack of floor space.

Cycling female snakes will occasionally produce vitellogenic follicles, then eventually resorb the follicles if are they not ovulated. Follicular stasis or preovulatory stasis is a condition in which follicles neither ovulate nor regress over time and is associated with clinical signs (e.g., lethargy and/or anorexia). Depending on snake size and species, the follicles may be evident as a swelling of the middle to caudal third of the snake. This condition is difficult to diagnose with certainty, mainly because of the interspecific differences in follicular size and development time (see Chapter 80).

Failure of eggs to hatch can be caused by inappropriate incubation temperatures, excessive temperature variation, inappropriate incubation humidity, fetal death, genetic or congenital abnormalities, egg infections, or because of egg infertility. Some neonates will slit the egg and yet fail to emerge and die within the egg when physically they appear normal upon postmortem examination.

A prolapse through the cloacal opening must be carefully evaluated to ascertain whether it is the cloaca, oviduct (in a female), or hemipenis (of a male). The oviduct can prolapse with a retained egg within it. Surgical treatments for prolapses are covered in Chapters 105 and 106).

RESPIRATORY SIGNS

Respiratory signs may include nasal discharge, oral often frothy discharge, dyspnea and open-mouth breathing, abnormal posture (including holding the head and neck elevated), sneezing, wheezes, stridor, and stentor (Fig. 133.11A–C). Respiratory sounds are considered increased

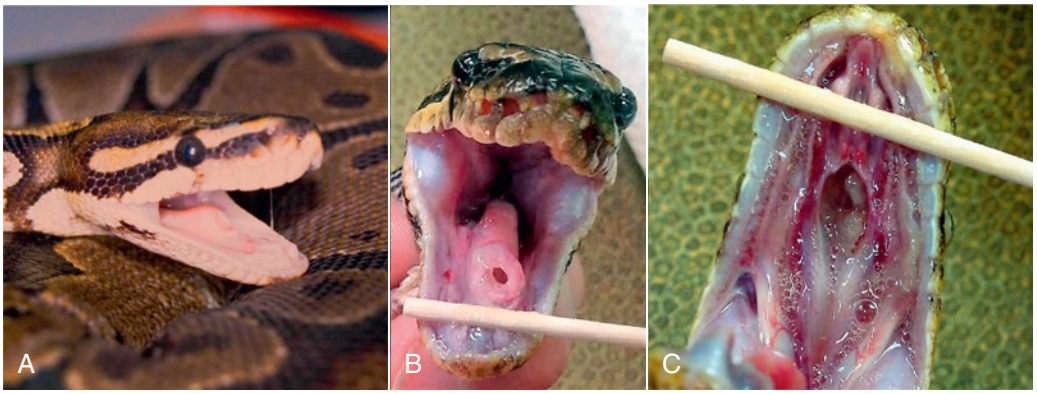

FIG 133.11 (A) Open-mouth breathing is abnormal in snakes and should be investigated. This ball python (*Python regius*) had severe pneumonia, diagnosed via tracheal wash and cytology. (B and C) A ball python on oral examination exhibiting increased fluid in the glottis and oral cavity, and mucopurulent material is present within the choana. Because the glottis resides within the choana with the mouth closed, and increased fluid and material are noted in the glottis with the mouth open, this mucopurulent material is likely coming from the lower respiratory tract. (A, Courtesy of Stephen J Divers; B and C, courtesy of Anibal Armendaris, Stahl Exotic Animal Veterinary Services.)

if audible in the relaxed snake. Abnormal gurgling or wheezing on inspiration, and especially on expiration, should alert the clinician to examine a snake's respiratory system. Some snakes may appear to increase their (normal) respiratory sounds when they become alert. Some snakes may also produce slightly increased breathing sounds when nearing shedding, because the skin lining the external nares thickens in preparation for ecdysis and can narrow the airways. These sounds must be evaluated in comparison with the normal sounds for each particular species, because defensive hissing may be confused with a respiratory problem. For example, *Pituophis* spp. have a cartilaginous structure at the epiglottis that allows the snake to make a loud hissing noise that is normal behavior for these species. Many snakes with respiratory disease are anorectic and lethargic, and sometimes owners may be unaware of the respiratory component to a snake's illness.

Oral and nasal discharges need to be carefully evaluated to ascertain that their origin is from the respiratory system, because gastroenteritis and stomatitis can present with similar discharges. Stomatitis often occurs concurrently with a respiratory infection. Pulmonary neoplasms are rare. Bacterial, mycotic, viral, or parasitic pneumonia may present with dyspnea or with oral or nasal discharges.[11] Snakes lack a diaphragm and have difficulty expelling excessive pulmonary and tracheal mucus. Aspiration pneumonia can also develop following regurgitation, vomiting, or assist-feeding a liquid food.

Dyspnea in snakes can be caused by occluded nostrils, caseous debris or foreign material within the choana, a tongue sheath abscess, an intraoral mass (abscess, granulomas, or neoplasm), a tracheal granuloma or chondroma, hyperthermia, exposure to airborne toxins or irritants (e.g., smoke, incense, or excessive ammonia within the cage), increase in tracheal or pulmonary mucus, or near-drowning events. Any of these conditions can present as open-mouth breathing, either constant or intermittent.

Anatomic snout disfigurements from abscesses, granulomas, cellulitis, or scars may also influence breathing patterns. Epistaxis is rare in snakes but can occur with skull, oral, or body trauma.

Snakes with respiratory disease will commonly inflate their throat region during respiration. Respiratory sounds of snakes can be audible. Abnormal gurgling or wheezing on inspiration, and especially on expiration, should alert the clinician to examine a snake's respiratory system. Concurrent respiratory disease can be present with severe gastrointestinal enlargement because of lung compression.

Physical examination, collection of hematologic and plasma biochemical parameters, diagnostic samples such as tracheal washes for cytology and culture, imaging modalities, and endoscopic evaluation are essential for respiratory disease diagnosis.[12]

SYSTEMIC SIGNS

Asthenia

Weakness is a nonspecific sign of disease. Disease entities that can be associated with weakness include hypothermia, malnutrition, cachexia, metabolic disease, electrolyte or acid-base abnormalities, anemia, cardiovascular disease, respiratory disease, gastrointestinal disease, dystocia, neuromuscular disease, spinal cord disease, neoplasia, or inflammatory processes including bacterial, fungal, or viral infections. Drug overdoses or intoxications can also be associated with weakness. Pain, including postoperative discomfort, can also manifest as weakness.

Weight Change and Body Condition

It is important to differentiate weight loss and gain from decreases and increases in body condition scores to identify underlying etiologies. Weight gain and obesity are commonly associated with excessive feeding and inadequate activity or exercise (rarely seen in wild snakes). Developing snakes will gain weight as well as length as they grow. Gravid females, constipation, or other causes of coelomic distension commonly can lead to weight gain.

Weight loss has many causes, including underfeeding, malnutrition, increased metabolic rate with inappropriately high environmental temperatures, failure to feed (anorexia) due to any variety of husbandry issues or diseases, maladaptation to captivity, parasites, a postpartum female, cardiac disease, chronic inflammation or infection, dehydration with resultant renal disease, neoplasia, starvation, protein losing nephropathy or hepatopathy, or cancer cachexia.

Coelomic Distension

Coelomic distention can be caused by numerous causes, such as gastrointestinal (GI) disease, organomegaly, neoplasia, and reproductive

VetBooks.ir

issues. Knowledge of snake anatomy and topography are important to help rule out specific diseases.

In the gastrointestinal system, coelomic distension can be the result of parasitism, including cryptosporidiosis, a blockage such as a foreign body or fecal impaction, a tumor or granuloma or abscess within the GI tract, intestinal with gas distension, gastrointestinal stasis and putrefaction of ingesta (a result of suboptimal temperatures where digestion cannot proceed effectively), or a normal meal. A fecal impaction or even retained feces yet to be voided may also appear as distension. Retention of large solid uroliths may enlarge the posterior coelom, often with palpable fluid around and anterior to these stones.

Non-GI signs that can cause coelomic distension include extramural organomegaly, such as kidney, liver, or heart. An abscess, granuloma, or neoplasm outside of the GI tract may also cause an abdominal enlargement. General obesity can also cause an enlarged coelom, usually in the posterior coelom because fat bodies are concentrated there.

An owner may not be aware that a snake is gravid, and so developing or retained ova or fetuses may also cause coelomic distension (Fig. 133.10). Reproductive-related distension occurs in the 60% to 70% region of the body from snout-to-vent length in cycling females and is correlated with folliculogenesis and ovulation.

Coelomic transudates (ascites) or exudates (coelomitis) can distend a large portion of a snake's body, and, similar to mammals, this may be attributed to hypoproteinemia, abnormal hepatic function, renal disease, cardiac disease, septicemia, or even neoplasia.[13] Diagnostic tests such as radiographs, gastrointestinal contrast radiographs, ultrasound, and advanced imaging may be useful in diagnosing the cause of coelomic distention.

Anorexia

Anorexia is a nonspecific sign that can be related to husbandry, biology, or disease, or a combination. Husbandry-related issues are very common and include inappropriate temperatures, an improper substrate (e.g., fossorial snake with no appropriate substrate), improper humidity, and excessive or inappropriate handling. A stressed snake with no or too few hiding places or one offered food at the wrong time of day may not feed. Anorexia may be the result of unsuitable caging, for example, in a poor location (high traffic, noisy, domestic pet presence) or inappropriate size.

Almost any disease condition can potentially cause anorexia, including gastrointestinal parasites (nematodes, coccidia including *Cryptosporidium serpentis,* cestodes, amoebas, and flagellated protozoans) and gastroenteritis from bacterial, fungal, or viral infections.[14] Snakes with renal disease or gout commonly stop feeding. Gastrointestinal foreign bodies, constipation, and impactions can lead to anorexia. Oral problems causing anorexia include stomatitis, respiratory disease, occluded nares, bedding trapped in the oral cavity, damage or a bite from a prey item, or a jaw fracture. If the tongue is damaged, missing, or has an abscess within the tongue sheath, the snake may be anorexic. Trauma to the head, oral cavity, or other areas on a snake's body may cause anorexia.

Other causes could be related to improper food items. If the snake has been misidentified, the owner may not be offering it suitable prey, for example, offering rodents to an insectivorous species such as a smooth green snake (*Opheodrys vernalis*). Freshly imported or newly captured snakes may take a while to acclimate to captivity before feeding. Some may refuse white laboratory mice and feed better on wild-caught native rodents or gray-brown-black domestic rodents. Failure of wild-caught snakes to adjust to captivity is called maladaptation syndrome. Even a newly acquired captive-bred snake may be temporarily anorexic as it adjusts to a new environment. A snake may not eat if the wrong food is offered or if the food is offered incorrectly, for example, on the ground for an arboreal snake or during the day for a nocturnal snake. Juvenile snakes of species with ontogenetic dietary shifts may be problem feeders during the transition, such as from ectothermic to endothermic prey.

Temperate zone snakes may enter a fall anorexia in preparation for brumation, and some new hatchlings that refuse food may feed after a short brumation period. Snakes nearing shedding will typically not feed until after ecdysis.

Reproductive conditions may be associated with anorexia. During the active breeding season, some snakes, especially males, will not feed until the breeding season has ended. Inexperienced owners may not appreciate when a female snake is gravid, and many females will go off feed until after parturition or oviposition.

Acute Mortalities

Often if the snake has been ill and is being treated, the cause may be already known. However, sometimes the owner is convinced it was a "sudden death" scenario without premonitory signs. A good history and full necropsy may be necessary to determine the cause of death or identify factors that could have led to its death. Frequently the death was from a more chronic condition and not sudden.

Husbandry issues can lead to a snake's death, including burns, overheating such as improper use or malfunction of heating devices, drowning, chronic dehydration, chronic malnutrition, trauma from the cage or caging accessories, and trauma from another family pet. Certain medication overdoses could lead to death, for example, gentamicin or environmental insecticides (e.g., dichlorvos strips). Severe parasitism or septicemia can lead to death. Viral infections including paramyxovirus and inclusion body (arenavirus) disease of boas and pythons may also lead to death. Aneurysms have been described in snakes; an aortic aneurysm has been reported in a Burmese python after constricting its meal.[15] Brumation can also be stressful in some snakes and unmask a subclinical condition. Many keepers and owners report an occasional death during brumation or shortly after emergence.

Be careful to correctly diagnose a snake as dead by checking clinical signs, including complete immobility, lack of respirations, absent response to tactile or pain stimuli, and lack of a detectable heartbeat. A snake can be clinically dead and maintain a heartbeat for several hours under some conditions. Use caution when handling deceased venomous snakes because accidental envenomation is possible.

Differential Diagnoses by Clinical Signs—Lizards

Stephen Barten and Shane Simpson

MUSCULOSKELETAL SIGNS

Lameness and Skeletal and Spinal Abnormalities

Metabolic bone diseases (MBDs), of various origins, are the most common causes of lameness, skeletal, and spinal abnormalities in lizards. MBDs can manifest as fibrous osteodystrophy, osteomalacia, osteoporosis, osteopetrosis, pathologic fractures, and more (see Chapter 158). Swollen or misshapen mandibles, limbs, or vertebral column are common, and lesions may be symmetrical or asymmetrical (Fig. 134.1). Other causes of lameness include fractures or soft tissue injuries from trauma, such as bites from cage mates, neoplasia, cellulitis, abscesses, and osteomyelitis. Joint abnormalities may result in lameness. The affected joints often are swollen and have a limited range of motion. Joint problems may be caused by septic arthritis or degenerative joint disease related to trauma or aging. Articular gout, periarticular gout, and pseudogout have been reported in several lizard species.[1,2] True gout consists of uric acid deposits in the joints. Pseudogout is caused by the accumulation of any crystal other than sodium urate (see Chapters 149 and 161).

Ossifying spondylosis related to age, osteomyelitis, or metabolic abnormalities can cause a lizard's spine and tail to be stiff and unyielding, resulting in an altered gait.

Hypertrophic osteopathy with profound periosteal proliferation of the long bones related to the presence of coelomic space-occupying masses has been reported in the green iguana (*Iguana iguana*).[3]

Tail

Most iguanid lizards as well as many skinks, geckos, and anguid lizards, undergo tail autotomy as a defensive strategy to avoid predation. Each caudal vertebra has a cartilaginous fracture plane through the vertebral body and neural arch. Fracture planes are absent in the cranial part of the tail to protect the hemipenes and fat deposits. In iguanas, the fracture planes are replaced by bone as the lizards grow, so the tail breaks off less easily in adults. The lost tail is regenerated with a cartilaginous rod for support and is covered with smaller, darker scales in an irregular pattern compared with the original tail. One exception is the crested gecko (*Correlophus ciliatus*), which undergoes tail autotomy but does not regenerate the tail once it is lost. Tail autotomy generally does not occur in agamid lizards, monitors, or true chameleons, and these species do not regenerate tails that are lost from trauma or amputation.[4]

Avascular necrosis of the tail is relatively common in green iguanas and central or inland bearded dragons (*Pogona vitticeps*) though is occasionally seen in other species. The distal tail becomes hard, dry, stiff, and discolored. A zone of devitalized tissue characterized by swelling, erythema, and occasional serous discharge often exists between necrotic and healthy tissue at the onset of the problem. Possible etiologies include trauma, hematogenous-borne infection, osteomyelitis of the caudal vertebrae, and iatrogenic damage secondary to blood collection or catheter placement.

Swelling of the ventral tail base, adjacent and caudal to the cloacal opening, in male lizards usually involves the hemipenes. Some male lizards such as green iguanas and various species of chameleons undergo dramatic enlargement of the hemipenes with sexual maturity. Naive keepers occasionally present young adult male lizards to have these normal but newly enlarged hemipenes evaluated. Other species such as blue-tongue lizards (*Tiliqua* spp.) can develop hemipenal sac abscessation (Fig. 134.2). Swelling of the ventral tail base is also caused by

FIG 134.1 Nutritional secondary hyperparathyroidism is the most common of the metabolic bone diseases seen in lizards. Affected animals can present with severe skeletal deformities, such as mandibular deformities as seen in this leopard gecko (*Eublepharis macularius*). (Courtesy of Stephen Barten.)

FIG 134.2 Hemipenal sac abscesses present as swellings on either side of the tail base. Abscesses can be bilateral or unilateral as in this eastern blue-tongue skink (*Tiliqua scincoides*). (Courtesy of Shane Simpson.)

VetBooks.ir

so-called seminal plugs. These consist of waxy, caseous debris that collects within the inverted hemipenes and most often are bilateral and symmetrical. The brown dry tips of the seminal plugs often can be seen protruding from the opening of each hemipenis in the caudolateral cloaca. Seminal plugs have been suggested to consist of dried semen and desquamated epithelial cells, but they have been shown to contain no sperm at all.[5] Seminal plugs have been associated with iatrogenic hypovitaminosis A in chameleons and leopard geckos (*Eublepharis macularius*).[6,7]

Deformities

Axial bifurcation, or conjoined (incomplete) twinning, has occasionally been reported in a variety of lizard species.[8,9] Congenital malformations of the head may include foreshortening of the upper jaw, cleft palate, and microphthalmia.[10] Congenitally short, absent, or kinked tails may also be seen.

Kyphosis and scoliosis of the spine occasionally is seen in green iguanas and other lizards. This condition can result from genetic defects, malnutrition, and pathology of the epaxial muscles. Congenital defects may be a result of genetic defects or improper temperatures during incubation. Defects that appear later in life may be genetic or the result of external factors, including infection, trauma, neoplasia, and malnutrition.

DERMATOLOGICAL SIGNS

Dermatitis, Abrasions, Ulcerations, and Open Sores

Rostral abrasions are common in active lizards, such as water dragons (*Physignathus* spp.) and basilisks (*Basiliscus* spp.), and result from repeated trauma with glass or wire cage walls during flight responses to stimuli. Abrasions on the palmar and plantar surfaces of the feet also occur in lizards kept in cages with rough or wire surfaces. Bite wounds from cage mates or live rodent prey or other trauma may result in defects in the skin. (See Chapter 142). Thermal burns result from contact with a heat source or fire and usually involve the ventral or dorsal surface (Fig. 134.3) (see Chapter 69). Chemical burns result from contact with cage disinfectants, such as sodium hypochlorite, that has not been rinsed away adequately. A thorough patient history reveals the cause of the lesion in these cases.

FIG 134.3 A severe, full-thickness burn on the ventrum of a lace monitor (*Varanus varius*) caused by an unprotected heat source with which the lizard was in direct contact. Extensive surgery and prolonged treatment was necessary, but this lizard made a full recovery. (Courtesy of Shane Simpson.)

Dermatitis may be ulcerative or necrotizing and result from gram-negative, gram-positive, or anaerobic bacteria and from various fungi and algae.

One significant organism is the fungal pathogen *Nannizziopsis guarroi*.[11–13] This is the causative agent of the syndrome known commonly as "yellow fungus disease" that primarily affects bearded dragons but has been reported in multiple other lizards, including veiled chameleons (*Chameleo calyptratus*) and green iguanas. Affected animals develop severe crusting and ulceration of the skin, particularly around the head, but it can spread to involve all parts of the body (Fig. 134.4) (see Chapter 31).

Dermatitis may also result from mites (*Ophionyssus* sp. and *Hirstiella* sp.). Myiasis may cause one or more open holes in the skin, and the fly larvae are usually visible moving within the hole.

Crusts, Scabs, Flakes, and Dysecdysis

Crusts and scabs may be seen as a result of bacterial dermatitis or burns. Flakes of skin may represent normal shedding. Most lizards shed in pieces, but in some species (e.g., geckos) the old skin comes off in one piece. In addition, some lizards eat their shed skin. Dysecdysis, or difficult shedding, may result in dry, flaking, adherent patches of dead skin (Fig. 134.5). The most common cause of dysecdysis is a lack of humidity. Retained skin surrounding the digits, dorsal spines, or tail tips shrinks as it dries, which compromises the blood flow. This results in necrosis and sloughing of the affected part.

FIG 134.4 *Nannizziopsis guarroi* causes "yellow fungus disease" in central bearded dragons (*Pogona vitticeps*). This fungal infection causes severe ulceration and crust formation predominantly around the head. Treatment may delay its spread and severity, but the infection is usually fatal. (Courtesy of Sue Ciampa.)

FIG 134.5 Lizards with dysecdysis will retain pieces of shed skin over their bodies, such as in this leopard gecko (*Eublepharis macularius*). (Courtesy of Stephen Barten.)

VetBooks.ir

Dysecdysis has been associated with iatrogenic hypovitaminosis A in chameleons and leopard geckos[7] (see Chapter 147).

Swellings, Nodules, and Blisters

Many lumps in lizards are caused by abscesses, which usually manifest as encapsulated, inspissated pockets of caseous debris. Rarely, reptile abscesses contain mucoid or liquid discharge. Abscesses often are subcutaneous, but they may occur within the coelomic cavity, the middle ear, or under the ocular spectacle. Abscesses usually occur after bacteria, including anaerobes, or fungi enter through a penetrating wound. Cellulitis often precedes the formation of a pocket of debris (see Chapter 138).

Fluid-filled blisters commonly result from conditions of excessive humidity or thermal burns. Cytology should always be done to differentiate between sterile and septic blisters regardless of the cause.

Day geckos (*Phelsuma* spp.) have endolymphatic sacs that are sometimes called calcium or chalk sacs. These appear as bilaterally symmetrical subcutaneous swellings on the lateral and ventrolateral neck. Similar glands occur in crested geckos (*Correlophis cilliatus*) and *Rhacodactylus* spp., such as the gargoyle geckos (*Rhacodactylus auriculatus*), but they are located dorsally in the oral cavity. Their function is to store calcium and thus are radiopaque on radiographs. Anecdotally they are larger in geckos that have been heavily supplemented with calcium and vitamin D. Endolymphatic sacs tend to be larger in females but have been reported in males and, to a lesser extent, juveniles. These are normal structures that might be mistaken for abscesses.

Sebaceous or keratinaceous cysts have been reported in lizards, primarily in the tails of green iguanas and in multiple locations on central bearded dragons. These resemble dry abscesses with a solid core of epidermal debris and can be gently peeled off the underlying skin to leave a shallow crater.[14]

A variety of neoplasms of the integument has been reported in lizards, and these may result in dermal or subcutaneous masses.[15] The types of neoplasias seen include papilloma, squamous cell carcinoma, melanoma, chromatophoroma, fibrosarcoma, and myxosarcoma, among others.

Subcutaneous nematodes and filarid parasites may cause subcutaneous masses. These are especially common in chameleons.[16,17]

Edema may cause swelling of the limbs, pharynx, or coelom.

Cases of pseudoaneurysm or dissecting aneurysm have been observed in the dorsolateral cervical region of captive bearded dragons[18] (Fig. 134.6) (see Chapter 68). Generally adult lizards will present with a large fluctuant to firm swelling on the dorsolateral neck just caudal to the skull. Attempts to aspirate the fluid-filled mass generally yield several milliliters of whole blood. After fluid evacuation, the mass immediately refills with blood, indicating communication with a large or high-pressure blood vessel.

In more chronic cases, the contents of the lesion coagulate and cannot be aspirated. The etiology of this syndrome is unknown. Extensive lesions of smooth muscle in the tunica media of the great vessels have been noted on histopathology and were characterized by distortion and disorientation of the smooth muscle fibers with marked intracellular edema. Hypertension cannot be ruled out as a possible etiology for this syndrome.

Abnormalities in Color, Abnormal Scale Patterns, and Color Change

Abnormalities in color commonly occur in reptiles and are often selected for in captive breeding programs. Red, yellow, and white skin pigments are present in addition to melanin. Amelanosis, hypomelanosis, anerythrism, melanosis, and leucism may be seen. Abnormal scale patterns caused by genetic mutations have also been selected for in breeding programs. For instance, popular morphs of the bearded dragon include "leatherbacks," with increased numbers of smaller-sized dorsal scales and fewer spikes, giving the skin a smoother texture, and "silkbacks," with scales so small the skin appears smooth like that of a human. Ontogenetic pattern changes occur in some lizards, for example, the leopard gecko. In this species, the young are banded but become spotted as they mature.

FIG 134.6 Aneurysms have been seen in adult central bearded dragons (*Pogona vitticeps*). When aspirated, frank blood is removed, and the lesion quickly refills. Treatment requires high-risk surgery. (Courtesy of Stephen Barten.)

Rapid color change is highly developed in many lizards but most notably among the chameleons (*Chamaeleo* spp.) and anoles (*Anolis* spp.). Control of the chromatophores may be hormonal or neurological or both. Male chameleons confronted with conspecific males or even their own mirror image quickly assume bright "threat" colors as they attack their rival. Chromatophores may react to stimulation from light or changes in temperature; lizards that are cold or in bright sunlight often become noticeably darker. Age, gender, and season may influence color change. Some male green iguanas have a pronounced orange hue develop during the breeding season as a normal condition, and this must be differentiated from the orange discoloration that is sometimes seen with systemic illness. Lizards with systemic disease or malnutrition often become duller or darker than normal. Lizards in an active shed cycle will have a dull appearance to their skin.

Mite infestation may result in color changes to the skin (see Chapter 139).

Scars

Scars from wounds, burns, and other trauma initially are white to pale pink and smooth and lack scales. With each successive shed, the scaleless area becomes smaller as new scales are produced around the periphery of the lesion. The scar does not change appreciably in appearance between sheds but is noticeably smaller immediately after a shed. Once the scarred area has healed, the new scales may be noted to be smaller and darker than the original scales. Also, they usually are arranged haphazardly rather than in even rows.

GASTROINTESTINAL SIGNS

Oral Cavity

Petechiae. Petechiae are uncommon in lizards. Causes include trauma associated with rostral abrasions, running into cage walls during escape

VetBooks.ir

attempts, and the forceful use of oral speculums. Focal, early stomatitis can result in petechiae, but this also is rare in lizards. Coagulation disorders are poorly documented in reptiles, but these could result in petechiae. Coagulopathy might also result from the ingestion of warfarin-type rodenticides or prey animals that had ingested rodenticides (see Chapter 88).

Stomatitis, Ulcerations, and Exudates. Stomatitis is much more common in snakes and chelonians than lizards. It is usually the result of poor husbandry conditions, including suboptimal temperatures, malnutrition, and overcrowding. A herpesvirus has been associated with a proliferative stomatitis in green tree monitors (*Varanus prasinus*).[19] However, generally stomatitis occurs secondary to other conditions such as pneumonia and septicemia. Signs can include inflammation, ulceration, abscessation, and caseous deposits (see Chapter 73).

Exposure gingivitis often is mistaken for stomatitis. Lizards that have or have had secondary nutritional hyperparathyroidism (NSHP) commonly have deformed mandibles and maxillae, resulting in the exposure of gingival tissue. This condition also is seen in cases with traumatic defects in the lips. The affected gingiva produces a dry, reddish-brown, scablike material. This condition does not respond to antibiotic therapy. The exposed gingiva should be kept moist with aqueous lubricants and barrier creams, with the discharge periodically removed.

Oral neoplasia has been seen in lizards.[20] Chemical or thermal burns, in theory, could result in oral ulcerations. Lizards with renal failure do not typically develop oral ulcers like those seen in feline patients. Visceral gout can result in inflammation of the oral cavity.

Oral exudates usually result from inflammation of the oral cavity, respiratory tract, or gastrointestinal tract. Stomatitis usually involves exudation. White or mucoid foam may be coughed up in cases of pneumonia. Less commonly, stomach contents may be regurgitated and be present in the oral cavity in cases of gastritis or gastrointestinal obstruction. Septicemia is often present in cases of stomatitis, pneumonia, and gastroenteritis. Inflammation of any tissues is caused by bacterial, viral, fungal, and parasitic agents. Appropriate diagnostic sampling is necessary to differentiate the causative agent.
Chameleons (*Chamaeleo* spp.) have temporal glands dorsolateral to the corners of their mouths that sometimes become infected and distended with caseous debris.

Oral Discharge and Ptyalism. Excessive white foam in the oral cavity is occasionally seen in lizards and is associated with septicemia and pneumonia. Affected lizards are usually moribund. Improper husbandry techniques, such as chilling, malnutrition, lack of parasite control, and overcrowding, are often part of the history.

Pharyngeal Edema. Pharyngeal edema has been associated with renal disease in green iguanas and old-world chameleons.[7] Some chameleon species have an accessory lung lobe attached to the trachea in the ventral neck. Swelling in this area can be caused by infection and cellulitis of this structure.

Mucous Membrane Color. Adult bearded dragons and many chameleons normally have yellow-orange mucous membranes that resemble icterus. Many lizards, including various species of chameleons, geckos, and monitors, have melanotic oral cavities. These can vary from jet black to dark purple in color, and the latter must be differentiated from cyanosis.

Icterus is an uncommon sign in lizards. When present, it may be prehepatic or hepatic and result in jaundiced mucous membranes; however, these tend to be a greenish color rather than yellow because of the accumulation of biliverdin rather than bilirubin. Cyanosis may result from respiratory or cardiac compromise but also is rare in reptiles. Erythema and congested mucous membranes may be seen in cases of stomatitis.

Reptile mucous membranes are normally pale pink to white in color and are significantly paler than those of a typical mammal, because the normal packed cell volumes of reptiles are lower than those of mammals.

Tongue. Chameleons (*Chamaeleo* spp.) and monitors (*Varanus* spp.) have long protrusible tongues that retract inside a sheath rostral to the glottis when not in use. Bacterial infection sometimes develops within that sheath. Symptoms include inflammation, discharge, and an inability to protrude the tongue because of adhesions between the tongue and sheath.

In chameleons, hypocalcemia commonly results from malnutrition, lack of ultraviolet B light, or renal disease. One of the first symptoms of hypocalcemia in this group is poor muscle tone manifested as flaccid paralysis of the tongue. The affected chameleons either cannot shoot their tongue at prey in a normal fashion or, if they do, are unable to retract it so that it hangs from their mouth.

The tip of the tongue in the green iguana, leopard gecko, and other lizard species is darker than the rest of the tongue, which may be mistaken for glossitis.

Dental Disease. The teeth of lizards are generally pleurodont (attached to the sides of the mandible without sockets), but in some families, the Agamidae and Chamaeleontidae, they are acrodont (attached to the biting edges of the jaws without sockets). Pleurodont teeth are regularly shed and replaced, and dental disease in these species is rare. Acrodont teeth are not replaced except in very young specimens, although new teeth may be added to the posterior end of the tooth row as the lizard grows. Many agamids have a few pleurodont teeth in the rostral portion of the dental arcade. Periodontal disease has been reported in captive acrodont lizards, including bearded dragons and frilled lizards (*Chlamydosaurus kingii*). Symptoms include gingival erythema, gingival recession, calculus formation, and, in severe cases, osteomyelitis and abscess formation[21–23] (see Chapter 159).

Teeth may fracture as a result of biting or chewing on objects, such as oral speculums. Infected gingiva can result. Teeth may become loosened as a result of NSHP or secondary renal hyperparathyroidism (RSHP).

Anorexia

Anorexia is a common sign among captive reptiles. It is not a disease itself but occurs secondary to other conditions. The causes may be environmental or medical.

Environmental causes of anorexia include low temperature, low humidity, excessive handling of shy specimens, stress from overcrowding, lack of a hide box for visual security, lack of ultraviolet light sources, and presentation of inappropriate or inadequate diets (e.g., carnivorous lizards, such as most monitors, do not accept vegetarian diets). It is therefore important, in the evaluation of the anorexic lizard, that the environmental conditions that *have* been provided and those that *should* be provided are reviewed.

In a few cases anorexia is normal in lizards. Gravid females usually eat less than normal, if at all, because developing eggs or fetuses fill a large percentage of the coelomic cavity and there is no space for expansion of the gastrointestinal tract with food. Assist feeding in this instance is extremely stressful (Fig. 134.7). Likewise, many male lizards become focused on territoriality, fighting with rivals, and searching for a mate during their breeding season, and eating takes on a low priority. Species

VetBooks.ir

FIG 134.7 A female central bearded dragon (*Pogona vitticeps*) that presented for anorexia and weight loss as a result of postovulatory egg retention. Assist feeding with a semiliquid diet resulted in food remaining in the esophagus and stomach because of the extraluminal pressure of the eggs. Ovariosalpingectomy relieved the dystocia and resulted in a normal return to function. (Courtesy of Stephen Barten.)

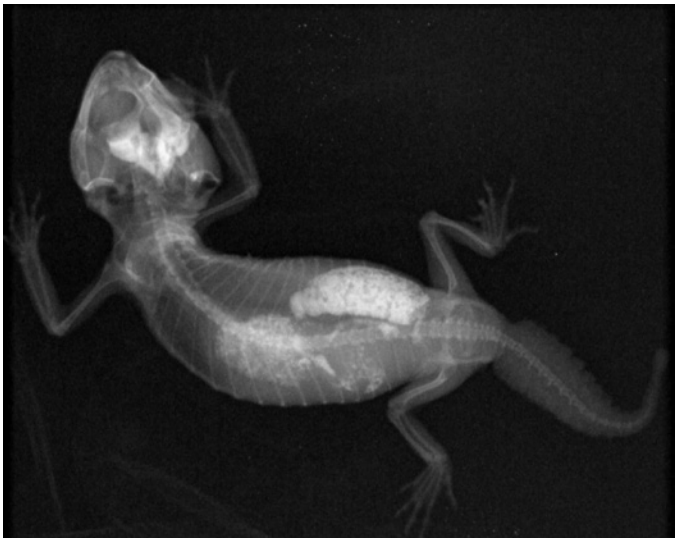

FIG 134.8 Constipation can be the result of many causes, including substrate ingestion such as sand. This radiograph of a smooth knob-tailed gecko (*Nephrurus levis*) clearly shows the large amount of ingested sand. (Courtesy of Shane Simpson.)

that normally brumate, especially wild-caught specimens, may have decreased appetites with decreasing photoperiod in the fall, even when environmental temperatures are kept high.

Medical causes of anorexia are varied. One of the most common signs of any disease is a decreased appetite. Anorexia is common with bacterial or viral infections, parasites, nutritional disorders, foreign body or impaction, stomatitis, and gastroenteritis. Renal disease, liver disease, metabolic disorders, neoplasia, toxemia, and so on all result in anorexia. NSHP often causes soft flexible mandibles and loosened teeth, which can preclude eating, and ileus of the gastrointestinal tract related to hypocalcemia. Tongue lesions or infection can prevent food prehension. A complete history, physical examination, and appropriate laboratory sampling are necessary to establish a diagnosis (see Chapter 42).

Vomiting and Regurgitation

Lizards have a more highly developed cardiac sphincter than snakes and as a result rarely regurgitate. Lizards that are vomiting or regurgitating food are often extremely ill. Causes include septicemia, toxemia, gastroenteritis, parasite burdens, gastrointestinal foreign bodies, and gastrointestinal obstruction caused by intussusception or constipation. Extramural causes of gastrointestinal obstruction include nephritis with renal enlargement, uroliths, the presence of eggs or fetuses, abscesses, neoplasia, and a narrowed pelvic canal from trauma or one of the MBDs. Spoiled food, inappropriate temperatures that prevent normal digestion, and postprandial handling can cause regurgitation. Vomiting may be seen during agonal struggles in terminal cases (see Chapter 73).

Diarrhea

Environmental conditions can result in diarrhea. Low environmental temperatures can cause incomplete digestion, bacterial overgrowth, and diarrhea. Sudden changes in the diet may cause diarrhea in herbivorous lizards, especially when fruits with a high water content are offered. Likewise, lack of fiber in the diet of these lizards can contribute to the formation of loose stools. Feeding chicks, chicken parts, other meat products, or dog food to carnivorous lizards can result in looser and more foul-smelling stool than when rodents are used. Diarrhea is caused by a variety of infectious and parasitic agents. Enteritis results from a number of bacteria, including *Salmonella* spp. Viral diseases are poorly documented in lizards, though agamid atadenovirus infection in bearded dragons is often associated with diarrhea.[24] Parasites that can cause diarrhea include hookworms (*Kalicephalus* sp.), ascarids, strongyles (*Rhabdias* sp. and *Strongyloides* sp.), *Entamoeba* sp., coccidia (*Eimeria* and *Isopora* sp.), flagellates (*Trichomonas* sp., *Monocercomonas* sp., and others), and, less commonly, ciliates (*Nyctotherus* sp.). *Cryptosporidium* spp. is more common in snakes than in lizards, but it has been reported in several species, including leopard geckos,[25] savannah monitors (*Varanus exanthematicus*),[26] and bearded dragons[27] (see Chapter 74).

Constipation

Lack of bowel movements has many potential causes. Associated husbandry issues include inappropriate temperatures, hypocalcemia, and related NSHP from insufficient dietary calcium, dietary vitamin D_3, or UVB lighting; inappropriate or insufficient water sources; lack of activity from a too-small cage,;inappropriate food items (long-haired rodent prey, hard-shelled insect prey); and ingestion of indigestible cage substrates such as gravel, rocks, sand, and bark (Fig. 134.8).

Diseases that cause constipation include parasitism and dehydration. Intussusception and cloacitis can cause physical obstruction of the gastrointestinal tract. Extramural causes of gastrointestinal obstruction include nephritis with renal enlargement, uroliths, the presence of eggs or fetuses, abscesses, neoplasia, a narrowed pelvic canal from trauma or NSHP, and neurological deficits related to vertebral lesions such as fracture, scoliosis, kyphosis, and various MBDs.

Constipation is a common presenting sign in bearded dragons. Affected patients have a history of not having defecated for 1 to 2 weeks, anorexia, and lethargy. Examination usually reveals a large mass of urates in the cloaca, preventing the passage of feces.

Prolapse From the Cloaca

Several organs can be prolapsed from the cloacal opening. These include the cloaca itself, the bladder when present, and the colon. Female reptiles

VetBooks.ir

can prolapse the shell gland, and males one or both hemipenes. Seminal plugs in males can be mistaken for a prolapsed organ.

A prolapse can occur as a result of anything that causes straining. The most common cause of a prolapsed cloaca in juvenile iguanas is poor muscle tone associated with hypocalcemia and spinal cord deficits from vertebral compression and fracture, usually a consequence of NSHP. Straining may be caused by any cause of gastroenteritis, including bacterial, fungal, viral, or parasitic enteritis; cloacitis; impactions or ingested foreign objects; intussusception; or constipation. Uroliths, bacterial cystitis, or dystocia can result in excessive straining. Extraluminal gastrointestinal blockage caused by renal enlargement, neoplasia, abscesses, or a narrowed pelvic canal from trauma or NSHP all result in straining. Dyspnea can cause straining (see Chapter 75).

REPRODUCTIVE SIGNS

Infertility

Normal courtship and breeding in reptiles is stimulated by seasonal fluctuations in temperature, photoperiod, or rainfall. Many species need a period of brumation to mate successfully. Males and females may fail to produce sperm and eggs, respectively, if they are kept at inappropriate temperatures, humidity levels, or photoperiod. The specific requirements of a species must be researched to avoid exposing them to inappropriate cycling techniques, such as temperatures that are too cold, resulting in illness. Social cues play a role, and for some species successful mating is enhanced by social groups or male-to-male combat, rather than just the introduction of a single male and single female. Some individual pairs may be incompatible with each other. In many of these cases the keeper has misidentified the gender of one or both in the pair. In other cases, the animals are too young to breed. Localized illness, such as infection of the reproductive tract or cloacitis, can prevent breeding, as can systemic illness such as septicemia, malnutrition, or renal failure (see Chapter 80).

Stillbirths and Hatch Failure

Improper environmental conditions for the gravid female or complications with incubating eggs commonly result in stillbirths or failure of eggs to hatch. Low or high environmental temperatures, low or high humidity levels, poor hygiene with mold or fungal contamination of the incubation media, and incubator failure are potential causes. Infection of the cloaca or oviduct, genetic abnormalities, and fetal or egg disease also may be involved (see Chapter 85).

Dystocia

The presence of eggs or fetuses does not indicate the diagnosis of dystocia. Normal gravid females develop distended coelomic cavities and become anorectic. Green iguanas usually refuse food for 4 weeks before they lay eggs.[28] However, they remain bright, alert, and responsive. Gravid lizards with dystocia quickly become depressed and unresponsive and without prompt treatment can die.

Nonobstructive causes of dystocia may include husbandry issues. Lack of a suitable egg-laying site is one of the most common causes leading to postovulatory egg retention. Iguanas need an enclosed egg-laying chamber, and chameleons often lay eggs in the soil of potted plants within their cage if a climbing branch reaches into the pot. Cool temperatures, malnutrition, dehydration, and poor physical condition from lack of exercise can contribute to dystocia. Infection of the reproductive tract can occur, but it can be difficult to differentiate whether the infection has caused the problem or infection is the result of retained ova or fetuses, especially in cases with a delayed presentation.

Obstructive causes of dystocia include anatomic defects that prevent the passage of eggs or young. Oversized, deformed, or fractured eggs may be too large to pass through the pelvic canal. The shell gland may have a stricture or torsion. Abscesses, enlarged kidneys, neoplasia, or uroliths may compress and obstruct the oviducts. A narrowed pelvic canal or other spinal deformity caused by one of the MBDs or trauma may prevent passage of eggs.

FIG 134.9 Coeliotomy to treat preovulatory follicular stasis in a red tegu (*Tupinambis rufescens*). Marked inflammation and a small amount of free yolk material are visible; these are abnormal and possibly because of trauma from jumping or falling. Without surgical intervention, these patients will succumb to septicemia. (Courtesy of Stephen Barten.)

Preovulatory egg retention occurs when a lizard undergoes vitellogenesis but does not ovulate (Fig. 134.9). The enlarged ova remain on the ovaries but fill the coelomic cavity and cause anorexia. In some cases they are resorbed; in others an ovariectomy is necessary (see Chapters 80, 105, and 148).

RESPIRATORY SIGNS

Dyspnea

Dyspnea may result from upper or lower airway disease. The nostrils can become plugged with unshed skin, normal discharge from the salt excretion glands, or inflammatory discharge from rhinitis and pneumonia. Both the external and internal nares must be examined for discharge, which may be serous, mucoid, or purulent. Pneumonia may be present at the same time as rhinitis. Plugged nostrils result in open-mouth breathing.

Lower respiratory disease with respiratory embarrassment results in dyspnea as the lizard attempts to obtain more oxygen. Pneumonia is caused by a variety of aerobic and anaerobic bacteria. Mycotic pneumonia has been seen in reptiles, including lizards, but is often considered a secondary invader.[29] Verminous pneumonia is usually accompanied by bacterial pneumonia. The helminths *Entomelas* spp. and *Rhabdias* spp. are the common lungworms in lizards.[30] Pentastomes, trematodes, and migrating nematode larvae also may cause verminous pneumonia in reptiles. Among lizards, parasites are most common in chameleons and monitors. Aspiration pneumonia may be a sequela of assist feeding and the oral administration of medication by inexperienced persons.

Untreated chronic respiratory tract disease often spreads to other areas, resulting in abscess formation in the oral cavity, periorbital space, and parenchymatous coelomic organs, notably the liver. Any lesion that compromises the opening of the glottis, such as abscesses or neoplasia of the oral cavity, can cause severe dyspnea.

Drowning and near-drowning injuries are more common in aquatic chelonians but may occur in lizards left soaking unattended or through misadventure.

VetBooks.ir

Primary neoplasms of the respiratory tract are rare in reptiles, but metastasis to the lungs may occur.[15]

Pulmonary edema from cardiac or hepatic disease can result in respiratory signs. Space-occupying coelomic lesions, such as ascites or neoplasia, prevent normal lung expansion and cause dyspnea.

Agonal respiration in terminal patients resembles dyspnea.

Open-mouth panting occurs in some lizards as a cooling mechanism during overheating.

Nasal Discharge

Some lizards have sodium-secreting, potassium-secreting, and chloride-secreting nasal salt glands.[29] These allow the lizard to excrete excess salts without losing significant amounts of water. These secretions appear as a clear, liquid nasal discharge that dries to a fine white powder, which may be observed around the nares or on the sides of the cage.

Sinusitis and rhinitis can produce nasal discharge as well. This material varies from clear with bubbles to thick and mucoid. Because of the position of the internal nares anterior in the oropharynx, stomatitis and pneumonia might also result in nasal discharge. Thorough physical examination helps differentiate between the two groups.

Epistaxis and hemoptysis most commonly occur from metastatic mineralization in green iguanas. Iatrogenic hypervitaminosis D and idiopathic causes are associated with marked hypercalcemia. The resulting mineral deposits commonly occur in the smooth muscle of blood vessels, making them abnormally rigid and prone to fracture with minor trauma, such as a short fall or vigorous restraint. When a mineralized vessel in the lungs fractures, marked epistaxis and hemoptysis result, often with fatal results. Metastatic mineralization is easily demonstrated on radiographs. Other causes of epistaxis are rare in lizards but might include necrotizing rhinitis and sinusitis caused by bacteria, mycoplasma, or fungi, acquired coagulopathy from septicemia, nutritional deficiency or liver insufficiency, rodenticide toxicity, neoplasia, and foreign bodies.

Causes of discharges in the oropharynx are discussed in Chapter 76.

Abnormal Vocalizations

Respiratory sounds may be associated with fluid within the respiratory tract as a result of pneumonia, aspiration, or near-drowning. These must be differentiated from hissing and snorting sounds often used as a defensive gesture in response to a perceived threat. Veiled chameleons will often vibrate their entire body along with hissing and gaping as a normal response to a threat, and this should not be confused with illness. Conversely, a lack of sound might be noted in a fully consolidated lung.

OCULAR SIGNS

Palpebral and Spectacle Abnormalities

Reversible, temporary, bilateral periorbital swelling is occasionally seen in some species of lizard because of venous sinus engorgement. This is particularly obvious when the lizard is restrained behind the head and struggles violently. More permanent venous congestion occurs with systemic and localized infection, cardiac disease, renal disease, and vascular abnormalities such as aneurysm.

Subcutaneous cellulitis, abscesses, and palpebral trauma are common around the eye. These usually result from penetrating wounds secondary to escape attempts, fights with cage mates, and burns from heat lamps.

In species with a spectacle, distention of the subspectacular space with clear lacrimal fluid results in a condition known as pseudobuphthalmos and occurs when the nasolacrimal duct is occluded (Fig. 134.10). Nasolacrimal occlusion can result from infection, pressure from surrounding inflamed tissues and mass lesions, fibrosis, or congenital malformation. The subspectacular space also can become distended with caseous debris from a bacterial infection ascending up the nasolacrimal duct or spreading hematogenously. Panophthalmitis must be differentiated from subspectacular abscessation. In the latter condition, the entire globe swells as the interior structures are destroyed by infection originating from wounds or hematogenous spread (see Chapter 71).

FIG 134.10 Pseudobuphthalmos in a rough knob-tailed gecko (*Nephrurus amyae*). The likely cause of this condition is a blockage of the nasolacrimal structures. (Courtesy of Shane Simpson.)

Blepharospasm may result from foreign bodies in the eye, such as sand and other particulate bedding materials. Corneal ulcers also cause blepharospasm and may result from foreign bodies, trauma, or infection with bacteria or viruses. Exposure to excessively strong artificial ultraviolet light sources can cause blepharospasm and keratitis.

Palpebral edema, squamous metaplasia, and photophobia have been associated with iatrogenic hypovitaminosis A in many species and commonly chameleons and leopard geckos.[6,7]

Mites and ticks are occasionally found in the ocular adnexa.

Corneal Abnormalities

Keratitis occurs in reptiles as a result of bacterial or fungal infection. Corneal ulcers may result from trauma, foreign bodies, or infection.

In those species with spectacles, exposure keratitis results from iatrogenic avulsion of the spectacle from improper treatment, perhaps related to misdiagnosis, of retained spectacles.

Leopard geckos occasionally develop a plug of caseous debris covering the cornea. Bacterial conjunctivitis, foreign objects such as sand substrate, chronic hyperthermia from excessive use of heat sources, and hypovitaminosis A may be contributing factors in this presentation.[7] The plug usually can be removed in a single piece with flushing and gentle manipulation. Because the inner surface conforms to the round surface of the cornea, the plug is commonly mistaken for a retained spectacle, but of course this species (Eublepharis means "true eyelids") lacks a spectacle.

Arcus lipoides corneae is a white band of material that may partially or completely surround the cornea near the limbus. This condition is associated with aging and requires no treatment.[14]

Lens Abnormalities

Juvenile cataracts with a postulated genetic etiology have been reported in monitor lizards.[31] Senile cataracts may occur in adult animals. Cataracts in brumating reptiles may sometimes be associated with damage from freezing.[31]

VetBooks.ir

NEUROLOGICAL SIGNS

Convulsions, Twitching, Coma, Ataxia, and Head Tilts

Neurological signs in reptiles usually overlap. A condition that causes ataxia frequently progresses through muscle weakness, twitching, convulsions, coma, and death. Muscle fasciculations, tetany, and convulsions sometimes are difficult to separate. Head tilts occasionally accompany other neurological signs; examples include juvenile bearded dragons infected with atadenovirus and idiopathic cases in other species.

One of the most common pathologic conditions in captive lizards is hypocalcemia resulting from unbalanced diets, lack of ultraviolet light sources, and inadequate environmental temperatures. Chronic NSHP cases may develop hypocalcemia with symptoms of tetany, muscle fasciculations, and eventually coma and death (see Chapter 84). Similar signs may also be seen with renal secondary hyperparathyroidism (RSHP) resulting in metabolic disturbances of calcium and phosphorus in particular. Additionally, dehydration and renal pathology can result in gout, causing incoordination and convulsions.

Xanthomatosis (cholesterol clefts) with lesions in the brain resulting in neurological signs have been reported in geckos and water dragons (*Physignathus cocincinus*).[32,33]

Hypoglycemia may result in convulsions, but this condition is rare in reptiles. A heavy parasite burden can result in weakness, lethargy, coma, and death.

Lizards with septicemia may develop brain abscesses with neurological symptoms including convulsions. Tumors involving the central nervous system of lizards are extremely rare.[15]

Neurological lesions may result from physical trauma, such as a blow to the head or damage from freezing.

Toxicity from a variety of substances may result in convulsions. Possible toxins include insecticides; pharmaceuticals such as metronidazole, ivermectin, and aminoglycoside antibiotics; bufotoxins from consumption of certain toads (e.g., the marine toad, *Rhinella marina)*; firefly and Monarch butterfly toxicoses in bearded dragons; and various chemicals such as paint solvents. Toxic plants are occasionally ingested by herbivorous species, the symptoms of which vary with the species of plant (see Chapter 88).

A rare dietary cause of neurological symptoms is vitamin B complex deficiencies. This condition may be seen in carnivorous reptiles that are fed large amounts of frozen fish or in herbivorous lizards fed large amounts of frozen vegetables. Freezing decreases vitamin levels and increases thiaminase activity, resulting in thiamine (B_1) deficiency. Biotin deficiency has been reported in monitors (*Varanus* spp.) fed raw eggs, which contain avidin, a substance with antibiotin activity.[14,34] Symptoms vary with severity but range from weakness and incoordination, through twitching and torticollis, and finally to convulsions and death. The diagnosis is confirmed with response to supplementation with B complex vitamins or histopathology.

Vitamin E and selenium deficiencies are rarely seen in herbivorous lizards with symptoms of muscle weakness, fasciculations, and convulsions. This condition is diagnosed with clinical improvement after the injection of vitamin E and selenium or muscle biopsy.

Paralysis and Paresis

By far the most common cause of paralysis or paresis is spinal cord lesions from the collapse of one or more vertebrae as a sequela to one of the MBDs. Depending on the site of the lesion, paraplegia or quadriplegia may be present. The onset usually is sudden, and a history of trauma may or may not be present. If the lizard is able to defecate and pass urates, the prognosis is fair; if not, the prognosis for recovery is poor. These signs must be differentiated from, but may accompany, muscle weakness, twitching, and fasciculations. Other causes of paralysis and paresis are rare but include spinal cord lesions from trauma such as vertebral fractures, spinal abscesses, and neoplasia.

BEHAVIORAL SIGNS

Aggression

Aggression is generally divided into offensive and defensive aggression. The former involves unprovoked attacks, and the latter is in response to a real or perceived threat or the defense of territory. Some species of lizards are naturally aggressive and pugnacious, for example, many monitor lizards, tegus (*Tupinambis* spp.), and the veiled chameleon. Acquired aggression can coincide with sexual maturation; the onset of breeding season (especially in male green iguanas); stimulation by the presence of conspecifics or mirror images; the display of throat fans, beards, and dewlaps by conspecifics; and exposure to unfiltered sunlight (especially in monitor lizards, Gila monsters, and beaded lizards [*Heloderma* sp.]).

Reproduction

Gravid females may exhibit behavior changes before egg laying that may be mistaken for illness. They often become anorectic and lethargic with distended abdomens. Other individuals become hyperactive, pacing and digging frantically as oviposition nears.

SYSTEMIC SIGNS

Weight Loss

A common cause of weight loss in captive reptiles is an inadequate intake of calories. Some keepers mistakenly offer meals that are too small or too infrequent for the lizard, and nutrition and husbandry must be investigated thoroughly.

Low environmental temperatures can hinder digestion even when adequate diets are eaten. This is especially true in folivorous iguanid lizards that rely on microbial fermentation in their hindgut to break down the cellulose in their high-fiber diet.

Intestinal parasites, renal failure, neoplasia (such as gastric neuroendocrine carcinoma in bearded dragons)[35] (Fig. 134.11), or any systemic disease can result in rapid weight loss.

Anorexia obviously results in weight loss and was discussed in detail earlier.

FIG 134.11 Neuroendocrine gastric carcinomas, as shown here attached to the gastric lumen of this dragon at necropsy, have been frequently reported in central bearded dragons (*Pogona vitticeps*). Affected animals often develop a persistent hyperglycemia and profound anemia and present with signs of weight loss and anorexia. (Courtesy of Stephen Barten.)

VetBooks.ir

Distended Coelom

Lizards store fat in paired, symmetrical fat bodies in their caudal coelomic cavity. In obese animals, these may be huge and cause a distended coelom. They appear as fat density on radiographs and often are palpable. Fat bodies may be mistaken for mass lesions.

An apparent distended coelom can result from an enlargement of any of the coelomic viscera. The liver and kidneys may become exaggerated with hepatic lipidosis, granulomatous inflammation, or neoplasia. The gastrointestinal tract can become distended with constipation, foreign objects (notably gravel, sand, or other bedding), obstruction, intussusception, or ileus from a spinal cord lesion or profound hypocalcemia. The bladder often becomes grossly distended with urine when denervated by spinal cord lesions related to trauma or one of the MBDs.

Ascites is caused by similar mechanisms in reptiles as in mammals. Hypoproteinemia, liver failure, renal failure, cardiac disease, septicemia, and neoplasia may cause ascites. Coelomic neoplasia can result in enlargement of the coelom.

Uroliths are occasionally seen in herbivorous lizards with dehydration or unbalanced diets (Fig. 134.12). These tend to be singular and stratified and may be large enough to distend the coelom.

Female lizards that are gravid or have egg retention have an enlarged coelom. The ova can be palpated or visualized with radiology and ultrasound.

FIG 134.12 Uroliths in the bladder of a *Uromastyx* sp. secondary to chronic urine retention because of paresis from a thoracic spinal lesion. Without intervention and removal these can get quite large resulting in distension of the coelom. (Courtesy of Stephen Barten.)

Lethargy

Environmental conditions, such as low temperatures, lack of ultraviolet light, lack of a hiding place, and social stress, can cause a lizard to be less active than normal. Lizards that are gravid or about to shed commonly have decreased activity. MBDs, nutritional deficiencies, egg retention, renal failure, infections, septicemia, parasite burdens, toxicity, and just about any illness may result in depression and lack of activity.

Often the owners of lizards with lethargy misdiagnose the etiology as attempted brumation, even in cases involving tropical species and the presence of high temperatures. Overly cool temperatures and short photoperiods must be corrected, but other causes should be investigated.

Polydipsia and Polyurea

Polydipsia and polyurea are uncommon signs in lizards, but chronic renal failure is the most common cause. Causes of renal failure include bacterial infection, granulomatous inflammation, chronic dehydration, and excessive use of aminoglycoside antibiotics. Hyperglycemia is uncommon in lizards and has been associated with neoplasia, septicemia, pancreatitis, and metabolic imbalances. True diabetes mellitus (with response to insulin) has not been documented in lizards. Profound hyperglycemia is usually secondary to other causes and not diabetes melitus[36] (see Chapters 79 and 152).

Acute Mortalities

Symptoms of disease in reptiles often are subtle, and owners commonly miss them. Thus many chronic diseases such as septicemia, malnutrition, renal failure, neoplasia, or gastrointestinal obstruction, for example, may present as sudden death when in fact they were chronic in nature. Sudden death often is an acute manifestation of chronic disease.

Heat stroke from exposure to direct sunlight while a reptile is in an enclosed container or thermostatic malfunction in a heating device can result in sudden death. Victims usually are warm to the touch. Drowning causes sudden death, but the history leaves little doubt as to the cause. Ingestion of certain toxic plants results in relatively rapid death. Several reported cases have been seen where the ingestion of a single firefly caused sudden death in bearded dragons.[37] Atadenovirus may cause sudden death with few or no symptoms in juvenile bearded dragons and other species.

Differential Diagnoses by Clinical Signs—Chelonians

Thomas H. Boyer

ACUTE MORTALITIES

Multiple deaths in a chelonian collection generally indicate infectious disease, environmental failure (e.g., thermostat failure), or intoxication. Common differentials include herpesvirus (Fig. 135.1), intranuclear coccidiosis, adenovirus, entamebiasis,[1] ranavirus, chlamydiosis, reovirus, and paramyxovirus. Indoors, or in a green house, overheating is also a possibility; temperatures above 38° to 43°C (100°–110°F) are rapidly lethal for all chelonians.

DERMATOLOGICAL SIGNS

Cutaneous or Subcutaneous Swelling

Box turtles (*Terrapene* spp.) and occasionally tortoises or aquatic turtles suffer from myiasis caused by *Cistudinomyia (Sarcophaga) cistudinis*. Maggots encyst subcutaneously and breathe through small black-rimmed pores prevalent on the neck, base of the legs, axillary and prefemoral fossae, and sometimes pericloacal area (Fig. 135.2). Swelling associated with joints or feet can indicate articular or periarticular gout; pseudogout or calcinosis circumscripta; joint, bone, or soft tissue infection; foreign bodies; parasites; puncture wounds; fracture; or luxation.[2,3] Aural abscesses are common (Fig. 135.3). Tumors, such as epidermal squamous papillomas, are a rare cause of skin lesions on the feet of aquatic turtles.[2] Bacterial (including mycobacteria) or fungal subcutaneous granulomas are more common. Fibropapillomas, common on green sea turtles (*Chelonia mydas*), are also seen on the other species of sea turtles and are thought to be caused by a herpesvirus (Fig. 135.4). Gas bubble disease can cause large, multifocal, extensive subcutaneous emphysema as a result of supersaturation of water, usually with oxygen.[4,5] Spirochid blood fluke eggs can cause intense granulomatous tissue reactions in many organs, including the skin.[6]

Erythema, petechiae, ecchymoses, purpura, and foul odor of the shell or skin are typically the result of unsanitary conditions (Fig. 135.5). Generally, these signs indicate a bacterial or fungal shell infection. Focal soft areas, palpable under the scutes, may be white to yellow to serosanguinous and indicate osteomyelitis. Shell infections can also result from bite wounds, trauma, calcinosis circumscripta, lack of basking areas, abrasive substrates, or inadequate environmental temperatures. More diffuse shell erythema can also occur with septicemia or starvation. Spirochid blood fluke eggs or granulomas may occlude blood vessels in aquatic turtles and manifest as ulcerative ecchmyotic shell lesions.[6] Chelonians normally have little odor, unless musk glands are expressed under duress.

Erythema

Erythematous skin can indicate septicemia (endotoxins, exotoxins, or hemoprotozoans[2] may cause vascular damage), bacterial dermatitis, burns, or hypervitaminosis A. Many juvenile fresh-water aquatic turtles have reddish aposematic coloration of the plastron, which fades with age and should not be mistaken for erythema (Fig. 135.6).

Aural Abscess (Protrusion of the Tympanic Scale)

Normally the tympanic skin overlying the aural cavity is slightly concave. Aural abscesses cause the skin to bulge outward from solid cellular debris (see Fig. 135.3 and Chapter 92), common in Emydid turtles (especially box turtles and sliders) but less so in tortoises.

Whitish Growth on Skin

Aquatic turtles shed their skin piecemeal, which often remains attached to the turtle, floating around the limbs or body. White growths can also be from scar tissue or fungal, viral, or parasitic infections.

Whitish Areas on Shell

White areas on the shell represent healed shell lesions, exposed healed bone missing scutes, mineral deposits, or ongoing shell infection—bacterial or fungal (see Fig. 7.26A–C versus Fig. 135.5A and B). Chelonian shell is capable of regeneration such that old areas of exposed, devitalized bone and scutes are pushed out by underlying, newly formed scutes and healthy bone. White areas may also be seen in annuli between scutes in rapidly growing turtles and tend to darken with age. Texas tortoises (*Gopherus berlandieri*) are afflicted by superficial whitish scute necrosis that spares the new growth annuli (Fig. 135.7), caused by *Fusarium semitectum*.[7]

Algae Growth on Shell

Green algae often colonize the shell of aquatic turtles, which is generally of little cause for concern. As long as husbandry conditions are adequate, benign neglect or simple periodic scrubbing keeps algae under control. Ultraviolet water filters can eliminate algae in the water.

Sloughing Skin

Chelonians normally shed their skin in a much more piecemeal fashion than squamates, but they still regularly shed. Full-thickness skin sloughing is abnormal and may be associated with iatrogenic hypervitaminosis A (see Chapter 84).[2] Bacterial infection, especially anaerobic bacteria, trauma, starvation, and chemical or thermal burns can also cause skin sloughing. Desert tortoises (*Gopherus agassizii*), kept too damp during hibernation, can develop ulcerative dermatitis from *Aeromonas hydrophila* within deep skin folds.

Sloughing Scutes

Terrestrial chelonians may slough scutes as a result of bacterial or fungal infections brought on by a moist environment or from chronic renal failure.[2] If renal failure is present, bone plates may loosen and ooze azotemic fluid. Ascites may also be present.[2] In tortoises, nutritional deficiencies may cause flaking and sloughing scutes that are secondarily

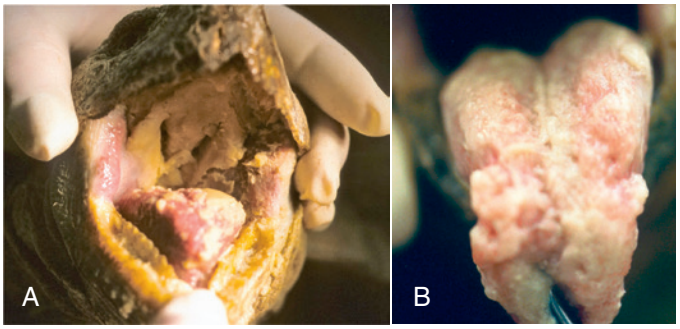

FIG 135.1 (A and B) Multiple deaths in a chelonian collection often indicate viral disease or intranuclear coccidiosis (if husbandry is confirmed as acceptable). This African spurred tortoise (*Centrochelys sulcata*) has classic diptheric plaques due to herpesvirus. (Courtesy of Thomas H. Boyer.)

FIG 135.2 (A and B) Several botfly pores are visible around the base of the neck in this ornate box turtle, *Terrapene ornata ornata*. Multiple larvae usually share one portal. (Courtesy of Thomas H. Boyer.)

infected with bacteria or fungi.[8] Aquatic species normally flake off portions of scutes and shed scutes annually.

Shell Ulceration and Necrosis

Traumatic injuries, such as bites from other turtles, or predators, can penetrate the outer keratin layer of the shell. Burns and bacterial or fungal infections can also lead to ulcers on the shell. In terrestrial chelonians, wet shell necrosis tends to be bacterial, and dry shell necrosis tends to be fungal. Ulcerative shell disease or shell necrosis is a chronic

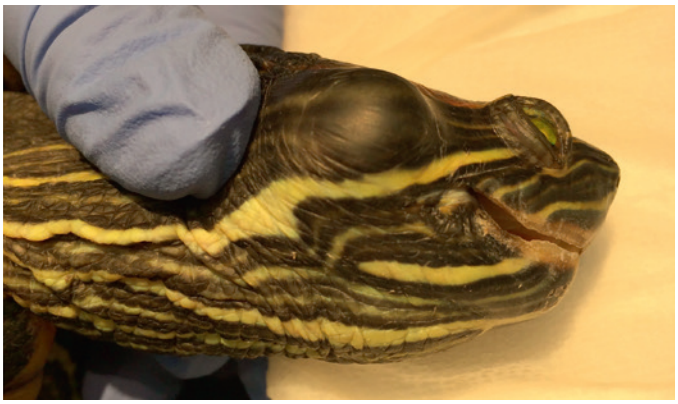

FIG 135.3 Swelling over the tympanic membrane in this slider *(Trachemys)* is generally a sign of an aural abscess; normally the tympanic membrane is slightly concave. (Courtesy of Thomas H. Boyer.)

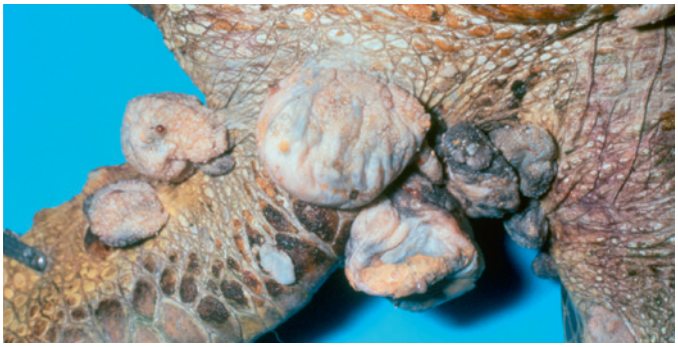

FIG 135.4 Fibropapillomas in sea turtles are thought to be caused by fibropapilloma-associated turtle herpesvirus (FPTHV) spread by marine leeches. (Courtesy of Thomas H. Boyer.)

contagious disease that causes pitting of the shell of aquatic turtles.[9] *Beneckea chitonovora*, a bacteria from shellfish, was thought to be the causative agent.[9] Septicemic cutaneous ulcerative disease causes irregular caseated crateriform ulcers (Fig. 135.8), especially on the ventral surfaces of aquatic turtles such as the softshell turtles.[2] Left untreated, septicemia, hepatic necrosis, paralysis, and death may ensue.[2] The etiologic agent was once thought to be *Citrobacter freundii,* yet poor husbandry and other gram-negative bacteria are undoubtedly involved.[2] Free-ranging desert tortoises can have cutaneous dyskeratosis with a high mortality rate.[10] Lesions commence at the seams and spread toward the middle of the scutes. Lesions are gray-white, sometimes orange, and have a roughened flaky appearance. The plastron is most heavily affected; nutritional deficiency or toxicity is suspected.

Fractures of the Shell

Shell fractures are the result of trauma from dogs, other vertebrate predators, large hoof stock, falls, automobiles, lawnmowers, or boats. Nutritional secondary hyperparathyroidism (NSHP) rarely predisposes to traumatic shell fractures; pathological folding fractures or deformity are more common.

Overgrown Rhamphotheca (Beak) and Toenails

Overgrowth of the rhamphotheca and toenails may indicate an underlying nutritional disease such as NSHP, protein deficiency, or excess. Lack of wear in captivity has been suggested as a cause, yet overgrowth is generally not a problem in captive turtles on balanced diets.[2] Elongated nails (but not rhamphotheca) on the front or rear feet (not both) is a normal secondary sex characteristic in some male chelonians (see Chapter 7).

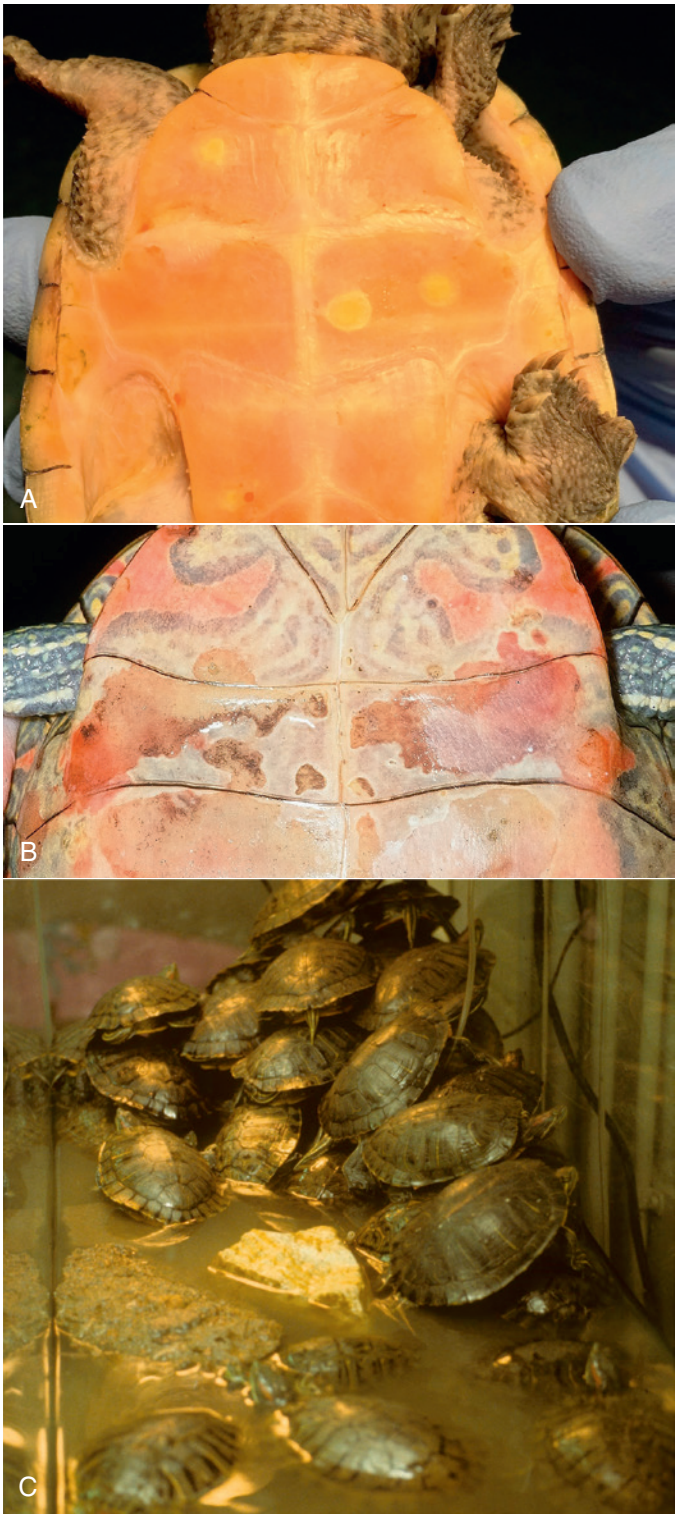

FIG 135.5 Bacterial shell disease (A and B) in aquatic turtles penetrates through the keratin scutes, resulting in osteomyelitis, typically related to unclean water (C). There should be no fluid, discoloration, or soft areas under the scutes of the shell. (Courtesy of Thomas H. Boyer.)

Soft Shell

A soft shell usually indicates NSHP (see Chapter 84), unless evidence of trauma or bacterial or fungal disease is present. Hatchling chelonians on an adequate ration should have a firm shell within the first few years. Shell should feel like solid bone, much like skull, with the exceptions of the few species that normally have soft shells, carapacial fenestrae, or shell kinesis (see Chapter 7).

FIG 135.6 Many aquatic turtles have aposematic coloration ventrally, such as this Mata Mata (*Chelus fimbriata*), that fades as they age. This must not be confused with erythema. (Courtesy of Thomas H. Boyer.)

FIG 135.7 Fusarium infection causing superficial scute necrosis in a Texas tortoise (*Gopherus berlandieri*). (Courtesy of Thomas H. Boyer.)

Distorted Shell

A distorted shell may indicate pathologic fractures and is common with NSHP or healed fractures from previous trauma. NSHP can cause scoliosis of the plastron, lordosis, upturned marginals, increased vertical growth, especially apparent in the bridge area, narrowed or increased shell openings, or lack of shell growth, resulting in a shell that appears too small for the chelonian and often associated penile prolapse. Scute abnormalities can be congenital or the result of various metabolic bone diseases.

Pyramidal Shell Growth

The etiology of pyramidal shell growth remains unknown but is undoubtedly multifactorial. Juvenile tortoises are most often affected.

VetBooks.ir

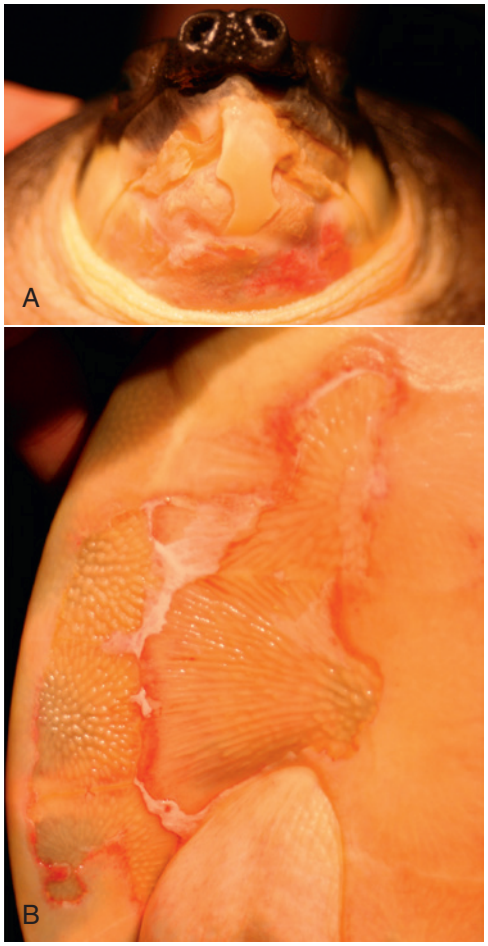

FIG 135.8 Septicemic cutaneous ulcerative disease in a Fly River turtle (*Carettochelys insculpta*). (Courtesy of Thomas H. Boyer.)

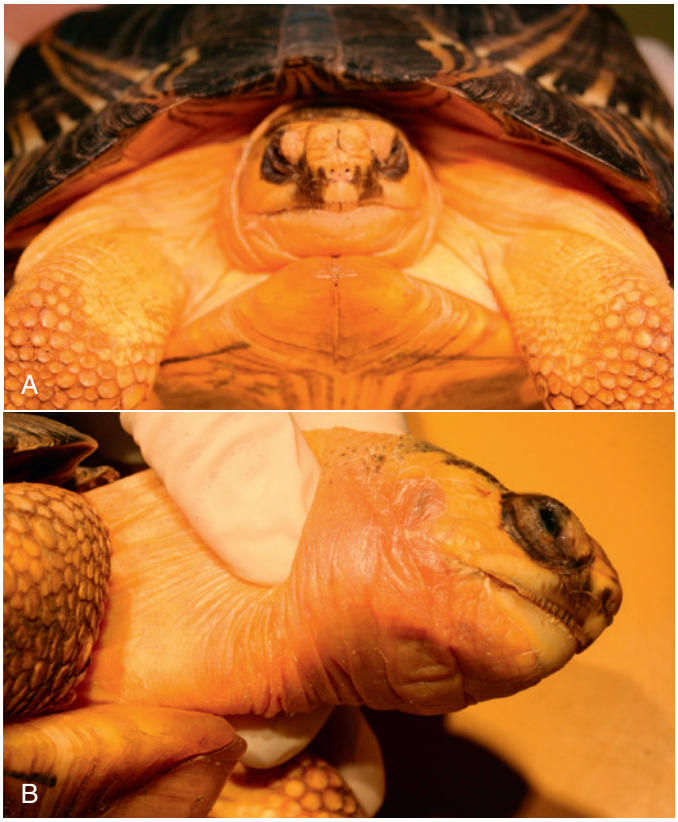

FIG 135.9 Goiter causing myxedema in a radiated tortoise (*Astrochelys radiata*), an unusual manifestation of intranuclear coccidiosis. Goiter is rare in tortoises. (Courtesy of Thomas H. Boyer.)

Suggested etiologies include NSHP, too-rapid growth, low humidity, continuous temperature maintenance (no nighttime temperature drop), and species predisposition but not protein excess.[11–13] For more information, see Chapter 27.

Dermal Fistulas

Trauma or myiasis can cause fistulas in the skin (see Cutaneous or Subcutaneous Swelling and Fig. 135.2A and B). Subcutaneous abscesses can also form fistulas.

Edema or Ascites

Edema can result from liver (e.g., hepatic lipidosis), kidney, or cardiopulmonary disease, from vascular or lymphatic obstruction or hypoproteinemia.[2] Obese chelonians often have excessive lipid deposition in the axial and prefemoral areas that may be confused with edema. Myxedema has been observed in chelonians (Fig. 135.9) with thyroid/thymus dysfunction (see Chapter 79).[2,14]

GASTROINTESTINAL SIGNS

Anorexia

Anorexia is a nonspecific sign of almost all chelonian illnesses. Some common causes include intestinal or colonic foreign bodies or impaction, NSHP, hepatic lipidosis, hypovitaminosis A, pneumonia, renal failure, low environmental temperature, parasites, and viral infections, especially herpesvirus and intranuclear coccidiosis. Acute bacterial infections can cause anorexia. Most chronic bacterial infections result in reduced appetite but not complete anorexia. Winter anorexia is common in wild-caught species that normally hibernate.

Poor Body Condition

Emaciation generally indicates starvation from disease, poor husbandry, chronic mycoplasmosis, intranuclear coccidiosis, parasites, neoplasia, or any other debilitating condition.

Pale Tongue and Mucous Membranes

The oral cavity should normally be pale pink, with the tongue even pinker. Pale mucous membranes (Fig. 135.10) are often the result of anemia of chronic disease (especially poor nutrition), poor peripheral circulation in severely debilitated animals, or blood loss. Note that many chelonians normally have lower PCVs than other reptiles or vertebrates. When interpreting blood normal values, always compare them to reference or observed ranges for that species (or closely related species), if previous results from the same animal/cagemate are not available.

Infectious Stomatitis

Herpesvirus can cause necrotic caseous oropharyngeal stomatitis, glossitis, pharnygitis, and tracheitis (see Figs. 135.1A and B and 135.11, as well as Chapters 30 and 169). (e.g., Russian tortoises, *Agrionemys horsfieldii*) may remain latently infected. Herpes has been reported in a variety of tortoises and turtles; all terrestrial chelonians are considered susceptible. Other than herpesvirus, ranavirus, mycobacterial infections, infectious stomatitis is rare in chelonians.

Moisture or Dried Mucus on Rhamphotheca (Beak)

Any accumulation of material on the beak is abnormal and may signify oral infection (herpesvirus, see Fig. 135.10), pneumonia, regurgitation,

VetBooks.ir

FIG 135.10 Pale mucous membranes in a common snapping turtle *(Chelydra serpentina)*. Oral examination is an essential component of the physical examination. (Courtesy of Thomas H. Boyer.)

FIG 135.11 Sunken eyes (dehydration) and oral mucus discharge (note the grass stuck to the mandible) are suspicious for herpesvirus infection. *Testudo* tortoises may be carriers of herpesvirus. This long-term captive tortoise developed an active herpesvirus infection during hibernation. (Courtesy of Thomas H. Boyer.)

ulceration, irritation from a foreign body,[15] broken jaw, or a cracked, overgrown, or misshapen rhamphotheca (see Overgrown Rhamphotheca [Beak] and Toenails earlier in this chapter).

Constipation

Chelonians typically defecate daily to every few days. Constipation can arise from small intestinal or, more commonly, colonic impactions, as a result of ingested foreign bodies, such as sand, gravel, rocks, cage litter, or yard debris. Fine sand and crushed gravel are of particular concern. Most tortoises often have a few stones in the gastrointestinal tract that pass uneventfully. Cystic calculi, low environmental temperature, and parasites are less common causes of constipation.

Emesis/Regurgitation

Parasites, foreign bodies, septicemia, and adverse drug reactions can cause regurgitation.[12] The author has seen several chelonians that vomited within 30 minutes of administration of enrofloxacin or vitamin A at normal dosages. Differential diagnoses should include causes of vomiting typical for other animals. Ptyalism, oronasal fluid regurgitation, and vomiting are commonly found in tortoises with intestinal/colonic impactions (Fig. 135.12A).[16] Tortoises may also present for acute and repeated emesis after ingestion of toadstools (species not determined; Jarchow JL, personal communication, 2001).

Bloating

Excessive intestinal gas production can result from fermentation of food within the gastrointestinal tract. This condition can result from an abrupt change to protein-rich or carbohydrate-rich foods; force-feeding sick chelonians inappropriate foods (such as dairy products) or excessive volumes to cachexic animals, especially with suboptimal temperatures; or intestinal/colonic obstruction or hypomotility.[2]

Diarrhea

Loose, watery stools can result from various parasites, bacterial or fungal infections, foreign bodies, or food (Fig. 135.13). Foods with a high water content, such as fruits, can cause diarrhea. For tortoises, lack of roughage, especially with indoor housing, often results in more watery stools, typically semiformed, which is not necessarily abnormal.

Mass Protruding From Cloaca

The phallus is the most common mass observed protruding from the cloaca. The phallus is a large pink, purple, or tan mass with a spade-shaped tip (see Fig. 7.32). Males periodically have erections that should be no cause for immediate concern unless necrotic or if it does not retract within several hours. See Chapters 75, 106, and 143 for more details. Differential diagnosis for masses protruding from the cloaca include prolapse of the urinary bladder (Fig. 135.14A), cloaca, colon (see Fig. 135.14B), or oviduct.[2]

Bleeding From Cloaca

Blood passing from the cloaca often indicates a phallus laceration. Differential diagnosis includes gastrointestinal, urogenital, or cloacal bleeding or parasites. Urocystoliths can be passed from the bladder and lodge in the proctodeum.[17] Cloacaliths have been seen in several tortoise species (Fig. 135.15A and B).

Dilated Cloaca

Urocystoliths can be passed from the bladder and lodge in the proctodeum for extended time and either pass on their own or must be physically broken down and extracted. This extended dilation of the proctodeum may result in a permanently dilated cloaca or slow reduction over many months (see Fig. 135.15C and D).

RESPIRATORY SIGNS

Nasal Discharge

Any nasal discharge, wet or dried, is abnormal in chelonians unless associated with drinking or eating watery foods. Pressure applied on the gular area should not elicit any nasal discharge nor should forcing the head posteriorly into the shell (Fig. 135.16A). Several species of *Mycoplasma* cause upper respiratory tract disease in a variety of chelonians[18] (see Chapter 72). All terrestrial chelonians should be considered susceptible. Clinical signs include clear to white discharge or bubbling from the nares, rhinitis, ocular discharge, conjunctivitis, mild palpebral edema, decreased to no appetite, lethargy, and weight loss, without lesions in the mouth. Nasal discharge may be wiped onto the forelimbs and build up (see Fig. 135.16B).

Several other maladies can cause nasal discharge, including herpesvirus (see Figs. 135.1A and B, 135.10, and 135.12B), ranavirus, adenovirus, intranuclear coccidiosis, chlamydiosis, reovirus, paramyxovirus, foreign bodies (see Fig. 135.12C and D), and oronasal fistulas (see Fig. 135.12E). Multiple deaths are common with viruses and intranuclear coccidiosis but atypical for mycoplasmosis. After mycoplasmosis, herpesvirus is the next most common cause of nasal discharge and almost always also

FIG 135.12 Nasal discharge is often the result of mycoplasmosis, but in this case (A) resulted from gastric reflux secondary to colonic foreign body obstruction. The differential diagnoses of nasal discharge also includes herpesvirus (B) (see Fig. 135.1A and B), ranavirus, adenovirus, intranuclear coccidiosis, chlamydiosis, reovirus, paramyxovirus, oral foreign bodies (C, bottle cap; D, blade of grass in choanae), and (E) oronasal fistulas. (Courtesy of Thomas H. Boyer.)

has whitish plaques in the oral cavity (see Chapter 30). Gastric reflux can also cause oronasal discharge (see Fig. 135.12A), and radiography can help exclude colonic obstruction.

Nasal Abnormalities

Chronic upper respiratory tract disease may erode or depigment the nares (Fig. 135.17 and Nasal Discharge section).[15] Chronic upper respiratory tract disease, NSHP in young growing tortoises, and mycobacteriosis may cause the area around the nares to bulge asymmetrically, much like atrophic rhinitis in swine (see Fig. 135.16B).

Dyspnea and Abnormal Breath Sounds

Dyspneic turtles may stretch the neck and gape their mouth with obvious labored breathing (Fig. 135.18) or pump the head and legs. Movement of

FIG 135.13 Diarrhea in a tortoise (A) compared with a normal stool from a tortoise on a high-fiber grass diet (B). (Courtesy of Thomas H. Boyer.)

the head and limbs is a normal part of respiration in most chelonians but becomes more pronounced with dyspnea. Gular pumping is associated with olfaction and is not a sign of dyspnea, although some aquatic turtles supplement respiration by buccopharyngeal pumping (bimodal respiration). Dyspnea or abnormal breath sounds, such as a click or slight whistle, usually indicate a lower respiratory tract infection or glottal/tracheal obstruction. Bacteria, particularly gram-negative bacteria, are the most common culprit. Other causes include fungal, viral, or parasitic disease; aspirated tracheal foreign bodies; or neoplasia, such as a tracheal chondromas.

Uneven Floating

Aquatic turtles normally float level from side-to-side but not front-to-back. As material accumulates in a pneumonic lung, the lung becomes heavier and the turtle lists (Fig. 135.19).[2] Any unilateral mass, such as an abscess, tumor, cystourolith, intestinal/colonic foreign bodies, or asymmetrical gas production, as with bloating, can cause similar signs.

Inability to Submerge

Emaciation, pneumonia, tumors, or gas accumulation within the coelom or gastrointestinal tract (from infection, trauma, or obstruction) may cause aquatic turtles to lose the ability to submerge. This is a common problem in sea turtles.

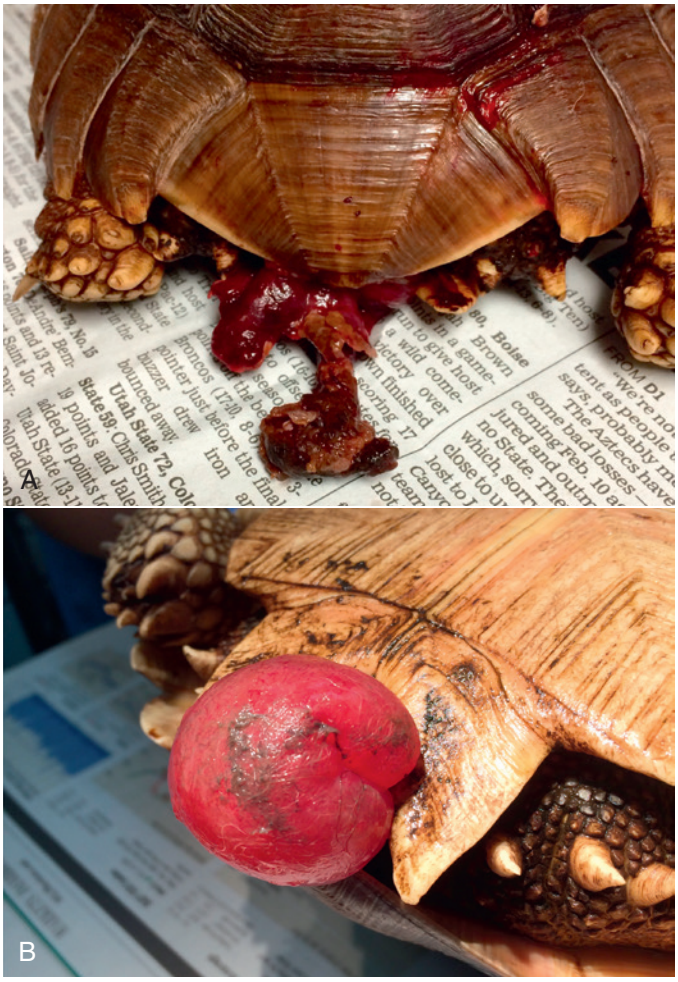

FIG 135.14 Prolapsed bladder (A) and colon (B) in African spurred tortoises (*Centrochelys sulcata*). (Courtesy of Thomas H. Boyer.)

REPRODUCTIVE SIGNS

Phallus Prolapse or Mass Protruding From Cloaca

See Mass Protruding from Cloaca earlier in this chapter (and Chapters 75 and 143).

Failure to Lay Eggs

Nutritional factors or improper husbandry (e.g., stressors, lack of nesting site) should be considered primary to all reproductive failures. Chelonians often fail to lay eggs because of NSHP, hypovitaminosis A, hypocalcemia, dehydration, or lack of an appropriate nesting area. Indoors, females may be reluctant to lay eggs if the substrate is not deep enough (should be twice the length of the carapace). A ruptured, large, or anomalous egg (Fig. 135.20); oviductal rupture; infection; or any mass impinging on the oviduct, such as a urolith, fecalith, or colonic foreign bodies, can also lead to egg retention.[2] Eggs may also become ectopically located in the urinary bladder, coelom, or colon, or lodged in the pelvis. See Chapter 80 for more details.

Mass in Coelom

The differential diagnoses for coelomic masses include ova, eggs, cystic calculi, intestinal or colonic foreign bodies, neoplasia, and abscesses.

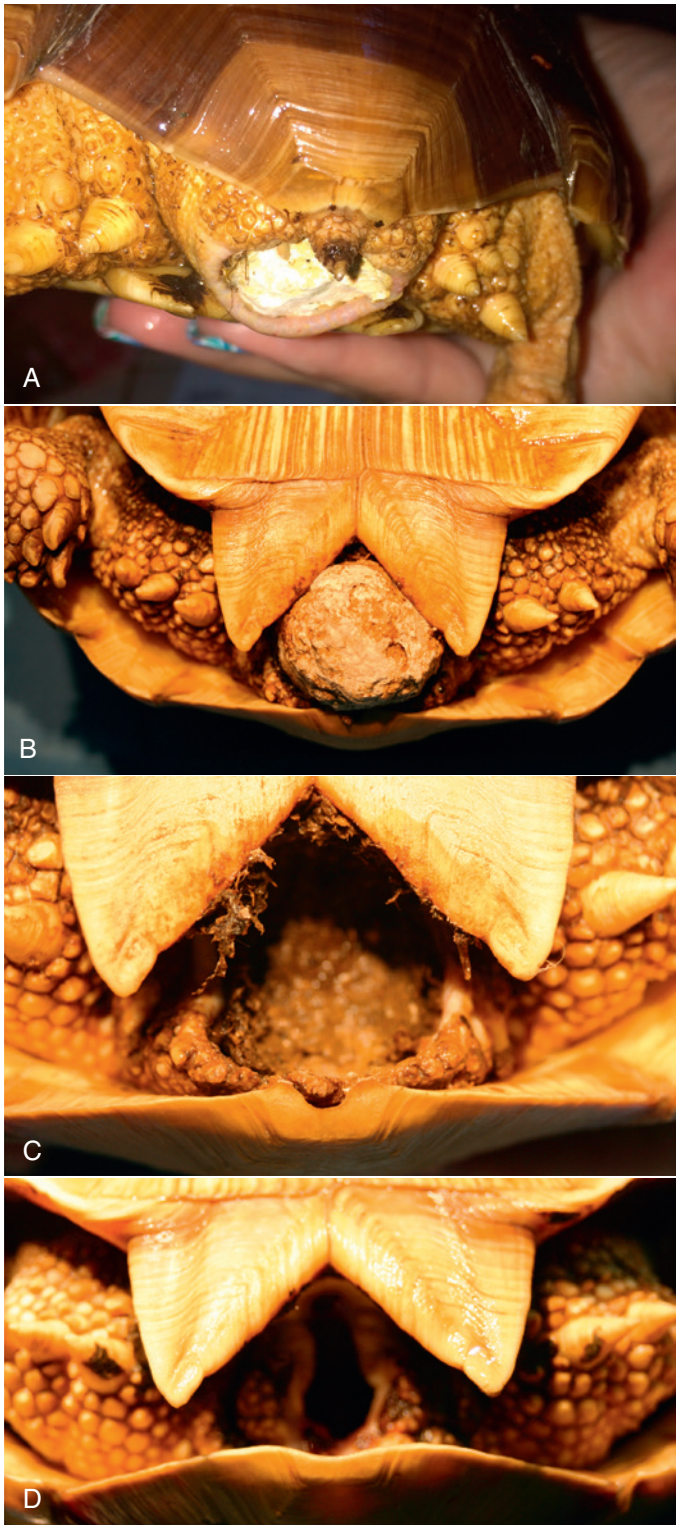

FIG 135.15 Cloacaliths (A and B) can cause constipation and cloacal dilation. In this African spurred tortoise (*Centrochelys sulcata*), note (C) the dilated cloaca and impacted feces immediately after removal and (D) persistent dilation more than a month later. (Courtesy of Thomas H. Boyer.)

FIG 135.16 Nasal discharge, often a sign of mycoplasmosis, should always be considered abnormal in chelonians (A); note how this tortoise is wiping nasal discharge onto the front right leg (B). (Courtesy of Thomas H. Boyer.)

MUSCULOSKELETAL SIGNS

Lameness

Lameness can result from abscesses, bite wounds, foreign bodies, fractures, osteomyelitis, luxations (Fig. 135.21), trauma, gout, pseudogout, or sepsis and, in females, as a short-term sequela to egg laying and imbalances in calcium homeostasis. Egg retention, cystic calculi, cloacaliths, or constipation can contribute to lameness. One should always consider nutritional or renal secondary hyperparathyroidism as a potential cause of lameness. Large breeding males can traumatize a limb from abruptly dismounting a female.

Asymmetrical Toenail Wear

Uneven wear of the toenails may be associated with lameness in terrestrial species.[15] Be aware of normal secondary sex characteristics (see Sexual Dimorphism in Chapter 7).

Swollen Joints

Joint swelling can result from nutritional disorders, infection, luxation, fracture, articular or periarticular gout, pseudogout, or calcinosis circumscripts.[2,3]

Swollen Long Bones

Long bone swelling can result from healed or healing fractures, neoplasia, osteomyelitis, or fibrous osteodystrophy. Fibrous osteodystrophy, so common in lizards with NSHP, is rare in chelonians.

FIG 135.17 Erosion of the nares (A) and bulbous distortion of the nares (B) in desert tortoises (*Gopherus* spp.) with chronic mycoplasmosis. (Courtesy of Thomas H. Boyer.)

FIG 135.18 Open-mouthed breathing as seen in this red eared slider (*Trachemys scripta elegans*) is abnormal in chelonians and often indicates lower respiratory tract disease if no oronasal symptoms are present. (Courtesy of Thomas H. Boyer.)

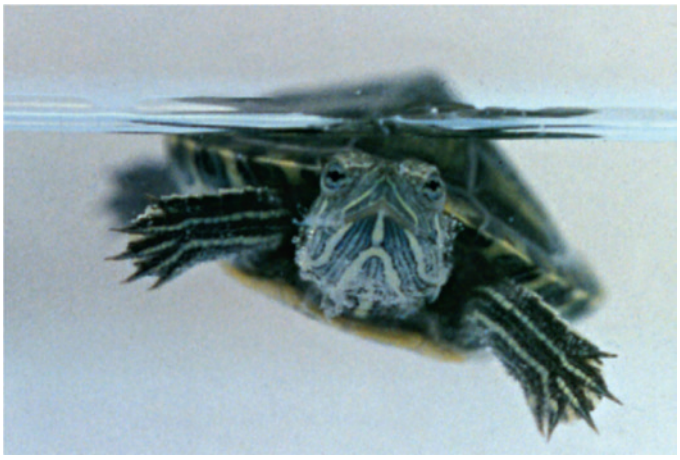

FIG 135.19 Listing laterally is often a sign of pneumonia in aquatic turtles; any unilateral mass or gas production can also cause turtles to list. (Courtesy of Thomas H. Boyer.)

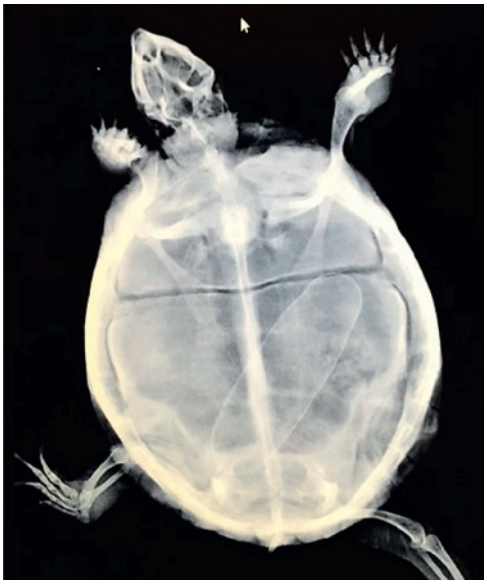

FIG 135.20 Ruptured, or large and anomalous eggs as noted in this radiograph of a box turtle (*Terrapene* sp.) are one of many potential causes of failure to lay. (Courtesy of Brian Loudis.)

FIG 135.21 Coxofemoral luxation in a Burmese black giant tortoise (*Manouria emys phayrei*), which caused unilateral left rear limb lameness and responded well to femoral head removal. Radiographs, preferably under anesthesia to allow full leg extension, are important to determine the cause of lameness in chelonians. (Courtesy of Thomas H. Boyer.)

VetBooks.ir

Temporal Muscle Atrophy

The temporal muscles are normally prominent with no visible occipital crest. Poor body condition may cause noticeable atrophy of the temporal muscles.[15,19]

NEUROLOGICAL SIGNS

Ataxia/Hypermetric Gait

Severe ataxia and a hypermetic gait have been observed in desert tortoises after episodes of hyperthermia, near-drowning, or joint luxation. Cerebellar injury may be present perhaps as a result of hypoxia, cerebral edema, or encephalitis. Toxin exposure, including the iatrogenic use of ivermectin or organophosphates in mite and tick sprays or the ingestion of toxins such as heavy metals, may also cause neurological signs.

Circling

Circling can be a sequela to freezing during hibernation (see Blindness), toxemia, septicemia, encephalitis, central nervous system damage, or hepatic encephalopathy.[20]

Flaccid Paresis, Paralysis, or Coma

A comatose turtle could have severe systemic illness, such as septicemia, organ failure, end-stage starvation, or be dead. Other less common causes include toxicity to ivermectin, Rhododendrons or other substances, shock, drowning, asphyxiation, hyperthermia, or bloat.[4] If it is uncertain whether the chelonian is still alive, check for a heart beat or pulse with a Doppler ultrasound, echocardiography, or electrocardiogram.

Hind-Limb Paresis

Chelonians can present with hind-limb paresis from the same causes as lameness, as well as from spinal cord damage.

OCULAR SIGNS

Blindness

Blindness has been reported in *Testudo* spp. after freezing and may be associated with hyphema, vitreal haze, lenticular opacities, and retinal damage.[20] Additional symptoms include anorexia, head tilt, circling, or holding the head high. Blindness from other causes is possible but not commonly seen.

Palpebra Edema

Palpebra edema may indicate hypovitaminosis A. Emaciated or dehydrated turtles, such as with herpesvirus infection, also tend to keep their eyes shut, but the globe is more sunken. The differential diagnosis can include trauma, foreign bodies, bacterial or viral infection (often with concurrent respiratory disease), parasites, or metabolic disturbances.[2] Box turtles may hold one eye shut due to aural abscess that may, or may not, be advanced enough to cause tympanic swelling. Ulcers, panophthalmitis, or fire ant stings can also cause blepharospasm.

Exophthalmia

Unilateral exophthalmia may result from retrobulbar abscess, tumor, or injury. Bilateral exophthalmia may result from vascular obstruction or generalized edema.[15] See Palpebra Edema section as well.

Enophthalmia

Bilateral enophthalmia (sunken eyes) can indicate microphthalmia; thiamine deficiency, especially with a diet of frozen fish rich in thiaminases[2]; emaciation or dehydration due to a myriad of chronic conditions, including herpesvirus infection (see Figs. 135.11 and 135.12B); or circulatory collapse (hypotension) in septic or debilitated chelonians. The eyes often sink into the orbit before death. Unilateral enophthalmia may result from orbital injury (particularly automobile trauma) or phthisis bulbi.[15]

Conjunctivitis and Ocular Discharge

Discharge from the eyes can accompany upper respiratory tract disease (see Nasal Discharge section under Respiratory Signs), ocular irritants, and hypovitaminosis A.[2] Sea turtles, red foot (*Chelonoidis carbonaria*), and yellow foot (*C. denticulata*) tortoises normally have a clear ocular discharge because they lack lacrimal ducts.

Differential Diagnoses by Clinical Signs—Crocodilians

Javier G. Nevarez

STRESS AND IMMUNOSUPPRESSION

Stress and immunosuppression are often underlying factors for many diseases affecting captive crocodilians. Stress has been defined as "a physiological answer to a perceived threat that includes, but is not restricted to, increased adrenal secretion."[1] Stress is also thought of as any event that challenges homeostasis, and likely the response to that challenge involves more than an adrenal response. The autonomic nervous system, the hypothalamic adrenal axis, neuropeptides, neurotransmitters, and neuroimmunologic mediators all have a role in the response of the immune system to stress.[2] Studies in crocodilians have evaluated the stress associated with restraint, long-term corticosterone implants, cold shock, and stocking densities.[3–6] Lance et al. provide an overview of the physiology and endocrinology of stress in crocodilians.[7] Catecholamines, glucocorticoids, glucose, and lactate have been implicated in the stress response of crocodilians. In addition, an argument is made for immunosuppression on the basis of changes observed in the white blood cells.[3–5,7] Factors that influence stress in crocodilian and reptile species are reviewed by Rooney and Guillette.[1] Enough evidence exists to suggest that stress plays an important role in the physiology of crocodilians, and it may indeed predispose them to illness. Overcrowding, handling, excessive noise, diet changes, water and air quality, temperature irregularities, and more should all be considered as predisposing or confounding factors of disease.

SYSTEMIC SIGNS

Anorexia, Lethargy, and Acute Mortalities

The first signs of illness in captive crocodilians are usually nonspecific in nature. These include anorexia, lethargy, and death. In commercial operations, the workers may notice excess food remaining from the day before, which is sometimes followed by a perceived change in the behavior of the animals. One should not underestimate these observations because most workers are well tuned to the daily routine and behavior of the animals. A visit to the ranch or farm should be performed during feeding time to avoid additional stress to the animals. This also allows observation of the feeding and water change practices. At this time, a thorough history and a collection of animals for diagnostics and necropsy can be obtained. In addition to routine samples, tissues should be frozen for possible bacterial, fungal, or viral cultures.

The list of differentials for nonspecific clinical signs must be narrowed after diagnostic results are obtained. However, one must remember that husbandry and disease go hand in hand. Most systemic diseases of captive crocodilians are thought to be secondary in nature. Bacterial and fungal diseases are commonly encountered. The majority of data available on bacterial disease in crocodilians are from studies involving the American alligator (*Alligator mississippiensis*). Table 136.1 presents a large number of isolates from diseased and nondiseased animals, including a survey of fecal coliforms.[8] Huchzermeyer et al. also have extensive data on enteric bacterial and fungal isolates from African Dwarf Crocodiles (Osteolaemus tetraspis).[9] Important bacterial infections reported in crocodilians include *Mycoplasma alligatoris,*[10] *Mycoplasma crocodyli,*[11] and *Chlamydia* spp.

Fungal organisms are often opportunistic invaders of the integument and respiratory system, but primary fungal infections are also reported. Viral diseases are likely underdiagnosed in reptile medicine because of the challenges in diagnostic techniques and scarce information. Poxvirus, West Nile virus (WNV), and herpesvirus have been reported as pathogens in crocodilians. An adenovirus-like infection in captive Nile Crocodiles (*Crocodylus niloticus*) has also been reported.[12] Coronavirus, influenza C virus, and paramyxovirus have been identified with transmission electron microscope in the feces of crocodilians, but their significance remains to be determined. Finally, evidence exists of seroconversion to paramyxovirus and eastern equine encephalitis virus in crocodilians.[13]

Toxicities are not common in captive crocodilians. Lead toxicity is reported from alligators fed lead-shot nutria. Clinical signs include weakness, lethargy, anorexia, and death. Feeding of nutria is no longer common practice.

For privately owned and zoo animals, there are additional differentials to be considered. A faulty or broken heater can lead to sudden death from electrocution. This can also present a risk for humans, therefore, it is important to isolate, protect, and inspect all equipment within the enclosure. A thermostat malfunction can lead to altered water temperatures that can affect the animal's behavior. In colder climates, animals may become lethargic if the heater is not working properly. Conversely, if a thermostat fails, allowing the heater to remain on, the animals' behavior may change because of increased temperatures. At first they may appear agitated but eventually anorexia and lethargy will occur if overheated. Overheating may also occur as a result of inappropriately sized or placed heat lamps.

Foreign bodies should be a differential for anorexic crocodilians, especially those in outdoor exhibits where trash, coins, and other objects may be tossed in by the public. It is also important to pick up and secure all tools such as buckets and hoses, which may also be ingested by animals.

Physiological anorexia can be observed as part of the normal reproductive cycle, in particular during the later stages of egg development. However, dystocia (egg binding) can lead to a more prolonged anorexia that may be the first indication that the animal is ill. Unless the actual mating date is known or the reproductive cycle is monitored by ultrasonography, it can be very difficult to ascertain what constitutes true dystocia. In animals housed outdoors in their natural climate, dystocia should be considered if oviposition has not occurred for 30 days past the expected date. For those housed indoors or outside their

Pseudomonas cepacia	Oral cavity[53]	No
Pseudomonas diminuta	Water[53]	No
Pseudomonas fluorescens	Water[53]	No
Pseudomonas pickettii	Oral cavity[53]	No
Pseudomonas vesicularis	Water[53]	No
Pseudomonas sp.	Lungs, pharynx[50]	Yes
	Water[53]	No
Salmonella typhimurium	Gastrointestinal tract[50]	Yes
Salmonella braenderup, anatum Arizona spp.	Cloaca[50]	No
Salmonella sp. *(subgroup III)*	Lung[57]	Yes
Serratia marcescens	Skin[55]	Yes
	Cloaca[8]	No
Serratia odorifera	Oral cavity[53]	No
Staphylococcus aureus	Lungs[56]	Yes
Staphylococcus cohnii	Blood[34]	Yes
Streptococcus sp., *hemolytic*	Lungs[10]	Yes
Vibrio parahaemolyticus	Blood[34]	Yes
Vibrio cholerae, putative	Cloaca[8]	No
Vibrio fluvialis	Cloaca[8]	No

natural climate, behavior together with plasma biochemistry, hematology, and diagnostic imaging can be used to aid in the diagnosis of dystocia.

Secondary nutritional hyperparathyroidism can also cause animals to be lethargic and anorexic. This is more common in juvenile animals. Older animals may succumb to secondary renal hyperparathyroidism.

Poor Growth and Runting

Another phenomenon seen in captive crocodilian operations is runting, the lack of growth and failure to thrive of some animals within a group. In some operations, animals are separated by size and some buildings contain only the runts. A clear size difference is observed in same-age animals between the runts and the otherwise healthy ones. These animals

VetBooks.ir

are not as hardy in the captive environment and are potentially more susceptible to disease. Dominance by other animals, environment, and even incubation factors[14] contribute to the presence of runts.

DERMATOLOGICAL SIGNS

Integumentary disease is often secondary to poor water quality, poor enclosure design, stress, and immunosuppression or a combination of these factors. Lacerations, abscesses, and draining tracts can all be observed in captive and wild crocodilians. Consequently, these open wounds can serve as a nidus for bacteria and fungi. An additional factor in commercial operations or small enclosures is the accumulation of a fatty slime layer on the surface of the water when meat supplements, in particular chicken, are fed in addition to a dry commercial diet. This slime attaches to the skin of the animals and the enclosure, creating an environment for bacterial and fungal growth. The same is true for accumulation of biofilm on the surface of the enclosure. A soap or detergent can be used as a surfactant to help reduce the fatty layer on the water surface. Any product used must be nontoxic, or the animals must be removed from the enclosure while in use. Fungal dermatitis is also common because many fungi thrive in the water column and environment of captive alligators. In most instances, both bacteria and fungi are present in skin lesions. Culture and sensitivity testing can be frustrating in these cases because of the mixed flora found in the lesions. The first step in addressing integumentary abnormalities is to analyze water quality and make improvements as needed. In addition to improvements in water quality, antimicrobial or antifungal therapy may be necessary. Medicating a large group of crocodilians is challenging because it must usually be done orally by mixing the medication with feed. In zoos or private collections, individual crocodilians can be medicated by injecting the prey item or via injection. A pole syringe can be used in large or aggressive animals. There is a lack of pharmacokinetic data for oral antimicrobials in crocodilians, and it has been shown that oral tetracycline is not effectively absorbed in American alligators.[15] These factors pose a challenge for effective treatment and the potential for promoting antimicrobial resistance. Therefore a combination of good hygiene, water treatments with disinfectants, and improved husbandry is recommended.

A number of parasites are known to affect the skin of crocodilians. *Paratrichosoma* spp. are capillaroid parasites that cause a zigzag lesion on the skin. These lesions appear to be purely cosmetic. This parasite is known to affect various crocodile species in the wild and is believed to have a stage of its lifecycle dependent on soil; therefore, it is not observed in captive scenarios where animals are kept on concrete.[13] Regardless of the etiology, good hygiene is essential in the prevention and treatment of integumentary disease in crocodilians. The etiology itself is at times not as important as what conditions predisposed them to the disease. A herpesvirus was identified via TEM from saltwater crocodiles *(Crocodylus porosus)* with concurrent pox virus and bacterial infection of the skin.[46]

Dermatophilosis (Brown Spot Disease)

Dermatophilosis causes brown-red to ulcerative lesions most commonly located between scales on the ventral skin (Fig. 136.1). Most of the cultures appear to resemble *Dermatophilus congolensis.*[16,17] These filamentous bacteria do not respond well to antibiotic therapy; therefore, intensive hygiene practices are necessary to prevent and control outbreaks.

Pox Virus

Parapoxvirus or poxlike viruses have been identified in five different crocodilian species: Spectacled caiman (*Caiman crocodilus fuscus*),[18,19] Brazilian caiman (*Caiman crocodilus yacare*),[20] Nile crocodile,[21,22] saltwater crocodile (*Crocodylus porosus*),[23] and freshwater crocodile (*Crocodylus johnstoni*).[23] In caimans, poxvirus is characterized by 1- to 3-mm-diameter, gray to white, coalescing to macular skin lesions. These can be found on the head, palpebrae, maxilla, mandible, limbs, palate, tongue, and gingiva.[18–20] Other signs observed include palpebral and generalized edema. Resolution of clinical signs was observed 6 weeks after improvement of husbandry in one case[19] and after 5 months in another case, with no changes in husbandry.[20]

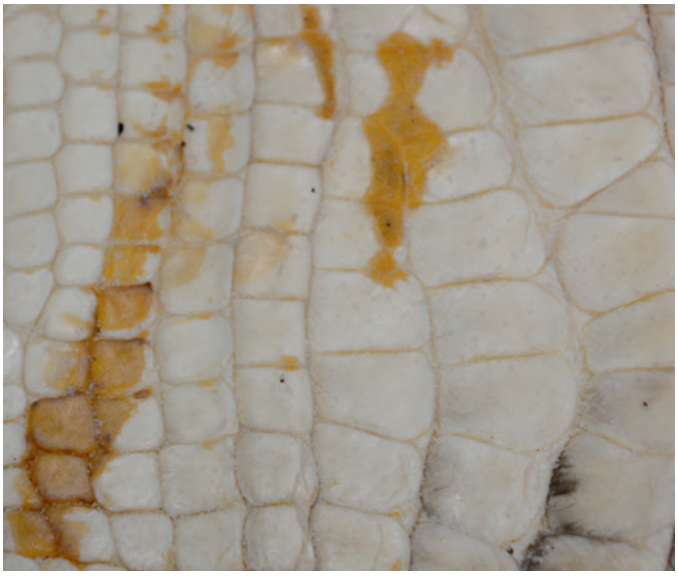

FIG 136.1 Brown lesions typical of dermatophilosis on the ventral skin of an American alligator (*A. mississippiensis*). Lesions usually arise at the junction of the scales and then spread outward. (Courtesy of Javier G. Nevarez.)

Lesions in crocodiles are described as 2- to 8-mm-diameter, yellow to brown, wartlike, sometimes firm, and unraised to raised nodules with occasional shallow ulcers. These lesions can be found on the head, palpebrae, nostrils, sides of the mouth, oral cavity, limbs, ventral neck, and coelom and at the root of the tail.[21,22] Resolution of lesions was reported to occur as early as 3 to 4 weeks.[21] Light microscopy reveals epithelial hyperplasia, acanthosis, hyperkeratosis, and necrosis, and at times Borrel and Bollinger's bodies are also visible.[18–22] Secondary bacterial and fungal infections may also be present. Horner reported the use of an autogenous vaccine to treat poxvirus in Nile crocodiles.[21] No specific treatment recommendations exist. Maintaining appropriate husbandry is essential in the prevention and resolution of poxvirus in crocodilian farms.

West Nile Virus

West Nile virus (WNV) has been reported to cause lymphohistiocytic proliferative syndrome of alligators (LPSA).[24,25] LPSA skin lesions are a chronic manifestation of WNV infection and occur in animals that have survived a WNV outbreak.[25] This production problem affects the quality of the hide and consequently decreases profit for alligator ranchers. Gross lesions can be seen as multifocal, 1 mm to 2 mm, gray to red foci on the ventral mandibular, abdominal, and sometimes tail scales (Fig. 136.2). They can be found on any section of a scale and do not appear concave or convex with respect to the scale's surface. Routine microscopic examination reveals dermal nodular lymphoid proliferation with perivascular cuffing. Similar lesions can be found in other tissues besides the skin. Identification of the lesions is complicated by the fact they are sometimes not seen until the hides are removed from the animal. Therefore antemortem identification alone is not very accurate.

VetBooks.ir

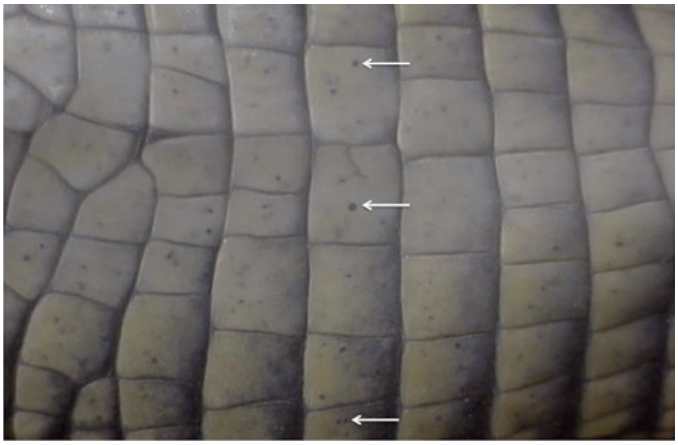

FIG 136.2 Gross lesions (arrows) of lymphohistiocytic proliferative syndrome of alligators on the ventral skin of an American alligator (*A. mississippiensis*). Lesions appear in animals that survived WNV infection. There are over 50 lesions in this image. (Courtesy of Javier G. Nevarez.)

FIG 136.3 Young alligator (*Alligator mississippiensis*) with the head tilt typical of those affected with West Nile virus. Notice that it still maintains an aggressive stand with the mouth open.

NEUROLOGICAL SIGNS

Neurological deficits are not commonly seen in crocodilians and deserve special attention if encountered. Clinical signs may include swimming in circles or on one side of the body, abnormal flotation, lethargy, ataxia, head tilt, and muscle tremors. Anorexia often accompanies the neurological signs. Thiamine deficiencies should be considered in animals fed a frozen fish diet. Signs of thiamine deficiency typically include severe lethargy that leads to coma.

Hypoglycemia has also been reported as a cause of neurological signs in alligators.[26] These animals have muscle tremors, loss of the righting reflex, and mydriasis. Stress seems to be the main contributing factor. The author has also observed neurological signs associated with low oxygen levels inside alligator enclosures. Neurological signs may also be observed after ingestion of metal foreign bodies, including coins, containing lead or zinc.

West Nile Virus

West Nile virus causes neurological signs in captive-reared American alligators raised indoors.[27,28] Presence of antibodies, but no clinical signs, is reported from free-ranging and captive crocodilians housed outdoors.[29,30] WNV in crocodilians is transmitted by mosquitoes and horizontally via fecal shedding. This represents an opportunity for zoonosis in captive operations. Strict building quarantine and hygiene strategies should be implemented to prevent spread to other animals in the facility. WNV is a reportable disease, and one should contact the state veterinarian when diagnosis is confirmed.

WNV can affect an animal of any age, but hatchlings often experience severe per-acute mortalities of up to 50% to 60%.[28] WNV has two disease stages in alligators, acute and chronic. Clinical signs during the acute stage include swimming in circles, head tilt (Fig. 136.3), muscle tremors, weakness, lethargy, anorexia, and death. Animals that survive the acute infection go on to develop LPSA skin lesions, the chronic stage of WNV. There is no treatment. Definitive diagnosis is accomplished with reverse transcriptase polymerase chain reaction (RT-PCR) of liver and brain. However, it must be noted that RT-PCR can detect viral RNA from a commercially available WNV vaccine for alligators (BIVI, St. Joseph, MO). Therefore vaccine status must be known before diagnosis. Maternal transfer of antibodies has also been observed in hatchlings.[31] Veterinarians should take additional precautions during necropsies of suspect animals. Aggressive mosquito control and vaccination have proven extremely effective at controlling WNV infection in commercial operations.

RESPIRATORY SIGNS

This is one of the most common presentations of captive crocodilians, second only to integumentary disease. Respiratory signs can often be confused with neurological signs, and a clear distinction must be established. However, respiratory disease may accompany neurological disease as a consequence of weakness leading to aspiration. Clinical signs associated with respiratory disease in crocodilians may include dyspnea, tachypnea, nasal discharge, excessive basking, abnormal swimming (either in circles or on one side of the body), and anorexia, among others. As the animals become weak, the basihyoid valve does not function properly and they can aspirate food or water. The pharyngeal anatomy of crocodilians makes aspiration unlikely in healthy animals. Therefore, if aspiration is suspected, evaluation for an underlying illness should be pursued. A number of rhinitis and pharyngitis syndromes have also been described in some crocodilian species.[13] Most respiratory infections are either bacterial or fungal in origin. An early report showed a fungal pneumonia associated with *Beauveria bassiana* in two alligators,[32] and *Fusarium moniliforme* was found in another case.[33]

Mycoplasmosis

One well-documented respiratory pathogen is *Mycoplasma alligatoris.* Clinical signs are nonspecific and include lethargy, weakness, anorexia, white ocular discharge, paresis, and edema (facial, periocular, cervical, limbs).[10] Pneumonia, pericarditis, and polyarthritis are often diagnosed on necropsy. Pathogenicity of *M. alligatoris* has been documented for *A. mississippiensis* and for the broad-nosed caiman (*Caiman latirostris*).[34,35] Other crocodilian species closely related to alligators are also potentially susceptible. Helmick et al. reviewed antimicrobial susceptibility for *M. alligatoris.*[36] A second *Mycoplasma* species, *M. crocodyli,* is known to affect Nile crocodiles.[11] Lesions are similar to those observed with *M. alligatoris.* Some studies have examined the use of an autogenous vaccine for *M. crocodyli,* but work is still needed to determine its true efficacy.[37,38] Currently antemortem diagnosis is difficult and requires a combination of serology and tissue biopsy for PCR. Therefore most cases are confirmed via histopathology and PCR postmortem.

VetBooks.ir

Mycobacteriosis

Although not commonly reported from crocodilians, the author has worked on a number of alligator cases with acid-fast organisms consistent with *Mycobacterium* sp. in the lungs. These animals had evidence of pneumonia on necropsy as shown by multiple white foci, 1 to 4 mm in diameter, on the lung parenchyma. Other cases of pulmonary and enteric mycobacterial infections have been suggested.[39] Difficulties of growing *Mycobacterium* sp. make its definitive diagnosis a challenge.

MUSCULOSKELETAL SIGNS

Musculoskeletal disease can be the result of alterations in the incubation temperature or environment (Fig. 136.4) or trauma from fighting (Figs. 136.5), transport, restraint, neoplasia, or secondary to nutritional disease.

FIG 136.4 Congenital abnormality in an American alligator (*Alligator mississippiensis*). This animal was hatched with this deformity and is able to eat and thrive among others in the group.

FIG 136.5 Mandibular fracture in a wild alligator *(A. mississippiensis)*. This type of lesion is not uncommon in wild animals, particulary in males during breeding season.

Limb fractures and partial amputations can be seen after altercations. It is possible for animals that have lost limbs after a fight to survive to the point of complete healing (Fig. 136.6). These lesions however may also lead to nerve or muscle damage and consequent paresis or paralysis. As mentioned in the respiratory signs section, *M. alligatoris* and *M. crocodyli* cause polyarthritis, which can be evident antemortem.

Nutritional secondary hyperparathyroidism can occur in young crocodilians not being fed whole prey or pelleted diets. Affected animals may also be runts of the group and have concurrent disease. The innate requirement of ultraviolet B light for the production of vitamin D_3 in crocodilians is not known. They appear to be able to obtain appropriate levels from their diet, but further research in this area is needed.

Gout also occurs in crocodilians (Figs. 136.7A and B). Clinical signs can be nonspecific in nature, but limb paresis/paralysis and joint enlargement may be observed. A case of gout with concurrent suspected hypovitaminosis A in crocodile hatchlings has been reported.[40]

Deficiencies of vitamins A, B, C, or E can also lead to a variety of musculoskeletal disorders. These are not commonly seen when commercial diets are fed in addition to meat products.

GASTROINTESTINAL SIGNS

Anorexia is likely the most common clinical sign associated with gastrointestinal disease in captive crocodilians. Foreign body ingestion, gastric ulcers, enteritis (Fig. 136.8), and trauma to the oral cavity can be observed in crocodilians. Ingestion of foreign bodies is more common in wild crocodilians. However, it must also be a differential in captive specimens. Malfunction of water pumps, water filters, or construction can lead to the presence of foreign bodies in the enclosures. In outdoor exhibits, the public is often responsible for the presence of foreign objects that are thrown into their enclosures. These can then be ingested by the animals and cause severe problems in the case of nails and other sharp objects (Fig. 136.9).

Infectious enteritis may be difficult to assess grossly because crocodilians have very thick intestinal walls normally. However, crocodilians appear to have a characteristic response to insult of the gastrointestinal tract. Accumulations of fibrous material or necrotizing lesions are commonly seen on necropsy (Fig. 136.10A and B). This reaction is aggressive and can even lead to obstructions caused by the fibrous material. Obstruction can also occur with fecal impactions and torsions. Gastric ulcerations and abnormalities of the gastric mucosa are also routinely observed on necropsy and may be associated with stress and diet. Finally, the intestinal tract contains a large amount of Peyer's

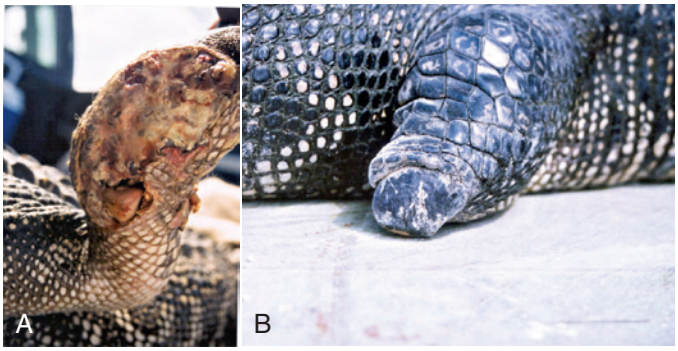

FIG 136.6 (A) Rear limb open fracture with tissue necrosis in a wild alligator *(A. mississippiensis)*. Wild animals can recover from these types of lesions, but they can lead to severe septicemia in captive ones. (B) Wild alligator with a healed lesion that resulted in amputation of the distal rear limb.

VetBooks.ir

patches and likely represents a site of aggressive inflammatory response to infectious agents. A novel herpesvirus was reported from an American alligator with lymphoid follicular inflammation of the cloaca.[45]

OCULAR SIGNS

Chlamydia

Chlamydiosis has been reported from *C. niloticus* (South Africa and Zimbabwe), *C. porosus* (Papua New Guinea), and *C. siamensis* (Thailand).[41-43] The author has also diagnosed Chlamydiosis in *A. mississippiensis* (United States). Although it has been proposed as a *Chlamydophila psittaci*-like strain in *C. niloticus*,[44] the *Chlamydia* species affecting crocodilians is likely a novel specie(s). Infection usually leads to hepatitis and/or conjunctivitis (Fig. 136.11), but lung and spleen can also be infected. Morbidity and mortality can exceed 50%, resulting in significant economic losses for farmed animals.[42] Treatment with oxytetracycline is anecdotally reported to be effective in crocodiles. This creates significant concerns for possible antimicrobial resistance, zoonosis, and the safety of the meat from these animals.

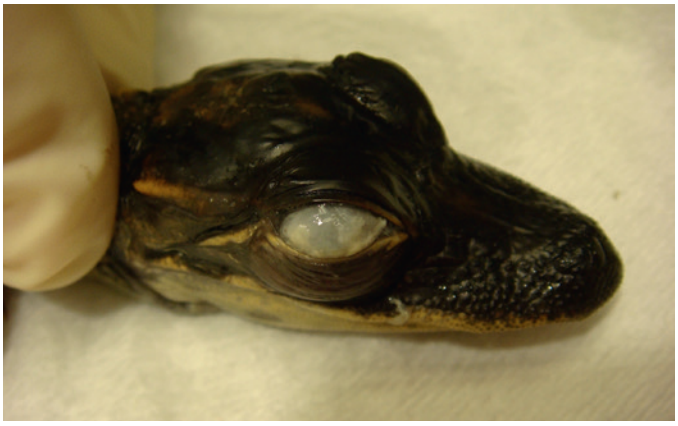

FIG 136.11 Keratitis and conjunctivitis because of chlamydiosis in a hatchling American alligator (*A. mississippiensis*). (Courtesy of Javier G. Nevarez.)

MISCELLANEOUS

A novel herpesvirus was reported from an American alligator with lymphoid follicular inflammation of the cloaca.[45] A herpesvirus was identified via TEM from saltwater crocodiles (*Crocodylus porosus*) with concurrent pox virus and bacterial infection of the skin.[46] In captive *C. porosus* and freshwater crocodiles (*C. johnstoni*) from Australia, three novel herpesviruses have been identfied.[47] *C. porosus* exhibited conjunctivitis-pharyngitis, systemic lymphoid proliferation and encephalitis, or lymphonodular skin lesions.[47,48] *C. johnstoni* had systemic lymphoid proliferation.[47] Chlamydiaceae was also identified from conjunctival and pharyngeal tissues of some of the *C. porosus* cases.[48] Of interest is that these syndromes occur concurrently with other infectious agents and have been associated with significant morbidity and mortality of infected animals.

Differential Diagnoses by Clinical Signs—Amphibians

Taylor Yaw and Leigh Clayton

This chapter reviews differentials for common presenting conditions in captive amphibians. The primary focus is adult anurans (frogs and toads) and caudates (newts, salamanders, and sirens); larval amphibians and caecilians are not covered in detail. Some guidance is provided for etiologies, diagnostic tests, and management, but readers are referred to other amphibian chapters in this text (see Chapters 12, 28, 52, 89, and 107) for more information on these topics.

ACUTE MORTALITIES

Unexpected deaths of individually housed amphibians and acute mortalities affecting several amphibians in a collection warrant immediate attention by the clinical veterinarian. Acute mortalities are most commonly due to infectious diseases (e.g., chytridiomycosis, ranavirus, lungworm, or bacterial septicemia), sudden environmental changes (e.g., tank flooding or drying, temperature changes), and toxin exposure (e.g., chloramine, chlorine, ammonia, bleach, insecticides). Essential diagnostic evaluations that should be considered include a full history, physical examination of remaining amphibians, water quality testing, skin scrapes, PCR testing (e.g., chytridiomycosis/ranavirus), gill biopsies, full necropsy (including cytology samples and cultures), and tissue submission for histology. Normal blood values for amphibians are largely undefined, but a simple blood smear may help appreciate changes that can be associated with bacterial septicemia. Affected populations should be isolated pending the diagnosis in case of an infectious cause.

Chytridiomycosis, caused by the fungal organism *Batrachochytrium dendrobatidis,* often causes death without premonitory clinical signs and must be considered as a differential in any acute mortality.[1] Nonspecific signs of anorexia, lethargy, ataxia, and cutaneous lesions may be seen before death.[2] Cutaneous lesions include hyperplasia, hyperemia, ulcerations, and brown discoloration of the dermis. This fungal infection has low host specificity and can cause high morbidity and mortality.[3,4] In the authors' experience, outbreaks in larger captive collections may have an insidious onset with increased mortality events over weeks to months. Husbandry parameters, especially temperature, should be reviewed, because outbreaks are often concurrent with environmental stressors. The organism can often be identified on wet mount preparations of shed skin, if the infection is heavy, and PCR of the skin. Chytridiomycosis is reportable to the World Organization for Animal Health (OIE).

Ranaviruses (family *Iridoviridae*) can also cause acute mortality without premonitory clinical signs and have been implicated in mass mortality events in wild amphibian populations.[5] Signs of lethargy, anorexia, buoyancy disorders, edema, coelomic distension, and ventral ecchymoses (especially in the pelvic region) may be observed before death. Internal hemorrhage and hydrocoelom are commonly observed on postmortem necropsy.[6] Several different ranaviruses have been described in amphibians (e.g., frog virus type III, Ambystoma tigrinum virus, Bohle iridovirus, and common midwife toad virus) with varying pathogenicity.[7–10] Susceptibility to the disease varies by species, developmental stage (late larval stage often most severe), and environmental factors.[6] Diagnosis is by histology, PCR, and cell culture; sequencing is needed for definitive identification. Lesions may appear very similar to those of bacterial dermatosepticemia due to secondary bacterial infections, making differentiation difficult without histology, cultures, and PCR. Ranaviruses are also reportable to the OIE.

Lung worms (e.g., *Rhabdias* spp.) can cause acute mortalities in adult amphibians through lung damage and secondary infections.[11] Clinical signs are rarely observed and, if present, are typically nonspecific (e.g., anorexia, poor body condition). The parasites have a direct life cycle and can build up rapidly. Premortem diagnosis may be made by finding ova or worms in oral, nasal, or fecal material. Adult worm burdens are typically obvious on necropsy and histology.

The term "red-leg disease" may still be seen in the literature and is often used interchangeably with bacterial septicemia, particularly *Aeromonas* spp., but is essentially a clinical syndrome that includes erythema and other signs of systemic inflammation.[12] Gram-negative bacteria (e.g., *Aeromonas*, *Pseudomonas*, *Citrobacter*, *Klebsiella*, *Salmonella*, *Proteus*, *Flavobacterium* spp.) are the most commonly reported in septic amphibians. Gram-positive bacteria may also cause disease, particularly atypical *Mycobacterium* and *Chlamydophila* spp., which can cause both acute septicemia and, more commonly, chronic granulomatous disease in amphibians.[5,13–16] Septicemia may be secondary to injury, gastrointestinal inflammation, or immunosuppression and is often correlated with husbandry-related issues.[11]

Abrupt environmental changes, especially changes in water availability and temperature, can lead to acute deaths. A detailed history is essential in identifying inappropriate husbandry (e.g., enclosure type, chemicals utilized for cleaning, diet, supplementation, temperature, humidity, water quality, lighting).[17] Where a visit is not possible, pictures or videos of the primary enclosure and its location in the room can be useful.

COELOMIC DISTENSION

Coelomic distension is one of the most common presenting signs in amphibians. Distension may be due to fluid, soft tissue (often fat or ova), or rarely gas (not covered in this chapter). A full history with water-quality parameters, physical examination, transillumination, radiographs, ultrasound, fine needle aspiration (with fluid evaluation, cytology, and bacterial culture), and PCR (e.g., ranavirus) are commonly utilized to differentiate causes.

Abnormal Fluid Accumulation (Hydrocoelom/Lymphedema)

Fluid may accumulate in focal areas within the lymphatic system but is more commonly generalized to the coelomic cavity (hydrocoelom) or entire lymphatic system (lymphedema) (Fig. 137.1). Hydrocoelom

VetBooks.ir

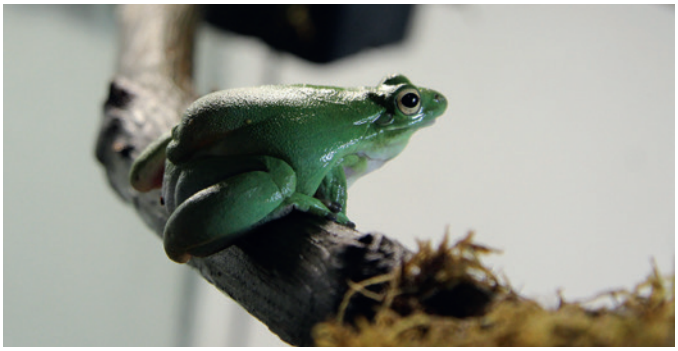

FIG 137.1 A green tree frog (*Hyla cinerea*) with hydrocoelom and lymphedema. These two conditions often present together and are difficult to differentiate in advanced cases. (Courtesy of Amanda Gensemer.)

FIG 137.2 A Panamanian golden frog (*Atelopus zeteki*) with coelomic distension due to egg masses. This amphibian also appears to be moderately dehydrated and in poor body condition. (Courtesy of Jessica Nelson.)

is limited to coelomic distension with a rounded coelom. Lymphedema is associated with a rounded appearance over the pelvis and loss of the linea alba, exophthalmos, and limb swelling. Amphibians may show no other clinical signs. Major causes for fluid accumulation include cutaneous lesions, infectious diseases, renal or hepatic diseases, and environmental problems.[14] Cutaneous lesions are covered later in this chapter.

The most common infectious diseases that cause fluid accumulation include chytridiomycosis, ranavirus, and bacterial septicemia. Differentiation of these diseases can be difficult, and further diagnostic assessments are required after initial examination. Secondary bacterial infection can impair diagnosis of underlying viral infections. Skin cytology or histology and PCR are crucial in identifying fungal and viral components. Aspiration of fluid followed by fluid analysis and cytology stains are helpful in identifying signs of infection. Culture and susceptibility of the fluid can guide treatment if a bacterial component is involved.

Renal disease is commonly associated with edema in both terrestrial and aquatic amphibians (Mangus LM, Proc AAZV 2008, p16).[13,14] In the authors' practice, it appears likely that both acute and chronic renal disease can be associated with edema. Infectious diseases capable of causing direct renal damage include local or systemic bacterial, viral, or fungal agents (e.g., mucormycosis, chromomycosis, zygomycosis), as well as myxozoan and microsporidial parasites.[14,18] Noninfectious causes of renal disease include degenerative disease, dehydration, neoplasia (primary and secondary), nutrition (e.g., high oxalates, high protein, hypovitaminosis A), and toxins (e.g., aminoglycosides, heavy metals, polyvinyl chloride glue).[14,19–21] Confirmation is often difficult unless the animal is large enough for renal biopsy for histology and culture.

Hepatic disease can cause edema through the direct effects of hepatocyte necrosis, impaired intrahepatic circulation, or due to low plasma protein levels.[22] Infectious causes of hepatic disease include local or systemic bacterial, viral, or fungal infections as described previously.[23,24] Noninfectious causes of hepatic disease include trauma, neoplasia (primary and secondary), and toxins (e.g., heavy metals, pesticides, herbicides). Tissue biopsy and histology are typically needed for confirmation.

Inappropriate husbandry can predispose amphibians to conditions associated with edema, particularly bacterial and viral infections. Additionally, short-term exposure to cool temperatures (e.g., during transport) has been associated with transient hydrocoelom a few days after exposure that normally resolves without intervention (Clayton, unpublished). Aquatic amphibians housed in water with low dissolved solutes may also accumulate fluid due to low osmotic pressure.[23]

Obesity

Compared with amphibians with edema, obese amphibians retain more definition over the pelvis and linea alba. Obesity is more likely in amphibians fed cholesterol-rich diets (e.g., laboratory rodents, crickets fed on dog food) and sedentary species that readily consume large amounts of food. The coelomic cavity is often firm on physical examination, and fat pads may be visualized via transillumination or ultrasound.

Reproductive Activity

Most amphibians produce large egg masses that may cause coelomic distension (Fig. 137.2). Many also have the ability to retain eggs until suitable environmental cues are received. They may have a pendulous appearance to the body cavity, and there may be focal edema around the upper thighs. Maturing eggs can become lodged in the oviduct, impeding oviposition and eventually forming adhesions requiring surgical attention.[25] Transillumination and ultrasound are often diagnostic, but endoscopy or exploratory coeliotomy may be needed.

Gastrointestinal Impaction/Foreign Bodies

Gastrointestinal impaction with food can cause coelomic distension. In many species, the stomach is distensible and amphibians may consume large food items with no issues. However, maldigestion and gastric stasis due to a primary disease process or husbandry issues can lead to gastric impaction. Gas accumulation can be severe, and the bacterial overgrowth can cause life-threatening complications.[26] In addition, many amphibians have indiscriminate eating habits and will ingest foreign material with food items (Fig. 137.3). Inappropriate feeding locations and ocular disease may predispose consumption of foreign material. Imaging along with endoscopy or exploratory coeliotomy may be indicated for diagnosis and treatment.

Organomegaly (Neoplasia and Granulomatous Disease)

Coelomic neoplasia may present as single or multiple masses in the coelomic cavity. Lymphoma, intestinal and gastric carcinomas, nephroblastomas, sertoli cell tumors, and pancreatic carcinomas have been reported in amphibians.[27,28] Focal granulomatous lesions can cause visceral enlargement and may be observed in one or more locations. Atypical mycobacteriosis, chlamydiosis, and fungal infections are most commonly reported in association with granulomas.[13–16,29] Encysted

FIG 137.3 Dorsoventral radiograph of a giant waxy tree frog (*Phyllomedusa bicolor*) with gastrointestinal foreign bodies.

metazoan parasites can also cause granulomas.[30] Ultrasound-guided fine needle aspirates of affected organs with appropriate cytology preparations (e.g., acid fast, Diff-Quik, and gram stains) and culture can be helpful in identifying infectious agents. Ultimately, biopsy and histology is often indicated for confirmation.

GASTROINTESTINAL SIGNS

Gastrointestinal disease is commonly identified in amphibians, but presenting signs vary. Depending on the number of individuals housed together and the enclosure design (e.g., heavily planted terrariums), caregivers may miss clinical signs such as diarrhea, poor body condition, or reduced appetite. Other signs, such as cloacal prolapse, may be readily appreciated. Standard diagnostics utilized to assess gastrointestinal health include a full history, physical examination, fecal analysis (float, direct preparation, cytology stains), transillumination, ultrasound, and radiographs (with or without positive contrast).

Tissue Prolapse

Prolapsed tissue may be intestinal, urinary, or reproductive (Fig. 137.4). Prolapsed tissue is usually a medical emergency, and owners should be instructed to move amphibians from enclosures with organic substrate into an appropriate medical and/or transport enclosure with high humidity. Definitive identification of the prolapsed tissue is not always possible but should be attempted. Prolapsed cloacal tissue is generally small, smooth, and pink. Prolapsed colon is smooth to ridged, with a tubular appearance. A central lumen and/or feces may be visible grossly on impression smear. Prolapsed urinary bladder is rounded with a thin wall and fluid contents. Prolapsed oviduct includes narrow, coiled tubules that may have longitudinal lines and eggs. In the authors' experience, cloacal and colon prolapses are the most common, followed by the urinary bladder.

Transient, self-limiting prolapses may have no obvious cause and can occur iatrogenically during manual restraint or anesthesia with

FIG 137.4 A smooth-sided toad (*Rhaebo guttatus*) with a prolapse of the colon and cloaca. (Courtesy of Jessica Nelson.)

tricaine methanesulfonate.[31] These typically resolve within a few hours of presentation. Common causes of prolapses include parasitism, intussusception, gastrointestinal foreign bodies, neoplasia, septicemia, toxemia, dehydration, extraluminal gastrointestinal blockage (e.g., renal neoplasia), toxins, hypoglycemia, hypocalcemia, and malnutrition.[23,24,30] Tissue impression smears and fine needle aspirates of prolapsed tissue may help in identification of tissue and underlying pathology (e.g., parasites).

Gastric prolapses are occasionally reported secondary to other conditions such as terminal disease, toxin exposure, or gastric parasites.[30,32] Iatrogenic gastric prolapse has been reported in leopard frogs (*Lithobates pipiens*) anesthetized with clove oil; prolapses resolved during the recovery phase of an anesthetic event.[33]

Anorexia (Hyporexia)

Anorexia or hyporexia are nonspecific clinical signs that can be associated with most diseases. A thorough history and observation can help distinguish between inappetance and a good appetite but inability to capture or prehend food. As body condition worsens, the amphibian's coelom becomes less distended, the limbs lose muscle, and weight declines (see Fig. 137.2). If the calorie and nutrient imbalance is severe, amphibians may present with neurological signs (e.g., tremors, muscle rigidity, ataxia). Causes of inappetance include inappropriate environmental conditions; musculoskeletal injuries involving the oral cavity; inflammation or infectious diseases (e.g., bacterial septicemia, atypical mycobacteriosis, ranavirus, chytridiomycosis); gastrointestinal, renal, or hepatic disease; neoplasia; and pain.[34] Inability to capture or prehend food is most commonly due to hypovitaminosis A, also known as short tongue syndrome (Pessier AP, Proc ARAV, 2002, p57).[35]

Thin Frog/Emaciation

Weight loss is a nonspecific clinical sign that can be associated with most diseases. Regular weight checks allow for earlier detection of weight loss than just monitoring for changes in body condition. When tracking weight, it is important to look at trends over time, because daily weight ranges can vary dramatically due to urination/defecation. Differentials include those for anorexia as listed previously, malabsorption or maldigestion (e.g., gastrointestinal parasites, inflammation, toxins), and increased metabolic rates (e.g., neoplasia, infectious disease).[17]

Reduced Fecal Production

Normal fecal output varies between species, and long intervals between fecal production are normal in species adapted to more arid conditions (e.g., Hylidae, some Bufonidae). The most common causes of reduced

VetBooks.ir

fecal production are anorexia or hyporexia (as stated previously). Other differentials can be divided into mechanical obstructions (e.g., gastric impaction, intraluminal mass, extraluminal mass, severe helminthiasis, intussusception, foreign body, stricture) and functional obstructions (e.g., inappropriate environmental conditions, systemic inflammation or infection, neurological disease, trauma).[30] Amphibians with prolonged anorexia tend to have minimal digesta, and animals with functional or mechanical obstructions tend to have full intestinal tracts that can be observed on palpation, diagnostic imaging, or transillumination.

Diarrhea

Diarrhea must be differentiated from polyuria, which can be difficult. Diarrhea in amphibians has been associated with husbandry related issues such as inappopriate temperature or humidity, or diets high in carbohydrates.[26] Other differentials include gastroenteritis, foreign bodies, and toxins (e.g., heavy metals).[30,32] Amoebiasis, coccidiosis, and some metazoan parasites (e.g., *Strongyloides* spp., *Acanthocephalus ranae*) have been implicated as primary pathogens of the gastrointestinal system.[32,36,37] Ciliates are common in the gastrointestinal tract of a wide variety of amphibians but are typically nonpathogenic.[30] Systemic fungal disease may affect the gastrointestinal tract, whereas *Mucor amphibiorum* can be a primary cause of gastroenteritis.[2,23,38,39] As previously mentioned, ranaviruses can cause intestinal distension with hemorrhage and diarrhea.[24]

DERMATOLOGICAL SIGNS

Amphibians may present with a wide variety of cutaneous disorders. Clinical signs may include coloration changes, erythema, petechiation, ulcerations, abrasions/lacerations, and increased shedding. In many cases, integument changes are due to systemic disease or are related to inappropriate environmental conditions. Differentials should include infectious diseases (e.g., chytridiomycosis, ranavirus, bacterial septicemia), environmental issues (e.g., inappropriate substrate, décor, temperature, water quality, humidity, nutrition), and toxin exposure (e.g., chlorine, ammonia, bleach). Common diagnostic evaluations include a full history, water quality, physical examination, skin scrape (wet mounts and cytology stains), impression smears, bacterial and fungal culture, and biopsy. Necropsy evaluation of the skin should also routinely include skin scrapings as well as histology from multiple sites.

Erythema

Erythema is a common, nonspecific clinical sign, often seen on the limbs and ventral abdomen of amphibians. Erythema can be related to handling, inappropriate environmental conditions, inflammatory or infectious disease, and some neoplastic processes.[4]

Amphibians may develop minor erythema in response to handling, which often dissipates rapidly. Major environmental causes of erythema include rough cage furniture, coarse substrate, use of coarse nets, and poor water quality or environmental irritants (e.g., disinfectants, detergents, chlorine, inappropriate pH). Inappropriate nutrition, in particular hypovitaminosis A, often leads to cutaneous lesions, including erythema. A detailed history with water quality parameters and observation of the enclosure is often diagnostic. Any systemic infection can cause hyperemia, including viral, bacterial, fungal, and parasitic infections. As previously noted, chytridiomycosis, ranavirus, and dermatosepticemia are common infectious processes that must be ruled out (see Acute Mortality section). Other fungal causes of cutaneous erythema not previously mentioned include *Basidiobolus ranarum, Mucor, Saprolegnia,* chromomycosis (e.g., *Cladosporium*), and *Ichthyophonus* spp.[2,4] A variety of cutaneous neoplasms have been described in amphibians. Although these often appear as proliferative masses, neoplasms such as squamous cell carcinomas, adenomas, and adenocarcinomas can exhibit several different characteristics, including erythema and ulcerations.[4]

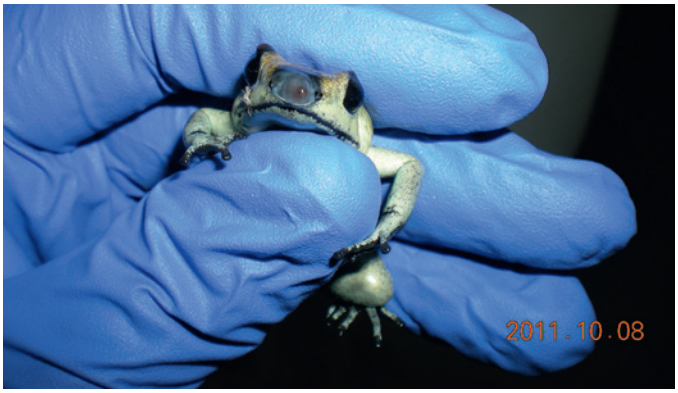

FIG 137.5 A deep rostral abrasion in a terrible poison dart frog (*Phylobates terribilis*). (Courtesy of Jessica Nelson.)

Abrasions/Lacerations

Abrasions and lacerations commonly occur from traumatic events. Common causes in captive amphibians are tank mate aggression, rostral trauma from enclosure surfaces (Fig. 137.5), entrapment in tank lids or under décor, bites from live prey, inappropriate substrate, and handling with dry hands. If appropriate environmental conditions are provided, most wounds heal well without medical intervention.

Dehydration

Signs of severe dehydration in amphibians include a dry or wrinkled appearance to the skin, dark coloration, sunken eyes, dry stringy mucus in the mouth, or weight loss (see Fig. 137.2). Excessive tackiness of the skin may be a subtle sign of mild dehydration in some species.[4]

Environmental issues, particularly inappropriate water sources, water quality, or temperature, are the most common causes of dehydration. All species of amphibians should have access to water. Other common causes of dehydration are cutaneous disease (e.g., chytridiomycosis, ranavirus, septicemia, thermal burns) and renal disease. Vomiting, diarrhea, and polyuria must also be considered as potential sources of fluid loss but are less common.

Cutaneous Masses

In amphibians, granulomatous inflammation and neoplasia are the most common causes of cutaneous masses. Granulomatous lesions can be due to atypical mycobacteriosis, *Chlamydophila* spp., chromomycosis, mucormycosis, and zygomycosis.[1,2] Cutaneous neoplasia in amphibians include epidermal papillomas, squamous cell carcinomas, cystadenomas, cystadenocarcinomas, melanophoromas, neuroepithelial tumors, and mast cell tumors.[4,28] Of these, epidermal papillomas have shown spontaneous regression. Impression smears, aspirates, and incisional or excisional biopsies for cytology, histology, culture, and PCR can help with diagnosis.

MUSCULOSKELETAL SIGNS

Amphibians showing musculoskeletal signs should be assessed for orthopedic issues, myopathies, and neuropathies. Common diagnostic evaluations include radiography and transillumination. Biopsies and advanced imaging may be indicated.

Ambulation Difficulties

Common musculoskeletal issues include pathologic fractures from secondary nutritional hyperparathyroidism and trauma. Although

neuropathies are not reported in the literature, autoimmune diseases, toxins, nutritional deficiencies, trauma, neoplasia, and toxins that could affect the nervous system should be considered as differentials. Secondary nutritional hyperparathyroidism is unfortunately common in amphibians.[11] The most common etiology is an imbalance of calcium, phosphorus, and vitamin D_3 in the diet, but high-fluoride, vitamin A, and oxalates can play a role.[26,40] Primary renal disease can also lead to abnormal bone development due to decreased production of active vitamin D_3. If severe, signs may include spastic tetany after strenuous movement that resolves with rest. If chronic, folding fractures of long bones, spinal changes, and loss of mineral deposition in bones may be present. A detailed history, diet review, and radiographs are often diagnostic.

Developmental Abnormalities (Polymelia and Spindly Leg)

Nutritional and parasitic causes are the most commonly reported etiologies of developmental abnormalities, but traumatic and genetic issues should also be considered. In wild anurans in the United States, polymelia (extra limbs) or amelia (missing limbs) may be due to the digenetic trematode *Ribeiroia ondatrae,* which encysts and disrupts developing limb buds.[41,42] Spindly leg is a developmental disease affecting tadpoles.[26] Classic signs are limited muscling of the limbs, inability to extract the forelimbs during metamorphosis, and a short, round coelom (Fig. 137.6). Enriched parental nutrition can reduce the incidence (Nelson J, Proc Am Assoc Zoo Keepers, 2014, p2).

OCULAR SIGNS

Common ocular presenting signs include increased corneal opacity, ulcers, and cataracts. A full history (including diet and lighting), physical examination, ocular examination with a slit lamp and ophthalmoscope, fluorescein staining, corneal scrapings, cultures, and tonometry are useful diagnostics.

Increased Corneal Opacity

Increased corneal opacity can be caused by edema, vascularization, fibrosis/scarring, pigmentation, or inflammatory cell or lipid infiltrate. Corneal lipidosis is the most commonly reported ocular disease in amphibians.[43] The disease tends to be bilateral and presents as hazy white or gray corneal opacities starting at the limbus and progressing centrally (Fig. 137.7). Stromal melanin deposition and neovascularization develop in more severe cases.[44] Corneal lipid deposition has been linked to increased lipid in the diet. Female animals may have an increased risk because of egg development. Histology is needed for confirmation of the disease process.

Conjunctivitis, Dacryocystitis, and Uveitis

Inflammation of the conjunctiva, uveal tract, and glandular tissue around the eye presents with redness, discharge, and edema of the affected tissues. If severe enough, increased white blood cells and protein in the anterior chamber may present as flare on ophthalmic examination. Bacterial septicemia is the most common cause, but other causes of systemic inflammation need to be ruled out. Culture and cytologic evaluation can be very helpful for diagnosis and treatment.

Corneal Ulceration

Ulceration can be classified based on depth, onset, and position of the ulceration. Typical signs of corneal ulceration include ocular inflammation, excessive discharge, sensitivity to light, and pain. Although causes of amphibian ulcers are poorly documented, mechanical damage, foreign bodies, inappropriate lighting, humidity, or temperature should all be considered.

Lens Opacity

Cataracts and nuclear sclerosis are common in amphibian lenses. Nuclear sclerosis is always bilateral, spherical, and translucent. Cataracts can be focal or diffuse and are not translucent. Etiologies of cataracts in amphibians are poorly documented, but potential causes include trauma, systemic inflammation, nutritional deficiencies, inappropriate lighting, toxins, and genetics.[44,45] Differentiation of cataracts and nuclear sclerosis can be accomplished by retroillumination.

Abscesses/Fibriscesses

Volker Schmidt

DEFINITION

An abscess is defined as a localized collection of purulent material (pus) consiting of degenerate or toxic heterophils, macrophages, lymphocytes, serum, and necrotic tissue in a confined cavity formed by the disintegration of tissues. The reptilian abscess is usually not liquefied but inspissated and surrounded by a fibrous capsule; hence the term fibriscess may be used[1] (Fig. 138.1).

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Microorganism (bacteria, fungi, parasites) or foreign bodies embedded in tissue can lead to fibriscess formation with a firm fibrous surrounding wall that is imprenetrable to drug therapy. The portal of entry for pathogenic organisms can be skin, ocular, and periocular tissue and the gastrointestinal or respiratory tracts. Once inside the body,

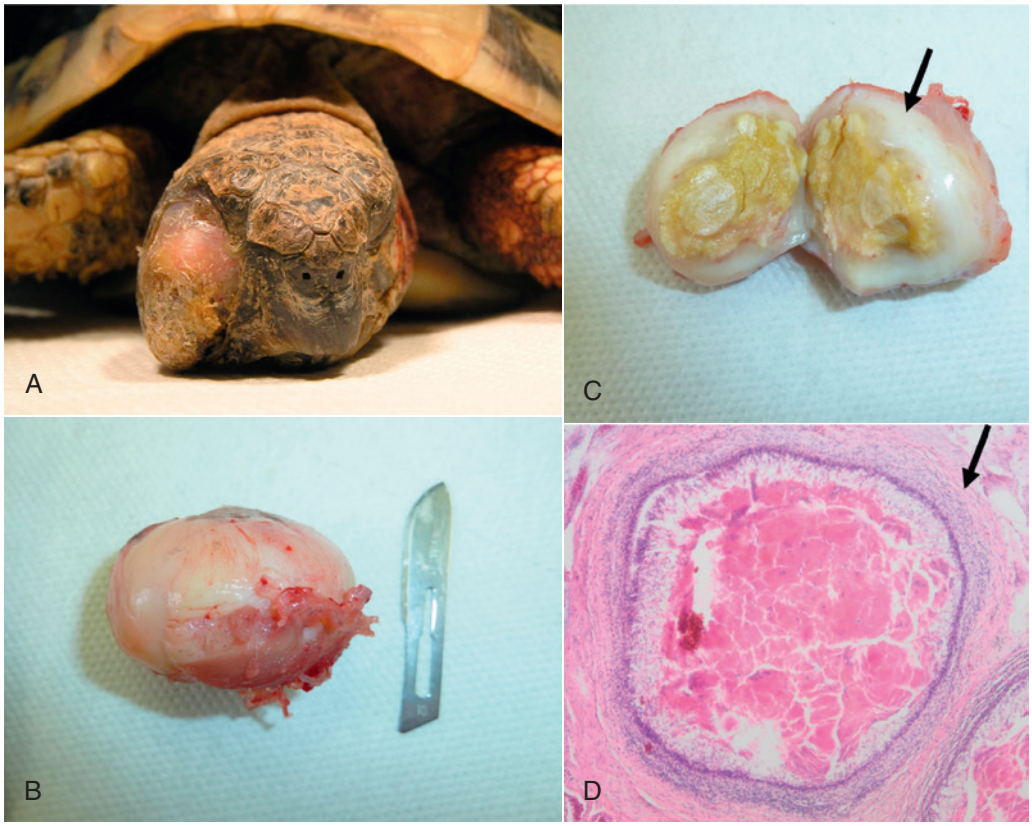

FIG 138.1 Subconjunctival fibriscess in a Hermann's tortoise (*Testudo hermanni*): (A) clinical picture, (B) surgically removed, (C) fibrous capsule (arrow) shown in cross-section, and (D) fibrious capsule (arrow) and central fibrin with bacterial colonies shown in microphotograph, HE stain, 100x. (Courtesy of Volker Schmidt, Department for Birds and Reptiles, University of Leipzig.)

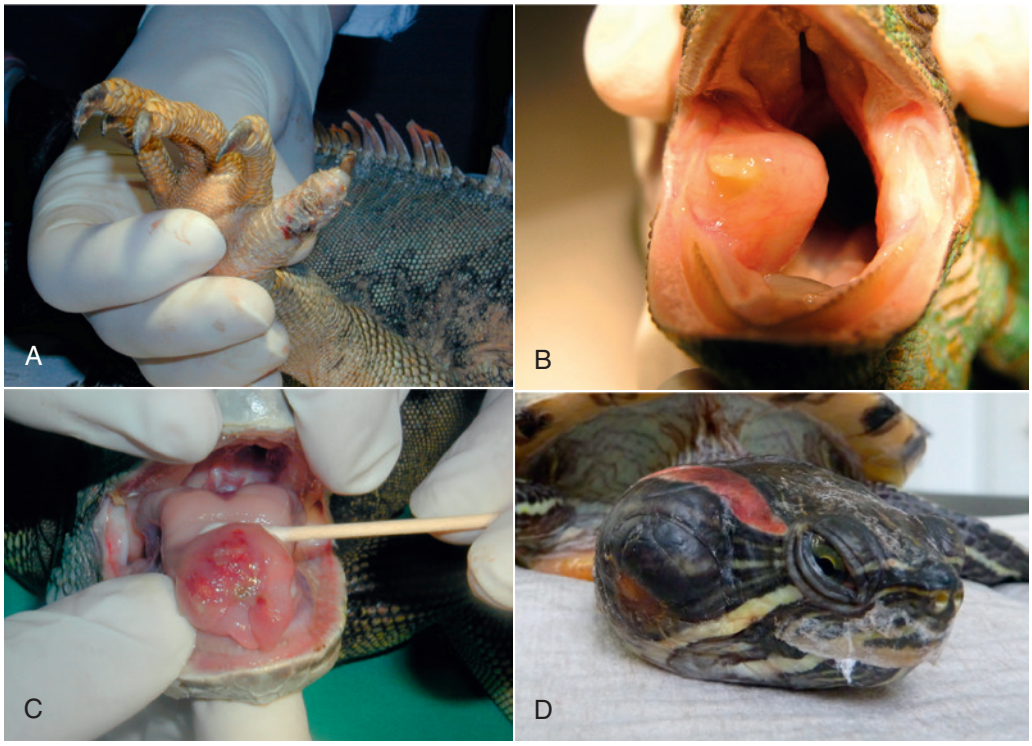

FIG 138.2 Different presentations for abscesses/fibriscesses: (A) cutanous manifestation in a green iguana (*Iguana iguana*) after traumatic injury, (B) glossal manifestation in a green iguana, (C) oral manifestation in a veiled chameleon (*Chamaeleo calyptratus*), and (D) aural manifestation in a red-eared slider (*Trachemys scripta elegans*) often predisposed by hypovitaminosis A. (Courtesy of Volker Schmidt, Department for Birds and Reptiles, University of Leipzig.)

hematogenous spread can disseminate pathogens to other internal organs and tissues. Beside traumatic injuries, which allow infection routes especially for bacteria, hypovitaminosis A results in squamous metaplasia of the epithelium, which often predisposes various reptile species to periocular, perioral, glossal, and aural fibriscesses[2–4] (Fig. 138.2).

CLINICAL SIGNS AND DIAGNOSTIC CONFIRMATION

All reptiles are susceptible to fibriscess formation. Depending on the organ system involved, the clinical signs may vary. Cutaneous or subcutaneous fibriscesses manifest as obvious, generally localized, swellings. Cellulitis, a deep diffuse suppurative infection in areas of low oxygen tension, can have a similar presentation to large fibriscesses but does not have the solid core. The differential diagnoses include any "mass lesions," such as neoplasia, hematomas, scar tissue, gout/pseudogout, and parasitic cysts. Pain on palpation (not always obvious), internal structure (fluid-filled versus solid), and previous history help with evaluation. Because of the solid nature of the fibriscesses, fine needle aspirates and exfoliative cytology are usually nonproductive. Cytology from aspirates usually reveals amorphous debris. Surgical exploration and/or removal of the mass in toto, when possible, followed by tissue cytology/histopathology and bacterial and fungal culture/sensitivity of tissue biopsies are important to confirm a diagnosis. Acid-fast (*Mycobacteria* and *Nocardia*), Gram (bacteria), Grocott (fungi), and periodic acid-schiff (fungi and bacteria) stains/reactions are useful to identify causative pathogens. Samples for microbiology should be collected from the inner lining of the fibrous capsule, not the necrotic center of the lesion, which is often sterile. Radiography, CT, ultrasonography, or MRI can be useful for internal evaluation.

PREFERRED TREATMENT(S)

The key to successful treatment is complete removal of the abscess cavity and surrounding fibrous capsule. Simple lancing and curettage, or removal of the internal caseous material, is not enough to prevent recurrence. Once the capsule has been removed, the wound is generally left open to heal by secondary intention and granulation. Second intention healing ensues, leaving minimal skin scarring in most cases. Healing times vary depending on many factors but in general can take anywhere from 4 to 6 weeks. Thorough surgical debridement is essential and often requires general anesthesia, although local or regional anesthesia may be sufficient in some dermatologic cases. Ablation of the abscess capsule/bed helps sterilize any material left behind after the debridement. Daily lavage and topical treatment of cutaneous lesions is an essential adjunct to initial surgical debridement. Topical antibiotics may be helpful but systemic treatment is seldom indicated following appropriate surgical removal. Incomplete removal often results in recurrence, even if systemic antimicrobials are used. Early in the treatment, weekly reevaluations are recommended.[5,6]

PROGNOSIS AND PREVENTION

Identification and correction of underlying deficiencies in husbandry (e.g., overcrowding, intraspecific agression, poor hygiene, malnutrition, etc.) will help prevent future occurrences. The owner should be given a cautiously optimistic prognosis, with the potential for recurrence or development of new lesions at different locations.

Acariasis

Kevin T. Fitzgerald

DEFINITION

Infestation with ticks and mites is known as acariasis. Although spiders are the best-known arachnids, ticks and mites are also members of this class. Larval ticks and mites have three pairs of legs, whereas nymphs and adults have four pairs. Head, thorax, and abdomen of ticks and mites are fused; also, they lack antennae and mandibles. These parasites can be difficult to eliminate, expensive to treat, and have a high incidence of recurrence. (See Chapters 32 and 69 for more details.)

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Infestation with ticks and mites invariably can be traced to unsanitary conditions, poor husbandry practices, and recent imports of infested animals. Parasitism by ticks and mites occurs in both wild and captive reptiles. Acariasis has been linked to a variety of problems ranging from simple itching and discomfort to dermatitis, anemia, failure to thrive, anemia, and possible transmission of blood-borne diseases. Any level of infestation should be regarded as serious.

Ophionyssus natricis (Parasitiformes, Macronyssidae)—the snake mite—is the most common mite found in reptiles (Fig. 139.1).[1,2] Normally infesting snakes, it can also be found in captive lizards and turtles. *Ophinyssus acertinus*—the lizard mite—is usually red and larger than the black snake mite. More than 250 other mite species can also parasitize reptiles. *Trombiculid* mites—"chigger mites"—affect reptiles but are only parasitic in the larval form. Mites are formidable blood-sucking parasites, and their reptilian hosts often can support up to 10,000 mites.

Seven genera of ticks parasitize reptiles. Both soft- and hard-bodied ticks are found in snakes, lizards, and turtles. Blood-sucking parasites, they can inflict painful bites and under certain conditions result in serious blood loss. Additionally, they may introduce toxins with their bites and have the potential to transmit microbial diseases to hosts and other species.[3] Larger and more conspicuous than mites, they are more likely to be noticed earlier and removed before serious conditions or life-threatening anemia develops.

CLINICAL SIGNS

Anorexia, dermatitis, pruritus, anemia, septicemia, dysecdysis, retained eye caps, dehydration, failure to thrive, and the potential for transmission of blood-borne pathogens have all been documented in tick and mite infestations in captive reptiles. Behavioral changes associated with these ectoparasites can also be observed. Infected snakes may remain coiled in water bowls and soak for extended periods, attempting to rid themselves of these pests. Reptiles may also become hyperactive and will frequently rub against glass or cage furniture in an effort to remove the parasites. Persistent or recurrent dysecdysis in snakes may signal infestation. Even if animals are successful in shedding ectoparasite-infected skin, they quickly become reinfected within the confines of the cage.

Due to the white "dustlike" mite waste material, the skin of mite-infested reptiles may have a dull, lackluster, "dirty" appearance. Skin folds under the chin, under scutes, in the periocular region around the eyes, inside skin folds around the cloaca, and tympanic recesses in lizards are all common regions where mites are found (Fig. 139.2). The host skin at these mites feeding sites becomes hyperemic, edematous, and infiltrated with heterophils, lymphocytes, and plasma cells. Mites vary in color depending on species, gender, and how recently they have fed. Reptiles affected with acarids may be debilitated but remarkably

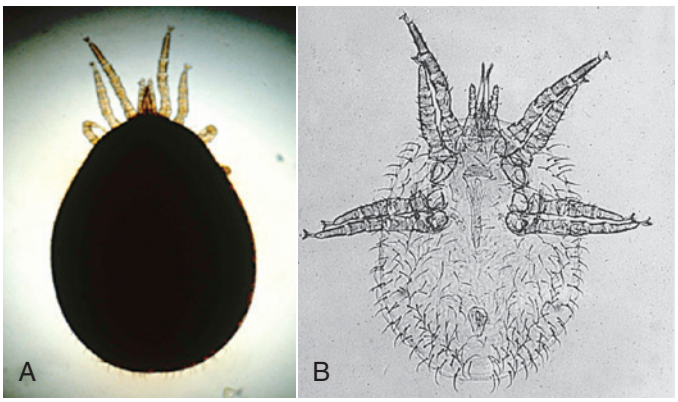

FIG 139.1 A snake mite under magnification. (Courtesy of R. Houston.)

FIG 139.2 A Burmese python (*Python bivittatus*) severely infested with mites. Note the large numbers in the periocular area. (Courtesy of Stephen Barten.)

VetBooks.ir

may still be active, feeding, and seemingly unaffected, even with tremendous parasite loads. Often the most common clinical presentation for reptiles with mites is toxicity from improper and unsafe eradication treatment. These toxicities can be severe, devastating, and often fatal.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Mites are most readily seen moving on or between scales of the head, around eyes, in axillary folds, or on the trunk of heavily infested lizards. In advanced cases, reptiles may have mites visibly swarming over the body or display conspicuously attached ticks. Casual observation may not be enough to declare animals or cages parasite free. Often mites are not noticed until owners find them on their own skin after handling infested reptiles. Wiping with a wet cotton swab, damp gauze sponge, or a shallow bath may reveal dislodged mites. Ticks are much easier to identify and areas typically targeted should be examined frequently. A regular inspection of captive reptiles and their environments should be performed to identify both free-living and parasite stages. Cages themselves, lids, hide boxes, and cage furniture must be routinely inspected and cleaned. Finally, magnification with a hand lens may help to provide a diagnosis.

TREATMENT

Acaricides—Mites

Preferred Treatment

1. Quarantine: Quarantine of new animals for at least 3 months before introduction into a collection. This may be the **most** important management and control method.
2. Permethrin: 0.5% permethrin spray (Provent-a-Mite, Pro-Products, Mahopec, NY). Lizards, snakes—environment treatment 1 second spray/sq ft.[2] Wait until dry before returning animals to enclosure. Safe, effective—only product licensed as an acaracide for reptiles. **This is the preferred treatment.**
3. Sanitation/cleaning: Mites are killed by hot water >122°F (750°C). Cages, shelves, and lids should be cleaned weekly.

Alternative Therapies

1. Ivermectin topical: 0.5 mL of ivermectin (10 mg/mL) added to 1 quart tap water and applied liberally to the cage and surroundings. Avoid spraying into water bowl. Can be sprayed or wiped on snakes and lizards. Shake solution thoroughly before applying (ivermectin is oil based). Weekly or every other week treatments for 6 to 8 weeks may be necessary in large collections. Ivermectin must never be used on or around chelonians or indigo snakes.[4]
2. Fipronil: 0.29% fipronil spray (Frontline Fipronil Spray Treatment, Merial, Duluth, GA).
3. Resmethrin II: Durakyl -0.35% remethrin (DVM Pharmaceuticals, Miami, FL)
4. Permectin II: 10% permethrin diluted to 1% in tap water used as a spray (Bioceutic Division, Beohringer-Ingelheim Animal Health, Inc., St. Joseph, MO).
5. Dilute pyrethrin: 0.03% dilute pyrethrin (Mite and Lice Bird Spray, 8 in 1 Products, Inc., Itauppage, NY).
6. Imidacloprid plus moxidectin: Commercial Imidacloprid (100 g/L) plus moxidectin (25 g/L)—Advocate Dog (Bayer Corp, Reading, UK) and Advantage Multi (Bayer Corp, Kansas City, MO) has been recommended.
7. Biologic control of mites: Utilization of predatory "cannibal" mites have been recommended as a biologic control for acariasis in lizards.[5]

Treatments No Longer Recommended (Either Unsafe or Ineffective)

- Chlorinated hydrocarbons (DDT)—toxicity
- Organophosphates (Trichlorfon)—toxicity
- 5% Sevin Dust—toxicity
- Dichlorvos strips—toxicity
- Silica gel powder—caustic, toxic
- Olive oil—stressful and not 100% effective
- Drying out cages—ineffective
- Bleach—never apply to animals
- Roccal-D, A-33 Dry—never apply to live animals
- Bathing/soaking—ineffective if done as only treatment
- Insect growth regulators—does not kill mites right away

Acaricides—Ticks

Preferred Treatment

1. Permethrin: Provent-a-Mite (Pro-Products, Mahopac, NY), safe and effective at killing ticks by a spray with a dilution of 0.01% and 0.5%.[6,7] Spray the animal from a few inches away (10 cm). **This is the preferred method.**

Alternative Treatments

1. Cyfluthrin: Cyfluthrin 0.01% (Tempo, Bayer Corp., Kansas City, MO) formulated for premise treatment coupled together with direct permethrin treatment of ticks on chelonians is safe and effective.
2. Ivermectin: Ivermectin has been suggested as a method of tick removal for ticks hiding in nostrils, loreal/labial pits, or other body recesses. Ivermectin must never be given to chelonians or indigo snakes.
3. Permethrin spray: Another permethrin spray (Preventic, Virbac, Ft. Worth, TX) has been suggested for cage, shelving, and room treatment of ticks. This is only for cage environments.
4. Manual removal: Ticks should be removed with delicate forceps. Ticks should be grabbed under the head on the mouth parts and extracted.

PROGNOSIS AND PREVENTION

Success of various therapy protocols for the management of ectoparasites in captive reptiles is dependent on how effective the therapy is in targeting and eradicating the specific life stages of the parasite and how thoroughly the affected housing environment is treated and managed.

In summary, successful treatment of mite infestations generally includes a combination of strategies: a rigorous quarantine system; utilization of the permethrin product Provent-a-mite; and disinfection of the cage, shelving, lids, and associated surfaces, as well as any permanent cage furniture, nondisposable hide-boxes, food, and water dishes. Continued vigilance is essential. Any treatment plan only dealing with the mites on the host and not managing the environment will fail.

Successful tick therapy involves physical removal of the parasite, spray application of the 0.5% permethrin product to affected areas in chelonians, and treatment of the environment and enclosure either with the permethrin product in lizards and snakes or cyfluthrin in chelonians.

Veterinarians treating reptiles must be aware of the zoonotic implications of these parasites and their potential impact on nontarget species.[1,3]

Amphibian Chytridiomycosis

Norin Chai and Brent R. Whitaker

DEFINITION AND KNOWN ETIOLOGICAL CAUSE(S)

Amphibian chytridiomycosis is a fungal disease caused by *Batrachochytrium dendrobatidis* (*Bd*) and *Batrachochytrium salamandrivorans* (*Bs*) (Chytridiomycota, Rhizophydiales).

CLINICAL SIGNIFICANCE

Bd has a broad host range and infects at least 520 species of anurans (frogs and toads), urodeles (salamanders and newts), and caecilians. *Bs* seems restricted to salamanders and newts.[1] Horizontal transmission may be direct or indirect, and *Bd* can grow on sterile bird feathers and arthropod exoskeletons. *Bd* can grow on the keratinous paw scales of waterfowl and survive in the gastrointestinal tract of crayfish, which have been suggested as potential nonamphibian vectors for *Bd*.[1] Bd has a global distribution highly linked with international movement of amphibians for research facilities and the pet trade. Asia has most recently been proposed as the origin of Bd. At this time, Bs has been found in Europe and Asia but not in North America. In an effort to prevent the introduction, establishment, and spread of *Bs* in the United States, the US Fish and Wildlife Service recently added all species in 20 genera of salamanders to the list of injurious amphibians (https://www.fws.gov/injuriouswildlife/pdf_files/List-of-Salamander-Species.pdf). This prevents the importation/movement of salamanders into the United States and between states, except by permit for zoologic, educational, medical, or scientific purposes.[2]

CLINICAL PRESENTATION

Gross lesions are generally limited to the skin in postmetamorphic amphibians and to the keratinized mouthparts in larval anurans. Clinical signs are variable and include peracute death, skin lesions (roughness, hyperemia, hyperplasia, small skin ulcers, excessive shedding), necrosis of digits/feet, dehydration, weight loss, loss of righting reflex, lethargy, and abnormal behavior (prolonged periods in the vivarium's water dish, failure to seek shelter, reluctance to flee). In anuran larvae, clinical signs are generally limited to depigmentation of the mouthparts, without morbidity and mortality. Infection due to *Bs* in metamorphosed urodelans is characterized by multifocal superficial erosions and extensive epidermal ulcerations, excessive shedding of the skin, anorexia, apathy, ataxia, and death.

DIAGNOSTIC CONFIRMATION

Cytologic examination of stained or unstained skin smears and skin fragments for the detection of zoosporangia provides rapid diagnosis. PCR or qPCR can be done on skin swabs from mouthparts of live anuran larvae and from the ventral pelvic patch, hind legs, and feet of live postmetamorphic, freshly dead, frozen, or ethanol-preserved postmetamorphic amphibians. Mouthparts of anuran larvae, fragments of shedding skin, multiple skin sections, and toe clips fixed in formalin can be sent for histopathology. Histopathologic changes due to *Bd* include multifocal hyperplastic and hyperkeratotic dermatitis, sloughing of the prominent keratin layer, and numerous fungal zoosporangia. In contrast, *Bs* infection is characterized by erosive skin lesions associated with the presence of numerous intracellular colonial thalli that spread over the epidermis with marked necrosis of the adjacent keratinocytes—hyperplasia and hyperkeratosis are absent.[1] Electronmicroscopy and immunohistochemistry using polyclonal antibodies may be used as an aid in histologic diagnosis.

PREFERRED TREATMENT(S) AND PREVENTION

There is no one treatment against chytridiomycosis that is effective in all species and at all life stages (Table 140.1). There are numerous

TABLE 140.1 Selected Treatments Against Chytridiomycosis

Treatments	Dosages—Protocols	Comments
Itraconazole	0.005% (50 mg/L) bath, 5 min/day for 10 days.	Safe and effective treatment in most situations.[3]
	0.01% bath, 5 min/day for 10 days.	Required with higher infection intensities.[3]
	0.0025% bath, 5 min/day for 6 days.	In juvenile *Litoria caerulea* and Gulf Coast toads (*Incilius nebulifer*).[4]
	0.01% bath, 30 min/day for 11 days.	Used in terrestrial African caecilian, *Geotrypetes seraphini*, and aquatic neotropical caecilian, *Potomotyphlus kaupii*.[5]
Voriconazole	Mixed to a concentration of 1.25 μg/mL water and sprayed on to animals daily for 7 days.	Used in Corroboree frog (*Pseudophryne corroboree*), Iberian midwife toad (*Alytes cisternasii*) juveniles, and a few individual poison dart frogs (Dendrobatidae family).[6,7]
Voriconazole and polymyxin E	Polymyxin E submersion baths (2000 IU/mL, 10 minutes) followed by spraying voriconazole (12.5 μg/mL) twice a day for 10 days at an ambient temperature of 20°C.	Effective treatment in *Salamandra salamandra*.[8]

VetBooks.ir

TABLE 140.1 Selected Treatments Against Chytridiomycosis—cont'd

Treatments	Dosages—Protocols	Comments
Chloramphenicol	Combination of continuous shallow immersion (23 of 24 hrs) in 20 mg/L chloramphenicol solution for 14 days, parenteral isotonic electrolyte fluid therapy for 6 days, and increased ambient temperature to 28°C for 14 days.	Effective combination treatment in green tree frogs (*Litoria caerulea*).[9]
Terbinafine	Dissolved in ethanol diluted in distilled water to create solutions of 0.01%–0.005% terbinafine and 1%–0.5% ethanol, respectively. Animals were bathed for 5 minutes daily for 5 consecutive days.	Popular treatment because it is commercially available as an athlete's foot preparation (Lamisil AT Spray, 1% terbinafine hydrochloride, Novartis Consumer Health, Parsippany, NJ).[3,10]
Increased environmental temperature	Environmental temperature is gradually increased over a period of 2 days. Animals are then maintained at this ambient temperature.	Effective treatment at 30°C for 10 consecutive days in *Rana catesbeiana* and *Acris crepitans*.[11] Effective treatment at 25°C for 10 consecutive days in salamanders.[12] Effective treatment at 32.2°C for 72 hrs in aquatic caecilians (*Typhlonectes natans*). Then over a period of 3–4 days the temperature was slowly returned to ambient.[13]

disinfectants that effectively kill *Bd*, including Virkon, a multipurpose disinfectant that contains oxone (potassium peroxymonosulfate), sodium dodecylbenzenesulfonate, sulfamic acid, and inorganic buffers (Antec International, Sudbury, UK) at 2 g/L^{-1} or a solution of 4% bleach.[14] Newly acquired animals should be maintained in quarantine as individuals in separate containers for at least 2 months. Collect skin swabs (or mouthpart swabs from tadpoles) for PCR assay on arrival and 7 weeks later. A thorough necropsy including PCR (ideally qPCR) on the appropriate tissues must be performed on any animals that die.

Aural/Tympanic Abscessation

Michelle Kischinovsky and Stephen J. Divers

DEFINITION

Aural abscessation is a condition characterized by an accumulation of caseous material within the middle ear or tympanic cavity, resulting in a protrusion of the tympanum (Fig. 141.1A). The condition exists in both free-ranging and captive reptilian populations and is most commonly seen in chelonians (tortoises and semiaquatic turtles).[1–7]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Aural abscess formation appears to be multifactorial and a result of several predisposing factors. No known cause has been identified; however, it is generally accepted that there exists a correlation between abscess formation and improper husbandry (e.g., suboptimal habitat temperatures, poor hygiene) leading to immunosuppression as well as inadequate nutrition resulting in vitamin A deficiency.[7] Hypovitaminosis A causes hyperplasia and squamous metaplasia of several epithelial tissues, including those of the pharynx, trachea, middle ear, and eustachian tube, leading to an accumulation of exfoliated squamous cells and keratinlike debris within the tympanic cavity, which eventually results in abscess formation.[2,7–9] This assumed relationship is supported by free-ranging Eastern box turtles (*Terrapene carolina carolina*) with pathological aural changes in association with organochloride-containing pesticides known to cause vitamin A metabolism disruption in other species.[8–11] The eustachian tubes, connecting the oropharynx to the middle ear, may provide a pathway for ascending pathogens into the tympanic cavity, which in an immunocompromised animal may contribute to abscess development. However, no consistent bacterial pathogen has been isolated, and most (mainly aerobic gram-negatives) are believed to be opportunistic commensals from the oral cavity.[2,6,12] Though less likely, hematogenous spread and traumatic etiology are possible.

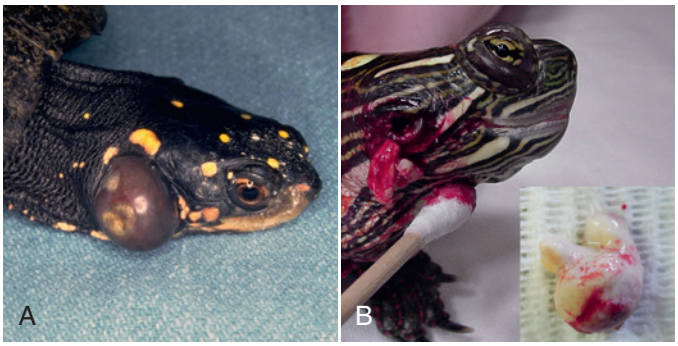

FIG 141.1 (A) Right aural abscess in a Chinese spotted turtle (*Clemmys guttata*). (B) Surgical removal of a right aural abscess from a slider (*Trachemys scripta*). *(Inset)* Removed aural abscess from a tortoise (*Testudo graeca*), demonstrating the caseous, inspissated nature of the infection. (Courtesy of Stephen J. Divers.)

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

The tympanic swelling(s) may present as unilateral or bilateral, semifirm to firm, and cause protrusion of the tympanic membrane rather than rupture. Obvious vestibular signs are generally lacking. The absence, in reptiles, of lysozomes (within their granulocytic leukocytes) results in a caseous, inspissated pus. Histologically, cases range from mild squamous metaplasia and hyperplasia to more severe cases involving pronounced inflammation and osteolysis.[2,8,12,13] Diagnosis can often be made solely by visual assessment. Additional tests may add therapeutic or prognostic value and can include fine-needle aspiration cystology (to aid differentiation from neoplasia) as well as hematology and blood chemistry to evaluate systemic disease involvement. Radiography and computed tomography may aid in determination of severity and appropriate management.[13]

PREFERRED TREATMENT(S)

Surgical management is recommended (see Chapter 92 for surgical details). Because of the avascular and inspissated structure of the abscess, it is easily manipulated out of the tympanic cavity in its entirety (see Fig. 141.1B). The deficit is lavaged and dressed daily, and the tympanum is left to heal by second intention. Antibiotics are seldom necessary.

PROGNOSIS AND PREVENTION

Complete excavation of aural debris, appropriate wound and secondary infection management, and correction of any concurrent suboptimal husbandry conditions result in a good prognosis. Recurrence does occur and is typically due to inadequate surgical debridement or failure to address the underlying predisposing factors.[7] Education with regard to appropriate husbandry, sanitation, and nutrition is most beneficial for prevention.

Bite Wounds and Prey-Induced Trauma

Marja J.L. Kik and T. Franciscus Scheelings

DEFINITION

This chapter covers injuries from dogs, cats, predators and rodent/invertebrate prey.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Bite injuries are common in captive and free-ranging reptiles. Injuries may occur as a result of predation, inter- or intraspecies hostility (e.g. dog or cat attack), or from live prey items (especially rodents and crickets).

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Housing sexually mature males together can often lead to serious and violent fighting resulting in extensive wounds (Fig. 142.1A). Conspecific aggression is not limited to sexual rivalry or courtship, as individuals housed in appropriate sex ratios may engage in combat in competition for food or basking resources. Although reptiles housed in mixed exhibits may appear to coexist harmoniously for extended periods, often there is an undercurrent of stress. Reptiles are typically solitary animals that may defend themselves vigorously against rivals. This can be a difficult conversation for clinicians to have with some keepers as there is a tendency to anthropomorphize the needs of the reptile for companionship.

Bite injuries may also occur from live prey items. Most reptiles will readily accept prekilled prey and the practice of offering live rodents should be discouraged (and may be illegal depending on location). Live rodents left unattended in a cage with an anorectic reptile eventually become hungry, frantic, and may attack or feed on the reptile (see Fig. 142.1B). Rodents may also bite when seized by a hungry reptile, resulting in wounds to the tongue, lips, eyes, or head of the reptile. The bite wounds can be superficial or severe even resulting in death.

Invertebrate prey left in enclosures can bite debilitated reptiles.[1] Although such wounds are typically superficial, they can lead to bacterial infections and even septicemia. Additionally, these nonfeeding interactions with free roaming insects may create stress. Some species of lizards can be fed invertebrates with a pair of forceps avoiding the need to leave them in the enclosure. For others, such as chameleons that utilize their projectile tongues to feed, small but deep containers can be used to localize and contain insects.

Another important source of bite wounds in reptiles comes from dog and cat attacks.[2] This is most common in free-ranging animals but may also occur when reptiles are left unattended in a yard or if they inadvertently escape from an enclosure. These injuries are often severe and commonly result in death or necessitate euthanasia.

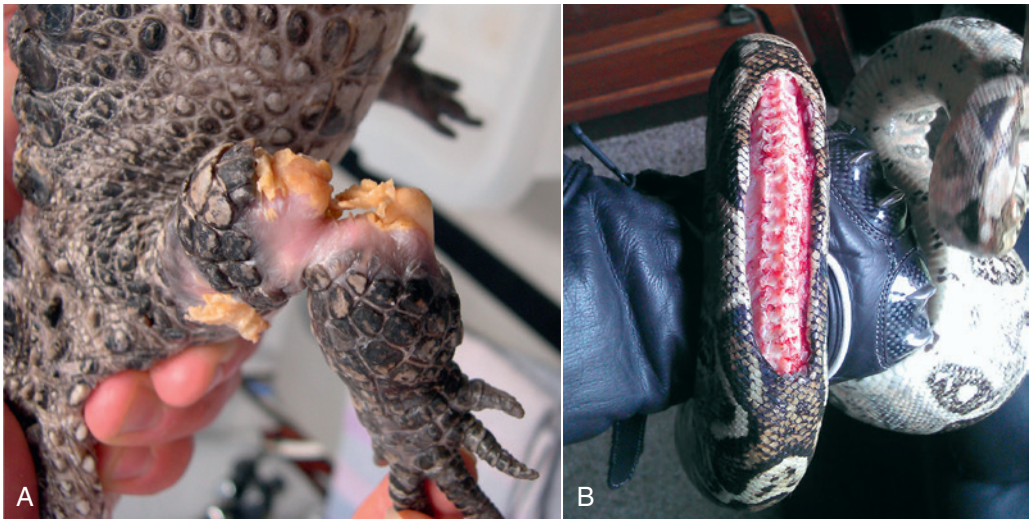

FIG 142.1 (A) Chinese alligator *(Alligator sinensis)* with evidence of severe intraspecific trauma by a cage mate. (B) Boa *(Boa constrictor)* with a bite injury from a rat. (Courtesy of Marja J.L. Kik.)

VetBooks.ir

PREFERRED TREATMENT(S)

Hemorrhage should be addressed. Bite wounds are always contaminated with a variety of microbiota.[3] The wounds should be flushed extensively with sterile saline. Treatment often requires sedation, analgesia and in severe cases general anesthesia (see Chapters 48 through 52).[4] Necrotic tissue should be surgically removed. Defects should only be sutured if wounds are fresh, and not punctures. Amputation should be considered for severely damaged appendages and ruptured globes enucleated. Contaminated, infected, or older (>6–12 hours) wounds should be cultured, not be sutured and be allowed to heal by secondary intention. In some cases, partial closure, still allowing drainage and flushing/treatment may be done. Dressings should be properly applied and changed regularly to keep the wound free from contamination and avoid complications such as myiasis. Topical and systemic antibiotics are often indicated and should be administered based on culture and sensitivity results. Additionally, hematology and diagnostic imaging may be warranted.

For aquatic turtles, wounds should be covered with sterile bandages, including a waterproof adhesive, in order to restore them to an aquatic environment (see Chapter 113 for an extensive discussion on shell treatment and repair). Additional supportive care may include esophageal tube placement for fluid and nutritional support (see Chapter 45). During convalescence animals should be housed under conditions that will not affect wound healing (e.g. unprinted newspaper, paper toweling, and damp towels for aquatic reptiles). See Section 3 husbandry and management, and Chapter 46 hospitalization for more details.

PROGNOSIS AND PREVENTION

Prognosis is varied and depends on the extent of the injury. Superficial wounds involving just the skin have a good prognosis. Deep wounds that result in puncture of the gastrointestinal tract or damage to other internal organs may carry a grave prognosis. In captive situations, these injuries can be avoided by altering husbandry practices and excluding dogs and cats and other predators from reptile areas.

Cloacal Prolapse

Stuart McArthur and Ross A. Machin

DEFINITION

A cloacal prolapse is a relatively irreducible, persistent, pathologic protrusion of tissue through the cloaca and vent. A cloacal organ prolapse is a common veterinary emergency seen in both first opinion and referral practice and occurs in all reptile taxa. A cloacal prolapse is a clinical sign, not a diagnosis, because in most cases, a pathologic prolapse is associated with deeper clinical issues and significant debility. The gastrointestinal, reproductive, and urinary systems all terminate at the cloaca, and therefore a wide variety of disorders may manifest as abnormalities around this anatomic structure, especially if obstructive. Prolapses have been described in free-ranging as well as captive reptiles (Machin R, McArthur S, personal observation, 2017).[1–12]

Cloacal anatomy is variable between the orders but is generally divided into three compartments between the caudal colon and the vent.[13–22] The anatomy and physiology of the cloaca is described in Chapter 75.

CLINICAL SIGNIFICANCE

Cloacal organ prolapse is a common reptile veterinary emergency. In one study including more than 3000 captive reptiles, the incidence of reptile prolapses was 1.9%, and they were more common in chelonians and lizards than in snakes. The most common prolapse was the phallus/hemipenes (35.7%). Prolapses were 3.47 times as likely in chelonians and lizards compared with snakes with no statistical differences between males and females, although females were 7.5 times more likely than males to present with a true cloacal prolapse involving no other organs. The authors concluded that species and sex may influence prevalence and type of cases seen.[1]

KNOWN ETIOLOGICAL CAUSE(S)

The presence of a cloacal prolapse is associated with a variety of complex multifactorial causes. These associations are summarized in Table 75.2. They include intestinal (e.g., infections, parasites, constipation, fecoliths, and neoplasia), urinary (e.g., infections and uroliths), reproductive (e.g., male courtship trauma or probing, belanoposthitis, mating injuries, paraphimosis, dystocia, chronic sexual activity, constipation, neurological dysfunction, substrate contamination, hemipenile plugs, hypothermia, neoplasia), metabolic (e.g., hypocalcemia, electrolyte derangements, dehydration, debility, hypothermia, collapse), and coelomic disease (e.g., ascites, coelomitis, neoplasia). In addition, normal tissue (e.g., phallus) may also be intermittently observed by owners during bathing, handling, or urination.[1–12]

CLINICAL PRESENTATION

Left untreated, a cloacal prolapse results in distress and likely pain. The condition must be regarded as a true veterinary emergency, because the prolapsed structure will become rapidly devitalized through ischemic necrosis if not protected and reperfused rapidly. With the possible exclusion of prolapses of the male copulatory organ, untreated prolapses involving the colon, bladder or oviduct are likely to be fatal because of the combined systemic effects of tissue necrosis and compromised body system functions.[1,10]

Treatment of most cloacal prolapses involves a skillful, simultaneous balance of medical and surgical interventions. The presentation therefore draws on many of the techniques described across the clinical disciplines. Information to assist a clinician facing this presentation is located within several sections of this book; surgical management is covered within Chapter 106 and throughout Section 10, whereas medical management is included in Chapter 75 and throughout Sections 5 and 9.

DIAGNOSTIC CONFIRMATION

A detailed history covering husbandry and species understanding is vital in the full diagnosis of a cloacal organ prolapse, because there are many factors that may contribute directly or indirectly to the presenting condition. Features of the history that deserve special attention include the species, age, the suitability of any source of heat or ultraviolet lighting used, the hygiene conditions the reptile has been kept in, whether the reptile was kept alone or in a group, the substrate used, and the humidity and photoperiod used.[11,12]

Organ differentiation may prove challenging due to exposure or trauma. A guide to identification of the organ involved in a cloacal prolapse is given in Table 75.1. It is always important to determine which organ has prolapsed, because this influences both the treatment options and the prognosis. The organ prolapses experienced by each reptile class are summarized in Table 75.1. Prolapsed structures may include hemipenes (snakes and lizards) or phallus (chelonians), cloacal masses or tissue, oviduct, shell gland, colon/rectum, bladder (chelonians), and ovaries (sea turtles).[1,3,4,6,8]

A considered therapeutic plan must have informed client consent. This is occasionally challenging, because many prolapses will require extensive medical management in parallel with surgical reduction or organ removal. Appropriate diagnostic investigations may include clinicopathology (hematology, biochemistry, microbiology, virology), diagnostic imaging (radiography/CT, ultrasonography or endoscopy initially), fecal testing (parasitology, bacteriology), and in some cases exploratory coeliotomy/coelioscopy or advanced imaging techniques may be required.

Following commencement of initial stabilization measures described earlier in Table 75.3, a diagnostic plan should be made and followed, allowing a therapeutic plan suitable to the specific patient.

PREFERRED TREATMENT(S)

It is necessary to treat both the prolapse and the underlying cause. Analgesia, physical manipulation, osmotic reduction, and lubrication

VetBooks.ir

FIG 143.1 Colonic intussusception and prolapse in a Hermann's tortoise (*Testudo hermanni*). The prolapse is fresh and has an obvious lumen.

FIG 143.2 The same *Testudo hermanni* as Fig. 143.1. A plastron osteotomy and coeliotomy have been performed. The prolapse has been reduced and the intussusception corrected. The colon will have pexy sutures to the coelomic membrane placed before the osteotomy is closed.

can sometimes be achieved simply by using materials such as local anesthetic mixed with lubricating gels. However, in many cases, addressing the prolapse may be more complicated. Analgesia options are also covered in Table 75.4.

In the case of a prolapsed phallus or hemipenis, application of lubrication after appropriate lavage often allows a fresh prolapse to then be gently replaced within the cloaca or in the case of a hemipenis inverted back within the ventral tail base. Here it can be retained through a suitable dressing or bandage, or in some cases through a temporary suture. Where the organ has significant devitalized tissue, amputation in a stabilized patient is preferable. Additional conditions behind the prolapse will also require correction; examples include bacterial or parasitic infections, dehydration, and hypocalcemia.

In the case of an oviduct or colon prolapse, a celiotomy is normally required to correctly reduce the prolapse and address factors that lie behind it (Fig. 143.1). If the prolapse is necrotic or devitalized, all or part of the prolapse may require removal during the coeliotomy procedure (Fig. 143.2). Additional conditions behind the prolapse will also require correction, including dystocia, cloacoliths, constipation, and parasitism.

In the case of a bladder prolapse, occasionally these may be reduced without the need for coeliotomy; however, some form of contrast imaging may be required to confirm correct reduction and ensure that that the structure has involuted correctly. It may be necessary to perform a coeliotomy to address any ectopic eggs or calculi within the bladder. Additional conditions behind the prolapse will also require correction.

The longer a prolapse is left vulnerable, with exposure to contaminated substrate, strangulated, engorged, and traumatized, the less likely it is to be viable and the more likely it will require removal.[6] Where organ identity cannot be differentiated because of severe secondary swelling, substrate contamination, avascular necrosis, or an inexperienced clinician, the client should be realistically informed about different options available for managing the patient. These options include referral for diagnostic procedures, surgical options, and possible complications, and they should be issued with a guarded prognosis.[6] For example, in many reptile species it may not be possible to remove a length of necrotic colon and still have a viable patient, and this may not be known until an intraoperative assessment can be made. Surgical procedures and protocols are covered in Chapter 106.

PROGNOSIS AND PREVENTION

The prognosis for a cloacal organ prolapse is dependent on multiple factors; most importantly this includes any underlying cause, the patient's condition, and the prolapse viability and duration of the prolapse. Treatment and prognosis in a young leopard gecko with a hemipenal prolapse that requires amputation following chronic sexual activity will be different than a monitor lizard with severe nutritional secondary hyperparathyroidism and colonic prolapse. Prognosis varies from excellent to grave, and euthanasia should be considered in the most serious cases.

Species understanding and educating owners and caretakers on appropriate husbandry, including stress reduction, environmental enrichment, balanced diet, supplementation, lighting, humidity, and adequate substrate are essential for minimizing or preventing many of these conditions.

Cloacal Scent Gland Adenitis

Scott J. Stahl

DEFINITION

Paired cloacal scent glands of snakes are uniquely ophidian and are present in all species of snakes.[1] The glands appear in both male and female snakes but are larger in females. These paired glands are located within the tail base (Fig. 144.1A). Cloacal scent glands are specialized exocrine glands that produce a thick semi-liquid material containing pheromones and semiochemicals used to actively mark objects and organisms.[1] See Chapter 80 for more details.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Cloacal scent gland adenitis has been reported in snakes and is not an uncommon presentation.[2] Clinically, scent gland adenitis appears to be more common in older, female, colubrid, and actively breeding snakes.[2] Without release the impacted scent material becomes thick, inspissated, and the gland becomes secondarily infected, swollen, hard, and may rupture.[2] Mineralization and neoplasia are possible and often unilateral. Captive related environmental factors affecting glandular release include humidity, substrate (paper or carpeting versus a natural substrate), poor sanitation, and presence or absence of conspecifics. The author has seen several cases of neoplasia associated with scent glands, and a fibrosarcoma was identified with scent gland adenitis in a colubrid snake (Couture et al, Proc ARAV, 2017, p 352).

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Typically, older and/or actively breeding females are overrepresented. Physical examination is often diagnostic, with snakes presenting with unilateral or bilateral swellings caudal and lateral, and in severe cases craniolateral, to the cloaca (see Fig. 144.1B). In severe cases rupture of the gland may occur. On palpation the gland may be soft to hard depending on changes and duration. Fine-needle aspiration and cytology can confirm gland involvement and may indicate neoplasia. Radiography is less useful except to confirm mineralization. Ultrasonography can help differentiate between neoplastic tissue and impaction. Biopsy for histopathology and microbiological testing at surgery is often necessary for a definitive diagnosis.

PREFERRED TREATMENT(S)

In cases of mild impaction gently massaging the gland (after warm water soak) to move material toward the gland opening may allow release. In larger snakes cannulation of the duct opening (under sedation/anesthesia) can be attempted with a urinary catheter or metal lacrimal duct cannula.[2] Unfortunately, with retention, glandular material becomes thick, grainy, often inspissated, and cannot pass out of the narrow duct opening, necessitating surgery. For surgical resolution, an incision is made between the lateral scale rows over the enlarged gland. The gland

FIG 144.1 (A) A prosection of a female ball python (*Python regius*) showing the location of the paired cloacal scent glands in the tail base. The caudal vent rim, and some subcaudal scales, have been removed to show the location of the left scent gland (grasped by hemostats) and the opening of the scent gland with scent gland material evident (at the tip of the scissors). (B) A leucistic western hognose snake (*Heterodon nasicus*) with cloacal scent gland adenitis in the right gland (at top near snake's head) showing; in severe cases, the gland swelling can be craniolateral to the vent not just caudal. This case was associated with bacterial adenitis. (A, Courtesy of Greg Costanzo, Stahl Exotic Animal Veterinary Services; B, courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

VetBooks.ir

is opened, impacted material is removed, and biopsies of the gland are collected for histopathology and microbiological culture. The gland can then be lavaged and a catheter passed to ensure patency. If the gland was cannulated, it can be closed or marsupialized to allow continued flushing and treatment.[2] Systemic antimicrobials and/or topical antimicrobials may be initiated based on histopathology and microbiological results along with local flushing with antiseptics. Surgical removal of the entire affected gland(s) is often the curative choice in cases that are severe, reoccurring, bilateral, or if neoplasia is suspected/confirmed (Couture et al., 2017, Proc ARAV, p 352).[2] (See Chapter 80 for more details on medical and surgical resolution of scent gland adenitis.)

PROGNOSIS AND PREVENTION

Prognosis is good with complete surgical removal of the gland(s) and if underlying conditions leading to blockage and/or inflammation of the gland are corrected after successful medical treatment. If neoplasia is confirmed, the type of neoplasm determines prognosis. Prevention involves correcting husbandry issues that may be contributing factors.

Diarrhea

Kevin Eatwell and Jenna Richardson

DEFINITION

Diarrhea is a clinical sign, not a disease. It can be defined as increased water content in the feces, resulting in soft or liquid feces. Compared with mammals, reptiles have a longer gastrointestinal transit time, and most normal reptile feces are therefore well formed and, in some cases, even desiccated.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Diarrhea can be classified as acute (sudden onset, self-limiting, short duration) or chronic (longer duration, recurrent). Causes of acute episodes include dietary indiscretion, sudden changes in diet, or inadequate temperature provision (see Chapter 74 for more details). Chronic diarrhea is often more concerning due to dehydration and electrolyte imbalances. As with mammals, steatorrhea and melena often indicate a small-bowel problem, whereas fresh blood and mucus are more likely large-bowel related. Potential causes of diarrhea include infectious enterocolitis (e.g., parasitic, bacterial, viral, mycotic), inflammatory or infiltrative diseases of the bowel (e.g., neoplasia), and intestinal malfunction (e.g., partial obstruction).

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Depending on the duration, severity, and underlying cause, the reptile may present bright and active or dull, lethargic, and dehydrated. As diarrhea has many potential causes, a diagnostic investigation is recommended. A full clinical history should be obtained to ascertain any changes in husbandry or diet (e.g., stocking density, hygiene, other reptiles owned, and any concurrent illness). It is also important to appreciate what "normal" feces are for the individual species to avoid misinterpretation based on appearance (Fig. 145.1A). A thorough clinical examination, including detailed palpation of the coelomic cavity and cloacal examination, should be performed. Initial diagnostic tests include fecal parasitology (wet preparation and salt flotation). Speciation of a particular parasite is rarely necessary; however, attempts should be made to place the parasite into a suitable treatment category (e.g., round worm, tape worm, protozoan). Hematology and biochemistry, diagnostic imaging (e.g., radiography, ultrasonography, CT, MRI), and endoscopy (e.g., gastroscopy, cloacoscopy, coelioscopy) may be required. Biopsy may be required for a definitive diagnosis. For more details, see Chapters 32, 74, and 120.

PREFERRED TREATMENT(S)

Treatment is aimed at resolving the underlying cause while providing supportive care to prevent worsening of the clinical condition. Rehydration therapy either parenterally or, if the gastrointestinal tract is functional, orally is recommended. Providing warm water baths may encourage the reptile to drink. Where substandard husbandry is a factor, a full review and correction as necessary will be required (e.g., poor hygiene, inappropriate temperature ranges, dietary items). For parasite burdens, a suitable parasiticide treatment should be selected, with repeat fecal analyses to ensure efficacy. Other therapies will be dependent upon a specific, definitive diagnosis.

PROGNOSIS AND PREVENTION

Prognosis of diarrhea is dependent on the inciting cause and duration of clinical signs. Sensible husbandry and dietary items should be provided. Good hygiene practices, low stocking density, and reducing stressors are all important considerations.

Digit Abnormalities

Geraldine Diethelm

DEFINITION

Digit abnormalities are visible abnormalities of the feet and digits.

CLINICAL SIGNIFICANCE

Foot and digit issues are commonly encountered and often associated with husbandry problems. If ignored they can progress to involve joints and bones, with ascending infections necessitating surgical debridement or even amputation.

ISCHEMIA

Dysecdysis or retained shed (Fig. 146.1) can lead to damage and the loss of toes from strictures formed around the nailbed, disrupting circulation to the appendage. These shedding issues are usually the result of poor husbandry, such as inadequate environmental humidity, or can be the result of generalized illness. Strangulation of digits may also occur from substrate issues such as entrapment with fibers or hair. Additionally, trauma from other environmental issues include digits caught in netting or damaged by screen, attacked by prey, cagemates, or predators (if outside or housepets indoors). Regardless of how damage occurs, infection can ascend and cause inflammation in the remaining digit (Fig. 146.2), joint, and more proximal tissue, ultimately leading to generalized sepsis. Amputation in cases of osteomyelitis, as well as early and aggressive antibiotic therapy, may be necessary to prevent further ascending infection. If infection progresses to involve joints or the spine the prognosis becomes guarded to poor. Husbandry changes, including hygiene, should be discussed with the caretaker in detail. (See Chapter 69 for more details.)

SWOLLEN TOES AND JOINTS

Even with no outward signs of trauma, the differential list should include trauma but also infection, fractures, fibrous osteodystrophy, gout and "pseudogout,"[1,2] and neoplasia. Patients may have nonspecific clinical signs such as anorexia but will often have difficulty ambulating or balancing. Swelling in metatarsal-phalangeal joints often occurs with gout/pseudogout. Diagnostically radiographs can show bone lysis in and around the joints, and needle aspirate cytology or biopsy histopathology will differentiate between infection, neoplasia, and crystal deposits. Whole body radiographs should be taken to exclude other boney involvement (e.g., spine) or calcification of other organ systems. Pain management with nonsteroidal antiinflammatories and/ or opioids should be included. Surgical debridement of any infected or necrotic material is necessary because antimicrobials do not penetrate avascular abscesses. Amputation to prevent spread of disease is a viable alternative to euthanasia. (See Chapter 81 for more details.)

TWITCHING TOES

Tremors or twitching toes are most commonly seen in nutritional or renal secondary hyperparathyroidism and hypocalcemic gravid lizards.

FIG 146.1 Dysecdysis in a leopard gecko *(Eublepharis macularius)*. (Courtesy of Stephen Barten.)

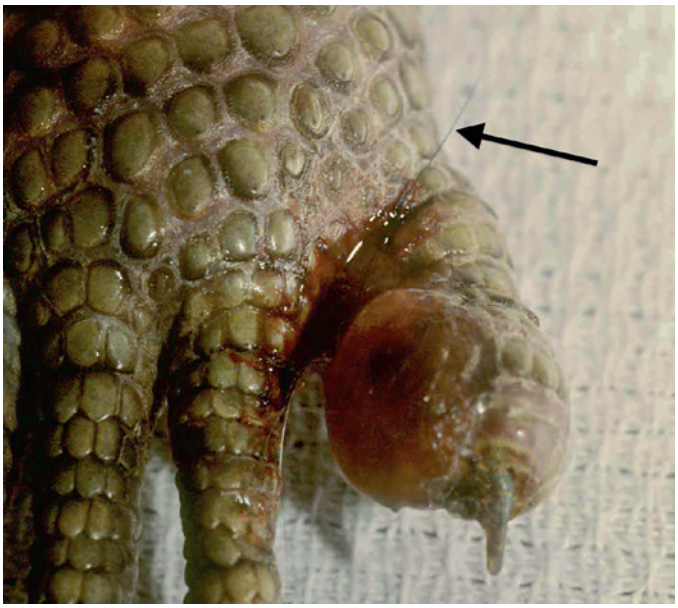

FIG 146.2 Onychitis in a savannah monitor (*Varanus exathematicus*) secondary to fiber (arrow) strangulation. (Courtesy of Douglas R. Mader.)

VetBooks.ir

(See Chapter 84 for more details.) Intermittent, uncontrollable tremors in the toes (and often involving other muscles as well) are typically initiated by excitement and movement. Decreased ionized and total calcium levels result in these clinical signs and, as the conditions worsen, can progress to constant tremoring, seizures, and eventually end in flaccid muscles and paralysis. Differentials should include heavy metal intoxication, hypoglycemia, hypothermia, and sepsis.

SKIN ABNORMALITIES

Necrotic, sloughing, or discolored skin may be caused by burns, trauma, and ectoparasites, as well as poor husbandry, leading to secondary infections.[3] These can result in generalized sepsis. Debridement, topical, and systemic treatment depending on cause, as well as correcting the environment, is necessary. Parasitic reinfestation will occur if the pet is reintroduced into a contaminated habitat. Mites can be detected visually or with a skin scraping. Cytology and culture of material beneath an "uncontaminated" blister or scab can aid in directing effective treatment. (See Chapter 69 for more details.)

Dysecdysis

Tom Hellebuyck and T. Franciscus Scheelings

DEFINITION

Dysecdysis is the abnormal or impaired shedding of the outer layer of skin of reptiles and amphibians.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Dysecdysis is one of the most commonly observed skin disorders and should be considered a nonspecific clinical finding.[1,2] Knowledge of the normal anatomy and physiology of the reptilian integument is important for recognizing dysecdysis and establishing an appropriate diagnostic and therapeutic approach. Dysecdysis may originate from numerous infectious (e.g., ectoparasites, fungi) (Fig. 147.1) and noninfectious conditions (e.g., low humidity), especially those that interfere with normal skin integrity (see Chapter 69) and disorders resulting in dehydration or hypoproteinemia (Fig. 147.2).[2,3] Dehydration may result in a reduction of fluid necessary at the cleavage zone for normal separation of the old and new epidermal layers. Hypoproteinemia may interfere with the normal enzyme production necessary for the breakdown of the fission layer.[2]

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Retention of sloughed skin may affect the entire integument and adnexa or may be restricted to certain areas (Fig. 147.1). Dysecdysis often presents as constricting bands of old skin, particularly around the digits (Fig. 147.3) and tail in lizards. Failure to recognize and remove incomplete sloughed skin in a timely manner may result in avascular necrosis and loss of distal extremities.[1,2] Retained spectacles in snakes and some geckos may result from the accumulation of several incomplete sloughs. Retained spectacles appear dull and wrinkled compared with normal eyes in nonshedding animals and may occur unilaterally or bilaterally. Discrimination between retained spectacles and other ophthalmologic disorders (e.g., subspectacular abscesses) may be challenging. Clinical evaluation for dysecdysis requires a good understanding of what is normal for the species being evaluated. Additionally, patient age and size, historical details regarding the frequency of past molts and skin issues, and concurrent illnesses should be appreciated. Following a thorough physical examination, additional diagnostic tests may be required to reveal the underlying cause and initiate appropriate therapy. Normal respiratory sounds may increase before and during shedding because of the presence of retained skin around the nostrils.[4] (See Chapter 69 for more details.)

PREFERRED TREATMENT(S)

Aggressively peeling back retained or shed skin should be avoided because these problems are rarely emergent. Premature removal of older epidermal layers before the newer layers have fully developed may result in ulceration or corneal exposure in the case of spectacles and considerable loss of proteinaceous fluids and may permanently damage or scar the skin/eyes (Fig. 147.4). Chronicity often directs the therapeutic approach (see Chapter 69).

Lightly spraying the animal and increasing environmental humidity may be sufficient in minor cases of dysecdysis. Short soaks in lukewarm water are often effective for removing larger portions of retained skin,

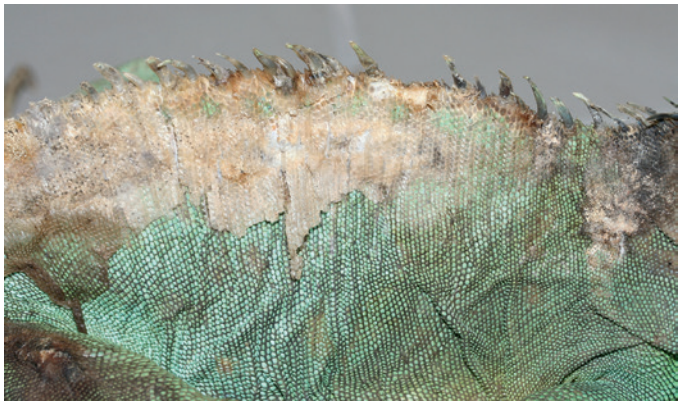

FIG 147.1 This Asian water dragon (*Physignathus concincinus*) shows localized dysecdysis as a consequence of severe dermatomycosis. (Courtesy of Tom Hellebuyck.)

FIG 147.2 In severely debilitated animals such as this collared lizard (*Crotaphytus collaris*), generalized dysecdysis may be observed as a consequence of dehydration and hypoproteinemia. (Courtesy of Tom Hellebuyck.)

VetBooks.ir

FIG 147.3 Constricting bands of old skin, particularly around the digits in lizards (A) often result in avascular necrosis and dry gangrene with eventual loss of digits, as seen in this tegu (*Tupinambis* sp.) (B). (Courtesy of Tom Hellebuyck.)

especially in snakes. Although various water additions are advocated, plain water is usually sufficient and safest.[2] For many desert-dwelling species, moist/humid retreats often facilitate shedding or resolve shedding disorders. Excessive moisture may result in decreased skin integrity and potentially predispose animals to bacterial and mycotic disease.[1]

FIG 147.4 Premature removal of older epidermal layers (e.g., during a shed cycle), as depicted in this Emerald tree boa (*Corallus caninus*), due to handling should be avoided, as considerable loss of fluids and proteins and even permanent damage and scarring of the integument may occur. (Courtesy of Tom Hellebuyck.)

PREVENTION

Dysecdysis is typically secondary, and it is effectively prevented by ensuring appropriate, species-specific husbandry. Both clinicians and owners should familiarize themselves with the captive management requirements of commonly kept species. Snakes and certain lizard species should not be handled during sloughing, as the skin is particularly vulnerable to traumatic injury and infection.

Dystocia and Follicular Stasis

Scott J. Stahl

DEFINITION

Dystocia is the inability to successfully expel term eggs or fetuses from the lower reproductive tract. Preovulatory follicular stasis refers to the inability to ovulate or resorb ova (see Chapter 80 for a more detailed discussion).

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Preovulatory follicular stasis occurs commonly in lizards, chelonians, and less often snakes.[1,2] Dystocia is often seasonal, as hormonal cycles, and thus reproductive activity, occur at specific times of the year. The etiologies for dystocia in captive reptiles are often multifactorial and may result from captive stress, inappropriate nesting sites, dehydration, malnutrition, obesity, salpingitis, malformed ova, broken or damaged eggs, obstructive coelomic pathology (e.g., cystic or cloacal calculus), infectious diseases (e.g., boid arenavirus), and abnormal reproductive anatomy.[1,2]

CLINICAL PRESENTATION

Detailed history, thorough husbandry review, and a good understanding of species-specific reproductive strategies are paramount. All chelonians and crocodilians are oviparous (egg-layers), as are most squamates; however, some lizard and snakes are viviparous (live-bearers). Dystocic reptiles may be restless (pacing and climbing), looking for possible mates or nesting sites (Fig. 148.1). Oviparous lizards and chelonians may dig in planters or substrate. Female aquatic turtles may spend extended time out of the water. Coelomic distention with reduced body condition, anorexia, and behavioral changes may be noted. Females may have produced a small clutch or litter but still appear gravid due to several retained eggs/fetuses. Alternatively, the breeder's records may indicate that the female is past her due date. Palpation may confirm enlarged follicles in squamates (not chelonians), but it can sometimes be difficult to differentiate preovulatory from postovulatory ova. Chelonians are more difficult to palpate, but in smaller species digital palpation in the prefemoral area, with the patient held vertically and gently tilted side to side, may allow shelled ova to be detected. It is usually not possible to palpate developing fetuses in viviparous squamates.

DIAGNOSTIC CONFIRMATION

Radiographically squamate preovulatory follicular stasis often appears as a cluster of spherical, dorsal structures that lack a shell. For dystocia cases, radiographs are important to identify the presence and number of shelled eggs and any abnormalities or obstructions (Fig. 148.2). Radiographic demonstration of skeletal structures is only possible late in gestation. Ultrasonography is preferred for identification of preovulatory follicular stasis and to differentiate between preovulatory and postovulatory

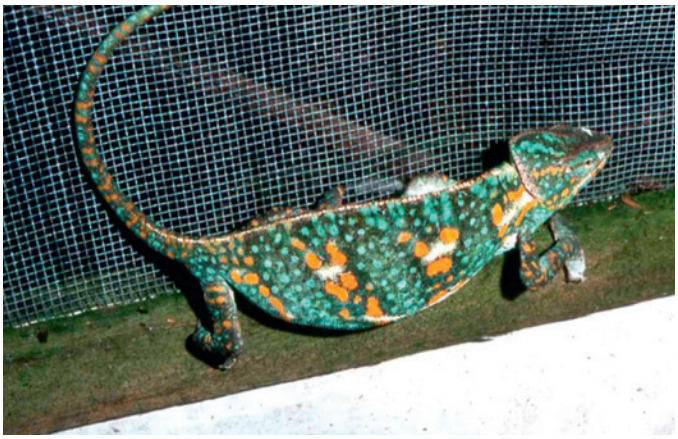

FIG 148.1 Behavior changes may be noted in gravid and dystocic reptiles. This female veiled chameleon (*Chameleo calyptratus*) became restless in her enclosure late in gestation, staying off the tree branches where she typically resided and pacing the cage floor perimeter, looking for an appropriate nesting site. Note the light blue (robin's egg) color spots on her skin, indicative of gravidity in this species. (Courtesy of Bill Love.)

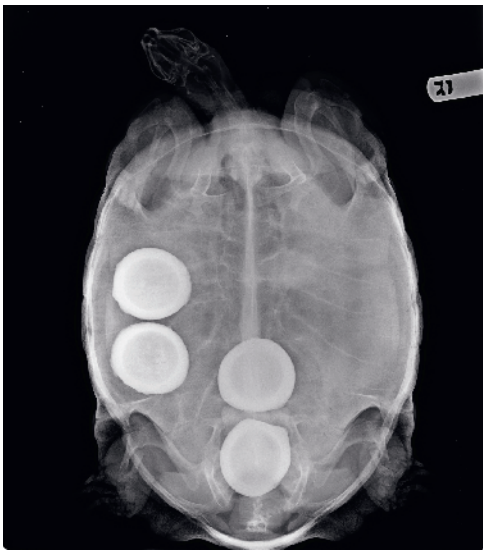

FIG 148.2 A dorsoventral radiograph of a star tortoise (*Geochelone elegans*) presented with chronic dystocia. Multiple treatments by the owner with oxytocin had failed. Chelonians are often responsive to oxytocin; however, before its use, radiographs are important to rule out obstructive dystocias or other concurrent complications such as cystic calculi. In this case note the abnormally thickened calcified shells, usually an indication of chronic retention or ectopic eggs. At surgery all eggs were found to be ectopic, three in the coelom and the most caudal irregularly shaped egg in the bladder. (Courtesy of Shoshana Sommer, Stahl Exotic Animal Veterinary Services.)

VetBooks.ir

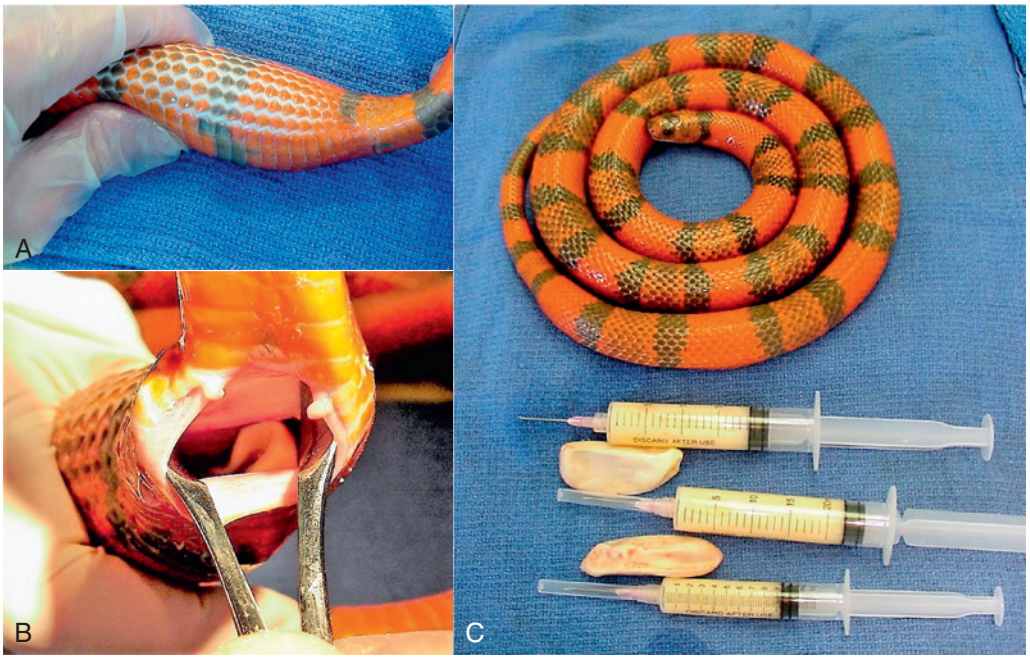

FIG 148.3 (A) A Honduran milk snake (*Lampropeltis triangulum hondurensis*) presented for dystocia after laying a partial clutch of eggs. With general anesthesia and once relaxed, the first egg was found to move freely and was manipulated toward the cloaca. (B) A vaginal speculum was used to dilate the cloaca and allow visualization, an 18-gauge needle was introduced directly into the egg, the liquid contents of the egg aspirated, and the collapsed egg then grasped with hemostats and removed; the procedure was repeated on the second egg. (C) The snake recovering from anesthesia after two eggs were removed through the cloaca. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

ova. Late gestational ultrasonography can determine fetus viability in viviparous species and help differentiate between normal or abnormal presentation. (See Chapter 80 for details on reproductive imaging.) Plasma biochemical changes often include elevations of total calcium but not ionized calcium, which may be low (<1 mmol/L), indicating hypocalcemia with related poor nutrition and husbandry. Complete blood count may show a stress leukocytosis or, in cases of inflammatory/infectious disease, a leukocytosis with left shift.

MEDICAL TREATMENT AND EGG MANIPULATION

Medical treatment may consist of provision of nest box(es) and oral or parenteral calcium supplementation in cases of hypo- to normocalcemia. In cases of unobstructive dystocia, induction using oxytocin, prostaglandins E, and F2a may be effective, with chelonians being more sensitive than squamates (see Chapter 80 for details). NSAIDs and antimicrobials may be indicated. Due to the linear anatomy of snakes, egg manipulation may be possible and is noninvasive.[1,2] However, general anesthesia is required to determine whether the eggs are adhered to the oviduct or if they move freely and can be gently manipulated through the cloaca (Fig. 148.3A). Per cloacal aspiration using a large-gauge needle (16–18g) to collapse can help with removal, per cloaca. (see Fig. 148.3C). Cloacoscopy may be useful in some cases in snakes and chelonians but less so in lizards and is best utilized when only one or several eggs are retained.[1,2] Retained eggs in snakes that are reluctant to move even with the use of anesthesia can be transcutaneously aspirated with a large-gauge (16–18) needle to collapse and assist with passing. This technique has an increased risk of complications and should only be used when all other options are considered or with economic limitations.

PREFERRED TREATMENT(S)

Surgical management is often the best option for resolving preovulatory follicular stasis (ovariectomy) or dystocia (ovariosalpingectomy), unless the reptile is part of a breeding program. For dystocia cases where future reproduction is important, once the patient is stable and all medical and less invasive management options have been considered, surgery (salpingotomy) may be indicated. (See Chapter 105 for details on performing these procedures.)

PROGNOSIS AND PREVENTION

Prognosis and outcome are generally good for dystocia cases with early diagnosis and intervention. During health examinations of female reptiles clinicians must discuss eventual hormonal influences, familiarize owners with signs of reproductive activity, and offer preventative ovariectomy as an option to avoid future issues.

Gout

Jorge Orós

DEFINITION

Gout is a metabolic disease characterized by overproduction or underexcretion of uric acid resulting in hyperuricemia and deposition of positively birefringent monosodium urate (MSU) crystals in tissues.[1]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Overproduction of uric acid resulting in hyperuricemia has been associated with high-protein diets (common in herbivorous reptiles fed a diet high in animal protein), whereas underexcretion of uric acid has been associated with dehydration (due to low environmental humidity or inadequate water availability) and/or kidney disease (see Chapter 66). Most cases of gout are the final stage of chronic diseases involving renal failure and/or dehydration.[2] Hypovitaminosis A has also been suggested in producing visceral gout in crocodile hatchlings by the mechanism of reduced renal excretion of uric acid through tubular squamous metaplasia.[3]

CLINICAL PRESENTATION

Articular gout results from the deposition of MSU crystals in the synovial fluid and synovial membranes, resulting in joint inflammation. Deposits of MSU can also be detected around the joints (periarticular gout) (Fig. 149.1). Visceral gout results from deposition of MSU crystals in other soft tissues, such as kidneys (Fig. 149.2), lungs, pericardial sac, serous membranes of liver and spleen, and subcutaneous tissue.[4] Articular gout often precedes visceral gout.[2] Deposits of MSU crystals are called tophi and consist of a complex of MSU crystals surrounded by granulomatous inflammation (see Fig. 149.2, Insert).[4]

DIAGNOSTIC CONFIRMATION

Elevations of plasma uric acid may be suggestive but can be within normal limits, especially for articular gout. Ultrasonography shows MSU crystal deposits as hyperechoic images without posterior acoustic shadowing, which enables their differentiation from calcifications. CT shows crystal aggregates but does not enable specific identification of MSU crystals. Dual-energy CT distinguishes urate crystals from deposits containing calcium.[5] Cytologic examination by phase contrast microscopy of joint aspirates is also useful to identify MSU crystals.[2] Visceral gout can be diagnosed by histopathologic examination of soft tissue biopsy. When using polarized light, the tissues must be fixed in absolute ethanol, because urate crystals tend to degrade and wash out during formalin (aqueous solution) fixation.[6] Determination of the glomerular filtration rate using iohexol excretion can also be useful to evaluate the renal function.[2] Differential diagnoses include hydroxyapatite deposition disease (HADD) and pseudogout or calcium pyrophosphate dihydrate (CPPD) deposition[6–8] and can be differentiated based on histologic appearance, histochemical staining for calcium, and birefringence under polarized light.

PREFERRED TREATMENT(S)[2,5,9,10]

Treatment consists of fluid therapy to correct dehydration and metabolic disturbances and the judicious use of antiinflammatories (if determined

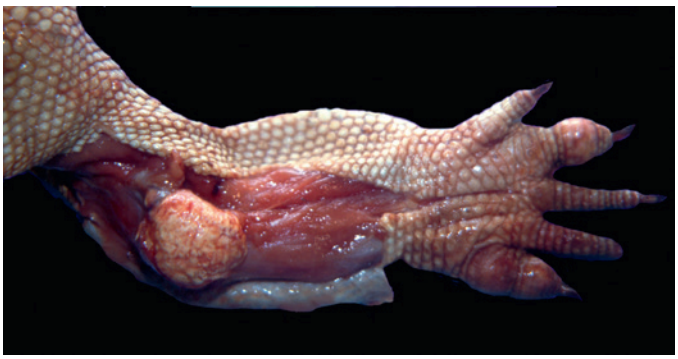

FIG 149.1 Periarticular gout in a savannah monitor (*Varanus exanthematicus*). Note the periarticular accumulation of tophi around the elbow and the swelling of several digits. (Courtesy of Jorge Orós.)

VetBooks.ir

safe based on renal evaluation). Surgical removal of isolated articular or periarticular gout, including limb amputation, may be one of the most effective treatment options. Managing pain with appropriate analgesics is important.

Uricostatic drugs may help to reduce uric acid production through competitive inhibition of xanthine oxidase. These drugs include allopurinol (25 mg/kg PO daily in the green iguana, *Iguana iguana*),[2] as well as oxypurinol and febuxostat (used in humans). Uricosuric drugs (e.g., sulphinpyrazone, probenecid, benzbromarone) in human medicine increase urinary uric acid excretion by blocking urate anion reabsorption by proximal renal tubule epithelial cells. Pegylated uricase therapy (pegloticase and pegadricase reserved for selected human patients) reduces urate levels by increasing its metabolism.

PROGNOSIS AND PREVENTION

The prognosis for severe visceral gout is poor to grave. The prognosis for articular gout depends on the extent of the lesions.

Hemoparasites

Giordano Nardini

DEFINITION

Hemoaparasites are parasitical infections identified within peripheral blood.

CLINICAL SIGNIFICANCE AND ETIOLOGICAL CAUSE(S)

Hemoparasites of reptiles are arguably symbiotes, and most infections are chronic and subclinical. Because they have an indirect life cycle, clinical disease of captive-bred indoor animals is rare.[1,2] The most serious pathogens are *Plasmodium* spp., especially in chelonians and lizards, which can cause anemia, erythroblastosis, and reduced tissue oxygen supply in lizards, and severe hemolytic anemia in chelonians (Fig. 150.1A and B).[1,3,4] *Saurocytozoon* has been reported in lizards, but it is considered harmless;[4] *Haemoproteus* is reported in lizards, turtles, and snakes. It is generally considered nonpathogenic but may cause hemolytic anemia in geckos.[3,4] *Haemogregarina* can be observed in freshwater turtles, tortoises, the tuatara, some lizards, most snakes, and crocodilians. Clinical signs including lethargy, open-mouth breathing, weight loss, and dehydration are uncommon but may be seen in unnatural or aberrant host species, or in immune-compromised patients.[2] In lizards and snakes anemia is possible.[4] *Haemolivia* are encountered in turtles and lizards and are usually nonpathogenic.[5,6] *Hepatozoon* are found primarily in snakes but also in geckos; in snakes, severe consequences on growth and reproduction are reported, including liver necrosis, inflammation, and neurologic signs.[4] *Karyolysus* has been primarily described in squamates and are rarely pathogenic.[3] *Hemococcidia*, *Lainsonia*, and *Schellackia* have been reported mostly in lizards; *Schellackia* may cause anemia.[3] *Piroplasmids*, *Sauroplasma*, and *Serpentoplasma* have been reported in lizards, chelonians, snakes, and chameleons but are not associated with clinical signs.[7] *Trypanosoma* and *Leishmania* can infect almost all reptile species. *Trypanosoma* can cause severe parasitemia, but infection is often subclinical and lifelong.[7] *Sauroleishmania* may be found primarily in lizards without pathogenicity.[4] *Microfilaria* can be detected in snakes, lizards, chameleons, and crocodilians as incidental findings without clinical signs, even though occlusion of terminal vessels is possible.[3,4]

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Stress (e.g., transport, inadequate captive microclimate, overcrowding, inadequate nutrition) can cause immunosuppression and lead to obvious disease.[1] However, parasite identification in blood smears is frequently an incidental finding. In immunocompromised, geriatric, and young animals, these parasites can cause lethargy, open-mouth breathing, weight loss, hemolytic anemia, splenomegaly, and dehydration.[2,6] Diagnosis is by the microscopic examination of quickly air-dried samples, preferably fixed with absolute methanol and stained with a Romanowsky-type stain or Giemsa/Wright-Giemsa.[1] Light microscopy allows recognition of the parasite genus, whereas morphologic species identification is often difficult and requires molecular analyses, especially for haemogregarines.[1,4] Sporozoites are found in blood cells (erythrocytes, leukocytes, and thrombocytes). Leishmania can be found in macrophages

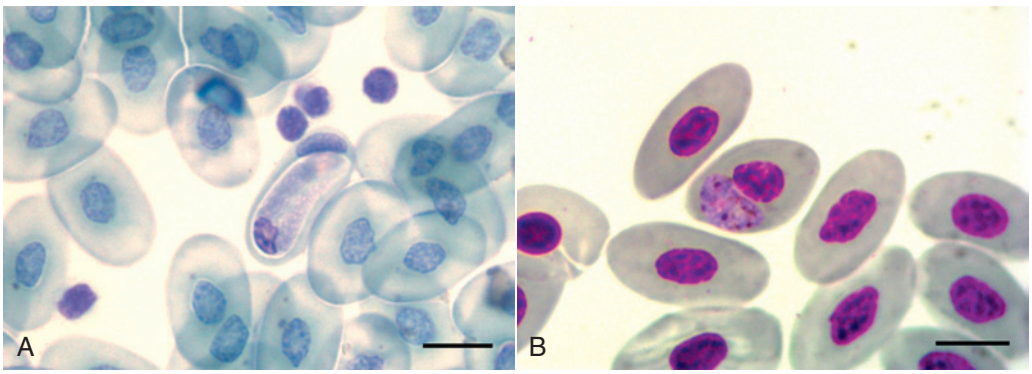

FIG 150.1 (A) *Haemogregarina* in erythrocyte from European pond turtle (*Emys orbicularis*). Giemsa stain; bar = 10 µm. VetBooks.ir

and usually is detected by culture techniques. Trypanosoma and microfilaria are found free in the blood film.[1,7]

PREFERRED TREATMENT(S)

No effective treatment is known for reptiles.[8] A decrease in haemogregarine parasitemia, but not clearance, has been noted with atovaquone-proguanil;[9] primaquine and chloroquine have been used against *Plasmodium* in chelonians. In patients with anemia and debilitation, treatment with iron-dextran and quinidine may be helpful.[8,10]

PROGNOSIS AND PREVENTION

Prognosis is generally good. Prevention is by quarantine combined with blood smear examinations, control of potential vectors, and, if necessary, treatment against ectoparasite transmission hosts.[8]

Hepatic Lipidosis

Stephen J. Divers

DEFINITION

Hepatic lipidosis is abnormal, excessive accumulation of intrahepatic fat. (See Chapter 67 for more detailed information.)

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Hepatic lipidosis is a metabolic derangement within the liver that can be associated with many diseases or syndromes. There are a host of factors that have been associated with increased hepatic fat, including high fat diets, reduced activity, nonbreeding females, nonhibernating temperate species, and certain toxins (e.g., ivermectin) (Fig. 151.1A). It is important to appreciate that increased intrahepatic fat is normal in temperate species before hibernation and in females preparing for folliculogenesis.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Hepatic lipidosis is usually chronic, with gradual reduction in appetite, activity, fecundity and fertility, weight gain (or weight loss late in the course of disease), hibernation problems, and changes in fecal character and color. Plasma biochemical changes including elevations in triglycerides, cholesterol, and lipoproteins are often apparent.[1] Reduced hepatic function can result in elevations of bile acids and hypoalbuminemia. Radiographically, hepatomegaly may be discernible in lizards and snakes but is challenging in chelonians. Ultrasonography and CT are more useful, especially when the hepatic parenchyma is compared with fat bodies. Reptiles with hepatic lipidosis typically exhibit hyperechoic livers and reduced radiographic attenuation (<20 HU).[2] Hepatic biopsy is required for histopathology (and cultures if infection present) in order to reach an antemortem definitive diagnosis.[3,4] Affected livers appear large, friable, and pale tan to yellow in color with a soft fatty "feel" (Fig. 151.1B and C).

PREFERRED TREATMENT(S)

In advanced cases correction of dehydration is the first priority. Vitamin K administration can be considered, especially if coagulopathy has been confirmed. A means of providing long-term fluid and nutritional support (e.g., esophagostomy tube) is typically required. The importance of nutritional support cannot be overemphasized and offers the best therapeutic approach to hepatic lipidosis. When providing nutritional support, it is important to consider (1) the patient's energy and nutritional requirements, (2) the patient's natural dietary preferences, and (3) the use of natural foods for long-term support. The use of artificial, critical care substitutes should only be during initial stabilization. It is important to avoid refeeding syndrome and gastric overload in reptiles that have been anorectic for prolonged periods.

Supplementation with L-carnitine (100 mg/kg/day) may improve hepatic metabolism of fat. Antioxidants such as S-adenosylmethionine (SAMe), which replaces the previous recommendation of methionine, and vitamin E, may also be beneficial. Doses are empirical or derived from allometric calculations from mammal doses.

PROGNOSIS AND PREVENTION

The prognosis is good if diagnosed early before the onset of severe clinical signs. Once hepatic dysfunction is advanced the prognosis is guarded and often requires prolonged nutritional support, medication, and nursing for months or even years. Addressing the following factors

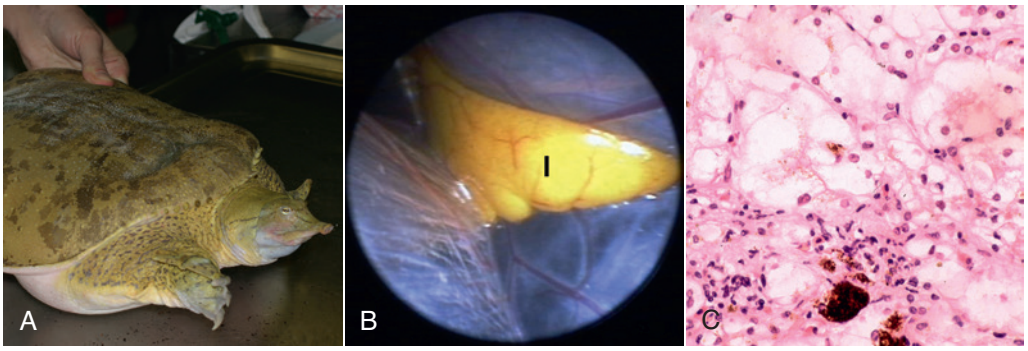

FIG 151.1 (A) Morbidly obese spiny softshell turtle (*Apalone spinifera*). (B) Endoscopic view of a bearded dragon (*Pogona vitticeps*) liver (l) with excessive intrahepatic fat. (C). VetBooks.ir

can often help reduce or prevent occurrence: (1) Provide a suitably large enclosure to facilitate exercise and foraging; (2) avoid excessive feeding (frequency and quantity); (3) facilitate the natural loss of fat from both hepatic and fat body reserve by permitting temperate species to hibernate and intact females the ability to reproduce (or sterilize); (4) keep health logs (including monthly weight and body lengths [straight carapace or snout-to-vent]) and seek annual or biennial health evaluations (including physical examinations and routine blood testing).

152

Hyperglycemia

Scott J. Stahl

DEFINITION

Hyperglycemia is defined as a persistent elevation of blood glucose above 300 mg/dL (16.7 mmol/L) and is an uncommon clinical biochemical abnormality in reptiles.[1,2]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Hyperglycemia has not been established as a consistent or specific indicator of pancreatic disease or diabetes mellitus (DM) in reptiles.[1,2] Elevations of blood glucose in reptiles are more often related to physiological variables, metabolic conditions, systemic diseases, stress, and neoplasia.[1–3] Risk factors for hyperglycemia include stress, seasonal variation (especially hibernation and breeding), diving, postprandial response, anorexia/starvation, metabolic disease (liver or renal disease), and neoplasia (pancreatic and nonpancreatic).[1–3] Blood glucose in reptiles appears to be regulated by insulin and glucagon, as in mammals. Generally, DM results from a lack of in insulin (type 1) or an inability of insulin to properly transport glucose into target cells (type 2). Damage to the pancreas from trauma, inflammation, neoplasia, or autoimmune disease resulting in damage or loss of pancreatic neuroendocrine cells can result in elevated blood glucose. Pancreatic pathology, including pancreatitis and primary pancreatic neoplasia, have been reported in reptiles, some associated with hyperglycemia and others not.[1,2] Although several cases of reptile diabetes mellitus have been reported, there is a lack of peer-reviewed publications to support this disease in reptiles.[1,2] Hyperglycemia has not been established as a consistent or specific indicator of pancreatic disease or DM in reptiles; however, there appears to be an association between nonpancreatic neoplasia and persistent hyperglycemia.[1,3] For example, gastric somatostatinoma (neuroendocrine gastric carcinoma) in bearded dragons (*Pogona vitticeps*) usually arise from gastric or pyloric mucosa with aggressive metastasis to multiple organs and are typically associated with severe hyperglycemia (Fig. 152.1).[3] For a review of pancreatic anatomy, physiology, and disease, as well as an overview of reported cases published with persistent hyperglycemia, see Chapter 79.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Husbandry details related to dietary intake and habits, temperature, humidity, lighting, and other important variables such as hibernation, seasonal cycles, and reproductive activity should be noted. Reptiles with hyperglycemia often present with nonspecific clinical signs (including anorexia, weight loss, and lethargy) and physical examination findings (including loss of muscle mass, weakness, loss of righting reflex, and severe depression). Some reptiles may present overconditioned or obese. Polyuria and polydipsia may be present but are not commonly appreciated.[1] Routine hematology, plasma biochemistry, diagnostic imaging, endoscopy, and exploratory coeliotomy may be required for a definitive diagnosis. In general, fasting blood glucose values for normal reptiles are between 60 to 100 mg/dL (3.0–5.5 mmol/L); however, they can range between 30 and 205 mg/dL (1.6–11.3 mmol/L)[1] (see Chapter 34). A single, fasting blood sample may reveal an elevation in blood glucose but has limited clinical significance. Multiple, serial sampling, or better still continuous (real-time) glucose monitoring is required to confirm persistent hyperglycemia, establish general trends, and determine clinical progression.[1,2] Glucosuria may or may not be noted, whereas the

FIG 152.1 A gastric mass (in the gastric lumen between the forceps) was found at necropsy in this bearded dragon (*Pogona vitticeps*), and histopathology identified a gastric somatostatinoma (neuroendocrine gastric carcinoma). These carcinomas arise from gastric or pyloric mucosa and often metastasize to multiple organs. Somatostatin suppresses pancreatic secretions of insulin, lowering insulin receptor sensitivity, likely resulting in the hyperglycemia seen in these cases. (Courtesy of Emily Nielsen, Stahl Exotic Animal Veterinary Services.)

VetBooks.ir

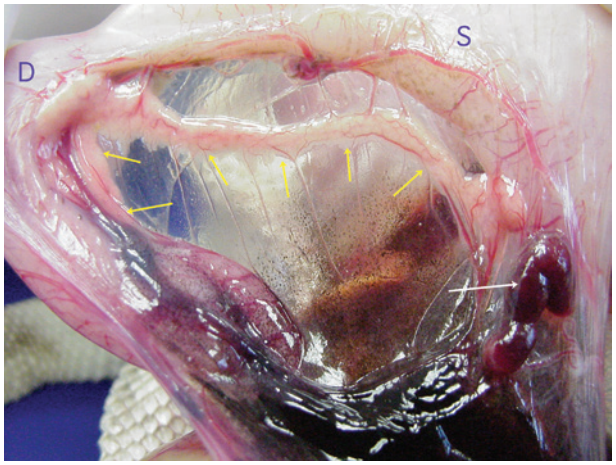

FIG 152.2 The normal pancreas of a bearded dragon (*Pogona vitticeps*) at necropsy. The light-colored pancreas (yellow arrows) is suspended in the mesentery between the stomach (S) and duodenum (D). The spleen (white arrow) is to the right. Note the anatomical complexity of the pancreas with several arms. Unfortunately, biopsy of the reptile pancreas for endocrine evaluation is complicated by high variability in the location of islet cell tissue in the pancreas. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

diagnostic value of insulin, glycated hemoglobin, and fructosamine are largely unknown.[1] Pancreatic biopsy and histopathology may be a valuable tool antemortem, however high variability exists in both the morphology and location of islet cell tissue, both in and outside the pancreas of reptiles (Fig. 152.2).[2] In postmortem cases, it is recommended to submit the entire pancreas, spleen, stomach, and small intestine for histopathologic analysis to avoid missing sites of islet concentration.[1] Metabolic diseases (hepatic and renal), pancreatic disease, and neoplasia should be considered.

PREFERRED TREATMENT(S)

Initial stabilization should include supplemental heat, fluid therapy, liver support, alimentation, and diagnosis-specific therapeutics. Once stable, persistent hyperglycemia should be established and underlying physiological issues, metabolic disease, and neoplasia excluded. If DM is truly determined (a rare diagnosis in reptiles), then insulin therapy (and/or hypoglycemic agents) and close monitoring should be pursued. Compared with mammals and birds, reptiles respond slowly to the administration of mammalian insulin, with lizards and crocodilians less sensitive compared with snakes and turtles.[2]

PREVENTION AND PROGNOSIS

Increasing the fiber in the diet of herbivores and omnivores may prove more effective than glucose-regulating agents. Prognosis for persistent hyperglycemia is guarded. Neoplastic or pancreas-associated hyperglycemia has a poor prognosis. Cases of persistent hyperglycemia related to other intrinsic and extrinsic variables may have a more favorable outcome.

Hypovitaminosis and Hypervitaminosis A

Thomas H. Boyer

DEFINITION

Hypovitaminosis A is a deficiency often associated with a failure to provide an assimilable form of vitamin A. Hypervitaminosis A relates to excessive vitamin A, which is often iatrogenic and associated with exaggerated dosing in an attempt to prevent or treat a deficiency.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Some omnivores and herbivores synthesize vitamin A from plant carotenoids and are resistant to dietary hypovitaminosis A. Insectivorous amphibians and lizards, as well as emydid turtles, often suffer from hypovitaminosis A, because they may be poor converters of carotenoids to vitamin A, and most insects are vitamin A deficient. Most commercial reptile multivitamin supplements contain β-carotene, which some reptiles cannot convert to vitamin A. Carnivores consuming whole vertebrates rarely suffer deficiency, because the liver is a plentiful source of vitamin A.

Hypervitaminosis A is primarily an iatrogenic disease caused by injections of highly concentrated vitamin A. Before the discovery of mycoplasmosis in tortoises in the early 1990s, it was common practice to give tortoises with upper respiratory tract disease vitamin A injections. This practice is now discouraged because tortoises rarely suffer from hypovitaminosis A because they are herbivores believed capable of converting dietary carotenoids to vitamin A.

CLINICAL PRESENTATION

Clinical signs of hypovitaminosis A manifest by hyperkeratosis and include blockage and swelling of lacrimal and salivary glands, swollen eyelids or lips, and ocular abnormalities (xeropthalmia, corneal keratitis, erosion, ulceration, and keratomalacia) that contribute to blepharospasm and corneal scarring (Fig. 153.1). Blindness can result from corneal scarring and a lack of retinol. Decreased appetite, difficulty catching prey, retained and recurrent hemipenal plugs in lizards, dysecdysis, less vibrant coloration, stomatitis, ear abscesses, pneumonia, or egg retention may also be reported. Farmed crocodiles on a vitamin A–deficient formulated diet had multifocal brown dorsal lingual nodules, as well as renal and visceral gout. In amphibians, especially toads and frogs, vitamin A deficiency causes short tongue syndrome (STS) because of a failure of the mucus-secreting glands in the tongue tip that allows prey to stick to the tongue. Superficially, the rapid-fire tongue appears to fall short of capturing prey.

DIAGNOSTIC CONFIRMATION

Most cases in clinical practice are diagnosed based on dietary history, clinical signs, response to therapy, and sometimes histopathology (hyperkeratosis and squamous metaplasia). Vitamin A levels are not easily measured because most is in the liver, and serum levels do not drop until liver levels are exhausted. Relatively large surgical biopsies or necropsy samples are required to obtain tissue vitamin A levels. Diagnosis of hypervitaminosis A (vitamin A toxicity) in chelonians is made by the clinical presentation of erythema and outer epidermal sloughing. This is usually associated with the recent injection of vitamin A.

PREFERRED TREATMENT(S)

Water-soluble vitamin A palmitate (such as Aquasol A) is more toxic than fat-soluble vitamin A palmitate and is not recommended. Treatment involves dietary improvement. For reptiles, 0.01 mL of fat-soluble vitamin A and D (500,000 IU vitamin A palmitate/mL, 100,000 IU vitamin D/mL) SC or PO, repeated in 2 weeks, reverses clinical signs in 2 to 4 weeks. Remove cellular debris under the eyelids and flush the eyes. Antimicrobials may be required if corneal ulceration or secondary

FIG 153.1 Hypovitaminosis A in a leopard gecko *(Eublepharis macularius)* with blepharedema and dysecdysis. Insectivores are prone to vitamin A deficiency because insects are deficient and most reptile multivitamins lack preformed vitamin A.

VetBooks.ir

infection is present and should be based upon culture and sensitivity testing for systemic therapy. Patients do not resume feeding until their eyes open, and therefore nutritional support may be indicated. For STS, 1 drop of vitamin A (vitamin A in oil, 10,000 IU/capsule, Jamieson Natural Sources) can be given PO or transdermally SID for 2 weeks. Treatment for hypervitaminosis A skin sloughing is similar to that for partial thickness thermal burns.

PROGNOSIS AND PREVENTION

Careful attention to the provision of an appropriate and balanced diet will prevent hypovitaminosis A. However, when treatment of a deficiency is required, it is safer to correct the diet and provide oral supplementation than to give injections. (See Chapters 27, 84, and 122 for more details.)

Inclusion Body Disease (Reptarenavirus)

Francesco C. Origgi

DEFINITION

Arenaviruses are enveloped RNA viruses and are candidate etiological agents (genus *Reptarenavirus*) for inclusion body disease (IBD).[1–4] IBD is a chronic, multisystemic wasting disease affecting several species of boid snakes worldwide. A similar disease has been documented also in *Colubridae* and *Viperidae*.[2]

CLINICAL SIGNS

The clinical signs are not pathognomonic and may vary, but generally comprise regurgitation, incoordination, disorientation, opistotonus, torticollis, disequilibrium, lack of righting reflex (Fig. 154.1A), flaccid paralysis, and head tremors. Secondary diseases in IBD-affected snakes include pneumonia, stomatitis, and lymphoproliferative and other neoplastic diseases.[2] Affected snakes (e.g., *Python bivittatus*) may die within several weeks or survive for many months (e.g., *Boa constrictor*).[2] Some species differences in clinical signs exist; for example, regurgitation is common in boas but not in pythons.[2] Acutely infected snakes may exhibit leukocytosis, relative lymphocytosis, lower total protein and globulin values, and elevation of aspartate transaminase values, compared with chronically affected animals.[2]

PATHOLOGY

Gross lesions include splenic and pancreatic atrophy with fibrosis and often secondary pneumonia.[2] The histological hallmarks of disease are the intracytoplasmic eosinophilic to amphophilic inclusions (viral nucleoproteins)[1,4] present in multiple tissues in boas and more limited to the CNS in pythons (see Fig. 154.1B).[2] The snake mite (*Ophionissus natricis*) has been implicated as a potential vector of the etiological agent.[2]

DIGNOSTIC CONFIRMATION

Diagnosis of IBD requires laboratory confirmation. Available tests include the following:

1. Reverse transcription polymerase chain reaction (RT-PCR) for the rapid detection of arenavirus RNA from oral and cloacal swabs, whole blood,[5] liver, or esophageal tonsilar biopsies (see Fig. 154.1C).
2. Immunohistochemistry (IHC)[1,3] can be performed on formalin-fixed, paraffin-embedded tissues, including liver, esophageal tonsils (see Fig. 154.1C), pancreas, kidney, and brain (antemortem biopsies when possible or postmortem tissues).[1]
3. Cytological examination of blood smears for detection of inclusions.[6]
4. Histopathology (liver and esophageal tonsilar biopsies [see Fig. 154.1C] or necropsy tissues).
5. Electron microscopy.
6. Virus isolation. Some snakes with inclusion bodies may be RT-PCR negative, and consequently molecular testing should be ideally complemented by histopathology and viral isolation.

PREFERRED TREATMENT(S)

Currently, no specific therapy is available for IBD. Isolation and/or euthanasia of animals within collections is often recommended.

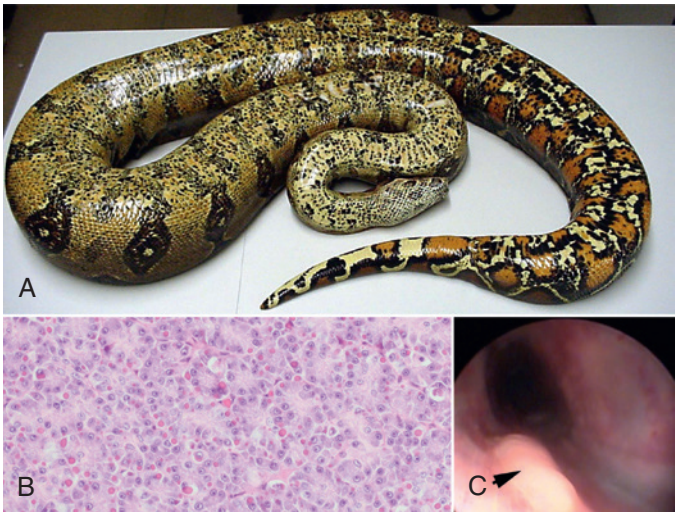

FIG 154.1 Clinical signs, diagnostic "hot spots," and histopathological findings associated with inclusion body disease of boid snakes. (A) A *Boa constrictor* in dorsal recumbency consistent with complete lack of righting reflex is shown in this image. This is a classic, although not pathognomonic, clinical sign observed in snakes with inclusion body disease. (B) Large numbers of glassy eosinophilic intracytoplasmic inclusions are disseminated in this section of pancreas. Histological support of molecular tests for the diagnosis of inclusion body disease is highly recommended. (C) In this endoscopic image of the esophagus of a snake, a prominent esophageal tonsil (arrow) is present. Esophageal tonsils are considered sampling site for antemortem diagnosis of inclusion body disease (A, Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services; B, courtesy of Francesco C. Origgi; C, courtesy of Stephen J. Divers.)

VetBooks.ir

PROGNOSIS AND PREVENTION

Disease progression in pythons is often rapid and prognosis poor to grave. In boas, the disease can be protracted, and with supportive care, snakes may live for months if not years. However, ultimately the prognosis is poor. Quarantine (at least 6 months), repeat testing, and isolation/removal of positive animals (or those showing consistent signs) are fundamental.[2] Routine testing of a representative set of animals in the collection is recommended. Virus replication is reduced at high temperatures (37°C).[7] Evidence of vertical transmission of co-infecting reptarenaviruses has been recently reported. A juvenile affected snake would develop inclusion bodies from the age of 2 months onward.[8]

Lizard Cryptosporidiosis

Kevin Eatwell and Jenna Richardson

DEFINITION

Cryptosporidium is a genus of protozoal parasites that are found in wild and captive reptiles. The organism belongs to the suborder Eimeriorina. In lizards, *C. varanii* (*syn C. saurophilum*) has an intestinal predilection, predominantly found in the small intestine mucosa, less commonly in the gastric mucosa, large intestine, and cloaca.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Many lizards infected with *Cryptosporidium* are subclinical with no obvious abnormalities. These individuals can spread infection through collections even if good hygiene is observed. In some individuals, *Cryptosporidium* spp. can lead to clinical disease, which can be highly debilitating for the lizard.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

In asymptomatic cases, oocysts are often detected during routine fecal endoparasite screening. In lizards displaying clinical signs, a chronic enteritis has been reported, with wasting disease seen in geckos (Fig. 155.1).[1,2] Physical examination findings can include loss of muscle mass, reduced appetite, anorexia, lethargy, weakness, diarrhea, and fecal staining may be evident around the cloaca. Cloacal prolapse and cystitis have been reported in a green iguana (*Iguana iguana*).[3] Diagnostic techniques include the identification of oocysts from feces, after modified Ziehl-Neelsen staining (Fig. 155.2). Immunofluorescence antibody tests (IFAT) on fecal samples can also be performed; however, as with the staining technique, the oocyst must be shed in the feces at time of testing for a positive result. As *Cryptosporidium* is intermittently shed; repeat tests for both techniques are required to avoid false negative results. Definitive diagnosis of disease requires intestinal biopsy.

For carnivorous lizards, the presence of *Cryptosporidium* oocysts in the feces may be an incidental finding, ingested with prey items. This can complicate the diagnosis, as the nonpathogenic *C. muris* and *C. parvum* can be difficult to differentiate from *C. varanii* without further testing. Correctly identifying the species can determine clinical outcomes, and this can be confirmed by polymerase chain reaction (PCR).[4]

PREFERRED TREATMENT(S)

Treatment is problematic, as there is no singular agent with proven efficacy. Treatment to eliminate the parasite is a high priority in reptiles because *Cryptosporidium* does not appear to be self-limiting, and chronic shedding occurs.[1] In one study, the burden of *Cryptosporidium* was found to be reduced after treatment using paromomycin (100 mg/kg every 24 hrs for days 1–7, 100 mg/kg twice weekly for days 14–49, 360 mg/kg every 48 hrs for days 50–60).[5] Treatment was effective in green iguanas using halofuginone (110 mg/kg every 7 days for 5 weeks) or a combination of sulfadiazine and trimethoprim (75 mg/kg every

FIG 155.1 Wasting disease is often seen in leopard geckos (*Eublepharis macularius*) infected with cryptosporidium. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

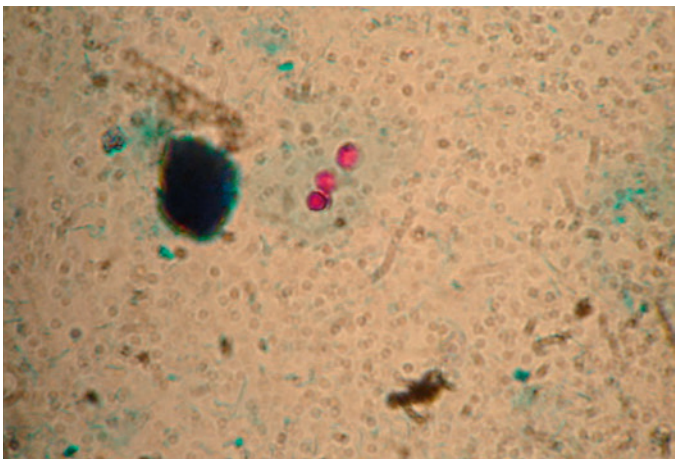

FIG 155.2 *Cryptosporidium* oocysts staining red on a ZN-stained fecal sample from a leopard gecko (*Eublepharis macularius*). The oocysts measure 4 to 8 microns in length. (Courtesy of Kevin Eatwell.)

VetBooks.ir

5 days for 5 weeks) or spiramycin and metronidazole (200 mg/kg every 5 days for 5 weeks) alongside hyperimmune bovine colostrum.[6]

PROGNOSIS AND PREVENTION

Cryptosporidiosis is transmitted via the feco-oral route, either by direct contact between lizards or via contaminated objects or enclosures. Ingestion of sporulated oocytes can then lead to infection. Environmental stressors, high stocking density of animals (particularly in young stock), and reduced health status can all promote the spread of the pathogen. Quarantine and repeat fecal analysis are recommended for all new additions to a collection.

Environmental hygiene is of utmost importance to reduce the environmental contamination by oocysts. Physical removal of all fecal material and contaminated substrate is required. The use of surfactants can aid the removal of organic material on solid surfaces. Specific treatments for the environmental destruction of oocysts include ammonia (5%) and formalin (10%) with a contact time of 18 hours at 4°C. Currently, moist heat (45°–60°C for 5–9 minutes), freezing, or desiccation appears to be the most effective ways to clear the environment after thorough cleaning. More details on protocols can be found in Chapter 18. The zoonotic potential of *Cryptosporidium* is low due to the host-specific nature of the parasite. Sensible hygiene precautions should be performed when both handling and cleaning enclosures.

Neurological Disorders

Karina A. Mathes and Simon R. Platt

Reptiles with neurological disorders can display a wide variety of neurological signs depending on the species, lesion localization, and underlying cause. The neurological examination should include: evaluation of awareness and alertness, posture, movement and gait, muscle size and tone, assessment of diverse reflexes, evaluation of cranial nerves (I-XII) (see Chapter 77), and response to pain. Evaluating mentation of some reptiles (especially turtles) requires some experience with normal behavior.[1] Reptiles, compared with mammals, may not respond as consistently to certain neurological tests. For example, responses can be quite variable when testing a healthy bearded dragon (*Pogona vitticeps*) for proprioception or a menace response, thus confounding the response (and meaning). Another difficulty encountered when assessing neurological reptiles is the nonspecific nature of clinical signs. Neurological signs are dependent on many factors, including species, lesion localization, and severity of the disease and can include head tilt, circling, buoyancy problems, inability to strike or swallow food, dysphagia, lethargy, blindness, abnormal head and/or body posture (Fig. 156.1), ataxia, loss of reflexes, opisthotonus, seizures, paresis or paralysis, obtundation, stupor, coma, and finally death.

Because of the variety of possible underlying causes, a thorough history and dietary and husbandry evaluation is essential. Neurological or neurological-like signs can be associated with specific neurological disease but also with musculoskeletal or systemic metabolic diseases.

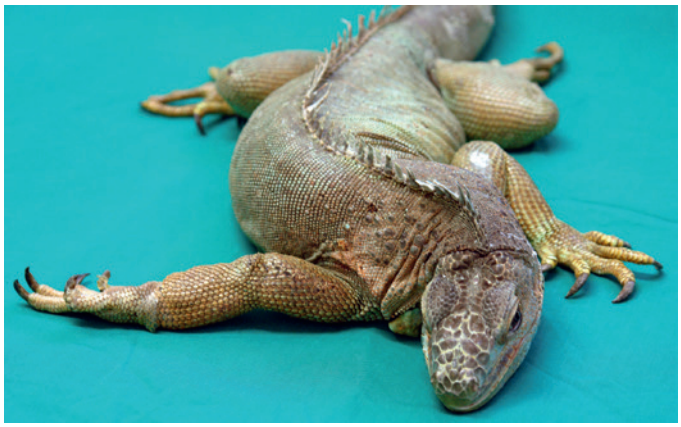

FIG 156.1 Female adult green iguana (*Iguana iguana*) with head tilt and abnormal body posture due to peripheral vestibular disease. (Courtesy of Karina A. Mathes.)

Causes of neurological disease in reptiles include infectious (e.g., viruses, bacteria, fungi, parasites) and noninfectious (e.g., hypoglycemia, hypocalcaemia, metabolic bone diseases, vitamin or mineral deficiencies, intoxication, hypothermia and hyperthermia, trauma (Fig. 156.2), hepatic or renal disease, dystocia, cystic calculi, congenital abnormalities, neoplasia) and vary with reptilian species. Table 156.1 summarizes etiologies for neurological disorders in reptiles. (See Chapter 77 for more details.)

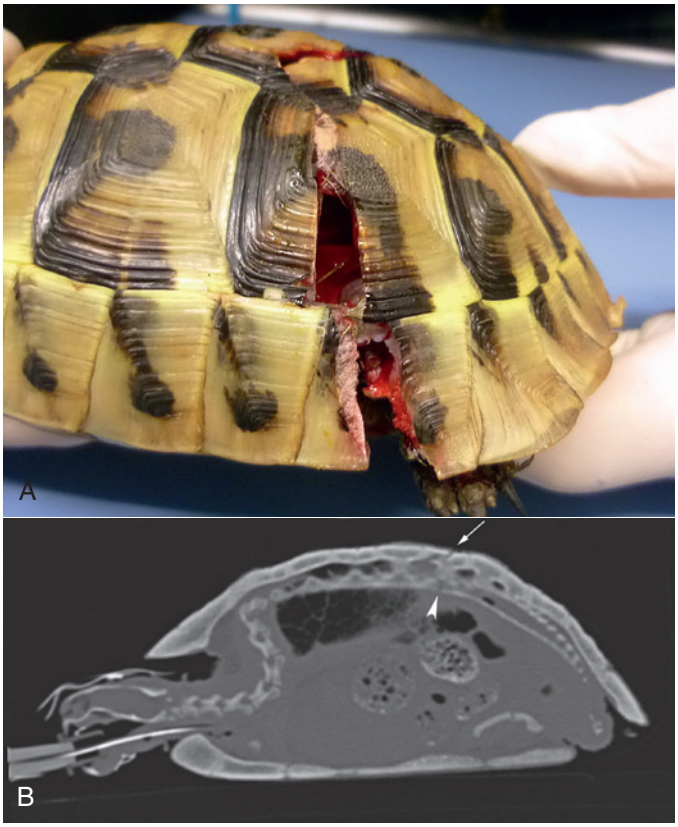

FIG 156.2 Photo (A) and computed tomography (B) of a subadult male Hermann's tortoise (*Testudo hermanni*) with fractures of the carapace (white arrow) and bridge after a car accident, with concurrent trauma of the spinal cord (white arrowhead) leading to paresis of both hind limbs. (Courtesy of Karina A. Mathes.)

TABLE 156.1 Potential Causes of Neurological Signs and Diseases in Reptiles

Clinical Presentation	Animals Affected	Etiology/Pathogen/ Disease	Diagnostic Confirmation	Treatment	Prognosis/ Prevention
Infectious Diseases					
Abnormal body position and movement pythons/ boas, regurgitation in boas, death in pythons;[2] Torticollis, dysequlibrium, opisthotonus, flaccid paralysis[3]	Snakes	Arenavirus[2,4,5] (previously IBD associated viruses[3,6])	Liver biopsy, blood smears, intracytoplasmic inclusions in multiple tissues; esophageal swabs, whole blood PCR	None specific	Poor prognosis if confirmed, quarantine
Neurorespiratory signs;[7,8] acute meningoencephalitis, flaccid paralysis;[9] head tremor, incoordination, opisthotonus[10]	Snakes Boelen's python Australian pythons	Ophidian paramyxoviruses (including ferlavirus)[7,8] Paramyxovirus infection in a Boelen's python [9] Sunshine virus[10]	Virus isolation from tissue samples, oral and cloacal swabs, electron microscopy, haemagglutination inhibition; virus isolation, PCR	None specific, treatment of secondary bacterial infections	Poor prognosis if confirmed, quarantine
Paresis[11,12] Paralysis[13]	Tortoises	Herpesvirus in tortoises[11,12]	Histopathology, electron microscopy	None specific, symptomatic	Poor prognosis
Meningoencephalitis,[14] circling[14,15]	Tortoises	Herpesvirus in Hermann's tortoises[14,15]	Histopathology, electron microscopy, neutralization test	None specific, symptomatic	Poor prognosis
Head tilt	Snakes	Adenovirus-like infection in a Colombian boa constrictor[16]	Histopathology, electron microscopy	None	Poor prognosis
Intention tremors, swimming abnormalities, opisthotonus	Alligators	West Nile virus in farmed American alligators[17]	Immunohistochemistry of various organs	None	Poor prognosis
Meningoencephalitis, abnormal posture,[18] and blindness[19]	Boa constrictor, reptiles, snakes.	*Staphylococcus aureus,* Salmonella, Mycobacteria[18,19]	Microbiology, fine needle biopsy, Ziehl-Neelsen acid fast stain	Antibiotics	Depending on the severity and location, poor
Vestibular syndrome, sometimes head tilt and circling[18]	Reptiles	Otitis media/interna; due to bacteria or other causes (as vitamin deficiencies, management mistakes)	Microbiology, histopathology	Surgery (removal), antibiotics, optimization of husbandry	Good if treated right
Lytic and proliferative vertebral disease[20]	Reptiles	Osteomyelitis; variety of bacteria and viruses	Microbiology	Antibiotics	Poor prognosis
Ataxia, tremors	Snakes	*Cryptococcus neoformans* in a boa [21]	Histopathology	Chloromycetin, tocopherol	Poor prognosis
Meningoencephalitis, opisthotonus (star gazing) in a boa [22]	Snakes, lizards, rarely chelonians	*Acanthamoeba* spp.[23,22]	Fecal analysis, histopathology	Metronidazole	Poor prognosis, strict quarantine
Seizures (gecko); pseudocysts in the brain (bull snake)[22]	Lizards and snakes	*Toxoplasma* spp. in a Mediterranean gecko[22] and a bullsnake [22]	Fecal analysis, histopathology	None reported in live reptiles[23]	Poor prognosis
Multisystemic infection reported, anorexia	Lizards	*Encephalitozoon* spp. in bearded dragons[24]	Histopathology, transmission electron microscopy	None	Poor prognosis
Varying degrees of paresis	Sea turtles	*Neospirorchis* spp. in wild loggerhead sea turtles[25]	Histopathology	None specific	Poor prognosis
Malnutrition/Deficiencies/Metabolic Diseases					
Muscle tremor, loss of righting reflex, mydriasis	Crocodilians	Hypoglycemia; unknown pathophysiology[26]	Blood glucose levels	Glucose	Depending on the severity
Muscle tremors, fasciculation, tetany	All reptiles	Hypocalcaemia; common in lizards (especially during reproduction)[27]	Measurement of ionized calcium	Calcium administration, correction of underlying causes	Depending on the severity and duration

TABLE 156.1 Potential Causes of Neurological Signs and Diseases in Reptiles—cont'd

Clinical Presentation	Animals Affected	Etiology/Pathogen/Disease	Diagnostic Confirmation	Treatment	Prognosis/Prevention
Variable, nonspecific signs, in case of acute hypocalcaemia: hypocalcemic tetany, loss of balance, loss of righting reflex	Reptiles	Metabolic bone diseases (MBDs); medical disorders that affect integrity and function of bone (i.e., nutritional or renal secondary hyperparathyroidism [NSHP, RSHP])[28]	Measurement of plasma calcium levels	Calcium supplementation, correct diet and housing, vitamin D, calcitonin	Good to grave depending on the etiology and severity
Stargazing, torticollis, seizures	Lizards (*Gecko* spp.)	Xanthomatosis; leaf-tailed geckos with hydrocephalus, encephalopathy[29]	Histopathology	None specific	Poor prognosis
Muscle twitching, incoordination, seizures, torticollis	Snakes (*Thamnophis* spp., *Natrix* spp.)	Thiamine deficiency; feeding frozen and thawed fish to fish-eaters[18,26]	Histopathology, medical history	Thiamine, diet change	Depending on the severity
Muscle tremor, generalized muscle weakness	Egg-eating snakes and lizards (e.g., varanids)	Biotin deficiency; feeding whole raw egg diet[18,26]	Medical history	Vitamin B, biotin, providing of a varied diet	Good prognosis
Muscle tremor, flexion of carpal joints	Green iguanas	Vitamin E/selenium deficiency; tentative diagnosis: nutritional myopathy [30]	Response to medical treatment with selen and vitamin E, elevation of GOT in serum	Selen, vitamin E	Good prognosis
Weakness, muscle tremors	Reptiles	Leaf-tailed geckos with renal encephalopathy (Raiti et al, Proc ARAV, 2000, pp 29–30)	Histopathology	None	Poor prognosis
Ataxia, incoordination, seizures	Reptiles	Gout crystals may form within CNS[27]	Hyperuricemia	Allopurinol, eliminate underlying cause	Poor prognosis if chronic
Intoxication					
Flaccid paralysis, death	Reptiles, especially chelonians	Chlorhexidine toxicosis in red-bellied short-necked turtles[31]	Medical history (immersion in chlorhexidine solution), necropsy	Thorough rinsing with tab water, bath	Poor prognosis
Head tilt, circling, opisthotonus, seizures, convulsions	Reptiles	Organophosphates in snakes[27]	Medical history (dichlorvos strip exposure)	Removal of the toxin, supportive therapy with fluids, sedatives, atropine	Guarded prognosis
Extreme paresis or flaccid paralysis, death	Chelonians, some lizard species	Red-footed tortoises treated with ivermectin [32]	Medical history (ivermectin injection in chelonians), necropsy	Oxygen flow, picrotoxin treatment	Guarded to poor prognosis
Diffuse neurological signs, death	Various snake species, including indigo and king snakes	High doses of metronidazole administration (>100 mg/kg) in indigo snakes[33]	Medical history (metronidazole administration)	Lowering metronidazole dosage down to 40 mg/kg	Guarded to poor prognosis if overdosed
Unusual neurological signs such as walking backward	Reptiles	Lead toxicosis in a Greek tortoise (Chitty, Proc ARAV, 2003, p 101)	Elevated blood lead levels, radiodense object in radiographs	Chelation therapy with sodium calcium edetate	Good prognosis when treated
Facial seizures, head shaking, mouth gaping, death	Bearded dragons	Fireflies containing lucibufagins, may be fatal in bearded dragons (Glor et al, Proc ARAV, 1999, pp 27–29)	Medical history (ingestion), necropsy	Not described	Guarded to poor prognosis
Disorientation, seizures, twitches, death (within hours)	Juvenile European tortoises	Ingestion of branches of English yew (*Taxus baccata*)[34]	Medical history (ingestion), necropsy	None specific, fluids, bath, peroral and cloacal administration of paraffin in surviving animals	Guarded to poor prognosis

VetBooks.ir

TABLE 156.1 Potential Causes of Neurological Signs and Diseases in Reptiles—cont'd

Clinical Presentation	Animals Affected	Etiology/Pathogen/ Disease	Diagnostic Confirmation	Treatment	Prognosis/ Prevention
Seizures, coma, death	Green iguanas	Ingestion of flowers of azalea (rhododendron)[35]	Medical history (ingestion)	Vomitus of the flower, oral fluid supplementation	Good prognosis if removal possible
Trauma					
Opisthotonus, seizures, paresis, paralysis	Reptiles	Traumas causing disorders of the nervous system[27]	Medical history, radiographs	Case depending surgery, supportive fluid therapy, antibiotics, glucocorticoids, mannitol, and where appropriate fracture fixation	Variable good to poor prognosis
Flaccid paralysis hind limbs	Lizards (desert iguana)	Vertebral fracture and spinal cord compression in a desert iguana[19]	Medical history, necropsy, and histopathology	None	Poor prognosis
Miscellaneous Causes					
Relative inability to move and strike prey	Snakes, Burmese python	Spinal osteopathy; *Osteitis deformans* (Paget's disease)[36]	Clinical examination, radiographs, computed tomography, histopathology	None	Poor prognosis
Paraparesis	Chelonians	Chronic dystocia[37]	Radiographs	Treatment of dystocia (conservative or surgically)	Good prognosis
Paraparesis	Reptiles with urinary bladder	Cystic calculi; green iguana with large bladder stone–obstructing pelvic canal[38]	Radiographs	Cystotomy, removal of the cystic calculi	Good prognosis
Head tilt, circling, blindness[27]	Tortoises	Hypothermia; tortoises after hibernation[27]	Medical history	Supportive treatment (including thiamine)	Poor prognosis
Decreased mobility/ inability to move, loss of righting ability	Rattlesnakes	Neoplasia; central nervous system tumor, spinal cord glioma[39]	Clinical examination, histopathology, immunohisto-chemistry	None reported	Poor prognosis
Acute neurological dysfunction, head tilt, obtundation, loss of proprioception and righting reflexes, ataxia, hyperesthesia	Australian water dragons	Unknown etiology; viral or toxic etiology suspected, encephalomalacia, necrosis in the brain[40]	Necropsy, histopathology	Supportive treatment, fluids, antibiotics, antifungals, corticosteroids, atropine—without effect	Poor prognosis

When treating reptiles, clinicians should be aware of their significant ability for tissue regeneration, including the nervous system. Reptiles in general take longer to heal than mammals or birds. Owners should be made aware that progression may be slow and be prepared to allow the time required for regeneration. Preferred medical or surgical treatment depends on the underlying cause. In these patients, it is important to focus on supportive care and environmental management for the necessary time that is required to allow maximal recovery from neurological disease.

Nutritional Secondary Hyperparathyroidism

Thomas H. Boyer and Peter W. Scott

DEFINITION

Nutritional secondary hyperparathyroidism (NSHP) occurs when chronic calcium deficiency causes the parathyroid glands to overproduce parathyroid hormone, which stimulates osteoclastic activity, weakens bone, and eventually kills the patient.

CLINICAL SIGNIFICANCE

NSHP, one type of metabolic bone disease, is the most common disease of captive reptiles.

KNOWN ETIOLOGICAL CAUSE(S)

Calcium (Ca) deficiency results from inadequate dietary Ca, a low Ca:P ratio in the diet, and/or lack of vitamin D. Many reptiles and amphibians seem to be more dependent on ultraviolet light (UVB, 290–300 nm) to synthesize vitamin D_3 or cholecalciferol than on dietary vitamin D. As a rule of thumb, UVB is recommended for all reptiles and amphibians, except for a few nocturnal geckos and snakes; however, even these species may benefit from UVB. Bone is the main storage site of Ca within the body; plasma Ca constitutes less than 1% in three main fractions: 45% ionized (free) Ca, 40% total (albumin bound) Ca, and 15% anion bound. When ionized Ca levels drop, parathyroid hormone levels increase, which increases Ca resorption from bone. If bone Ca levels are not replenished, bone weakens, softens, and fractures, and/or fibrous osteodystrophy may develop (lizards) or the shell softens (chelonians). In lizards, life-threatening reductions in ionized Ca can lead to tremors in the digits, limbs, large muscle masses (spasms), seizures, tetany, or flaccid paresis.

Ca is deficient in many vegetables, most fruits, and almost all insects, as well as organ and muscle meats. All whole vertebrates are excellent sources of Ca (because of their bone); hence, Ca deficiency is rarely seen in reptiles and amphibians that eat whole vertebrate prey. Some invertebrates, such as crustaceans, are good sources of Ca, provided the shell is consumed.

CLINICAL PRESENTATION

Signs of NSHP include lethargy, weakness, reluctance to move, declining appetite, and lack of growth or weight gain. Sprawl—and partial to complete lack of truncal and proximal tail, or shell, lifting when ambulating—is common. Lizards are prone to spinal damage from vertebral fractures, which may result in paraparesis or paraplegia of the rear legs and a horizontal flattening of the ribcage and scapula (barrel chested). Both lizards and crocodilians may have bowed, thickened, or fractured long bones or mandibles, pliable mandible and maxillae, overbite, kyphoscoliosis, lordosis or rhoecosis (all three), and walk on the forelimbs rather than plantigrade (Fig. 157.1). Chameleons have a noticeably weakened grip, decreased prehensile ability of their tail, and fall repeatedly. Crocodilians may have teeth that protrude laterally, fall out, or are lucent around their edges. Chelonians have soft shells (normally the shell should feel solid, like skull) (Fig. 157.2) and splay out their legs, but they do not typically have long bone fractures or

FIG 157.1 Nutritional secondary hyperthyroidism in a veiled chameleon (*Chamaeleo calyptratus*); note the sprawl, bowed legs, mandibular and maxillary malalignment, and uneven spine. This patient made a full recovery.

FIG 157.2 Nutritional secondary hyperthyroidism in a desert tortoise (*Gopherus agassizii* or *G. morafkai*). Young anorexic tortoises with soft shells usually die.

VetBooks.ir

fibrous osteodystrophy. In box turtles, the marginal scutes may curl dorsally, the body appears too small for the shell, and the phallus or cloaca may prolapse. Clinical signs in amphibians include lack of truncal lifting, dorsal curling of the toes, vertebral or mandibular deformities, long bone fractures, subcutaneous edema, anasarca, or absence of radio-opaque calcium carbonate in endolymphatic sacs.

DIAGNOSTIC CONFIRMATION

Clinical signs, combined with detailed dietary history, often will suggest a diagnosis. Radiographs are useful to assess fractures and overall bone radiopacity. Radiographs are equivocal in early cases; in mammals 40% to 50% of bone loss must be present to be detected radiographically. Decreased radiographic opacity is more obvious in advanced cases, especially in thin bones. Biochemistry is useful for assessment and excluding kidney involvement, but care must be taken with restraint and venipuncture. Typically, both total and ionized Ca are within normal limits, or low; because bone is such a vast reservoir, reproductively active females may have elevated Ca. With obvious clinical signs diagnostics are often not essential for treatment. More sensitive measures of bone density include quantitative computed tomography and dual energy x-ray absorptiometry.

PREFERRED TREATMENT(S)

Medical treatment includes calcium supplementation, nutritional support, improved husbandry (especially provision of UVB), analgesia, and perhaps calcitonin. Oral calcium supplementation is easiest via calcium-rich syrups, either Ca glubionate (1.8 gm/5 mL or 24 mg/mL elemental Ca) or Ca gluconate (23% w/v or 21 mg/mL elemental Ca), dosed at 1 mL/kg PO bid. Calcium is continued for 1 to 3 months or until the patient is eating calcium-enriched foods well on its own, moving normally and gaining weight. Salmon calcitonin injections have been recommended at 50 IU/kg IM, repeat in 1 week, if normocalcemic, or 1 week after starting calcium supplementation. Do not give calcitonin if hypocalcemic or neurologic signs are present. Patients with hypocalcemic tetany can be treated with 100 mg/kg 10% Ca gluconate IM or intracoelomically q 6 hours until tetany ceases, then switched to oral calcium syrups. Otherwise Ca injections are not recommended. Nutritional support is critical; the patient must start gaining weight and growing, otherwise extensive skeletal damage will not be repaired. Surgical fixation of pathologic fractures is contraindicated.

PROGNOSIS AND PREVENTION

Prognosis is dependent on severity of clinical signs; lizards and crocodilians respond better than chelonians. Early diagnosis and aggressive veterinary treatment is essential; chronic NSHP has a poorer prognosis. Owners must be committed to several months of daily treatment. If no decreased radiopacity of bone is visible, the prognosis is good to excellent. Hypocalcemia and decreasing radiopacity of bone worsens the prognosis. Paresis, paralysis, or obstipation are poor prognostic indicators. Small chelonians with soft shells that are not eating typically die.

Good nutrition with adequate Ca supplementation and UV light is critical; for more information, see Chapters 27, 84, and 122.

Paramyxoviruses (Ferlaviruses)

Francesco C. Origgi

DEFINITION, CLINICAL SIGNIFICANCE, AND KNOWN ETIOLOGICAL CAUSE(S)

With the exception of "Sunshine virus" affecting Australian pythons, all the other partially characterized reptile paramyxoviruses (single-stranded, RNA viruses) are comprised within the genus *Ferlavirus,* subfamily *Paramyxovirinae,* family *Paramyxoviridae.*[1] Lethal infections have been documented mainly in snakes (*Colubridae*, *Elapidae*, *Viperidae*, *Crotalidae*, *Boidae*, and *Pythonidae*) but also in lizards and chelonians.[1,2]

CLINICAL PRESENTATION

Clinical signs are nonpathognomonic and range from no to severe respiratory disease with or without tracheal exudate.[1–3] Neurologic signs have also been described.[1,2] Snakes (*Antaresia* sp., *Aspidites* sp., and *Morelia* sp.) infected with Sunshine virus showed neurorespiratory signs.[1]

Gross lesions in snakes range from none to caseous-necrotic material in the lung(s), hemorrhages,[1–3] and dermatitis.[4] A characteristic microscopic feature of Ferlavirus infections is a proliferative interstitial pneumonia (Fig. 158.1), with occasional intracytoplasmic eosinophilic inclusions in snakes and lizards.[2] Gross findings in snakes infected with Sunshine virus are often unremarkable.[1] The most consistent histologic change is severe spongiosis of the white matter of the hindbrain.[1] Paramyxovirus infections in chelonians may be associated with pneumonia, degenerative liver disease, stomatitis, and dermatitis.[1] Ferlavirus delivered intratracheally causes disease.[3,5] Vertical transmission has also been considered for Sunshine virus.[6]

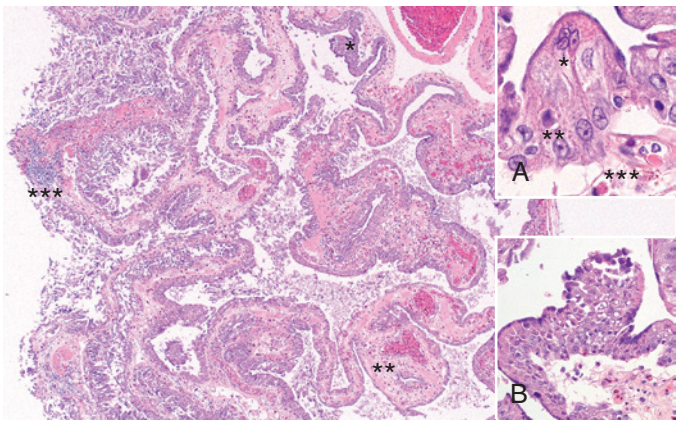

FIG 158.1 Lung of a snake with interstitial proliferative pneumonia. The respiratory epithelium is moderately to markedly thickened (single asterisk), with expansion of the interstitium secondary to edema (double asterisk) and inflammatory infiltration (triple asterisks). *(Inset A)* A classic syncytium is shown (single asterisk). An inflammatory mononuclear cell is infiltrating the epithelium (exocytosis) (double asterisk) and an intact degranulated granulocyte is also present (triple asterisk). *(Inset B)* Marked thickening and proliferation of the respiratory epithelium. (Courtesy of Francesco C. Origgi.)

DIAGNOSTIC CONFIRMATION

Confirmation of clinical suspicion requires laboratory testing (serology, molecular tests, viral isolation, immunohistochemistry, histopathology, and electron microscopy). The most common serologic test is hemagglutination inhibition (HI), whereas the most common molecular test is reverse transcription PCR (RT-PCR) targeting the partial sequence of the L gene.[1,2] A specific RT-PCR is available for Sunshine virus.[1] RT-PCR testing can detect Ferlavirus RNA in the tissues as early as 4 days postinfection (PI), and infected animals remain positive for at least 49 days PI. Lung, small intestine, pancreas, and brain are the tissues of choice for postmortem diagnosis.[3] Overall detection rate (RT-PCR and virus isolation combined) in tissues was shown to be 72%. For antemortem diagnosis, it is best combining RT-PCR and viral isolation on tracheal wash with viral detection as early as 16 days PI. Cloacal swabs may be positive as early as 28 days PI.[3] Detection of HI titers requires a minimum of 16 days and becomes more robust at 28 days.[7] Serologic test results might not be comparable when using different Ferlavirus strains as antigen.[1] Ideal laboratory diagnosis should comprise molecular, serologic, and histopathologic investigations and virus isolation.

PREFERRED TREATMENT(S)

No specific therapies exist against Ferlavirus infection. Supportive therapy has been suggested, with appropriate antimicrobials if secondary infections exist.[1]

PROGNOSIS AND PREVENTION

Quarantine (up to 6 months) while carrying out repeated molecular and serologic tests is critical. Isolation and testing of resident reptiles showing consistent signs is recommended. Prognosis is guarded to poor.

Periodontal Disease

Scott J. Stahl

DEFINITION

Periodontal disease involves bacterial or fungal invasion of the unique periodontal tissues of lizard species with acrodont dentition, specifically agamids (bearded dragons, *Pogona vitticeps*; Asian water dragons, *Physignathus cocincinus*; frilled dragons, *Chlamydosaurus kingii*), and all old-world chameleons.[1–4]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Acrodont dentition in lizards appears to predispose to periodontal disease.[1,2] With acrodont teeth only a thin layer of gingival tissue is present along the lateral and medial surfaces of the mandibular and maxillary bones. If this fragile gingival tissue is damaged/abraded, plaque can accumulate, pockets may occur, and microorganisms can colonize, often followed by invasion of deeper tissues and bone. Predisposition for periodontal disease with acrodont dentition may also be related to captive diet and the feeding of less abrasive, cultured insects and soft fruits.[1–3]

Early plaque accumulation with gingivitis is associated with an aerobic, gram-positive cocci bacterial population.[1] With more advanced plaque deposition and increased gingival inflammation, anaerobic organisms, including gram-negative bacteria and spirochetes, invade.[1] *Aspergillosis* spp. was identified in mycotic periodontal disease in a panther chameleon *Furcifer pardalis*.[4]

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Lizards may present with anorexia, soft tissue swellings, or irregular labial closure along mandibular or maxillary bones. Lizards may also have no clinical signs, and oral lesions may be detected during a routine examination using a soft oral speculum to avoid further dental trauma.

Dental probes are useful to assess lesion depth. Early lesions show visible calculus and marginal gingival erythema, with progressive calculus buildup, increased gingival swelling, gingival margin recession, and exposure of underlying mandibular and maxillary bone. In advanced disease, gingival hyperplasia and pockets form with suppurative gingivitis and subcutaneous abscessation. Areas of focal and multifocal osteomyelitis then develop, resulting in loss of bone and teeth and finally pathological fractures and fatal systemic illness. Radiography or CT is useful to assess bone lysis, pathological fractures, bone sequestra, and periosteal proliferation.[1] Culture and sensitivity should be utilized to identify organisms involved and determine appropriate antimicrobial therapy. Because mixed infections are common, both aerobic, anaerobic, and fungal cultures should be submitted, with gram stains used to guide initial drug choices. Biopsy of bone and/or associated soft tissue is the most definitive method for identifying pathogens. Establishing an association between organisms and lesions with histopathology is important, especially in the oral cavity where many opportunistic organisms are present.

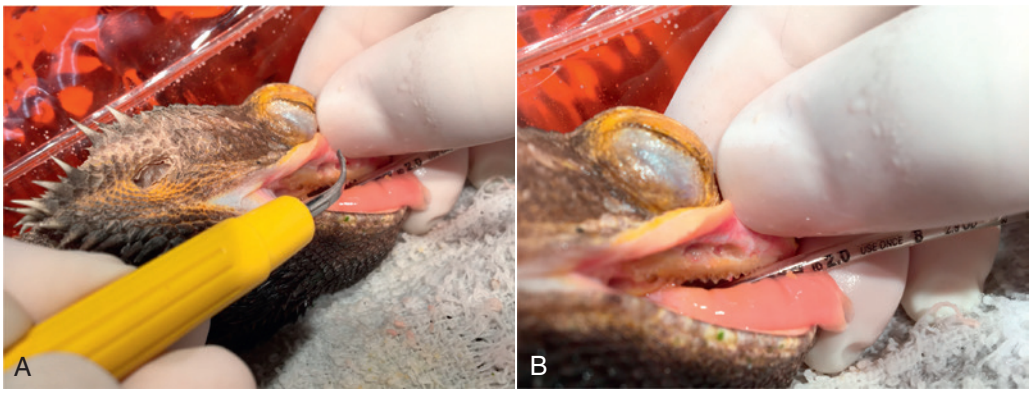

FIG 159.1 (A) An ultrasonic dental scaler is used to gently clean periodontal lesions in this bearded dragon (*Pogona vitticeps*) while under general anesthesia. Once periodontal lesions are present, periodic cleaning under sedation or anesthesia may be necessary to minimize progression of the disease and avoid systemic illness. The patient is intubated to maintain gas anesthesia and to protect the airway during cleaning. (B) The periodontal lesions evident in this same bearded dragon after debridement and cleaning. Notice the significant soft tissue and bone loss and subsequent exposure that will require close monitoring and continued management. (Courtesy of Octavio Romo-Flamand, Stahl Exotic Animal Veterinary Services.)

VetBooks.ir

PREFERRED TREATMENT(S)

Once stable, a thorough oral examination under sedation or general anesthesia is recommended. While under anesthesia, cultures and biopsies may be collected. Removal of calculus is performed, and gingival sulci are cleaned using dental instrumentation and following standard precautions (Fig. 159.1A and B). With deeper lesions, surgical debridement (guided by imaging) and removal of unhealthy tissue and bone is important to expose infected tissue and allow continued topical therapy. Standard wound flushing solutions such as 0.05% chlorhexidine can be used to flush wounds every 1 to 3 days.[1–3]

While awaiting results of culture and sensitivity and/or histopathology, lizards may be started on a first-line, broad-spectrum antibiotic regimen. Due to the high incidence of mixed bacterial infections (aerobic and anaerobic organisms) and the severity of osteomyelitis, combination antimicrobial therapy (gram negative and anaerobic targeting specific drugs) is recommended. With osteomyelitis, systemic antimicrobials may need to be used for 4 to 6 weeks or longer depending on severity.[1,2] Nonsteroidal antiinflammatories, to reduce inflammation and pain, as well as opioids for analgesia are important in the management of these cases (see Chapter 50).

PROGNOSIS AND PREVENTION

Prognosis varies from fair to poor depending on the condition of the lizard at presentation, amount of tissue and bone lost, and the presence of osteomyelitis. Regardless, once initial aggressive treatment is complete, lifetime dental prophylaxis will be required using oral cleansing products (Maxiguard Oragel, Addison Biological Laboratory, Fayette, MO) at home with regular veterinary dental prophylaxis under sedation or general anesthesia.[1–3] Feeding hard-bodied insects (cockroaches, locusts, grasshoppers) and/or (for omnivorous species) more fibrous vegetables (pumpkin, sweet potato, leafy greens) may help to strengthen and keep gingival tissue clean and healthy.[1–3]

Pneumonia

Stephen J. Divers

DEFINITION

Pneumonia may occur as a primary entity, secondary to stomatitis and aspiration, by hematogenous spread (e.g., endocarditis) or by direct/close anatomical association (e.g., hepatitis, coelomitis). Pneumonia can be focal, multifocal, or diffuse, unilateral or bilateral. Many infections involve commensal or environmental organisms that become pathogenic in an immunocompromised host. Poor captive management, including inappropriate temperatures, ventilation, and humidty, are often intimitely involved with pathogenesis.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Bacterial pneumonia is probably most common and has been associated with aerobic gram-positive and gram-negative species. *Mycoplasma* spp. are important respiratory pathogens of tortoises, crocodilians, and pythons. A number of fungi have been associated with pneumonia in reptiles, including *Aspergillus*, *Candida*, *Fusarium*, *Mucor*, *Geotrichum*, *Penicillium*, *Cladosporium*, *Rhizopus*, *Chrysosporium*, *Paecilomyces*, and *Beauveria.* A variety of viruses have been detected in association with respiratory pathology, including herpesvirus and iridovirus (chelonia), poxvirus (lizards), paramyxovirus, and nidovirus (snakes).

Several genera of digenetic trematodes inhabit the oral cavity, but adults often migrate deeper and can cause focal lesions. Infection of aquatic turtles with digenetic spirorchid trematodes may result in pneumonia. Migrating nematode larvae have caused respiratory signs and/or pulmonary lesions in tortoises (*Angusticaecum*), chameleons (*Hexametra*), and pythons (*Ophidascaris*). Adult lungworms (*Rhabdias*) reside within the lungs of snakes and lizards, whereas migrating larvae (*Strongyloides*) may also be associated with pulmonary lesions. Pentastomid (segmented, wormlike) parasites undergo extensive visecral migrations before locating within the lungs (and less commonly the trachea and nasal passages). Pentastomids can cause localized lesions, and moulting can induce antigenic responses.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Cases of acute or peracute pneumonia may present as sudden death, although lethargy, anorexia, and respiratory signs, including dyspnea and open-mouth breathing, are common. In aquatic chelonians, asymmetrical position may be evident, with the affected side floating lower than the contralateral side. Although diagnostic imaging may provide convincing evidence of lung disease, a definitive diagnosis relies on the collection of material for histopathology (or cytology) and microbiology (Figs. 160.1 and 160.2). Therefore endoscopic lung

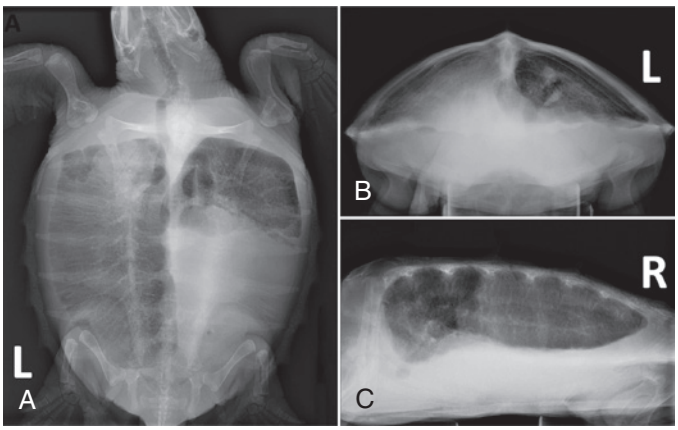

FIG 160.1 Dorsoventral (A), horizontal beam craniocaudal (B), and right lateral (C) radiographic views of a loggerhead sea turtle (*Caretta caretta*) with pronounced consolidation of the mid-to-caudal right lung. (Courtesy of Stephen J. Divers.)

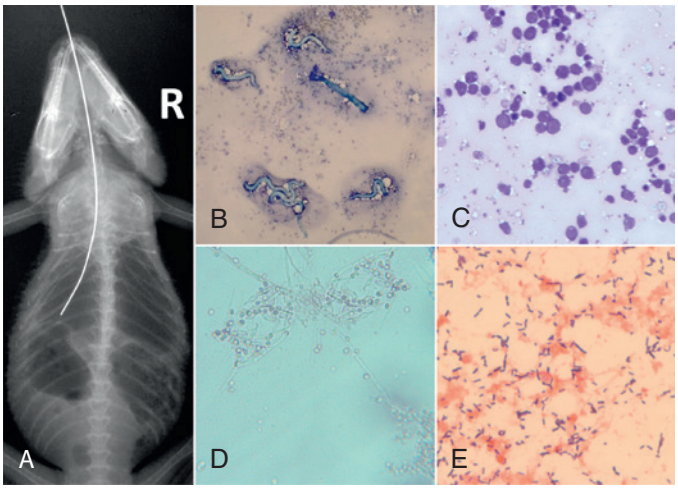

FIG 160.2 (A) Use of a curved stylet to ensure catheterization and lavage of the left lung in a bearded dragon (*Pogona vitticeps*). (B) Lung lavage cytology from a snake with verminous pneumonia demonstrating multiple nematode larvae (Diff Quik, x200). (C) Lung lavage cytology from a tortoise with mycotic pneumonia demonstrating large gram-positive structures consistent with yeast (Diff Quik, x 1000). (D) Lung lavage cytology from a sea turtle with mycotic pneumonia demonstrating fungal hyphae and conidia (wet prep, x1000). (E) Lung lavage from an agamid lizard with bacterial pneumonia demonstrating gram-positive bacilli (gram stain, x1000). (Courtesy of Stephen J. Divers.)

VetBooks.ir

evaluation and biopsy, or lavage, are typically utilized. Verminous cases typically rely on lung lavage and fecal evaluations. Where serological tests exist (e.g., ophidian paramyxovirus), they should be utilized, with paired rising titers differentiating between active infection versus past exposure. PCR testing can be used to confirm the presence of a virus but not necessarily disease.

PREFERRED TREATMENT(S)

High-volume lung lavage and aspiration, or cooperage, have been employed to remove considerable quantities of exudate from the lower respiratory tract of anesthetized or sedated squamates. Systemic and local application of antimicrobials, based upon culture and sensitivity or MIC results, are typically required. Prolonged treatment is often required, along with correction of any predisposing husbandry or nutritional components. Large encapsulated lesions require surgical removal, but even small encapsulated granulomas are often resistant to drug therapy. Pulmonary nematodiasis is often treated with benzimadazoles. Pentastomids can be treated with ivermectin, but parasite death can result in massive antigenic reactions, and physical removal may be necessary.

PROGNOSIS AND PREVENTION

If left untreated most cases progress to generalized sepsis and death, although chronic granulomata or abscesses can develop. Typically the prognosis is poor when dealing with extensive disease. Prevention through strict hygiene and appropriate quarantine practices (including serological testing) is preferable. Improvements in husbandry and nutrition can strongly affect outcome. See Chapter 76 for more details and references.

VetBooks.ir

Pseudogout

Jorge Orós

DEFINITION

Pseudogout or calcium pyrophosphate dihydrate (CPPD) is an arthropathy caused by crystal deposits in articular tissues, most commonly fibrocartilage and hyaline cartilage.[1]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSES(S)

There are few confirmed reports of CPPD crystal deposition in reptiles, and they have been presumably associated with chronic renal disease, nutritional imbalance, and joint trauma.[2,3] In humans, risk factors include aging, osteoarthritis, previous joint trauma/injury, familial/hereditary predisposition, and metabolic diseases such as hyperparathyroidism, hemochromatosis, hypomagnesemia, and hypophosphatasia.[4] The key role of local excess of inorganic pyrophosphate (PPi) in cartilage has been demonstrated in humans.[5] PPi is produced endogenously, and crystallization occurs only in the extracellular cartilage matrix, an area of poor vascularity. The passage of crystals to the synovial fluid seems to be required to induce inflammation.[6] CPPD crystals are recognized by innate immune system cells as danger signals, and then activated cells secrete recruiting and activating cytokines, where interleukin-1 plays a central role.[6]

CLINICAL PRESENTATION

Affected reptiles usually exhibit limited and painful mobility.[3] Nodular enlargement of the affected joint may also be noticed.[2] The presentation of both gout and pseudogout in the same animal has also been reported.[3]

DIAGNOSTIC CONFIRMATION

Diagnosis must be based on the identification of CPPD crystals in a synovial fluid sample or from biopsied tissue.[3] CPPD crystals are pleomorphic with rhomboid, rectangular, and rod-shaped forms,[6] and they are variably birefringent under polarized light.[6] Nondecalcified sections of tissue containing CPPD crystals stain positive with Von Kossa or Alizarin Red S stains.[3] In human medicine, chondrocalcinosis on radiographs is considered indicative of CPPD deposition[6] (Fig. 161.1). Ultrasonography shows CPPD crystals as hyperechoic deposits in the depth of hyaline joint cartilage or hyperechoic aggregates in fibrocartilages; their posterior acoustic shadowing enables their differentiation from gout.[6] CT shows calcified deposits but does not enable specific identification of CPPD crystals; in contrast with gout, dual-energy CT has rarely been used in calcium crystal deposition. MRI is relatively insensitive to CPPD deposits.[6]

Differential diagnoses include hydroxyapatite deposition disease (HADD),[7,8] osteoarthritis,[6] and gout.[3] The nonaqueous alcoholic eosin stain is used to allow differentiation of CPPD crystals (exhibiting birefringence) and hydroxyapatite crystals (absence of birefringence) in tissue sections.[9] However, the potential effect of a decalcifier on the birefringence of hydroxyapatite deposits has been reported.[7] By contrast, monosodium urate crystals are needlelike and strongly birefringent, and, in tissue sections, they stain negative with Von Kossa stain.

FIG 161.1 Radiograph of the left front foot of a tegu (*Tupinambis teguixin*) showing dramatic soft tissue swelling and mineral deposition. Histopathology on a surgical biopsy of the tissue confirmed a diagnosis of pseudogout with deposition of calcium crystals consistent with calcium pyrophosphate deposition disease. (Courtesy of Gregory Costanzo, Stahl Exotic Animal Veterinary Services.)

VetBooks.ir

PREFERRED TREATMENT(S)[2,10]

No treatment has proven effective in dissolving CPPD crystals; phosphocitrates, pyrophosphatase, and probenecid have failed *in vivo* human testing. Antiinflammatory drugs, including NSAIDs, glucocorticoids (systemic or intra-articular), colchicine, hydroxychloroquine, and methotrexate are used in humans, but their efficacy in reptiles is unknown. Surgical removal may be the most effective treatment, with limb amputation recommended in severe cases. Analgesics for pain management are recommended.

PROGNOSIS AND PREVENTION

Based on the scarce reports, the prognosis for pseudogout in reptiles is guarded to poor.

Renal Disease

Stephen J. Divers

DEFINITION

Renal dysfunction and disease can be caused by degenerative (most common), inflammatory, infectious, or toxic etiologies, and it frequently results in nitrogenous waste accumulation (e.g., uremia, gout) and electrolyte imbalances.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Degenerative nephrosis represents the most common renal diseases encountered (glomerulonephrosis, tubulonephrosis). Inflammatory conditions are less common but can be associated with bacterial, viral, fungal, and parasitic infections. Severe, acute infections can cause acute renal failure. Therefore, it is important to diagnose these conditions accurately, because prompt and appropriate therapy may result in reclamation of temporarily lost renal function and a complete recovery. Toxic nephropathies have been associated with aminoglycosides and exogenous vitamin D_3 supplementation. Heavy metals, including lead, tend to bioaccumulate in liver and kidney tissues and might be expected to compromise function. When the majority of renal function has been lost, gout and aberrant phosphorus and calcium metabolism (soft tissue mineralization) may result.

High-protein diets are considered a predisposing cause of hyperuricemia, gout, and nephrosis in herbivorous reptiles. The maintenance of high-humidity rainforest species in dry, overheated, captive conditions may result in chronic dehydration and nephropathy. Various bacteria including gram-negative aerobes, *Listeria*, *Leptospira*, *Streptococcus*, *Mycobacteria*, and *Chlamydia* have been isolated from reptile kidneys, either as primary agents of nephritis or secondary to generalized sepsis.

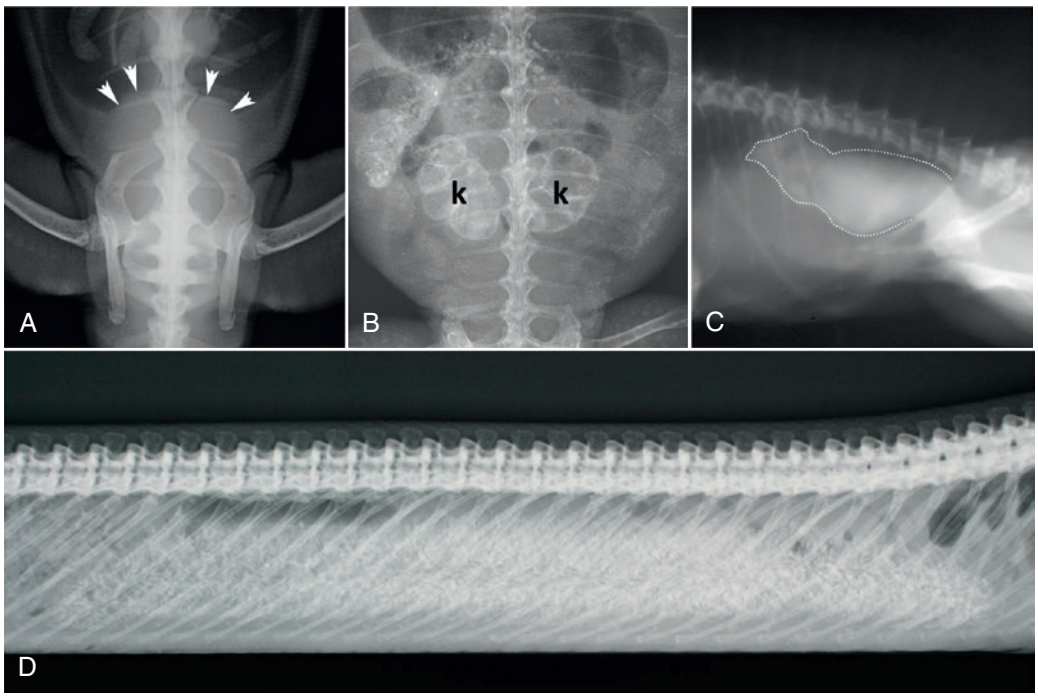

FIG 162.1 (A) Dorsoventral radiograph of the caudal coelom of a green iguana (*Iguana iguana*) demonstrating protrusion of the renal silhouettes (*arrows*) cranial to the pelvic rim, suggestive of renal enlargement. VetBooks.ir

Renal geotrichosis, phaeohyphomycosis, cryptococcosis, coccidioidomycosis, and candidiasis have also been identified in select individuals with renal pathology. *Entamoeba invadens*, *Hexamita parva*, *Myxidium*, *Klossiella*, and *Caryospora* are documented protozoan causes of nephritis and renal necrosis, whereas *Spirorchis* nematodes have been reported from aquatic chelonians and filarial nematodes from lizards. Herpesviruses, adenoviruses, arenaviruses, and iridoviruses have been associated with inflammatory and/or necrotic renal lesions.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Typically, chronic nephropathy cases present late in the course of disease when the majority of renal function has been lost, and clinical signs typically include anorexia, weight loss, and poor body condition. Plasma biochemistry may reveal abnormalities associated with electrolytes (Na, K, Ca, P), albumin, and nitrogenous waste excretion (uric acid, urea, and ammonia). Hematology is less specific but may indicate leukocytosis. Radiography, ultrasonography, CT, and MRI may reveal abnormalities in terms of shape, size, mineralization, and blood flow (Fig. 162.1). Iohexol excretion studies are possible to measure glomerular filtration rate and hence determine renal function. Renal biopsy (often endoscopic) is ultimately required for definitive diagnosis, although urinalysis, especially sediment evaluation, can provide valuable clinical insight in cases of parasitic, bacterial, or fungal nephritis (Fig. 162.2). In cases of bacterial or fungal nephritis, culture and sensitivity or, when available, MIC testing is indicated.

PREFERRED TREATMENT(S)

Fluid therapy is used routinely and should be tailored to correct any electrolyte imbalances, with serial biochemistry used to evaluate hydration and progress. Hyperuricemia must be controlled to prevent gout, and allopurinol has been shown to be effective. Other treatments that may be indicated include antimicrobials, intestinal phosphate binders, colchicine, enalapril, calcitriol, or other agents used for management of renal conditions in other species. Antimicrobials should be used only when infection has been demonstrated, with drug selection based on culture and sensitivity or, when available, MIC testing. Protein restriction and selective provision of pyrimidines (thymine and cytosine) over purines (guanine and adenosine) may help reduce uric acid production.

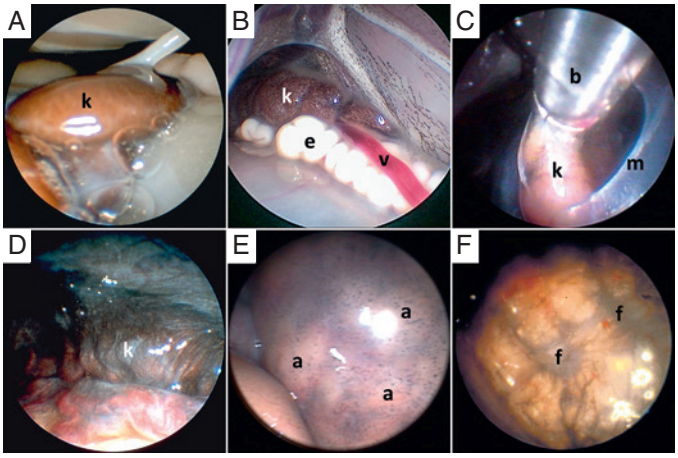

FIG 162.2 Endoscopic views of reptile kidneys using a 2.7 mm telescope. (A) Cranial pole of the left kidney (*k*) of a boa constrictor (*Boa constrictor*). (B) Cranial pole of the right kidney (*k*), right epididymis (*e*), and right renal vein (*v*) of a green iguana (*Iguana iguana*). (C) Biopsy of the left kidney (*k*) of a freshwater turtle (*Trachemys scripta*) using 1.7 mm biopsy forceps (b), introduced through an incision in the coelomic membrane (*m*). (D) Enlarged kidney (*k*) protruding into the coelom of a leopard tortoise (*Stigmochelys pardalis*). (E) Kidney of a male red-eared slider (*Trachemys scripta elegans*) exhibiting areas of pallor (*a*) that were confirmed as microabscesses after biopsy. (F) Kidney of a female Greek tortoise (*Testudo graeca*) exhibiting fibrous bands (*f*) across the surface. Biopsy confirmed tubulonephrosis with fibrosis. (Courtesy of Stephen J. Divers.)

PROGNOSIS AND PREVENTION

Prognosis depends on the degree of renal function remaining and the extent of the pathologic change but is generally poor with chronic conditions. Prevention usually centers on good husbandry, including suitable thermal environment, appropriate humidity/temperature, and removal of animal protein from herbivorous diets. (See Chapter 66 for more details and references.)

VetBooks.ir

Salmonellosis

Janos Gal and Cathy A. Johnson-Delaney

DEFINITION

Salmonella is a genus of rod-shaped, gram-negative, facultative anaerobic bacteria. They are considered to be a component of the indigenous microflora of reptiles and amphibians, and disease may only manifest after immunosuppressive effects of malnutrition, diet and husbandry errors, stress, concurrent disease, etc.[1–3]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Salmonellae are often found within the gastrointestinal tract of reptiles, spread via the fecal-oral route, and rarely cause disease. Surveys of wild reptiles have shown an incidence of 2.2% to 41% of various *Salmonella* serotypes.[4–6] One zoo population had a 45% infection rate.[7] Although infection and excretion is common, disease is rare, but the zoonotic implications are important.[1,2,8,9] Human salmonellosis often presents with gastrointestinal signs, including acute diarrhea, vomiting, fever, abdominal pain, dehydration, etc.[2] There are known cases in Europe, but overall the numbers appear lower than reported in the United States (see Chapter 174).[9]

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Salmonellae in reptiles usually cause asymptomatic gastrointestinal infections with a lifelong carrier state and intermittent shedding.[1–3,5,7] Onset of clinical disease may be due to predisposing factors such as improper husbandry, transit stress, malnutrition, and concurrent disease. A selected list of serotypes linked with illness in reptiles is listed in Table 163.1. A wide variety of clinical signs and disease processes may be seen, including anorexia, lethargy, paresis, cachexia, dyspnea, coelomitis, abscesses/granulomas, dermatitis, hypovolemic shock, and death.[3,4,6–8,10–12] Lesions may include necrotic dermatitis; inflammatory, necrotic foci in parenchymal organs; edema in the intestinal submucosa; inflammatory cellular infiltration of the lung; ulcerative enteritis with pseudomembrane formation; spinal osteomyelitis with necrotic lesions; chronic oophoritis; and follicular degeneration (Fig. 163.1), hemorrhages, and pericardial exudates.[3,6,8,10,12] *Salmonella enterica subsp. arizonae* serotype 56:Z4,Z23 shows high tropism for bone tissue in different species of reptiles, causing subacute, chronic, progressive, spinal osteomyeleitis.[10–12] Due to spinal malformations, affected reptiles have abnormal locomotion.[10,12] Culturing requires selective agar and enrichment.[13] Enzyme-linked immunosorbent assays may have higher sensitivity than cultures. Polymerase chain reaction testing has higher sensitivity and specificity than cultures.[3] Serotyping and pulsed-field

VetBooks.ir

gel electrophoresis (PFGE) subtyping of *Salmonella* isolates should be performed. In addition to culture, it is important to demonstrate a host pathological response by cytology or histopathology to differentiate between commensal and disease-requiring treatment situations.[12,13] It is not recommended to "test" or "culture" a clinically healthy reptile to attempt to declare it "salmonella free" because of the high likelihood of false negatives due to intermittent shedding.[1,2]

PREFERRED TREATMENT(S)

Attempts to treat reptiles with antibiotics to eliminate *Salmonella* spp. from their intestinal tract have not proven to be effective and cannot be recommended. In clinically asymptomatic animals, antibiotic treatment is contraindicated because it increases the risk of antimicrobial-resistant *Salmonella* strains, which, if transmitted to humans, would complicate their treatment. Attempts to raise "salmonella-free" reptiles have been equally unsuccessful.[1,2]

Supportive care includes fluid therapy, supplemental feeding, and correcting any husbandry deficiencies.[3] In cases of confirmed osteomyelitis, treatment includes antimicrobial agents selected on *in vitro* sensitivity testing, along with antiinflammatory and analgesic drugs. Surgical debridement and/or amputation/removal of the infected and necrotic bone is indicated where possible. The prognosis depends on the stage and location of the osteomyelitis. Advanced cases or those involving the spine carry a poor prognosis.[14]

PROGNOSIS AND PREVENTION

Appropriate management, stocking densities, and hygiene are helpful. Clinicians must educate owners on the likely prevalence of *Salmonella* in healthy reptiles and amphibians, and how to safely work with them. Updated safety guidelines are available from the Association of Reptilian and Amphibian Veterinarians (ARAV) at their website (arav.org/salmonella-bacteria-reptiles).

Shell Abnormalities

Jean Meyer and Paolo Selleri

DEFINITION

Shell damage or disease causes disruption of the integrity of the keratin scutes and/or the bony shell.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Infection, trauma (burns, falls, dog or predator bites, car accidents, boat strikes, lawn mowers, crush injuries, persistent courtship/rival behaviors), or neoplasia (e.g., squamous cell carcinoma) lead to cell destruction and/or devitalization with subsequent loss of the epidermal scutes, ulceration, abscess formation, necrosis, and osteolysis (Fig. 164.1A and B). Infections are commonly bacterial (e.g., *Citrobacter freundii*, *Beneckea chitinovora*, *Aeromonas hydrophila*, *Mycobacterium kansasii*, *Clostridium* sp.) and/or fungal (e.g. *Mucor* spp., *Purpureocillium* (*Paecilomyces*) *lilacinus*, *Aphanomyces sinensis*, *Fusarium semitectum*, *Exophiala oligosperma*). Many fungal species may be cultivated from shell lesions but can reflect secondary infection. Viral shell disease is less common but can be associated with herpesviruses (fibropapillomatosis) (primary lesions) and picornaviruses (secondary osteodystrophy). Nutritional or renal secondary hyperparathyroidism may lead to an osteodystrophic softening of the shell.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Precontrast and postcontrast CT is preferred for evaluating complex fractures or shell disease, although three-view radiography may reveal fracture lines and sequestra (see Chapter 70). Full-thickness shell biopsies should be submitted for histopathology and microbiology and are most reliable. Gram and cytologically stained smears from swabs or tissue impressions may indicate bacterial, fungal, or neoplastic involvement. Aerobic and anaerobic bacterial and fungal cultures from deep swabs or tissue biopsies should be routinely performed. Mycobacterial cultures or PCR should be considered if acid-fast organisms are seen. Antimicrobial selection should be based upon sensitivity testing, with a focus on drugs with known pharmacokinetics.

PREFERRED TREATMENT(S)

Traumatized chelonians should be stabilized with regard to analgesia, supportive fluid therapy, hemostasis, and soft tissue wound care. Eviscerations should be evaluated and replaced after thorough flushing with sterile saline. Surgical stabilization of the fractures should be performed under general anesthesia, after any infection has been resolved. Open wounds necessitate frequent dressing changes every 1 to 3 days. Ulcerated and infected wounds should be initially flushed using antiseptic solutions and sterile saline. Debridement should be performed under sedation with local anesthesia or general anesthesia. Repeated/daily lavage and wet to dry bandages may be required for continued debridement, which can be followed by wound products (e.g., Pronto Vet Gel, Braun, Medical AG, Sempach, Switzerland) and bandaging to promote granulation and healing (Fig. 164.2A and B). Topical antiseptic and antimicrobial products should also be considered.

FIG 164.1 Lawn mower injury penetrating the coelomic cavity. (A) Open wound treatment led to sealing of the defect by metaplastic calcification within 5 months (B).

VetBooks.ir

FIG 164.2 Dyskeratosis on the carapace of a Hermann's torotise *(Testudo hermanni)* before (A) and after (B) debridement. Bacterial and fungal infection lead to extensive keratolysis and osteolysis. Defects are sealed with ossified and keratinized granulation tissue.

Vacuum-assisted wound closure with silver impregnated bandaging materials is indicated for extensive lesions. Antimicrobial therapy should be based upon culture and sensitivity testing (see Chapters 70 and 113).

Serious burns require fluid therapy, analgesia, nutritional support, and strict asepsis. Surgical debridement and wound dressing may be required. With the exception of severe burns or integumental loss, antimicrobials should only be used when infection has been confirmed, and narrow spectrum agents effective against the cultured pathogen(s) are preferred. Only where there is significant loss to the integument or severe burns predisposed to infection is the use of broad-spectrum antimicrobials indicated (e.g., 1st- and 2nd-generation cepahlosporins, potentiated sulphonamides, tetracyclines). Metronidazole should be included if anaerobes are present or suspected. Secondary mycotic overgrowth of exposed bone surfaces is effectively treated with local antifungals (e.g., Terbinafine).

PROGNOSIS AND PREVENTION

The prognosis is generally favorable, but complications may result from overlooked visceral trauma, generalized coelomitis/sepsis, or secondary organ failure. Traumatic injuries can often be prevented by taking appropriate precautions (e.g., checking grass before mowing; no unsupervised contact between chelonians and other animals, including children). Appropriate quarantine and housing are required to reduce the incidence of infectious disease and intraspecific trauma.

See Chapter 70 for more details, including references.

VetBooks.ir

Snake Cryptosporidiosis

Rodney W. Schnellbacher

DEFINITION

Cryptosporidiosis is caused by coccidian protozoa of the apicomplexan genus. *Cryptosporidium serpentis* infections have been reported in at least 40 species of captive and wild snakes.[1] Although many species are affected, Viperidae (especially rattlesnakes) and amelanotic colubrid snakes appear to be particularly susceptible. *Cryptosporidium varanii* (syn. *C. saurophilum*) has also been identified in a few species of snakes; however, no adverse clinical signs were identified.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Cryptosporidiosis in snakes is a devastating disease that can lead to the loss of valuable animals in a collection. With no effective treatment, it usually results in morbidity and eventually euthanasia. Cryptosporidiosis in snakes is usually characterized by chronic clinical or subclinical infections, leading to primary hypertrophic gastritis. Enteritis, with or without gastritis, as well as a few cases of biliary involvement have also been observed. *Cryptosporidum* spp. is transmitted through the fecal-oral route, by direct contact, or through contaminated fomites. It does not appear to be zoonotic. There is no evidence of infection in snakes from ingestion of avian/mammalian prey infected with *Cryptosporidium*.[2] However, nonreptilian oocytes can be ingested, passed through in stool, and remain infective for mammals and avian species.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Clinical signs of cryptosporidiosis are related to gastrointestinal inflammation and hyperplasia (Fig. 165.1). Signs consist of anorexia, weight loss, postprandial vomiting (usually 3–4 days after prey ingestion), lethargy, and midbody swelling of gastric region (Fig. 165.2). Clinically affected snakes may live for days to years. Most snakes that test positive are subclinical, showing no outward signs, and are intermittent fecal shedders, oscillating between no or high levels of oocyte shedding. Differential diagnoses for vomiting and midbody swelling include suboptimal temperatures, inappropriate prey size, stress, obstruction, hibernation-associated necrotizing gastroenteritis, parasitism from other protozoa and nematodes, neoplasia, and infectious gastroenteritis (bacterial, fungal, and viral). Diagnosis can be challenging and is based on clinical signs, physical examination, oocyte analysis, histopathology, and molecular testing. Severely affected snakes often have a firm, thickened, palpable stomach. Ultrasonography or contrast gastric radiography can show gastric mucosal thickening and a delay in gastric emptying (Fig. 165.3). Endoscopically, the stomach rugae can be grossly enlarged, inflamed, or thickened. Diagnosis via oocyte testing can be variable due to intermittent shedding. *Cryptosporidium* sp. oocysts, 4 to 8 µm long, can be detected

FIG 165.1 Gross necropsy of an eastern milk snake (*Lampropeltis Triangulum*) performed after humane euthanasia showing gastric hyperplasia and hyperemia with thickened rugal folds. Histopathology confirmed cryptosporidiosis. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

FIG 165.2 The same eastern milk snake (*Lampropeltis triangulum*) as in Fig. 165.1 at presentation with a history of chronic regurgitation, notable weight loss, and midbody swelling evident. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

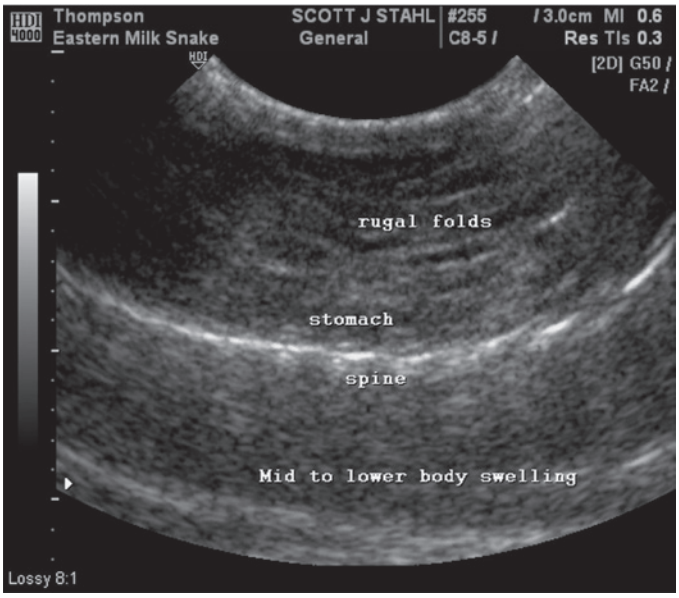

FIG 165.3 Ultrasound image of the same milk snake (*Lampropeltis triangulum*) identifying the midbody swelling as the stomach (located above the spine in the scan; the wording below the spine is a label of the scan itself) with thickened gastric rugal folds, characteristic for cryptosporidiosis in snakes. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

on light microscopy in unstained feces, mucus, or gastric lavage samples, and if detected must be differentiated from mammalian or avian prey *Cryptosporidium* spp. (Fig. 165.4). Sensitivity of fecal testing increases with serial testing, centrifugation concentration techniques, and the use of acid-fast, immunofluorescent staining and PCR (for differentiating mammalian/avian *Cryptosporidium* spp). Gastric lavage (20 mL/kg) is more useful than mucous or feces. Samples are best collected 3 days after feeding. The increased gastric metabolism after feeding is thought to increase *Cryptosporidium* metabolism. Gastric biopsy and histology are the only definitive diagnostic tests (see Chapter 32 for more details).

PREFERRED TREATMENT(S)

Cryptosporidiosis is difficult to treat successfully. Infected and shedding animals should be placed in permanent quarantine or humanely euthanized. Supportive care, including small meals via gavage tube, improvement in environmental conditions, and a reduction of predisposing stressors, may improve health conditions in some individuals. However, animals may become chronic shedders and carriers, with the potential to infect other snakes, and thus should not remain within a collection. Some pharmacological anticoccidial drugs have been shown to reduce the number of organisms or fecal shedding but are ineffective in eliminating all stages of infection; however, treatment with paromomycin was successful in one study in bearded dragons (*Pogona vitticeps*).[3] Hyperimmune bovine colostrum has shown to be efficacious in the treatment of *Cryptosporidium* sp. in a few snakes but is commercially unavailable (see Chapter 32 for more details).[4]

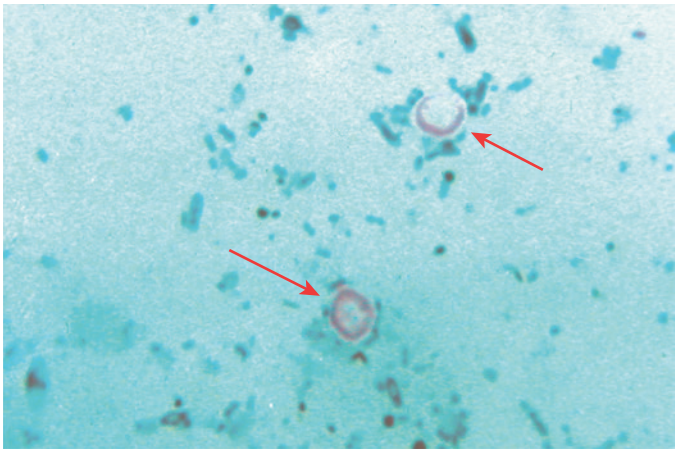

FIG 165.4 *Cryptosporidium serpentis* stained with a modified acid-fast stain (arrows) in a direct wet smear prepared from fecal specimens of a subclinically infected corn snake (*Pantherophis guttatus*). The mean size of *Cryptosporidium serpentis* oocysts is 6.3 × 5.5 µm.

PROGNOSIS AND PREVENTION

Cryptosporidiosis is difficult to manage, and prevention is accomplished through strict hygiene, quarantine, isolation, and diagnostic screening to prevent the introduction of positive snakes into a collection. Reptiles should not be euthanized based on the presence of *Cryptosporidium* in fecal or gastric samples without confirmation of actual disease by biopsy and histopathology. *Cryptosporidium* oocytes are very stable in the environment and may remain infective for 2 to 6 months. Cleanliness and removal of organic matter should be emphasized. Disinfection using 5% ammonia, 10% formalin, or hydrogen peroxide–based products is effective in eliminating oocyst infectivity after 18 hours of contact at 4°C. Exposure to moist heat between 45° and 60°C for 5 to 9 minutes is also effective. Cryptosporidiosis has a poor prognosis and is usually fatal. If supportive therapy is initiated, the animal's quality of life should be considered. Without clinical improvement and/or an unwillingness to eventually eat on its own, euthanasia may be necessary.

Spinal Osteopathy

Kevin T. Fitzgerald and S. Emi Knafo

DEFINITION

Proliferative spinal osteopathy (PSO) has been described in turtles, lizards, and snakes.[1] Most commonly reported in snakes, these proliferative and progressive spinal lesions have been shown to be associated with chronic bacterial infections. Most frequently, *Salmonella* ssp. are implicated.[2,3] The lesions of spinal osteopathy in reptiles have been compared with osteitis deformans (Paget's disease) in humans.[4] This disease is a localized disorder initially marked by excessive bone resorption followed by deformity and then by excessive bone formation. Affected animals can be dramatically debilitated. See Chapter 81 for more detailed discussion of PSO.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Osteoarthritis is defined as a disorder of moveable joints characterized by deterioration of articular cartilage, osteophyte formation, bone remodeling, and low-grade nonpurulent inflammation.[5] Osteoarthritis can be inflammatory or noninflammatory, caused by trauma, dietary deficiency (hypovitaminosis D, hypervitaminosis A), unknown viral infection, prolonged inactivity due to cage confinement, slow-developing neoplasia, and association with bacterial infection and septicemia. Speculation exists that the spinal lesions may be caused by an immune-mediated reaction from septicemia and triggered by bacterial endotoxins. An association between spinal disease and previous soft tissue bacterial infections has been suggested in various reptiles. *Salmonella,* a bacteria frequently cultured from the gastrointestinal tract of reptiles, but nonpathogenic to the host, has been implicated in vertebral osteomyelitis in snakes.[2,3]

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Clinical signs of PSO in reptiles may vary in severity and location of lesions. Animals with vertebral lesions can show limited movement or no movement at all in affected areas. The affected vertebral regions can be remarkably extensive, sometimes as much as 30 cm (12 in) long. Clinical signs can include vertebral column stiffness and resultant decreased mobility, kyphosis, scoliosis, and occasionally pathologic fractures.

On examination, focal nodular swellings may be visible along the dorsum or bulges on the sides of the body (Fig. 166.1A). Palpation of the spine may reveal variably sized segments of ankylosis, kyphosis, scoliosis, or lordosis. Hyperreflexia or upper motor neuron signs are often seen cranial to the spinal lesion. Caudal to the affected area motor deficits in the somatic musculature, as well as slight or dramatic torsion of the body, may be noted. Additionally torticollis, trembling, and subtle or acute spinal kinking may be exhibited.

Eventually, affected animals cannot move, strike, or swallow prey. If severe luxation and rotation of vertebrae are present, animals may display bizarre corkscrew postures. Affected lizards may show proprioceptive

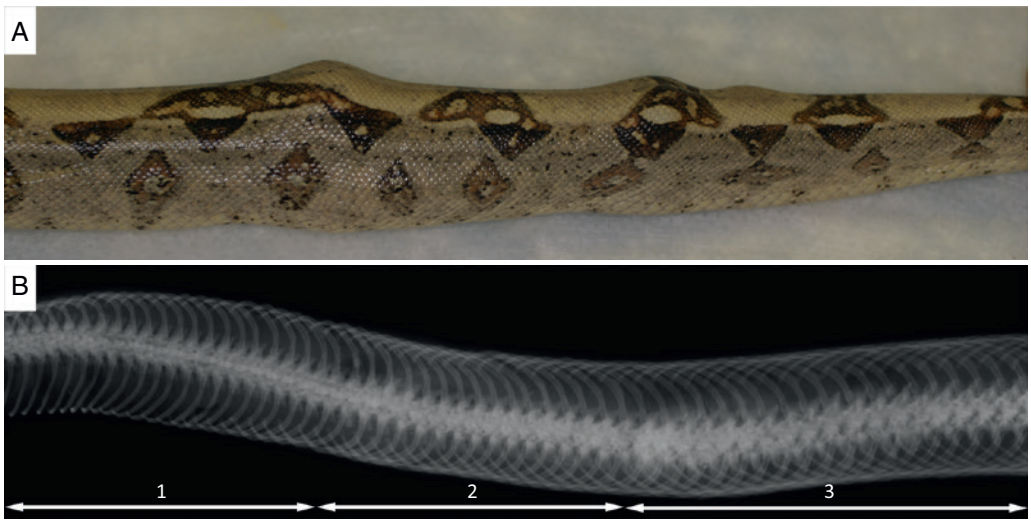

FIG 166.1 Spinal osteopathy in a boa constrictor *(Boa constrictor).* (A) Clinical presentation demonstrating deformity and swellings associated with the spine. (B) Dorsoventral radiograph of the spine demonstrating normal (1), mildly (2), and severely (2) affected regions. (Courtesy of Stephen J. Divers.)

VetBooks.ir

deficits, severely distorted postures, and partial to total paresis depending on the size and location of the lesion. It is interesting to observe that even severely debilitated animals may continue to eat and drink.

Successful diagnosis of PSO depends on clinical history, physical examination, radiology/CT, bone or blood culture, histopathology, and findings at necropsy. Histopathology is closest to a gold standard for confirming PSO, but it is not always practical or possible. Radiographically, changes associated with PSO typically show evidence of segmented fusion of adjacent affected vertebra (Fig. 166.1B). Vertebrae can be fused dorsally, ventrally, or laterally by foci of irregular proliferative bone, sclerosis of vertebral end plates, and with varying degrees of lysis of vertebral bodies often noted. In advanced stages, periarticular bony proliferation may involve dorsolateral articular facets and costovertebral joints, often resulting in bridging of joint spaces (osseous metaplasia), and ankylosis (Fig. 166.2). Pathologic fractures may be noted and are often associated with proliferative reactive bone exostoses. Radiographs are useful to confirm the presence and severity of spinal disease but cannot identify infection or inflammation. Advanced diagnostics such as nuclear (bone scan) imaging may help identify the site of active disease. Bacterial culture of bone biopsies can be helpful; however, evidence exists that bony lesions of spinal osteopathy may not develop until 22 to 26 months after the initial episode of local infection or septicemia.[6] Animals with radiographic evidence of PSO should have a blood culture. Biopsy of bone in living reptiles is possible, though heavy epaxial muscles over vertebrae make access a challenge. Antemortem rib and vertebral biopsy carries a potential risk of iatrogenic fracture.

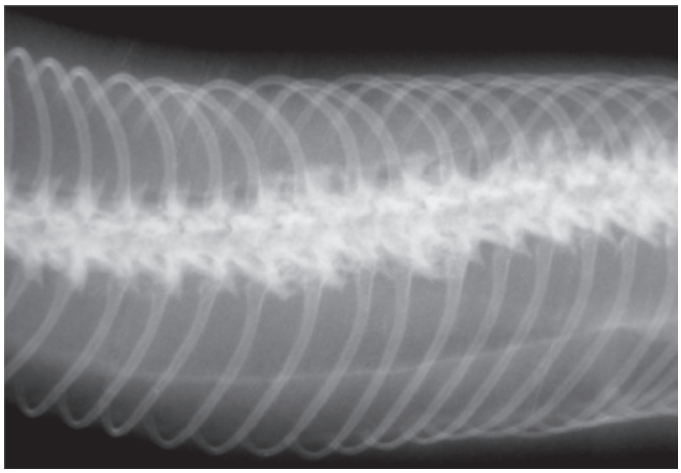

FIG 166.2 Snakes with spinal osteopathy have evidence of segmented fusion of adjacent vertebrae by foci of irregular proliferative bone. Early on, sclerosis is seen on vertebral end plates with or without lysis of the vertebrae. In advanced stages, periarticular bony proliferation involves the dorsolateral articular facets and costovertebral joints. Eventually, osseous metaplasia may bridge adjoining vertebrae (ankylosis). (Courtesy of Douglas R. Mader.)

PREFERRED TREATMENT(S)

Early diagnosis is essential for successful therapy. Effective treatment can include appropriate antibiotic selection, surgical debridement of granulomatous or lytic areas, use of antiinflammatory medications, and separation of affected and unaffected individuals. Parenteral administration of medication may need to be continued for extended periods. Carprofen and meloxicam have been recommended; although clinical efficacy is difficult to assess. Recently a case report documented establishment of a vascular access port in an iguana for administration of a chemotherapy agent.[7] This may be a reasonable method to deliver therapeutic levels of antibiotics and other drugs in affected reptiles needing long-term therapy.

PROGNOSIS AND PREVENTION

At present, prognosis for reptiles with PSO is poor to grave. Most animals display advanced lesions at the time of presentation. Radiography and CT can be useful to determine severity and monitor progression. Early recognition of this process through implementation of a thorough diagnostic investigation, aggressive long-term antibiotic and analgesic therapy, and/or surgical debridement are the most potentially effective therapies at this time.

VetBooks.ir

Stomatitis

Ryan De Voe

DEFINITION

Stomatitis is characterized by inflammation and typically infection of the tissues of the oral cavity. Infections can extend from the oral cavity and may result in cellulitis, sinusitis/rhinitis, osteomyelitis, and with aspiration of infectious agents into the lower respiratory tract (pneumonia). More details can be found in Chapter 73.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Although a number of pathogens appear capable of causing primary infections, stomatitis usually occurs secondary to presumed predispositions, such as immunosuppression, poor husbandry conditions, malnutrition, or trauma. Stomatitis is often a sign of systemic disease. Damage to the rostral tissues caused by rubbing on or crashing into barriers, as well as bites from prey items in snakes and carnivorous lizards, can result in stomatitis. Trauma may cause disfigurement, resulting in exposure of the gingiva and associated stomatitis due to desiccation and devitalization of mucous membranes. Lizards with acrodont dentition are susceptible to periodontal disease because of the vulnerable nature of their periodontal tissue. Once this tissue is damaged, invasion of bone from opportunistic organisms (bacterial, fungal) often results and may progress to osteomyelitis (see Chapter 159).[1] Squamous metaplasia of oral mucosa and glandular epithelium due to hypovitaminosis A can create a suitable environment for secondary infections. Nutritional secondary hyperparathyroidism with deformity of the lip margins can cause chronic exposure of the gingiva and stomatitis. The infectious component of stomatitis is caused by a variety of opportunistic bacterial and/or fungal isolates. These bacteria and fungi are often part of the animal's normal oral flora or ubiquitous in the environment. Primarily gram-negative bacteria but also gram-positive and/or anaerobic isolates can cause clinically significant infections. Mycobacterial and mycotic organisms have also occasionally been associated with stomatitis.

Parasitic disease may also result in clinical stomatitis. Nematodes that typically occupy the lower gastrointestinal tract or nasal cavity can occasionally be identified in the oral cavity and may result in pathology.[2] Spirorchid nematodes and their eggs can embolize in small vessels, causing ischemia of oral structures. A number of fluke (monogentic and digentic trematode) species parasitize the oral cavity of various reptile species and can cause or exacerbate existing stomatitis, though usually the presence of these parasites is of little clinical concern to the host.

Certain viral pathogens have a tropism for the oral mucosa and will cause a primary stomatitis. Herpesviruses are well-known causes of stomatitis in chelonians and other reptile taxa.[3–5] Ranavirus infections can also cause stomatitis that can be grossly indistinguishable from herpesvirus infections in some species. Recently nidovirus was found to be associated with stomatitis/pharyngitis in ball pythons (*Python regius*).[6]

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Investigation of reptile stomatitis should focus on defining the pathology in the oral cavity, evaluating overall health, and identifying a predisposing factor or etiology.

Clinical signs may consist of perioral or intraoral swelling/abscessation, pytalism/discharge, disruption of the lip margins, the inability to close the mouth properly, mucosal hyperemia, petechiation and ulceration, mucosal plaques, and dysfunction of the tongue, larynx, and associated structures (Figs. 167.1 and 167.2). Occasionally even with oral pathology there may be no visible abnormalities noted with the mouth closed; therefore, a thorough oral examination is always indicated. Examination of the tongue, especially in snakes, varanid lizards, and chameleons is important to identify glossitis, lingual necrosis, and abscessation of the tongue sheath. Endoscopic evaluation of the oral cavity facilitates access to oral structures and provides magnification. Collection of material from lesions via swabs and scrapes for cytology, culture and sensitivity, virus isolation, and molecular diagnostics should be considered. Radiography or CT is often indicated to identify periodontal disease and osteolysis. Biopsies for histopathology are useful, especially in cases that do not respond as expected to therapy. A minimum database consisting of at minimum a complete blood cell count, differential cell count, and a plasma chemistry panel is recommended in all cases of

FIG 167.1 Labial deformity in a boa constrictor (*Boa constrictor*), which can result in chronic exposure and damage to gingiva, predisposing to stomatitis. (Courtesy of Stephen J. Divers.)

stomatitis to help provide insight into the overall condition and health of the animal.

PREFERRED TREATMENT(S)

Animals that are being treated for stomatitis should be kept in optimized husbandry conditions. Appropriate thermal and humidity gradients within their habitat, comfortable hide areas, and adequate lighting are all important in supporting a convalescing reptile (see Section 3 and Chapter 46). Many reptiles with stomatitis will be anorexic or hypophagic when presented. Gavage feeding, or placement of an esophagostomy tube, may be necessary to bypass a diseased and potentially painful oral cavity (see Chapter 45). Debridement of diseased tissue is required in many cases. Loose teeth that can be removed with little effort should be extracted. Necrotic bone should be debrided. Deep tracts should be marsupialized to facilitate local therapy if there is any question regarding residual diseased tissue following debridement. Systemic therapy with antimicrobial and nonsteroidal antiinflammatory agents may be indicated. Initial antimicrobial therapy should be based on cytology and gram stains and modified by culture/sensitivity results. Local antimicrobial therapy is also usually part of a successful treatment regimen. Cleansing and flushing of affected areas with disinfectants such as dilute chlorhexidine and tris-EDTA solutions can be used effectively. Silver sulfadiazine cream is a commonly used topical therapeutic and has the benefit of being water soluble. When cavities or fistulas are present, sugar or unpasteurized medicinal honey can be effective topically.

PROGNOSIS AND PREVENTION

Prognosis is dependent on cause and severity and can range from good to poor. Mycobacterial or viral etiologies or cases involving bone with associated osteomyelitis have a more guarded prognosis. Prevention of stomatitis in captive reptiles centers on the provision of adequate husbandry, diet, and biosecurity. In cases where there is chronic exposure of gingival tissue, maintenance therapy is often indicated. Periodic cleansing with the aforementioned disinfectants, application of various veterinary oral products such as vitamin C–containing oral cleansing gels, and application of beeswax, petroleum jelly, or other products to protect exposed tissue can be used effectively in maintenance therapy.

Tail Abnormalities

Richard S. Funk, Robert Johnson, and Stephen J. Divers

DEFINITION

Tail damage results from a variety of causes, including mechanical, traumatic, infectious, and physiological etiologies.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

A reptile's tail is a caudal extension of the vertebral column and often used for social signaling, locomotion (counterbalance, swimming), predator avoidance, and even prey luring. In some lizards fat is stored within the tail. Common causes of tail damage and deformity include trauma, autotomy, infection, or a congenital defect. Tail trauma can be caused by cage-mate aggression, the tail being mistaken for a food item and grabbed during feeding, or deliberate or accidental injury inflicted by a human. Caudal autotomy (tail drop) can occur in many lizard species (but not in chameleons, most agamids, monitors, helodermatids, xenosaurids, and lanthanotids), and tuataras but has also been reported in some snakes and amphisbaenids.[1,2] In some lizards the ability to autotomize and regenerate the tail is lost with maturity (including *Ctenosaura*, *Cyclura*, *Iguana*, *Sauromalus*, and some *Tiliqua*). The clinician must be careful in handling susceptible species so as not to cause iatrogenic tail loss (Fig. 168.1A).

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Ascending vascular necrosis of the tail tip is common in the green iguana (*Iguana iguana*), the bearded dragon (*Pogona vitticeps*), monitors (*Varanidae*), tegus (*Teiidae*), and others. Although multifactorial,

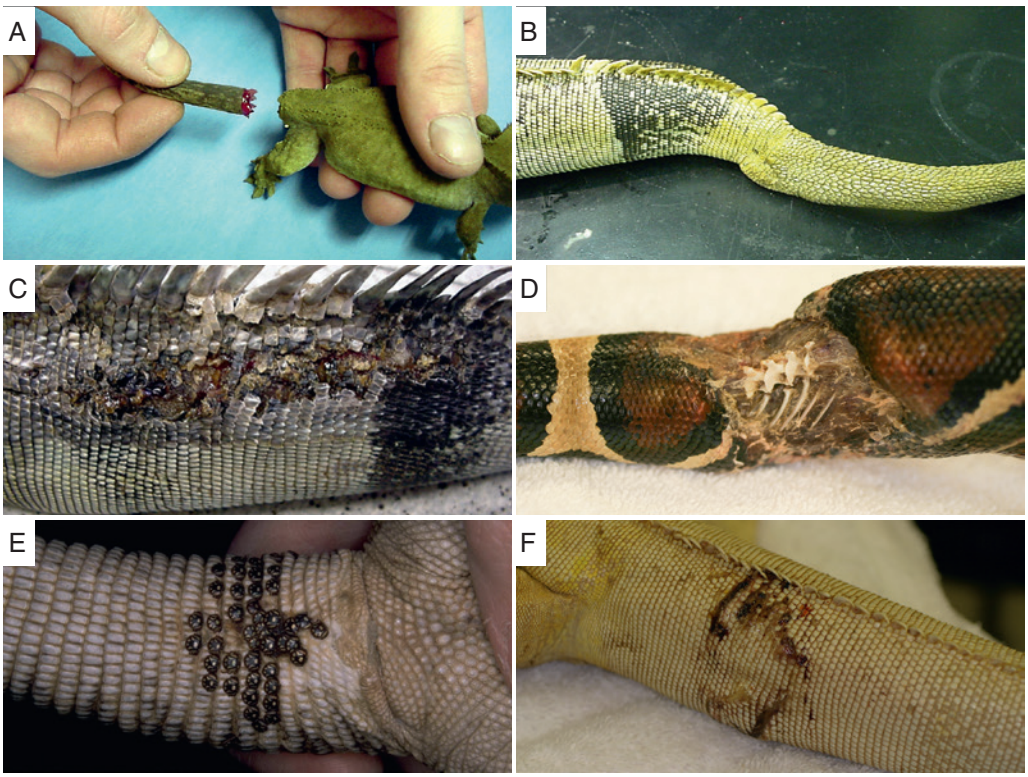

FIG 168.1 (A) Tail autotomy in a *Rhacodactylus* lizard associated with handling. (B) Imperfect tail regeneration in an iguanid lizard. Note the kink at the level of regeneration and the smaller scalation characteristic of regenerated tails in many species. (C) Dorsal tail necrosis and secondary bacterial and fungal infection in a green iguana (*Iguana iguana*) secondary to thermal burn. (D) Rodent-induced tail trauma in a *Boa constrictor*. (E) Ticks feeding along the tail base of a recently imported savannah monitor (*Varanus exanthematicus*). VetBooks.ir

a common cause is aggressive or defensive animals slapping their tails against the cage wall or other objects causing injury and necrosis. Vessel calcification, thromboembolism, and reduced peripheral circulation can cause ischemic tail necrosis. A number of different bacteria may be cultured from these necrotic lesions, including *Neisseria iguanae*.[3] Cloacal prolapses and cloacitis may lead to inflammatory lesions on the base of the adjacent tail. Both male and female snakes have paired scent glands located within the base of the tail. These may enlarge as secretions accumulate and may become inspissated or abscessed with a resultant enlargement of the tail base and even ulceration and rupture. The hemipenes of male squamates are located within the tail base, ventral to the scent glands. These may become swollen, impacted, and even abscessed. The condition may be associated with hypovitaminosis A in some species such as geckos and chameleons.[4] Overzealous or improper probing for sex identification, usually in the hands of inexperienced keepers, has been known to cause tail base damage.

Some lizards may develop a forked or deformed tail from an incomplete tail autotomy (see Fig. 168.1B). Tails may also suffer injuries from thermal burns associated with heat lamps and heating pads (see Fig. 168.1C). Occasionally tail skin may be damaged or lost when stuck to tape used in building or decorating an enclosure.

A common cause for tail trauma including tip amputation is trauma from a live rodent bite (see Fig. 168.1D). Damage to the tail skin may result from bacterial or fungal dermatitis/abscesses, contact dermatitis, dysecdysis, ectoparasites (e.g., snake mites, ticks; see Fig. 168.1E), neoplasia, or owner-induced trauma such as forcibly pulling the pet from a refuge or slamming the cage door on the tail. Tail paralysis can be caused by fracture or luxation of one or more caudal vertebrae, a bacterial or protozoal infection that involves the caudal spinal cord, neoplasia, or proliferative ossifying spondylosis or osteomyelitis lesions that usually are bacterial and resistant to resolution (see Fig. 168.1F).

Some terrestrial chelonians (e.g., *Terrapene*), especially juveniles, may lose their tails or tail tips due to retained shed skin when kept in low humidity environments. Wild-caught reptiles commonly exhibit scars or wounds on their tails, presumably from predators or occasionally from prey, other mechanical injuries, or from their human captors.

Iatrogenic tail swelling/infection may result from venipuncture of the caudal (tail) vein. Attention to aseptic technique, proper choice of needle size, limited number of attempts, and mild pressure at the venipuncture site following the procedure should prevent these complications. Tail venipuncture of lizards that can drop their tails should be carefully considered, and sedation/anesthesia may be preferred. Rarely, iatrogenic necrosis of the tail tip may occur after venipuncture.

PREFERRED TREATMENT(S)

Hemipenal plugs can often be removed manually, either by gently grasping and retracting the exposed dried tip, or by a combination of retraction and digital expression with pressure applied in a caudal to cranial direction. Some cases require sedation and sometimes surgical intervention. Many of the conditions discussed previously can be treated with therapeutic agents if indicated; amputation if necessary; surgical removal of abscesses, granulomas, or tumors; or surgical closure of skin defects if possible. Delays in treatment may result in a greater likelihood of infection and permanent scarification.

In the case of surgical amputation of the whole tail, or a portion thereof, the clinician may be able to "assist" natural regeneration by autotomizing it at a natural plane. The wound should be left unsutured so as not to hinder regeneration. In this case conservative treatment, even with a temporary bandage, may be suitable (see Chapter 112).

Testudinid Herpesviruses

Francesco C. Origgi

DEFINITION

There are at least 20 different chelonian herpesviruses (*Herpesviridae,* subfamily *Alphaherpesvirinae*).[1] Four of them are closely related and have been renamed *Testudinid herpesviruses* (TeHVs) (previously "tortoise herpesviruses").[2] *Testudinid herpesvirus* 3 (TeHV3) is considered the most widespread and pathogenic. Any tortoise is considered susceptible, but different species sensitivity exists.[1,2] Highest incidence of disease is seen in early spring and fall.[1] Two distinct genogroups (A, B) of TeHV3 exist and have been associated with lesions of different severity (B > A).[1] The other TeHVs comprise TeHV1 overrepresented in Russian tortoises (*Agrionemys horsfieldii*), TeHV2 in the Agassiz's desert tortoises (*Gopherus agassizii*), and TeHV4 detected in both healthy and diseased African tortoises (Bowsprit tortoise [*Chersinia angulata*] and Leopard tortoise [*Stigmochelys pardalis*]).[3] Transmission is most likely by close contact, although evidence of a likely vertical transmission has been recently reported.[3] Intranasal and intramuscular live virus inoculations cause disease.[2,4]

CLINICAL PRESENTATION

Clinical signs are stomatitis and glossitis with oral and/or nasal discharge, conjunctivitis with ocular discharge, dyspnea, neurological signs, cervical edema, anorexia, and weight loss.[2] Experimentally, stomatitis and glossitis may occur within 12 days postinfection and is detectable for about 2.5 weeks in Greek tortoises (*Testudo graeca*) (see Fig. 169.1). Complete resolution of the clinical signs follows in survivors.[2,4]

Oral diphtheronecrotic plaques are classic (see Fig. 169.1A).[4] TeHV3 is neurotropic;[4] however, the eosinophilic to amphophilic intranuclear inclusions can be seen in virtually any epithelial tissue besides the CNS. Indirect evidence of latency in infected animals exists.[4] Virus reactivation is unpredictable; however, viral shedding in infected tortoises has been reported to occur more commonly after hibernation.[2,3]

DIAGNOSTIC CONFIRMATION

Laboratory confirmation of herpesvirus infection in tortoises is necessary because of the lack of pathognomonic clinical signs and their transitory nature. Differential diagnoses include ranavirus, virus X (Picornavirus) and *Mycoplasma* sp infections.[2] Serological (mainly serum neutralization [SN] and enzyme-linked immunosorbent assay [ELISA]) and molecular tests (mainly PCR) are available together with virus isolation, electron microscopy, and histopathology. SN testing can be applied to any tortoise species as long as the specific herpesvirus strain is available as an isolate, whereas ELISA testing has been validated in Greek and Hermann's (*T. hermanni*) tortoises for TeHV3.[2] Detection of anti-TeHV1 and TeHV2 antibodies in Greek and Hermann's and also other species of tortoises by ELISA is also possible (Origgi F, personal communication). A minimum of two ELISA tests repeated at least 8 weeks apart are necessary to definitively determine infection to TeHV3, and 10 weeks apart are

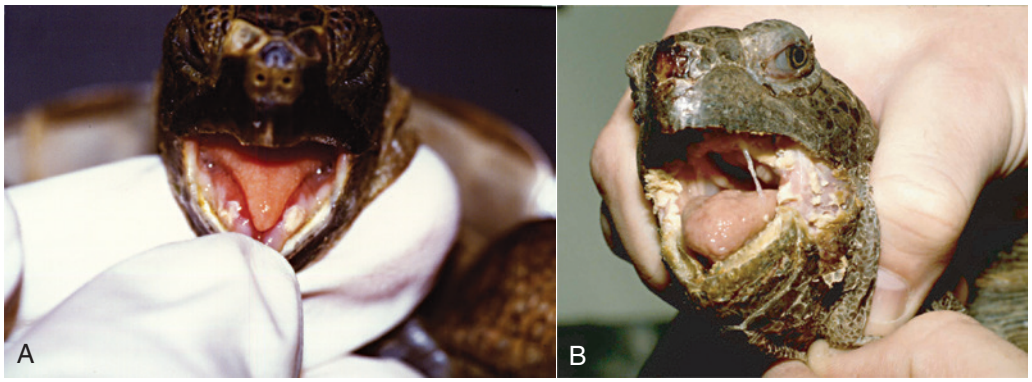

FIG 169.1 (A) Herpesviral stomatitis in a Greek tortoise (*Testudo graeca*). Shown are oral diphtheritic plaques surrounded by hemorrhagic inflammation of the mucosa. Plaques are in the early stage of formation. Notice the perfect symmetry of the lesions. Plaques might not necessarily be symmetrical and may occur also on the tongue. (B) Herpesviral stomatitis and rhinitis in a California desert tortoise (*Gopherus agassizii*). Note the oral plaques and hemorrhagic nasal discharge. (A, Courtesy of Francesco C. Origgi; B, courtesy of Douglas R. Mader.)

VetBooks.ir

suggested for SN.[2] Both tests are equally reliable.[2] Lack of seroconversion may occur.[4] PCR tests include both genotype specific- and pan-herpesvirus protocols.[2] The PCR products need to be sequenced. Virus isolation is the definitive proof of herpesvirus infection. Serology is particularly helpful in chronically infected animals with no clinical disease. Molecular testing is the test of choice during the acute stage of the infection.[2]

PREFERRED TREATMENT(S)

Acyclovir and gancyclovir reduce viral replication *in vitro*.[5] Either 80 mg/kg per os SID or TID of acyclovir have been proposed; however, the effective concentration could not be reached in vivo after a dose of 80 mg/kg.[2] Supportive therapy such as fluid therapy and antimicrobials for secondary infections may also be helpful.[2] Vaccination treatments have been unsuccessful.[2]

PROGNOSIS AND PREVENTION

Herpesvirus infection is for life. Quarantine (6 months or longer) while repeating serological and molecular tests is critical, and separating animals with consistent signs is necessary.[3] Overcrowding and mixing species should be avoided.[2]

Thermal Burns

Michael Pees and Tom Hellebuyck

DEFINITION

Thermal burns are injuries caused by direct or indirect contact with heated objects or excessive infrared radiation. Burns are generally classified from first up to fourth degree.

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Thermal burns are commonly observed in captive reptiles. These injuries can range from mild to life threatening but should always be considered medical emergencies. See Chapter 69 for a more detailed discussion on the treatment, prognosis, and prevention of thermal burns.

The main causes for this condition are the use of inadequate heating equipment or other management faults with respect to environmental temperature maintenance. Common faults are unguarded heat bulbs, hot rocks (Fig. 170.1), or heat mats. The latter are often of poor quality and can reach temperatures that directly lead to thermal damage. It is still not understood why reptiles do not react appropriately to temperatures that will cause immediate burns (e.g., snakes curling around heat bulbs with extreme temperatures), but it is essential that owners are aware of this issue and prepare the reptile's environment appropriately.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Often historical review of husbandry practices and patient behavior, and a thorough physical examination, will indicate a thermal burn. The classification of thermal burns used in mammals as first-, second-, third-, and fourth-degree burns can also be applied to reptiles (see Chapter 69). Although first-degree burns often appear harmless and might be treated by the owner, clinical monitoring is recommended, because secondary problems (e.g., bacterial infections) may occur. Severity and prognosis depend on several factors, including the kind of heat source (radiant, conductive) and the temperature and time of contact, but also the overall general condition of the reptile, the severity of the skin damage, and the species involved.

Diagnosis and confirmation is based on a combination of clinical signs and investigation into husbandry practices.

PREFERRED TREATMENT(S)

Therapy should be initiated as soon as possible, and proper wound management is essential. Reptiles have a remarkable ability to cope even with extensive wounds, but healing might take several months, and medical treatment should be continued until the wound is closed. Wound cleaning, using mild antiseptics (e.g., chlorhexidine), and a hygienic environment (e.g., paper, towels) are important. Enzyme ointments might be helpful to clean necrotic wounds and stimulate secondary healing. A suitable wet-to-dry bandage may also help with further debridement, whereas iodine gauze can be used to prevent/reduce infection. Systemic antimicrobials should be considered for serious and widespread burns, especially if surgical debridement is planned. The importance of microbiologic examination and susceptibility testing cannot be overemphasized. Fluid and protein loss should be corrected. Analgesia is required for first- and second-degree burns; however, third- and fourth-degree alterations typically result in nerve-ending destruction (Fig. 170.2) and are often less painful.

FIG 170.1 Third-degree burn at the ventral body surface in a ball python (*Python regius*) as a consequence of the inappropriate use of a hot rock. (Courtesy of Tom Hellebuyck.)

FIG 170.2 Third-degree dorsal burn in a chameleon due to an inappropriately installed heat lamp. The wound healed after several weeks of supportive treatment. (Courtesy of Michael Pees.)

VetBooks.ir

Once reepithelization starts, wound dressings should support healing, and low-level laser therapy (photobiomodulation) may be helpful.[1,2] Scar formation and repigmentation may occur over months and may result in recurrent dysecdysis at the site of damage.

PROGNOSIS AND PREVENTION

Prognosis is dependent on the severity of the condition and an effective therapeutic approach. Appreciation of the natural behavior of reptiles, and establishment of an appropriate and safe thermal environment are necessary. Clinicians should discuss appropriate thermal guidelines with clients.

VetBooks.ir

Tortoise Mycoplasmosis

Lori D. Wendland and Mary B. Brown

DEFINITION

Mycoplasmosis is an important cause of upper respiratory tract disease (URTD) in tortoises.[1]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

Members of the Testudinidae appear to be highly susceptible to *Mycoplasma agassizzi* infection.[1] To date, *M. testudineum* is found only in gopher and desert tortoises (*Gopherus* spp.). In the Emydidae family, a third of *M. agassizii*-like sp. has been identified by PCR.[2] Increased tortoise densities, inappropriate temperature, poor nutrition, and concurrent infections may all exacerbate mycoplasmosis in captive tortoises. Transmission is via direct contact, particularly when animals have nasal discharge. Nasal cavity lesions vary in severity and may include multifocal to focally extensive subepithelial lymphoid aggregates, a mixed inflammatory cell infiltrate, basal cell hyperplasia, mucous and olfactory epithelial metaplasia, and erosion of the ciliated epithelium. *M. testudenium* appears to cause more focal and less severe damage.

CLINICAL PRESENTATION

Clinical signs, alone or in concert, include serous to mucopurulent nasal and ocular discharge, edematous and erythemic conjunctiva, and periocular and palpebral edema (Fig. 171.1A and B). In severe cases, nasal cavities may be completely obstructed with a thick, caseous discharge, and nasal cavity erosion can occur. Once infected, clinical signs may be intermittent or absent, but animals rarely clear mycoplasmal infections. Subclinical animals may have no apparent clinical signs, yet be seropositive, have histopathological lesions, and may shed. Clinical signs intensify and abate cyclically in chronic infections; animals may remain asymptomatic for years before recurrence. In animals that repeatedly exhibit clinical signs, grooves extending ventrally from the nares, eroded nares, and depigmentation around the nares can be observed.

DIAGNOSTIC CONFIRMATION

Optimal diagnostics include both ELISA serology (plasma or serum) and PCR (choanal swabs, nasal discharge, or flushes) coupled with health assessment and observation for clinical signs.[3,4] Western blots are not recommended unless multiple strains or the homologous strain is used as the antigen.[5] ELISA may not detect tortoises in the earliest stages of infection but is the most likely to detect clinically silent, intermittently shedding, as well as chronically infected animals. PCR/qPCR may detect animals in early stages of infection or those currently shedding; however, false negative results can occur in chronically affected, intermittently shedding, or clinically asymptomatic animals or with inadequate sampling of nasal passages. Culture is generally not used, as *M. agassizii* is fastidious, takes up to 6 weeks for primary isolation, and requires experienced laboratory personnel.

PREFERRED TREATMENT(S)

Treatment recommendations are extralabel, and exact doses may vary for tortoise species.[6] Tetracyclines, fluoroquinolones, lincosamides,

FIG 171.1 (A) Gopher tortoise (*Gopherus polyphemus*) with conjunctivitis, ocular discharge, and severe palpebral edema from mycoplasmosis. (B) Epistaxis, nasal and ocular discharge, and conjunctival hyperemia are seen in this gopher tortoise. These signs may develop as early as 2 weeks after infection.

VetBooks.ir

macrolides, and certain aminoglycocides are effective against *Mycoplasma;* antibiotics targeting cell walls are not effective. Topical (ocular and nasal) antibiotic-corticosteroid combinations used with oral or parenteral antibiotics may minimize the local inflammatory response.[6] Longer treatment may be required in more severely affected animals. Supportive care and housing in the upper ranges of preferred optimal temperature zone will improve response to treatment.

PROGNOSIS AND PREVENTION

Use standard infection control practice for infectious disease, and isolation of ill tortoises for more intensive monitoring and treatment may help contain the flare-ups and decrease frequency of clinical disease. Once diagnosed with URTD, consider that animal as persistently infected and a potential source of infection. Use stringent disinfection and sanitation protocols (e.g., 3%–5% bleach solution). Separate eggs and hatchlings from adults, as hatchlings may develop more acute, fulminant disease. Use adequate husbandry practices to minimize stress and exposure to naive animals. Increased tortoise densities and higher organic load could facilitate environmental persistence. See Chapter 72 for more details.

Urolithiasis (Cystic Calculi and Cloacal Uroliths)

Krista A. Keller

DEFINITION

Urolithiasis has been reported in chelonians, lizards, and snakes.[1–7] Urolith location may be anywhere along the urinary tract, although cystic calculi are most common.[1–7] Most uroliths are composed of urate salts; however, calcium carbonate, oxalate, and mixed compositions are reported.[1–3,5]

CLINICAL SIGNIFICANCE AND KNOWN ETIOLOGICAL CAUSE(S)

It has been proposed that chronic dehydration and overheating may factor in the etiology of urolithiasis.[3] Urine modification occurs across the bladder epithelium, with water reabsorption along a concentration gradient resulting in further urine concentration approaching that of plasma.[8,9] Thus chronic dehydration and overheating may increase water absorption from the bladder, leading to supersaturation of urate excreta and reduced urination, predisposing to urolith formation. High-protein diets and biological niduses (e.g. parasites, eggs) may also predispose to calculus formation.

CLINICAL PRESENTATION AND DIAGNOSTIC CONFIRMATION

Many cystic calculi have a long subclinical stage where no abnormalities are noted. Physical examination findings suggestive of a cystic or cloacal calculus include cloacal prolapse, egg retention, tenesmus, and lack of production of feces or urine.[3] Physical examination findings that may confirm a cystic calculus include palpation of a hard structure in the prefemoral fossa of chelonians (Fig. 172.1) or the caudal coelom of lizards. Digital cloacal palpation may yield a hard structure within the cloaca. Radiographs are a confirmatory and screening test for uroliths revealing radio-opaque laminar structures in the caudal coelom (Fig. 172.2A) or intrapelvic region (see Fig. 172.2B). Radiolucent uroliths have also been reported but are uncommon.[3] There may be a predisposition in chelonians for cystic calculi location in the left lobe of the urinary bladder.[3] Hematology, plasma biochemistry, and urinalysis do not appear to be routinely beneficial in the diagnosis of urolithiasis in reptiles.[3] However, obstructive uroliths may cause biochemical changes indicative of postrenal obstruction.[1,3,4]

PREFERRED TREATMENT(S)

There are no medical dissolution recommendations for calculi in reptiles, and surgical intervention is recommended. Cystic calculi can be removed during cystotomy (Fig. 172.3), and recurrent cases can be managed with cystectomy.[6] Cloacal calculi can be removed through the cloaca with improved visualization when using cloacoscopy concurrently.[3,4]

A Weitlaner rectractor is being used to retract the coelomic membrane, while a curved Kelly hemostat is being used to break down the large cystolith to allow for easier removal. (Courtesy of Krista A. Keller.)

PROGNOSIS AND PREVENTION

The prolonged subclinical stage of cystic calculi has prompted many clinicians not to treat this condition. However, a retrospective study has indicated urolithiasis as a cause of death in 50% of chelonians necropsied with urolithiasis, indicating the need for veterinary intervention.[3] Because of the association of urate urolithiasis with chronic dehydration and overheating, species-specific husbandry recommendations remain the best preventative measure. All species should have access to water and both the high and the low temperatures of their preferred optimum temperature zones at all times.

Vomiting and Regurgitation

Richard S. Funk and Scott J. Stahl

DEFINITION AND CLINICAL SIGNIFICANCE

Vomiting, or emesis, is defined as a forceful ejection of food from the stomach and anterior intestines. Regurgitation involves the discharge of undigested food immediately, or within a few hours after eating, and is generally passive from the esophagus or pharynx. Both vomiting and regurgitation are clinical signs, not diseases.

CLINICAL PRESENTATION

These two clinical signs can be difficult to differentiate in reptiles. In mammals, testing the pH may help differentiate, with vomitus more acidic (usually pH <3). Often, the vomited or regurgitated material is found in the cage, but unfortunately the history is often incomplete, not allowing differentiation. If the environmental temperature(s) are too cool and food is not properly digested, the material vomited may appear relatively fresh, which adds to the challenge. Turtles and tortoises rarely vomit or regurgitate; consequently, these are serious clinical signs. A thorough history and complete physical examination are important in determining potential causes for vomiting or regurgitation. Behavioral changes, usually related to husbandry issues, are commonplace. For example, nervous snakes that are not provided a secure hiding box may vomit if disturbed or handled after eating a meal. Concurrent diarrhea associated with vomiting often indicates nonspecific gastrointestinal disorders and/or other nongastrointestinal disease. Reptiles with chronic vomiting are likely dehydrated and may have acid-base and electrolyte imbalances. In most reptiles, vomiting, not regurgitation, is occurring and etiologies for vomiting in reptiles are less clearly elucidated than in companion mammals. Consumption of too large a meal, maintenance of the reptile at temperatures not conducive to proper digestion, or the ingestion of partially autolyzed prey items may result in vomiting and diarrhea.

Infectious causes of vomiting include bacterial (including *Chlamydia*) and fungal infections; parasites such as cryptosporidiosis, ascariasis, cestodiasis, and amebiasis; and viral diseases such as adenoviruses and inclusion body disease (reptarenavirus) of boid snakes (see Chapters 30, 32, and 73). In snakes, cryptosporidiosis is a common cause of vomiting and often associated with a midbody (gastric) swelling.

Historically, snakes with cryptosporidiosis usually vomit 2 to 3 days after ingestion the associated gastric pathology inhibits proper digestion, and as the prey item putrefies. Iatrogenic vomiting may also occur after ingestion of oral medications or medicated food; certain specific drugs such as apomorphine, levamisole, xylazine, miticides, and organophosphates; and some species-specific related responses to certain drugs and even the route of administration used (e.g., parenteral enrofloxacin in red-footed tortoises, *Chelonoidis carbonaria*). Poisonings such as the ingestion of toads, resulting in *Bufo* toxicity, and organophosphate or other pesticide intoxication can cause vomiting (see Chapter 88). Inflammatory processes such as pancreatitis, peritonitis (coelomitis), or pyometra, which are commonly associated with gastrointestinal clinical signs in mammals, have not been consistently associated with vomiting in reptiles. Gastrointestinal foreign body (Fig. 173.1 A–C), obstructive neoplasm or granuloma, stricture, intussusception, or congenital defects/atresia may result in vomiting.

Several etiologies exist for regurgitation, with environmental and behavioral causes as described for vomiting being the most common. Other causes include esophageal, pharyngeal, or oral lesions such as stomatitis, esophagitis, neoplasia, esophageal laceration or perforation, strictures, granulomas, and foreign bodies. If regurgitation is chronic, dramatic weight loss and secondary aspiration pneumonia can occur.

DIAGNOSTIC CONFIRMATION

After a detailed history and thorough physical examination, indications for survey and contrast radiography and/or advanced imaging, including CT and MRI, may be recommended. Laboratory analysis and patient evaluation may include complete blood count and chemistry profile. Also, infectious disease–testing, including bacterial and fungal cultures, fecal parasite analysis, PCR testing and acid-fast stains for *Cryptosporidia* in snakes, and samples for virology, may need to be performed. Endoscopy of the esophagus and gastrointestinal system and/or exploratory surgery to obtain appropriate biopsies for histopathology may be required for a definitive diagnosis. For cryptosporidiosis in snakes, a gastric biopsy and histopathology may be required for a definitive diagnosis (see Chapters 73 and 165).

PREFERRED TREATMENT(S)

Correction of dehydration, acid-base imbalances, and mismanagement (such as handling, temperature, provision of shelters, quarantine, and hygiene) is important. Supportive care, including providing appropriate thermal requirements and fluid therapy followed by appropriate chemotherapeutics (e.g., antimicrobials, antiparasitics, gastrointestinal protectants) is critical in managing these cases. Use of antiemetic medications such as metoclopramide may be beneficial. For a review of therapy see Section 11.

Tube- or assist-feeding may be necessary once the underlying problems have been addressed (see Chapter 45).

VetBooks.ir

FIG 173.1 (A) An Argentine boa (*Boa constrictor occidentalis*) presented for vomiting and midbody swelling. Radiographs revealed a foreign body completely filling the stomach, and on inquiry the owner remembered feeding the snake a frozen thawed rat placed on a t-shirt in the cage, which was missing. (B) At surgery, a gastrotomy was performed, and the t-shirt was manipulated out of the stomach. (C) Snake recovering from anesthesia with t-shirt displayed postop. The snake was fed a small rodent meal 1 month later, vomiting resolved, and the snake made a full recovery. (Courtesy of Scott J. Stahl, Stahl Exotic Animal Veterinary Services.)

PROGNOSIS AND PREVENTION

Prognosis is dependent on the diagnosis. See Chapter 73 for more information on gastroenterology. If a diagnosis of cryptosporidiosis is confirmed in a snake with clinical signs, the prognosis is poor as no known curative treatment is available. Importantly, these snakes are potentially contagious to other snakes and should be removed from the collection. Vomiting and regurgitation are clinical signs and not specific diseases. If the cause can be identified and corrected, the resulting clinical signs can likely be resolved. Appropriate quarantine, husbandry, and nutrition, with routine health care, can be largely preventative.

Zoonoses and Public Health

Cathy A. Johnson-Delaney and Janos Gal

Most veterinary practitioners working with herpetological species are aware of common zoonoses; however, owners may not be aware of the risks posed by their pets. The veterinarian is often responsible for educating owners. Zoological collections, breeding facilities, wildlife professionals, and research facilities must also be aware of potential risks to their staff and the public. Physicians are often less familiar with reptile zoonoses and with veterinary technology, diagnostics, and treatments used to minimize the risks of zoonoses. The physician rarely seeks consultation with the patient's veterinarian about potential or confirmed problems. Client educational handouts that cover prevention of zoonotic disease from reptiles are helpful; however, veterinarians should be wary of giving advice on human health issues and should always direct an unwell client to their physician.

Humans that are particularly at risk for zoonoses include immunosuppressed or immunocompromised individuals: infants and children under the age of 5 years, the elderly, and those with chronic immunosuppressive disease or who are receiving immunosuppressive therapy.[1–6]

Reptiles have been documented to carry many potential pathogens that, under the right conditions, can cause infections in humans; however, the recovery of such an organism from the reptile does not mandate that the pathogen will be passed to the human and cause disease.[7] Many potential zoonotic pathogens have been isolated from reptiles and amphibians (Table 174.1). Evaluation of the risk potential includes identification of any possible pathogenic organisms, the nature and duration of contact the owner has with the reptile, sources of infection or reinfection by the reptile (i.e., food sources, sanitation measures, housing and husbandry practices), original source of the reptile (e.g., wild caught, domestically bred, exposure to other reptiles), and sources of infection to the reptile during transport and sale (e.g., shipping conditions, pet store housing).

Captive-bred reptiles may be infected with fewer pathogens if the breeders have been careful about screening their wild-caught breeding stock and are meticulous about sanitation. In reality, although some parasitic organisms have been eliminated from the captive-bred reptile, largely because of lack of appropriate intermediate hosts or other determinants in the life cycles, bacterial, fungal, and viral organisms are still found in abundance.[7,8] Bacterial pathogens can originate from contaminated food sources. Risk of transmission may be greater from a live food, such as a chick or a mouse, than from processed food.[7]

Reptiles should not be housed in the kitchen or other areas where food is prepared or eaten. The most important factor to decrease the chance of reptile zoonoses is to always thoroughly wash hands with soap after handling any animal, food/water utensils, or cage furniture (Table 174.2).[6] Young children should not handle reptiles unless under close supervision, and any oral contact with the reptile or cage furniture must be prevented. Protective gloves should be worn while cleaning the enclosure or utensils (see Chapter 18 for cleaning agents). Water and fecal materials should be drained into the toilet rather than dumped in the sink or bathtub. A splash-guard face shield is recommended to minimize inhalation of potential aerosols or waterborne pathogens coming in contact with mucous membranes during the cleaning process.[7,8] The reptile should have its own soak tub/container rather than the using the owner's sink or bathtub.[6] It is inappropriate to use a children's wading pool outdoors for housing turtles, given the difficulty of preventing children from gaining access (Fig. 174.1).

The risk of transmission can also be minimized by screening the reptile for pathogens as part of a regular preventive health maintenance program.[7] Many reptile veterinarians recommend regular health examinations for pet reptiles, which may include bacterial culturing, particularly for *Salmonella;* however, culture is not recommended because a negative result does not guarantee a reptile is free of *Salmonella* due to intermittent shedding. Owners must be educated that safeguards should always be taken, as any reptile may harbour potentially pathogenic organisms.

BACTERIA

Salmonella

The most recognized reptilian and amphibian zoonosis is salmonellosis.[9] More than 2400 serotypes exist. *Salmonella* is pathogenic to a variety of animals, and although some serotypes are host specific (e.g., *S. java* and *S. urbana* of turtles), all serotypes within *S. enterica* should be considered as potential pathogens for animals and humans.[10,11] *Salmonella* survives well in the environment contaminated by animal feces. There is evidence that amphibians (frogs and toads) in captivity have been associated with *Salmonella* outbreaks.[9]

History. The zoonotic significance of salmonellosis was first reported in 1963 when a 7-month-old child acquired the disease from a pet turtle, although the potential had been recognized since 1946 when *Salmonella* spp. were originally isolated from turtles. In 1968 in response to information about the association of reptile-associated salmonellosis (RAS) and pet turtles, the state of Washington issued a regulation requiring that turtles sold in the state be certified as *Salmonella*-free.[7,8] Because positive results showing that a turtle is free of *Salmonella* spp. is virtually impossible, in large part because of variability in excretion of the organism, this regulation effectively stopped the sale of pet turtles

TABLE 174.2 *Salmonella* and Reptiles: Veterinary Guidelines

Veterinarians who treat reptiles should be aware of the following information and recommendations concerning reptiles and *Salmonella* spp:

- *Salmonella* carriage appears to be highly prevalent in reptiles. Reptiles should be considered to be nonclinical carriers of *Salmonella*; the organism is intermittently or continuously shed in their feces and, if ingested by humans, may result in serious illness.
- Veterinarians treating reptiles play an important role in informing reptile-owning clients about salmonellosis and advising them on precautions for reducing the risk of acquiring *Salmonella* infection from reptiles.
- Because *Salmonella* may be shed intermittently in the feces of reptiles, it is not possible to determine whether any individual living reptile is free of *Salmonella*.
- Bacterial culture of fecal specimens from reptiles will not detect all carriers and is not recommended.

Abbreviated information included. Full text posted at http://arav.org, May 2016.

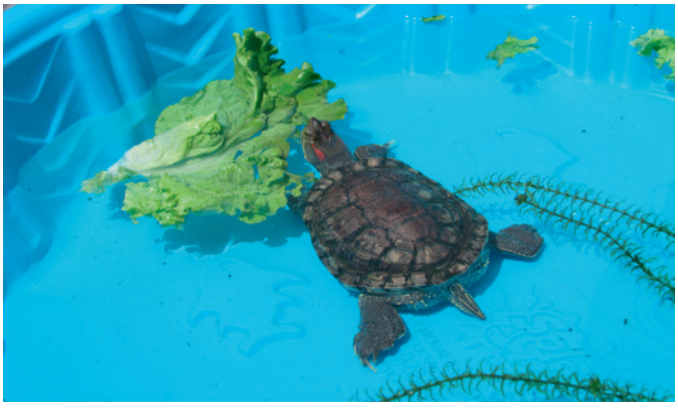

FIG 174.1 This red eared slider (*Trachemys scripta elegans*) is being housed in a children's-style pool, which should be exclusively used for the turtle, and children kept from playing in this pool. (Courtesy of Cathy A. Johnson-Delaney.)

in Washington. Subsequently, other state public health departments conducted detailed surveys of the incidence of turtle-associated salmonellosis.

Epidemiological studies at the time showed that 14% or approximately 280,000 of the estimated 2 million cases of salmonellosis in the United States seen yearly were turtle associated.[12,13] One survey suggested that at least 22% of cases required hospitalization, which denotes a serious health hazard. A great number of cases probably occur that go unreported, because signs may be nonspecific and self-limiting. RAS in children is most commonly due to contact with turtles (42% of cases in one study), although it is also reported in infants younger than 6 months of age via indirect contact with other species of reptiles that were housed indoors.[13]

In 1972 the Department of Health, Education, and Welfare, United States Food and Drug Administration (FDA), banned the importation of turtles and turtle eggs and interstate shipment of turtles not certified free of *Salmonella* spp. or *Arizona hinshawii* (now classified as *S. arizonae*) by the state of origin.[13,14] In June 1975 the FDA ruled it illegal in the United States to sell viable turtle eggs or live turtles with a carapace length less than 10.2 cm (4 inches), with exceptions made for educational or scientific institutions and marine turtles (families Dermochelidae and Chelonidae). Marine turtles had not been shown to be a reservoir of *Salmonella* spp. and are used to restock coastal waters through the United States conservation programs. Also exempt are turtles sold or held for sale and distribution, turtle eggs not used in connection with a business, and turtles and turtle eggs destined for export only. Carapace length (<4 inches [10.2 cm]) was used as a measure of the potential to transmit *Salmonella* based on the assumption that larger turtles were less likely to be purchased or handled by children under the age of 10 years, the age group most at risk. Any turtle smaller than that carapace size might fit into a child's mouth.[7,13]

After enactment, there was a marked decrease in turtle-associated salmonellosis; however, despite regulations, *Salmonella* colonization of pet turtles continues and cases of human infection from pet turtles and other reptiles continues, especially from lizards.[15–18]

Infection Dynamics. Although more than 2000 recognized serotypes (serovars) of *Salmonella* exist, close to 1000 different serotypes have been isolated from reptiles, many of which have been associated with zoonotic disease in humans.[19–21] All serotypes are considered potentially pathogenic for humans.[7] The variability in excretion of *Salmonella* from reptiles has contributed to the difficulties in isolating the organisms and identifying carriers.[3,22] In one study of RAS in Minnesota during 1996 to 2011, 3.5% of nontypoidal, sporadic salmonellosis cases had reptile exposure; 47% were from lizards, 20% from snakes, and 19% from turtles, whereas 14% reported multiple species of reptile exposure. The three most common serotypes were *typhimurium* (15%), *enteritidis* (7%), and subspecies IV serotypes (7%).[23] A multistate outbreak between 2009 to 2011 of *Salmonella enterica* serovar Typhimurium was traced to contact with water frogs or their habitat.[24] Turtles cultured negative with routine cloacal swabbing and water examination for periods up to 6 months have then later been found to actively excrete the organism. The latent phase of excretion may be interrupted by stress. The organism may be cultured from the feces or cloaca 1 day and not the next.[3,7,22]

Estimates of reptiles harboring *Salmonella* spp. have been reported to be as high as 83.6% to 93.7%, depending on the method of testing. *S.*

VetBooks.ir

enterica subsp. *arizonae* is more prevalent in snakes, estimated at 78.8% harboring the organism. One study utilized polymerase chain reaction (PCR) to demonstrate infection rates of *Salmonella* in hatchling green iguanas (*Iguana iguana*) of 67% to 94%.[25] A retrospective study done at the Bronx Zoo found that *Salmonella enterica* subsp. *enterica* was the most common in cultures (78/175 animals—45%). *Salmonella enterica* subsp. *diarizonae* was common (42/175 animals—24%). It was recovered almost exclusively from snakes, many of which had been clinically ill.[26]

In 1996 the Centers for Disease Control and Prevention (CDC) estimated that approximately 3% to 5% of the 2 to 6 million human salmonellosis cases per year were RAS.[2,3,25] Increasingly reported were human cases associated with iguanas.[2,3,6,22,27,28] In the United States between 2006 and 2014, fifteen multistate *Salmonella* outbreaks were recorded as associated with handling pet turtles.[17]

Although the rate of infection is quite high, most reptiles are asymptomatic. The relationship may be a saprophytic one.[7,29] Reptiles may shed the bacteria intermittently.[29] Isolation of the organism from the reptile does not really elucidate its role in causing disease in the reptile or potential for zoonotic transmission. Strains identified in causing disease in reptiles are listed in Table 166.1.

Reported Human Salmonellosis From Reptiles. Reptiles have been implicated as sources of human salmonellosis as well as livestock and poultry.[7,18] Another risk previously undocumented was from indirect contact from reptiles to children in a zoological exhibit. In one report, children were determined to have become infected from touching the wooden barrier that reptiles (Komodo dragons, *Varanus komodoensis*) had contaminated.[7,30]

Although the public is generally aware of the relationship between turtles and *Salmonella,* they are not as well informed about the connection with other reptiles, including lizards (green iguanas, bearded dragons [*Pogona vitticeps*], crested geckos [*Correlophus ciliatus*], water dragons [*Physignathus cocincinus*]), and snakes. Cases from iguanas were increasingly reported during the years iguanas were popular as pets.[1,3,5–7,11,16,25,28] *Salmonella* I4,[5],12:i:-, Cotham, and Kisarawe have been linked to contact with bearded dragons.[31,32] Pet crested geckos were linked to an outbreak of *Salmonella muenchen.*[33] Other lizards, including chameleons, have been linked with *Salmonella* infections in humans.[7] An infant contracted *Salmonella* serotype Nima carried by a boa that the father routinely handled. The clothing was implicated as the fomite.[11] Reports of RAS from pet turtles continues to dominate the literature and public health recommendations.

In 2008 there was a multistate outbreak of human *Salmonella enterica typhimurium*, with 135 cases in 25 states and the District of Columbia; 45% were in children 5 years of age and younger. In some cases there was contact only with the aquarium rather than the actual turtle. Some involved illegally sized turtles that had been purchased from a street vendor.[34]

The only regulations in effect to deal with the *Salmonella* problem in the United States are the regulations concerning small pet turtles. A client education brochure on *Salmonella* from pet turtles is available from http://www.cdc.gov/healthypets/resources/turtle_brochure.pdf. The Association of Reptilian and Amphibian Veterinarians (ARAV) also has information at http://www.arav.org (Table 174.2).

Attempts to treat reptiles with antibiotics to eliminate *Salmonella* spp. from their intestinal tract have not proven to be effective. Doing so increases the risk of emergence of antimicrobial-resistant *Salmonella* strains, which, if transmitted to humans, would complicate treatment. Attempts to raise "*Salmonella*-free" reptiles have been equally unsuccessful.

With this information in mind, the following guidelines have been developed by the ARAV, in cooperation with the Centers for Disease Control and Prevention (CDC), to help disseminate information to veterinarians and to the general public on how to minimize risks of exposure to *Salmonella* spp. and to help prevent development of reptile-associated salmonellosis in humans.

1. Veterinarians who treat reptiles should educate their clients who own reptiles about *Salmonella* spp. and provide information on the recommended precautions for reducing the risk of transmission of *Salmonella* spp. from reptiles to humans.
2. All veterinarians, staff, and clients who handle reptiles should follow recommended precautions for reducing the risk of transmitting *Salmonella* spp. from reptiles to humans.
3. All reptiles should be presumed to be carrying *Salmonella* spp. in their intestinal tract and to be continuously or intermittently shedding it in their feces. Bacterial culture of fecal specimens from reptiles to determine *Salmonella* infection status is discouraged. If veterinarians are called upon to assist health officials in determining the cause of salmonellosis in a person, bacterial culture of combined fecal and cloacal specimens from reptiles with which that person has had direct or indirect contact are recommended.
4. It is not recommended to treat healthy reptiles with antimicrobial agents with the intention of eliminating *Salmonella* spp. from the intestinal tract. Clients who request treatment of healthy reptiles for *Salmonella* spp. should be discouraged from such treatment and cautioned about the possibility of causing the emergence of antimicrobial-resistant *Salmonella* strains that might pose a greater health risk to humans.

This information was developed by the ARAV in collaboration with the CDC and is intended for information purposes only; please seek advice from your physician and your reptile's veterinarian if questions or problems occur.

Salmonella Bacteria and Reptiles: Information for Owners. This section was adapted from http://arav.org, May 2016.

Most, if not all, reptiles carry *Salmonella* bacteria in their intestinal tract and intermittently or continuously shed these bacteria in their feces. *Salmonella* bacteria usually do not cause any illness in reptiles but can cause serious illness in people.

Salmonella bacteria are easily spread from reptiles to humans. Humans may become infected when they place their hands into their mouths after touching an object, including a food item, that has been in contact with the stool of reptiles. For example, infants have become infected after drinking from bottles of infant formula that became contaminated during preparation. Individuals who prepared the formula had not washed their hands after touching a reptile, or reptiles were allowed to walk on the kitchen counters. For *Salmonella* bacteria to spread from reptiles to humans, the bacteria must be ingested. Therefore simply touching or holding a reptile will not result in the spread of the bacteria unless something contaminated with reptile feces or the reptile itself is placed in the mouth.

Most *Salmonella* infections in humans result in a mild, self-limiting illness characterized by diarrhea, fever, and abdominal cramps. However, the infection can spread to the bloodstream, bone marrow, or nervous system, leading to severe, and sometimes fatal, illness. Such severe infections are more likely to occur in infants and in individuals whose immune system is compromised (e.g., bone marrow transplant recipients, persons with diabetes mellitus, persons infected with the human immunodeficiency virus, and chemotherapy patients).

Unfortunately, *Salmonella* bacteria cannot be eliminated from the intestinal tract of reptiles. Administration of antibiotics to eliminate these bacteria has been unsuccessful and may result in the emergence of *Salmonella* bacteria that are resistant to antibiotics.

Attempts to raise or identify reptiles that do not carry *Salmonella* bacteria have also been unsuccessful; therefore bacterial culture of stool

VetBooks.ir

samples in an attempt to identify reptiles that are not carrying *Salmonella* bacteria is not recommended.

Fortunately, the spread of *Salmonella* bacteria from reptiles to humans can be easily prevented by using the following routine precautions:

- Always wash your hands with hot, soapy water after handling reptiles, reptile cages and equipment, and the stool of reptiles.
- Do not allow reptiles to have access to the kitchen, dining room, or any other area in which food is prepared. Also, do not allow reptiles to have access to bathroom sinks and tubs or to any area where infants are bathed. Consider keeping your reptiles caged or limiting the parts of the house where reptiles are allowed to roam free. Always wash your hands after coming into contact with any area where reptiles are allowed or roam free.
- Do not eat, drink, or smoke while handling reptiles, reptile cages, or reptile equipment. Do not kiss reptiles or share food or drink with them.
- Do not use the kitchen sink, kitchen counters, bathroom sinks, or bathtubs to bathe reptiles or to wash reptile cages, dishes, or aquariums. Reptile owners may wish to purchase a plastic basin or tub in which to bathe or swim their reptiles. Waste water and fecal material should be disposed of in the toilet instead of the bathtub or household sink.

The CDC recommends that children less than 5 years of age avoid contact with reptiles and that households with children less than 1 year of age not own reptiles. The ARAV encourages reptile owners with young children to discuss steps to minimize risks associated with owning reptiles with their reptile's veterinarian and their physician. Children should be supervised when they are handling reptiles to ensure that they do not place their hands, or any objects that a reptile has contacted, in their mouths. Reptiles should not be kept in child-care centers.

Aeromonas

Aeromonas spp. have been associated with diseases in fish, amphibians, and reptiles. They are also opportunistic pathogens and have been frequently cultured from clinically healthy reptiles.[35] In one survey of red-eared sliders purchased from 27 different suppliers, *Aeromonas* spp. were isolated from 63%. One survey cultured the oral cavity of 60 pet ball pythons (*Python regius*), and a wide range of gram-negative bacteria was cultured, including *Aeromonas hydrophila*, *Pseudomonas* spp., *Morganella morganii*, *Acinetobacter calcoaceticus*, *Salmonella* spp., *Staphylococcus* spp., and various anaerobic Clostridium species.[35]

Potential infection to humans may occur from contact with the water and open wounds or injuries or from bites or scratches inflicted by reptiles living in aquatic environments.

Plesiomonas

Plesiomonas shigelloides, formerly *Aeromonas shigelloides*, isolated from a boa constrictor with a progressive ulcerative stomatitis was reported to have caused acute gastroenteritis in a healthy young man. This organism may be considered part of the normal commensal flora.[36]

Campylobacter

Campylobacter spp. (*C. jejuni*, *C. fetus*, etc.) are enteric bacteria found in reptiles and mammals. *Campylobacter fetus* has also been isolated from feces of a healthy western hognose snake (*Heterodon nasicus*) and an ill blotched blue-tongue lizard (*Tiliqua nigrolutea*).[37] In one survey of 179 reptiles (human-raised, pet shop, and wild), *C. fetus* was identified in 9.7% in turtles, 1.7% in lizards, and 5.0% in snakes. Only one strain (ST-43) isolated from a red-footed tortoise (*Chelonoidis carbonaria*) was closely related to mammalian strains.[38] In 2004, an isolate from a human with exposure to reptiles was classified as *C. fetus* subsp. *testudinum* subsp. *nov*. Infected humans had a history of eating Asian food thought to be made from turtles or other reptiles or experienced direct exposure to live reptiles.[37] Pet reptiles should be considered a potential reservoir of *Campylobacter* spp. with zoonotic potential.[39,40]

Other Enteric Bacteria

Many other species of potentially pathogenic bacteria can be isolated from both clinically healthy and diseased reptiles. *Citrobacter* spp., *Enterobacter* spp., *Klebsiella* spp., *Proteus* spp., and *Serratia* spp. were isolated in one study of bacterial flora in red-eared sliders.[41] Clinically asymptomatic lizards and snakes are also known to carry *Klebsiella* spp., *Proteus* spp., and a variety of gram-negative enteric bacteria, which may be transmitted by direct contact.

Yersinia enterocolitica can cause a variety of illnesses in humans, including severe gastroenteritis with abdominal pain that mimics appendicitis. *Y. enterocolitica* and the closely related *Y. intermedia* have been isolated from a number of wildlife species, including snapping turtles (*Chelydra serpentina*).[42] A survey was done of wild European pond turtles (*Emys orbicularis*). Thirty-six bacterial species were isolated, several of which were considered potential zoonotic organisms, including *Salmonella enterica* serovars *newport, daytona, braenderup*; *Listeria monocytogenes*; *Yersinia enterocolitica*; *Yersinia ruckeri*; *Klebsiella pneumoniae*; *Vibrio fluvialis*; and *Serratia marcescens.* The study concluded that the small number of potential human pathogens isolated indicated that the European pond turtle was of relatively minor importance as a threat to public health.[43]

Pseudomonas spp. gram-negative rods have been cultured from both clinically healthy and diseased reptiles.[35] *Pseudomonas* spp. are common bacteria in oral lesions in snakes.[35] Potentially, humans can contract infection through direct contact with the organism after scratches or bite wounds, inhalation, or ingestion.

Clostridium

Clostridium butyricum producing botulinum type E neurotoxin (BoNT/E) caused disease in two infants. The agent was isolated from water that housed yellow-bellied turtles (*Trachemys scripta scripta*). The turtles were housed in the first infant's home. The second infant was infected after a person had fed the turtle before holding and feeding the infant.[44]

Mycobacterium

Several species of Mycobacterium known to cause infection in humans have been isolated from reptiles, including *M. marinum*, *M. avium*, and *M. tuberculosis.* The majority of *Mycobacterium* spp. isolated from reptiles are classified as atypical forms (e.g., *M. chelonae*).[45] Many of these belong to the Runyon Group IV, which are considered resistant to antibiotics.[45] *M. marinum* has been implicated in cutaneous and subcutaneous nodular disease in humans ("fisherman's finger," swimming pool granuloma).[45] Direct contact with the organism through scratches in the skin, during handling of the animal, or while cleaning its habitat resulted in the human infection.[45] Crocodilians may be used for leather and meat and, if infected, are a potential threat to slaughter staff and tanners.[45] Potential routes of transmission of *Mycobacterium* spp. organisms to humans from infected reptiles include direct contact through defects, scratches, or bites in the skin or with inhalation and contact with oral or respiratory mucosa. The veterinarian, technicians, and staff who handle reptiles with chronic, purulent, or granulomatous lesions should protect themselves by wearing appropriate gloves, mask, face/eye shield (particularly when cleaning cages and tanks), and other garments. Treatment of infected reptiles is not recommended because of the zoonotic potential. The owner should be instructed in proper methods of sanitizing the reptile's environment to minimize exposure and eliminate the organisms.

Coxiella burnetii

In 1978 a cluster of human cases of Q fever caused by the rickettsia *Coxiella burnetii* was diagnosed in employees of an exotic bird and reptile importing company in New York state. These employees had been involved in unpacking and deticking a shipment of ball pythons imported from Ghana. Speculation was that the employees had been infected by inhaling aerosolized particles containing *C. burnetii* during the handling of the pythons or ticks or excreta of the ticks or pythons.[46] It has been identified in snakes, lizards, and turtles during serological surveillance of wildlife, and reptiles may serve as reservoir hosts for the transmission of *C. burnetii* by infected ticks to mammals.[47]

Chlamydia

A study of zoo animals in Japan found that *Chlamydia pneumoniae* DNA was found in 8.1% of reptiles, representing a potential public health risk, as the DNA was close to what had been found in human patients. No human infections directly associated with these reptiles were reported.[7,48]

FUNGI

Zygomycosis, also known as phycomycosis, mucormycosis, or entomophthoromycosis, refers to a group of diseases in humans caused by several genera and species of fungi belonging to the class Zygomycetes, orders Entomophthorales and Mucorales. Zygomycetes are ubiquitous saprophytes that produce a large number of spores. Many genera have been found in reptiles that have zoonotic potential. *Entomophthorales* contains members of *Basidiobolus ranarum* (*B. haptosporus*), which, found in anurans, has been documented to cause a granulomatous disease in humans primarily in the subcutaneous tissues.[49,50] *Metarhizium anisopliae* var. *anisopliae* has been found in reptiles. Infections from this fungus in humans are rare and described in an immunocompromised host.[51] *Beauveria bassiana* has caused a fatal granulomatous pulmonary infection in an American alligator and a red-eared slider. Infection of this organism in humans is rarely described.[51] *Purpureocillium lilacinum* has been associated with a number of reptile species. It was the cause of skin lesions in juvenile Chinese soft-shelled turtles (*Apalone sinens*) being raised at large-scale farms for human food and should be considered an important opportunistic pathogen in humans.[51]

Many different mycotic agents have been isolated from diseased reptiles that could also cause infection in humans, including *Aspergillus* spp., *Candida* spp., *Trichosporon* spp., and *Trichophyton* spp. Zoonotic transmission of these fungal agents, although possible, has not appeared in the literature.

VIRUSES

Reptiles may act as reservoir hosts to Western equine encephalitis (WEE; genus: Alphavirus; family: Togaviridae), which causes disease in humans and horses. Infection has been detected in reptile serological surveys, although it does not appear to cause disease. *Culex tarsalis* acts as the vector and can transmit the virus between reptiles. It is thought that reptiles function as reservoir hosts due to their low metabolic rate and reduced immune response during the winter[52] (Fig. 174.2).

Reptiles should not be housed outdoors during an epizootic outbreak in horses in an area. Eastern equine encephalitis virus (EEEV) is also considered zoonotic and may cause fatal encephalitis in humans.[53] In Europe, three species of mosquitoes have been identified that can transmit the virus. Sources for the introduction of the virus have been linked to the exotic pet trade, including reptiles.[53] In the United States, evidence is supporting the role of snakes in the transmission cycle, particularly as overwintering hosts.[54,55]

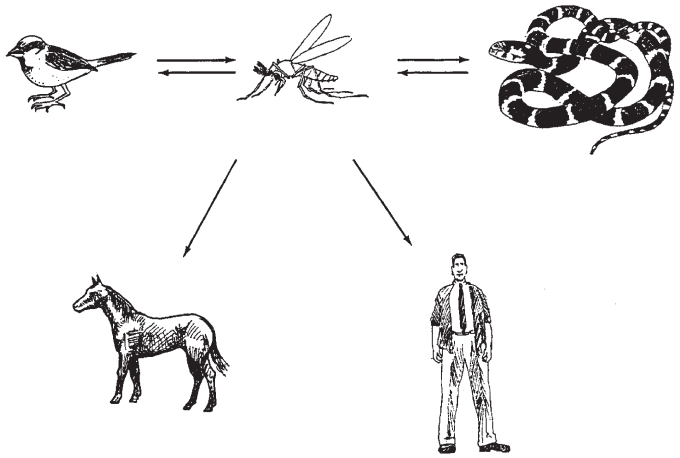

FIG 174.2 Life cycle of western equine encephalitis.

West Nile virus (WNV) is a mosquito-borne flavivirus that is transmitted by various species of *Culex mosquitoes*. WNV is known to have zoonotic potential as a result of infectivity in a wide variety of mammals and birds. Although flaviviruses and arboviruses have been reported to affect ectotherms and in some cases serve as reservoirs, reptiles and amphibians were not initially considered a primary species at risk.[56] The virus emerged in North America in 1999 when it infected and caused deaths in humans, horses, and birds. By 2001, WNV had spread into the southeastern United States and was considered an epizootic, as alligators (*A. mississipiensis*) and a captive crocodile monitor (*Varanus salvadori*) developed neurological signs.[57] The disease had previously been reported in farmed Nile crocodiles (*Crocodylus niloticus*) in Israel.[52,57] WNV has caused substantial losses in farmed American alligators. Eleven different mosquito species can carry the virus. Mosquitoes were probably the most important component of transmission of WNV at alligator farms.[58] WNV has now spread across the western hemisphere.[59] The potential role of reptiles and amphibians in the life cycle and epidemiology of WNV is still not conclusive.[57] If wild and captive species are susceptible, then the range of WNV and zoonotic potential will increase, and captive nonnative herpetological species can serve as reservoirs for the virus.

PROTOZOA

Despite the high numbers of protozoal organisms found in reptiles, most are ectotherm specific. Many varieties are not associated with known disease in the reptile, and their significance as zoonotic pathogens is also unknown. Many may be opportunistic pathogens of the reptile and opportunistic zoonotic pathogens to susceptible humans. Free-living amoebae may also be found in reptile feces. These include *Acanthamoeba*, *Naegleria*, Hartmanella, *Vahlkampfia*, and *Echinamoeba* sp. There is a potential zoonotic risk.

Cryptospordium

Cryptosporidium is a coccidian protozoan in the family Cryptosporidiidae, suborder Eimeriina. The parasite is not species specific and can easily be transmitted. It has been isolated in many different hosts, including mammals, birds, and reptiles. One study in Italy sampled 120 captive snakes, of which 35% were found to be shedding Cryptosporidium oocysts. Some of the species were considered to have zoonotic potential, although a number were specific for rodents and resulted from the ingestion of the infected prey.[60] The authors concluded that there may be possible public health implications. Another study looked at isolates from captive European tortoises (*Testudo graeca*, *T. hermanni*, and

T.marginata) in Italy.[61] The zoonotic *Cryptosporidium pestis* (*Cryptosporidium parvum* "bovine genotype") was identified, and the conclusion of the study was that there may be a risk to humans.[61] There have been no documented cases of human cryptosporidiosis from reptile sources.

PENTASTOMIDA

The pentastomes are currently classified in a separate phylum, Pentastomida. Infection by pentastomids may be referred to as pentastomiasis, linguatuliasis or linguatulosis, porocephalosis, or porocephaliasis.[62]

Nine genera have been identified in snakes, three in lizards, four in crocodiles, and two in turtles. *Armillifer* spp. are the most common genera identified from pythonids and viperids, *Kiricephalus* spp. from colubrids, and *Porocephalus* spp. from boids and crotalids. A variety of herbivorous vertebrates may serve as intermediate hosts, including rodents and artiodactylids. Carnivores, nonhuman primates, and humans may serve as incidental hosts[62,63] (Fig. 174.3). Eggs migrate up the respiratory tract, are swallowed, and passed in feces. The life cycle of the pentastomid is considered an oddity in that the intermediate host (rodent, mammal) is higher in the phylogenic scheme than the definitive host (snake, reptile), an uncommon occurrence among parasites.[62,63]

Humans, as aberrant hosts, contract the infection by consuming water or foods contaminated with eggs eliminated in the saliva or feces of snakes by consuming raw or undercooked snake meat or by handling infected reptiles and then placing contaminated hands in the mouth. Other intermediate hosts are infected through ingestion of contaminated water, plants, or the snakes themselves.[64] This may be considered a neglected tropical disease that may become more widespread as tropical species of reptiles are exported for the pet trade.[65] A case has been published of fatal pentastomiasis from *Armillifer armillatus*.[66] The fact that humans can serve as incidental hosts for reptilian pentastomes should alert veterinarians to recognize the zoonotic potential of these parasites. Veterinarians need to educate pet owners about the zoonotic potential of pentastomiasis. Newly acquired wild-caught reptiles should be examined, and, ideally, at least two successive fecal specimens from the reptile should be examined to reduce the possibility of false-negative results. The need for prompt removal of feces from the reptile's habitat should be stressed. The owner should be instructed on the proper disposal of snake feces (i.e., flush down the toilet versus the family garbage can) and to wear gloves while doing so. Reptile food sources (such as live rodents) should not be allowed to come in contact with the reptile's feces.

FIG 174.3 Pentastomid parasite from the lung tissue of a macaque monkey.

HELMINTHS

Reptiles act as the second intermediate hosts for cestodes in the genera *Spirometra* and *Diphyllobothrium*. *Spirometra mansoni*, *S. mansonoides*, *S. erinaceieuropaei* (*D. erinacei*), *S. theileri*, and *S. proliferum* have been associated with sparganosis in humans (i.e., infection with the second-stage larvae called the sparganum or plerocercoid) (Fig. 174.4). Man is generally infected through ingestion of raw or undercooked, infected amphibian, reptile, bird, or mammal meat or through direct contact with infected amphibian or reptile meat used as a poultice for anti-phlogistic effects in some Southeast Asian cultures. Use of the poultice has been linked to an ocular form of sparganosis, whereas cerebral

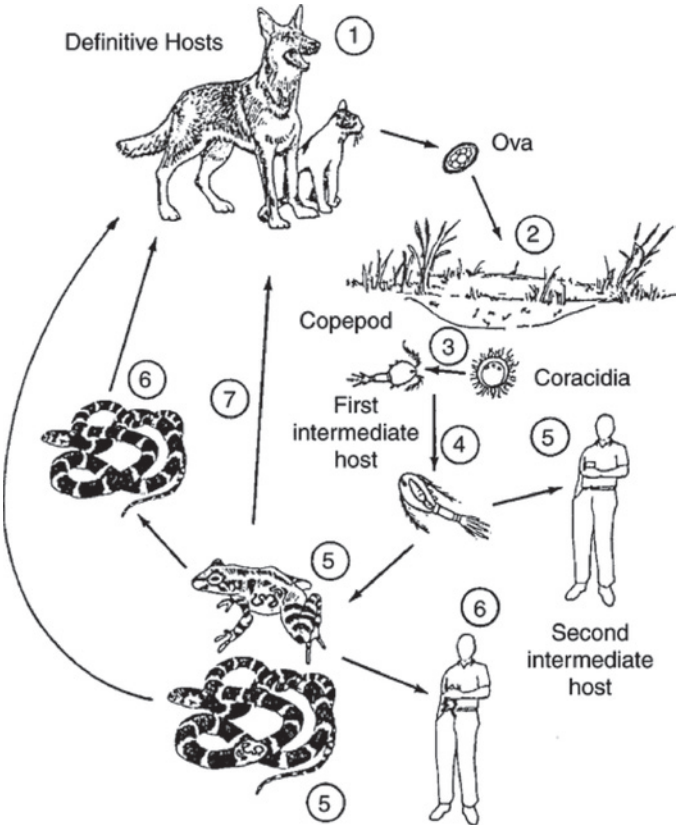

FIG 174.4 Transmission cycle in sparganosis. (1) Definitive host (canids, felids). Pleroceroid attaches to intestinal mucosa, matures in 10 to 30 days, produces eggs. (2) Eggs passed in feces, end up in water containing copepods of the genus *Cyclops*. In the water, eggs become free ciliated embryos called coracidia. (3) Coracidia ingested by first intermediate host (*Cyclops*). (4) Develop into first-stage larvae, "procercoid," in the tissues of *Cyclops*. (5) Ingestion of procercoids in infected *Cyclops* via water by second intermediate host (vertebrates: reptiles, amphibians, birds, small mammals [rodents, insectivores], swine, nonhuman primates, humans). (6) Develop into a "plerocercoid" or "sparganum" in the tissues of the vertebrate host. Plerocercoids in an ingested, infected vertebrate can encyst in new vertebrate host. Humans can be infected with ingestion of either a procercoid or a plerocercoid. (7) Infected vertebrate host with plerocercoids ingested.

VetBooks.ir

sparganosis has also been reported.[62] Humans are an incidental host and usually do not play a role in the life cycle of the parasite. Because parasitic life cycles require certain environmental conditions, and most captive reptiles are not intended for human consumption, sparganosis poses a minimal zoonotic risk.

ARTHROPODS

Arthropods that affect reptiles do not pose a direct zoonotic threat. Instead, their importance may be as vectors for viral or bacterial diseases, with the reptile serving as a reservoir or amplification host. The arthropods may cross species, biting reptiles, birds, and mammals, including humans. *Aedes* and *Culex* genera of mosquitoes may feed on reptiles, serving as possible reservoirs for Western equine encephalitis virus, Eastern equine encephalitis, and West Nile virus.[67]

Ornithodoros turicata, also known as the relapsing fever tick, is native to the United States and Mexico and can occasionally be found on reptiles. Heavy infestations have been found on box turtles (*Terrapene* spp.), gopher tortoises (*Gopherus polyphemus*), and rattlesnakes (*Crotalus* spp.). It transmits relapsing fever (also known as tick-borne relapsing fever, borreliosis, or spirochetosis) to humans. The tick may also be a vector of *Leptospira pomona.* All stages readily attack humans.[67]

Immature stages of *Haemaphysalis punctata* have been found on reptiles in Europe, northwestern Africa, and southwestern Asia. This tick may transmit the agent of Siberian (or North Asian) tick typhus (*Rickettsia siberica*). Immature stages of another tick, *H. concinna*, have been found on various reptiles in Europe and northern Asia. This tick transmits the agents of Russian spring-summer encephalitis (a flavivirus) and Siberian tick typhus.[67]

The immature stages of *Ixodes pacificus* are found on garter snakes (*Thamnophis* spp.) and spiny lizards (*Sceloporus* spp.) in the Pacific coastal region of North America. The bite itself causes irritation and trauma in humans and has been implicated in the transmission of tularemia (*Francisella tularensis*). It also may transmit Lyme disease (*Borrelia burgdorferi*). In the United States, *Anaplasma phagocytophilum* was isolated from multiple species of snakes and lizards. This organism causes the potentially fatal tick-borne disease human granulocytic anaplasmosis.[68] In central Europe, *Ixodes ricinus* may occur on European green lizards (*Lacerta viridis*).[69] It has been found to carry Anaplasma, Borrelia, and Rickettsia.[68] However, this tick's bite also causes severe irritation and paralysis in man and may transmit central European tick-borne encephalitis, Lyme disease, and agents of Boutonneuse fever (*R. conorii*).[67]

A study was conducted to look at ticks and the diseases they carried on reptiles and amphibians being imported into Japan for the pet trade.[68] Two species of ticks were identified that are known to bite humans: *Amblyomma dissimile* and *Hyalomma aegyptium.* Four human pathogens were found in ticks on reptiles imported from Zambia*: Rickettsia africae*, *Rickettsia raoultii*, *Ehrlichia chaffeensis*, and *Candidatus Neoehrlichia mikurensis. E. chaffeensis* causes human monocytic ehrlichiosis, which is an acute febrile systemic illness. *Candidatus Neoehrlichia mikurensis* causes febrile disease in humans.[68] Reptiles and amphibians imported into Japan for the pet trade are not quarantined, so tick-infested animals may go directly into the pet trade.

A study in the Republic of Korea looked at the incidence of reptile-associated ticks and their infection with the severe fever with thrombocytopenia syndrome (SFTS) virus. The study looked at 132 reptiles: 2 species of lizard (49), 1 species of skink (15), and 8 species of snakes (68). Eighty-four ticks were collected in two genera (*Ixodes* and *Amblyomma*). Analysis of the SFTS virus of the ticks collected from two lizards and one snake demonstrated a close relationship with SFTS virus strains found in humans and ticks in Korea, China, and Japan. The study concluded that lizards and snakes may be potential hosts of SFTS virus.[70]

Larvae of trombiculid mites have been found on reptiles caught in the wild or maintained in outdoor enclosures in endemic areas. The most common species in North America is *Eutrombicula alfreddugesi* (also called *Trombicula irritans*), the common chigger. It has been found throughout the western hemisphere on box turtles, various snakes including racers (*Masticophis* spp.), hog-nosed snakes (*Heterodon* spp.), king snakes (*Lampropeltis* spp.), garter snakes (*Thamnophis* spp.), and various lizards. *E. splendens*, common in the southeastern United States, has been found on snakes and lizards. In Europe, *Neotrombicula autumnalis*, the common harvest mite, has been found on lizards and snakes. Only the larvae of these genera are parasitic. The adults are free-living. Control on the reptile includes topical insecticides and cleaning the environment. All of these mites have been reported to cause dermatitis in humans.[67,71,72]

Ophionyssus natricis, a dermanyssid mite of snakes and occasionally lizards, may bite humans. The mite is worldwide in distribution, and heavy infestations can lead to severe anemia, anorexia, lethargy, and death of the host snake. A documented case in humans involved an infested pet python. The family had pruritic papular lesions that had black central dots from skin puncture and bleeding. Some of the lesions appeared vesicular or bullous. They had noticed what they called "small insects" fixed on their skin and large numbers of the same on the snake and in the chair the snake usually occupied. The snake, its cage, and the chair were liberally dusted with a pyrethrum powder. No further bites were noted.[71]

Working With Free-Ranging Amphibians and Reptiles

Terry M. Norton, Kimberly M. Andrews, and Lora L. Smith

Capturing free-ranging animals for identification purposes, as well as for global positioning systems (GPS) and radio/satellite telemetry applications, is common in amphibian and reptile research and conservation efforts. In the past, these efforts have been predominantly performed by research biologists with minimal veterinary input. Institutional animal care and use committees (IACUC) are now required by most research institutions and for publication of research in the peer-reviewed literature. Veterinarians are being asked more frequently for their input, advice, and expertise in areas of infectious disease prevention, aseptic techniques, pain management, anesthesia, and surgery, all of which are critical in the topics discussed in this chapter. The techniques described here are not all-inclusive but are either commonly used by the authors or represent important techniques used by the scientific community.

AMPHIBIAN AND REPTILE CAPTURE TECHNIQUES

A variety of techniques are available for capturing amphibians and reptiles. Passive capture methods generally do not restrict an animal's movements; thus, they are less likely to result in stress or injury to the animal. Active sampling methods require careful monitoring to prevent morbidity or mortality but can yield valuable data on population size, individual growth rates, health, reproductive state, and survival. A general overview of commonly used passive and active capture methods for amphibians and reptiles is presented in Table 175.1, along with selected references that provide more detail on specific methodologies. Additional information on these methods can be found in Norton et al.[1]

HANDLING

Recommended Precautions to Prevent Disease and Other Health Problems

Infectious diseases can be transmitted within and between amphibian and reptile populations when handled for various procedures by field workers. Some examples of significant infectious and parasitic diseases that may be transmitted when appropriate precautions are not taken include chytrid fungus (*Batrachochytrium dendrobatidis*), snake fungal disease (*Ophidiomyces ophiodiicola*), iridoviruses, *Cryptosporidium serpentis*, paramyxovirus, *Entamoeba invadens*, *Mycoplasma agassizii*, and herpesviruses (see Chapters 29 through 32 for details). The following are some general guidelines for handling and manipulating herpetofauna in the field:

- Avoid using insecticides before handling amphibians and reptiles.
- Wash hands with disinfectant hand wash or wear separate disposable examination gloves after handling each animal.
- Clean any handling equipment with an appropriate disinfectant between each animal.
- Use a separate clean, well-ventilated container or bag for each animal if temporary containment or transport is needed.
- Avoid high or low temperatures during transport of the animal.
- Do not allow contact between animals from different populations when handling or transporting them.
- If wild amphibians or reptiles are held in captivity for various procedures such as surgical placement of radio transmitters, each animal should be isolated in a well-ventilated container that can be easily disinfected. Wood enclosures should be avoided because they cannot be disinfected. Animals should be maintained at their preferred optimal temperature zone with a thermogradient.

MARKING

Recommended Precautions to Prevent Disease and Other Health Problems

Field researchers working with amphibians and reptiles should have some basic aseptic technique and disease prevention protocols established for the field site and species under investigation that are practical but effective. The ultimate goal should be preventing individual animal infections and spreading of disease from one individual to another within a population and, most importantly, preventing population-level disease outbreaks. A risk assessment should be conducted for each project that evaluates the appropriate level of precautions that should be taken for that specific situation.

Amphibians. Because of the permeable nature of the amphibian skin, they are very sensitive to human handling and many toxins at levels that are well tolerated without ill effects by reptiles, birds, and mammals. Soaps, lotions, and natural oils can all irritate or damage the skin. Researchers should wear powderless vinyl or plastic gloves when handling amphibians. Many of the common antiseptics and disinfectants are toxic to amphibians (e.g., surgical scrubs with soaps or detergents, iodine products, chlorhexidine, quaternary ammonium compounds, chlorine, alcohol, and ammonia). For these reasons, surgical, injection, and tag sites should be wiped clean of debris and secretions with sterile saline before the procedure (see Chapter 89).[2]

Reptiles. Depending on the procedure, the area should be cleaned at least once with a surgical scrub (betadine or chlorhexidine), followed by 70% isopropyl alcohol. For invasive surgical procedures, such as internal placement of radio transmitters, surgical preparation that repeats this process four times is recommended. Examination gloves should be worn when minor invasive procedures are performed on reptiles and should be changed between animals. Where feasible, hand washing or an alcohol-based hand disinfectant should be used between animals. Ideally, instruments such as tagging applicators, passive integrated transponder (PIT) tag injectors, and other instruments should be gas-sterilized ahead of time or used with high-level disinfection (2% accelerated hydrogen peroxide, Revital-Ox High Level Disinfectant,

VetBooks.ir

TABLE 175.1 Amphibian and Reptile Capture Techniques

Sampling Method	Description	Target Organisms
Passive		
Cover objects	Untreated lumber, tin roofing, or plastic sheets placed flush with ground offer artificial cover.[84–86]	Terrestrial salamanders, snakes
Leaf litter bags	Bags made from plastic bird netting stocked with leaf litter from a stream offers substrate for aquatic salamander larvae.[87,88]	Salamanders
PVC pipe refugia	Polyvinylchloride pipes (1″–2.5″ diameter) or bamboo placed in the ground or hung vertically on trees offer artificial habitat.[89–93]	Tree frogs
Basking traps	Basking traps consist of either a wire basket anchored to an existing basking log or a floating artificial basking platform to attract turtles. Traps can be checked when the sun is high, and turtles would be expected to be basking.[94,95]	Freshwater turtles
Active		
Netting	Dip nets are effective for capturing amphibian larvae in shallow water. Seine and trammel nets can be used to capture larger amphibians and reptiles in waist-deep water.[96] Foraging sea turtles can be collected by independent fishery trawlers. Twenty-meter, four-seam nets with 20 cm mesh, without turtle excluder devices, are used by one research vessel to capture sea turtles.[97]	Larval amphibians, freshwater turtles, diamond-backed terrapins, sea turtles
Hoop traps	In streams, baited hoop traps are set with the opening pointed downstream, which allows the scent of bait to disperse downstream.[98–100] In ponds or lakes, hoop traps can be set either perpendicular or parallel to the bank, and the top of the trap should be above water to allow turtles to breathe. A fyke net extended from the open end of the trap can guide turtles into the trap.[98]	Freshwater turtles
Funnel traps	These traps come in several forms but rely on inverted funnels to direct animals into the trap. Traps may be handmade from aluminum window screen, plastic trashcans, or be commercially available, e.g., crayfish or minnow traps.[101,102] Funnel traps should be set partially submerged to safely capture air-breathing aquatic organisms.	Larval anurans, aquatic salamanders, and snakes
Pitfall traps	Pitfall (bucket) traps of different sizes can be placed flush with the ground along drift fences (see below) or at the entrance of tortoise burrows.[103] To capture tortoises, the bucket opening must be disguised with newspaper and loose sand. Pitfall traps should be shaded and checked frequently to prevent the animal from overheating.	Small amphibians and reptiles, tortoises
Drift fences	A drift fence is a barrier that directs animals toward traps and may be made from aluminum flashing, hardware cloth, or siltation fence.[104,105] Pitfall, wooden box traps,[106,107] or funnel traps[102] set at the ends or along the fence are effective for small vertebrates. Traps should be well shaded and contain a water source or wetted sponge. Pitfall traps should have drainage holes for rainfall to prevent animals from drowning.	Terrestrial and semiterrestrial amphibians and reptiles
Rod and reel, noose	A rod and reel (treble hook and fishing line) can be used to snag the animal on the osteoderms or bony scutes of the dorsum.[108] A catch pole and noose can be used for further restraint. Spotlights can be used at night to detect eyeshine for nocturnal sampling.	Crocodilians
Cage traps	One-door live cage traps (Havahart; Woodstream Corp., Lititz, PA) can be placed at the entrance of tortoise burrows.[109] The trap should be shaded and checked 2–3 times per day to prevent overheating and stress. Larger versions of these (wire or mesh) can be used to capture crocodilians.[108]	Tortoises, crocodilians
Hand capture	Many amphibians and reptiles can be captured by hand or by using snake sticks/tongs in the instance of venomous snakes. Scuba, snorkeling, and jump/catch/hand grab techniques have been used for freshwater turtles, diamond-backed terrapins, and sea turtles. Nesting female sea turtles can be sighted during nightly beach patrols and processed when she enters a trancelike state without disrupting normal nesting behavior.	Frogs, salamanders, snakes, turtles

See Norton et al.[1] for more detailed descriptions of these techniques.

Steris Corp, Mentor, OH) and sterile water rinsing between animals in the field. A review of the advantages and disadvantages of the available antiseptics and disinfectants can be found in Chapter 18. For true disinfection of instruments, an 8-minute soak time is required before use on the next animal. This precaution may not be practical in every situation; thus, the researcher will need to establish specific protocols depending on the species, potential for disease transmission, and numbers of animals being processed.

Manual Restraint, Analgesia, and Anesthesia

Many of the procedures discussed in this section can be performed with manual restraint alone. Some procedures, depending on the species, may require local anesthesia, pain management, sedation, or general anesthesia. The research team should consult and collaborate with a veterinarian experienced with amphibians and reptiles when deciding on the implementation of appropriate protocols. Chapters 48 to 52 in this book may be consulted for details in this area.

Marking and Identification Methods

Associated risks and benefits of marking animals for later identification should be carefully considered, and the decision about whether or not to mark individuals should be based on well-conceived research questions. Where research objectives are not long term and permanent marks are not necessary, minimally invasive methods for marking and identifying

VetBooks.ir

TABLE 175.2 Temporary and Semipermanent Marking Methods for Amphibians and Reptiles

Marking Method	Description	Target Organisms
Photo identification	High-resolution digital photographs that clearly show natural patterns, anomalies, and injuries of individuals can be taken each time the animal is captured. Photographs of the pineal spot of leatherback sea turtles can be useful for later identification.[110]	Salamanders; snakes; freshwater, marine, and terrestrial turtles
Paint marking	Different color combinations and paint locations can yield numerous individual marks.[18,111–113] Care should be taken to use nontoxic paints, or nail polish, and to apply the minimum amount necessary to identify the animal.	Lizards, snakes, aquatic and terrestrial turtles
Colored beads	Small colored and numbered beads attached to the tail of crocodilians or behind the head of lizards using fishing line[114] or surgical monofilament.[115]	Crocodilians, lizards
Fluorescent polymers and tags	Fluorescent acrylic polymers (also called visible implant elastomers) can be injected into the skin of amphibians. Different injection sites, color combinations, and numbers of marks can allow for large numbers of individuals to be uniquely marked.[116] Small prenumbered fluorescent tags also can be implanted subcutaneously in amphibians.[117]	Frogs, salamanders
Tattoo	Tattooing with a battery-powered tattoo handle has been used to mark the fleshy carapace of softshell turtles as an alternative to shell notching.[118]	Softshell turtles
Claw clipping	Claws of freshwater turtles such as diamond-backed terrapin and softshell turtles may be clipped in a unique sequence to identify individuals.[119]	Freshwater turtles
External tags	Both plastic and metal tags are used to mark crocodilians and sea turtles.[120,121] However, retention of external tags is generally low due to breakage, wear, and entanglement in nets or conspecific encounters. In addition to individual marking codes, contact information can be placed on the back tags to assist with tag recoveries.[121]	Crocodilians, sea turtles

Additional details on these methods are available in Norton et al.[1]

individuals are recommended (Table 175.2). Many of the permanent marking techniques described below are performed by biologists in the field studying large populations of amphibians and reptiles. As this field evolves, veterinarians are becoming more involved and can assist biologists in making decisions about practical but appropriate techniques and where clean and sterile techniques need to be utilized. Apart from zoos and individuals of high value, these techniques are rarely indicated in clinical practice where pet reptiles are involved; however, it is helpful for veterinarians dealing with these species to be familiar with the current marking and identification practices that are performed.

Permanent Marking Methods

Passive integrated transponder tags. Passive radio frequency identification (RFID) tags (or PIT tags) are one of the most widely used and reliable tools for marking amphibians and reptiles.[3,4] A PIT tag is an electronic microchip encased in biocompatible glass that ranges in size from 8 to 22 mm long and about 2 mm in diameter; the smallest tags weigh less than 0.10 g. Tags can be purchased in preloaded sterile syringes or individually and loaded into a sterilized stainless-steel syringe for implantation. All PIT tags should be sterilized before insertion if this has not been done by the commercial source. The preferred technique for sterilization is ethylene oxide gas (STERIS Isomedix Services, Mentor, OH) or hydrogen peroxide plasma sterilization (Sterrad, Advanced Sterilization Products, Irvine, CA). Sterility should be maintained during the loading and insertion of the PIT tag. Infection rates are low provided that appropriate sterilization and site-cleaning techniques are employed.[5]

Tags are dormant until activated by a handheld reader (Fig. 175.1), which generates a close-range electromagnetic field. Each tag contains a unique alphanumeric code that allows an indefinite number of individuals to be marked. The detection range for PIT tags varies with the size of the tag and type of reader. PIT tags can be expensive when large numbers of individuals are marked but have the benefit of small size and a potentially infinite life span. In addition to marking individuals, PIT tags can be used to monitor thermoregulatory behavior and movements of animals. BioMedic Data Systems, Inc. (Seaford, DE) produces

FIG 175.1 The unique alphanumeric code of a passive integrated transponder (PIT) tag is activated when scanned by a manufacturer-specific PIT tag reader. (Courtesy of L. Paden.)

temperature-sensitive PIT tags that have been used to monitor body temperature in snakes.[6,7]

PIT tags are injected most commonly under the skin, into muscle or the body cavity (Fig. 175.2). Application of tissue glue at the insertion site can help with tag retention and can control bleeding. In frogs and toads, PIT tags can be inserted subcutaneously after the area is cleaned as described earlier. For subcutaneous implantation, approximately 4 mm of skin on the ventral surface can be pinched and the tag inserted via syringe.[8] With the advent of smaller tags and insertion needles, PIT tags can now be injected in many amphibian species without the need of a surgical incision. In eastern hellbenders (*Cryptobranchus alleganiensis alleganiensis*), PIT tags were implanted successfully in the dorsal side of the tail approximately 8 cm posterior to the hind leg.[9]

In reptiles, PIT tags are generally implanted subcutaneously, although implantation sites vary by taxa. For example, in crocodilians, PIT tags can be injected subcutaneously at the junction of the ninth and tenth ventral scale rows posterior to the cloaca.[3] In lizards, PIT tags can be

FIG 175.2 Intracoelomic injection of a passive integrated transponder (PIT) tag into an eastern king snake (*Lampropeltis getula*) with the use of a 12-gauge needle. (Courtesy of D.E. Scott.)

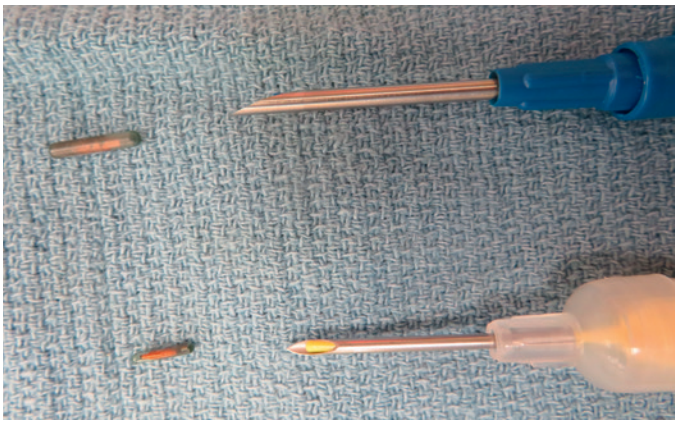

FIG 175.3 Very small passive integrated transponders (PIT) and associated syringe and needle are now available, which allows for easier placement in hatchling and small reptiles. An 8.4 mm PIT tag is shown next to a 12.5 mm PIT tag. (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

FIG 175.4 Shell marginal notched with a triangular file. (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

FIG 175.5 Use of a handheld drill to mark marginals on larger freshwater turtles. (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

inserted subcutaneously on the side of the animal[10] or anterior to the left hind limb in large lizards or tuatara.[11] In snakes of all sizes, PIT tags can be implanted subcutaneously between the second and third left dorsal scale rows, approximately two-thirds of the way down the body.[4,12] They can also be inserted into the coelom (see Fig. 175.2).

PIT tags in adult freshwater turtles, terrapins, and tortoises can be injected into the loose skin at the shoulder or hind limb on either side of the body. Buhlmann and Tuberville[13] describe a method for implanting PIT tags in small aquatic turtle species such as *Sternotherus* and *Kinosternon* spp. They recommend holding the animal vertically and carefully inserting the needle above a hind limb to implant the tag adjacent and parallel to the bridge of the shell. Before the development of the 8.4 mm PIT tags, researchers had to surgically implant sterile PIT tags in hatchling and small turtles and tortoises by making a small incision into the inguinal skin just in front of the back leg. Local anesthesia or sedation was required.[1] Now the smaller PIT tags can be injected subcutaneously (Fig. 175.3). PIT tags appear to have high retention rates but may migrate from the implantation site;[3] thus, scanning the entire body for tags is recommended.

PIT tags are also commonly used to mark most species of sea turtles. Tags are placed in the left front flipper either in the triceps superficialis muscle (shoulder area) or in the flexor carpi ulnaris (posterior aspect of the flipper, anterior and immediately distal to the second large scale). Tags should not be inserted through fibropapillomas or any abnormal skin. PIT tags are generally used as a secondary marking method in sea turtles, because flipper tags are often lost.[14,15]

Shell notching and drilling. Adult turtles and tortoises can be marked permanently on the 11 to 12 marginal scales of the carapace. Marginal scales at the anterior and posterior portion of the shell are generally flared and have a thin edge that can be carefully notched using a triangular file (Fig. 175.4), cordless Dremel tool,[16] or drilled using a cordless drill with a small bit (Fig. 175.5).[17] The area to be marked should be cleaned with povidone-iodine and alcohol at least once before marking, and the file or bit should be soaked in an appropriate disinfectant between individuals.[16] Lateral marginals on the bridge connecting the carapace and plastron (scales 4–7) should not be marked because they are generally not flared and there is a risk of penetrating the body cavity.

Several different numbering or alphabetical schemes can be derived when scute notching or drilling is used, but in general, scales in each of the four quadrants of the turtle (i.e., front right, front left, rear right, rear left) are assigned a series of numbers (e.g., 1s, 10s, 100s, and 1000s) or letters, such that thousands of individuals can be uniquely marked (see Fig. 175.4).[16] Hatchling turtles can be marked with the same numeric and alphabetical system with the use of fingernail clippers to create a notch in the marginal scutes.

VetBooks.ir

Drilling a hole in a marginal scale can be faster and produce a cleaner, more long-lasting mark than a notch. As a turtle grows, holes migrate toward the edge of the scale, but the mark is generally still visible. In sea turtles, the keratin layer may obscure the hole, so a flashlight can be shined beneath the shell to determine where the keratin layer extends beyond the bone. If so, the same drill pattern can simply be reapplied at the highest part of the keratin. Scale drilling provides an inexpensive alternative to PIT tagging. However, it does not work as well on sea turtles as on freshwater turtles because of their thick shells, extensive growth, and the frequency of marginal shell injury that can obscure marks.

Most chelonians tolerate notching of the shell without analgesia or sedation, but if a drill is used to create a hole in the shell, adequate sedation and analgesia is indicated. Opiates (e.g., hydromorphone, tramadol) in combination with low-dose ketamine and dexmedetomidine are good choices because they are effective, and the alpha-2 is reversible (See section 6).

Toe clipping. Historically, frogs, salamanders, lizards, and juvenile crocodilians were often marked by removal of toes or toe clipping.[18,19] There is some controversy about the level of pain produced by this procedure and whether analgesia or sedation should be used when toe clipping is performed.[2] When large numbers of animals are processed, it may be impractical to provide such intensive care. Researchers using this technique should keep this in mind and consider seeking alternative identification methods when available, and although acceptable if approved under an institutional animal care and use committee, it is never acceptable in clinical practice. The advantage of toe clipping is the low cost and large numbers of unique marks available if individual digits and limbs are assigned a different series of numbers. A single toe can also be removed as a basic cohort mark if unique identification of an individual is not necessary for the research objectives. Excised toes can be preserved in ethanol for genetic analysis or skeletochronology.[20,21]

To facilitate recognition of a toe-clip mark versus a natural injury, researchers can remove multiple toes on different feet. Removal of adjacent toes should be avoided. The thumbs of adult male frogs, which are used in amplexus, should never be removed, nor should more than two digits on any one limb be removed. Stainless steel toenail scissors can be used and toes should be excised at a slight angle. Scissors should be disinfected with an appropriate product before use and between animals. A drop of tissue glue can be used to stop the bleeding. In addition to pain from the procedure, there is concern that toe clipping may affect survival of individuals. Studies have shown that the number of toes clipped may negatively affect frog survival,[22] particularly in arboreal species (e.g., tree frogs, *Hyla* spp.). However, a laboratory study on squirrel tree frogs (*Hyla squirella*) found no difference in growth and survival after toe clipping.[23] Many salamanders and some frogs can regenerate toes quickly; thus, the reliability of the method is further limited. Both toe clips and injectable fluorescent polymers (Table 29.2) have been used to mark individual amphibians;[24] the advantage of using both methods is increased reliability in identifying individuals over time, although the effects of such invasive marking methods on behavior and long-term survival are not known.[25]

Toe clipping is more effective in lizards and juvenile crocodilians than in amphibians because their toes do not regenerate. However, the technique may have negative effects on behavior of arboreal lizards, which have subdigital toe pads for clinging to vegetation.[26] In contrast, a number of studies have demonstrated that toe clipping does not affect sprint speed, which is a measure of fitness in terrestrial lizards.[27–29] The frequency of natural toe loss in lizards has been used as further evidence that toe clipping in lizards is unlikely to influence survival,[30] yet natural toe loss can preclude recognition of toe clips.[31] Although the technique has been used with juvenile American alligators (*Alligator mississippiensis*), natural toe loss from conspecific interactions is frequent and can reduce accuracy and detectability in recaptures. The authors recommend alternative methods for marking juvenile crocodilians and large lizards (see Table 175.2); however, toe clipping (as described previously) is an inexpensive method for marking small amphibians and reptiles (e.g., tree frogs and small lizards) for short-term studies requiring identification of individuals. Again, it is considered unacceptable in clinical practice.

Scale clipping. Scale clipping is an inexpensive technique that is frequently used to mark snakes. Removal of the scale, with small, sharp, sterile scissors, leaves a scar that persists after shedding, and the marks can be accurately read for many years. The method was originally described for subcaudal scales,[32] but Brown and Parker presented a marking system using ventral scales,[33] which are larger and easier to remove than subcaudals.[34] Depending on the numbering system, the entire scale can be removed, or the left or right half of the ventral scale can be removed.[33] Application of tissue glue or New Skin can prevent excessive bleeding. This technique can be used on snakes of all sizes, but fewer scales should be removed and smaller scissors may be required for neonates or small snake species. Local anesthesia with lidocaine (2%; Butler Animal Health Supply, Dublin, OH) or bupivacaine (0.5%, Pfizer, Inc., New York, NY) can provide adequate analgesia for this procedure. A nonsteroidal antiinflammatory drug such as meloxicam may provide postprocedure analgesia.

Scute clipping. Tail scute clipping is one of the more common, affordable, and persistent methods of marking crocodilians. Detectability of clipped tail scutes is reduced slightly with juveniles because of their accelerated growth rates, but overall this technique is the most efficient in terms of ease of application and the ability to identify large numbers of individuals of all age classes.[31] Enumeration systems vary and can consist of numeric or alphabetical ordering. Both left and right sides of dorsal scutes can be incorporated, in addition to tail scutes, to increase the number of potential marks. A sterilized utility knife (X-Acto, Elmer's Products, Inc., Columbus, OH) can be useful for making a clean cut in the least amount of time. Preferably, a fresh, sterile blade will be used on each individual, as dull blades will result in multiple cuts to mark the animal, thereby increasing handling time and stress. The tail scute must be removed down into the muscle; the cut should be made just below where the scales merge with the adjoining scales (Fig. 175.6). If the scute clipping is performed properly, a small amount of bleeding will occur, which indicates that the mark will truly be permanent. Appropriate aseptic technique, as described earlier, should be used. Local anesthesia with lidocaine or bupivacaine will provide appropriate analgesia but is difficult to administer because of the tight skin and lack of subcutaneous tissue.

Branding. Heat branding is a fast, affordable, and straightforward method for marking snakes and is similar mechanically to scale clipping in that it removes the scale tissue. Although the method was originally

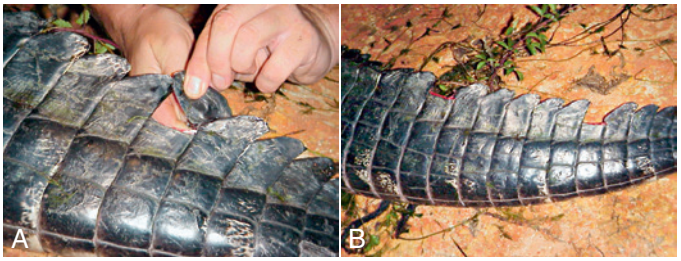

FIG 175.6 (A) Removal of a dorsal scute from the tail of an American alligator (*Alligator mississippiensis*). (B) Completed pattern of a double clip on an American alligator tail. (Courtesy of C. Hagen.)

described as a method to mark amphibians and reptiles,[35] it is most appropriate for use with snakes.[36] Disposable medical cautery units can be used to brand individual scales in patterns similar to those recommended for scale clipping;[37] however, the brands should also be applied to four to five lateral scales that correspond to the marked ventral scales to differentiate between marks and scars from natural injuries (Fig. 175.7). Cautery tips will last longer if overhanging scale material is trimmed off on keeled-scale snakes before branding. High and low temperature settings are available on some cautery units; the low temperature units setting should be used with neonates or small snake species. This technique has been used successfully on a broad array of snake species, both neonates and adults.[37]

Freeze branding, which alters the pigmentation of the scales, has also been used to mark lizards, snakes, and crocodilians. Freeze branding can be achieved with dry ice, ethyl alcohol, or liquid halocarbon (Freon) applied to the skin with a round-tipped copper wire or a synthetic sponge-tipped dowel for 20 to 30 seconds.[38] Freeze branding has several shortcomings over heat branding. The marks are more difficult to apply in the field and are variable depending on the original color pattern of the animal and can be difficult to read.

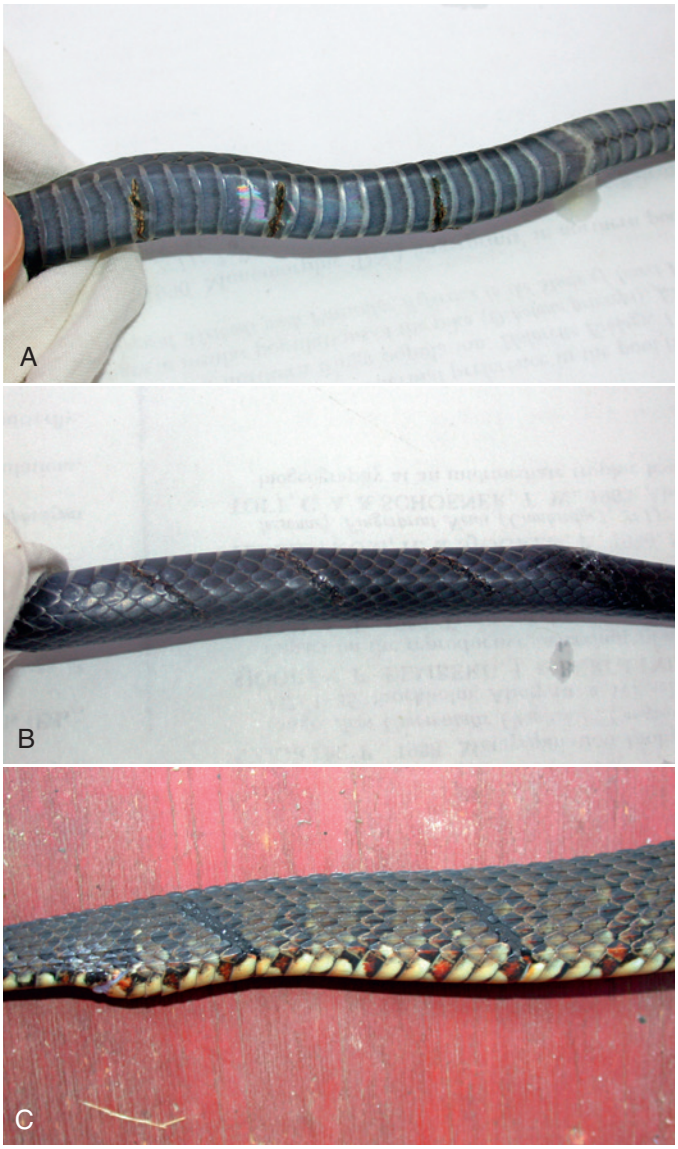

FIG 175.7 (A) Ventral scale pattern after heat branding on a black racer (*Coluber constrictor*). This image displays code 146 (anal plate is skipped). (B) Lateral scale pattern after heat branding for the same individual code as in (A). (C) Image of healed lateral marks from heat branding on a banded water snake (*Nerodia fasciata*). (Courtesy of J.D. Willson.)

Cohort marks. Magnetized wire tags were used historically to mark large numbers of sea turtles but cannot be used to differentiate individuals unless used in conjunction with another marking technique.[39] Wire tags are typically placed in foreflippers[40] and require a magnetometer for field identification. They are less expensive than PIT tags, have high retention rates (95%–100%),[41] and appear to be effective for the lifetime of the animal.[42] However, the disadvantage of this technique is that magnetometers can be expensive and may detect false-positive animals if there are other magnetic components in the area of the animal,[40] and therefore are no longer a common practice for sea turtles. However, there is potential for this technique to be used for batch marking in other taxa.

Living tags have been used to identify cohorts or year classes of hatchling and juvenile sea turtles[43–45] by applying the mark to different scutes to represent different year classes.[39,46] Living tags are created by autografting a piece of light-colored plastron tissue into a darker scute on the carapace.[40] Grafts can be obtained with the use of a surgical biopsy punch and can be secured with surgical glue.[44] Tags grow with the turtle and appear as spots or streaks in older individuals. It does take a trained eye to identify a mark, particularly on adults that received the tags as hatchlings.

TELEMETRY

The purpose of this section is to introduce some basic principles of telemetry and describe techniques (e.g., VHF, GPS, satellite, biotelemetry, archival data recorders) that have worked well for the authors and other researchers; an exhaustive review of the literature will not be provided due to the rapid rate of change and increased application with these technologies. Amphibians and reptiles are difficult animals to study because they are often cryptic and wary. They can spend considerable periods of time submerged in water or below ground and often live in habitats that are inaccessible to researchers. The ongoing advancement and miniaturization of electronic tagging technology has provided the means to effectively study these animals in the wild with minimal disturbance.[47] In addition, data on physiological function (e.g., heart rate, body temperature, and feeding habits) may be collected. Telemetry refers to an active transmission of data coming from an animal, with the objective of remotely collecting data on an animal's location, behavior and physiology, and characteristics of the environment.[36] Acoustic, electric, magnetic, and electromagnetic (e.g., visible light, radio wave, and microwave) forms of energy can be used to transmit data.[36]

The most commonly used spatial technology for herpetofauna is radio telemetry, which utilizes high-frequency radio waves. The equipment to conduct radio telemetry studies includes a transmitter, a power source (e.g., battery), and a transmitting antenna, all of which must be attached to the animal. Transmitter packages can be externally attached through a variety of methods or surgically implanted internally. Radio signals are detected by receiving antennae, which can be handheld, positioned on land at specific locations, or carried via vehicles, ships, planes, or satellites.[36] Satellite telemetry, including GPS, enables information to be relayed from the transmitter to a receiver via satellites. Biotelemetry refers to the transmission of biological information from sensors on the animal, without direct contact between the transmitter and receiver. Internal physiological data such as heart rate, body temperature, or electrocardiographic results; behavioral data such as diving time and depth; and environmental information such as ambient temperature, light, or salinity can all be relayed. Archival data recorders

VetBooks.ir

are self-contained biotelemetric units that collect and archive data for later recovery. This technology allows for researchers to gather information on wide-ranging (e.g., sea turtles) or secretive species that would otherwise be difficult or impossible to study. A wide range of designs, sizes, and methods of application allow for study of a variety of species and are now available for customization through a variety of manufacturers (http://www.telonics.com/wildlife.php, https://atstrack.com/).

Disadvantages and limitations of this technology include (1) high cost and complexity of use, (2) battery capacity and size limitations on transmission longevity and strength, and (3) the physical presence of the device may affect the animal's behavior or that of a conspecific. Internal implantation of transmitter packages requires anesthesia and surgery. Attachment and retention of the transmitter package often presents many challenges. In most instances, transmitting devices should eventually detach from the animal or be removed, which may require recapture and potentially another surgery. Recovery of archival recorders is required to retrieve data, which may also necessitate recapture and even another surgery.

The researcher should select a transmitter package and attachment method appropriate to the animal. The general rule of thumb is that a transmitter package (i.e., battery, transmitter, and antenna) should not exceed 5% of the animal's body mass,[34] and the attachment and placement should not impede the animal's movements, physiology, reproductive success, and survival. Trade-offs between transmitter attachment methods and transmitter weight, transmitter longevity, and transmission range should be determined to optimize performance so that the particular study's objectives can be met.

Radio Telemetry: Nonsurgical Placement

Amphibians. Telemetry placement in amphibians is complicated by their generally small body size and sensitive skin. Most manufacturers can configure a transmitter based on the body size and life history of the focal species. However, projected battery life of the transmitter is limited by battery size, so small transmitters may need to be refurbished with a fresh battery or replaced frequently (every 1–2 weeks to up to 3 months, depending on the size of the transmitter package). Transmitters may be attached externally to frogs with the use of belts or harnesses lined with small beads to prevent abrasion of the skin (Fig. 175.8). The belt must have enough slack to prevent wear on the skin but must be tight enough to prevent the animal from jumping out of the harness or becoming entangled. For external transmitter placement, the antenna is loose and will trail behind the animal (Fig. 175.9). Because of the body shape and fossorial habit of many salamanders, external attachment of transmitters is generally not used (see the following section on surgical placement of radio transmitters).

Reptiles

Crocodilians. Methods for acquisition and monitoring of behavioral and physiological variables from free-ranging crocodilians through the use of data loggers and via radio, satellite, and acoustic telemetry have been described.[48–51] Radio telemetry has been most widely used to track the movement patterns of crocodilians in addition to body temperatures and heart rates. Measuring body temperature via radio telemetry requires that the transmitter be located internally either via ingestion[52] or by surgical implantation into the coelomic cavity.[53,54] The nuchal shield has been most commonly used as the site for external transmitter attachment. This placement allows the antenna to come out of the water each time the animal surfaces.

In the American alligator, transmitter placement can be conducted in the field at the time of capture in the span of 45 to 60 minutes. The alligator is moved to a shady location to reduce stress and manually restrained. After the alligator is manually restrained, the right forelimb is cleaned with alcohol and an injection of Ketoprofen, a nonsteroidal antiinflammatory drug, is administered at a dosage of 0.2 mL/10 kg (2 mg/kg, 100 mg/mL vial) IM. The body mass of the alligator is estimated based on body length and girth data. The nuchal shield is then cleaned using three alternating applications of povidone-iodine scrub and alcohol. After cleaning, a 22-gauge needle is used to make multiple injections of a local anesthetic, lidocaine, subcutaneously in the area surrounding the nuchal shield at a maximum dose of 2.5 mL/10 kg (5 mg/kg, 20 mg/mL, typically 3 syringes with 1.5 mL of lidocaine and 1.5 mL of sodium bicarbonate will be used). The site is then again prepared with two applications of povidone-iodine scrub and alcohol. At least 10 minutes will be given to allow lidocaine to take effect before drilling. Four small holes are drilled with a sterilized drill bit into the nuchal scutes. Sterilized galvanized steel wire is threaded through the holes and secured to the transmitter through four loops on the side of the transmitter

VetBooks.ir

(Fig. 175.10). Finally, a marine-grade epoxy (J-B Weld WaterWeld Epoxy Putty, Sulfur Springs, TX) is placed around the transmitter to increase transmitter retention time. To camouflage the device, dried epoxy is covered either in dirt or nontoxic paint.

Satellite telemetry has also been used successfully to study long-range movements of estuarine crocodiles (*Crocodylus porosus*).[49] Before attachment of the device, the area around the nuchal shield is surgically prepared after administration of a local anesthetic. Two holes are drilled into each of four scutes in the nuchal shield. A KiwiSat 101 transmitter is attached to the scutes with the use of plastic-coated stainless-steel wire threaded through the drill holes in the scute and then through four steel loops on the sides of the transmitter and fastened with lead crimps (Fig. 175.11). Fifty percent of the animals sent signals for more than 10 months, and four sent signals for more than 15 months.[49]

Archival tags (data loggers) have been used to record diving behaviors, fine-scale movement patterns, and heart rates of crocodilians.[55] Large volumes of data can be stored within these tags and downloaded at a later time. The greatest challenge with this technology is retrieving the tags, which requires additional technologies (e.g., radio telemetry or satellite telemetry) to locate the tag or animal. The tags float and can be designed with a time-release mechanism.[1] Franklin and colleagues describe a technique using a tag and transmitter encased in a neoprene sleeve that incorporated a polystyrene float (Fig. 175.12).[50] Manual restraint and a local anesthetic were used to place the tag. Holes were drilled through the center of four scutes to align with wires from the data package. The wires were threaded through the holes in a manner that minimized any loops of wire being exposed so that the telemetry package would not become snagged. Plastic-coated wire was secured with crimp sleeves.

FIG 175.10 Satellite transmitter placed between the nuchal scutes in an American alligator (*Alligator mississippiensis*) using sterilized galvanized steel wire threaded through the holes and secured to the transmitter through four loops on the side of the transmitter. (Courtesy of Kimberly M. Andrews.)

Lizards. Radio telemetry has been used to study aspects of behavior and spatial ecology in a variety of lizard species, including the beaded lizard (*Heloderma horridum*), Gila monster (*Heloderma suspectum*), Yarrow's spiny lizard (*Sceloporus jarrovi*), lace monitor (*Varanus varius*), southern alligator lizard (*Eligaria multicarinata*), land mullet skink (*Egernia major*), eastern bearded dragon (*Pogona barbata*),[56] and water dragon (*Physignathus lesueurii*).[57] Goodman reviewed a variety of telemetry techniques that have been used in West Indian iguanas (*Cyclura* spp.), including ingested transmitters; transmitters externally applied with duct tape; suture of transmitters to the dorsal crest (Fig. 175.13); transmitter collars, belts, and harnesses (Fig. 175.14); and use of various adhesives to attach transmitters.[56] The signal range did not differ dramatically between most methods but did differ across habitats and among transmitter models, especially in relation to free antenna length.

An additional consideration is the trade-off between signal strength and battery life. Different researchers using the same model of transmitter may select reduced signal strength to increase battery life if the focal species is not wide-ranging; thus, there is substantial variation in signal range and battery life among research projects.[56] Knapp and Owens[58] conducted radio telemetry on hatchling Andros Iguanas (*Cyclura cychlura cychlura*) by placing transmitters on the dorsal side of the pelvic girdle with test monofilament line wrapped around the lizard's body to secure it. This method may also be useful for hatchlings and small lizards of other species.

A harness to attach radio transmitters to water dragons was made by cutting a sheet of nylon mesh or fly screen in the shape of a square with two extending straps.[57] Cutting the square and straps to fit the individual lizard is critical; if they are too large, it may get caught on vegetation, and if too small, it may cause discomfort or abrasions to the skin. The radio transmitter was glued to the harness with adhesive (Super Glue; Super Glue Corp., Rancho Cucamonga, CA) before attaching the harness to the animal. The square part of the harness was placed firmly on the lizard's back above the forearms, while the straps were then pulled over the shoulders, crossed on the chest, and pulled up under the lizard's forearms. After pulling the straps snug, they were adhered to the square with cyanoacylate glue (Super Glue) and to one

another where they crossed on the cranial coelom. The mesh was held together at glue points with forceps. The harness was easily removed by cutting the straps with scissors. Water dragons were monitored for up to 2 months without any harness losses or any noticeable problems for the lizards.

Snakes. Radio or GPS transmitters can be attached externally to snakes to collect short-term movement data.[59,60] The method is ideal for use with juvenile snakes or small-bodied species.[61] Transmitters should be attached dorsolaterally, approximately two-thirds of the snout-to-vent length behind the head with cyanoacylate glue (Fig. 175.15). Transmitters are typically shed during ecdysis and can be retrieved for use on another animal. In rattlesnakes, devices can be attached to the rattle using epoxy and suture material (Fig. 175.16). These transmitters are particularly helpful to use when a snake is waiting for surgical implantation of a radio transmitter. This way the snake can be maintained in a free-ranging state until a surgery can be planned.

FIG 175.12 Data logger (archival tag) with self-release device attached to the nuchal scutes of an estuarine crocodile (*Crocodylus porosus*). The data logger recorded water depth, acceleration in three dimensions, compass bearing, speed, and body temperature. (Courtesy of C.E. Franklin.)

Freshwater turtles, terrapins, and tortoises. The predominant way transmitters have been attached to turtles is by mounting the tag onto the carapace. Different techniques have varying levels of success depending on the life history traits, age, and size of the study animals (Fig. 175.17). Boarman and collegues[62] reviewed 113 scientific papers, reports, and semitechnical articles on radio tracking projects regarding turtles with transmitters attached to the carapace by a variety of methods, including epoxy, silicone sealant, dental acrylic, and other types of adhesives. Additionally, there were descriptions of transmitters being strapped on with harnesses or attached via bolts, wire, cable, or nylon ties or with monofilament line, which was passed through holes drilled into the posterior carapace or marginal scutes. In these cases, the transmitter was either attached to the carapace or allowed to trail behind the turtles.

Although there needs to be further research evaluating the effects of transmitters on study animals,[61] there are many possible behavioral (e.g., mating disruptions) and physical problems that can be caused by improper transmitter placement. Shell deformities occurred on hatchling

VetBooks.ir

gopher tortoises (*Gopherus polyphemus*) because the epoxy holding transmitters encroached on growth areas,[63] an issue of substantial concern with young, growing animals in particular. Also, transmitters may become entangled in vegetation, usually among gaps between the shell and the transmitter or the antenna. Lastly, transmitters may attract the attention of predators and humans and therefore should be camouflaged in some way (Fig. 175.18). Boarman and colleagues recommended a process for transmitter placement in desert tortoises (*Gopherus agassizii*) that is applicable to other nonmarine turtles:[62]

1. Test the transmitter to confirm that it is functional.
2. Clean dirt off the carapace.
3. Preposition the transmitter to first left or right coastal (pleural) scute and fit as flush to the carapace as possible.
4. To position the antenna, cut short sections of flexible 3 mm plastic tubing and attach each section to the first four vertebral scutes using epoxy. Each section should be cut slightly shorter than its associated scute. Cyanoacylate glue can be used to hold each section of tubing in place while quick-drying, pliable epoxy putty (nonexothermic that does not heat up) is spread over each section of tubing in a continuous layer from the scute on the side of the tube to the scute surface on the opposite side of the tube. Avoid getting any epoxy on the scute sutures or neighboring scutes to allow for shell growth.
5. Place the antenna through the tube sections leaving approximately 50 to 120 mm hanging loose beyond the posterior of the animal.
6. Attach the transmitter with epoxy putty, using care not to bridge the scute margins and leaving no spaces between the transmitter and the carapace to get caught in vegetation.
7. Paint the transmitter and putty to reduce reflectivity and contrast and to protect the camouflage capabilities of the animal to reduce predation risk.

In addition to these points, the transmitter placement site should be disinfected, as described earlier in the chapter. The transmitter should not be applied to an abnormal part of the shell (e.g., deformation or site of infection). The carapace can be roughened slightly with sandpaper or a rotary tool (e.g., Dremel) before the epoxy is applied. The authors have had success with using a marine epoxy putty for the initial attachment of the transmitter and then coating it with a liquid epoxy (Power-Fast+, Fast Set Formula; Powers Fasteners, Inc. Brewster, NY). The epoxy putty alone may be successful for securing devices to terrestrial and aquatic turtles and crocodilians, but it is recommended that liquid epoxy be used in most marine turtle species. A digital, distant-laser thermal monitoring device (Raynger ST; Raytek Corporation, Santa Cruz, CA) should be used to make sure exothermic epoxy does not rise above 37.8°C (100°F) during the curing process. If necessary, the area can be sprayed with cool water. In immature growing turtles, it is important not to cross scute suture lines to avoid interfering with the growth of the shell. Hatchling and juvenile tortoises can be radio tracked using small, lightweight radio transmitters attached to the costal scutes with silicon aquarium sealant. This sealant is readily removed without damaging the shell of the tortoise.

Bolts and other fasteners can be used to attach radio transmitters to the carapace of aquatic turtles.[57] A surgical preparation and sterile technique should be used in this procedure, because it requires drilling through the bone of the shell. Transmitter packages with aluminum plates with holes at either end for attachment and whip antennae are available through several manufacturers (e.g., Model A1–2F, Holohil, LTD., Ontario, Canada; Model MOD-125, Telonics, Inc., Mesa, AZ). The preferred site of attachment is on top of the posterior marginal scutes and underlying the peripheral bones of the carapace, typically in a region above one of the hind limbs.[58] Attachment at this site is less likely to create drag or impede movement through substrate or vegetation. The most posterior scute should not be used because it will likely interfere with mating behavior. It is important to preplace the transmitter on the shell to mark the spots to be drilled and to assess how the transmitter fits in relation to the curvature of the shell. If necessary, a small amount of epoxy can be used to create a flat surface for attachment. Holes drilled too close to the outside edge may break down from wear, allowing the fastener to slip, and holes drilled too close to the scute seams often result in excessive bleeding. For pig-nosed turtles (*Carettochelys insculpta*), the epoxy was replaced with neoprene strips cut to the size of the

transmitter, which softened the pressure of the transmitter against the shell. Additionally, pig-nosed turtles have no scutes, so it was critical to ensure that the holes were drilled on or near the seams between the marginal bones, which are clearly visible beneath the skin in this species. Tags were attached with stainless steel bolts and locking nuts threaded with nylon to prevent loosening and corrosion-resistant metal backing plates. The nut should be on top (transmitter side) to allow full leg movement and prevent abrasion of the skin on the legs. Gaps between the tag and the shell were filled with epoxy putty to prevent debris and vegetation from becoming entangled.

Sea turtles. Satellite telemetry has been used most extensively to study long-term, large spatial movements and activities of sea turtles and estuarine crocodiles. This technique is especially important in the marine environment, where very high-frequency (VHF) signals are greatly attenuated and distances to be covered are usually large.[64] The primary disadvantage of this technology is the cost of the transmitters and satellite time.

Most published sea turtle tracking research has focused on postnesting females because of their accessibility. For example, a study was conducted on the Georgia coast to evaluate internesting intervals and postnesting migratory behavior in female loggerhead sea turtles (*Caretta caretta*) (Scott JA, unpublished data, 2006). In this study, a variety of methodologies including acoustic, radio, and satellite telemetry were used to evaluate short- and long-term movement patterns, nest-site fidelity, and interactions with shrimp trawl fishery (Fig. 175.19).

Until recently, very limited information was available on the spatial ecology of male loggerhead sea turtles during the breeding season. Arendt and colleagues evaluated the movement and diving patterns of resident and migrant adult male loggerhead sea turtles during the breeding season in Cape Canaveral, Florida,[65] and after dispersal postbreeding.[66]

A variety of satellite attachment techniques have been used in sea turtles, including tethering of buoyant transmitter housing to the posterior end of the shell, attachment of "backpack-style" transmitters to the anterior vertebral scute with fiberglass cloth and polyester resin, fiberglass filler, two-part epoxy/putty, and combinations of these techniques.[67] Retention time of satellite tags has been and continues to be problematic. Integration of antifouling paints and an alternative adhesive, steel-reinforced epoxy putty (Sonic-Weld, Ed Greene & Co, Tallahassee, FL)[69] has increased retention time.[68]

The GSTC has utilized this technology to track rehabilitated loggerhead sea turtles after release (Fig. 175.20). Satellite placement techniques have been similar to those previously described,[70] except that the transmitter is partially covered with epoxy with only the saltwater switches exposed (Fig. 175.21). A laser temperature gun is used to monitor the temperature of the epoxy; when it reaches 37.8°C (100°F), water is used to reduce temperature. Although these transmitters could theoretically last for 3 years, data collection for more than 1 year has been rare, most likely because of physical damage to the antennae or transmitters and/or biological fouling of the saltwater switch sensor.

Radio Telemetry: Surgical Placement

Only healthy animals should be selected for surgical radio telemetry placement. The signal strength and frequency of the transmitter provided by the manufacturer should be verified with a receiver before placement in the animal to avoid implanting a nonfunctioning transmitter. Surgical procedures should be conducted during the appropriate time of year so that surgical sites can heal adequately. Anesthesia and procedures should be conducted by a veterinarian with extensive surgical experience with herpetofauna. Arrangements can be made with local human hospitals, veterinary schools, or other specialty facilities if this is not available to the researcher. The benefits far outweigh the costs. Although not ideal, individuals without a veterinary degree will likely continue to conduct surgeries following IACUC approval. At a minimum, these individuals should receive specialized training in anesthesia, surgery, and sterile techniques and have close consultation with an experienced veterinarian.

All telemetry devices and data loggers should be sterilized with either ethylene oxide gas or hydrogen peroxide plasma sterilization before surgical implantation, as previously described for PIT tags. High-level (cold) disinfection is inadequate and not recommended.

General Guidelines for Amphibian Surgery. In general, because of their size, many amphibians are not well suited for internal placement of telemetry packages. Internal placement of radio telemetry had been described for large frogs[71,72] and salamanders (e.g., tiger salamanders [*Ambystoma tigrinum*] and spotted salamanders [*Ambystoma maculatum*],[73] and the eastern hellbender[9]). Presurgical preparation of the

patient includes ensuring good hydration and electrolyte balance by soaking the animal in a shallow water bath for 60 minutes before surgery. The amphibian can be weighed preoperatively and postoperatively to monitor hydration. The amphibian should be fasted before surgery for a minimum of 4 hours.[74] Appropriate analgesia and anesthesia should be used for internal transmitter placement and other invasive and potentially painful procedures. Although other anesthetic options are available, buffered tricaine methanesulfonate (MS-222; Argent Chemical Laboratories, Inc., Redmond, WA) has been used widely by veterinarians and researchers for anesthesia in amphibians and appears to have a wide margin of safety.[74] After being anesthetized, the amphibian is removed from the anesthetic bath to avoid overdosing or prolonged anesthesia. Well-oxygenated clean water should be provided during anesthesia, and additional anesthetic can be added, if needed.

Although amphibian skin secretions are known to have antimicrobial properties, sterile techniques should be followed. Because of the potential for toxicity from the various available antiseptics, it is recommended that the patient be rinsed with sterile water before placement of sterile drapes. Surgical instruments should be heat or gas sterilized. A small incision is made into the skin, thin muscle layer, and coelomic lining to enter the coelomic cavity. The authors have used transmitters in which the antenna is tightly coiled around the battery, and the entire package is encapsulated in acrylic (see Fig. 175.9D). The transmitter is placed into the coelom, and the incision is closed. The least reactive suture material should be used; polydioxanone (PDS II, Ethicon, Inc., Somerville, NJ) is recommended for internal sutures and skin, and alternatively nylon can be used for skin sutures.[75] Triclosan-impregnanted poliglecaprone (Monocryl-plus, Ethicon) suture offers the advantages of faster absorption (4–8 weeks depending on metabolism) and local antimicrobial effects to reduce dehiscence.[76] Internal transmitters will need to be removed or replaced, which is a consideration that researchers should be aware of when working with rare species, those

VetBooks.ir

that are difficult to capture, or species that are particularly susceptible to stress.

PIT tags can also be implanted into the body cavity of frogs and salamanders, either by syringe and needle or through a small (2 mm to 3 mm) incision in the skin with the use of surgical methods previously described. In salamanders, the tags can be inserted along the side of the body, approximately 5 mm anterior to the hind leg;[77] tags should be inserted anteriorly, parallel to the long axis of the body. Incisions can be closed with a small amount of cyanoacrylate glue. Anesthetized amphibians should not be released until they are fully recovered.

General Guidelines for Reptile Surgery. Presurgical health screening is recommended. Appropriate analgesia and anesthesia should be used and tailored to each species undergoing surgery. In most cases, injectable sedatives and anesthetics will be followed by intubation and gas anesthesia. Appropriate cardiac and respiratory monitoring equipment should be available. Recommended suture material includes polydioxanone (PDS II),[78] an absorbable suture, that is used internally and in the skin or alternatively nonabsorbable nylon (Ethicon; Ethicon, Inc., Somerville, NJ) can be used for the skin. Triclosan-impregnanted poliglecaprone (Monocryl-plus, Ethicon) suture offers the advantages of faster absorption (4–8 weeks depending on metabolism) and local antimicrobial effects to reduce dehiscence.

Crocodilians. Intracoelomic radio transmitter implantation in crocodilians has been conducted under injectable anesthesia with subsequent intubation and manual ventilation with a bag valve mask (Ambu bag) or Hudson Demand Valve.[48–51] A small skin incision was made between scales in the flank of the abdominal region, just anterior to the right hind limb. Muscle layers beneath the skin were carefully separated to reveal the coelomic lining. Hemostats were used to secure the coelomic lining, and an incision was made to enter the coelom, where the transmitter was inserted. To avoid disturbance when the animals were tracked, the researchers used an automatic and continuous recording station positioned at least 100 m from the waterhole to simultaneously monitor up to 10 individuals. Radio signals from the temperature-sensitive transmitters were received by a four-piece Yagi aerial antenna, mounted 25 m directly above the waterhole that the crocodiles inhabited.[50] Alternatively, using a similar surgical approach, researchers implanted a multichannel radio telemetry system to measure blood flow and pressure, electrocardiographic data, and body temperature in several captive American alligators.[79] The technique has been reported to be promising for free-ranging crocodilians.[50]

The authors (TMN, KMA) developed a technique for surgical implantation of radio transmitters in the muscle of the proximal tail of American alligators. The technique was used on six alligators and is successful on animals that do not occupy estuarine or marine waters that attenuate VHF signals.[80] Following the induction of ketamine-dexmedetomidine-opiate anesthesia, lidocaine was infiltrated into the incision area. Intubation and ventilation with a bag valve mask were performed in all cases. Gas anesthesia can be used to further control anesthesia but has not been necessary with the injectable drug combination used. Following skin preparation, a 3 cm to 5 cm skin incision was made between scales about a third of the way down from the dorsal aspect of the tail. Blunt dissection was used to create a pocket between muscle planes, where the transmitter was inserted (Fig. 175.22). Holohil Systems Ltd. (Ontario, Canada) transmitters (Model SI-2, 50 mm × 11 mm, 36-month battery projected life) developed for snakes have been used. Sterilized copper tubing is threaded caudad subcutaneously before the antenna is threaded through the rigid tubing. A small skin incision at the distal end of the tubing is made to allow the tubing to be removed, leaving the antennae in place. It is difficult to thread the tubing because of the stiffness of the scales; thus, more than one incision was usually needed. The surgical site was closed routinely.

A technique recently described subcutaneous implantation of temperature- or pressure-sensitive acoustic telemetry devices in estuarine crocodiles.[50] The animals ranged from 2 to 5 m in length. The crocodiles were manually restrained, and a local anesthetic was infiltrated into the surgical site. A 2 cm skin incision was made, and a small pocket was formed under the skin along a skinfold, with the use of blunt-ended scissors (Fig. 175.23). The transmitter was then inserted (V16, Vemco-cylindrical, 72 mm long and 15 mm in diameter with rounded ends). The transmitter was positioned so that when the animal surfaced, it remained well below the water. The researchers used fixed receiver stations. The technology has potential to be extremely useful in crocodiles, because the signal transmission occurs through water, and transmission operates irrespective of salinity. Furthermore, the transmitters can be programmed to have a life span of more than 10 years. A variety of sensors are available to measure temperature and pressure (water depth). The signals can be actively tracked or detected by automatic stationary receivers. The authors reported excellent transmission; animals were detected more than 500 m away with the use of a directional hydrophone and active tracking receiver. At the time of the publication, the transmitters had been functioning well for more than 9 months.

Lizards. An effective technique for surgically implanting transmitters in the coelom of anegada ground iguanas (*Cyclura pinguis*) has been reported and has potential for use in other lizard species.[81] With this technique, two-point fixation of the transmitter to the internal body wall was achieved. Antenna placement in the coelom was a critical part of the procedure. Of 23 iguanas, 20 transmitted good signals for at least 10 months after surgery (Fig. 175.24).

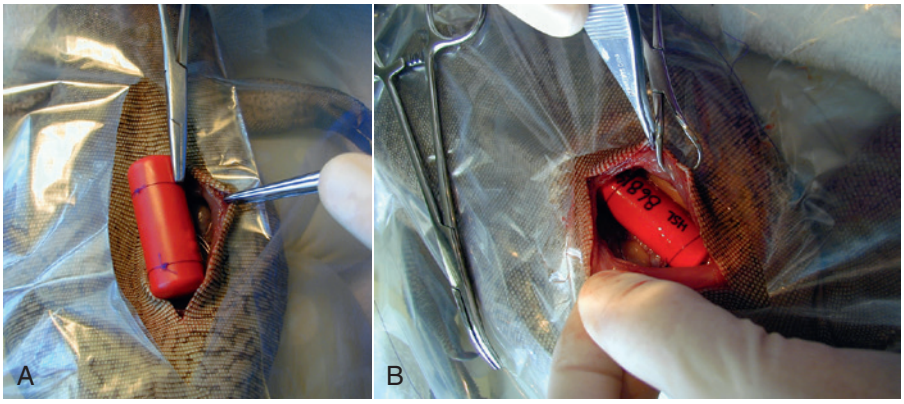

FIG 175.24 (A and B) Surgical intracoelomic placement of radio transmitters in Caribbean iguanas (*Cyclura* spp.) (Courtesy of Fort Worth Zoo Animal Health.)

Another method was described by Doody and colleagues for surgical implantation of radio transmitters in a semiaquatic monitor lizard (*Varanus mertensi*).[57] Gas anesthesia was used. The site was aseptically prepared for implantation. A 2 cm to 3 cm skin incision was made longitudinally on the lateral side of the coelom, approximately 2 to 3 cm anterior from the hind limbs. Muscle was incised to gain access to the coelomic lining, which was then incised. Transmitters (Holohil Systems Ltd, Ontario, Canada, Model 2I-T, 3 g, 2.5 cm × 0.6 cm) with a 10 cm external whip antenna were inserted into the coelom. The transmitter was positioned longitudinally within the coelom. A thin-walled brass tube was threaded subcutaneously from the anterior point of incision along the lateral fold of the animal to just behind the head. The external antenna was positioned inside the tube, and the tube was removed through a small incision made just behind the head, leaving the antenna in place under the skin. No significant adverse effects were noted, according to the authors, over a 2-year study period. Fifty individuals were implanted, and 37 transmitted for more than 16 days; 4 were tracked successfully for 2 years.

Snakes. Radio telemetry devices have been surgically placed in the coelomic cavity of a variety of snake species. Complete healing takes approximately 4 to 8 weeks in reptiles maintained in ideal thermoregulatory conditions. The methodology that follows is a modification of that described previously.[82]

Snout-to-vent and snout-to-tail measurements are taken. The snout-to-vent measurement is divided by three; this distance is measured from the cloaca (vent) anteriorly and used for the incision site for transmitter placement. A permanent marker can be used to mark the skin incision site. The snake is prepared for sterile surgery in a routine fashion. A 3- to 5-cm lateral skin incision is made between the second and third scale rows and then reflected ventrally past the ribs so that an incision can be made in the coelomic lining, which allows access to the coelomic cavity. Care should be taken not to incise the air sac while making the incision in the coelomic lining or accidentally insert the transmitter into the respiratory system.

An appropriately sized transmitter should be selected. Temperature-sensitive transmitters available from select manufacturers or micro-temperature data loggers (iButtons; Maxim Integrated Devices, Sunnyvale, CA) that have been coated in multipurpose rubber coating (PlastiDip; Plasti Dip International, Blaine, MN) and gas sterilized can also be implanted intracoelomically caudal to the transmitter to record body temperatures. Sterilized copper tubing (rigid dog urinary catheter or a similar rigid sterile instrument) is threaded subcutaneously anteriorly. The antenna is threaded into the lumen of the tubing. A small skin incision is made at the level of the anterior end of the tubing. The tubing is removed, leaving the antennae in place. The antenna can be anchored to musculature by one suture (placed approximately 0.5 cm anterior to the transmitter), which reduces the chances of the antennae protruding from the incision site. Care is taken to ensure that the antenna is not crimped (Fig. 175.25). Surgical closure is routine.

Although this technique is expedient and successful in most snake species if proper procedures and sterilization techniques are applied,

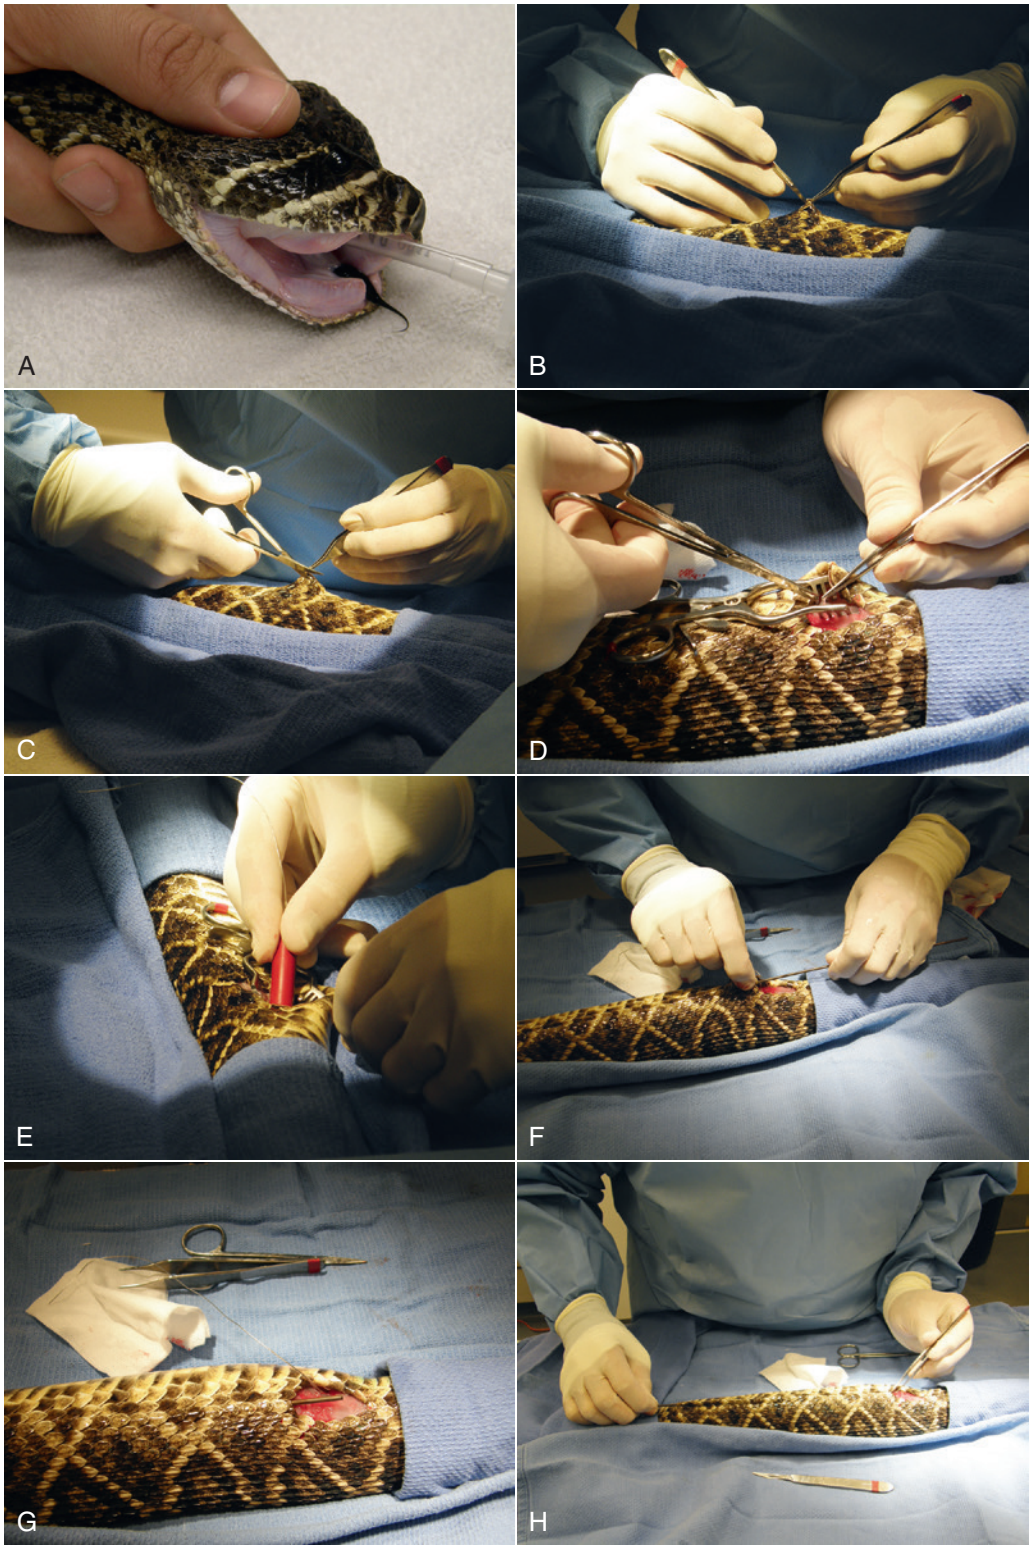

FIG 175.25 Surgical placement of a radio transmitter into the coelom of an eastern diamondback rattlesnake (*Crotalus adamanteus*). (A) Isoflurane anesthesia is administered through an endotracheal tube. (B) Initial stab incision into the skin with a scalpel blade. (C) Skin incision is completed with scissors. (D) Incision of coelomic lining with scissors. Retractors improve exposure. (E) Radio transmitter is being placed into the coelom. (F) Threading copper tubing subcutaneously. (G) Copper tubing in place for threading antenna. (H) Small incision is made to pull out the copper tubing while leaving the antenna in place. (Courtesy of Terry M. Norton, Georgia Sea Turtle Center.)

VetBooks.ir

some species of snakes, such as the eastern indigo snake (*Drymarchon couperi*), are prone to developing bacterial infections at the transmitter site. Recent studies on the eastern Massasauga rattlesnake (*Sisturus catenatus catenatus*) indicate bacterial infections still occur with some frequency, despite proper incorporation of sterile techniques.[83]

CONCLUSION

Capture techniques, marking of individuals for identification purposes, and telemetry placement techniques are used extensively in herpetological research and conservation activities. It is critical that veterinarians and biologists continue to work together to develop sound protocols that provide vital research information while causing minimal negative effects to the individual animals and populations that are being studied and preserved.

Medical Management and Rehabilitation of Sea Turtles

Charles J. Innis

Fisheries interactions, boat trauma, habitat degradation, poaching, disease, oil spills, and unusual weather events are resulting in increasing numbers of sea turtle injuries, stranding events, mortality, veterinary research, and intervention (Walsh MT et al, Proc ARAV, 2014, p 36).[1–18,20–22] The extensive, but not comprehensive, reference list provided herein reflects numerous recent studies, but the reader is encouraged to explore the many important previous references cited within those studies.

COMMON MEDICAL CONDITIONS

Traumatic injuries may occur due to boat strike, fisheries gear entanglement or hooking, and predator injuries (Fig. 176.1).[1,3] Hook and line or trash ingestion may lead to perforation or obstruction of the digestive tract (Fig. 176.2).[1,6,8,16] Forced submergence by fishing gear may result in near drowning and associated physical and physiological derangements,[3] and decompression sickness may be seen when sea turtles are captured at depth and rapidly brought to the ocean surface (Fig. 176.3).[9]

Sea turtles are susceptible to severe hypothermia or "cold-stunning" in autumn and winter when water temperatures rapidly drop.[4,10–17] Hypothermic turtles are prone to a variety of secondary conditions, including pneumonia, sepsis, and osteomyelitis.[14–16]

Sea turtles are sometimes found stranded in chronically debilitated condition, and various monikers such as "lethargic loggerhead syndrome" and "debilitated turtle syndrome" have been coined.[18] Such turtles are often emaciated, weak, fragile, anemic, and hypoproteinemic.[18] Careful handling may be required to prevent iatrogenic avulsion of skin and bone attachments.

Traumatic injuries or chronic pneumonia may allow air to leak from the lungs into the coelom (pneumocoelom) (Walsh MT et al, Proc ARAV, 2014, p 36). Similarly, any gas-producing coelomic infection or gastrointestinal disease with secondary gas accumulation may cause buoyancy problems. Animals with neurologic damage, especially spinal trauma, may also have buoyancy problems.

Heavy metals and pesticides have been detected in sea turtles, and their presence is sometimes associated with clinicopathologic abnormalities.[20] Brevetoxin, domoic acid, and saxitoxin may also cause toxicity as seen in other marine species.[21] Sea turtles have been exposed to crude oil and petroleum products in small- and large-scale exposure events.[5] Physical, physiological, and postmortem assessments may reveal variably extensive oiling with evidence of oil ingestion and aspiration in some cases. Oiled turtles may be affected by acidosis, electrolyte abnormalities, and presumed physiological stress response, likely caused by combined effects of oiling, hyperthermia, and transport.[5] An experimental study that exposed loggerhead turtles to oil cited possible hemolytic anemia and salt gland dysfunction, but these conditions were not well characterized.[22]

Sea turtles are commonly affected by opportunistic bacterial and fungal infections, often secondary to trauma or hypothermia. It has

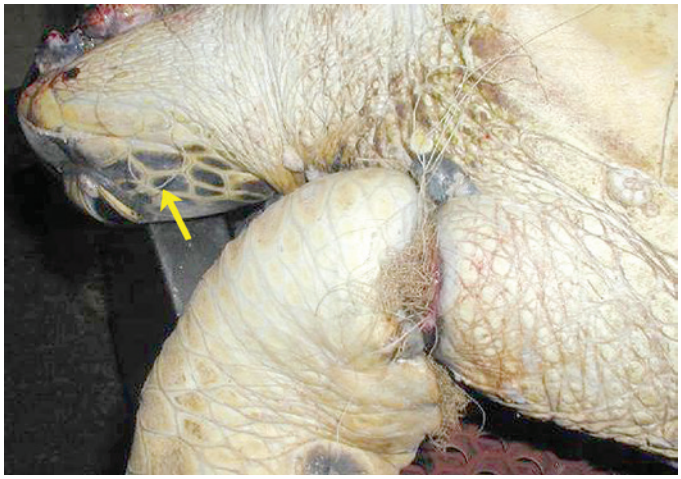

FIG 176.1 Loggerhead turtle (*Caretta caretta*) with nylon fishing line entangling and strangling the flipper. The yellow arrow points to the ingested portion of the line. (Courtesy of Douglas R. Mader.)

been shown that hypothermia results in significantly increased plasma corticosterone concentrations, which could contribute to immunocompromise.[14] Most often, infections are caused by bacteria and fungi that are normally present in the environment or associated with the turtle's oral, nasal, cloacal, and digestive tract. Common isolates include various gram-negative aerobic bacteria, *Enterococcus* spp., *Mycobacteria* spp., and *Fusarium* spp.[15,23–26]

Fibropapillomatosis (FP) is common in sea turtles in tropical waters worldwide, especially green turtles (*Chelonia mydas*). It is associated with chelonid fibropapilloma-associated herpesvirus (CFPHV).[26] This debilitating disease is characterized by the proliferation of cutaneous and visceral FP (Fig. 176.4). If FP occurs on or around the eyes, it can lead to visual impairment. Large lesions on the flippers or carapace may affect swimming. Internal FP may develop within the viscera; thus MRI and coelioscopy may be useful for diagnosis.[16] Herpesviruses have also been isolated from cases of "gray patch disease" and "lung-eye-trachea disease" in green sea turtles, and a herpesvirus was described as a cause of cutaneous and mucosal lesions in loggerhead turtles (*Caretta caretta*).[27]

Spirorchid trematodes are common, but they may or may not lead to clinically relevant disease.[7] Adult spirorchids generally reside within the heart or great vessels. When the parasites reproduce, eggs are released into the vasculature, becoming lodged in capillaries and causing granulomas. Spirorchids are among the proposed causes of neurologic syndromes that have been seen in sea turtles.[7]

The coccidian parasite *Caryospora chelonae* may cause fatal enteritis, especially in juvenile green turtles (Pelton CA et al, Proc 44th Annu Conf Internat Assoc Aquat Anim Med, 2012, pp 81–82).[2] Other parasites and epibiota such as nematodes, cestodes, leeches, and barnacles may be seen but are often incidental findings.[29] Sea turtles may be intermediate hosts for some parasite species. Although many debilitated turtles become heavily covered by epibiota, the presence of heavy epibiotia is not always associated with illness, and one study found no clinicopathologic correlates to epibiota coverage.[29]

PHYSICAL EXAMINATION

Sea turtles are relatively easy to examine compared with other turtles, because they cannot withdraw their head and limbs into their shell. Heart rate should be determined using Doppler or ultrasonography, and respiratory rate should be noted visually. Turtles should be weighed and body temperature recorded using a flexible cloacal thermometer gently inserted as deeply as possible, and body measurements should be collected. The mouth is relatively easy to open with gentle traction on the lower jaw or pharyngeal skin. Stranded turtles often have eye injuries caused by scavengers or foreign material (e.g., sand); thus a thorough eye examination, including corneal fluorescent staining, is required. Sea turtle corneas are very sensitive but are desensitized by proparacaine ophthalmic solution.[30] Tonometry data have been reported for loggerhead and Kemp's ridley turtles (*Lepidochelys kempii*), with results of 5 to 12 and 2 to 9 mm Hg (ranges), respectively.[31] A comprehensive neurologic examination should be performed.[32]

CLINICAL PATHOLOGY

There have been more clinical pathology studies published for sea turtles, including data for both healthy and unhealthy turtles, than for any other group of reptiles.[33–49] The number of studies prohibits comprehensive citation, thus the references listed herein have been limited to several of the most recent for each species. Readers are encouraged to explore the many clinicopathologic studies cited within these studies for further insight, taking care to understand the context of the study in which the data were collected (e.g., wild vs captive, adult vs juvenile, postprandial or fasted, injured vs healthy). Recently larger data sets have allowed for the development of mortality prediction indices based on clinicopathologic data.[13,47] Clear trends in improvement of clinicopathologic values during the course of hospitalization have been demonstrated in several studies.[14,15,38,47]

Blood is usually collected from various locations along the external jugular vein. Depending on the site of needle insertion, these sites have also been referred to as the dorsal cervical sinus, postoccipital sinus, or supravertebral sinus.[16] The dorsal coccygeal vein and the interdigital veins may also be used.[49] The subcarapacial sinus can be accessed easily in sea turtles, but serious adverse sequelae have been described for some cases due to its proximity to the cervical spinal cord, including transient paresis and death (Innis CJ et al, Proc ARAV, 2010, pp 8–10). The author reserves use of the subcarapacial sinus for emergency situations when no other vascular access can be obtained.

Blood handling should follow standard reptilian methods, taking care to avoid artifactual influences such as hemolysis, delayed centrifugation, and excessive anticoagulant ratio. Ethylenediamine tetraacetic acid (EDTA) causes lysis of Kemp's ridley turtle blood cells and is generally avoided for all sea turtles, with heparin preferred. No significant differences were found in leatherback turtle (*Dermochelys coriacea*) plasma biochemical values between samples collected in sodium heparin versus lithium heparin, although in general lithium heparin is recommended.[46]

FIG 176.5 Blood collection from a branch of the external jugular vein of a Kemp's ridley turtle (*Lepidochelys kempii*). (Courtesy of New England Aquarium.)

FIG 176.6 Blood collection from supravertebral sinus of a green turtle (*Chelonia mydas*) (Courtesy of Douglas R. Mader.)

For access to the external jugular vein, the head is extended and slightly ventroflexed. The vein is located paravertebrally, lateral to the straplike retractor muscles of the neck (Fig. 176.5). For venipuncture of the supravertebral or postocciptal sinus, the needle is placed to either side of the nuchal crest, caudal to the skull and directed axially toward the dorsal midline of the vertebra (Fig. 176.6).[16] Accidental aspiration of lymph can occur at any venipuncture site, whereas cerebrospinal fluid may be obtained from sites close to the spinal cord.

Healthy carnivorous sea turtles have much higher blood urea nitrogen (BUN) concentrations than terrestrial vertebrates; however, debilitated or nesting sea turtles often have relatively low BUN.[18,44] Interestingly, sea turtles sometimes show increasing BUN values during rehabilitation even though they have not yet accepted food, which suggests that anorexia alone may not explain the reduced BUN seen at admission. Green turtles are more herbivorous than other sea turtle species and have relatively lower BUN values.[10] Plasma uric acid concentrations tend to be quite low in healthy sea turtles (generally <120 µmol/L; 2 mg/dL). Severely elevated uric-acid values are associated with a poor prognosis. Plasma uric acid concentrations are negatively associated with glomerular filtration rate in hypothermic Kemp's ridley turtles.[11]

Both hypoglycemia and hyperglycemia are common in ill sea turtles.[12] In contrast to many other vertebrates, healthy sea turtles often have lower total plasma calcium concentrations and often have an inverse calcium:phosphorus ratio.[18,29] Ionized calcium concentrations in healthy sea turtles are often approximately 1.0 mmol/L.[3,5,12] Hypoproteinemia and hypoalbuminemia are common.[17] Albumin concentrations for turtles are most accurately measured by electrophoresis rather than the bromcresol green method.[51] Protein electrophoresis data have been published for several sea turtle species, but clinical use of these data has not yet become routine.[3,18,43] A variety of plasma enzyme activities are often measured, and the tissues of origin for these enzymes have recently been documented for loggerhead and Kemp's ridley turtles.[35,37] Overall, these enzymes are found in a variety of tissues and thus are nonspecific indicators of cellular injury. Debilitated sea turtles often have elevated sodium, potassium, chloride, magnesium (ionized and total), and ionized calcium concentrations, presumably due to a combination of dehydration, reduced renal and salt gland function, and ingestion or aspiration of sea water.[12] However, a spectrum of derangements is seen, and some individuals may be hypokalemic or hypocalcemic.[12] Severe elevations of sodium and potassium concentrations are associated with mortality.[12] Consistent with observations in other reptiles, creatinine is generally low in sea turtles and considered to be of little clinical importance; however, one study did conclude that creatinine may be of value for prognostication of survival for loggerhead turtles.[47] Sea turtle hematocrit values are generally in the high-20 to mid-30 percentiles. White blood cell counts of healthy sea turtles generally range from 2000 to 25,000 cells/µl ($2–25 \times 10^9$ cells/L) but are often <10,000 cells/µL (10×10^9 cells/L).

A number of acid-base and blood gas studies have been conducted for sea turtles. Recent studies generally use point-of-care analyzers, which perform analyses at 37°C. The majority of sea turtle physiology and clinical medicine papers utilize mathematical formulae to correct the data for the turtle's body temperature.[3,5,10,12,13,34,38,39] Analyzer-corrected values for pH and PCO_2 may be similar enough to the manually calculated values to be clinically useful.[39] In contrast, analyzer-corrected values for PO_2 do not agree well with manually calculated values.[39] Reptile hematocrit values calculated by automated analyzers are considered inaccurate compared with the manual packed call volume determinations; however, one study of green turtles reported good correlation of analyzer-generated hematocrit versus manual PCV.[39] Temperature-corrected venous pH in healthy sea turtles at 25°C is generally 7.4 to 7.6, varying somewhat among different studies. Acidosis (both respiratory and metabolic) may be seen in ill, injured, or anesthetized turtles.[5,12,16,34,38] High lactate concentrations have been described in hypothermic sea turtles and anesthetized sea turtles, presumably due to anaerobic metabolism caused by hypoventilation and reduced perfusion.[12,34]

DIAGNOSTIC IMAGING

Radiography, ultrasonography, MRI, CT, scintigraphy, and endoscopy are important tools for the assessment of sea turtles. The reader is referred to a number of primary studies that provide detailed anatomic descriptions using various diagnostic imaging modalities.[52–59] Commonly, imaging is needed for characterization and localization of pneumonia, bone lesions, central nervous system trauma, fish hook or other foreign body ingestion, pneumocoelom, etc. (Figs. 176.2 and 176.7). Unlike some other turtle species, the lung fields of sea turtles are generally well delineated on dorsoventral radiographs (see Figs. 176.2 and 176.7). Gastrointestinal contrast studies may be useful for sea turtles, with due consideration of their normally long gastrointestinal transit time of 2 to 3 weeks.[54] Ultrasound windows are generally limited to the cervical, axillary, and prefemoral spaces. Scintigraphy has been validated as a method for serial monitoring of bone lesions in Kemp's ridley turtles (Fig. 176.8).[59]

MICROBIOLOGIC AND MOLECULAR DIAGNOSTICS

As for other reptiles, bacterial and fungal cultures and antimicrobial susceptibility are important. When possible, cultures should be incubated at both 37° and 25°C in light of the typically lower than mammalian body temperature of sea turtles. Blood cultures should be considered and are often informative.[14] Molecular methods may be needed for definitive identification of *Mycobacteria* sp., fungi, and chelonian herpesviruses.[23,25–27]

THERAPEUTICS

Principles of therapy for sea turtles follow standard guidelines. Medications are often administered orally. Subcutaneous injections may be given in the lateral cervical and shoulder region or the prefemoral space. Intramuscular injections are most often given in the pectoral muscles. Intracoelomic (ICe) injections are delivered via the prefemoral space but appear to offer little benefit and greater risk compared with SC

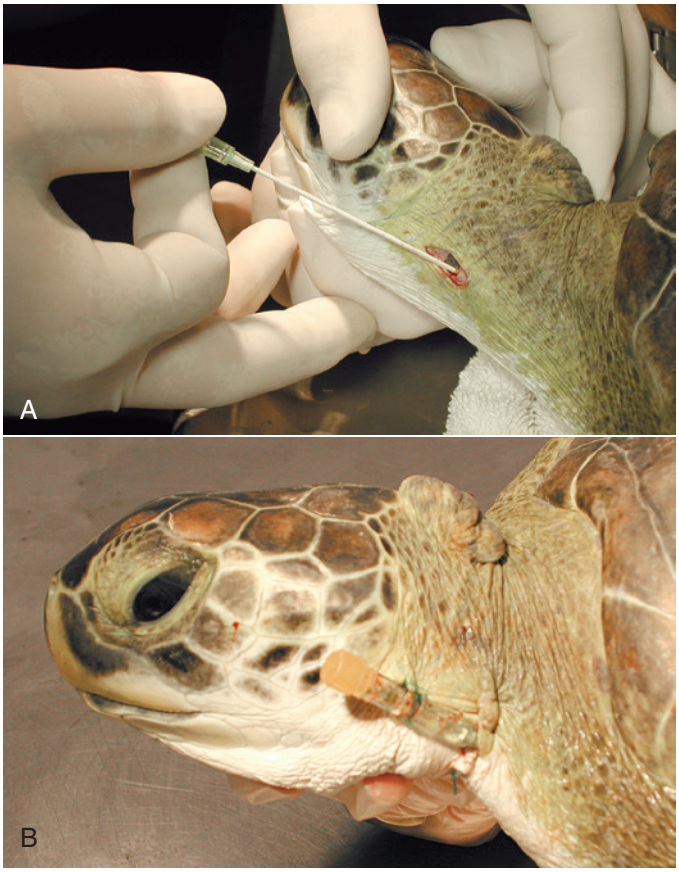

FIG 176.9 (A) A cutdown approach exposes a branch of the external jugular vein to place an IV catheter. (B) Catheter sutured in place. (Courtesy of Douglas R. Mader.)

injection. IV injections can be given in any of the locations discussed for venipuncture, with the jugular vein being preferred, and only with caution using the subcarapacial sinus (Innis CJ et al, Proc ARAV, 2010, pp 8–10). Similarly, given the proximity of the dorsal coccygeal vein and coccygeal spinal cord, caution is warranted. The author accidentally administered contrast media intrathecally, instead of intravenously, via the dorsal coccygeal approach in a Kemp's ridley turtle. Jugular vein catheterization, including central venous catheterization using ultrasound guidance or cut-down techniques, has been effective for sea turtles (Fig. 176.9).[60] Although intraosseous (IO) catheters have been used, they have not become routinely accepted and are unnecessary in most cases.

Bathing sea turtles in fresh water provides a simple form of fluid therapy. However, the author has occasionally observed overhydration, hyponatremia, and even death in several juvenile Kemp's ridley turtles exposed to freshwater. Ortiz et al. experimentally exposed four juvenile Kemp's ridley turtles to freshwater for 4 days and documented decreased plasma sodium, potassium, and chloride concentrations within 48 hours.[61] However, no apparent deleterious effects were noted, and most parameters returned to baseline within 48 hours after return to salt water. Clinical observations suggest that many sea turtle patients are tolerant of freshwater exposure, but close monitoring is essential.

Fluids are generally administered to sea turtles at a maintenance rate of 10 to 20 mL/kg/d SC, PO, ICe, or IV, but higher volumes may be needed for dehydrated patients. Crystalloid fluids commonly used in sea turtles include lactated ringer's solution (LRS), 0.45% saline with 2.5 % dextrose, Normosol-R (Hospira, Inc., Lake Forest, IL), and 0.9% saline. Various cocktails of these fluids are also frequently used. For example, many facilities use reptile ringer's solution made from two

VetBooks.ir

parts 0.45% saline with 2.5% dextrose and one part LRS. Camacho et al. reported positive effects in loggerhead turtles treated with a 1:1 ratio of 0.9% saline and LRS.[37] Clinically, LRS appears to be effective and safe for sea turtles.[38] Colloids, blood products, and total parenteral nutrition may be useful for severely hypoalbuminemic, anemic, and hypovolemic patients (Manire CA et al, 2014, Proc 45th Annu Conf Intern Assoc Aquat Anim Med).[62]

Sodium bicarbonate (1 mEq/kg) may be added to fluids to provide increased buffering capacity for acidotic turtles. Dextrose may be added up to concentrations of 2.5% for SC administration to hypoglycemic turtles. Camacho et al. effectively treated hypoglycemic loggerhead turtles and demonstrated significantly increased blood glucose concentration after intracoelomic injection of 0.45% saline and 2.5% dextrose at 20 mL/kg.[38] Calcium gluconate 50 to 100 mg/kg may be added to fluids for turtles with low blood ionized calcium concentrations. Potassium chloride may be added to fluids for hypokalemic turtles (e.g., 20 mEq/L). Severely hypoglycemic turtles may also benefit from IV injection of 50% dextrose (e.g., 0.5 mL/kg). If given as a direct IV bolus, some clinicians prefer to dilute dextrose to a 10% concentration to reduce the likelihood of perivascular tissue reaction. Alternatively, oral glucose supplements such as corn syrup (0.5 mL/kg) or honey may be effective in some cases.

Pharmacokinetic studies are available for ceftazidime, florfenicol, enrofloxacin, danofloxacin, marbofloxacin, oxytetracycline, clindamycin, and ticarcillin, with additional limited data from clinical cases for plasma concentrations of gentamicin, clarithromycin, and tobramycin (Innis C, Proc ARAV, 2014, p 68).[63–64,66–70] Florfenicol, clindamycin, and clarithromycin are expected to lack efficacy in sea turtles based on these studies (Innis C, Proc ARAV, 2014, p 68).[63] Limited clinical investigations indicate that the dosing regimens predicted from single-dose studies may result in unexpected plasma drug concentrations (Innis C, Proc ARAV, 2014, p 68). When possible, plasma drug concentration monitoring is recommended. For gram-positive bacterial infections, ampicillin 30 mg/kg SID appears to be useful.[15] For mycobacterial infections, combination drug therapy including two or three drugs may be needed (e.g., aminoglycoside, tetracycline, and quinolone). Recent positive outcomes and appropriate plasma concentrations have been seen with tobramycin use in Kemp's ridley sea turtles (5 mg/kg IM q3d) (Innis C, Proc ARAV, 2014, p 68).

Fungal infections are common in sea turtles, and deep internal fungal infections such as pneumonia carry a poor prognosis (Fig. 176.10).[24–26,71]

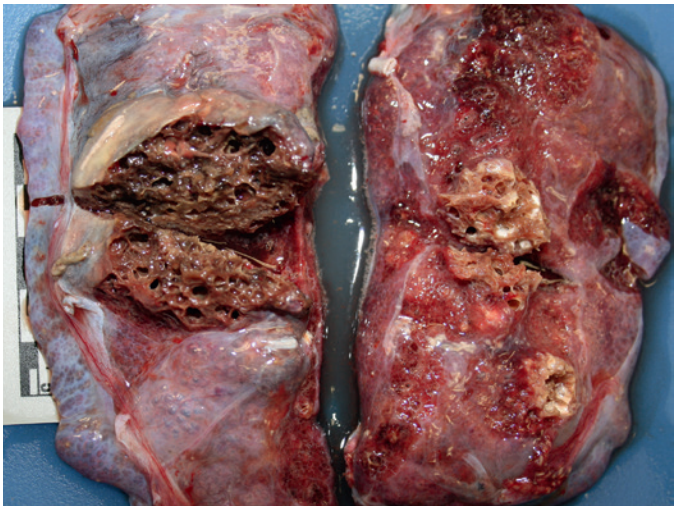

FIG 176.10 Lungs of a Kemp's ridley turtle (*Lepidochelys kempii*) after removal from the body during necropsy. The cut surfaces reveal severe consolidation and white plaques. Histopathologic evaluation revealed severe fungal pneumonia. (Courtesy of New England Aquarium.)

Localized superficial infections such as fungal dermal granulomas may be managed by debridement and topical and systemic therapy.[26] Nebulization of antifungal agents may also be considered. In Kemp's ridley turtles, itraconazole delivered orally at 5 mg/kg SID or 15 mg/kg q3d provided steady-state plasma itraconazole concentrations of approximately 1 µg/mL, which are expected to be efficacious against some filamentous fungi.[71] Pharmacokinetics of fluconazole have been determined in loggerhead turtles and Kemp's ridley turtles; however, comparison of the achieved plasma concentrations to MIC data for many sea turtle fungal isolates suggests that many of these isolates are fluconazole resistant.[24,26] The author has used terbinafine safely for many Kemp's ridley sea turtles at 20 mg/kg PO SID, with treatment durations often lasting several months, although plasma concentrations have not yet been evaluated.

Most clinicians elect to treat sea turtles for parasites only if clinically indicated or if the turtle is to be maintained in permanent captivity. Pharmacokinetic data for oral praziquantel in loggerhead turtles indicate a dosing scheme of 25 mg/kg given three times in 1 day at 3-hour intervals.[72] Anthelminthics such as oxfendazole, fenbendazole, albendazole, thiabendazole, pyrantel, and levamisole may be considered for treatment of nematode infections in sea turtles based on their general safety and efficacy in other reptiles. Metronidazole 50 mg/kg SID × 5 to 7 days may be an effective treatment for *Caryopsora* infections (Manire C, personal communication, 2016). Pelton et al. reported that trimethoprim-sulfa appeared ineffective in eliminating coccidia from a green turtle; however, the turtle was successfully treated with toltrazuril 10 mg/kg PO q7d × 3 (Pelton CA et al, Proc 44th Annu Conf Internat Assoc Aquat Anim Med, 2012, pp 81–82). Another green turtle was successfully treated for coccidia using ponazuril 20 mg/kg PO q7d × 4, but displayed transient anorexia and plasma biochemical abnormalities (Pelton CA et al, Proc 44th Annu Conf Internat Assoc Aquat Anim Med, 2012, pp 81–82).

Topical wound care products, vacuum-assisted wound therapy, acupuncture, and photobiomodulation therapy are routinely used for sea turtles. As for other species, sea turtles likely benefit from therapeutics that target the cardiorespiratory, gastrointestinal, and urinary tract and other organ systems when appropriate. Drugs such as atropine, epinephrine, doxapram, metoclopramide, cisapride, enalapril, furosemide, and others are used with clinical discretion despite a lack of sea turtle–specific data. Furosemide was successfully used for management of brevetoxicosis in loggerhead turtles.[21] Epoetin-α administered at 100 U/kg IM three times weekly in conjunction with iron supplementation increased packed cell volume and shortened treatment time for anemic turtles (Perry SM et al, Proc ExoticsCon, 2015, p 531).

Detailed discussion of analgesia principles and options for reptiles is provided elsewhere (see Chapter 50). Most clinicians utilize nonsteroidal antiinflammatory drugs (NSAIDs) and opiates for sea turtles despite limited pharmacokinetic data and absence of pharmacodynamic data. There is one report of gastrointestinal bleeding in sea turtles that may have been caused by flunixin,[16] but the author has used it short-term without incident in several patients. Meloxicam has become popular for sea turtles, but pharmacokinetic data indicate low plasma concentrations and short half-life.[74] At this time, the choice of NSAID, dose, and dosing interval remain at clinical discretion. Tramadol pharmacokinetics in loggerhead turtles suggest a dosing regimen of 5 to 10 mg/kg PO q48 to 72 hours.[75]

MANAGEMENT OF OILED TURTLES

When treating oiled turtles, human handlers must wear personal protective equipment. External oil can be removed by bathing in dishwashing liquid. Oil is physically removed from the eyes and oral cavity using cotton swabs, gauze, and food-grade oil (e.g., mayonnaise or cod liver oil). Such oils and activated charcoal may also be delivered by tube feeding to facilitate passage and limit absorption of ingested oil.

VetBooks.ir

MANAGEMENT OF BUOYANCY DISORDERS

Treatment and correction of buoyancy problems involves identification of the etiology.[76] Removal of excessive gas by coelomocentesis is successful in some cases. Placement of the animal in freshwater may help because freshwater-specific gravity is lower than that of seawater. Buoyancy problems secondary to spinal trauma carry a poor prognosis, and euthanasia may be warranted. Lung lacerations may be repaired coelioscopically (Walsh MT et al, Proc ARAV, 2014, p 36).

EUTHANASIA

In general, euthanasia of sea turtles is reserved for cases with complete blindness, multiple missing limbs, permanent buoyancy anomalies, paralysis that prevents effective swimming, or to end the suffering of a moribund patient. Due to the endangered status of sea turtles, clinicians must obtain permission from relevant legal authorities. Euthanasia methods should follow modern accepted guidelines for euthanasia methods for reptiles, such as the American Veterinary Medical Association Guidelines for the Euthanasia of Animals. Multimodal euthanasia is recommended (see also Chapter 47).

ANESTHESIA

Anesthesia can be induced with propofol (3–10 mg/kg IV). Dexmedetomidine (0.025–0.1 mg/kg IV) combined with ketamine (2.5–10 mg/kg IV) is also safe and effective, and it is useful for larger turtles due to its relatively low volume of delivery.[34,77–80] Midazolam has been used to sedate leatherback hatchlings at 2 to 3 mg/kg IV and has been used in combination with medetomidine, ketamine, and butorphanol in loggerhead turtles.[79,80] Alfaxalone 3 to 10 mg/kg IV is effective for loggerhead turtles.[81] Tiletamine/zolazepam (3 mg/kg IV or IM) has been recommended in the past, but further observations suggest that recovery times may be unacceptably long (Mader D, personal communication, 2017).[16] Moon and Stabenau reported conscious direct orotracheal intubation and isoflurane induction in Kemp's ridley turtles, and Chittick et al. maintained loggerhead turtles with sevoflurane (0.5%–2.5%) in oxygen.[78,82] Intermittent positive pressure ventilation is required during general anesthesia.

Postanesthetic recovery may take minutes to hours depending on choice of drugs, length of the procedure, body temperature, and individual variation. Sea turtles commonly go through several episodes of apparent recovery before consciousness is completely regained. During prolonged recovery, physiological assessment (e.g., blood gas analysis) is warranted. Reversal drugs should be given if available, and other supportive drugs such as epinephrine, atropine, and doxapram should be considered. Turtles are often kept out of the water and not returned to their tanks for at least 24 hours after anesthetic recovery, although cautious earlier introductions are acceptable for fully recovered individuals.

SURGERY

Common surgical procedures include shell and soft-tissue laceration repair, long bone fracture repair, amputation, enucleation, FP excision, hook removal, and coeliotomy.[83–85] The relatively large prefemoral space allows for effective coeliotomy, exteriorization of portions of the digestive tract, and access to many other viscera, including the reproductive tract, kidneys, liver, bladder, and lungs.[83,85] Access to the esophagus and stomach via a supraplastron approach or axillary approach may be required for hook removal depending on hook location (Fig. 176.11).[84,85] Coelioscopic or coelioscopic-assisted techniques are used routinely (Walsh MT et al, Proc ARAV, 2014, p 36).

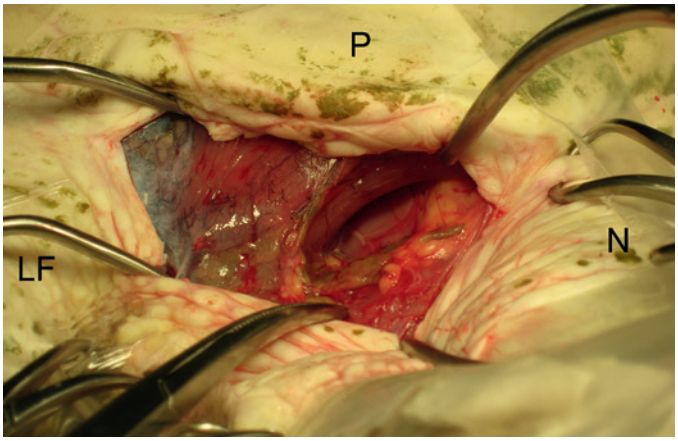

FIG 176.11 Supraplastron approach for access to the distal esophagus during hook removal from a Kemp's ridley turtle (*Lepidochelys kempii*). The patient is in dorsal recumbency, and the incision is held open with retractors. LF, Cranial aspect of left forelimb; N, caudoventral neck; P, plastron (gular scute). (Courtesy of New England Aquarium.)

Hooks and line occasionally pass through a sea turtle's digestive system over time without causing obvious problems, but more commonly they become impaled along the digestive tract warranting surgical removal.[1] Clinicians must use judgment in determining whether conservative monitoring or surgical intervention is warranted. Several approaches to hook removal have been described.[1,53] Hooks located near the heart base are especially dangerous and difficult to remove due to the risk of trauma to the bronchi, great vessels, and heart (see Fig. 174.2). Fatal hemorrhage has sometimes occurred during such surgeries.

Entanglement in fishing lines, nets, and trap lines is common (see Fig. 174.1). The offending material needs to be carefully removed, and the tissue assessed for viability. Sometimes viability is initially unclear, thus patience is needed to monitor healing and viability over time. Amputation is considered as needed. The decision to release a turtle after amputation is dependent on clinical outcome, expected ability to survive in the wild, and discussion with regulatory agencies. In general, release of a turtle with a single amputation is expected, whereas multiple amputations may justify permanent captivity or euthanasia. One exception may be leatherback turtles, for which single forelimb amputation may not be viable but additional study is warranted.

CO_2 laser excision appears to be an effective method for controlling FP.[16] Clinicians should recall herpes latency and understand that surgical excision does not eliminate infection, thus future relapses are possible.

Govett et al. evaluated tissue response to four different absorbable skin sutures in loggerhead turtles.[86] Histologically, polyglactin 910 produced the greatest tissue reaction, whereas poliglecaprone 25 and polyglyconate caused the least tissue reaction. In general, skin sutures need to be left in place for a minimum of 4 to 6 weeks.

MANAGEMENT OF HYPOTHERMIC (COLD-STUNNED) TURTLES

Hypothermic events that affect sea turtles may be classified as acute or chronic. Acute events often occur in winter in the southern United States and are of short duration.[4] These events may involve hundreds or thousands of turtles in a short period of time. Many acutely hypothermic turtles improve quickly with rewarming and supportive care and can be released as soon as appropriate environmental conditions exist.[10] Chronic hypothermic events typically occur in higher latitudes

VetBooks.ir

during late autumn and early winter when turtles fail to move to warmer zones. In such events, turtles may be affected by cold for days to weeks before eventual stranding and are thus often in poor physical and physiological condition. Chronically hypothermic turtles are commonly affected by acidosis, respiratory and cardiac failure, decreased renal function, pneumonia, sepsis, and other pathological processes.[12–17,48]

Chronically hypothermic turtles should initially be kept within 2°C to 3°C (3°F–5°F) of their core body temperature.[16] Animals are placed on towels or padding in a climate-controlled space that increases their core temperature to 13°C (55°C) over the first 24 hours. Most animals are treated with fluid therapy. In animals with poor cardiac contractility, as determined by echocardiography and severe bradycardia, atropine (0.05–0.2 mg/kg IV) or epinephrine (0.1 mg/kg IM or IV) may be effective. Although its use has fallen from favor in domestic animal medicine because it increases CNS oxygen demand, doxapram (5 mg/kg) may be effective in stimulating ventilation when administered intravenously in apneic turtles. Cold-stunned turtles that require mechanical ventilation carry a poor prognosis, but if caseload and resources permit, ventilation may save some individuals.[87]

Hypothermic turtles should be provided a shallow freshwater bath adjusted to their core body temperature within the first 24 hours. Stronger turtles may be given access to shallow seawater within 24 to 48 hours, and weaker turtles continue with shallow fresh or brackish water bathing until their hydration and strength have improved.

After the first day of care, patient temperature is raised 3°C (5°F) per day until the temperature reaches 25°C (78°F). Chronically hypothermic turtles may require months of care using the diagnostic and therapeutic methods described previously. Hypothermic turtles are generally not fed until they are able to swim on their own, and their hydration and electrolytes have returned to within normal limits. Body condition, attitude, and activity level should be carefully evaluated before assist-feeding is instituted. In many cases, turtles begin feeding in several weeks voluntarily. Anorectic turtles may be managed with vitamin B complex, tube feeding, thyroxine, or other appetite stimulants (New England Aquarium, unpublished data). The outcome for hypothermic turtles is generally good, with 50% to 80% of turtles successfully rehabilitated and released.[15,16]

LEATHERBACK TURTLE EVALUATION AND CARE

The largest extant species of turtle, the oceanic leatherback turtle, is a unique patient. Adult leatherbacks are often over 150 cm in curved carapace length and can weigh several hundred kilograms. There are approximately eight documented cases of leatherback rehabilitation attempts, some of which are only documented in the popular press and none of which are thoroughly described in the peer-reviewed literature (Fig. 176.12) (Innis CJ et al, Proc 47th Annu Conf Intern Assoc Aquat Anim Med, 2013, pp 77–78).[60] Common reasons for leatherback stranding include boat strike, entanglement, or postentanglement injuries. A body of data has been generated on physical examination, clinicopathologic, microbiologic, toxicologic, parasitologic, and pathologic findings for this species (Innis CJ et al, Proc 47th Annu Conf Intern Assoc Aquat Anim Med, 2013, pp 77–78).[3,34,43,44,46,60,89–91] Entangled and stranded leatherbacks show evidence of physiological stress and negative energy balance.[3,89] Methods for field anesthesia of adult and hatchling leatherbacks have been developed.[34,79] Solitary large intestinal diverticulitis and adrenal coccidiosis are interesting, highly prevalent lesions in this species that appear to be unrelated to the cause of death (e.g., seen in turtles killed by boat strike or entanglement).[90,91]

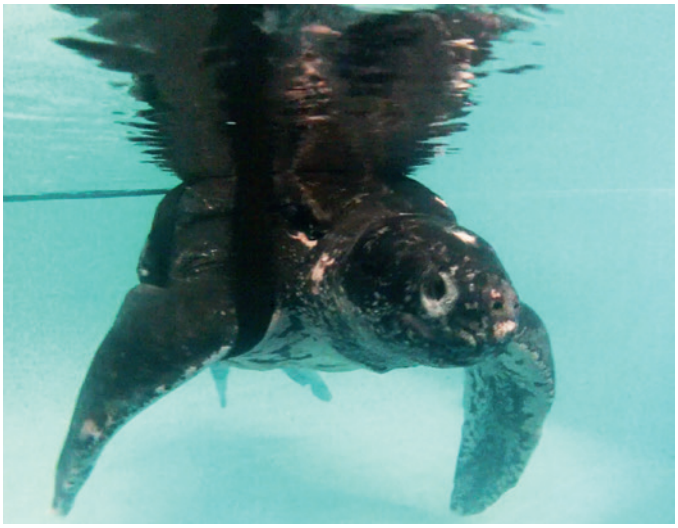

FIG 176.12 A hospitalized adult male leatherback turtle (*Dermochelys coriacea*). A harness loosely surrounds the forelimbs to prevent the turtle from colliding with the tank walls. (Courtesy of New England Aquarium.)

Among the few hospitalized leatherbacks, success seems to be greatest when the rehabilitation period is minimized and release is expedited (e.g., several days or less). Supportive care is provided, and as soon as possible the turtle is released at sea. In the only case where postrelease outcome was monitored, a male leatherback traveled 5600 km in 97 days, with diving patterns comparable to healthy leatherbacks tracked in the same region (Innis CJ et al, Proc 47th Annu Conf Intern Assoc Aquat Anim Med, 2013, pp 77–78).

TRANSPORT AND RELEASE

A recent study indicated that Kemp's ridley turtles transported by vehicle for 13 or 26 hours demonstrated a significant physiological stress response, including increased plasma corticosterone and blood glucose proportional to the duration of transport. However, their general physiological status (e.g., heart rate, respiratory rate, electrolytes, blood gases) remained stable.[36] Methods to reduce stress during transport should be employed (e.g., padded, quiet, dark crates) and are worthy of further study. The location at which sea turtles are released is usually determined by governing authorities with assistance from biologists and veterinarians.

ACKNOWLEDGMENTS

The staff and volunteers of Massachusetts Audubon Wellfleet Bay Sanctuary and the New England Aquarium provided access and care for many of the turtles on which this chapter is based.

Commercial Reptile Farming

Walter Mustin and Javier G. Nevarez

Most people think of cattle, poultry, and swine as agricultural farming, but there is a lesser known agricultural sector, reptile farming. Specifically, this chapter will provide information about commercial reptile farms that produce reptiles as a source of food and textiles. Reptiles are farmed on six continents worldwide and make an appreciable contribution to human well-being through food security and poverty alleviation. In addition, it provides an avenue for the protection of reptile species. Annual production of Chinese softshell turtles alone totaled 344,800 tonnes in 2014.[1] World trade of crocodilian skins exceeded 1.8 million in 2013.[2] The exports of American alligator (*Alligator mississippiensis*) skins from the United States in 2013 numbered 481,341 with an average per skin value of US$241 resulting in an economic value of US$116m.[2] The economic impact of all reptile farms worldwide is not known, but it can be estimated at hundreds of millions of dollars.[2] The benefits of these operations go well beyond the economic impact. These farms also serve as an important source of food in developing countries. In 2013 exports of crocodilian meat were approximately 550 tonnes.[2] These values are only for reported exports and do not take into account local consumption of crocodilian meat, which has a direct impact on the nutrition of local families.

When regulations and enforcement are in place, these farms are also an integral part of creating economic incentives to help protect threatened and endangered reptile species. Engaging local communities is a critical part of the conservation of any species. When those communities benefit economically from conservation, programs are more likely to be successful. Self-sustaining farms maintaining breeding adults and ranching operations where eggs and/or reptiles are collected from the wild and reared in captivity are two systems to commercially farm crocodilians, Caribbean green sea turtles (*Chelonia mydas*), and fresh water chelonians. Many of these species are protected under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Therefore their commercial trade across international borders of participating countries is tightly regulated. Captive-bred green sea turtle mariculture and crocodilian farming demonstrate renewable programs with benefits to man and positive conservation implications for endangered and threatened species. Veterinarians working with these species in commercial operations should ensure that animals are maintained according to proper rules and regulations within the country. Furthermore they should strive to improve animal welfare by applying recommendations from the Farm Animal Welfare Committee (e.g., the five freedoms) or the AVMA Animal Welfare Principles.[3,4]

MARICULTURE OF GREEN SEA TURTLES AT THE CAYMAN TURTLE CONSERVATION AND EDUCATION CENTRE

History/Background Information

The Cayman Turtle Conservation and Education Centre Ltd. (CTCEC), first established in 1968 as Mariculture Ltd., and later purchased by the Cayman Islands Government and renamed The Cayman Turtle Farm, Ltd., now operates as a self-sustaining green sea turtle husbandry and research centre where no eggs or adults are removed from the wild. Captive breeders, second-generation offspring from wild stock and eggs legally collected from 1968 to 1978,[5,6] lay their eggs on an artificial beach, part of the 9.3-hectare production, research, and tourist facility. Eggs are collected and incubated in a purpose-built temperature-controlled hatchery for approximately 60 days, after which the hatchlings are transferred to tanks and grown out for eventual release, processing, or for use as breeders. The Centre produces a legal source of turtle meat for widespread local consumption, maintaining cultural culinary practices while providing a deterrent to illegal take.[7] In addition, scientists invited to the facility over a 40-year period have contributed to research on sea turtle health, genetics, sex determination, reproduction, physiology, imprinting, and migratory behavior—all in a unique environment where large numbers of green sea turtles of known ages can be studied in a controlled setting.

From the Centre's inception in 1968, Centre researchers have confronted and solved husbandry problems relating to the reproduction, culture, and health of green sea turtles starting with the initial transfer and successful incubation of eggs obtained from Costa Rica in 1968.[6,8] In 1980 the Centre held and successfully pioneered breeding protocols for the highly endangered Kemp's ridley turtle (*Lepidochelys kempii*) (Wood et al, unpublished data). This research continues to enrich our understanding of sea turtle biology and conservation.

Laws and Regulations

All species of marine turtles are protected under Caymanian law, which includes the *National Conservation Law, 2013,* and the *Marine Conservation (Turtle Protection) Regulations (2008 Revision)*. Under this legislation, administered by the Ministry of Tourism, Environment, Development and Commerce, the capture, possession, trade, and export of protected species is prohibited unless authorized by permit. This applies as well to turtles originating from the CTCEC. In 1973 the US *Endangered Species Act* placed the green sea turtle and other sea turtles under

protection, making it illegal to catch, sell, import or own any part of the listed species. CITES came into effect in 1977 with green sea turtles listed on Appendix II and later transferred from Appendix II to Appendix I (1977). CITES regulations are implemented by the Cayman Islands through the Cayman *Endangered Species Protection and Propagation Law of 1978* and subsequently through the *Endangered Species (Trade and Transport) Law, 2004.*

Husbandry

Tanks. Turtles are kept in 0.5 to 166 m^3 tanks deep enough for them to submerge completely and exhibit normal swimming behavior. Breeders are kept in a 2837 m^3 saltwater pond. Tank materials used include concrete and fiberglass with smooth, nonabrasive surfaces that prevent injury to the turtles and allow for easy cleaning.

Water Supply. A continuous flow-through system utilizes high-volume electric axle flow pumps (FPI Pumps, Pompano, FL) to deliver 5000 gpm (18.9 m^3pm) of fresh, unfiltered seawater to turtles held in concrete tanks and the breeder pond (Fig. 177.1). Back-up diesel pumps provide redundancy during power outages (see Fig. 177.1)

The water distribution design ensures that fresh seawater flows directly from the ocean to each tank and returns to the ocean without passing through other tanks, preventing the transfer of waste water and minimizing the potential transfer of pathogens between tanks (Fig. 177.2). Depth ranges from 0.7 to 5 meters depending on the size of turtles held. Tank water turnover rates range from 11 to 150 minutes (Table 177.1).

Stocking Density. Specific tank densities are a function of turtle age, size, tank area, depth, volume, water temperature, and flow rates. Tanks full of water allow the turtles, like fish, three-dimensional movement. In contrast, drained tanks confine turtles to a given tank's two-dimensional surface area. Percent coverage (% coverage) is a term the Centre uses to describe the percentage of turtles combined area relative to the tank surface area, where % coverage = (number of turtles × average turtle area/tank area) × 100. Drained tanks where turtles (without stacking or touching each other) completely cover the tank bottom are examples

TABLE 177.1 Tank Size, Volume, and Water Turnover

Tank	Vol (m^3)	Flow Rate (L/min)	Water Turnover (min)
Hatchling tank (102 cm × 165 cm)	0.5	45	11
Hatchling tank (152 cm × 178 cm)	1.4	45	30
Hatchling tank (165 cm × 213 cm)	1.9	45	42
Grow-out tank (9 m × 9 m)	61	757	81
Grow-out tank (15 m × 15 m)	166	1136	146
Breeder pond* (0.2165 ha)	2837	18927	150

*With even slope for 3 meters up to beach.

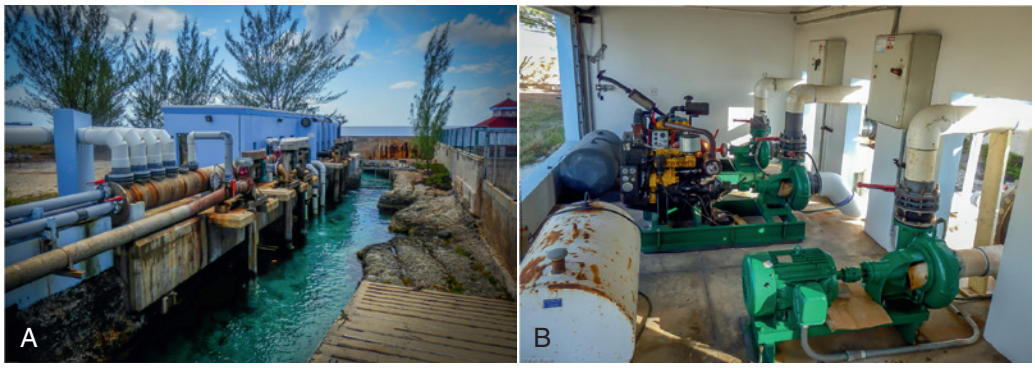

FIG 177.1 (A) Axile flow pumps deliver 5000 gpm (18.9 m^3pm) each of fresh, unfiltered seawater to turtles held in concrete tanks and the breeder pond. (B) Back-up diesel pumps provide redundancy during power outages.

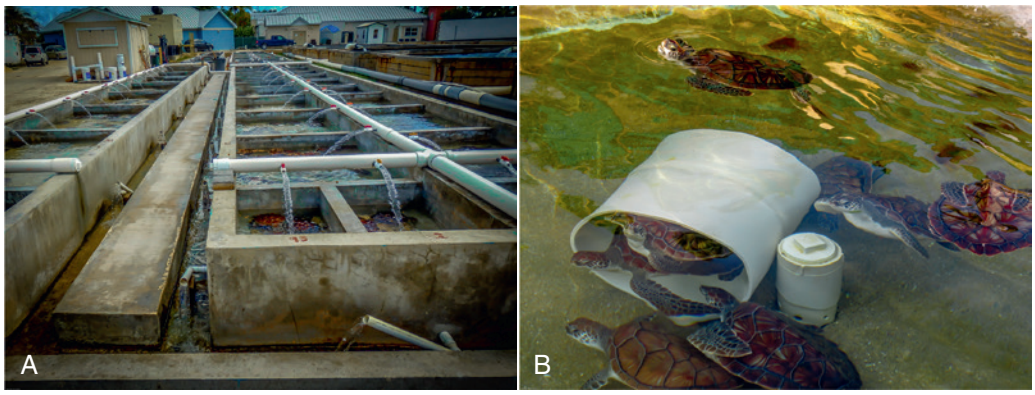

FIG 177.2 (A) The water distribution design ensures that fresh seawater flows directly from the ocean to each tank and returns to the ocean without passing through other tanks. Submerged containers provide enrichment, cover, and shade. (B) Submerged containers such as PVC pipe coupling or plastic flowerpots are effective structures that provide cover, shade, and refuge.

of 100% coverage. The CTCEC hatchling and production tank densities are such that coverage is limited to a maximum of 50%. Turtles are stocked in tanks initially at low percentage coverage. As they grow and their coverage approaches 50%, either their numbers are reduced or they are moved to a larger tank. Table 177.2 shows suggested hatchling tank density schedules that factor in % coverage and other criteria. Table 177.3 shows grow-out tank density schedule for yearling to harvest-size turtles of 5 years.

TABLE 177.2 Grow-Out Tank Density Schedule

Tank Size	Age of Stock	No. of Stock Range
9 m × 9 m (61 m^3)	Yearlings	300–800
15 m × 15 m (166 m^3)	2 years	500–800
15 m × 15 m (166 m^3)	3 years	360–500
15 m × 15 m (166 m^3)	4 years	260–360
15 m × 15 m (166 m^3)	5 years	200–260

60	36.10	South fresh

Diet. A variety of nutritionally complete grain-based commercial extruded floating fish feeds from 0.3 to 1.5 cm diameter are used at CTCEC to grow turtles from hatchlings to breeder size (Table 177.4). Utilizing these diets, sexual maturity of captive green turtles occurs in less than 10 years.

Rations are determined based on a percentage of body weight and age. Early growth is exponential, with 5-year-olds averaging 36 kg (see Table 177.3). Qualitative and quantitative amino acid requirements for hatchling green turtles have been determined.[9] Hatchlings are started on 40% protein diets (Triton 4010 Transition, Cargill, MN). Yearlings and adults receive 36% protein diets (Southfresh Feeds, Demopolis, AL). Decreasing protein levels reflect the natural transition from carnivorous to herbivorous wild diets of green sea turtles. Breeders receive a custom 36% protein diet with added omega-3 fatty acids. Feeding frequency varies from 6 to 7 times/day for hatchlings to 3 times daily for juveniles and adults. Turtles fed too infrequently or an inadequate amount can become aggressive and bite one another. Resulting lesions can become a target for further aggression. However, overfeeding significantly contributes to decreased water quality from uneaten food. Hatchlings are sampled and weighed monthly to adjust rations relative to established growth curves.

Enrichment, Shade, and Cover. Environmental enrichment effectively reduces stereotypic pattern swimming and resting behaviors while increasing random swimming and focused behavior in sea turtles.[10] Floating and submerged enrichment devices are employed at CTCEC to add complexity to the tank environment. Submerged containers such as PVC pipe coupling or plastic flowerpots are effective structures that provide cover, shade, and refuge (see Fig. 177.2). Shade cloths deployed above the tanks provide a refuge from direct sun exposure (Fig. 177.3).

Hygiene and Preventative Medicine. Successful hatchling husbandry requires regular and sustained removal of uneaten food, feces, and organic material from the water and tank surfaces. Hatchling tanks are drained daily, with the sides and floor scrubbed with a brush, and refilled. Dilute chlorine solutions (100 ppm) are used on tanks weekly after turtles have been temporarily removed from the tanks. Tanks are thoroughly rinsed with fresh seawater before restocking. Excess carapace algal growth can be controlled by scrubbing lightly with 3M Scotch Bright pads (St. Paul, MN) combined with a 15-minute bath in a Halamid Aqua (Chloramine T trihydrate) (Ferndale, WA) solution at 2000 ppm. All turtles 18 months old and older are vaccinated against *Clostridium botulinum* using Botumink (United Vaccines, Inc., Madison, WI), containing *Clostridium botulinum* type C toxoid. A withdrawal period of 60 days precedes harvest. External lesions are routinely treated topically using a 1:1 mixture of petroleum jelly and 1% silver sulfadiazine cream (Dr. Reddy's Laboratories, Shreveport, LA). Necropsies are performed routinely. Animals with clinical signs are isolated in a quarantine area for further tests, observation, and, if needed, treatment. Turtles are randomly sampled for health checks as part of a preventative medicine program.

Breeding Program

Breeding occurs in a communal breeder pond where breeders are housed at a ratio of five females to every male. Females lay multiple clutches on an artificial beach from April to September, with a mean nesting interval of 11 days (see Fig. 177.3). Multiple paternity has been found in 100% of CTCEC clutches.[11] Eggs are transferred from the artificial beach to the hatchery (at or within 12 hours of oviposition) and are packed in (38 × 24 × 30 cm) Styrofoam boxes, sandwiched between layers of sand and light fabric in a way that allow the fabric to be raised for periodic egg inspection (Fig. 177.4). Eggs are incubated an average of 68 days. Upon emergence, hatchlings are transferred to plastic trays (62 cm × 42 cm × 15 cm) until such time that their external yolks are fully absorbed and their plastrons have closed (1–10 days). They are then transferred to outdoor purpose-built concrete hatchery tanks.

Slaughter and Processing

Harvest-sized turtles (mean of 45 kg) are euthanized by captive bolt followed by exsanguination and are processed in a purpose-built, government-inspected abattoir. Dress out of approximately 50% yields a variety of products, including turtle steak, stew, menavalins, and bone, which are sold fresh locally to individuals and restaurants.[7]

FIG 177.4 Eggs are transferred from the artificial beach to the hatchery (at or within 12 hours of oviposition) and are packed in sand-filled Styrofoam boxes (38 × 24 × 30 cm).

COMMERCIAL REPTILE FARMING OF CROCODILIANS

History and Background

Of the 23 species of crocodilians, the skin and/or meat of 14 species are currently traded internationally (Table 177.5).[12] In the commercial trade, crocodilian skins are traditionally divided as classic (*Alligator mississippiensis*, *C. porosus*, *C., novaeguineea*, *C. niloticus*) and caiman skins.[12] In 2013, there were 878,332 classic skins and 1,010,302 caiman skins in the commercial trade.[2] Although the total commercial value of crocodilian skins is unknown, it can be estimated at over US$200m per year. In addition to skins, crocodilian meat, teeth, and other body parts are also commercially traded, providing additional value.

Twelve species are captive bred in commercial farms (i.e., egg production from captive animals) or ranches, whereas the other two species, *Caiman yacare* in Paraguay and *Melanosuchus niger* in Brazil, are collected through wild harvest only (see Table 177.5).[12] Ranching operations

collect eggs, live hatchlings, or juveniles from the wild with the subsequent growth of the animals in captivity until they reach the market size for the species. All commercially traded species are listed on Appendix I or II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Countries that participate in CITES must demonstrate that commercial trade has no detrimental effect on the wild populations of the species. As part of CITES regulations, all commercial crocodilian skins must be tagged upon skinning of the animal (Fig. 177.5). Some species have different CITES classifications in different countries. Trade of wild-caught CITES I crocodilians is not allowed, but CITES I species are still commercially traded if they are reared in farming or ranching operations only. This sustainable use of crocodilians has contributed to the protection and preservation of various species around the world. In addition it has led to a dominance of legal trade and minimized illegal trade of crocodilian species. In addition to CITES regulations, each country has their own regulatory control over the farming and ranching of their native crocodilian species. In the United States the regulatory control is at the state level whereas in other countries it falls under the federal government or its equivalent. Some countries have produced best management practices documents to assist in the oversight and regulation of their crocodilian operations (Table 177.6).[12–18] Some of these documents also provide specifics as to the welfare and management of the animals.

FIG 177.5 Example of identification tags attached through the distal part of the tail skin. The pink tag is a CITES tag and the yellow is attached by the tannery for additional control. The number on each tag has been partially obscured for confidentiality purposes.

ALLIGATORS

In the United States, the American alligator is the only crocodilian species in commercial trade. The American alligator population was at critically low levels during the 1960s, but federal and state conservation programs designed to protect wild populations through a 10-year ban on wild harvest brought their population numbers back to sustainable levels. Consequently, captive farming and ranching operations developed.

Farming and ranching operations can be found in Louisiana, Florida, Texas, Georgia, and other southern states where alligators occur naturally. The Louisiana Alligator Industry (LAI) stands as one of the most successful examples of viable, sustainable use of wild species in commercial trade. The Louisiana Department of Wildlife and Fisheries (LDWF) regulates the state's alligator management program. An alligator ranching program was established in 1986. The success of this program can be further documented by an increase in exports in parallel with an increase in the wild populations. In 1986 the United States exported 31,000 alligator skins.[2] This pales in comparison to the 481,304 skins exported in 2013, one of the highest production years for the industry.[2] Today the population of wild alligators is estimated at well over 1 million animals, a 90% increase from the 1960s estimates.

As of 2016 there were 56 alligator ranches that produced approximately 300,000 to 350,000 alligators every year valued at over US $50 million for the hides alone (Elsey R, personal communication, 2016). Under this program, the LDWF granted egg harvest permits to licensed alligator ranchers in the state. Egg collection takes place between June and August. Egg numbers can range from 20 to 60 per nest. Once eggs are collected, they are taken to a private facility for incubation. Eggs collected from the wild are at different stages of incubation, so once in the alligator ranch it may take anywhere from a few weeks to months for the eggs to hatch depending on the time of collection. The total incubation period is approximately 65 days. The majority of alligator ranchers do not attempt to select for a specific sex, which is determined

TABLE 177.6 Currently Existing Documents That Address Codes of Practice and Best Management Recommendations for Crocodilians

by incubation temperature. Once alligators hatch, they are placed in indoor buildings where they are raised until the time of slaughter at 10 to 12 months. Market-size alligators average 36 inches in length (tip of snout to tip of the tail). The alligator hides are then sold to dealers and tanners for further processing. The Louisiana program is the largest supplier of alligator hides in the world. Louisiana alligator hides will eventually end up in high-end retail products such as watch bands, shoes, purses, and other fashion items. These products have the benefit of coming from a natural renewable resource that is environmentally friendly and helps contribute to the wild populations of alligators. In addition to the hide, alligator meat is sold to processing plants and distributed to restaurants, supermarkets, and specialty stores.

The conservation aspect of the Louisiana alligator program comes from the 12% of alligators in each facility (based on the yearly egg hatch) that is destined for release back to their natural habitat each year. This percent of alligators to be released was determined based on an expected survival of the eggs that hatch in the wild and amounts to approximately 40,000 to 50,000 juvenile alligators being released back to the wild every year (LDWF annual report, 2015).[19] Alligators are identified using toe tags and a tail notch before release by personnel from LDWF. Health surveillance of alligators has been performed in alligators destined for release. Veterinary evaluation of disease occurrences in ranches also allows for determination of any potential pathogens of concern for wild populations. This program has been extremely successful and is a model for other crocodilian species around the world.

Husbandry

Housing. Currently the majority of alligators are housed indoors (Fig. 177.6) in fiberglass tubs or concrete pens with a plastic liner to protect their skin. Some facilities have started utilizing custom-built plastic pens similar to those encountered in fish aquaculture. Currently, there are no specific regulations for enclosure size/type or environmental requirements (e.g., air quality, photoperiod) for farmed alligators. Farmers often experiment to evaluate new options for housing of captive alligators.

Water Supply. The water in alligator ranches can be from well, city, or surface sources (i.e., bayous). Facilities have either insulated storage tanks or an on-demand heating system (Fig. 177.7) in order to supply water at the appropriate temperature of 85° to 90°F (29°–32°C). Currently there are no established water quality parameters for alligators similar to what is found in fisheries. Additional research is needed in this area to determine water quality parameters for optimum health and growth.

Stocking Density. Currently there are no specific regulations for enclosure size for alligators. Guidelines for stocking density of alligators are reported as 1 square foot per animal up to 24 inches (61 cm), 3 square feet for those 24 to 48 inches (61–122 cm), and one additional square foot (929 cm^2) for every additional 6 inches (15 cm) beyond 48 inches in length.[18] These recommendations are based on land square footage and do not take into account water volume/depth. Currently most ranches use 18 to 20 inches of water depth within varied pen dimensions. Therefore designing stocking density recommendations based on water volume would be more appropriate. Water levels are increased as the animals grow in order to increase the volume and adjust for their body size. Lower stocking densities have been associated with better growth and lower corticosterone levels.[20] This is an area

FIG 177.6 (A) Building used in the ranching operation of American alligators (*Alligator mississippiensis*) in Louisiana. (B) Indoor pen housing hatchling alligators. Tables are provided for haul out and feeding area. (A, From Mitchell M, Tully T. *Manual of Exotic Pet Practice*. St. Louis: WB Saunders; 2009, Figure 6.2.; B, courtesy of Javier G. Nevarez.)

VetBooks.ir

that requires further research to determine what stocking densities provide the ideal combination of efficient growth and optimal health.

Diet. Different feeding regimens and specific nutritional requirements for alligators have been evaluated (Coulson et al, Proc Louisiana Aquaculture Conf, 1992, pp 48–51).[21,22,24,25] Ongoing alligator nutrition research is being performed by the Louisiana State University Agricultural Center.There are commercial, extruded pelletized diets available for alligators. These diets are generally comprised of 45% to 56% protein, less than 11% fat, and fiber content less than 3%. Typically hatchlings are fed the higher protein diet for the first 3 months, and then lower protein diets are used. The majority of the operations will feed a commercial diet exclusively, whereas others mix in fish or chicken. Wooden tables are sometimes placed in the pens and used as a feeding surface, whereas others place the food directly in the water. There is no standardized feeding rate. Some operations feed once per day whereas others feed twice daily. Alligators are typically fed 6 days per week.

Hygiene. There is a wide range of cleaning protocols used across operations. However, in general terms there are two main systems: a fill and flush system and a continuous flow system. In the first system, the pens are drained, flushed, and refilled every 2 to 3 days depending on the age class. In the latter system, there is a continuous but often variable and unknown flow of water into the pens. These pens are only emptied and fully flushed once to twice weekly. When pens are emptied, the walls and floors should be thoroughly scrubbed to reduce the biofilm that forms on the plastic liners. The large amount of organic matter produced by alligators compared with fish precludes the effective use of currently available filtration methods such as bead and sand filters. The development of adequate filtration methods or the use of naturally filtered effluent waters is an area that requires further research. Land application was found to be a viable approach for handling wastewater from alligator farms.[26] Air quality is also an important consideration. Some farms have implemented the use of fans to circulate air through the pens (Fig. 177.8) to improve this aspect, but this is an area that requires further research to determine the best equipment and techniques for this purpose. Finally, implementation of biosecurity protocols such as controlled entry, use of footbaths, and so on, is critical for the control of diseases (Fig. 177.9).

Preventive Medicine. There is currently a WNV vaccine specifically manufactured for use in alligators (Boehringer Ingelheim Vetmedica, Inc., St. Joseph, MO). It requires two injections administered intramuscularly 3 to 4 weeks apart, with a single yearly booster thereafter. This is the only commercial vaccine available for crocodilians and is strongly recommended for ranches located in areas prone to WNV outbreaks. One of the most effective methods of disease prevention and control is veterinary consultation to evaluate production practices and disease outbreaks. In most instances, necropsy of affected animals is the most comprehensive and effective way to make a definitive diagnosis. Open lines of communication and collaboration between ranchers, veterinarians, and the state agencies are also effective in identifying any potential health issues that may require additional evaluation of animals destined for release to the wild. This helps to ensure the safeguard of wild populations and minimize the introduction of novel disease to the natural habitat.

Breeding Program

Captive breeding programs for American alligators have diminished over the years and represent a minority of the operations. This is not a significant source of animals, but some hatchlings are provided through captive breeding.

Slaughter and Processing

In 2016 the Louisiana Department of Wildlife and Fisheries established a regulation that requires all alligator ranchers and farmers to slaughter the animals according to established guidelines by the AVMA and Swiss Federal Veterinary Office (FVO).[27] Specifically, it includes the use of penetrating and nonpenetrating captive bolt (Fig. 47.2) and spinal cord severance followed immediately by pithing. Decapitation and spinal severance alone are not acceptable methods. This regulation had the

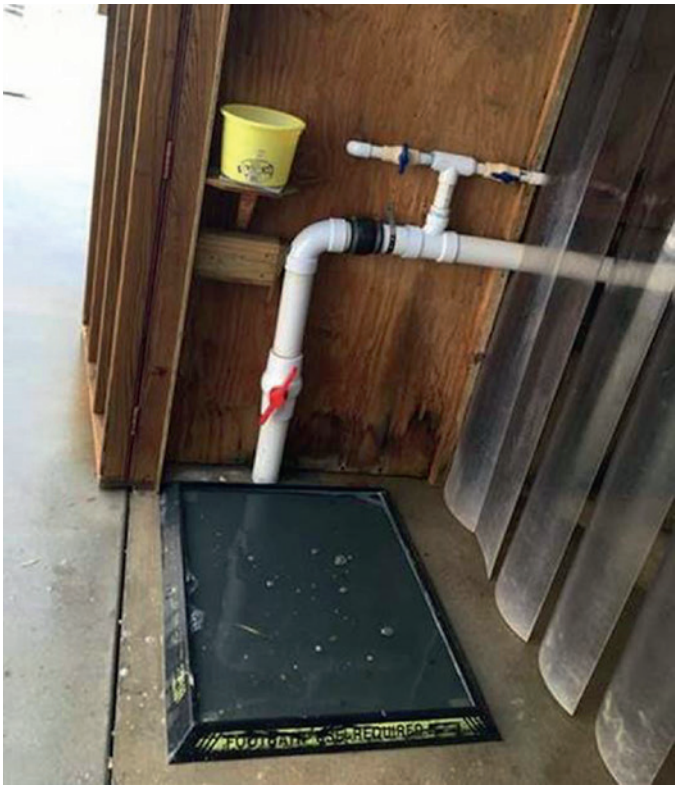

FIG 177.9 Biosecurity measures at an alligator ranch. A foot bath and hand wash station are used before entering the building. Solution is made fresh daily. In addition, doors (shown open) and plastic curtain prevent entry of mosquitoes and other pests into the building. (Courtesy of Javier G. Nevarez.)

full support of the Louisiana Alligators Farmers and Ranchers Association and represents the first instance of regulatory governing of slaughter methods for a commercial reptile species in the United States. These guidelines and regulations also acknowledge that methods may be refined as more research becomes available and strongly encourage consultation with veterinarians to ensure that the methods being used are the most humane possible for each species and circumstance. Further discussion on slaughter can be found in Chapter 47.

CROCODILES AND CAIMANS

There are nine species of crocodiles and three species of caiman in commercial trade (see Table 177.5).[2] In general, crocodiles and caimans are reared in a different manner than alligators. Captive breeding is still an active part of the commercial trade for eight of the crocodile species and two of the caiman species. Ranching is becoming more widespread but still represents a lower proportion of the source for these species. Aspects of their husbandry in commercial operations vary considerably with the wider range of species and countries in which they are reared. Therefore we provide general information about these species and how their captive rearing differs from that of alligators. CITES regulations are in place, but their implementation may vary on a per-country basis.

Husbandry

Housing. In captive breeding operations, the adult animals and often the juveniles are housed in communal outdoor ponds or pens (Fig. 177.10). These can vary from natural earthen ponds to artificial concrete structures. For outdoor rearing, it is also important to provide enough water depth and shade to ensure the animals can seek protection from the sun. Some facilities will keep hatchlings outdoors whereas others maintain them indoors for a period of time. Some facilities are starting to rear animals indoors only, but this practice is not currently widespread.

Water Supply. The water source is more likely to be from well or other natural sources (i.e., lakes, rivers). The use of a water heating system is only necessary where needed as per the local climate and often only used for animals being reared indoors. Animals housed outdoors will experience a more natural variation in temperature because the outdoors ponds and pens are less likely to be heated. Although water temperatures of 85° to 90°F (29°–32°C) will offer maximum growth, the focus in these operations is to ensure the animals have enough water depth to allow for a thermal gradient during the colder times of the year.

Stocking Densities. Stocking densities are a consideration for animal health and husbandry and in the case of crocodiles are also important due to the aggressive nature of some species, such as *C. porosus.* Specific recommendations are available for *C. porosus* and *C. niloticus* (Box 177.1).[12] These recommendations are based on surface area but do not take into account water volume. Because crocodiles and caimans are often housed outdoors, enclosure designs often involve both dry land areas, as well as water areas.

Diet. Diets for crocodiles and caimans vary widely because commercial, extruded pelletized diets are not readily available or not readily accepted by all species. For this reason, whole prey, offal, and animal carcasses from other species (e.g., poultry, swine), with vitamin and mineral supplements, are commonly used.[12] Some farms in South Africa produce their own feed using proprietary formulas. Hatchlings are usually fed daily, and the frequency is decreased to four to five times weekly for juveniles and two to three times weekly for brood stock.[12] The time of the year and season may also influence the type of food and frequency of feeding.

Hygiene. Due to the wide range of species, housing conditions, and countries, hygiene protocols are highly variable. There is little to no treatment of water in natural earthen ponds. Outdoor and indoor pens will have water changes at varying frequencies. Although some farms have biosecurity protocols, this is not widespread.

Preventive Medicine. Crocodile species reared in outdoor earthen ponds are more likely to be exposed to parasites and other diseases due to environmental exposure. In these instances, routine monitoring of fecal examinations and histopathologic evaluation of tissues after slaughter would help establish baseline references for the diseases encountered in a particular facility so that management techniques can

FIG 177.10 Outside enclosure at a Morelet's crocodile (*Crocodylus moreletii*) farm in Mexico. (From Mitchell M, Tully T. *Manual of Exotic Pet Practice.* St. Louis: WB Saunders; 2009, Figure 6.1.)

BOX 177.1 Recommended Stocking Densities for *C. porosus, C. niloticus,* and *A. mississippiensis*

Crocodylus porosus	
Hatchlings	10–15 animals/m^2
Animals up to 1 m	2–4 animals/m^2
Animals 1–2 m	0.5–1 animals/m^2
Crocodylus niloticus	
Hatchlings	<15 animals/m^2
Animals 1–1.5 m	2–4 animals/m^2
Animals 1.5–2 m	1–2 animals/m^2
Alligator mississippiensis	
Animals <0.6 m	<11.1 animals/m^2
Animals 0.6–1.2 m	3.7 animals/m^2
Animals 1.2–1.35 m	2.8 animals/m^2
Animals 1.35–1.5 m	2.2 animals/m^2
Animals >1.5 m	Add 0.09 m^2 per animal for every 0.15 m beyond 1.5 m length

VetBooks.ir

be applied as needed. Release of animals back to the wild is not as common practice for crocodiles as it is for American alligators. Nonetheless by being reared outdoors, there is still the potential for disease exposure to wild populations via environmental exposure.

Breeding Programs

Captive breeding programs are a common aspect of commercial crocodile and caiman production; however, the specifics of the breeding program will vary according to species and individual farm management. Nonetheless, once the females lay eggs, most facilities will collect them for artificial incubation. Breeding can occur in large communal ponds or in smaller ponds with one male and one to five females.[12]

Slaughter and Processing

The slaughter of crocodiles is carried out by methods recommended within the Analysis of Humane Killing Methods for Reptiles in the Skin Trade published by the Swiss FVO.[28] Further discussion on slaughter can be found in Chapter 47.

GENERAL COMMENTS ON OTHER SPECIES

In addition to sea turtles and crocodilians, freshwater turtles are also widely grown in farms worldwide. These farms supply turtles for laboratory research and educational purposes, the pet trade, and also as food sources. Softshell turtles and sliders (*Trachemys* spp.) are some of the most common species being bred for the food trade. The majority of these farms are closed operations with their own brood stock animals housed in outdoor earthen ponds (Fig. 177.11). Eggs are usually artificially incubated and hatchlings reared in grow-out pens or ponds. Asian countries are one of the largest markets for turtle meat. In Western countries, cultural factors have not allowed reptile meat to become mainstream. Although turtle soup and alligator meat may be more commonplace in the southeastern United States, meat from other species like green iguanas (*Iguana iguana*) is not welcomed with the same gusto. The availability of farmed turtle meat has curbed some of the illegal trade, but in some countries illegal trade is still very active. One drawback from reptile farms is that like any agriculture endeavor, they can be very labor intensive, and it can take years before a new farm can generate revenue. This of course does not address the immediate economic needs of people and makes it less attractive than traditional farming. When farms are properly managed and regulated by the government, they can have a significant impact on the conservation of the species and the quality of life of the people in local communities.

FIG 177.11 Turtle farm pond in Louisiana. This is an earthen pond with a concrete edge and soil area for nesting. (Courtesy of Javier G. Nevarez.)

CONCLUSION

Reptile farming and ranching is a sustainable and profitable agricultural venture in many countries. The benefits are significant for both animal and human populations. A key aspect of the success and sustainability of this trade will be the ability to maintain healthy populations and safeguard the welfare of the animals. This of course is perceived differently across countries but is quickly becoming a critical issue for the long-term survival of farms and ranches. This is an area in which veterinary involvement can have a significant impact. By improving the welfare and health of the animals, farms and ranches can in turn improve productivity. Nonetheless this still remains a challenge in many countries where not even cattle or other traditional agricultural species receive proper veterinary care. The Crocodile Specialist Group has a veterinary group with international members who are actively involved in the care of wild and captive crocodilians. This group serves as a resource for farmers, ranchers, and veterinarians. There is a need for continued research on all aspects of the captive rearing of reptiles in the food trade. This research often has important benefits for the wild populations as well. It is up to current and future generations to ensure that this continues to be a sustainable and renewable industry that benefits the wild population and the communities that share their environment.

ACKNOWLEDGEMENTS

We would like to thank Dr. Ruth Elsey from the Louisiana Department of Wildlife and Fisheries for her guidance and editorial review during preparation of the alligator section of this chapter. Additionally, we thank Mr. Joe Parsons from the Cayman Turtle Conservation and Research Centre for his insight and review of the turtle section of this chapter.

Large Zoo and Private Collection Management

Paul M. Gibbons

People keep reptiles in large collections for both commercial and noncommercial purposes. Commercial breeding facilities supply the pet trade and produce meat and leather. Noncommercial facilities maintain reptiles for rescue and rehabilitation, for lifetime sanctuary, for pleasure as a hobby, for exhibit and education, and for the conservation of endangered species. Commercial reptile farming is discussed in Chapter 177 and the pet trade is discussed in Chapter 179. This chapter focuses on the management of large collections that are kept for the primary purposes of exhibition, education, and conservation.

Reptile caretakers should provide the five freedoms that all animals need for a life worth living, regardless of the purpose for which they keep them (Table 178.1).[1] To achieve this goal, every captive environment should include species-appropriate physical complexity without potential stressors. Multiple options for heat, humidity, light, water, caging, vegetation, refuge, and substrate must be provided in a manner that allows the reptiles to control how they interact with their environment. Temperature, light, and humidity must cycle daily and seasonally. Provision of feed and water must be based on species-specific natural history. Most reptiles do not feed daily, and some species are adapted to habitats that receive moisture in the absence of rain or experience regular periods without rain or surface moisture. Behavioral enrichment is based on providing varied opportunities for the reptile to select from a mosaic of environmental features and to interact with nonthreatening conspecifics and appropriate prey or browse. Captive reptiles require opportunities to solve the range of problems they might normally face in the wild, with minimal exposure to situations that will induce substantial fight or flight responses. Such enriching care is necessary to achieve the goal of a healthy, reproductively successful, sustainable, large collection.

Large private or public facilities should, at a minimum, meet the standards of regional independent certifying agencies and maintain current certification. Examples of such agencies include the Association of Zoos and Aquariums (AZA) in the United States and the European Association of Zoos and Aquariums. These organizations serve not only to regularly evaluate the operations of member facilities, but they also host the regional authorities for the management of interinstitutional captive populations, studbooks, and species survival plan programs. Current standards for veterinary medical programs and veterinary hospitals at large facilities have been established and are regularly updated by the AZA and the American Association of Zoo Veterinarians.[2]

The International Union for Conservation of Nature (IUCN) is composed of both governmental and nongovernmental organizations. It provides public and private organizations with the knowledge and tools that enable human progress, economic development, and nature conservation to occur together. The Species Survival Commission (IUCN-SSC) is a global network of more than 10,000 scientists working together toward a vision of "a just world that values and conserves nature through positive action to reduce the loss of diversity of life on Earth."[3] Reptile specialist groups include the Anoline Specialist Group, Boa and Python Specialist Group, Chameleon Specialist Group, Crocodile Specialist Group, Iguana Specialist Group, Marine Turtle Specialist Group, Monitor Lizard Specialist Group, Sea Snake Specialist Group, Snake and Lizard Red List Authority, Tortoise and Freshwater Turtle Specialist Group, and Viper Specialist Group. These groups monitor and report on wild population status and conservation programs and maintain the IUCN Red List of Threatened Species for their taxonomic group. The IUCN-SSC Conservation Breeding Specialist Group saves threatened species by increasing the effectiveness of conservation efforts worldwide and provides planning expertise to governments, specialist groups, zoos and aquariums, and other wildlife organizations. Leaders and staff of large private and public collections should actively contribute to these groups and maintain the highest possible level of participation in global species conservation programs.

POPULATION SUSTAINABILITY

Zoologic institutions direct their sustainability efforts toward maintaining healthy, sustainable captive populations, whereas species conservation organizations direct their efforts toward maintaining healthy, self-sustaining wild populations. Both of these directives play an important role in the overall sustainability of reptile metapopulations (*in situ* and *ex situ*), and the differences between them help to explain differences in their activities.

TABLE 178.1 The Five Freedoms of Animal Welfare

Freedom from hunger and thirst	by ready access to fresh water and a diet to maintain full health and vigor
Freedom from discomfort	by an appropriate environment, including shelter and a comfortable resting area
Freedom from pain, injury, or disease	by prevention or rapid diagnosis and treatment
Freedom to express normal behavior	by providing sufficient space, proper facilities, and company of the animal's own kind
Freedom from fear and distress	by ensuring conditions and treatment that avoid mental suffering

Management for Sustainable Captive Populations

The goals of AZA Species Survival Plan (SSP) programs are to maintain self-sustaining zoo and aquarium populations, to maintain or increase the captive populations' genetic diversity, to meet exhibit/education needs, to meet conservation or reintroduction goals, to prevent unnecessary surplus animals, and to minimize inbreeding.[4] In practice, this has led to a focus on creating captive populations that will sustain 90% gene diversity for 100+ years or 10 generations with a positive growth rate so they can survive at least 100 years or 10 generations.[5] This priority is directed toward avoiding the risk of inbreeding depression in the captive population, and it is worth pursuing when the goal of preventing extinction is not compromised by doing so. For some endangered species, the wild population is small, and the captive population cannot be augmented by additional wild founders. In these cases, the priority of the captive breeding program must shift to meet conservation and reintroduction goals to prevent imminent extinction, and inbreeding should be encouraged as needed to increase the size of the remaining global metapopulation. The benefit of preserving the species outweighs the assumed costs associated with inbreeding. The available evidence suggests that many reptile populations, whether naturally occurring or introduced, have become self-sustaining in the face of inbreeding, probably via natural selection and because many species do not naturally outbreed.[6–9] Further research into the normal level of inbreeding in reptile species is warranted.

Captive Management for Sustainable Wild Populations

Conservation breeding is ideally undertaken within the context of a broad conservation action plan that includes a multistakeholder assessment of the conservation status of the species and its habitat and outlines conservation priorities (see Chapter 181). The IUCN provides many tools to support the creation of an action plan, including guidelines on the use of *ex situ* management for species conservation,[10] reintroductions and other conservation translocations,[11] and wildlife disease risk analysis.[12] Effective conservation action plans arise from a formal Population and Habitat Viability Assessment (PHVA) in the form of a workshop that helps people organize and evaluate the available information across a range of disciplines and perspectives. The PHVA can be augmented by an Integrated Collection Assessment and Planning workshop that brings together the stakeholders of the *in situ* and *ex situ* communities to apply the IUCN guidelines for *ex situ* management[10] for regional or global planning. In some cases captive breeding is a primary component of a conservation action plan and in others its importance is superseded by interventions, such as creating a protected area, preventing poaching, eliminating invasive alien species, or otherwise supporting the overall health of the local ecosystem where the species occurs naturally. Ideally, the captive breeding component of the plan is directed toward fulfilling specific objectives to prevent extinction. In many cases, however, substantial new knowledge must be obtained by the reptile caretakers to be successful in keeping the animals alive and then breeding, incubating, hatching, and raising them to an age or size when they can be released in a reintroduction program. These technical limitations can justify the initiation of a captive breeding program in the early stages of a conservation program, many years before the ultimate demographic and genetic needs are defined, the factors leading to the wild population decline have improved, and release sites are secured. Surplus offspring must not be overcrowded and can be transferred into additional assurance colonies, or opportunities should be created for the offspring to participate in creating wild or semiwild populations in locations where they can fulfil the function of an extinct species in an ecological restoration program, a process known as ecological replacement.[13]

For threatened species, a captive assurance population improves the demographic viability of the metapopulation and reduces the risk of extinction in the face of unpredictable threats to the wild population, including disease outbreaks, political instability, catastrophic weather events, and failure of habitat protection efforts. Offspring from captive populations can also be utilized to counteract the challenges faced by small wild populations through head-start programs that address high juvenile mortality and population reinforcement to balance age and sex distribution. The offspring from captive breeding programs can be translocated to recover wild populations when wild stock is not available for translocation.

Every effort should be made to locate *ex situ* breeding colonies as near to the indigenous range of the threatened species as possible. This proximity allows the species to experience the daily and seasonal cycles of light, heat, precipitation, and humidity to which it is adapted. In addition, caretakers can most easily recreate the adapted habitat by providing the feed and environmental features (vegetation, substrate, water, slope, shelter, obstacles, parasites, pathogens, commensal organisms, etc.) present there. After one or more local assurance populations have been established, then additional assurance colonies may be considered in the region and in distant locations. The further from the indigenous range, the greater the risk that captive-raised individuals will lose the traits required for life in the wild, including locomotion, predator avoidance, foraging skills, social interactions, physical fitness, and immunological response.[14] In addition, the risk of exposure to novel pathogens probably also increases with distance from the adapted habitat. This emphasizes the importance of recreating, to the best of a caretaker's ability, a captive environment that matches that of the reptile's native habitat so it can gain the psychological, behavioral, and immunologic competence necessary for longevity and reproduction when captive-raised individuals are repatriated and released.

HUSBANDRY CONSIDERATIONS FOR LARGE COLLECTIONS

Purpose of the Collection and Species to be Housed

Funding, space, labor, and expertise are limited in all facilities, and resources must be directed toward species that best serve the goals of the organization. Zoological institutions select species for their educational value, as representatives of a particular ecosystem, as ambassadors for wild populations, to demonstrate biologic diversity (interesting or unusual features), to inspire people, and to breed for species survival programs. Conservation organizations choose species that require captive breeding to protect them from extinction, particularly when an assurance colony is prescribed in an endangered species recovery plan. On occasion, qualified facilities are called upon to care for reptiles that have been seized from the illegal trade by authorities. A receiving institution may reserve the right to refuse such requests if the species is not among those selected by the facility, and resources are limited to preclude the provision of adequate care.

The first step in planning a captive environment is to gather information about a species' native habitat. A wealth of information exists about the care of common pet species, but such information can be difficult to acquire for rare and endangered species. It may become necessary for the search to expand from electronic resources to printed materials in public and university libraries and even consultation with experienced people and herpetologists. In some cases, it may be important to have multiple visits to the indigenous habitat of the species in question during different seasons to observe and record firsthand how a species interacts with its environment throughout the year. Many rare and endangered species of reptiles require husbandry parameters that differ from the species that are common in captive collections. Commonly

kept reptile species have become "common" at least in part because they are particularly hardy and can withstand a range of environmental conditions. The impressed tortoise (*Manouria impressa*) is a good example of a species with specialized needs that was impossible to maintain in captivity before someone observed and reported on its natural history. It is dormant during the dry season and becomes active foraging on the fruiting bodies of fresh mushrooms (Basidiomycota) during the wet season. It lives in dense mountain forests with consistent high humidity, minimal direct sunlight, and moderate temperatures. Even near the native range, creating these features in a captive habitat is difficult for the most experienced reptile caretakers, so conservation efforts for this species must focus on protecting wild populations and their habitat.

Animal Identification and Animal Record Systems

Individual animals in large collections must be uniquely identified to track their signalment, lineage, and medical history, and many identification techniques are available.[15] Photographs can be very helpful because individuals have differences in scalation, scutes, and color patterns, and images that include metadata for identification (e.g., the local identifier and date of the photo) should be captured and stored on accession, at progressing life stages, and at deaccession. Veterinary medical and animal collection records should be electronic, and duplicates should be kept off site in case of fire or a natural disaster. Ideally, all animals should be recorded in Species360 (http://www.species360.org, Bloomington, MN; formerly the International Species Information System), the global, nonprofit, nongovernmental, membership-based organization that systematically gathers and shares information about the animals kept in member facilities. Full participation is evidence that a facility meets modern zoological standards and provides others the opportunity to readily evaluate the collection at a participating facility.

Human Resources

Management of human resources is among the greatest challenges in caring for large collections. Some people who wish to work with reptiles exhibit a set of behavioral traits that interferes with their success. These traits include overconfidence and a reliance on intuitive decision-making that is based on unsystematically recorded personal experience. People who exhibit these and similar traits should be avoided or replaced to achieve the goal of long-term consistent success with species that have highly specialized needs. Skilled, educated, experienced, curious people who are intrinsically motivated to learn about the natural history and husbandry of reptiles may, however, prefer not to perform repetitive tasks, including waste management, cleaning, and feeding. These tasks are necessary to manage large collections and can be assigned to people with limited knowledge, skills, and abilities who are willing to learn, follow protocols, and most importantly, seek assistance when they encounter something that is unfamiliar or outside the protocols.

Staff training and interactions should encourage communication among all levels, and managers should make every effort to be open to and grateful for questioning. Employees who can recognize when a knowledge gap exists, notify their supervisors, seek to learn, and then improve their work using newly acquired knowledge should be acknowledged in public and rewarded. This culture will promote a healthy work environment and maximizes success with the most difficult species.

Senior and supervisory staff must routinely inspect animal enclosures for the regular degradation of habitat quality. Items shift position, plants get trampled or eaten, and substrates become compacted, undergo composting, and lose important compositional features over time. Artificial lighting degrades, and equipment fails. It is ideal for senior staff to perform all of the routine husbandry tasks at regular intervals (e.g., once per week) to identify challenges or impediments to the execution of protocols. All husbandry staff members should participate in regularly scheduled "morbidity and mortality" rounds to review existing protocols, discuss areas for improvement, and explore new ideas about how to solve difficult problems. Enclosure planning must harmonize ergonomics for the staff, natural history needs of the reptile, provision of environmental parameters, and esthetics.

Building and Enclosure Design Considerations

Indoor Facilities

The interior of large structures such as greenhouses and naturally lighted warehouses with windows and skylights can be managed to provide the background environmental parameters for species from regions with a similar climate. Major climatic zones that are home to reptiles include arid, tropical, mediterranean, montane, and temperate zones. Each indoor facility can be designed to create the daily and seasonal cycles in temperature, humidity, and day length that correspond to a major climatic zone. Individual enclosures within the larger structure are then modified to meet species-specific microclimate needs for vegetation cover, substrate type, shade, basking sites, water, fog, and precipitation. Computerized climate control equipment used in the horticultural industry includes circulating temperature-controlled water systems (Fig. 178.1), centrifugal humidifiers (Fig. 178.2), evaporative coolers, air conditioners, vents, air circulators, and shade systems. It is particularly important to either insulate or heat the flooring of buildings where reptiles are kept in close contact with the floor. Concrete that is not insulated will serve as a heat sink and during cold weather will cause reptiles to exhibit unnatural thermoregulatory behavior that can be life threatening (see Fig. 178.1). Natural sunlight is the best source of background lighting and should be minimally filtered. Mesh screens and ultraviolet-transmitting acrylic panels allow the broadest range of light wavelengths, with or without ventilation as needed. Background

FIG 178.1 Rigid foam board insulation is placed within the load-bearing foundation, and rebar is arranged into a grid on which flexible crosslinked polyethylene (PEX) tubing is secured in place before pouring the concrete slab flooring of a facility that will house reptiles. Warm water is then circulated through the floor by a thermostatically controlled pump. (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

VetBooks.ir

FIG 178.2 A centrifugal humidifier creates a very fine suspended mist similar to that found in cloud forests. (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

lighting for day length can be provided with fixed lamps that emit diffuse visible light (incandescent, fluorescent, or LED) if the latitude of the species in the wild differs substantially from that of the facility, and specific needs for infrared and ultraviolet wavelengths can be provided at the microhabitat level.

Outdoor Facilities

Reptiles should be kept outdoors whenever possible. Considerations include potential for escape, the risk of venomous and dangerous species accidentally interacting with people, seasonality, predation, and whether the local environment satisfies the environmental needs of the species. All enclosures for healthy animals at facilities located within the natural range of the species should be outdoors. Judgment is needed to make decisions about daily and seasonal cycles to decide how to optimize the local weather for nonnative species. Relatively small, insulated housing can be constructed for use during brief periods of inclement weather and outfitted with thermostatically controlled radiant heaters to blunt nighttime low temperatures and timer-controlled lighting to maintain diurnal light cycles (Figs. 178.3 and 178.4). A patchwork of shelter from the sun may be all that is necessary for facilities located within the native range of the species (Fig. 178.5). Species that are kept outdoors either within their native range or in a location where the climate closely matches the native range can reproduce (mate, nest, incubate, and hatch) with little to no assistance from caretakers if species-specific social and microhabitat needs are met.

MANAGEMENT OF HUSBANDRY RESOURCES

Large collections of reptiles are often managed by keeping them in groups. To be successful, enclosures that house groups of reptiles must contain replicates of the husbandry resources, including perches, crevices, shelters, basking sites, browse plants, drinking sites, immersion sites, and feeding areas (Fig. 178.6). Multiple visual barriers are necessary,

FIG 178.3 Relatively small, well-insulated structures can be used for shelter during brief periods of inclement weather to minimize the need for large structures when maintaining species that can be housed outdoors on most days. (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

FIG 178.4 The interior of small outdoor structures can be outfitted with thermostatically controlled radiant heaters to blunt nighttime low temperatures and timer-controlled lighting to maintain diurnal light cycles. (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

FIG 178.5 Tortoises facilities that are located within the native range of the species may need only to create barriers between groups, feeding slabs, water depressions, and minimal shelter from the sun. Note that this prerelease breeding facility in Bagan, Myanmar, is completely enclosed with heavy-gauge wire mesh to prevent theft. (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

VetBooks.ir

FIG 178.6 A well-appointed enclosure with suitable complexity, shelters, visual barriers, feeding sites, and water dishes to house two male and four female Egyptian tortoises (*Testudo kleinmanni*). (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

FIG 178.7 When reptiles are housed in groups, the amount of feeding space must be sufficient for all individuals to eat concurrently as shown with this group of hatchling Burmese Black Mountain tortoises (*Manouria emys phayrei*). (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

FIG 178.8 Divided feeding plates can improve feeding opportunities for individual reptiles that eat more slowly than others, as shown in this mixed-species group of Asian box turtles (*Cuora* spp.). Similarly divided rectangular troughs can be used to provide food or water to groups of tortoises and larger lizards. (Courtesy of Max Maurer, Turtle Conservancy.)

so individuals need not be in constant visual contact. The animals that comprise the group must be matched by size and behavioral traits. Each individual should be weighed and examined at regular intervals, once every 2 to 4 weeks for most species, to monitor for problems. Some species are predisposed to fighting and cannot be kept in groups, some can be kept in groups until they reach adulthood, and some live peacefully in large groups with only a rare individual that must be separated because it either fights with the others or is not able to fend for itself. The number of individuals in an enclosure must be matched with the individual characteristics of the captive habitat, and social interactions must be managed. There must be sufficient linear space for all of the individuals to eat at the same time (Fig. 178.7). This can be accomplished by creating large or multiple feeding areas or by placing barriers between individuals during feeding. Technology from the food animal agriculture industry, such as divided feeding troughs, can be adapted for reptiles (Fig. 178.8). Heat should be provided in a mosaic with multiple basking sites and multiple areas that are shaded and sheltered from excessive heat. Heat and light from the sun are ideal because they move together in a routine diurnal pattern across an enclosure, providing a thermal environment that varies predictably throughout the day, so the reptiles can choose preferred basking sites as they change.

DISEASE MANAGEMENT

New Acquisitions

The principles of quarantine are described in Chapter 19. It should strengthen the health of new acquisitions in preparation for entry into a large collection. Husbandry in quarantine must not sacrifice any of the essential components of long-term maintenance, including environmental complexity, options, and cycles. Quarantine, both before and after transfer, is a time for the veterinary staff to learn how well the immune competence of a new acquisition matches that of the collection it is to enter. Some microorganisms and parasites that have the potential to cause primary disease or deleterious effects during exposure to poor husbandry can be treated during quarantine. Ideally, quarantine will prevent the introduction of pathogens that do not already exist in the collection with the assumption that immunologically naïve

VetBooks.ir

TABLE 178.2 Common Pathogens of Concern When Introducing New Individuals Into a Collection[18]

Group	Agent	Species	Screening Samples	Recommended Tests
Chelonians				
	Tortoise intranuclear coccidiosis	Tortoises, some turtles	Swab of conjunctiva, oral mucosa, and cloaca	qPCR
	Herpesvirus	Tortoises	Oral swab; plasma	PCR, qPCR; paired PN or ELISA
	Mycoplasmosis	Leopard tortoise, star tortoises, *Testudo* spp., *Gopherus* spp.	Swab of conjunctiva, nasal, choanal mucosa; plasma	PCR; paired ELISA
	Systemic amoebiasis	Tortoises and turtles	Feces (fresh and preserved in PVA), cloacal swab	PCR, fecal microscopy direct and trichrome stain
	Iridovirus	Tortoises and turtles	Swab of oral/cloacal mucosa, urine	PCR
Lizards				
	Adenovirus	Bearded dragons	Cloacal swab or wash	qPCR
	Cryptosporidiosis	Leopard geckos, Gila monsters, chameleons, monitors	Gastric lavage, fecal	PCR, IFA, acid-fast stain
Snakes				
	Reptarenavirus (inclusion body disease)	Boas, pythons	Choanal swab	PCR (RNA)
	Paramyxovirus	Viperids, colubrids, less common in pythons/boas	Choanal swab; plasma	PCR (RNA); paired HI
	Nidovirus	Pythons	Choanal/pharyngeal swab	PCR (RNA)
	Cryptosporidiosis	Boas, pythons, colubrids	Gastric lavage, fecal	Acid-fast stain, PCR
Crocodilians				
	Mycoplasmosis	Alligators and crocodiles	Respiratory sample; plasma	PCR; paired ELISA

ELISA, Enzyme-linked immunosorbent assay; *HI*, hemagglutination inhibition; *IFA*, indirect fluorescent antibody immunofluorescent assay; *PCR*, consensus PCR and sequencing; *PN*, plasma neutralization; *PVA*, polyvinyl alcohol; *qPCR*, quantitative PCR.

populations are more susceptible to illness than those that have already been exposed. The collection may experience undesirable morbidity and mortality as it gains herd immunity to a pathogen to which it has previously not been exposed. It may be wise, however, to create a herd that is immunocompetent and prepared for exposure to pathogens that are known to exist in wild populations. Quarantine can be extended for animals undergoing treatment for known diseases, but must be kept as brief as possible. No consensus exists on the minimum duration of reptile quarantine and the logical basis for it. Incubation periods have not been defined for most reptile pathogens. Testing should be based on a risk assessment and directed toward matching immunocompetence among groups (Table 178.2). In situations where there is no evidence of known pathogens, but concerns remain about unknown pathogens and the benefit of introducing a new animal outweighs the risk of losing one or two established individuals, then the new individual can be placed initially with one or two individuals from the established collection. This biological assay can help detect whether a serious yet previously unknown contagious disease is present because it will affect either the newly acquired individual or the test subject(s) without spreading through the entire collection.

Preventive Medicine

The epidemiologic triad considers host, environment, and pathogen factors. Many of the common diseases of captive reptiles can be prevented by providing the necessary environmental parameters to support the health of the reptile and by identifying and eliminating stressors. Many pathogens are opportunistic and can be present in a collection without causing disease unless the environmental parameters change, or a stressor is introduced. Examples of such diseases include cryptosporidiosis, mycoplasmosis, and amoebiasis. In addition, many nematodes and protozoa that are present in wild reptiles and are directly transmitted can gradually increase over time until they exceed a threshold and then cause disease. The veterinarians who are responsible for managing the health of large collections can use epidemiologic principles to survey for the presence of known, testable, disease-causing organisms and design prophylactic treatment plans accordingly. Similar to large collections of other vertebrates, strategic administration of anthelminthics or antiprotozoal drugs and outdoor enclosure (pasture) management are indicated. Transmission is multifactorial and differs among pathogens; known intermediate hosts should be eliminated when possible. Reptile environments should strike a balance that enhances populations of nonpathogenic microbes and decomposing invertebrates to reduce transmission of pathogens. The combination of environmental features that create this balance may not have been specifically characterized, but general features include sufficient space (not overcrowded), adequate ventilation, live plant communities, circulating water, and good soil drainage. The volume of water and surface area for biologic filtration must be sufficient to maintain nitrogen cycling, and water should be exchanged as needed to prevent the accumulation of nitrogenous wastes. Regular monitoring of environmental quality parameters, including nitrogen cycling and coliform counts, can help to determine whether environmental systems require intervention. Daily spot-cleaning of substrates to remove feces and urine can increase the capacity of an enclosure where biologic systems are not sufficient. Disinfected habitats can be useful when managing reptiles for brief periods of hospitalization, but they present many difficult and unnecessary challenges

VetBooks.ir

when used for the long-term maintenance and breeding of reptiles, without providing the intended benefit of reduced disease. In place of disinfection, reptile habitats should be designed to enhance populations of nonpathogenic microorganisms, so pathogens cannot thrive in the environment.

Biosecurity

Biosecurity standards for large collections are directed toward decreasing the risk of disease transmission to susceptible individuals. Written protocols should be regularly reviewed by all of the staff and revised as needed. People must move through the facility with a clear understanding of the likelihood that infectious diseases can be transmitted on hands, shoes, and equipment, in feed, and on free-living animals and pests. Traffic patterns through the facility are orchestrated so that cleaning and feeding routines are accomplished in a specific sequence moving from youngest to oldest animals and working with known sick animals at the end of every day. Feed should be prepared in advance and carried away from the kitchen/food preparation area one time daily without returning. Items used inside of enclosures, including feed plates, should be cleaned in an area that is separate from the kitchen. Disposable gloves should be changed, or hands should be washed with hot, soapy water to remove organic material before feed preparation, between enclosures, after handling animals, and after cleaning equipment. Each enclosure should be entered only once each day, and then only with personal protective equipment including shoe covers and gloves. Enclosures with reptiles that are infected with known pathogens should only be entered with shoe covers, gloves, and designated gowns or coveralls. Equipment is also designated and clearly labeled for each separate area of the facility or group of animals and never transferred to a new area. Small equipment cabinets or boxes help facilitate adherence to the protocols and can be designed to fit into the esthetics of exhibit design (Fig. 178.9). Footbaths may be useful to prevent introduction of pathogens into the hospital or quarantine, and they must be maintained to avoid deactivation of the disinfectant by organic material that is dislodged from the soles of shoes. Regular training sessions for staff members are essential to explain the justification for biosecurity protocols, demonstrate how they are implemented, and identify ways to improve.

FIG 178.9 A conveniently located biosecurity box that holds gloves, shoe covers, and equipment that has been designated for use only within its adjacent outdoor enclosure is one part of a biosecurity program at the Turtle Conservancy's conservation breeding center. (Courtesy of Paul M. Gibbons, Turtle Conservancy.)

Sick Individuals

Early signs of illness can be difficult to notice in reptiles, especially in large collections or naturalistic exhibits. Animal caretakers must learn each species' normal behavior and routine, and observe all of the individuals in the collection every day. For example, many diurnal reptiles bask in the early morning and eat when their body has reached the optimal temperature for metabolism. They then retreat from the sun and may be observed basking intermittently throughout the afternoon to maintain their body temperature until sunset when they retreat for the night. Accordingly, feed should be provided in the morning and caretakers should take the time to observe each enclosure for sufficient time after feeding to determine which individuals have eaten. Conversely, feed for nocturnal reptiles should be provided in the evening. Not all reptiles will eat every time feed is presented, so individual patterns should be recorded, and any deviation from the normal pattern should be noted and the individual animal identified for observation. One method to identify sick animals is to place a temporary marker, such as a small dab of typing correction fluid or brightly colored nail polish on the skin or shell of the suspect individual. If abnormal behavior continues, then the individual should be separated from the group and placed under observation in an enclosure that is separate from the intake quarantine area and provided with normal husbandry conditions. This offers an opportunity for closer observation and to better determine whether it continues to exhibit abnormal behavior. Body condition is a more useful indicator of chronic nutritional status because absolute body weight can be misleading unless serial measurements over many years are available for review. In general, juvenile reptiles should steadily gain weight over time, and adults should maintain their weight within approximately the 10% to 15% range. It is important to note that body weight normally changes by 10% or more when reptiles nest, defecate, or urinate. In addition, a reptile in poor body condition can retain urine or feces to regain or maintain body weight, and ascites is a common problem that confounds the interpretation of body weight. So rely on body condition, using weight as a logical guide with limitations, to assess nutritional or hydration status. If the observed behavioral concerns and body condition do not improve when the reptile is isolated, then a diagnosis should be obtained and a therapeutic plan instituted. Depending on the relative value of an individual to the goals of the collection (breeder, genetically valuable offspring, or surplus), euthanasia may be considered for individuals with metabolic, degenerative, neoplastic, or other chronic diseases and those that do not respond well to routine treatment. A policy on euthanasia should be clearly defined and implemented to avoid prolonged periods of disease in individuals that will eventually be euthanized.

Necropsy

Chapter 40 describes techniques and protocols for necropsy in reptiles. All animals in a large collection that die spontaneously or are euthanized should undergo gross necropsy. All those in which a cause of death cannot be determined by gross necropsy should be submitted for histopathologic diagnosis. Gross lesions should be photographed. Samples of blood, fluids, and tissue should be collected at the time of gross necropsy and preserved for future testing to determine an etiologic diagnosis based on histopathologic findings. If the facilities and funding permit, tissue samples should be preserved indefinitely for future retrospective disease analyses and genetic banking.

Integrated Pest Management

An integrated pest management program uses regular monitoring to determine what pests are present and then uses the safest approaches to control pest populations while considering environmental concerns.[17]

VetBooks.ir

Pests can consume animal diets, introduce or transmit disease, cause stress, or prey upon susceptible reptiles. The pest management program takes into account the biology of the pests and the effects of the control program on the animal collection and the people involved. A comprehensive program includes a clear definition of the scope and magnitude of the problem, identifies appropriate expertise, outlines a safe and effective plan, implements the program, regularly evaluates the results, and makes improvements when necessary. Indirect suppression methods are the most effective and include modifying enclosures/exhibits, changing human behavior, and educating the staff.[17] Indirect suppression is based on eliminating desirable resources for the pests and is focused on sanitation and cleanliness in animal enclosures and feed storage/preparation areas. Direct suppression or mechanical control of pests differs depending on the pest species and should include a combination of approaches that may include exclusion, baiting, repellants, trapping, removal, euthanasia, and relocation (Fig. 178.10). The most important pests in reptile collections include ants, rodents, procyonids, carnivores, and birds.

FIG 178.10 Escaped prey can serve as vectors of pathogens. Feral feeder crickets can be captured in a simple trap constructed from a 2-liter plastic bottle with dry feed inside. Masking tape provides a runway for crickets to climb into the inverted opening, which is raised above the substrate to prevent them from climbing out. (Courtesy of Paul M. Gibbons.)

CONCLUSION

The principles of managing large reptile collections for educational exhibits or conservation are similar to those of smaller collections, with the added elements of animal identification, recordkeeping, and staff training in husbandry, health, pest management, and biosecurity protocols. The main purpose of breeding endangered species in noncommercial large collections is to prevent extinction, and maintaining genetic diversity is a secondary goal that should be addressed only after the techniques have been refined to keep the species alive and then to breed, nest, incubate, hatch, and raise them to become competent adults that will survive when they are released to restore wild populations.

Breeders, Wholesalers, and Retailers

Drury R. Reavill and Chris Griffin

Evaluation of recently obtained reptiles from the growing population of captive-bred or wild-caught animals available as pets can be daunting for practitioners. The many different species presented for examination and the dizzying range of requirements for their needs—from husbandry to diet—can overwhelm the time constraints of a veterinary visit. Additionally, the common diseases, parameters of health, and appropriate laboratory tests recommended can vary tremendously.

For collections of reptiles, a herd health approach should be utilized, and a basic knowledge and understanding of reptilian biology, anatomy, and diseases is important. This chapter will present an overview of the species of reptiles currently available in the pet trade, the common husbandry issues and infectious diseases seen, and recommended therapeutic guidelines.

The species of reptiles presented to veterinarians generally fall into two categories: those reptiles that have adapted well to captivity and have been successfully captive bred in large numbers, and those species readily harvested from wild populations. There have been trends in the popularity of reptiles kept as pets. In the 1960s and 1970s, the red-eared slider turtle (*Trachemys scripta elegans*) was a common pet and readily reproduced in commercial ponds. The common green iguana (*Iguana iguana*), though not easily captive bred, was readily imported from farms in South and Central America and thus was popular in the 1990s. Bearded dragons (*Pogona vitticeps*) and a variety of chameleons and geckos are the current popular pets. Large snakes have always had a fan base that seems unchanged over time. Each different species has introduced various disease conditions and challenged reptile veterinarians to provide optimal health care by attempting to understand the natural history of these unique animals. The common reptile species available to the public in the past decade are listed in Table 179.1.[1]

BREEDING COLLECTIONS

Some studies suggest captive-bred animals have better health and survival rates compared with wild-caught specimens.[2,3] These captive-bred animals may be healthier due, in part, to the care of breeding stock and management of disease that can be controlled. There are many diseases presented clinically that can be diagnosed by select antemortem testing. Testing a collection in a systematic manner with a focus on disease prevention may be helpful when dealing with closed breeding collections. A closed collection, characterized by no new animals brought into the collection for breeding or other purposes, is rare; all new breeding animals would be the offspring of the current breeding stock. For breeders, keeping a closed collection is the ideal but is often not adhered to as new morphs or choice individuals of the species being bred become available (Fig. 179.1). In these cases, quarantine is vital, and during the quarantine process testing for the most common pathogens as well as pursuing a diagnosis for any abnormal physical findings is important.

Ideal quarantine facilities should have separate housing and air space from the established breeding population (Fig. 179.2). Biosecurity, especially in terms of isolation of recent acquisitions and separation of species, is important, probably more so with a breeding collection.[2] Disinfectant foot dips are used in some facilities, as well as adequate hand-washing stations. Ideally, quarantined animals are given care last after the breeding population or have different people in charge of each

Table 179.1 Common Species Available in the Retail Trade

Chelonian	Lizard	Snake
Russian tortoise (*Agrionemys horsfieldii*)	Leopard gecko (*Eublepharis macularius*)	Ball python (*Python regius*)
Red-eared slider (*Trachemys scripta elegans*)	Bearded dragon (*Pogona vitticeps*)	Common boa (*Boa constrictor imperator*)
Malayan box turtle (*Cuora amboinensis*)	Green water dragons (*Physignathus cocincinus*)	Corn snake (*Elaphe guttata*)
Box turtle (*Terrapene* spp.)	Common green iguana (*Iguana iguana*)	Ribbon snake (*Thamnophis sauritus*)
African side-neck turtle (Pelomedusidae family)	Anole (family Polychrotidae)	Milk snake (*Lampropeltis triangulum*)
Marginated tortoise (*Testudo marginata*)	Savannah monitor (*Varanus exanthematicus*)	Garter snake (*Thamnophis* spp.)
Red-footed tortoise (*Chelonoidis carbonaria*)	Emerald swift (*Sceloporus malachiticus*)	Green tree python (*Morelia viridis*)
African-spurred or sulcata tortoise (*Centrochelys sulcata*)	Blue-tongued skink (*Tiliqua* sp.)	King snake species (genus *Lampropeltis*)
Greek tortoise (*Testudo graeca*)	Ameiva (family Teiidae)	Rat snake (genus *Pantherophis*)
	Chameleon species (*Trioceros jacksonii, Furcifer pardalis, Chamaeleo calyptratus*)	
	Uromastyx species (*Uromastyx aegyptia, Uromastyx* [*dispar*] *maliensis*)	

population group. Quarantine lengths will depend on the species and can range from 30 to 90 days. The decision when to move animals into the breeding population can be based on assessment of health (eating, drinking, normal behaviors), the source of the animal (wild caught vs. captive bred), results of diagnostic tests and response to any therapies, and vendor/seller reputation (see Chapter 19 for further details).

When assessing breeding collections, it is a good idea to avoid upsetting the routines of breeding animals, so collecting samples and performing examinations is best done before breeding seasons when possible. At a minimum, a review of the records kept by the breeder should be performed once yearly and during every disease outbreak or unexplained cluster of deaths (Table 179.2).[2] Each individual breeding animal should have a calendar log-book entry indicating weights, breeding dates, number of young produced, fecal output, meals offered, meals eaten, shed times, cage cleaning, changes in behavior, and antivenom classification if venomous. Fecal testing, especially in species where parasites are common, can be performed twice yearly, and physical examinations should be done once or twice yearly.

Valuable animals, either as breeders or producers of venom, may warrant more thorough evaluations. These should include (but not be limited to) a detailed history, a thorough physical examination, fecal parasite examinations (e.g., direct, float, and/or special stains), laboratory analysis (complete blood count/chemistry profile), diagnostic imaging, and histology, cytology, and microbiology when indicated (Fig. 179.3).

WHOLESALE AND RETAIL COLLECTIONS

In wholesale and retail situations where individuals are constantly in flux (both in numbers and in species), it becomes quite challenging to

FIG 179.3 The physical examination will be determined by the type and size of animal (leopard geckos, *Eublepharis macularius,* in this figure). Evaluation should include assessment of body condition, color, activity, any swellings/masses, and integrity of the skin. (Courtesy of Chris Griffin.)

TABLE 179.2 Common Infectious Diseases Outbreaks in Reptiles Collections

Disease	Species	Diagnostic Sampling
Atadenovirus	Bearded dragons	Biopsy (liver, stomach, esophagus, kidney) and polymerase chain reaction assay (PCR)
Coccidia	Lizards	Fecal analysis
Cryptosporidiosis	Squamates, chelonians	Fecal acid fast, PCR, histology
Herpesvirus	Chelonians	PCR, electron microscopy, and viral isolation
Microsporidia	Bearded dragons	Histology
Mycoplasma	Chelonians, squamates, crocodilians	Culture, enzyme-linked immunosorbent assay (ELISA), and polymerase chain reaction assay
Paramyxovirus	Snake	Hemagglutination inhibition assay (HI), viral isolation, or PCR
Ranavirus	Box turtles, red-eared sliders	Histology, PCR
Reptarenavirus (IBD)	Boas, pythons	PCR, histology

maintain any sort of continuity of testing or rigid quarantine procedures. Realistically, only animals that appear significantly abnormal will be presented to the veterinary hospital, and basic diagnostics or euthanasia may be all that is allowed. There are financial reasons for this, and although this can be frustrating, a positive impact can still be made for the animals that find themselves part of this pet store experience. Not every case needs advanced imaging or molecular testing, but for unusual cases advanced testing and/or necropsy and histopathology (if the patient dies or is euthanized) should be recommended.

Although a separate room and air space is recommended for quarantine, some physical facilities are not so designed. At a minimum, new arrivals should not be mixed with the current population. Some practical options are grouping neonates or hatchlings together if they originate from the same source. Keeping the same species isolated in the same air space/room is an easy solution, especially if they all came from the same vendor and are moved through as a group before adding new animals. Mixing species and group housing different age groups should be discouraged. Specific quarantine periods need to be determined for each species.

Cage cards can be instrumental in recognizing problems that may arise during quarantine. One of the most important aspects of identifying sick reptiles in the pet store is the proper training of the employees/caretakers. Good observational skills and an understanding of basic health and behavior are paramount to early detection of illness and should then lead to veterinary evaluation. The presentation of a sick reptile 1 to 2 days into an illness often results in a better prognosis than evaluating a reptile 14 to 21 days later. A cage card will help remind employees/caretakers of what needs to be recorded and trigger an early warning of potential problems (Fig. 179.4). This training can also result in better education of customers as to the needs of their new purchase; the public often looks to the sales force as a source of knowledge about the care of exotic animal species.[4]

HUSBANDRY-RELATED CONDITIONS

Deficiencies in husbandry are the most common factor causing illnesses in captive reptiles. For a thorough review of husbandry, see Section 3. Stress, including overcrowding, exposure to sick animals (and their body fluids/excrements), poor nutrition, improper thermal gradients, and many other aspects of care may predispose animals to many of the illnesses that plague reptiles in the pet trade (Fig. 179.5). Many reptiles are shipped to pet stores in containers that are either too small or overcrowded with the same (or different) species and with minimal ability for thermal regulation. Many are shipped from a breeder to a distribution center before being sent to a pet store, and these animals (usually younger ones) may be without food or water for several days during transportation. The basics of thermal support, humidity, feeding opportunities, hiding options, and a reasonable animal-to-space ratio are often not provided, even within a pet store setting.[5,6] These factors may trigger new health conditions or a flare-up of preexisting conditions. Examples include

VetBooks.ir

FIG 179.5 Shell damage during shipping of a Russian tortoise (*Agrionemys horsfieldii*). (Courtesy of Drury R. Reavill.)

FIG 179.6 A red-eared slider (*Trachemys scripta elegans*) with significant loss of body condition and obvious muscle wasting. (Courtesy of Drury R. Reavill.)

adenoviral or coccidial infections in bearded dragons and cryptosporidial infections in leopard geckos (*Eublepharis macularius*).[7]

Addressing the basic husbandry needs in the store does not need to be complex, and ultimately having healthy animals for sale should result in increased profits/sales. It should be easy to clean enclosures and replace substrate. Visual barriers are important to some species and essential for others. Individual housing may be necessary. Water should be supplied in a manner preferred by the species (e.g., water bowl, tank with a haulout for aquatic species; misting or drip systems for old-world chameleons).

POSTMORTEM EVALUATIONS

In situations where there is increasing morbidity and/or mortality, a complete postmortem evaluation can provide answers. Selecting the most typical presentation of the disease is important in identifying a widespread problem versus a disease condition involving only one animal in a collection. Sometimes necropsies on multiple animals are required to establish the full spectrum of the problem. Indeed, an elective euthanasia and necropsy is often a more rewarding approach, both financially and clinically.

In general, the most recently deceased (or electively euthanized) animal should be considered for necropsy submission during an outbreak of disease or multiple unexplained deaths. Animals that were "found dead in cage" are often not suitable, as heated cages will accelerate autolysis. When possible, paired tissue samples from the same patient (or from multiple patients if more than one is euthanized/dies) should be collected—the first set should be placed in formalin for histopathological evaluation and the second set should be frozen in case future molecular testing (such as PCR) is indicated. Culture swabs should be taken if granulomas or abscesses are observed, and a portion of the affected tissue (if available) can be included in the culture media to increase the chances of isolate recovery (this may be especially true with fungal infections). Intestinal cultures for *Salmonella* may be needed if there are zoonotic concerns.[5] All persons involved with reptiles should be informed and follow the current published guidelines (https://arav.org/salmonella-reptiles-veterinary-guidelines).

Most facilities that will perform a complete postmortem will have procedures in place for body disposal. For animals not submitted for a necropsy (including histopathology), disposal is dictated by local laws. Most locations recommend cremation. Some uncommon species may be held for taxidermy or skeletal preparations. Large species (giant tortoises) in breeding facilities may be buried on-site after consultation with local laws, due to the difficulty in transporting these large specimens.

DISEASE CONDITIONS

The information in the following sections is from case files collected from a large clinical practice and a pathology service.[1] These common disease conditions may not be representative for reptile collections across the world. With increasing awareness of threats to wild populations, additional diagnostic modalities are becoming available that may improve the ability to identify specific disease agents affecting captive populations. A recent example is a Nidovirus that has been associated with a respiratory disease condition in ball pythons (*Python regius*) that had been recognized since the late 1990s as associated with many other etiologies.[8] Another example involves the emergence of highly contagious fungal skin diseases that may result in systemic disease and potentially infect apparently healthy reptiles. The classification scheme for these fungal infections is evolving as more reptile species, both wild and captive populations, are examined and identified. The fungus *Ophidiomyces ophiodiicola* (formerly *Chrysosporium ophiodiicola*) is increasingly being identified in wild rattlesnakes and several species of colubrids, including racers and rat snakes.[9,10] The fungus Nannizziopsis is considered a primary pathogen causing dermal infections across different classes of reptiles, most commonly bearded dragons and chameleons; crocodiles; and snakes.[10]

Common Clinical Diseases

Many of the common presentations that are seen in practice are manageable, and most do not necessarily require terminal diagnostic procedures. The most common conditions are discussed here.

In turtles and tortoises, poor nutritional status, failure to thrive, poor/abnormal shell development, and anorexia are common (Fig. 179.6).

In lizards, enteric parasitic infections are common and include coccidia, pinworms, and protozoans in bearded dragons; cryptosporidosis in leopard geckos; and protozoans in most species (pathogenicity determined by clinical signs and/or histology evidence of associated lesions). Gram-negative enteritis is common in many species. Nutritional secondary hyperparathyroidism (resulting in hypocalcemia and associated changes) remains common in iguanas, uromastyx lizards, bearded dragons, leopard geckos, and chameleons (Fig. 179.7) Ocular issues including conjunctivitis from environmental factors (e.g., reptile bark) or retained sheds (possibly from humidity/hydration issues) and

VetBooks.ir

FIG 179.7 The bilateral swelling of the mandible in this green iguana (*Iguana iguana*) is due to fibrous tissue hypertrophy attempting to stabilize soft bones and is a classic sign of nutritional secondary hyperparathyroidism due to poor management. (Courtesy of Chris Griffin.)

FIG 179.8 In leopard geckos (*Eublepharis macularius*), the skin of the eyelid may be retained following abnormal ecdysis. Failure to shed this skin can result in an accumulation of keratin in the conjunctival sac, subsequent irritation, and infection. (Courtesy of Chris Griffin.)

FIG 179.9 A poorly thriving veiled chameleon (*Chameleo calyptratus*) with secondary diseases (including necrosis of the tail tip). (Courtesy of Chris Griffin.)

FIG 179.10 Asian water dragon (*Physignathus cocincinus*) with multiple irregular foci of brown-gray hyperkeratotic plaques and dysecdysis due to skin mycosis. (Courtesy of Drury R. Reavill.)

hypovitaminosis A in insectivorous lizards are common (Fig. 179.8). Stomatitis is commonly seen in water dragons, blue-tongued skinks, bearded dragons, and leopard geckos. Atadenovirus in bearded dragons may be more common than reported, and concurrent infections with atadenovirus and parasites (e.g., coccidia and cryptosporidia) can result in more severe signs and a greater chance of mortality.[11] Failure to thrive, a catch-all term used in captive animals to describe illnesses that are not specifically identified but compromise the animal, is seen in more "sensitive" species (e.g., most chameleon species, some geckos, uromastyx, and water dragons) (Fig. 179.9).

Dermal mycoses (formerly classified as Chrysosporium-related dermatitis) are a common skin lesion in anoles, *Ameiva* species, bearded dragons, green iguanas, chameleons, geckos, water dragons, curly-tailed lizards (*Leiocephalus* spp.), and even snakes. Recent molecular analysis has classified these as belonging to the genera Nannizziopsis, Paranannizziopsis, and Ophidiomyces, with a trend to some host specificity.[10] In general, the lesions present as multiple irregular patches of thickened skin supporting a hyperkeratotic exudate (Fig. 179.10). The diagnosis can be made by the fungal morphological and histological features of the lesions, although confirmation is by culture and PCR. These fungi are a group of keratinophilic fungus that can result in a fatal granulomatous dermatitis[12,13] (Fig. 179.11).

In snakes, mites (*Ophionyssus* spp.), retained shed skin, and dehydration are common in all species. Failure to feed (especially with shy species such as ball pythons) with resulting weight loss and/or failure to thrive is common (Fig. 179.12). Neurological signs (weakness) associated with a generalized debilitated state and/or concurrent ectoparasites or viral infections are also common.

Eye lesions in snakes are usually associated with the spectacle rather than the globe itself. Retained spectacles are common and usually related to a poor shed or mites. Infections of the subspectactular space may be seen in snakes that are under stress while also having difficulty shedding, suffering from stomatitis (and possible nasolacrimal duct involvement as a pathway for pathogens to get to this space), or suffering from a traumatic injury (bite from prey). Primary eye diseases are less common but may result from trauma or developmental issues.[14]

Diagnosis and treatment of the aforementioned conditions can be found in a variety of resources, including other sections of this book.

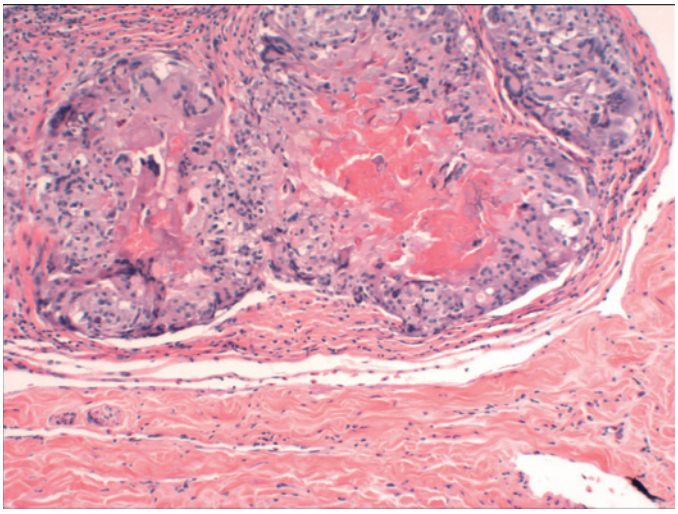

FIG 179.11 Fungal granulomas with a central core of bright eosinophilic debris surrounded by multinucleate giant cells and macrophages. H&E stain; ×10. (Courtesy of Drury R. Reavill.)

FIG 179.12 Significant loss of muscle mass and severe dehydration are evident in this boa constrictor (*Boa constrictor*). (Courtesy of Drury R. Reavill.)

The reader is referred to the appropriate chapters on specific diagnostic testing and therapeutics for these conditions.

Viral infections are probably more common than previously thought in all species of reptiles. Improved viral identification techniques combined with continued research may shed light on this aspect of reptile disease in the future (see Chapter 30).

Of all the infectious presentations commonly seen, cryptosporidiosis (in any species) may be the most frustrating because the morbidity/mortality rate is close to 100% in diagnosed patients, despite a variety of attempted treatments. Concurrent viral infections (e.g., atadenovirus in bearded dragons) may increase the likelihood of mortality in these cases. Although testing all animals for cryptosporidia and removing chronically infected carriers from the collection may be a consideration for small collections, this may be cost prohibitive in large collections or inappropriate with valuable species. Quarantine, use of proper hygiene, and separation of healthy reptiles from those with obvious clinical signs are viable options. Antemortem tests include fecal acid-fast stain, histological biopsy of the gastric mucosa, or PCR. However, some testing may result in false positives by identifying cryptosporidia from prey items such as rodents.

Diseases Identified Postmortem in Retail Animals

A review of reptiles from several retail facilities submitted to a pathology service identified some disease trends in common pet species (Table 179.3).[1] The majority of the reptiles in the review study were young animals, not older breeding stock. The results of this review are discussed in the following sections. In general, across all reptile groups, the most commonly diseased organ system was the gastrointestinal tract. This suggests that close evaluation of the gastrointestinal system is a priority and also stresses that nutritional support is an essential part of the therapy.

Chelonians. Of the turtles and tortoises examined, the most common finding was chelonid herpesvirus infection of Russian tortoises (*Agrionemys horsfieldii*), which in many cases was from outbreaks involving multiple animals. Herpesvirus-associated rhinitis, stomatitis, glossitis, tracheitis, bronchopneumonia, and, uncommonly, necrotizing hepatitis have been reported in a number of tortoise species: Hermann's tortoises (*Testudo hermanni*); Russian, spur-thighed tortoises (*Testudo graeca*); and marginated tortoises (*Testudo marginata*) (Fig. 179.13). This herpesviral infection is frequently complicated by secondary bacterial infections and generally results in severe debilitation of the tortoise. The transmission is most likely from infected carriers, although the pathogenesis of this viral infection has not been fully described. The early lesions in these Russian tortoises were stomatitis and glossitis. This suggests that specifically testing for herpesvirus in tortoises with this presentation can help separate those animals with this typically fatal disease from those with other potentially treatable conditions.[15]

Nonspecific dermatitis (not involving the shell) was also a commonly recognized postmortem lesion in chelonians, primarily in water turtles such as red-eared sliders (Fig. 179.14). On the basis of the history, these lesions were suspected to be traumatic in origin and were slow to resolve with apparently adequate therapy. Bacterial involvement in cases of dermatitis was based on the presence of bacteria identified in the inflammation and/or bacterial granulomas present within the dermis on histological examination. Fungal dermatitis of chelonians was not identified in this collection of cases.

Sporadic findings of intestinal parasitism were noted. These included nematode, trematode, and cryptosporidial enteropathies.[16] A small number of tortoises and turtles also had a nonspecific enteritis in which a disease etiology was not identified.

Primary pneumonia was uncommon and was usually associated with a variety of systemic diseases.

A small number of the freshwater and box turtles (Emydidae) had intravascular parasites consistent with spirorchid fluke eggs. Adult spirorchid flukes (blood flukes) inhabit the cardiovascular system (heart and blood vessels) of many freshwater and marine turtles. These are analogous to the schistosomes of birds and mammals. Eggs deposited by the adults are carried through the circulatory system and can block small blood vessels in many organs, producing microgranulomas. The eggs then migrate to the lumen of the intestines, which can lead to necrosis and bacteremia. In freshwater turtles, the intermediate host is a snail, of which at least one species has been identified, *Helisoma anceps*.[17] Because antemortem testing is unlikely to identify this infection in the individual animal, a postmortem diagnosis should warrant treatment for all exposed turtles in a collection.[18]

TABLE 179.3 Summary of Disease Conditions Recognized by Pathological Evaluation*

Lesions/Disease Agents	Chelonians (50/349)	Lizards (108/349)	Snakes (119/349)
Adenovirus† with associated lesions in the liver and/or intestines	—	26 (24%)	3 (2.5%)
Autolyzed sample‡	2 (4%)	3 (2.8%)	1 (0.8%)
Bacteremia	—	1 (1%)	4 (3.4%)
CANV-like† (fungal dermatitis)	—	22 (20.4%)	—
Debilitation, severe§	3 (6%)	12 (11.1%)	49 (41%)
Dermatitis, bacterial†	8 (16%)	9 (8.3%)	1 (0.8%)
Dermatitis, nonspecific‖	2 (4%)	7 (6.5%)	—
Dermatitis, other fungus (not CANV)	—	3 (2.8%)	1 (0.8%)
Encephalitis, nonspecific‖	—	2 (1.8%)	2 (1.7%)
Entamoeba	1 (2%)	1 (1%)	—
Enteritis and/or gastritis, cryptosporidia†	2 (4%)	48 (44.4%)	8 (6.7%)
Enteritis, coccidia	—	7 (6.5%)	—
Enteritis, nematodes	4 (8%)	8 (7.4%)	3 (2.5%)
Enteritis, nonspecific‖	5 (10%)	14 (13%)	52 (43.7%)
Enteritis, protozoal flagellates	—	2 (1.8%)	2 (1.7%)
Enteritis, trematodes	1 (2%)	2 (1.8%)	—
Hepatitis, nonspecific‖	1 (2%)	17 (15.7%)	8 (6.7%)
Herpesvirus† (including necrotizing hepatitis and stomatitis)	19 (38%)	—	—
IBD†	—	—	14 (12.8%)
Kidney, protozoal flagellates	—	5 (4.6%)	—
Mycobacteria†	1 (systemic) (2%)	—	—
Myocarditis, nonspecific‖	1 (2%)	2 (1.8%)	—
Pneumonia, fungal	—	1 (1%)	—
Pneumonia, nonspecific‖	5 (10%)	7 (6.5%)	9 (7.6%)
Renal urate tophi	—	1 (1%)	—
Sarcocyst within skeletal muscle	3 (6%)	—	—
Schistosomes	4 (8%)	—	—
Shell necrosis	2 (4%)	—	—
Skin mites	—	—	5 (4.2%)
Stomatitis, nonspecific‖	2 (4%)	—	—
Trematode, intestines	1 (2%)	—	—
Vacuolar hepatopathy	—	3 (2.8%)	—

CANV, *Chrysosporium* anamorph of *Nannizziopsis vriesii*; *IBD*, inclusion body disease.
*The numbers will not equal 100%, because animals may have had more than one lesion.
†The etiology, in some cases, was confirmed by further diagnosis with polymerase chain reaction or cultures.
‡The submitted animal was too autolyzed to identify any lesions on histological examination.
§Debilitation was determined by loss of coelomic cavity fat, muscle wasting, and hepatic atrophy.
‖No specific etiological agent was identified.

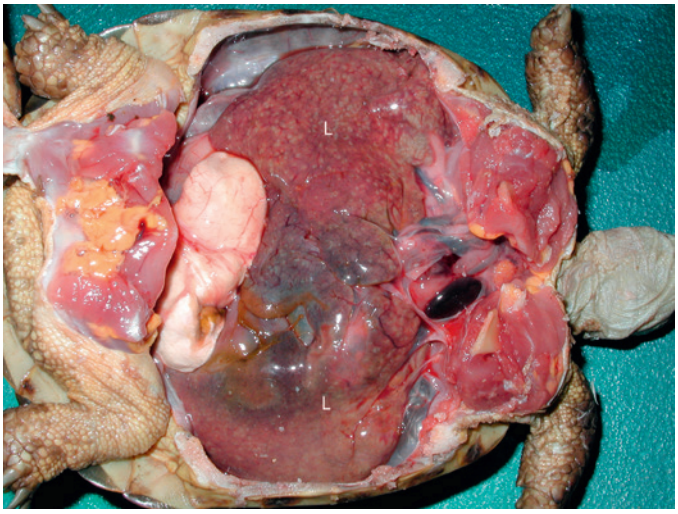

FIG 179.13 Russian tortoise (*Agrionemys horsfieldii*) with multiple foci of hepatic necrosis due to herpesvirus. L, Liver. (Courtesy of Drury R. Reavill.)

FIG 179.14 Erosive and ulcerative dermatitis on the dorsal neck of a red-eared slider (*Trachemys scripta elegans*), suspected to be caused by trauma. (Courtesy of Drury R. Reavill.)

VetBooks.ir

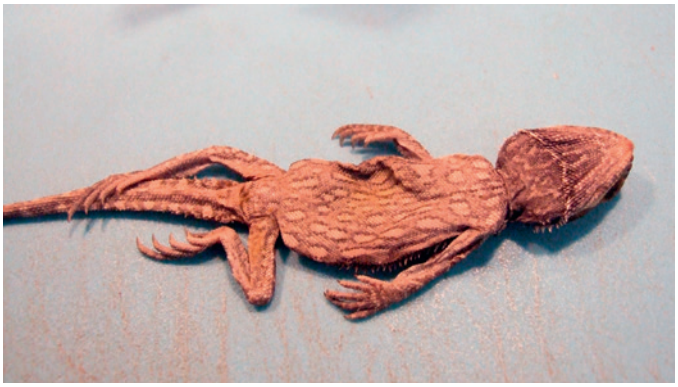

FIG 179.15 A bearded dragon (*Pogona vitticeps*) with enteric cryptosporidiosis. There is loss of body condition with muscle wasting and dehydration. (Courtesy of Drury R. Reavill.)

Lizards. Of the abnormalities reported in lizards, the most common finding was cryptosporidial enteritis and/or gastritis. This is most likely overrepresented because the most common lizards in the pet trade are leopard geckos; and these lizards are frequently infected. Smaller numbers of bearded dragons and water dragons also had cryptosporidial enteropathies. Because these lizards were severely emaciated and dehydrated on postmortem evaluation, the cryptosporidial infections were deemed to be a significant contributor to disease and, ultimately, death (Fig. 179.15).

Atadenovirus infection involving the liver and gastrointestinal tract is common in bearded dragons. This viral infection became established in lizard-breeding colonies in the United States and can result in high mortality rates for immunocompromised animals. The common clinical signs in young bearded dragons are progressive weakness and anorexia. Frequently, these emaciated lizards have concurrent intestinal coccidial infections (Fig. 179.16A).

Dermatitis, including bacterial, fungal, and in some cases with no apparent etiological agent, is commonly seen in young lizards. Additionally nonspecific hepatitis and enteritis are recognized as frequent lesions. The lack of etiological agents for these two conditions could be due to attempts at antemortem therapies. Systemic debilitation, which contributed to decline and death, is characterized by hepatic atrophy and/or atrophy of the coelomic cavity fat pads.

Snakes. Generalized debilitation was a common presentation, especially for young snakes. Almost half of the animals had significant hepatic atrophy, as well as atrophy of the coelomic cavity fat pads. A nonspecific enteritis and/or enterocolitis was also a common finding that could be accounted for by poor husbandry such as inadequate heat and/or humidity.

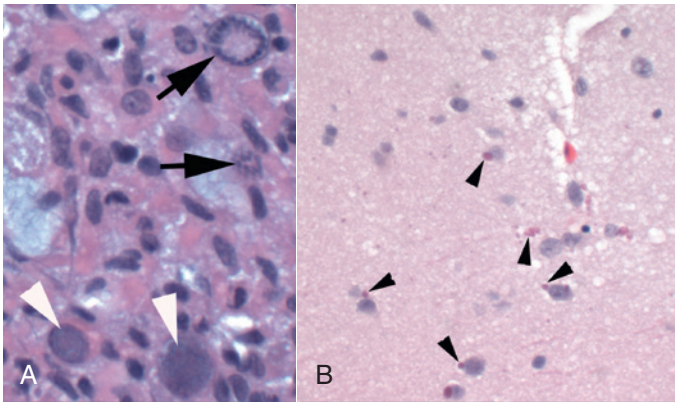

FIG 179.16 (A) Histology of the intestinal mucosa of a bearded dragon (*Pogona vitticeps*) with coccidia (black arrows) and adenovirus (*white arrowheads*). H&E stain, ×40. (B) Round to oval intracytoplasmic viral inclusions (arrowheads) in the brain of a python characteristic of boid inclusion body disease caused by reptarenavirus. H&E stain, ×40. (Courtesy of Drury R. Reavill.)

Inclusion body disease (IBD) of boids, recently associated with the arenavirus, was a frequent finding because the majority of snakes in the pet trade are susceptible to IBD, including the common boa (*Boa constrictor imperator*) (see Fig. 179.16B)[19] (see Chapter 30).
Skin mites and gastric cryptosporidiosis were also common, and both diseases are well described in the literature.[20,21]

Diseases Identified Postmortem in Breeding Stock

In general across all reptile groups, tumors, reproductive disorders primarily in females, degenerative lesions of the kidney and liver, and chronic infections such as IBD and mycobacteriosis can develop. These conditions are described in detail in other chapters. Knowing the common diseases in a population of animals and conducting a thorough examination with appropriate diagnostic testing can result in better health of those animals entering the pet trade and improvement in animal welfare.

Laboratory Management and Medicine

Dorcas P. O'Rourke, Peter Nowlan, and Leslie Retnam

Reptiles and amphibians are encountered in an array of institutional settings, from corporate biomedical research facilities to veterinary colleges and herpetology teaching collections. Some amphibian species, such as the African clawed frog (*Xenopus laevis*), have become so commonplace that entire books are devoted to their husbandry and care in laboratory animal settings.[1] African clawed frogs were originally used for pregnancy assays and toxicology research; more recent biomedical uses include oocyte harvesting for molecular biology research and, along with *Silurana* (*Xenopus*) *tropicalis,* developmental biology studies. In addition to *Xenopus*, commonly used laboratory species of amphibians include axolotls (*Ambystoma mexicanum*), American bullfrogs (*Lithobates catesbeianus*), leopard frogs (*Lithobates pipiens*), tiger salamanders (*Ambystoma tigrinum*), and marine toads (*Rhinella marinum*). Axolotls have long been popular as animal models for limb regeneration studies; research has expanded to include cardiac and central nervous system regeneration. Bullfrogs and leopard frogs are commonly used in physiology laboratory instruction and in endocrinology, nociception, and infectious disease research. Tiger salamanders and marine toads are used as models for studies involving neurology and ophthalmology. Most recently, wild and captive populations of amphibians have been used in environmental toxicology, endocrine disrupter, and chytridiomycosis investigations.

Reptiles are relatively uncommon in biomedical research institutions but are frequently found in universities. Among reptiles, green anoles (*Anolis carolinensis*) and brown anoles (*Anolis sagrei*) are most commonly used for physiology, endocrinology, and behavior research. Parthenogenesis and other reproductive strategies are studied in whiptail lizards (*Aspidoscelis* spp.). Red-eared sliders (*Trachemys scripta elegans*) and related aquatic turtle species are used in physiology laboratories and for infectious disease research. Snakes are typically found in teaching collections and displays and are also used to study behavior, ecology, and evolution. Venom biochemistry and therapeutic use of venom components are specific areas of medical interest. Crocodilians are used commonly in biochemistry, physiology, and environmental toxicology research. Both reptiles and amphibians are extensively studied by herpetologists in laboratories and in the field to better understand their ecology and evolutionary biology and by veterinarians interested in medicine and surgery of these animals.

REGULATORY OVERSIGHT AND ACCREDITATION GUIDELINES

In the United States the USDA requires registration as a research facility if USDA-covered species are used in research and teaching. Registered facilities are subject to at least annual unannounced inspections by veterinary medical officers of the USDA. Significant uncorrected deficiencies in animal care and use programs can ultimately lead to fines and facility closure. At this time, USDA regulations cover only a defined subset of mammals. They are not applicable to reptiles and amphibians and will not be further included in this discussion. The US Government Principles, Public Health Service (PHS) Policy,[2] and *Guide for the Care and Use of Laboratory Animals* (*Guide*)[3] are much broader in scope and cover all vertebrate species. A division of NIH, the Office of Laboratory Animal Welfare (OLAW), is charged with overseeing institutional compliance with the US Government Principles, the PHS Policy, and the *Guide*.[4] This is accomplished through several mechanisms, including reviewing and approving an institution's PHS Assurance and conducting visits to the institution, if warranted. Conducting NIH-funded research activities without approval by an Institutional Animal Care and Use Committee (IACUC) can result in an investigator having to return grant money. In addition to required federal oversight, many universities and research facilities are voluntarily accredited by the AAALAC, International (AAALAC). AAALAC requires adherence to all applicable national, regional, and local legislation and uses the *Guide* as one of its three primary resources.[5] AAALAC conducts triennial site visits to accredited institutions to review animal care and use programs.

US federal wildlife and fisheries agencies require permits to conduct research on certain wildlife species; these will be addressed later. State agencies dealing with natural resources, fisheries, and wildlife may require permits or regulate acquisition and possession of certain species. Local regulations may also apply. When planning research or teaching activities involving reptiles and amphibians, investigators should check federal, state, and local regulatory requirements governing their species of interest.

The Canadian Council on Animal Care (CCAC) is a nonprofit, national organization for setting and overseeing standards of animal care throughout Canada[6]; this is accomplished through peer review assessments and program certification. The *CCAC Guidelines on: The Care and Use of Wildlife* includes amphibians and reptiles.[7]

In Europe, regulatory oversight of research animals involves a number of independent countries and is therefore quite complex. Briefly, there are two overarching regulatory institutions. The Council of Europe,[8] representing 47 independent European states, publishes the European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes, Guidelines for Accommodation and Care of Animals (ETS 123, Appendix A), which is relevant to reptile and amphibian research use.[9]

The European Union (EU) has regulatory control over 26 member states and has issued Directive EU 63/2010, which requires each member state to provide an authorization process for the conduct of research using any nonhuman vertebrate animal and cephalopods, and establishment of an oversight agency, the Competent Authority (CA), Directive EU 63/2010 must be implemented by member states. Although there

VetBooks.ir

is some flexibility regarding implementation, serious deviations can result in legal action.

EU directive 63/2010 contains a series of appendices that describe requirements relating to animal care and well-being. Annex I lists species that must be acquired from registered breeders and that must be purpose-bred for research, including *Xenopus laevis*, *Silurana tropicalis*, *Rana temporaria*, and *Lithobates pipiens.* Annex III lays down housing conditions for various animals, including reptiles and amphibians.[10] The requirements of Annex III are mandatory, whereas adherence to the more detailed Council of Europe ETS 123 is voluntary. It is important to note that not all members of the Council of Europe are members of the European Union.

Once all appropriate authorizations are in place, parties are subject to regular inspections by inspectors of the Competent Authority (CA). Additionally, each authorized establishment must have an animal welfare body and a compliance officer to monitor study conduct and demonstrate a robust mechanism for ensuring compliance with both the general conditions of the law and the specific conditions of individual authorizations.

Researchers must be trained and competent in theoretical aspects of the law, ethical review 3Rs, and in the practical elements of individual procedures, inclusive of euthanasia; these training programs must be approved by the CA.

In Australia, the eighth edition of the *Australian Code for the Care and Use of Animals for Scientific Purposes* (*Code*) covers all vertebrates and cephalopods and provides an ethical framework and principles for all areas of science using animals, including research, teaching, biologic product production, and environmental studies. The *Code* is endorsed by the National Health and Medical Research Council, Australian Research Council, Commonwealth Scientific Industrial Research Organization, and Universities Australia.[11] States and territories can also require registration and/or licensing to conduct animal research.

In New Zealand, reptiles and amphibians fall under the definition of "animals" under s 2 (1) (a) of the animal welfare legislation. Any research, testing, and teaching (defined in s 5 of the legislation) using such animals can only be done by an institution holding a Code of Ethical Conduct (CEC) approved by the Director General for Primary Industries and following approval by an animal ethics committee properly constituted under the CEC, as required by the Animal Welfare Act. Additionally, native frogs, lizards, and the tuatara are protected, and permits to catch or carry out research on these species are required from the Department of Conservation.[12] The Australian and New Zealand Council for the Care of Animals in Research and Teaching (ANZCCART) provides well-researched, objective information on ethical use of animals in research and teaching.[13]

In Singapore, the Agri-Food and Veterinary Authority (AVA) requires research institutes using vertebrates for scientific purposes (including reptiles and amphibians) to be licensed. Research institutes are subject to at least one annual inspection by inspectors from the AVA.

AAALAC International accredited units can be found in Canada, Singapore, Australia, and throughout Europe.

FUNDING AGENCY REQUIREMENTS

During the 1980s in the United States, several federal agencies formed the Interagency Research Animal Committee (IRAC). Members of this group developed and published the US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training (US Government Principles). Agencies that committed to adhere to these principles when conducting and sponsoring research include the Department of Health and Human Services (including the National Institutes of Health [NIH], Centers for Disease Control [CDC], and Food and Drug Administration [FDA]), the Department of Defense (DoD), Department of Agriculture (USDA), Department of the Interior (DoI), the Environmental Protection Agency (EPA), the National Aeronautics and Space Administration (NASA), and the National Science Foundation (NSF).[14]

TABLE 180.1 US Federal Agency Compliance Requirements

Agency	Govt. Principles	PHS Policy	Guide	Other
NIH	X	X	X	
NSF	X	X	X	
DOD	X		X	
NASA		X		NASA Policy
FDA				GLP
EPA				GLP

DOD, Department of Defense; *EPA,* Environmental Protection Agency; *FDA,* Food and Drug Administration; *GLP,* good laboratory practices; *NASA,* National Aeronautics and Space Administration; *NIH,* National Institutes of Health; *NSF,* National Science Foundation.

Agency compliance requirements are in Table 180.1. Additionally, private granting agencies such as the Morris Animal Foundation require IACUC or equivalent body approval;[15] others may request information on IACUC approval or adherence to animal care guidelines on grant applications.[16,17]

The Natural Sciences and Engineering Research Council of Canada requires all animal research to comply with the CCAC policies and guidelines.[18]

In Australia, the primary federal government funding agency for working with reptiles and amphibians is the Australian Research Council (ARC). The ARC endorses the Australian Code for the Care and Use of Animals for Scientific Purposes.[11] Internally funded university studies are also subject to the Australian Code and state animal research and conservation laws.

In New Zealand, any funding agency would require that all relevant permits (AEC, Department of Conservation [DOC]) have been obtained.

Funding from the Singapore government for biomedical research comes primarily from either the National Research Foundation (NRF), National Medical Research Council (NMRC), or the Biomedical Medical Research Council (BMRC). The application process to obtain funds from the government to conduct research, teaching, and testing on reptiles and amphibians would not be any different from using other live vertebrates.

PUBLICATION REQUIREMENTS

Many professional organizations have standards for ethical conduct of research and criteria for publication in scientific journals.[19–21] The Society for the Study of Amphibians and Reptiles (SSAR), American Society of Ichthyologists and Herpetologists (ASIH), and Herpetologists League (HL) have published *Guidelines for Use of Live Amphibians and Reptiles in Field and Laboratory Research*,[22] which discuss ethical research conduct and expectations for IACUC approval. Other journals have similar requirements (Table 180.2).[23–28]

If an individual wishes to conduct a study and is not affiliated with a university or other institution, she/he may either be able to obtain an adjunct appointment or collaborate with a faculty member of an institution that has a research program and an IACUC in place.

The *Canadian Veterinary Journal* will only consider manuscripts that have obtained IACUC or equivalent approval and have followed CCAC guidelines or equivalent.[29]

VetBooks.ir

Journal of the American Association for Laboratory Animal Science[25]
Comparative Medicine[25]
Journal of Zoo and Wildlife Medicine[26]
Journal of Herpetological Medicine and Surgery[27]
Journal of Wildlife Diseases[28]

European journals broadly adhere to the international guidelines of major journals. Many have implemented the "ARRIVE" guidelines for design of studies using animals[30] and require an ethical review and evidence of compliance with local legislative requirements.

The EU Directive requires project authorization for nonhuman vertebrates or cephalopods to be granted by the CAs of each member state; this process involves an ethical review.

In Australia, each journal's editorial policy delineates specific requirements; however, these increasingly include the ARRIVE guidelines.

The leading journals in New Zealand require ethics approval for publication of research involving the manipulation of animals. The Royal Society of New Zealand's (RSNZ) policy on the ethical use of nonhuman subjects in research states that RSNZ journals endorse the ANZCCART (NZ) policy for the responsible use of animals in science.

The *New Zealand Veterinary Journal* requires conformation with ethical standards described in the Ministry of Agriculture and Forestry (MAF) User's Guide to Part 6 of the New Zealand Animal Welfare Act 1999, the Good Practice Guide for the Use of Animals in Research, Testing and Teaching, published by the National Animal Ethics Advisory Committee (2002), and approval by an accredited animal ethics committee, in accordance with Part 6 of the Animal Welfare Act 1999.

In Singapore, similar to Australia and New Zealand, publications involving amphibians and reptiles for scientific purposes are required to meet specific criteria of the journal.

THE GUIDE FOR THE CARE AND USE OF LABORATORY ANIMALS

The *Guide for the Care and Use of Laboratory Animals* (*Guide*) is used by many institutions within the United States and increasingly internationally when developing and implementing internal policies and procedures for vertebrate animal care and use. Although the term *laboratory animal* appears somewhat misleading, the *Guide* is careful to clearly define laboratory animals as all vertebrates used in research, teaching, and testing. The most recent edition of the *Guide* specifically addresses husbandry and care of aquatic species in research settings. It further explains that even though it does not specifically discuss wildlife and aquatic species in natural settings, it does provide ethical considerations and general principles that are equally relevant to these circumstances.[3]

Performance standards are an integral component of the *Guide.* The *Guide* provides basic standards for animal care and use programs and establishes desired outcomes but allows institutions flexibility in how they achieve those outcomes. For example, air exchange rates in animal rooms must be sufficient to prevent accumulation of excess humidity and ammonia, which is a respiratory irritant. Therefore typical air exchange rates are 10 to 15 air changes per hour. However, species such as reptiles and amphibians with slower metabolic rates and less waste production do not generally require the same rapid turnover of room air; in fact, air exchanges that are too rapid can desiccate species that require high humidity. Consequently, rooms with lower air exchange rates may be preferred for these species and can be appropriately justified through the use of these performance standards. AAALAC-accredited institutions can also refer to recognized reference resources,[31] such as Guidelines for Use of Live Amphibians and Reptiles in Field and Laboratory Research.[22]

In Canada, the *Guide to the Care and Use of Experimental Animals, Vol. 2* (1984), *Guidelines on the Care and Use of Wildlife* (2003), and *CCAC Species-specific Recommendations on: Amphibians and Reptiles* (2004) provide information on reptile and amphibian care and use.[32]

In Europe, the other document that gives more detailed information of best practice and guidelines for reptiles and amphibians is the Council of Europe ETS 123 Appendix A guidelines.

Unlike the *Guide*, which provides a comprehensive overview of all aspects of managing an animal care and research program, there is no single EU document that covers topics such as researcher and staff health and safety, animal transport, captive colony health monitoring, zoonotic disease transmission, and other related components of animal care and use. These subjects are contained in separate documents, and many of them may be national in nature rather than pan-European.

In Australia, the New South Wales animal regulatory body that governs animal research has some useful guidelines on wildlife research that would apply to reptiles and amphibians;[33] other state governments may have similar guidelines. The National Health and Medical Research Council (NHMRC) published guidelines on well-being of animals used in research, and they contain a wildlife section that makes reference to reptiles and amphibians.[34]

New Zealand documents to assist researchers and animal ethics committees on the use of amphibians and reptiles for procedures, such as marking/identification, animal welfare, and practicalities and public perceptions in New Zealand,[35] include the *Guide to the Preparation of Codes of Ethical Conduct*[36] and *Good Practice Guide for the Use of Animals in Research Testing and Teaching.*[37]

In Singapore, the Guidelines for the Care and Use of Animals for Scientific Purposes published by the National Advisory Committee for Laboratory Animal Research (NACLAR) in 2004 is the primary document.[38]

INSTITUTIONAL ANIMAL CARE AND USE COMMITTEE/ANIMAL WELFARE BODY/ETHICS COMMITTEE

The aforementioned US regulations and guidelines require animal care and use program oversight by a body such as an IACUC. For PHS-assured institutions, there must be at least five members on the IACUC. Membership must include a laboratory animal veterinarian, a practicing scientist, a nonscientist, and a community member with no institutional affiliation.[2] Animal care programs with reptiles and amphibians often find it advantageous to appoint IACUC members with experience in these groups of vertebrates. An alternative approach is to utilize consultants with expertise in the species being reviewed; these individuals can often provide valuable information that will enable the IACUC to make sound decisions on proposed animal use.

The IACUC is charged with several important functions, including review of the animal care and use program at least every 6 months.[2] Components of this review include evaluation of the institution's training program for researchers and research staff, animal care personnel, and the IACUC itself; the occupational health and safety program; the

VetBooks.ir

veterinary care program; security and disaster plan; deviations from standards in the *Guide;* and mechanisms for reporting concerns about animal welfare.

Collaborations between researchers at institutions are becoming quite common and can create some challenges for IACUCs. Whenever collaborations across institutions occur, there should be a formal written agreement addressing the responsibilities for oversight and IACUC review.[3] These agreements help eliminate ambiguity and reduce redundancy in oversight.

Another IACUC responsibility is inspecting animal facilities and use areas every 6 months. Although inspection of animal housing areas, surgery and procedure areas, and research laboratories is relatively straightforward, accessing remote field stations and research sites can be difficult (Fig. 180.1). Accessibility is further complicated by the seasonality of field work. One solution for evaluating field research is for the IACUC to request videos or photographs of procedures conducted during the field season.

The IACUC must review all proposals for research, teaching, and testing involving vertebrate animals and also must review any proposed changes to approved ongoing activities. No work may begin until protocols and amendments are fully approved by the IACUC. When submitting protocols for consideration by the IACUC, investigators should realize that the content contained in many of the questions is information required by federal regulations and guidelines. This includes rationale and purpose of the animal use; justification of species and animal numbers (statistically justified if appropriate); consideration of the impact on animal well-being and availability of alternatives; assurance that the work is not unnecessarily duplicative; provision of information confirming appropriate training and experience with proposed procedures and species; identification of hazards and methods to minimize risk; description of animal procedures in nontechnical language; provision of information on atypical housing and husbandry; detailed description of anesthesia, analgesia, surgical and other procedures, and postprocedural care; provision of criteria for intervention and rationale for selected endpoints; and description of euthanasia or other disposition of animals.[3] Euthanasia methods must be consistent with the American Veterinary Medical Association (AVMA) Guidelines for the Euthanasia of Animals.[39] The IACUC is required to carefully consider experimental endpoints and humane endpoints and to determine a method of dealing with unexpected outcomes.[3]

Certain procedures demand intense scrutiny by the IACUC, are typically covered in significant detail in protocols, and require rigorous justification. These include prolonged restraint, multiple survival surgery procedures, food and fluid restriction or regulation, and use of nonpharmaceutical–grade substances.[3] Use of hypothermia for anesthesia in reptiles and amphibians remains controversial and continues to be discouraged.[40,41]

Researchers and instructors submitting protocols involving reptiles and amphibians should be aware of additional items for consideration. Although embryos are not typically covered by the PHS policy, larval forms of amphibians and fish are covered and require a protocol. The use of dead animals or their tissues is not covered unless the animals were killed for the purpose of the collection or if the animals were manipulated before death for the purpose of the study. In those cases, a protocol is required.[42]

Field studies can include a wide range of activities, from capture, identification, and release to invasive sample collection and surgery. Manipulation of animals in the field brings risks and challenges to both animals and personnel, and these must be addressed in the animal care and use protocol. Investigators are encouraged to consult with professional guidelines when planning field studies.[22]

Methods of capture should be described in detail in the protocol. A description of the capture device or method should be provided so that IACUC members unfamiliar with it can clearly understand its operation. Live traps must be checked frequently enough to minimize stress and risk from predators, and any items placed in the trap that increase animal well-being should be included in the description. Site selection should consider protection from the elements and methods to prevent inadvertent capture of nontarget species. Expected mortality rates, adverse effects associated with the capture method, and humane endpoints should also be addressed.

Once reptiles and amphibians are captured, they should be processed as soon as feasible so that stress associated with excess handling is minimized. In some cases, processing requires transportation to a research laboratory, field station, or another site. Animals must be transported in secure containers that prevent escape and injury. During transport, vehicles must have adequate climate control to prevent animals from exposure to temperature extremes. Adequate hydration must also be maintained.

Compared with more traditional laboratory animal species, there are significantly fewer vendors from which to purchase reptiles and amphibians for research and teaching (*Xenopus* is a notable exception). Vendors providing reptiles and amphibians tend to collect from wild or farmed populations, and the condition of animals can be quite variable, depending on the season collected and the holding facilities used (Fig. 180.2). If possible, investigators are encouraged to buy purpose-bred animals from reputable vendors, to ensure healthy research subjects, and to protect wild populations. If reptiles and amphibians are wild-caught, the investigator is responsible for obtaining all appropriate permits; the IACUC will ask for necessary documentation.

FIG 180.1 (A and B) Field stations are often located at remote sites and require specialized transportation, making them difficult for the Institutional Animal Care and Use Committee (IACUC) to access. (Courtesy of Dorcas P. O'Rourke.)

VetBooks.ir

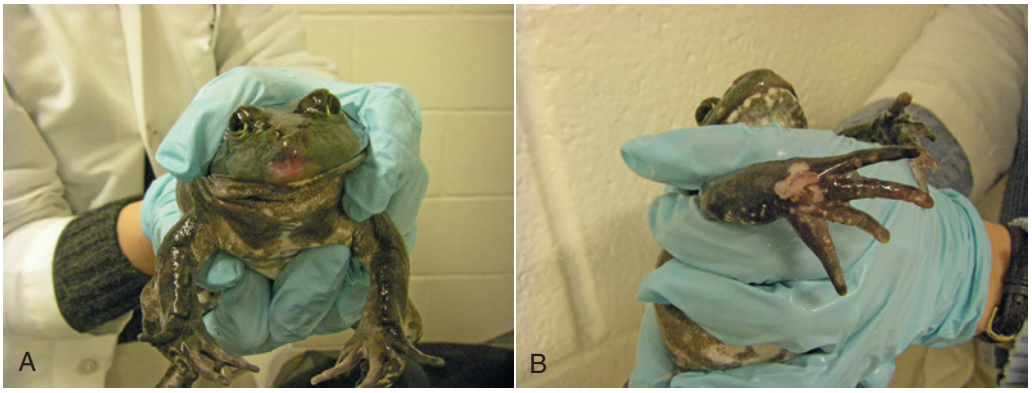

FIG 180.2 (A and B) Wild-caught animals purchased from vendors may have widely variable health status. (Courtesy of Dorcas P. O'Rourke.)

Federal permits may be required for conducting research on reptiles and amphibians. Agencies granting these permits evaluate the risk to the species and population proposed for study and set the criteria for collection, including numbers allowed to be taken. IACUCs may rely on the permitting agency's decision when determining appropriateness of species and numbers. If work is done on federal lands, such as National Park Service land, site-specific permits may be required.[43] Endangered or threatened species of reptiles and amphibians fall under the Endangered Species Act (ESA) and require special permits from the US Fish and Wildlife Service (USFWS); sea turtles require an ESA permit from the National Marine Fisheries Service (NMFS). If endangered species are to be imported or exported, a Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) permit is required. CITES permits fall under the authority of the USFWS. State permits may be required in addition to federal permits, and investigators should contact both federal and state agencies for current requirements before protocol preparation and submission.

Occupational health and safety (OHS) concerns must be addressed when research or teaching activities involving reptiles and amphibians is planned. In addition to standard OHS procedures, personnel should be evaluated on the basis of risk and provided appropriate training in relevant zoonoses.[44] They must be instructed in how to correctly use personal protective equipment when required. Written procedures must be in place for dealing with injuries sustained while handling reptiles and amphibians because bites from large lizards, crocodilians, and venomous snakes can be life threatening, and toxins secreted from parotoid glands of some toad species can be problematic. Housing and working with venomous reptiles is especially dangerous, and specific standard operating procedures for handling animals and responding to envenomation must be written and followed. Field studies also require attention to incidental hazards, including extreme heat, water, ticks, venomous species, and plant toxins. Investigators should be prepared to respond to IACUC questions regarding both direct and incidental OHS concerns.

Performing procedures in the field brings additional challenges to the researcher. Methods of individual animal identification are more limited than in the laboratory, and some techniques such as toe clipping remain controversial.[45,46] Identification methods must be described in detail to the IACUC, and justification must be provided in the protocol for proposed methods that cause pain or impact mobility. Survival surgery must be conducted aseptically; this often requires creative approaches and careful planning when the project is designed. Appropriate anesthesia and analgesia must be provided. Inhalant anesthetic vaporizers designed for laboratory rodents are reasonably easy to transport and set up in field stations. Analgesic selection should be species-appropriate and take into consideration potential drug effects on released animals. Consultation with the institutional veterinarian allows the researcher to plan procedures that address animal welfare in the context of the scientific goals of the study.

Similarly, euthanasia in the field presents a special set of challenges. Drugs typically used for euthanasia, such as sodium pentobarbital, cannot be used in carcasses left for scavengers. If physical methods such as gunshots are used for large crocodilians, the investigator must be prepared to provide evidence of both proficiency and safety in use of that method. In addition to the proposed euthanasia method, the investigator must also provide a proposed method for ensuring death. Any deviations from euthanasia methods approved in the AVMA euthanasia guidelines must be rigorously justified to the IACUC in the protocol (see Chapter 47).

In Canada, Animal Care Committees (ACCs) are required by CCAC guidelines. The structure and function of ACCs is similar to US IACUCs. In Europe, the oversight body in the institute or establishment is the Animal Welfare Body (AWB), which has a mandate to monitor and enforce the conditions of the project authorizations and the housing environment provided by the authorized establishments. The AWB must consist of, at a minimum, the person responsible for the welfare of animals in the establishment, a scientific member, and it shall receive advice from the designated veterinarian. However, in many institutes, the committee will incorporate many more scientists and also include the veterinarian as a member. Tasks to be fulfilled by the AWB include advising staff on matters relating to the welfare of animals in relation to their acquisition, accommodation, care, and use; advising staff on the application of the 3Rs and ensuring they are kept informed on developments in this area; having in place an internal mechanism for monitoring, reporting, and follow-up in relation to the welfare of animals housed in its establishments; following the development and outcome of projects, taking into account the effects on animals and advise with regard to elements that may further contribute to the 3Rs; and advising on rehoming schemes. Many establishments incorporate an animal research ethics committee into the AWB, and it effectively functions as an IACUC, except that the final decision regarding the authorization normally rests with the Competent Authority (CA). The AWB is expected to foster a culture of care. In Singapore, the IACUC system follows the US IACUC system closely.

HOUSING AND CARE OF REPTILES AND AMPHIBIANS IN THE LABORATORY ANIMAL FACILITY

The *Guide* contains few specific criteria for housing and caring for reptiles and amphibians. Rather, it relies on the institution's application of performance standards and IACUC approval of those performance

VetBooks.ir

standards. Specific information on reptile and amphibian husbandry and care in laboratory animal facilities is available,[9,47,48] and detailed nutrition and husbandry information is also provided in chapters in this book (see Section 3). Before working with an unfamiliar species, the investigator and veterinarian have a responsibility to learn as much as they can regarding the biology and natural history of that species to develop appropriate guidelines, provide a rationale to justify care standards to the IACUC, and instruct the animal care staff in proper techniques (see Section 2).

Reptiles and amphibians should be housed in enclosures that provide a safe, secure, species-appropriate environment (Fig. 180.3). Cages should be constructed of materials that are nontoxic and can be sanitized. There must be enough room for the animal to engage in species-appropriate behaviors. Hiding places, visual barriers, and substrates conducive to burrowing are essential for most species, and branches or other perches are required for arboreal animals. Group housing may be appropriate for some species of reptiles and amphibians but contraindicated in territorial or cannibalistic species. Provision of an appropriate humidity level is critical to the health and well-being of the animals. The typical range of 30% to 70% relative humidity maintained in animal facilities may be inappropriate for desert species or tropical rainforest species. Although some amphibians do well in warmer temperatures, many species thrive in much cooler temperatures than reptiles; consequently, it may be ill-advised to keep both amphibians and reptiles in the same room. It may be acceptable to house different species of reptiles or different species of amphibians within the same room because of similar environmental requirements; however, careful attention must be paid to the health status of the animals and availability of satisfactory equipment and techniques to prevent cross-contamination. Provision of thermal gradients, basking sites, and full spectrum lighting may be necessary for some species. Aquatic amphibians require water quality analysis as well as chlorine and toxin removal, and husbandry records must reflect this. Feed must be used before expiration dates to ensure nutritional quality. If used, live vertebrate prey must be covered in the protocol, and attention must also be given to their issues of pain, distress, and humane endpoints. For example, the investigator must discuss why humanely euthanized prey cannot be used. Duration of time that the uneaten prey animal is left in the predator's enclosure should be described, as well as disposition of the prey animal once it is removed from the cage. Sanitation methods and intervals will likely differ from the general recommendations in the *Guide,* and the investigator should be able to provide rationale for these variances. Tanks housing aquatic amphibian species with recirculating life support systems and biofilters may require routine partial water changes and excess debris removal but may not require a complete breakdown and sanitation for prolonged periods, provided that appropriate water quality is maintained. Desert species of reptiles that are singly housed may tolerate less frequent cage changes if enclosures do not become excessively soiled. Territorial species of salamanders that scent mark can become stressed if cage changes occur too frequently. In all cases, it is critical to balance the health requirements with the behavioral needs of the species. In semicaptive or outdoor housing, it is important to consider impacts of environmental factors, such as extreme temperatures, drought, or precipitation. Many environments for semicaptive animals provide limited opportunities for escape from inclement weather, and care must be taken to provide extra protection. Similarly, extra effort should be made to exclude predators.

Institutional veterinarians should have experience with the species housed or must be able to consult specialists who can provide advice and training. There should be appropriate provisions for quarantine of newly arrived animals, isolation of sick animals, routine health surveillance of colonies, and facilities and equipment for anesthesia, surgery, and necropsy. The institutional veterinarian also has responsibility for oversight of other aspects of the program, so researchers should work collaboratively with these individuals when developing and proposing animal care procedures.

FIG 180.3 (A and B) Reptiles and amphibians should be housed in safe, secure, species-appropriate environments. (B, Courtesy of Dorcas P. O'Rourke.)

VetBooks.ir

CONCLUSION

In summary, investigators interested in submitting proposals for research, teaching, or testing involving reptiles and amphibians should become familiar with national, state, and institutional requirements, as well as those of granting agencies and professional organizations. Collaborative planning with institutional veterinarians and appropriate ethics committees will educate all parties to the species needs and care, as well as the scientific goals, and should facilitate the process of protocol approval.

Conservation

Shannon T. Ferrell

Conservation can be defined as the protection of a species and its habitat from extinction with the intention of having a viable, sustainable population. Biologists and wildlife managers have typically utilized an assortment of tools to protect a species: habitat preservation/restoration, captive breeding populations, biosecurity from invasive species and predators, economic incentives for the human populace, education, and combating both the illegal trade and the overzealous harvest of animals.[1] The role of this chapter is to briefly examine the conservation of herpetofauna with an emphasis on new philosophies, technologies, and analysis of current programs and methodologies. An excellent review of herpetofauna conservation programs and veterinary involvement is already available.[2]

CURRENT REALITIES—CONSERVATION STATUS

The IUCN (International Union for the Conservation of Nature) Red List provides a global comprehensive inventory of the conservation status of both plants and animals. Assessment of the conservation status of amphibian and reptile species by the IUCN through the Global Amphibian and the Global Reptile Assessments was started in 2004 and 2006, respectively, with continued updates of selected species on an ongoing basis. As of 2016, 26 species of reptiles and 35 species of amphibians are completely extinct, or extinct in the wild, based on conservative estimates from the IUCN.[3] Other estimates place the number of extinct amphibian species at 194.[4] Nineteen percent of 5145 assessed reptile species and 31% of the 6525 assessed amphibian species are also considered threatened (critically to vulnerable).[3] Given the number of reptile species is approximately 9084, the IUCN assessment of reptile species is far from being completed, and it is difficult to fully know how many species are possibly in the threatened category.[5] Assessments of reptile species have mostly relied on regional workshops and the IUCN Species Survival Commissions, which can possibly create geographic and taxonomic bias in the process.[5] For example, North America, Madagascar, and New Caledonia have complete reviews of their reptiles, with more limited evaluations of those species in the Philippines, Europe, and some island groups.[5] Analyses of reptile populations in Asia, Africa, and Latin America are lacking, which can create the task of prioritizing conservation efforts difficult and, likely, biased.[5]

The current rate of amphibian extinction based on losses since 1970 is estimated to be four orders of magnitude (10^4) greater than the normal background level of extinction, whereas another study calculates this same rate to range from 25,039 to 45,474 times the background extinction rate.[4,6] Based on fossil records, five waves of mass animal extinctions have occurred on the planet, with a profound loss of biodiversity during a brief period of time.[7] Considering the reported rate loss of amphibian species in the last century, a sixth mass extinction event is becoming apparent for many species on the planet, but especially amphibians based on their limited geographical distributions in threatened ecosystems.[7]

CAUSATIVE FACTORS—POPULATION DECLINES

The factors associated with amphibian and reptile declines are numerous and varied, with no single factor occurring in isolation but likely working in a synergistic fashion with other factors to extirpate species even in pristine habitats.[8] The most cited factors for herpetofauna declines are (1) habitat alteration, (2) invasive species, (3) climate change, (4) pollution, (5) trade, and (6) infectious diseases.[4,6,9–12]

Habitat Alteration

Habitat loss is intuitively grasped as an obvious cause for animal population declines. Further examination of habitat management practices and policies reveals that even in protected regions, fragmentation of the environment with structures such as roads creates barriers to genetic flow, as animals cannot migrate pass these impediments.[12,13] Moreover, the division of a once-contiguous habitat into smaller, nonassociated sections is highly disruptive even though the surface area of habitat might remain the same by acquiring additional nonadjacent sections.[12,14] With amphibians, the type of habitat to be preserved is highly species-specific and dependent on the life cycle. Some species can be relatively restricted to regions around bodies of water, whereas others can be found in the forest adjacent to a body of water.[14] Research has demonstrated that the uplands forest is critically important when considering protection for wetlands, because many amphibians use the body of water for reproduction, and then the adults and metamorphed progeny will disperse into the forest.[12,14] Furthermore, old-growth forest cover has long been recognized as beneficial to herpetofauna, but human disruption of the landscape has highly fragmented this resource. Because of the financial and political restraints, completely protecting large tracts of forest can be difficult. However, studies in Australia have shown benefit to regrowth of previously cleared forest for maintaining some degree of both reptile population numbers and species biodiversity.[15,16] Overall, habitat fragmentation experiments conducted over the last 35 years on multiple continents and biomes have resulted in a loss of general biodiversity of 13% to 75% in the experimental zones. In addition, significant impacts on ecosystem function were detected in the fragmentation experiments because nutrient cycles were altered and biomass decreased.[17]

Invasive Species

Invasive species can be defined as animals whose presence in a region is attributable to human actions that allowed them to overcome biogeographic barriers and are capable of sustaining a self-replacing population over several life cycles.[18] These species constitute a continued

VetBooks.ir

and growing threat to native herpetofauna by direct competition, predation, hybridization, spread of pathogens, and other indirect effects.[18–20] To provide perspective on the breadth of the problem and its etiology, 50,000 nonnative species of animals and plants have been brought into the United States during its history, with the majority of these species introduced for their economic value; however, not all these introductions were permanent or invasive.[21] The most complete review of the costs associated with the prevention and management of nonindigenous species in the United States placed the annual cost to the country at $120 billion.[21] One study evaluating the effects of invasive species on biodiversity determined that the number of reported invasive species (plant or animal) to the Convention on Biological Diversity are underestimated and highly dependent on the level of development and research efforts within a country.[20] Mammalian predators have been the most successful and well-documented invasive taxa, directly causing declines in indigenous reptiles and amphibians, both on the mainland and on islands.[22] A primary factor in the extinctions of at least 14% of all bird, mammal, and reptile species are domestic feral cats (*Felis catus*), who are also the principal threat to at least 8% of the remaining critically endangered birds, mammals, and reptiles.[23] Many reptile species have additionally been impacted by other mammalian predators such as the small Asian mongoose (*Herpestes javanicus*).[21,24,25]

The rise of the exotic animal trade has additionally generated a plethora of reptile and amphibian invasive species that threaten native mammals, birds, reptiles, and amphibians.[26,27] Invasive herpetofauna often have significant impacts on native species, including direct competition for resources, hybridization, inducement of phenotypic change, and species extinction.[26] The prevalent and striking example is the Burmese python (*Python bivittatus*) in the state of Florida, where these large, ambush predators have gained a substantial foothold within the Everglades and surrounding regions due to the hospitable environmental conditions in Florida and the lack of any natural predators.[28] These snakes have attacked humans, pets, large crocodilians, and endangered/threatened species such as the Key Largo woodrat (*Neotoma floridana smalli*) and wood storks (*Mycteria americana*), and they are considered to be responsible for significant declines in wild mammal populations in southern Florida.[27,28] Additional invasive reptile species of particular concern, especially in parts of the United States, are the red-eared slider (*Trachemys scripta*), the brown tree snake (*Boiga irregularis*), the Nile monitor (*Varanus niloticus*), other miscellaneous large constrictors (pythons, boas, and anacondas), and many other lizards such as iguanids and anoles.[27]

Although amphibians are largely thought to be prey items, the cane toad (*Rhinella marina*) serves as a reminder that any species outside of its natural environment can present unique challenges to a naïve ecosystem. These hardy amphibians were introduced throughout the world as biological means to control insects before pesticides, but Australia stands dramatically altered after introducing this amphibian predator into Queensland in 1935.[19] Cane toads are still slowly migrating across Australia while simultaneously reducing numerous animal species through two principal means: consumption of cane toads with resulting fatal intoxication or direct competition for resources such as food during dry seasons and shelters.[19] The ingestion of adult cane toads by native reptilian and mammalian predators has resulted in numerous mortalities from the secreted bufotoxins.[19,29] The affected reptiles in Australia include diverse species of lizards, crocodiles, turtles, and snakes (Fig. 181.1). Finally, the North American bullfrog (*Rana catesbeiana*), the Cuban tree frog (*Osteopilus septentrionalis*), and the Caribbean tree frog (*Eleutherodactylus coqui*) represent other widely dispersed and problematic invasive amphibians (Pitt W et al, Proc 11th Wildlife Damage Management Conf, 2005, pp 112–119).[27,30]

A review of eradication programs found an 86% success rate in targeting and eliminating invasive plants and animals on the mainland or islands, with 94.6% of the reported programs targeting vertebrates. However, 97% of the studied eradication programs in the review occurred on islands. The review study could not find any successful, completed, large-scale eradication program on a mainland location with a well-established invasive species.[32] Given these challenges, focus has shifted from the improbable complete eradication of an established invasive species on the mainland to strategies that embrace mitigation and control. Conversely, full-scale eradication of invasive species on islands is being more actively promoted.[33] Islands might only encompass roughly 5.5% of the world's land surface area; however, these fragile habitats hold more than 15% of terrestrial species.[22] Eradication of invasive mammals is a common tool on islands for the conservation of threatened species and has been attempted on more than 700 islands. Rodents, domestic goats, and cats are the three taxa most commonly eradicated from islands.[22] Regardless of the species, removal of invasive animals from islands inhabited by humans is often more difficult and prone to failure than uninhabited islands.[33]

FIG 181.1 A blue-tongued skink (*Tiliqua scincoides*) ingests an invasive cane toad (*Rhinella marina*) that could lead to a fatal intoxication. (Courtesy of Jonathan Webb, University of Technology.)

Climate Change

Fluctuations in global temperatures with secondary effects on general weather patterns are slowly being recognized as a biologic crisis as years of meteorologic data are concurrently evaluated with animal movements and extinctions. With the overall trend of global warmth in the last few decades, there has been an evident movement of animals toward the poles and away from the equators, likely to escape abnormally high temperatures.[34] Past extinction rates for reptiles on Aegean islands were found to be greater than for those same species existing on the mainland, when incorporating climatic change into the model, especially for reptiles from cooler environments on isolated, smaller lands.[11] The explanation for the higher extinction rate on islands is the inability to diminish the effects of temperature fluctuations through migration to more appropriate habitats. However, this effect will likely be similar on the mainland as habitat is fragmented through human activities creating similar "islands" of geographic isolation.[11]

Another subtle effect of climate change is the possibility of increasing embryo mortality in reptile eggs and possibly disrupting the adaptive effects of temperature sex determination.[35] Temperature sex determination (TSD) is the environmental, irreversible determination of embryonic sex used by some reptiles during the thermosensitive period of incubation. Some species of turtles use type Ia TSD, where male progeny are produced at the lower range of incubation temperatures. Mixed sex ratios are seen at intermediate temperatures, and female progeny hatch at the higher end of the incubation temperature range. Previous work in painted turtles (*Chrysemys picta*) with type Ia TSD found that increasing

the temperature variance around the low mean temperature for male progeny resulted in higher ratios of feminization, leading to a decoupling of the expected effect of the low incubation temperature.[36] A later study in painted turtles demonstrated that greater thermal variance (±5°C) around the respective mean incubation temperatures for each sex (normally 100% male or 100% female) reversed the expected sex ratios of the painted turtles, creating more females at low temperatures and more males at higher temperatures.[35] In addition, either by elevating the mean incubation temperature or by elevating the thermal variance around the female incubation temperature range, the developmental rate of turtle embryos was decreased, and the overall embryonic mortality was increased.[35] These aforementioned effects on sex and embryonic development will have critical impacts on reptile populations as climatic because change conceivably alters both the mean incubation temperatures and temperature variance in reptile nests.[37] Adapting to these climatic challenges, certain turtle species are nesting earlier in the season to take advantage of cooler temperatures that could protect the sex ratios of their progeny.[37] Finally, evidence exists that highly adaptable species, such as certain turtles, might be capable of changing their sex-determining mechanism (conversion from TSD to genetic sex determination) in response to climatic changes.[38]

Pollution

Environmental pollution has repeatedly been listed as another factor in amphibian and reptile declines through direct and indirect toxicologic effects, resulting in severely compromised animals or death.[39–41] Exposure to heavy metals, organophosphates, fertilizers, polychlorinated biphenyls, and other agents have been described as affecting herpetofauna, with the research mostly focused on assessing exposure in wild populations.[40,41] A recent assertion is that amphibians can serve as monitors of environmental quality or "canaries in the coal mine," because their permeable skin, complex biphasic life cycle, and developmental periods in water make them uniquely more susceptible to environmental contaminants.[42] Reptiles are also being investigated as possible bioindicators of environmental pollution due to their longevity and geographic distribution in a variety of different habitats (Fig. 181.2).[43] In reality, with the current, insufficient knowledge base regarding amphibian population sizes and natural population dynamics, amphibians likely are no better than other taxa as indicators of environmental health.[42] One meta-analysis compared the toxicity data regarding numerous water contaminants for amphibians with the same toxicity data for other animal taxa and found that amphibians are more moderate in their responses to a large number of waterborne toxins compared with other animal taxa.[44] However, the authors reiterated that particular amphibians are much more sensitive to certain chemicals than other taxa and that one should review both the species and the information on the chemical agent before drawing conclusions regarding environmental quality.[44] Interestingly, one study, evaluating the use of six different taxa as indicators of biodiversity, found that woody plants and birds were more useful indicators than aquatic or terrestrial herpetofauna in assessing the level of biodiversity in northern Greece.[45]

Whereas the aforementioned environmental contaminants can result in obvious mortality, pollutants known as endocrine-disrupting contaminants (EDCs) can severely affect amphibian and reptile populations through their effects on recruitment for reproduction with little overt effect on immediate individual survival.[46] The WHO and the United Nations define EDCs as exogenous substances or mixtures that alter the functions of the endocrine system and consequently cause adverse health effects in an intact organism, its progeny, or its population.[47] In the past, mostly pesticides or synthetic hormones such as diethylstiberol (DES) were investigated as EDCs in wildlife.[48] The number and types of identified EDCs are growing, as research identifies the various pathways these chemical agents can directly or indirectly affect hormonal systems.[47,48] During the critical periods of organogenesis, minute exposures to EDCs can have significant and permanent effects on the development of certain tissues, especially reproductive organs.[48,49] Numerous studies have highlighted the effects of endocrine disruptors on reproduction in multiple animal species through their estrogenic, androgenic, antiandrogenic, and antithyroid actions.[48] Broad-snouted caiman (*Caiman latirostris*) embryos exposed to bisphenol A, a plasticizer, or endosulfan, an organochlorine pesticide, in ovo demonstrated significant changes in testicular development compared with controls.[49] In three anuran species, exposure to 17α-ethinylestradiol (EE2), a synthetically stabilized estrogen that is the principal ingredient in many female contraceptive pills, at environmentally relevant concentrations during development, resulted in the expression of the female phenotype in genetic males.[50] Inert EE2 is often excreted in human urine, poorly eliminated by sewage plants, and resistant to degradation, accumulating in aquatic sediments.[50] Atrazine is an environmentally persistent, mobile pesticide, with worldwide distribution that can possibly feminize exposed amphibians.[51] In one research study using *Xenopus laevis*, some genetic males exposed to atrazine were capable of producing viable eggs due to testicular oogenesis when bred with normal males. However, the progeny were 100% male as expected, which would obviously impact a population's reproductive fitness.[8,51] Additional contaminants viewed as possible endocrine disruptors of the reproductive system through more indirect pathways are nitrates, chemicals that affect cytochrome activities in the liver, and drugs altering prostaglandin function in the reproductive tract, such as dichlorodiphenyltrichloroethane (DDT).[48]

Trade

Reptiles and amphibians, and/or products produced from their bodies, represent a large amount of the international trade in wildlife. Trade encompasses both legal and illegal transactions, with the majority focusing on commerce for food, leather products, biomedical research, and the pet trade.[52,53] In just evaluating Europe, the trade in reptiles alone accounted for 84% of the value of all European Union (EU) animal imports, reflecting a combination of leather products and skins. Live reptile imports into the EU only represented 22% of the value of animal

VetBooks.ir

imports.[53] Amphibians are also imported into the EU in large quantities for meat and the pet trade. About 90 to 230 million individual frog legs are imported annually into the EU, with some estimates placing 84% of these imports being wild caught and supplied from Indonesia.[52] Finally, one examination of the international amphibian trade using species listed by CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora) and associated country reports for legal import data calculated roughly 480,000 amphibian bodies (live or otherwise) were traded over a 29-year period.[9] The preponderance of live amphibians in international trade consists of three genera in descending order, *Mantella*, *Dendrobates*, and *Ambystoma*, with the vast majority of these live amphibians being wild caught.[9] Based on limited reports of confiscation data, the illegal trade of amphibians is considered to be approximately 10% of the legal trade volume, in part because of the lack of stringent standards and control for amphibian movements.[9,52]

From 2001 to 2012, the trade in live reptiles has declined by about one third based on CITES import data. Importations have declined in animals from both the wild and captive breeding, with the majority of the reductions involving a drop in the trade of the green iguana (*Iguana iguana*).[53] The pet trade likely represents the bulk of the trade in live reptiles, and the survival of animals in the pet trade can have significant effects on the continued demand for replacements. One recent study in the United Kingdom detailed that 3.6% of reptiles acquired as pets in the home died within 1 year of purchase, with captive-bred reptiles having the best chance for long-term survival, which is compatible with other earlier reports.[54]

The demand for live reptiles is still high, with possible sustainable alternatives to harvesting wild populations being captive breeding and ranching. Ranching is defined by CITES as "rearing in a controlled environment of specimens which have been taken as eggs or juveniles from the wild, where they would have a very low probability of survival."[53] Ranching is considered to have a relatively benign impact on wild populations, and possibly a positive one, if some of the ranched juveniles are released back into the wild in their country of origin instead of going into the market.[53] Finally, no matter the decline in the herpetofauna trade as reported by evaluations of the data from CITES, it is imperative to consider much of the trade is not recorded by these entities if the trade is domestic, illegal, or involves a non-CITES–listed species (Fig. 181.3).[53]

FIG 181.3 Government confiscation of illegally imported Indian star tortoises (*Geochelone elegans*) to undergo a health evaluation before entry into quarantine in a holding facility. (Courtesy of Shannon Ferrell, Zoo de Granby.)

The trade of amphibians internationally has been linked to the transfer of infectious diseases that has put an additional strain on threatened species in their native habitats and contributed to the extinction of species in some habitats.[55] The spread of *Batrachochytrium dendrobatidis* (*Bd*) has been linked to the global amphibian trade, with a growing concern that a more virulent form of this fungal pathogen has emerged through genomic recombination of different variants from multiple geographic regions.[52,56] Poison dart frogs (*Dendrobates* spp.) and western clawed frogs (*Xenopus tropicalis*) are routinely noted as potential vectors of *Bd*. In spite of decades of extensive discussion about this pathogen, methods of limiting its international dissemination are still lacking. For example, a recent surveillance program evaluating the incidence of *Bd* and ranavirus in amphibians leaving Hong Kong in commercial animal shipments found an incidence of 11.7% and 56.8%, respectively, based on skin and cloacal swabs via polymerase chain reaction analysis.[57]

Batrachochytrium salamandrivorans (*Bsal*) emerged in 2013 as a new lethal fungal pathogen restricted to salamanders and newts (Urodela) in Europe, causing lethal skin infections similar to *Bd*.[58] The current hypothesis is that this fungus had evolved with Asian salamanders with little overt pathology in the current native populations; however, the movement in amphibians from Asia to Europe has transferred this fungus to naïve populations of urodeles in western Europe lacking the appropriate resistance.[59] *Bsal* has now been detected in the Netherlands, Germany, and the United Kingdom in both captive and wild populations of salamanders. *Salamandra salamandra* is especially affected and is almost at the point of extinction in the Netherlands.[52,59] Recommendations have been suggested to stop the importation of Asian salamanders to Europe to arrest the distribution of this fungus, but the implementation of these recommendations has been delayed.

Amphibian ranaviruses have been transmitted to novel environments via both the pet trade and the use of amphibians as bait for fishing in the United States.[57,60] The North American bullfrog and tiger salamander (*Ambystoma tigrinum*) have been implicated in the movement of ranavirus throughout the world via international trade.[52] In 2008 the World Organization for Animal Health (OIE) officially recognized both ranavirus and *Bd* as notifiable diseases, but no further actions have been made to limit the movement of either pathogen across the world through biosecurity measures and routine testing of amphibian shipments.[10,52] Finally, *Mycobacterium* has been introduced into different locales through the movement of western clawed frogs and farmed east Asian bullfrogs (*Hoplobatrachus rugulosus*).[61,62] An additional important factor is that water used to house amphibians during shipments is commonly contaminated both with chytrid fungus and ranavirus. The transfer of this water to another country or region and its release into the sanitation system without appropriate disinfection serves as another method to transmit infectious diseases to native amphibians without ever releasing a nonindigenous species into the environment.[57]

Infectious Diseases

Infectious diseases are unlikely to cause an extinction of a species as a sole factor, especially if disease transmission is a density-dependent factor. If density dependent, as the population diminishes below a certain threshold, transmission of the disease drops off rapidly, preserving enough individuals to effectively reproduce.[63] Rather complex interactions between the pathogen, the host, and the environment often dictate the extent and the duration that an infectious disease can spread within a population.[63,64]

Chytridiomycosis and amphibian ranavirus have been implicated in numerous large-scale mortality events in amphibians.[63] However, *Bd* provides a salient example of a population-limiting disease that cannot be simplistically and consistently tied to all amphibian declines. For

example, this fungal pathogen has caused numerous losses of amphibian populations in Australia, Central America, and possibly other countries in South America.[4] Conversely, *Bd* has had apparently minor effects on populations in Asia, Europe, and mainland Africa.[4] In addition, in countries with significant amphibian declines such as New Guinea and Madagascar, this pathogen has not been reported as a significant factor.[4] Pertaining to the relationship of host, pathogen, and the environment, exposure of amphibian tadpoles to sublethal levels of ultraviolet B (UV-B) radiation had no effect on leukocyte counts or on their response to an acute antigen challenge. However, the resulting metamorphs did have significant reductions in these aforementioned immune parameters, providing a possible explanation for how environmental changes in UV-B radiation levels could increase the susceptibility of amphibian populations to novel pathogens such as *Bd*.[65]

Ranavirus-induced mortality events in amphibians have been documented on five continents, in varying environmental conditions, and in most taxonomic families of amphibians.[63] The importance of ranavirus to significantly affect amphibian populations is disputed as no clear picture exists as to the distribution, level of virulence, and pathology of these viruses in varying amphibian species.[63,66] It is most likely that the virus functions synergistically with other factors to evoke large-scale mortality events. For example, habitat fragmentation can lead to genetic isolation in some amphibian populations, leading them more likely to suffer from ranavirus epizootics.[63]

CHALLENGES AND HORIZONS

Captive Breeding

Most veterinarians participating in herpetofauna conservation will be involved in translocation projects through the release of conceivably healthy animals to augment the present population (reinforcement) or to reclaim a habitat where the indigenous species has disappeared (reintroduction) (Fig. 181.4).[67] The translocated animals will be either wild-caught specimens that are simply being moved to another location or captive-bred progeny. Important caveats regarding the challenges of these programs should be evaluated, and efforts should be made to reduce any anticipated issues. Captive breeding is a contentious tool for the preservation of species.[68] First, resources, financial and temporal, are shifted from habitat preservation and threat mitigation to the propagation of a species in a captive setting. Many would argue that these resources are more effective when used for in situ conservation efforts.[68] In situ operations that by definition occur within the range country/region of the species of interest are simpler because of the required climatic factors, light cycles, food items, and more.[66] The release of captive-bred or ranched herpetofauna through conservation translocations has been done for years to combat population declines in native habitats. To be a successful program, these released animals must contribute to the population of reproductively active adults in greater numbers than would naturally occur.[69] Head-start programs have been controversial for many years and will likely continue to be so until more objective evaluations are performed to validate their utility as a conservation tool.[70] The underlying areas of concern are the associated costs of the release programs, the questionable rate of successes, the possibility for disease transmission, and the lack of addressing the underlying problem within the declining population.[71]

FIG 181.4 Three female Jamaican iguanas (*Cyclura collei*) being released to native habitat after captive rearing in a head-start facility within Jamaica. (Courtesy of Rick Hudson, Fort Worth Zoo.)

Additionally, the progeny of captive-breeding programs suffer from numerous problems associated with a small founder population, such as inbreeding depression, rapid adaptation to captivity, and removal of natural selection.[72] Recent studies have attempted to assess the impacts of captive breeding on the fitness of the prospective progeny to be released. Based on models in fruit flies, adaptation to captivity can be relatively rapid under benign environmental conditions.[72] The predominant concerns in captive progeny are a lack of appropriate response to predators and difficulty in finding food sources. Tadpoles of the Mallorcan midwife toad (*Alytes muletensis*) bred in captivity for successive generations lose their adaptive genetic responses to predators (shallow tail fin depth and rapid growth rate) compared with wild-caught tadpoles.[73] Another study remarked that captive-bred *Rana pipiens* metamorphs exhibited abnormal movement behavior after release, which could affect their ability to locate food sources compared with native *Rana pipiens* in the same area.[74] In conclusion, animal populations can rapidly adapt to captivity within a few generations, and captive-breeding programs should recognize this problem during program design and throughout subsequent monitoring. Recommendations have been made to both preserve genetic diversity but prevent the adaptation to captivity through (1) maintaining a captive environment as close to natural conditions as possible; (2) decreasing the selection pressure from captive environments by reducing mortality rates and ensuring that each individual contributes to reproduction; (3) dividing the captive population into smaller subpopulations that are more fit and diverse than one large population of the same size; (4) increasing the generational interval through delayed matings and cryopreservation techniques as selection and adaptation happen on a generational level; and (5) introducing wild individuals, if possible, into the breeding program.[72]

Further attention also needs to be given to providing a captive situation that helps promote normal physical and mental development of the progeny. Animals are often raised in high-density settings that can lead to disease transmission, stress, and the need for intensive management practices, such as the routine disinfection of the premises, easy-to-clean cages, etc., to reduce disease transmission. This necessity for cleanliness leads to amphibian larvae often being restricted to an aquarium setting with uniform depth and sheer vertical walls. This environment further lacks microclimates, a natural light cycle, appropriate prey variety, and exposure to appropriate microbiota for intestinal flora.[75,76] In addition, prey items are offered, with more emphasis placed on cost and ease. Whether the diet items are truly appropriate for growth based on the ability to ingest and to digest the diet by the larvae or metamorphs is often a secondary concern. The production of healthy progeny capable of surviving after release from captivity to their native environment would likely be improved by deemphasizing a sterile, high-intensive management system with more emphasis given to lower population densities and a more appropriate habitat/diet.[75]

VetBooks.ir

Metrics of Evaluation

Evaluating the success of any animal conservation program can be perplexing because of the limited resources available, the cryptic nature of some species making population evaluations difficult, the limited historic data on the population, and in many circumstances, the lack of robust criteria for assessing success of the project.[77,78] Explicitly defining the objectives and providing the data on the observed inputs and outputs can help in this process. Inputs are the resources used in the project, such as monies, equipment, and time. Outputs are the amounts of some specific activity delivered by a project (i.e., progeny released to the environment), which can then help to indicate whether a project has met its specific objectives (i.e., mandated release goal of 500 tadpoles every year).[79] However, assessing the impact or outcomes (the broader consequences of the project for the population and the environment, which are better indicators of long-term success or failure) is essential.[79] Independent evaluators can use a selection of different methods to appraise the actual effects of a project.[78,79]

Many projects simply consider the number of animals translocated as the primary output, but the more salient criteria is the survival of these animals and whether they contribute to the reproduction of the population.[77] Monitoring after release can be considered the most challenging, but likely the most critical, step in any program. However, it is rarely implemented and, if so, in a haphazard fashion.[77,80] Researchers in the Wyoming Toad (*Bufo baxteri*) Project have evaluated a promising methodology for assessing the survival of released metamorphs based on demographic data and a projection model, although the accuracy and reliability with any single year of data is challenging.[77] Monitoring over subsequent years gradually should increase the reliability of demographic estimates and related management inferences, such as the number of metamorphs to release in a year that will survive to become reproductive females.[77]

Genomics

Genomics is considered a discipline of genetics that concerns itself with the study of the genome of organisms through the use of DNA sequencing, bioinformatics, and recombinant DNA to grasp the actual sequences in the genes and their functions. In the past, genetic tools have been extremely useful for (1) estimating the population size of a species where direct estimate data of the population are lacking, (2) protecting genetic diversity in captive-breeding operations, (3) detecting levels of species hybridization, (4) analyzing the frequency and degree of genetic connectivity between adjacent populations, and, finally, (5) using these data to determine important genetic priorities and make informed management decisions.[42,81] Future directions of genomic research are to continue the complete sequencing of various species of reptiles and amphibians to form a bank of genomic data. This databank can then be used to improve retention of genetic diversity in captive-breeding groups through more detailed breeding recommendations and identifying genetic diversity in wild populations that warrant specific conservation efforts. In addition, discussion has been given to analyzing the genome of various animals within a species for factors of disease resistance, which could be useful for evaluating in translocated wild animals or their captive progeny before release into a wild habitat.[81] Of particular merit, by combining genomics with geographical data, conservation biologists can locate specific features in the environment that influence animal movement and genetic movement within a habitat. These features, such as small sections of forest between two habitats or a mature road in a wildlife habitat, can be assessed as having a positive or negative effect on genetic variability within populations. With this information, land managers can demonstrate more objectively the necessity to conserve or to possibly mitigate the damage of specific geographic features.[81] Finally, genomics can offer a means to assess the success of conservation programs by verifying the genetic diversity after captive animal releases into a threatened population or even just monitoring the viability of a population after conservation of habitat.

Eradication of Invasive Species

Full elimination of any invasive species is difficult on large land masses for many reasons. Hidden environments in the ecosystem, cryptic behavior, high fecundity, lack of predators, incidental species morbidity and mortality with baiting, costs, politics, poor planning and execution, continued reintroductions such as with exotic pets, etc., all work to make invasive eradication close to impossible.[18] As described earlier with the cane toad, the migration of this species has only been slowed, but never halted in Australia.[19] Similar situations have emerged with other introduced species on other continents, despite widespread public and governmental support for eradication measures. In light of these difficulties, conservation biologists have advocated prevention as the primary objective, with an emphasis on information dissemination about the problem to the general public, stringent biosecurity measures, and quarantine procedures.[26,82] The next step in the process if prevention has failed is to have an early detection system with continual surveillance, interception, and immediate removal of a species from a novel ecosystem. Propagule pressure, defined as the frequency with which a species is introduced into a habitat combined with the animal number in each episode, is considered to be the main factor in whether a species becomes established.[82] Therefore decreasing both the introduction frequency and the number of animals introduced can have major benefits in the management of invasive species.[82] The brown tree snake (*Boiga irregularis*) and its possible movement from Guam, where it has extirpated 10 of 13 bird species on the island and bitten thousands of people over a decade, to Hawaii is a case study where prevention and early detection have helped retard the transfer of this aggressive snake.[83] The final step of management through eradication, containment, and control is more commonly studied and practiced because the species of concern has usually already invaded and caused a permanent change in the environment.[26,82] Methods used for eradication (described later) can also be used to simply control both the numbers and distribution of an invasive species if full-scale complete eradication is not feasible.[84] Finally, a detailed system of prevention and early detection that relies on a historic database of exotic animal introductions for a country would be useful for decreasing the frequency and severity of future invasive species incursions as denoted by the successes in New Zealand in dropping this incursion rate since the database's inception.[26,82]

The essential five factors considered critical to a successful eradication effort are (1) early detection of an invasion with abrupt removal efforts, (2) sufficient resources for completion and follow-up surveys, (3) an agency capable of enforcing cooperation, (4) understanding the natural history of the species to target vulnerabilities, and (5) motivated, persistent personnel.[85] The general grouping of eradication methods for invasive species are mechanical, chemical, and biologic.[84] Sponsored hunting, fencing, and trapping are the common examples of mechanical control in which animals are physically removed or excluded from an area.[30,86] Baiting with toxins such as rodenticides as done on islands or the spraying of coqui frogs with citric acid in Hawaii provide examples of chemical control methods.[22,30,86] Finally, many invasive pest species were introduced as predators to control either a native species or an already introduced nonnative species. Obviously, biologic control using predators is highly controversial and fraught with possible unforeseen consequences.[87] A good example of this complexity was the introduction of the mongoose to Jamaica, Puerto Rico, miscellaneous Caribbean islands, and Hawaii to control introduced rats on sugar cane plantations.[21] Sadly, the mongoose did not inhabit the same environmental niche as

FIG 181.5 One of the primary mammalian invasive species, a small Asiatic mongoose (*Herpestes javanicus*), is removing an egg from an iguana nest. (Courtesy of Rick Hudson and Rick Van Veen, International Iguana Foundation.)

the rats and had questionable benefit on any reduction of the rodent population. However, the mongoose persisted in the ecosystem to plague native lizard species such as the Jamaican iguana (*Cyclura collei*), amphibians, and sea turtles, causing approximately 7 to 12 extinctions of herpetofauna species (Fig. 181.5).[21,25] The success of biologic control methods in some reviews of invasive species eradication only found limited success (<20% achieved complete control and only 41% achieved partial control).[87]

Due to the pressing need to save animal species in light of these precipitous changes, a translocation strategy called assisted colonization has been advocated.[71] In this management technique, species are transported from their native habitat to a region outside their normal physical range (i.e., movement of African reptiles to similar environments in North America) to foster their survival in the face of threats such as climate change. This translocation methodology could have numerous and unforeseen consequences on indigenous animals and their environment in spite of the proposed use of risk assessments to anticipate and mitigate possible impacts. In reality, assisted colonization is viewed by some biologists as another example where an introduced species could become invasive and threaten native populations with extinction.[71]

Enrichment

Enrichment can have three components: environmental, where an environment is provided that offers the animal the chance to pursue normal psychological and physical activity; social, where the opportunities exist for the interaction with other animals; and behavioral, where the animal can demonstrate specific behaviors or behavioral repertoires.[88] Success in captive breeding programs relies on having the necessary species-specific prerequisites for health, reproduction, and development of the progeny. This necessity has largely been recognized in mammals and birds with a gradual application to reptiles and amphibians.[88,89] Beyond simple reproduction, enrichment programs can be used to select for the progeny of amphibians and reptiles who might have the physical and mental attributes to better survive upon release into their native habitat. In addition, researchers question the value of releasing captive-bred progeny into an environment without some basic training in food and predator recognition. Training programs in reptiles have been suggested that could bridge this deficit, while providing both physical and mental stimulation to progeny before their eventual release. Prerelease desert survival training of captive desert tortoises (*Gopherus agassizii*) in California reportedly had significantly improved success with release trials.[88] Furthermore, blue-tongue skinks (*Tiliqua scincoides intermedia*) were successfully trained with aversive methods to prevent lizards from ingesting toxic cane toads with significant improvements in survival compared with control animals.[90]

However, another study in the common water snake (*Nerodia sipedon sipedon*) found no benefit to prerelease enrichment compared with controls in any measure of postrelease behavior or performance.[70] More importantly, introducing older, larger snakes who had simply undergone a period of simulated winter dormancy resulted in a higher overall survival rate than release of smaller individuals in the previous years, which was similar to the findings in head-started garter snakes.[69,70] In addition, captive-reared snakes that were released into the wild still only grew at a third of the rate of their similarly aged wild conspecifics, pointing to some defect in the ability to hunt in the wild.[70] It is likely that enrichment programs targeting the acquisition of specific associations or skills (i.e., the distaste for cane toad flesh) will be useful if carefully conceived and developed versus merely the introduction of various objects or activities as enrichment that are not directly related to survival.

Prerelease training in amphibians appears to be an important factor for improving survival.[68] Tadpoles produced in a typical laboratory setting have a higher likelihood of predation, and metamorphs are more susceptible to moving in a haphazard direction from a lack of familiarity with normal light cycles and the Y-axis orientation in nature.[75] Using a wire-mesh enclosure placed into the release habitat that incorporates land, land/water interface, and water, tadpoles and metamorphs in this enclosure could remain protected from predators and experience normal light cycles and the Y-axis orientation.[75]

Governance

Although a paucity of independently assessed data was present, a recent study evaluating the outcome success of conservation strategies demonstrated that the allowed use of natural resources (i.e., harvest), the access to markets for those natural resources, and a greater community involvement in the conservation projects were all important factors for successful outcomes.[91] To make these strategies manifest on a regional or national level, conservation institutions such as wildlife and environmental health agencies are looking at internal transformation of their institutional structures.[92] The core guiding principle in the United States has always been the public trust doctrine, where wildlife is owned by the public who entrust wildlife preservation and management to the government at various levels.[92] Because ecologic, political, and economic problems develop in tandem, a set of governance principles are emerging that focus still on the public trust as the foundation with more emphasis on social and economic sciences to foster a greater public participation and personal investment in both habitat and animal conservation.[92,93] Specifically, whether a conservation institution is a zoo, a nongovernmental organization, or a governmental agency, consideration should be given to four key components to create an adaptive and effective entity, if possible: (1) broad-based funding, (2) trustee-based governance, (3) multidisciplinary science as the basis of recommendations from professional staff, and (4) participation of diverse stakeholders and partners.[92]

Relating to governance of habitat management, some biologists argue that conservation targets in the past have been overly precise and narrow in terms of objective goals and methods, leading to outright failure through unintended consequences.[94] Advocates of this view propose that wildlife managers embrace a variety of habitats for a species, even if less than ideal, expanding decision flexibility through less-rigid regulation, and support modifying plans to local circumstances, as needed. In the realm of international wildlife trade, recommendations have been made to create within the current CITES system a new illegal

VetBooks.ir

animal trade database to include estimates of illegal trade for all countries and animals, overall world supply of any specific animal product, the demand for these animal products within countries, and their market prices. This information could then be used constructively for more realistically evaluating the utility and efficacy of wildlife trade decisions made by CITES.[95] Finally, CITES trade bans have been implemented for dealing with nontrade threats such as climate change. However, these bans have led to decreased local community support for conservation programs, because the financial benefits to safeguarding the species diminished greatly after the trade restrictions were put into practice. Biologists suggest not using CITES trade bans for nontrade threats and to continue to foster community stakeholders in participatory management with some obvious benefit to community members.[96]

Education

Conservation education is primarily taught through intellectual exercises with varied amounts of visual aids and oral presentations, which appear to have a questionable efficacy and persistent impact on their target audience.[97] In addition, certain groups of animals, such as snakes, are not as highly charismatic as other "flagship" species and might also have been attributed negative stereotypes in various cultures.[97,98] One study found only a modest benefit in changing attitudes regarding snakes after a physical presentation of a snake in a classroom with young children.[98] The children were allowed a brief tactile experience and some didactic lesson material. However, a later study with children found that a field trip in an outdoor setting where the children hunted for and examined nonvenomous snakes had a more significant lasting impact in changing attitudes.[97] The authors point to the necessity for outdoor education with the resulting direct physical and emotional connections to build a better rapport and appreciation for wildlife in young children. These studies highlight the necessity to potentially change how the conservation message is conveyed. Significant strides in conservation might be best obtained by emphasizing less the direct scientific details and more the physical reality of herpetofauna in their native habitats through participatory experiences that might last a lifetime (Fig. 181.6).

FIG 181.6 A visit by local school children to a reptile head-start program with an opportunity to converse with a veterinarian and participate in a basic health examination. (Courtesy of Rick Hudson, Fort Worth Zoo.)

CONCLUSION

With the physical and political challenges facing conservation issues, facile resignation and apathy can appear to be the logical reactions. However, as veterinarians, biologists, and interested private citizens, our actions, both personal and professional, can serve to affect significant positive changes in herpetofauna conservation. By persevering in the face of this adversity, we create models for our colleagues and future generations to hopefully emulate. Failing at this task is not simply a loss of biologic diversity on the planet but harkens to our own demise.

Herpetofauna and Ecosystem Health

Scott Connelly

Although often unnoticed in nature, reptiles and amphibians are broadly distributed and represent a great deal of global species-level diversity. Additionally, a disproportionally high level of vertebrate abundance is comprised of herpetofauna in some ecosystems; in humid tropical regions, for example, anurans are often the most abundant vertebrates, and densities of 20,000 frogs per hectare have been recorded at sites within Puerto Rico.[1] As such, reptiles and amphibians can contribute significantly to a wide range of ecological processes, such as energy flow and nutrient regulation, and can strongly influence ecosystem structure. As ectotherms, ingested material is efficiently converted to biomass (rather than mostly lost as heat, as is the case with endotherms) and subsequently may become available energy for upper trophic levels. This energy flux may be especially important with respect to amphibians, as most species have complex life histories that require both aquatic and terrestrial habitats and different food resources dependent on the developmental stage of the individual.

Reptiles and amphibians are similar in many ways regarding their susceptibility to environmental stress, and documenting the causes for, and the magnitude of, their global population declines has received a fair amount of effort during the past two decades.[2,3] This is especially true for amphibians, following the widespread and ongoing species losses due to chytridiomycosis in the late 1980s and other more recent emerging wildlife diseases, such as ranaviruses (Fig. 182.1). However, many reptile populations are imperilled as well, and it has been suggested that reptilian declines are similar in severity, taxonomic breadth, and geographical scale to those currently documented in amphibians.[4] Regional assessments throughout Europe and Africa indicate that between 10% to 20% of reptilian species are threatened with extinction.[5] Like many amphibian declines, losses of reptiles have been attributed to a range of drivers, including habitat degradation, invasive species, pollution, disease, climate change, UV-B radiation, chemical contaminants, commercial exploitation, as well as combinations of these factors.[4,6,7] However, far less focus has been placed on characterizing and quantifying the role that herpetofauna play in supporting overall ecosystem health and, in particular quantifying ecosystem-level responses resulting from their declining abundance and biodiversity.

"Ecosystem health" is a term that encompasses some suite of attributes that can be used to describe the overall condition of a system. These attributes may include the ability of the ecosystem to function within a range of limits and might take into account a measure of system resilience to change, its organization, and vigor. Recently there has been an increased understanding and acknowledgment of the importance of ecosystem services for human well-being. A characterization of ecosystem health may be useful in determining the sustainability of a system, which can be defined as the ability to meet current societal needs from ecosystem services, including provisioning, regulating, and supporting and cultural services, without sacrificing the ability of future societies to meet their needs.[8,9] Therefore, it has been suggested that an accurate assessment of ecosystem health needs to include a measure of its sustainability; that is, the system's ability to maintain its structure and function through time in spite of external stressors, such as changes in population size. A number of recent studies have demonstrated that biologically diverse ecosystems tend to be more productive, and there has been growing evidence that species extinctions are changing basic processes important to both the productivity and sustainability of global ecosystems,[10] thereby either directly or indirectly influencing the well-being of humans. Unfortunately, we are only beginning to understand the ecosystem-level consequences of changing amphibian and reptile populations on aquatic, riparian, and terrestrial ecosystems,[11] and a complete understanding of the relationships between intact herpetofauna communities and benefits to human populations remains elusive.

INDIRECT ECOSYSTEM SERVICES

Studies investigating the ecological roles of reptiles and amphibians have indicated that their populations, or more specifically declines in their populations, can have measurable effects on ecosystem health, and that in some systems herpetofauna are considered keystone species due to their disproportionally large impact on ecosystem structure and

FIG 182.1 Critically endangered *Hyloscirtus colymba* tree frog from Central America, with clear chytridiomycosis symptoms. (Courtesy of Scott Connelly.)

FIG 182.2 Tadpole of *Atelopus zetecki* on a stream bottom, feeding on benthic periphyton and biofilm. (Courtesy of Scott Connelly.)

function. These organisms have been shown to influence a wide range of ecosystem function and processes, such as primary production, decomposition, nutrient cycling, pollination, seed dispersal, and the control of pathogens and pests.

In tropical systems amphibians are often abundant, both as terrestrial adults and as tadpoles, which have been recorded at densities of 1200 tadpoles/m^2. Because frog larvae may play a variety of functional feeding roles, such as carnivore, herbivore, detritivore, filter-feeder, and suspension-feeders,[12] their declining populations should be expected to influence a number of ecological processes. Grazing tadpoles have been found to dramatically decrease primary producer community biomass, both in pond[13] and stream ecosystems,[11] with levels of periphyton biomass often directly related to tadpole densities (Fig. 182.2). Tadpole feeding can also change algal community composition, with studies in tropical streams indicating that tadpole grazing can increase algal species-level biodiversity, and furthermore shift algal assemblages from communities dominated by large upright diatom species to communities characterized by small adnate diatoms when grazed.[14] Additionally, tadpoles have been shown to stimulate algal growth: although algal-grazing tadpoles can significantly reduce algal standing biomass, the algal community that remains after grazing can be more productive, on a per-biomass basis, than algal communities not subjected to grazing.[14]

NUTRIENT AND ENERGY TRANSPORT AND DECOMPOSITION

The potentially important role that amphibians play in the movement of biomass and nutrients through ecosystems has been long recognized, although only a handful of studies have provided reliable estimates of abundance and density of amphibians needed to reveal their true ecological importance. A classic study by Burton and Likens estimated that salamanders within a temperate experimental forest were accountable for ~20% of the energy flow through all bird and mammal populations at the site.[15] More recently, work by Semlitsch et al. found that some previous studies underestimated densities of salamander communities by as much as an order of magnitude, and therefore failed to appreciate the full impact of the roles of salamanders with respect to nutrient and energy flux, and their functional role in regulating invertebrate prey, through ingestion and carbon retention in forests.[16]

Likewise, tadpoles have been shown to influence organic matter dynamics in freshwater systems. The physical disturbance to the aquatic environment, or bioturbation, resulting from larval amphibian feeding activity not only reduces the accumulation of benthic sediments by direct consumption but can also result in the resuspension and transport of organic matter into the water column. Organic matter transport resulting from aquatic amphibian feeding, in combination with the production and transport of tadpole feces, can be an important source of energy and nutrients (e.g., nitrogen) for downstream communities of aquatic consumers.[11] Additionally, because many anuran species have aquatic larvae that metamorphose to terrestrial adults, they can act as a flux of nutrients from aquatic systems to terrestrial systems. Seale, for example, found that through the ingestion of blue-green algae, and the assimilation of the nitrogen contained within, amphibians moved significant quantities of nitrogen from the aquatic to the terrestrial environment via metamorphosis.[17]

Due in part to their relatively large size, sea turtles may play an important role in the transport of nutrients and energy from marine to terrestrial ecosystems. In a study of nesting loggerhead sea turtles (*Caretta caretta*), it was found that 34% of the energy contained in deposited eggs was transferred to terrestrial dune vegetation, detritivores, and decomposers, and 28% of the energy deposited through oviposition was ingested by predators.[18] Similar trends were documented with respect to the fate of the nitrogen and phosphorus content of the eggs, indicating that where present, these organisms can play a significant role in ecosystem dynamics.[18]

FOOD CHAINS, INVERTEBRATE RESPONSE, AND FUNCTIONAL REDUNDANCY

Herpetological populations have been shown to impact invertebrate communities, both directly and indirectly. Salamanders studied in forested systems, for example, have been found to reduce beetle and fly larvae, adult beetles, ants, and springtails, and increase communities of mites, millipedes, and spiders, presumably indirectly by reducing the competitors and predators of these invertebrates.[19] Insectivorous adult frogs can directly influence prey communities and indirectly alter ecosystem-level processes in terrestrial habitats and have been shown to reduce numbers of aerial insects and rates of plant herbivory.[20] In tropical streams that have experienced catastrophic losses of amphibians due to the pathogenic *Batrachochytrium dendrobatidis* fungus, the dominant larval frog functional group lost was the algal grazers; therefore, subsequent ecosystem responses to their declines might be expected to be most apparent among other invertebrate consumers that also rely on the periphyton food resource. This response was found, as grazing macroinvertebrate communities shifted from generally smaller-bodied to larger-bodied insects.[21] However, even after a number of years of post tadpole declines, no other grazing taxa fully compensated for the role that tadpoles played in the system, suggesting a lack of functional redundancy. Additionally, aquatic macroinvertebrate functional structure differed in unexpected ways, as aquatic insect shredder production significantly decreased after tadpole losses, indicating that less obvious trophic interactions may exist between tadpoles and other taxonomic groups.[21]

Reptilian predators may have significant effects on invertebrate communities as well. Through a manipulative study examining *Anolis* spp. lizards, it was found that the presence of the lizards not only reduced the total number of spider prey and overall prey species richness, but the declines in prey numbers was in large part driven by the resulting loss of rare spider species. Additionally, it was found that the lizards may induce sublethal effects on their prey, as the mean body lengths of a rare spider were larger where the lizard predators were removed.[22]

Because a number of terrestrial turtles and lizards forage on plant foliage, flowers, and fruits, they may exert influence on the biomass and composition of plant communities not only through the direct consumption of biomass but also through the role they may play as pollinators and seed dispersers. In a study examining vegetative

VetBooks.ir

consumption by spiny-tailed iguanas (*Ctenosaura hemilopha*), germination trials from ingested and passed seeds indicate that although the lizards may function as seed dispersers of some plant species, especially Cactaceae, the iguanas are poor dispersers for other tree species because they destroy the seeds by ingesting the fruit.[23] However, our understanding of the strength of the herpetofauna on seed dispersal may be underestimated, as the consumption of flowers and fruits by turtles and lizards may influence the terrestrial community composition in other indirect ways and may potentially have measurable economic significance.[24,25]

HUMAN HEALTH, DISEASE, AND MOSQUITOS

Adult mosquitos are a key vector for a suite of wildlife and human diseases,[26] including Zika, malaria, West Nile virus, yellow fever, and others. The World Health Organization estimated yearly costs associated with malaria at nearly $12 billion, which slowed economic growth by 1.3% annually.[27] Indirectly or directly, tadpoles and salamander larvae have been found to affect populations of aquatic grazers or filter feeders, such as dipteran larvae.[28,29] Many *Anopheles* and *Culex* mosquito larvae are filter-feeders, which ingest primarily phytoplankton suspended on the water surface, whereas many larval *Aedes* and *Culiseta* mosquitos feed primarily on periphyton.[30,31] Therefore, feeding by both frog larvae and controphic mosquito larvae can alter algal communities and reduce algal biomass. Competition for limited food resources has the potential for tadpoles to directly lower the growth rates, developmental times, and survivorship of the dipterans. Studies from Papua New Guinea and Australia have suggested that competition with cane toad tadpoles has resulted in smaller female mosquito size and fitness, thereby decreasing the likelihood of mosquito-transmitted disease to humans.[32] Although some tadpole species may increase the ability of aquatic fly larvae to acquire energy by removing sediments from periphyton and thereby exposing additional food resources,[33] most frog/mosquito interactions are generally competitive, and the reduction or removal of larval amphibians will benefit the aquatic mosquito larvae.[34,35] Although adult mosquitos are not likely an important dietetic component of any adult amphibian species, some tadpole species feed on mosquito eggs,[36] and the presence or absence of amphibian larvae has been shown to influence where mosquitos chose to oviposit.[37,38] Direct ingestion of mosquito larvae by the larvae of spadefoot toads[39] and the frog *Hoplobatrachus occipitalis* has been documented, and a significant component of the stomach contents of aquatic tiger salamander (*Ambystoma tigrinum*) larvae have been found to be the larvae and pupae of mosquitos.[40]

WATER QUALITY

A number of studies have characterized how amphibians are impacted by various chemicals, anthropogenically applied nutrients, and other pollutants in the watershed, leading to amphibians often being referred to as "canaries in the coalmine." However, far less research has focused on the influence that amphibians exert on water quality. Many frog larvae are filter-feeders, and as such filter volumes of water equal to their body mass every several minutes; at high tadpole densities their entire aquatic environment can be turned over quickly.[41] Tadpoles have been found to remove bacteria from water bodies and may decrease eutrophication of aquatic systems by ingesting nitrogen-fixing algae.[17]

FOOD AND MATERIALS FROM HERPETOFAUNA

Of the variety of services that intact ecosystems provide to humans, food production is one of the most essential, and the harvesting of wildlife is an important source of protein in many cultures. In rural areas of Mexico, for example, bushmeat has been estimated to comprise approximately 70% of the protein consumed by humans, with turtles, crocodiles, iguanas, and snakes among the animals hunted.[42] Likewise, in Honduras indigenous people consume several frog, turtle, and lizard species to fulfill basic food needs (Fig. 182.3).[43] Although the widespread harvesting of sea turtles for meat, eggs, and shells has greatly decreased due to overexploitation and resulting species protection efforts, egg harvesting, following stringent conservation guidelines, continues to provide income and protein for some Central American communities.[44] The harvesting of herpetofauna continues to provide food security and significant sources of protein for many local communities throughout much of Latin America, including Argentina, Brazil, Colombia, Peru, Venezuela, and other countries. Apart from the value that herpetofauna provide as a direct food source for humans, their role as consumers of agricultural pests is becoming recognized. Peltzer et al., for example, found that the diets of three frog species found in agricultural soybean fields consisted primarily of herbivore pests of the plants and suggested that the frogs act as important biological control agents in the soybean fields.[45]

FIG 182.3 An adult tropical *Leptodactylus pentadactylus* (smokey jungle frog), a species commonly harvested for their meat. (Courtesy of Scott Connelly.)

In addition to the human value provided as a food source, amphibians and reptiles also provide economic benefits in other consumptive ways. Prestridge et al. reported that the pet trade, for example, was a driver for the importation of 1.48 billion live amphibian and reptiles, including poison dart frogs, boa constrictors, and king snakes, among other species, into Texas alone.[46] Retail prices for these individuals ranged from $30 to over $20,000. Frogs in the genera of *Agalychnis* and *Dendrobates*, and reptiles (*Boa constrictor*, *Basiliscus* spp., and *Sceloporus malachitus,* for example) generated over $1.5 million in revenue for Nicaragua (Figs. 182.4 and 182.5).[47] Products obtained from reptiles, such as hides, have been a significant export for a number of countries; the export of caiman and crocodile hides from the Neotropics to North American and European buyers has been substantial and totaled 300,000 hides from Bolivia and over 11 million from Colombia for the 30-year span between 1950 and 1980.[48] The export of herpetofauna products from countries with especially high levels of biodiversity can create significant revenue. Colombia, for example, generated over $50 million in income between 1929 and 1969 from wildlife exports, with approximately 37% resulting from reptiles.

MEDICINAL, ETHNOBOTANY, AND CULTURAL USES

Amphibians use skin secretions and compounds for a number of biological purposes, including territorial marking, predator defense, and combating microbial infections. Although relatively few chemical properties of amphibians and reptiles have been systematically tested for their potential medicinal properties, humans have recognized for hundreds of years that herpetofauna produce a suite of potentially useful compounds. Amphibians have been used in traditional medicines globally to treat a number of conditions, from warts to heart disease.[49] In the neotropics, more than 60 species of amphibians and reptiles are used in traditional medicine. For example, *Leptodactylus* spp. are sold to treat ailments such as asthma, skin ailments, and tumors.[50] Building on this knowledge, a number of studies have investigated the potential that herpetofauna, particularly anurans, caudates, and snakes, have to contribute to medicine and to the development of novel pharmaceuticals. For example, antimicrobial peptides from frog skin secretions have shown the potential to inhibit infection and transfer of the HIV.[51] A toxin, epibatidine, isolated from the South American poison dart frog *Epipedobates tricolor*, has been shown to be an effective painkiller in rodents,[52] and there has been optimism that synthetic variants of this chemical without side effects can be developed as an alternative to medicinal opiates, such as opioid addiction. In Western culture, ~50% of all manufactured pharmaceutical drugs have been derived from natural sources.[53]

INVASIVES AND ECOSYSTEM STRUCTURE AND FUNCTION

Invasive species are widely recognized as a primary threat to global biodiversity. Although the impact that introduced herpetofauna has on ecosystem structure and function has received relatively little attention, several well-documented case studies indicate that where biological invasions of herpetofauna are successful, dramatic and widespread ecosystem change may follow. For example, the inadvertent introduction of the brown tree snake (*Boiga irregularis*) to Guam has had far-reaching biological consequences, including the extirpations or extinctions of a number of native lizard and bird species.[54] Similarly, declines ranging from 88% to 100% of raccoon, opossum, bobcat, rabbit, fox, and other mammalian species in the Florida Everglades have been attributed to the spread of the invasive Burmese python (*Python bivittatus*).[55] Introductions of amphibians have also driven widespread ecosystem change, with the global spatial expansion of bullfrogs (*Lithobates catesbeianus*) responsible for declines in native species through competition, predation, and habitat displacement.[56] Bullfrogs have also been found to be carriers of pathogens such as the chytrid fungus, and, through their anthropogenic range expansions, have the potential to spread disease, further contributing to species declines.[57] Although the coqui frog (*Eleutherodactylus coqui*), which was introduced to the Hawaiian Islands in the 1980s, has not been found necessarily to compete with native birds for resources, the frogs were associated with ~35% higher abundance of nonnative birds, suggesting that the frogs serve as a food resource for generalist birds that may prey on small vertebrates such as frogs.[58] Due in part to the high densities they may achieve, herpetofauna such as the coqui frog have the potential to alter the concentrations and flow of nutrients; increase overall nutrient availability through their feces, urine, and carcasses; and ultimately stimulate new plant growth.[59]

CONCLUSION

There remains a need to better quantify the ecosystem-level roles of herpetofauna, particularly in light of widespread and ongoing population declines resulting from habitat alteration and loss, overexploitation, disease, and the suite of other stressors that amphibians and reptiles are currently facing.[3,4] How these organisms affect ecosystem structure, function, and overall health is in many ways poorly understood. Quantitative information on basic life history traits (such as growth rates, life spans, and reproductive cycles) and ecosystem roles (such as the part they play in food web dynamics, energy flow, and nutrient cycling) on many taxa is still needed. However, of the studies done, it is apparent that intact amphibian and reptile populations play essential ecological roles in many ecosystems and therefore possess great potential to both directly and indirectly affect human well-being.

Laws and Regulations—International

Margaret E. Cooper

Reptiles are not the most popular of species. Since time immemorial, reptiles have had bad press in myths and literature. Human beings are often afraid of snakes due to their defense mechanisms of bites, poison, and constriction. People who encounter a snake rarely stop to distinguish between a dangerous or a harmless species and often destroy them before identification. The Crocodilia are also readily recognized as dangerous, and there are countless records of the toll they have taken on people who live and work in their proximity. In parts of Africa contact with chameleons is believed to confer infertility. Only tortoises, turtles, terrapins, and some lizards are widely perceived as being of little or no threat to humans.

Reptile populations that live in the wild are at risk of depletion through habitat decline, persecution, climate change, trade (legitimate and illegal), marine pollution in the case of sea-dwelling species, and inadequate conservation measures, including law enforcement.

The law relating to reptiles has been divided into three parts for this book:

Chapter 183: Laws and Regulations—International
Chapter 184: Laws and Regulations—European
Chapter 185: Laws and Regulations—Americas

In practice, the different levels of law—international, regional, and national—are all interrelated (see Table 184.1). Legislation affects both free-living (free-ranging) and captive reptiles.

This chapter considers the international law affecting reptiles (Box 183.1) and lists the national laws on wildlife and animal welfare of some of the countries not included in the other two chapters (Table 183.1).

ASPECTS OF LEGISLATION AFFECTING REPTILES

For the most part, the international legislation affecting reptiles relates to their conservation. In this field there are a number of international and regional treaties that relate to reptiles or from which reptiles benefit in general terms (see Box 183.1).

The Reptilia are a significant part of the world's biodiversity and worthy of protection. This can be addressed through habitat and species conservation measures and the control of trade. Education has an important role to play in promoting conservation and sustainable use together with changing negative attitudes toward some species. It is essential that these measures are backed by legislation and that the international treaties that address these issues are supported. The law may not always be considered the most successful conservation tool, particularly in locations where there is poor regulatory infrastructure. However, conservationists are beginning to advocate support of better investigative and judicial powers (coupled with training in skills and the understanding of the importance of species protection) and asking for better legislation and effective enforcement of the law.[1]

Many reptiles are traded for their skins and other parts, and live specimens are supplied to collections, both private and public. They are also in demand for entertainment and display, or they are kept purely out of interest and enthusiasm. Some of this trade is supplied from substantial ranching or captive-breeding enterprises; others are bred on a smaller scale, both commercially or by hobbyists. When endangered species of reptiles are traded across national boundaries permits are likely to be required (as discussed later).

When reptiles are kept in captivity they are dependent on their keepers for their essential needs and general welfare. A keeper should have sufficient knowledge and skills to ensure their well-being and compliance with animal welfare legislation. Such legislation is usually the responsibility of individual countries (see Chapters 184 and 185). The keeping of reptiles in captivity is often regulated at a national or local authority level, and the keeper, be it a private collection, zoological display, or other use, may require a license (see Chapters 184 and 185).

For countries in the Americas, see Chapter 185, Table 185.1.

There is some legislation at the regional level in the European Union (EU) and Council of Europe (COE); this is discussed in Chapter 184.

SOURCES OF INFORMATION ON INTERNATIONAL LEGISLATION

Copies of most international and regional legislation is available on the Internet, and many key treaties also have a website providing the relevant documentation (i.e., the treaty and other legislation and decisions made by the parties subsequent to the treaty, together with detailed information on the implementation of the treaty).

Conservation bodies, such as the International Union for Conservation of Nature (IUCN; https://www.iucn.org/) and the United Nations Environment Programme/UN Environment (UNEP; https://www.unenvironment.org/) have relevant publications, species status reports, guidelines, and other publications.

The IUCN (https://www.iucn.org/) provides ECOLEX, an environmental law resource and library, and the Red List, a definitive authority on the conservation status of animals and plants. The IUCN Species Survival Commission has 10 specialist groups that have experts and resources, in some cases including veterinary expertise relating to particular species, for example, the crocodile, marine turtle, and viper specialist groups (see https://www.iucn.org/ssc-groups/amphibians-reptiles).

TRAFFIC Bulletin (http://www.traffic.org/bulletin/) carries investigations into the trade in endangered species and reports on law enforcement regarding prosecutions of illegal trading. An IUCN publication on wildlife prosecutions reports that among 285 animals of various species, 10 were reptiles (see https://portals.iucn.org/library/sites/library/files/documents/2016-044.pdf).

Special interest NGOs are often very well informed regarding the legislation related to their field of interest and may have useful websites or contacts.

INTERNATIONAL CONSERVATION LEGISLATION

At the international level most of the law regarding reptiles relates to the conservation of species and habitat and comprises international treaties (also called conventions) that are made between countries at diplomatic level and subsequently ratified by national governments. The latter are obliged to put binding agreements such as treaties into effect in their national legislation—thus providing for implementation and enforcement.

The primary conservation treaties are listed in Box 183.1. The two species-orientated conventions, CITES and CMS, are intended to protect listed species, including reptiles, whereas the Ramsar (Wetland Convention) and World Heritage Conventions are aimed at protecting habitat and other significant sites through the designation of protected areas. Although such sites are rarely designated specifically for the benefit of reptiles, species found in such areas will benefit from the protective status accorded to Ramsar and World Heritage sites.

Convention on Biological Diversity

The CBD deals with the conservation and sustainable use of biodiversity in its broadest sense, together with the fair equitable sharing of benefits arising from genetic resources. The latter is supplemented by the Nagoya Protocol on Access and Benefit Sharing (ABS) of 2010, which requires the governments that are party to it to provide a fair and transparent framework for recording and sharing any benefits obtained from genetic resources (by research or commercial development) and ensuring that any benefits are equitably shared with the country from which the genetic resource originated. Any benefit sharing must be on mutually agreed terms. Where new material is collected in a country that is party to the Protocol, a benefit-sharing agreement should be drawn up. Many resource-rich countries already have existing terms and condition for *in situ* or in-country collection or research. Scientific research institutions, museums, and commercial bodies with existing collections and materials are setting up procedures for assessing and reporting work that produces, or may produce in the future, a benefit to another country. Veterinarians and scientists carrying out research or development with genetic resources, for example, snake venom, should be aware of the new responsibilities if they are working with any of the approximately 100 countries that have joined the Protocol. The European Union and UK already have legislation in place (https://www.gov.uk/guidance/abs).

Convention on International Trade in Endangered Species of Wild Fauna and Flora

CITES is also discussed in Chapters 184 and 185. There are 183 parties to this treaty (as of November 2017); the most recent to join are the EU (2015; the 28 EU states formerly operated as individual parties) and Tajikistan and Tonga (2016). The main purpose of the Treaty it to control the trade in the endangered species listed in Appendices I, II, and III of the Convention. A permit is required to authorize the "trade" of CITES species between countries. The term "trade" in effect means the *movement* for any purpose across national borders. Thus, if a species is listed on an Appendix, a permit is still required even if the purpose is scientific or veterinary rather than commercial. In the case of species listed in Appendix I (as being considered at risk of extinction), permits are not normally given for commercial purposes, whereas a permit may be available for other purposes. A summary of the key provisions is provided in this section.

There are 87 species and 8 subspecies of reptiles in Appendix I, 1278 species and 4 subspecies in Appendix II, and 61 species in Appendix III. As at October 4, 2017, the reptiles listed include alligators; crocodiles and caimans; lizards; geckos; skinks; monitor lizards; many snakes including boas, pythons, and vipers; all sea turtles; and many turtles, terrapins, and tortoises (Table 183.2). Before applying for a CITES permit the current status (the Appendices are updated biannually) of a particular reptile should be ascertained on the CITES website: https://www.cites.org/eng/app/appendices.php. A downloadable list at: https://cites.org/sites/default/files/eng/app/2017/E-Appendices-2017-10-04.pdf.

It is also necessary to check the CITES permit required for a species in the specific countries of import and export, as the status may have been upgraded in the national legislation. This is particularly important with the European Union and UK CITES regulations in which many species have been upgraded.

The essential provisions of the CITES Convention:

- Certain species of reptiles are listed in Appendix I (because they are threatened with extinction), Appendix II (because they may become extinct if trade is not controlled), and Appendix III (when a country asks for cooperation in preventing illegal or unsustainable trade of a species) of the Convention (https://cites.org/eng/app/index.php).
- The CITES provisions apply to live animals, carcasses, and derivatives of listed species (see following section).
- Any international trade of such CITES-listed species must be authorized by a CITES import and export permit issued by the CITES Management Authority of the appropriate country. For a list of these, see CITES website (https://cites.org/eng/cms/index.php/component/cp).
- Trade means international (cross-frontier) movement, whether commercial or not and for whatever purpose (see previous comments).
- In the case of Appendix I species, a permit may be given only for movement that is not of a primarily commercial nature (see previous comments).

TABLE 183.2 Reptile Species Listed in Appendices I, II, and III of CITES (as of October 4, 2017)

Appendix I	Appendix II	Appendix III
Class Reptilia (Reptiles)		
Crocodilia: Alligators, caimans, crocodiles		
	Crocodilia spp. (except the species included in Appendix I)	
Alligatoridae: Alligators, caimans		
Alligator sinensis		
Caiman crocodilus apaporiensis		
Caiman latirostris (except the population of Argentina, which is included in Appendix II)		
Melanosuchus niger (except the population of Brazil, which is included in Appendix II, and the population of Ecuador, which is included in Appendix II and is subject to a zero annual export quota until an annual export quota has been approved by the CITES secretariat and the IUCN/SSC Crocodile Specialist Group)		
Crocodylidae: Crocodiles		
Crocodylus acutus (except the population of the Integrated Management District of Mangroves of the Bay of Cispata, Tinajones, La Balsa, and surrounding areas, Department of Córdoba, Colombia, and the population of Cuba, which are included in Appendix II)		
Crocodylus cataphractus		
Crocodylus intermedius		
Crocodylus mindorensis		
Crocodylus moreletii (except the population of Belize, which is included in Appendix II with a zero quota for wild specimens traded for commercial purposes, and the population of Mexico, which is included in Appendix II)		
Crocodylus niloticus [except the populations of Botswana, Egypt (subject to a zero quota for wild specimens traded for commercial purposes), Ethiopia, Kenya, Madagascar, Malawi, Mozambique, Namibia, South Africa, Uganda, the United Republic of Tanzania (subject to an annual export quota of no more than 1,600 wild specimens including hunting trophies, in addition to ranched specimens), Zambia and Zimbabwe, which are included in Appendix II]		
Crocodylus palustris		
Crocodylus porosus {except the populations of Australia, Indonesia, Malaysia [wild harvest restricted to the state of Sarawak and a zero quota for wild specimens for the other states of Malaysia (Sabah and Peninsular Malaysia), with no change in the zero quota unless approved by the Parties] and Papua New Guinea, which are included in Appendix II}		
Crocodylus rhombifer		
Crocodylus siamensis		
Osteolaemus tetraspis		
Tomistoma schlegelii		
Gavialidae: Gavials		
Gavialis gangeticus		
Rhynchocephalia		
Sphenodontidae: Tuataras		
Sphenodon spp.

Source: CITES Secretariat.

- Permits are provided for the commercial movement of Appendix II species. Captive-bred specimens of Appendix I species are, subject to certain requirements, treated as if they were listed in Appendix II.
- Special certificates may also be given for the movement of captive-bred animals that are pets or in a traveling exhibition.
- Simplified permit procedures are available in special circumstances such as for the movement of biological and veterinary samples and museum specimens (see later).
- Specific criteria exist for the issue of permits: the trade must not be detrimental to the survival of the species; the animal must have been legally obtained; the animal must be prepared and shipped so as to ensure that it is not at risk of injury, damage to health, or cruel treatment during transportation; the importer must be able to house and care for the animal appropriately (see later).

The detailed provisions of CITES are complex, and further information can be obtained from the CITES Convention website at http://www.cites.org/; and, in view of the extensive additional provisions in the EU law, at the EU website at http://ec.europa.eu/environment/cites/legislation_en.htm and from national resources such as the UK Government CITES website at https://www.gov.uk/guidance/cites-imports-and-exports (also see Chapter 184). For a detailed study of the functioning of CITES, see Wijnstekers.[2]

MATTERS OF PARTICULAR INTEREST TO VETERINARIANS

Derivatives of CITES Specimens

The CITES provisions apply not only to live specimens but also to carcasses, parts, and other derivatives. Originally envisaged to include material such as ivory, traditional medicines, reptile skins, and other artifacts, the provisions also apply to biological and veterinary samples. The CITES permit procedure has often led to the delay of, and damage to, biological and veterinary material essential to the health and management of CITES animals when it is sent to another country for diagnosis, research, or other purposes. CITES now recognizes this problem and provides for a "fast-track," or simplified/partially completed permit procedure in respect of urgent noncommercial samples. See Resolution Conf. 12.3 (Rev. CoP17) permits and certificate (https://cites.org/sites/default/files/document/E-Res-12-03-R17.pdf).[3] This provision may not be well known in many countries, but it is included in Commission Regulation (EC) No 865/2006, Article 18. CITES has also decided that urine and feces are not considered to be derivatives (so do not require CITES permits) under Resolution Conf. 9.6 (Rev. CoP16): Trade in readily recognizable parts and derivatives (https://cites.org/eng/res/09/09-06R16.php).

Transportation

- Animals that are CITES-listed species must be transported in accordance with the CITES "Guidelines for transport and preparation for shipment of live wild animals and plants."[4]
- In the case of air transport, they must be transported in accordance with the most recent airline rules governing the transport of live animals.[5]
- Public road and rail carriers may also have their own requirements.
- International and national postal regulations may forbid the transport by mail of living reptiles. Very precise requirements also exist for the mailing of animal carcasses and pathogens, including special packaging and labeling. These are based on the UN packaging requirements (see, for example, the World Health Organization Guidelines at http://www.who.int/csr/emc97_3.pdf, the relevant national legislation and numerous institutional guidelines).[3]

Captive-Bred Appendix I Specimens

As mentioned previously, such animals may be traded under Appendix II permits. There is an extensive trade in Appendix I reptiles that have been bred in captivity (http://ec.europa.eu/environment/cites/pdf/reports/non_cites_reptiles.pdf). For example, there are many crocodiles, snakes, chameleons, and other reptiles that are also bred for trade in large- or small-scale enterprises.

The criteria set by CITES for captive-bred Appendix I animals to qualify for trade under Appendix II permits is strict, and there is provision for the registration of ranching operations (e.g., crocodile farms) with CITES and identification of the animals and products. There is useful advice and veterinary expertise available from the IUCN specialist groups (as discussed earlier), particularly the Crocodile Specialist Group (http://www.iucncsg.org/).

Many reptiles that are not on CITES are also traded in many parts of the world. The impact on wild populations has been widely studied.[6]

Case Studies

There are various sources of information on law enforcement. CITES infringements and associated prosecutions in many countries are reported in the TRAFFIC Bulletin (http://www.traffic.org/bulletin). Herpetological societies will often note significant cases that have implications for their members, and they will also have information on the impact of relevant legislation, much of which may be available on their websites. Surveys and studies may also provide data on law enforcement.[7,8]

VetBooks.ir

Convention on the Conservation of Migratory Species of Wild Animals

This convention is intended to bring together countries through which certain species routinely pass (range states) in order to provide consistent protection.

There are two appendices. Appendix I requires the parties to the convention to provide full protection to the species listed. Appendix II lists species for which the range states should make agreements regarding measures to take to improve protection within their countries.

The only reptiles listed on Appendices I and II are the yellow-headed side-neck and all marine turtles, as well as the gharial (Appendix I only) and the saltwater crocodile (Appendix II only).

Appendix II agreements that have been made regarding sea turtles follow.

- The Memorandum of Understanding on the Conservation and Management of Marine Turtles and their Habitats of the Indian Ocean and South-East Asia (IOSEA Marine Turtle MOU) and its associated Conservation and Management Plan. (http://www.cms.int/en/legalinstrument/iosea-marine-turtles)
- Memorandum of Understanding concerning Conservation Measures for Marine Turtles of the Atlantic Coast of Africa; see: Conservation Measures for Marine Turtles of the Atlantic Coast of Africa—TS No. 5 (http://www.cms.int/atlantic-turtles/)

Considering how widespread is the habitat of the marine turtle species, such agreements play an important part in developing protection for the various species and in encouraging cooperation between the range states for their protection.

REGIONAL COOPERATION

United Nations Environment (UNEP) Regional Seas Programme

The Regional Seas Programme is designed to bring together countries to conserve the marine environment. This includes not only species and habitat protection but also environmental issues such as marine pollution.

The Programme is divided into 18 regional seas areas, such as the Caribbean, Eastern Africa, the Mediterranean, Black Sea, and the Arctic. There are 143 participating countries and 18 Regional Seas Conventions and numerous Action Plans. This provides a structure whereby nations that have a coastline are encouraged to collaborate and to take responsibility for the marine environment within their territories.

In many cases the culture, politics, economics, and languages of these counties are diverse and may not have marine protection as a priority. The multilateral regional treaties and action plans that address issues of pollution, degradation of coasts and reefs, and the need for legal protection of the marine environment bring the countries together to address marine issues, develop legislation, and arrange cooperation. This is of particular value for marine species such as sea turtles that feed and nest in coastal areas that form part of the territory of a country but migrate through the high seas for which there is no national legal responsibility. For further information, see http://web.unep.org/regionalseas/who-we-are/regional-seas-programmes.

LAW ENFORCEMENT

Implementing legislation and law enforcement are a matter for national law and individual governments. International cooperation in law enforcement is receiving prominence these days. The trade in endangered species is in large part an international matter and the combat of illegal trade requires cooperation and collaboration between governments and enforcing authorities such as the police or wildlife authorities. A number of international or regional cooperative bodies have been set up with such aims, notably the International Consortium on Combating Wildlife Crime, INTERPOL, the Global Partnership on Wildlife Conservation and Crime (World Bank), the Lusaka Agreement Task Force, and the ASEAN Wildlife Enforcement Network. Many nongovernment organizations also contribute support for the enforcement of wildlife conservation legislation (Cooper).[1]

OTHER LEGISLATION

Animal Welfare

Most legislation regarding animal welfare is made at national level, although in Europe there are provisions in EU and COE law (see Chapter 184).

The Organisation Mondiale de la Santé Animale/World Organisation for Animal Health (OIE/WOAH) has taken responsibility for animal welfare standards on the international scene and has drawn up international standards for animal welfare. At the present these are primarily for domesticated species, although the standard on the use of animals in research and education applies to mammals, birds, and reptiles (see http://www.oie.int/index.php?id=169&L=0&htmfile=chapitre_aw_research_education.htm). WOAH is also working on standards for the slaughter of farmed reptiles (http://www.oie.int/infographic/StandardsAW/index.html).

Although legislation on zoos is largely a national matter (see Chapter 184) there are animal welfare standards set on an international basis by the World Association of Zoo Zoos and Aquariums in its animal welfare strategy (see http://www.waza.org/files/webcontent/1.public_site/5.conservation/animal_welfare/WAZA%20Animal%20Welfare%20Strategy%202015_Portrait.pdf).

However, there is considerable concern worldwide regarding the need to encourage animal welfare, because the quality of care for animals varies substantially from country to country. In countries where there is little or no legislation or no interest in enforcing such laws as they exist, it may be possible to develop protocols or standards based on the "five freedoms." These were first put forward in the UK in 1965 in respect of farm livestock and have since been incorporated into legislation for other species and situations, such as zoos and general animal welfare law in a number of countries (see the statement by FAWC[9] at http://webarchive.nationalarchives.gov.uk/20110618120810/http://www.fawc.org.uk/freedoms.htm). The principles are often taught in veterinary schools and provide a widely accepted basis for animal care and management. They are as follows:

1. Freedom from Hunger and Thirst—by ready access to fresh water and a diet to maintain full health and vigor.
2. Freedom from Discomfort—by providing an appropriate environment, including shelter and a comfortable resting area.
3. Freedom from Pain, Injury, or Disease—by prevention or rapid diagnosis and treatment.
4. Freedom to Express Normal Behavior—by providing sufficient space, proper facilities, and company of the animal's own kind.
5. Freedom from Fear and Distress—by ensuring conditions and treatment that avoid mental suffering.

Animal Health

Animal health controls are exercised by most countries when animals, derivatives, or biological samples are imported. While the health controls on domestic and some nondomestic species are strict, reptiles do not always fall within this remit and may be exempt; on the other hand, New Zealand does not allow the importation of reptiles other than for zoos. It is necessary to find out from the animal health authority of the

VetBooks.ir

country of importation the documentation and veterinary checks that are required, because requirements may vary from time to time.

Nonnative Species

When planning exportation of reptiles to a country where they constitute an alien species, a permit may be necessary under its nonnative species legislation. Even if importation is allowed, it is likely that it will be illegal to keep or release it without a license to do so.

CONCLUSION

While the veterinarian and others who are working with reptiles may find that national legislation is the normal source of regulation that is likely to affect the management care and treatment of reptiles, it is useful to be aware of the influence that international law has in formulating a country's laws in conservation, animal health and welfare, and other issues. Some of the literature surrounding these topics may be of use, especially to those working in conservation, production, or trade of reptiles.

Laws and Regulations—Europe

Margaret E. Cooper

The geographic area of Europe extends from the west of Iceland to the east of Russia and from Norway in the Barents Sea above the Arctic Circle to Crete in the Mediterranean Sea and comprises many countries that are diverse in their geography, ecology, history, culture, legal systems, and attitudes toward animals. Not surprisingly, considerable variation exists in the legislation relating to animals, including reptiles, from one country to another not only as to content, form, and stage of development but also in effectiveness and enforcement. Legislation in Europe is heavily influenced by the European Union and the Council of Europe.

SOURCES OF INFORMATION ON LEGISLATION

One can usually obtain printed copies of national legislation from the official government printer, and in some countries (e.g., France, Germany), publishers produce bound volumes of codes of legislation that are to be found in the larger bookshops. International and regional, and in some countries national, legislation is available on the Internet. The laws of individual countries normally are produced in the national language; however, in countries where the language is not widely spoken (such as the Scandinavian counties, the Netherlands, or the newer members of the European Union [EU]); a translation may be available in, for example, English or French. The EU website provides a portal to information on the EU and links to the legislation of member countries (http://europa.eu/index_en.htm). The legislation is available via EUR-Lex at http://eur-lex.europa.eu/homepage.html, a comprehensive website on EU law. The ECOLEX website provides access to a wide range of animal and environmental laws from many countries at http://www.ecolex.org/ecolex/index.php.

Specialist bodies, such as the herpetological societies or wildlife or animal welfare organizations, may have copies of translations of legislation and may also have information or expertise on the application or enforcement of laws relevant to their fields of operation. The newsletter and website of the Federation of Veterinarians of Europe (http://www.fve.org/) is a valuable source of information on recent or forthcoming changes in laws relevant to animal health, animal welfare, veterinary law, and the profession.

Levels of Legislation

Legislation can be found at several levels, ranging from global conventions to city bylaws. These are described in Table 184.1, and examples of the

TABLE 184.1 Levels of Legislation Relating to Reptiles

Level	Description	Type of Legislation	Subjects Relevant to Reptiles
International (or global)	Treaties that all countries may join and that give rise to legal obligations.	International treaties, conventions, agreements.	International conservation conventions (see Box 183.1).
Regional	Multilateral legislation in which countries of a certain region are eligible to participate.	European Union Regulations and Directives. Council of Europe Conventions.	Legislation on conservation, animal health, animal transport, veterinary profession, veterinary medicines, health, and safety.
National (or federal)	Legislation of individual countries. Note: In the United Kingdom, much of the older legislation applies to England, Wales, and Scotland, but since devolution (July 1, 1999), the three countries make some laws separately through the English and Scottish Parliaments and the Welsh Assembly, causing divergence of content. Northern Ireland always has its separate legislation.	Primary laws passed by national parliament. Secondary legislation: orders or regulations made under primary legislation.	Laws on conservation, zoos, research, animal welfare, import/export, veterinary profession, medicinal products, health, and safety.
State	In countries with a federal constitution, each constituent state (e.g., a land in Germany and a canton in Switzerland) may have its own laws (as with states in the United States or Australia and the provinces of Canada).	Laws produced by individual constituent states and effective only within that state.	As for national (see previous), depending on scope given to state by national (federal) law or constitution.
Local	Laws made by local government authorities. Sometimes they also implement national laws.	Laws or bylaws made or implemented by local government authorities under national or state legislation.	Laws on keeping animals for specified purposes (e.g., exhibition). Bylaws regulating, for example, the keeping of animals.

COE, Council of Europe; *EU,* European Union.

legislation relevant to reptiles that has been produced at these levels are shown in Box 183.1 and Table 184.2. Where global or regional legislation on a particular field of law exists, countries that are parties are likely to have some similarity in the content of their relevant national laws.

IMPLEMENTATION AND ENFORCEMENT OF LEGISLATION

Differences also exist in the legal systems as between individual nations. For instance, many have codified legislation (e.g., France) and written constitutions (most nations), whereas Britain has neither of these. Countries may also have fundamentally different judicial systems. For this reason, the implementation (i.e., putting legal obligations into effect, usually with legislation) and enforcement (i.e., ensuring that the legislation is obeyed) of global and regional legislation is the responsibility of individual countries.

EUROPEAN REGIONAL LEGISLATION

The two regional European law-making bodies are the European Union (http://europa.eu/index_en.htm) and the Council of Europe (COE)(http://www.coe.int/en/; http://en.strasbourg-europe.eu/member-states,44987, en.html). Table 184.3 provides some information that may help to clarify their status and the effect of their legislation on reptiles.

FREE-RANGING REPTILES

General

The legal protection of reptiles in the wild includes both species protection and habitat protection. Thus a country's law may specifically afford protection for particular species of reptile, but in addition, reptiles also derive benefit from protection of the habitat in which they can be found.

Substantial wildlife conservation legislation is relevant to reptiles at all levels.[1] See Chapter 183 and Tables 184.2 and 184.4. Most countries have national species and habitat legislation, which is usually a combination of their implementation of global and regional legislation and national provisions. The legislation specifies species and habitats to be protected, methods of protection, offences, penalties, and enforcement powers.

Protected Species

Free-living reptiles have the benefit of protective legislation at a regional and national level. The species covered vary from country to country

VetBooks.ir

TABLE 184.3 European Institutions That Make Regional Wildlife Conservation Legislation

Institution	Membership	Legislation	Legislation Relevant to Reptiles	Implementation
EU Primary aims of EU: economic, political, and legislative EU aims: also foreign policy and crime prevention	28 member states: Austria, Belgium, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, Netherlands, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, United Kingdom*.	Regulations have direct application in EU member countries. Directives have to be transposed by each EU country into its national law. Enforcement is responsibility of each EU country. Member countries can be required by the European Court of Justice to implement directives, backed by financial penalty.	†Habitats Directive Transport Directive Scientific Research Directive †CITES Regulations (full titles in text) Professional Directives Medicines Directives	Should be implemented by all member countries.
COE Primary aims: social and cultural, especially democracy, rule of law, and human rights	COE has 47 members and 5 observer countries (including Canada, the Holy See, Japan, Mexico, United States). Nonmembers of COE can join its conventions. 350 NGOs have consultative status.	Conventions must be implemented by member countries that have ratified or acceded to them. Other countries can accede. No specific means to make a country implement a convention.	Relevant conventions: Wildlife conservation (Berne) (ETS 104) Welfare of animals during transport 1968 (ETS 065) Revised 2003 (ETS 193) Scientific research (ETS 123) Pets (ETS 125)	Ratified by: 47 members, 5 other countries and EU 24 countries and Russia 12 countries 21 countries and EC 21 countries

COE, Council of Europe; *ETS,* European Treaty Series; *EU,* European Union; *NGO,* nongovernmental organization.
*In a referendum held on June 23, 2016, the United Kingdom voted to leave the EU. Under the Treaty on European Union (Lisbon Treaty) Article 50, a member state must inform the EU Council of its intention to leave and then, following a maximum of 2 years (unless extended) allowed for negotiation of terms, exit occurs. The United Kingdom will leave the EU on March 29, 2019, and transitional arrangements will apply until the end of 2020.
†See Table 184.2 for the full titles of these laws.

and relate primarily to the species that occur naturally in that country. Table 184.4 shows the listings of protected reptiles for the COE, EU, and by way of an example of national law, English conservation legislation.

Typical Prohibited or Controlled Activities Relating to Reptiles in the Wild

Core offenses likely to be included in a country's species protection legislation are:

- Deliberate killing, taking, or injuring of a protected reptile or its young or eggs.
- Deliberate disturbance of a protected reptile.
- Deliberate disturbance of its breeding or resting place.
- Use of prohibited or nonselective methods (e.g., poison, nets, traps, lights, vehicles) of capture, or killing of protected reptiles that may deplete or disturb local populations or are inhumane.
- Trade (e.g., sale, exchange, barter, transport, or display for sale) in live animals, dead specimens, or derivatives thereof.
- Release of alien (nonnative) species.

Many of these activities can be authorized by license for specified purposes (e.g., conservation, research, education, exhibition, captive breeding, trade in captive-bred specimens, public health, or crop or property protection).

Variation in National Laws

National laws that incorporate some or all of the previous laws may also vary in quantity, quality, and effectiveness, but some uniformity of content does exist within the EU or COE (because the national laws must reflect the regional laws) and among countries that have implemented the global conventions (see Table 184.4 and relevant convention websites). However, the level of protection of a particular species may also vary, because its conservation status can differ from one country to another. This may be so in spite of the listed status of a species at the regional level, because a country can derogate from the main legislation when a species is not at risk, not present, or a country is not willing to protect it; conversely, a country may impose a higher status or stricter regulation than that required by the regional legislation. Likewise, the quality of enforcement is variable, for example, because of the extent of the powers provided or the different degrees of political will or financial resources.

Fieldwork That Involves Reptiles

In addition to the foregoing legislation, those who carry out scientific research in the field using free-living reptiles may need to obtain research authorization or licenses to comply with the species protection laws, or permission to enter the area where the reptiles are studied. If the work involves population management, one should have regard to the IUCN Guidelines on reintroductions, translocation, and other topics.[2–5]

CAPTIVE REPTILES

General

The keeping of animals, including reptiles, is mainly regulated by national or state legislation, although day-to-day control may be the responsibility of local government authorities. The control is likely to depend on the nature of the species and the purpose for which they are kept. Regulation may include provisions for licensing and inspection and require compliance with standards or guidelines.

Reptiles Kept as Pets

The private keeping of reptiles is often controlled, usually at local government authority level, especially if the species (e.g., large or venomous reptiles) represents a risk to the public. Some countries may regulate the keeping of any species of reptile. Others may be selective, as in Britain, where the keeping of specified species is subject to licensing and inspection under the Dangerous Wild Animals Act 1976 (as

EU, European Union; *WCA,* Wildlife and Countryside Act.
*Full protection.
†Partial protection (killing, injuring, sale).

amended). The animals must be kept in secure and appropriate accommodation, and the keeper must be insured. Reptiles subject to the Act include all crocodilians, some colubrids, all elaphids, front-fanged venomous vipers, and the Helodermatidae (http://www.legislation.gov.uk/uksi/2007/2465/schedule/made).

The COE European Convention for the Protection of Pet Animals 1987 has broad provisions for the responsible keeping of pets, defined as "any animal kept or intended to be kept by man in particular in his household for private enjoyment and companionship." It requires the keeper of a pet animal to adhere to basic principles of animal welfare (see subsequently), and Article 4 provides that a pet should not be caused unnecessary pain, suffering, or distress, nor be abandoned. The keeper of a pet must be responsible for its health and welfare and provide accommodations, care, and attention that take account of the ethologic needs of the animal in accordance with its species and breed. In particular, keepers must give it suitable and sufficient food and water and adequate opportunities for exercise and take reasonable measures to prevent its escape.

Keeping of Protected Species

Restrictions may exist under national wildlife laws (see previous) on the possession of reptiles, particularly if wild caught. A license may be necessary to keep, breed, or trade in native or specified wild-caught or captive-bred reptiles. The keeper of a CITES species may be required to prove that it was imported or obtained legally in accordance with CITES legislation. In the EU, any commercial use of an Annex A CITES species must be authorized (as discussed later).

Exhibition, Display, and Entertainment

Reptiles are used or displayed for purposes such as zoos, circuses, cabarets, or education; such activities are likely to be subject to controls, usually through licensing by a local government authority. Great variation exists in the legislation, enforcement, and actual quality of care provided for exhibited animals in different countries. Countries are required to implement several supranational laws, which are mentioned subsequently.

The COE Pets Convention applies general welfare provisions (see previous) to pets, including reptiles, that are used in exhibitions, entertainment, and competitions and requires that these activities must not interfere with their health and well-being.

The Council Directive 1999/22/EC relating to the keeping of wild animals in zoos applies to collections open to the public and requires EU countries to regulate zoos as briefly summarized:

- The Directive applies to collections of "wild species" that are exhibited to the public on 7 or more days in a year.
- Zoos must be licensed and inspected.
- Accommodation for animals must take into account their biological and conservation needs and provide enrichment; zoos must provide good husbandry, veterinary care, and nutrition.
- Records must be kept; measures must be taken to prevent escapes of animals or the access of pests and to provide for dispersal of animals in the event of closure.
- Zoos must also make a contribution to conservation (e.g., by way of research, training, exchange of information, captive breeding,

reintroduction) and to public education relating to their animals and their habitats.
- The Directive was modeled on the British Zoo Licensing Act 1981 (although the latter has been amended to comply with the Directive).
- British zoos must also comply with the Secretary of State's Standards of Modern Zoo Practice (see https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/69596/standards-of-zoo-practice.pdf).
- The EU has produced an EU Zoos Directive Good Practices Document (see http://ec.europa.eu/environment/nature/pdf/EU_Zoos_Directive_Good_Practices.pdf).
- The EC CITES Regulations[6] (see Table 184.2), in addition to regulating international trade in CITES species (see subsequent), also requires that any use of species listed in Annex A of the Regulation for commercial purposes must be authorized by an Article 10 or, for zoos, an Article 30 certificate. This applies not only to the usual aspects of trade but also to display, which is interpreted to include any exhibit with a commercial element such as zoos, cabarets, and trade shows. Annex A includes all CITES Convention Appendix I animals together with a number of other species that have been upgraded to that status within the EU (http://ec.europa.eu/environment/cites/info_permits_en.htm).

Scientific Research

The COE European Convention for the Protection of Vertebrate Animals used for Experimental and other Scientific Purposes was formed in 1987. The EC Council Directive 86/609/EEC of November 24, 1986, on the approximation of laws, regulations, and administrative provisions of the Member States concerned the protection of animals used for experimental and other scientific purposes has been revised by Directive 2010/63/EU. This legislation relates to experimental or other scientific use of an animal that may cause pain, suffering, distress, or lasting harm and applies to all nonhuman vertebrates, including reptiles, both captive and free-living. Some countries also have detailed regulations or guidance that supplements the main legislation. The controls can include (as in Britain) licensing, inspection, and ethical review; pain controls; veterinary supervision; and the training of researchers. Other countries may or may not have controls of varying content.

TRADE

The trade in endangered species between individual countries is regulated by CITES. This is described in Chapter 183 and the EU CITES Regulations are listed in Table 184.2 and in Cooper.[7]

The essential provisions of EU legislation are summarized later. Other (non-EU) countries in Europe operate CITES by implementing the global Convention on an individual basis. Note that:
- The Regulations implement CITES directly in all EU member countries; they do not have national legislation on CITES.
- Exception: enforcement is the responsibility of individual EU countries (e.g., in Britain by the Control of Trade in Endangered Species [Enforcement] Regulations 1997, as amended).
- Many species (in addition to those in the CITES Appendices) are included in Annexes A to D of the Regulation. The species listed and the status accorded to them may be stricter than the requirements of the CITES Convention. For example, some CITES Convention Appendix II species such as the Mediterranean tortoises have been upgraded to Annex A (equivalent to CITES Convention Appendix I status) and others, not listed on the Convention, have been put onto Annex B (Appendix II status).
- Once legally in the EU, CITES specimens can be moved freely around the EU.
- The importation into the EU of certain Annex B species (including many reptiles) has been suspended (see lists in Commission Regulation (EU) No 888/2014 amended EU 2015/736).
- The "fast track" procedures described in Chapter 183 are incorporated in the Regulations.

For current lists of EU CITES species, see Commission Regulation (EU) No 2017/160 and the list of websites in Table 184.2. The EU CITES provisions are explained in the Reference Guide to the Wildlife Trade Regulations.[6]

EU Trade in CITES Species

Within the EU area and within individual EU countries, the trade of Annex A species (which includes, inter alia, all CITES Appendix I species) is additionally controlled under the CITES Regulations as follows:
- Annex A species may not be used for primarily commercial purposes.
- Annex A species that have been captive-bred from captive-bred parents may be used for commercial purposes if authorized by an Article 10 certificate (or Article 30 for zoos).
- To obtain a certificate, one must produce evidence to show that the animal was legally imported or captive-bred.
- Annex A species in commercial use must be permanently marked with a microchip transponder that conforms to ISO Standards 11784:1996 (E) and 11785:1996 (E) (where this is not physically possible, then with another permanent form of identification). Note: In Britain, although hatchling tortoises are less than 10 centimeters long, they do not need to be marked.
- A CITES animal that has been legally imported or for which an Article 10 certificate has been issued can be traded (in accordance with the terms of the certificate) freely within the EU.
- For an example of these provisions at a national level, see AHVLA[8]
- A thriving trade exists in captive-bred reptiles as pets, among hobbyists, or for other purposes.
- Licensing controls are often imposed on the taking and/or sale of indigenous (and possibly other) reptiles under national wildlife legislation and in conformity with the Habitats Directive and the Berne Convention.
- Local authorities may regulate pet traders and their premises.
- Law enforcement measures are important to deal with illegal trade.

ANIMAL HEALTH CONTROLS

Animal health laws also apply cross-frontier controls, but they operate entirely separately from the CITES provisions described previously.

European Union Directives on Import and Export

Animal health legislation often requires authorization (usually issued by the ministry responsible for agriculture) to import many species of mammal and bird. This legislation also involves veterinary health certification and quarantine for live animals. For such controls to apply to reptiles is unusual. However, permission may be necessary to import pathogenic reptile material, for example, blood or tissues, particularly when the samples are not fixed. Authorization may include conditions relating to packaging, storage, and disposal of the material.[9,10]

National Wildlife Legislation: the Export of Indigenous Species

Some countries forbid the export of indigenous species or derivatives thereof except under license. In addition, national controls may be found on the export and exploitation of genetic materials under legislation implementing the Biodiversity Convention. This might apply to material derived from reptiles and intended for diagnosis, research, or screening for potential value in developing modern medicines.

VetBooks.ir

National Wildlife Legislation: the in-Country Trade in Wildlife

National wildlife legislation usually regulates trade in its indigenous wildlife. The law prohibits the collection and trade in indigenous wildlife, even if the species are not listed on CITES and are not being exported.

Customs and Excise

Animals imported normally are subject to a country's taxes such as customs duty and value added (sales) tax.

REPTILES AND VETERINARY PRACTICE

Veterinary Professional Law

Veterinary practice in most European countries is regulated according to the usual provisions that relate to the registration of veterinarians and control of the profession, together with restrictions on the practice of veterinary medicine by laypersons.

Because the legislation is at national level, the precise provisions and levels of enforcement vary from country to country. To verify whether a reptile must be treated by a veterinarian, one must inquire as to whether reptiles are included in the range of species that must be treated by a registered veterinarian and whether the procedure is one that must be carried out by a veterinarian.

European Union nationals with EU veterinary qualifications are entitled to practice in any EU country. They must register in the given country. Directives 78/1026/EEC and 78/1027/EEC concern the recognition of qualifications and freedom of movement. The nationals may also have to provide a certificate of good standing from the EU country in which they were first or previously registered.

Britain also gives recognition to some (British) Commonwealth degrees from Australia, Canada, New Zealand, and South Africa and also American Veterinary Medical Association (AVMA)–recognized veterinary degrees from the United States (see http://www.rcvs.org.uk/).

Veterinary Medicinal Products

The pharmaceutical legislation that controls the sale, supply, prescription, and administration of veterinary drugs varies from very strict in some countries (with prosecutions and professional conduct [malpractice] proceedings in respect of breaches of the law or for the abuse or mishandling of substances) to lax in other countries. The EU regulates veterinary medicinal products through many regulations and directives. However, the sale, supply, and administration of veterinary medicinal products are controlled by national legislation in accordance with (inter alia) the appropriate directives. Prescription-only medicines for use in animals should normally be prescribed by a veterinarian. In light of the relatively few drugs that are approved for use in reptiles, the veterinarian may have to resort to "off-label" prescribing. In the EU, this must be done with the client's consent, and the drugs must be chosen in accordance with the "cascade" principles. If any patient is eventually to be used for food, then strict withdrawal periods must be observed (see https://www.bsava.com/Resources/BSAVAMedicinesGuide/Prescribingcascade.aspx; http://www.fve.org/uploads/publications/docs/fve_bro_cascade_jan2014.pdf).

OCCUPATIONAL HEALTH AND SAFETY

Occupational health and safety legislation is strong in some countries, including the EU where many directives exist on the subject. In countries in which the legislation is strictly enforced, the management of health and safety is all-pervasive and requires employers use the principles of risk assessment. Thus, in the case of reptiles kept in a zoo or veterinary practice, a risk assessment must be made of the hazards involved, the risks they pose, and the persons affected. Special hazards of reptiles include bites, envenomation, constriction, and salmonellosis. Measures to remove or reduce the risk, written records, and provision for monitoring and reviewing the procedures must be put in place. Legislation may also exist for specific health and safety situations, such as radiography and dangerous substances, fire, and first aid. Information on the EU legislation is available at the website of the European Agency for Safety and Health at Work at https://osha.europa.eu/en/safety-and-health-legislation.

In many other countries, little development may be seen of health and safety so far, and any measures that the veterinarian takes are on a voluntary basis. Any protective measures may help to reduce the risk of compensation claims (on the basis of negligence or employers' liability) that arise from accidents.

WELFARE

European Legislation

There are no international welfare laws relating to the humane treatment of animals, although the OIE (World Organisation for Animal Health, http://www.oie.int/en/) now includes "Recommendations for Animal Welfare" in its Terrestrial Animal Health Code.

Some broad provisions exist in the COE European Convention for the Protection of Pet Animals 1987 (ratified by 13 countries). It covers "any animal kept or intended to be kept by man in particular in his household for private enjoyment and companionship" and therefore includes reptiles kept as pets.

Article 3: Basic principles for animal welfare includes:

1. Nobody shall cause a pet animal unnecessary pain, suffering, or distress.
2. Nobody shall abandon a pet animal.

The article also contains provisions for responsible pet keeping (see previous).

National Legislation

Most countries have national legislation against cruelty to animals, and some may have extensive welfare law. The species covered by animal protection laws vary greatly, so examination of a country's legislation in detail is necessary to find whether it extends to reptiles, captive or free-living.

The provisions vary a great deal, but the forms of animal use or abuse that are addressed may include:

- Specific acts of cruelty
- A general category: causing unnecessary suffering
- The responsibility of the keeper of an animal to provide food, water, and suitable environment
- Poisoning, trapping, and cruel sports
- Mutilations (procedures carried out for nonmedical reasons, e.g., ligation of venom ducts in snakes)
- Use of anesthesia (and analgesics) during surgery
- Specific uses such as research and zoos if separate legislation is not provided
- Transportation (see later)

Some laws include most of the foregoing topics under one law; others have separate provisions, for example, for animals used in scientific research. The English and Welsh legislation is the Animal Welfare Act 2006, and there are comparable laws for Scotland and Northern Ireland. The legislation applies to all domesticated vertebrate species and other vertebrates that are in captivity or under a person's control. The acts include two key provisions: first, the offense of causing unnecessary

VetBooks.ir

suffering, and second, the duty of care that is imposed on those who keep animals. This duty requires a person to provide, so far as is reasonable in the circumstances, for the welfare needs of any animal (in accordance with good practice) for which s/he is responsible. The animal must be provided with a suitable environment and diet, be allowed to exhibit normal patterns of behavior, be housed singly or with others as appropriate, and be protected from pain, suffering, injury, and distress. There are also provisions forbidding mutilations, animal fighting, and poisoning.

Welfare During Transportation

European legislation exists on the humane transportation of animals, and this should have been transposed into national legislation. For example, in the English law there are provisions both general and specific that apply to reptiles.

Under the European Convention for the Protection of Animals during International Transport 1968, revised 2003, COE member countries must make provision for the welfare of vertebrate animals (including reptiles) during international transport. The requirements for noncommercial transportation are basic (i.e., that the animal should be fit to travel and that its health and welfare should be safeguarded during the journey). The stipulations for commercial transport are more stringent.

The Council Regulation (EC) No. 1/2005 on the protection of animals during transport and related operations) lays down requirements for the conditions of transport of vertebrate animals within, to, and from the Member States of the EU. It applies to animals that are transported for commercial purposes, for example, reptiles being carried by a commercial breeder or a zoo. It does not apply to transport for noncommercial purposes, transport to and from a veterinary surgery or clinic, or to pets accompanied by their owner on a private journey or when taken to or from a noncommercial event (e.g., as a hobby). Commercial transport requires a transporter authorization, trained handlers and vehicles that meet specified standards. There are conditions relating to journey times, rest times, food, and water for the animals. Animals must be fit to travel.

In England, The Welfare of Animals (Transport) (England) Order 2006 (and comparable legislation in the rest of the UK) implements the European legislation and has some additional requirements that are applicable to animals and circumstances not covered by the EU Regulation, such as reptiles traveling for noncommercial purposes.

Animals of any sort, including invertebrates, must not be transported in any way that causes or is likely to cause them injury or unnecessary suffering. Appropriate transport, containers, and environmental conditions must be provided during transport.

Animals that are CITES-listed species must be transported in accordance with the CITES "Guidelines for transport and preparation for shipment of live wild animals and plants."[11] In the case of air transport, they must be transported in accordance with the most recent airline rules governing the transport of live animals.[12]

Public road and rail carriers may also have their own requirements.

International and national postal regulations may forbid the transport by mail of living reptiles. Very precise requirements also exist for the mailing of animal carcasses and pathogens, including special packaging and labeling. These are based on the UN packaging requirements; see, for example, the World Health Organization Guidelines at http://www.who.int/csr/emc97_3.pdf, the relevant national legislation and numerous institutional guidelines, and Cooper.[9]

CASE STUDIES

There are various sources of reports of law enforcement. CITES infringements and associated prosecutions in many countries are reported in the TRAFFIC Bulletin (http://www.traffic.org/bulletin). Herpetologic societies will often note significant cases that have implications for their members.

CONCLUSION

A wide variety of legislation relates to reptiles either specifically or by way of general application. Although the details of national legislation cannot be included here, this chapter attempts to bring together as many as possible of the relevant principles that may be found in the law of the many countries of Europe. It is also intended to guide the reader toward appropriate sources of further and more specific information on the subject of reptile law.

Laws and Regulations—Americas

Gregory A. Lewbart and Daniel T. Lewbart

The hobby of captive herpetology is expanding, and more people and herptile (amphibians and reptiles) species are becoming a part of this expanding industry. Although captive breeding is much more popular and successful than it has been in decades past, many wild-caught specimens still find their way into captivity (some illegally) (Fig. 185.1). In some cases, maintenance of cultivated herptiles may also be against certain laws (Fig. 185.2). This chapter focuses on the international, federal, national, state, and local laws regarding herptiles and the authorities that enforce these regulations. Table 185.1 and Box 185.1 highlight information about non-US laws and resources. Several examples of specific regulation enforcement are also included and discussed.

The IUCN Red List of Threatened Species

This excellent resource provides current information for many of the world's plant and animal species at risk. The goal of the IUCN Red List is to "provide information and analyses on the status, trends and threats to species in order to inform and catalyse action for biodiversity conservation." The resource can be accessed via this link: http://www.iucnredlist.org. Following are standard references, one for the loggerhead and one for the hawksbill sea turtle:

Ceriani S.A., Meylan A.B. 2015. *Caretta caretta (North West Atlantic subpopulation)*. The IUCN Red List of Threatened Species 2015: e.T84131194A84131608.http://dx.doi.org/10.2305/IUCN.UK.2015-4.RLTS.T84131194A84131608.en. Accessed on September 15, 2018.

THE CONVENTION ON INTERNATIONAL TRADE IN ENDANGERED SPECIES OF WILD FAUNA AND FLORA (CITES)

Most readers are familiar with the acronym CITES. This multinational agreement was originally written in 1973, was entered into force in 1975, and is meant to protect vulnerable and endangered plants and animals throughout the world from overexploitation. CITES is strictly an international treaty among the participating countries, and enforcement of the CITES provisions is up to the individual member countries (so regulation of CITES is far from consistent beyond the essential requirements of the convention). To date, 183 countries are parties to the CITES Convention. For details about CITES, see the informative website at http://www.cites.org.

Listed CITES animals fall into one of three categories (Appendix I, II, or III), with Appendix I the most protective. However, even Appendix I species can be commercially exploited through a loophole called a "Reservation," which allows participating countries to make exemptions for certain species (e.g., Japan's taking of sea turtles). CITES regulations only apply to the international import and export of listed species, which means legally imported CITES species can be transported, traded, or sold within a given country subject to the legislation of that country (see Chapter 183 for more details).

CITES permits are issued by the management authority for the relevant country; for the United States these and other required permits are available through the US Fish & Wildlife Service Office of

FIG 185.1 These North Carolina diamondback terrapins (*Malaclemys terrapin*) were hatched in captivity. This species is listed as a species of concern at both the state and federal level. (Courtesy of Gregory A. Lewbart.)

FIG 185.2 This North Carolina spotted turtle (*Clemmys guttata*) was injured by a motor vehicle and is undergoing rehabilitation. This species is listed as federally endangered in Canada, is protected in most US states, is being considered for US federal protection, and is listed as endangered by the IUCN. UNITED STATES FEDERAL REGULATIONS

Endangered Species Act

The US Endangered Species Act (ESA) is a federal act that was established in 1973 to protect rare animals and plants, both native and nonnative (see Figs. 185.1 through 185.5). The ESA has also been a model for state endangered species programs and serves as the state regulatory plan in those states without their own legislation. All species of included animals and plants are listed as either threatened or endangered. It also implements CITES in the United States (https://www.fws.gov/). The details of the ESA can be found in title 50, Part 17, of the Code of Federal Regulations (ref: 50 CFR 17). Special permits are required for just about any activity involving a listed species (currently 181 species of herptiles are listed). Some endangered herptiles are the Wyoming toad (*Bufo baxteri*), Shenandoah salamander (*Plethodon shenandoah*), American crocodile (*Crocodylus acutus*), leatherback sea turtle (*Dermochelys coriacea*), Jamaican iguana (*Cyclura collei*), and Puerto Rican boa (*Epicrates inornata*). Some threatened herptiles are goliath frog (*Conraua goliath*), loggerhead sea turtle (*Caretta caretta*), Turks and Caicos iguana (*Cyclura carinata carinata*), and giant garter snake (*Thamnophis gigas*).

Some "special rules" apply to certain situations involving threatened (not endangered) species. These rules eliminate the normal ESA permit requirements. Examples of these special rules include the American alligator (*Alligator mississippiensis*) (state laws apply) and by-catch (accidental capture) of loggerhead, olive ridley (*Lepidochelys olivacea*), and green sea turtles (*Chelonia mydas*).

FIG 185.5 These hatchling pigmy rattlesnakes (*Sistrurus miliaris*) were found on a coastal North Carolina island and are protected in this state. (Courtesy of Gregory A. Lewbart.)

National Marine Fisheries Service Regulations

The ESA regulations are enforced by both the United States Fish and Wildlife Service (USFWS) and the National Marine Fisheries Service (NMFS); USFWS has jurisdiction only when sea turtles are ashore. Incidental capture permits are required by fishermen who are likely to accidentally take sea turtles. Detailed requirements exist for handling both living and dead-by-catch sea turtles (50 CFR 222.50 and 227.72).

The ESA permits for endangered species are only granted for the following reasons: legitimate scientific research, propagation, species survival, and incidental take. Permits for threatened species may be granted for zoological exhibition, educational purposes, and those listed previously for threatened species. ESA and CITES permits are required for species subject to both documents (in the United States, a single ESA permit fulfills CITES requirements). The ESA only regulates transactions at the interstate level (intrastate commercial activities involving legally obtained species are not regulated by the ESA). Individual states may restrict commercial activity of threatened and endangered species.

Designated United States Ports of Entry

All wildlife entering the United States must do so via one of the following ports of entry unless specified otherwise (50 CFR 14.11 and 14.12):

VetBooks.ir

Atlanta, Baltimore, Boston, Chicago, Dallas/Fort Worth, Honolulu, Los Angeles, Miami, Newark, New Orleans, New York, Portland (Ore), San Francisco, or Seattle. All wildlife shipments are subject to inspection by both the USFWS and the US Customs Service. Specific ports of entry exceptions exist for wildlife (not requiring special permits) originating in Canada and Mexico.

Special Turtle Regulations

The US Food and Drug Administration (FDA) and Public Health Service (PHS) regulate the import of any turtle under 4 inches carapace length and turtle eggs. Restrictions on foreign imports can be found in the PHS regulations (42 CFR 71). Six or fewer turtles and eggs can be imported without a PHS permit for noncommercial purposes. Seven or more turtles/eggs may be authorized with a permit if used for legitimate scientific, educational, or exhibition purposes. Interstate and intrastate transport is governed by the FDA (21 CFR 1240). No turtles of less than 4 inches carapace length, or turtle eggs, may be sold as pets in the United States. Exceptions include legitimate scientific, educational, or exhibition purposes. Confiscated turtles and eggs in violation are subject to humane destruction by the FDA. For more information, go to https://www.fda.gov.

US STATE LAWS

Most US states have their own laws governing the taking and keeping of native reptile species. Some states also regulate the sale and captivity of exotic amphibian and reptile species. See Box 185.2 for a complete listing of state regulatory agencies. Current websites have been included, because laws relating to herptiles are dynamic and the websites allow the interested reader to browse various pertinent web pages.

The Lacey Act (from the USFWS Website)

Passed in 1900, the Lacey Act prohibits import, export, transportation, sale, receipt, acquisition, or purchase of fish, wildlife, or plants that are taken, possessed, transported, or sold in violation of any federal, state, tribal, or foreign law. The 1981 amendments to the Act were designed to strengthen federal laws and improve federal assistance to states and foreign governments in enforcement of fish and wildlife laws. The Act has become a vital tool in efforts to control smuggling and trade in illegally taken fish and wildlife. Another aspect of the Lacey Act regulates the transportation of live wildlife, requiring that animals be transported into the United States under humane and healthful conditions. The Act also allows the interior secretary to designate those wildlife species considered injurious to humans and prohibit their importation into the country.

Individuals convicted of violating the Lacey Act may be fined up to $100,000 and sentenced up to 1 year in jail for misdemeanors and up to $250,000 and 5 years of imprisonment for felony violations. Fines for organizations in violation of the Act are up to $250,000 and $500,000 for misdemeanor and felony violations, respectively. In addition, vehicles, aircraft, and equipment used in the violation, as well as illegal fish, wildlife, and plants, may be subject to forfeiture. Persons who

CANADIAN FEDERAL REGULATIONS

Canada uses The Wild Animal and Plant Protection and Regulation of International and Interprovincial Trade Act (WAPPRIITA) for regulation and enforcement of its laws regarding both native and nonnative wildlife. The WAPPRIITA web address is http://www.ec.gc.ca/alef-ewe/default.asp?lang=en&n=65FDC5E7-1

Here is a summary of the WAPPRIITA from the website:
"The Act applies to the following animal and plant species:

- Species on the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) control list;
- Foreign species whose capture, possession, and export are prohibited or regulated by laws in their country of origin;
- Canadian species whose capture, possession, and transportation are regulated by provincial or territorial laws;
- Species whose introduction into Canadian ecosystems could endanger Canadian species.

The Act forbids the import, export, and interprovincial transportation of these species, unless the specimens are accompanied by the appropriate documents (licences, permits). In all cases, the Act applies to the plant or animal, alive or dead, as well as to its parts and any derived products."

MEXICAN FEDERAL REGULATIONS

The United Mexican States (Mexico) has a rich native herpetofauna with the most reptile species of any country on earth.[1] Over half of the 700-plus species of reptiles are endemic, and along with its nearly 300 species of amphibians, Mexico contains nearly 10% of the earth's herpetofauna diversity.[2] Mexico has been a CITES signatory since 1991 but faces many challenges enforcing illegal trade in wildlife, including herpetofauna. For a thorough review of wildlife conservation in Mexico see Valdez et al. (2006).[2] The National Office of Wildlife, a division of the Ministry of Environment and Natural Resources, oversees wildlife management in Mexico. A copy of the laws pertaining to native wildlife is entitled: "NOM-059-SEMARNAT-2010, Environmental protection – Native species of Mexico forest flora and fauna – Categories of risk and specifications for their inclusion, exclusion or change – List of species at risk." The following link provides information on purchasing a copy of these regulations: http://mexlaws.com/SEMARNAT/NOM-059-SEMARNAT-2010.htm.

CENTRAL AND SOUTH AMERICAN REGULATIONS

There are 27 Caribbean, Central, and South American countries that all have their own laws and regulations regarding wildlife. All of these nations are CITES signatories. For those interested in specific information regarding a particular country, the Latin American Network Information Center provides a starting point: http://www.lanic.utexas.edu/la/region/environment/ (accessed April 15, 2018).

CASE EXAMPLES

Case 1

Facts: A 27-year-old Windsor Ontario man traveled to the United States by car on 6 occasions in 2014 to retrieve illegally taken native US turtles. He used various methods to smuggle the turtles out of Detroit and into China, including taping tutles to his legs and groin, packing them in boots and cereral boxes, and stuffing them into suitcases. The species of turtles smuggled included the diamondback terrapin (*Malaclemys terrapin*) (see Fig. 185.1) and the spotted turtle (*Clemmys guttata*) (see Fig. 185.2), the latter being listed on the IUCN red list as endangered and the former as threatened. Sometimes the man smuggled the turtles himself and other times he employed a runner. On one occasion he was apprehended with 51 turtles on his person. Each count that the man pleaded guilty to carried a maximun $250,000 fine and 10 years in prison.
Laws violated: CITES, ESA, Lacey Act, and Michigan Wildlife Laws.
Outcome: The defendant was fined $3500 and sentenced to 2 years probation.

Case 2

Facts: In 2012, a 58-year-old Brunswick, Georgia, man was convicted of stealing 156 loggerhead sea turtle eggs (see Fig. 185.3) from nests on Salelo Island, Georgia. The eggs, with a black market value of $15 each, were packed to be sold.
Laws violated: ESA and Lacey Act.
Outcome: The defendant was sentenced to 6 months in jail and required to do 156 hours of community service, one for each egg.

Case 2a

Facts: In 2015, the same man as above (now 61) was convicted of stealing 84 loggerhead sea turtle eggs, again from nests on Salelo Island, Georgia. The eggs, now with a black market value of $25 each, were packed to be sold.
Laws Violated: ESA and Lacey Act.
Outcome: The defendant was sentenced to 21 months in jail, with a comment by the judge that the defendant's next stop would be federal prison.

Case 3

Facts: In 2013, a 28-year-old woman from New York was convicted of conspiring to smuggle 18,000 threatened and endangered reptiles from the United States into Canada.
Laws violated: CITES and ESA.
Outcome: The defendant was sentenced to 18 months in prison and 3 years of supervised release.

Case 4

Facts: In 2015, a 41-year-old man was charged with three counts of purchasing or threatening to purchase threatened turtles illegally captured from the wild. The case involved 100 North American wood turtles with a value of $40,000.
Laws violated: CITES, ESA, United States Postal Laws, and Illinois State Wildlife Laws.
Outcome: The perpetrator was sentenced to 41 months in jail, 3 years of supervised release, $100 special assessment, and was ordered to pay $41,000 restitution.

Case 5

Facts: In 2016, a California development company was convicted of securities fraud and violation of the Endangered Species Act. The company, as required by law, was supposed to mitigate for losses of wildlife and wildlife habitat. In this case it was for a 107-acre development in Contra Costa County. The developer attempted to defraud the city of Dublin with a forged receipt for $3.2 million.
Laws violated: CITES, ESA, and Lacey Act.
Outcome: In January 1999, the Florida businessman pleaded guilty to seven felony counts of conspiracy, smuggling, and violating the Lacey Act and CITES. In April 1999 he was sentenced to 30 months in prison. The conviction of the smuggler was made possible by Operation

VetBooks.ir

Chameleon, a sting operation run by the US Fish and Wildlife Service with cooperation from authorities in Florida, Virginia, Canada, Germany, Mexico, The Netherlands, South Africa, Belize, and Japan.

Case 6

Facts: In 2012 a 63-year-old Tyler, Texas, ecotourism guide smuggled 7 live snakes from Peru into the United States. He purchased the snakes at a market in Lima and smuggled them to Dallas–Fort Worth airport via Lima and Miami. The snakes were illegally obtained and smuggled on his person. He was refused boarding on a Tyler Texas shuttle flight and after taking ground transportation was arrested at his home by Texas game wardens. The perpetrator knew what he did was illegal and was subject to 5 years in federal prison.
Laws violated: Peruvian wildlife laws and Lacey Act.
Outcome: The defendant was sentenced to 3 years probation by a US district judge.

Case 7

Facts: In 2013, eight people were arrested in Puerto Rico for the illegal take, possession, and sale of sea turtle parts intended for human consumption. DNA analysis by the Fish and Wildlife Service Forensic Laboratory identified 15 hawksbill (*Eretmochelys imbricata*) (see Fig. 185.4) and 7 green turtles (*Chelonia mydas*). Enforcement officers from the Puerto Rico Environmental Crimes Task Force, the Puerto Rico Police Department, the Puerto Rico Department of Natural Resources, and the US Marshals Service were all involved in the arrests.
Laws violated: CITES, Lacey Act, and ESA.
Outcome: The defendants faced a maximum 5 years in prison and a $250,000 fine if found guilty.

Forensics

John E. Cooper, Melinda Merck, and Margaret E. Cooper

This chapter is primarily directed at veterinarians who work with reptiles and amphibians (here referred to as "herpetologic veterinarians") but may also be of use to nonveterinarians, such as field biologists, herpetologists, zoological staff, experienced hobbyists, and lawyers who are asked to advise in this field. Forensic veterinary medicine can be defined as the application of veterinary knowledge to the purpose of the law. Although the use of veterinary forensic medicine is most commonly associated with providing evidence (to the prosecution or to the defense) in court cases relating to the maltreatment of animals or the protection of endangered species, it can also be applied to such matters as environmental impact studies, insurance claims, and allegations of professional misconduct.

Forensic work that involves reptiles and amphibians most often arises from prosecutions for ill-treatment or the smuggling of endangered species. Nevertheless, there are other circumstances in which expert veterinary evidence is required such as theft, keeping reptiles without, or in breach of, an appropriate permit or illegal taking from the wild or unlicensed trade. Public health prosecutions may arise from keeping reptiles and amphibians or from unauthorized importation as bushmeat. Reptiles may be implicated in human abuse situations, for example, the identification of wounds or the cause of injury or death. Civil law claims for compensation for death, personal injury, or damage to property involving reptiles may require an expert veterinary opinion, and likewise in the case of breach of contract, sale of goods, veterinary malpractice, and the verification of insurance claims.

Traditional uses of reptiles or amphibians present particular legal and ethical challenges and at times may lead to investigations and prosecutions under welfare or conservation legislation[1,2] (also see later discussion).

Cooper and Cooper discuss situations in which forensic investigations and evidence are relevant, and Baker provides a brief overview of forensic herpetology.[3–5] Reptiles and amphibians can be the subject of evidence submitted to planning inquiries where their presence on land proposed for development is significant and in cases where human health (especially zoonoses) or environmental pollution is an issue.

A reptile or amphibian may be involved in a potential legal case either as the *victim* or as the causative element (as the *perpetrator* itself or through the *agency* of a person). Investigations are most likely to address questions relating to species identification and origin, cause of death, injury or ill health, and determination of the cause and effects of diseases and wounds sustained by reptiles and amphibians as well as caused by them.

LEGAL CONSIDERATIONS

Some herpetologists and herpetologic veterinarians are aware of legislation that affects their professional activities concerning reptiles and amphibians. It is important that an investigator (expert) understand the particular legal basis of the case for which he/she is to provide evidence. They should also be aware of additional implications for the investigator, such as the welfare of a live animal being examined or the need for authorization to possess animals (particularly endangered species) or their derivatives (including diagnostic specimens) and to transport, store, or dispose of them.

General Legal Principles

Kinds of Law. It is important that the forensic expert is aware of some basic aspects of law such as:

a. Criminal law: Legislation that creates offenses. These are enforced by the state and punished primarily by fines and imprisonment;
b. Civil law: Cases between individuals or legal entities for which the remedies are financial compensation and injunctions;
c. Substantive law: The law upon which a case is based;
d. Procedural law: The rules that dictate how a court or other tribunal deals with a case.

Judicial Systems. In most countries there are separate court systems for different kinds of litigation, particularly civil and criminal. There are a variety of other tribunals for matters such as planning (zoning) and professional discipline. Each system has its own procedural rules, which may include specific instructions for expert witnesses.

The actual procedure regarding evidence varies from country to country. Most "common law" countries (i.e., those that have derived their judicial systems from England [British Commonwealth countries and the United States]) hold adversarial hearings in which either side presents its arguments and its expert evidence to a judge (or equivalent). However, "Roman law" countries (most continental European countries) practice a more inquisitional procedure whereby the presiding lawyer conducts the hearing, which may include expert evidence.

Relevant Law

Legislation is found at international, regional, national/federal, state/provincial, and local levels. For the most part the law that is used to enforce legislation is the national, state, or local laws (see Chapters 183 through 185).

In countries with a federal structure, most of the laws relating to reptiles and amphibians are made at state/provincial level. Consequently there is little uniformity at this level in the provisions, the enforcement powers, and their effectiveness. This is also true of the variability between the laws of different countries. It is therefore necessary to check carefully whether reptiles are included in the definition of "animal" in any piece of legislation. Likewise each law should be examined in detail to determine to what extent it applies to the species and issues in question. An experienced expert can guide a lawyer who is new to the law on animals.

VetBooks.ir

Law relating to reptiles and amphibians is covered in some detail in Chapters 183, 184, and 185, which deal primarily with international, European, and American law, along with some examples of the welfare and conservation laws of other countries. For a more detailed discussion of the various topics with particular reference to forensic evidence, see Cooper.[6–8]

Comments on Aspects Particularly Relevant to Forensics

Conservation. The law generally provides protection for specified species that are at risk, usually in terms of prohibiting or regulating taking, killing, or injuring. Hunting and other harmful sports, trapping, or poisoning are often also controlled. Trade may be prohibited or regulated. All these offenses may require forensic evidence (for example, as to identification, harm caused, time of death, behavior, or ecology) when prosecuted or defended. Reptiles and amphibians dangerous to humans may not be protected in some counties (or even may be classified as vermin), or there may be an exception for self-defense.

Trade. Trade, both legal and illegal, in reptiles and amphibians is widespread. Some species (such as crocodilians) are valuable commercially for their skins or other derivatives or for traditional medicines; other taxa are popular for pets, exhibition, or breeding. Frequent reports of illegal trade are published by TRAFFIC (the wildlife trade monitoring network) and other organizations or governments. Forensic evidence on the identification and origin of confiscated species is required to support prosecutions (and the defense). Animal welfare offenses (including transportation) are often involved as well.

International Trade or Movement. Cross-frontier trade in reptiles and amphibians is common and frequently illegal[9,10]. The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) is a global treaty that regulates the movement of listed species, including many species of reptiles and amphibians (see the Chapters 183 through 185). Most federal countries regulate CITES through national laws, and the EU has regulations that directly apply in all member countries.

Animal Health. Reptiles and amphibians may require a health certification or veterinary check in some countries, and tissue and other diagnostic research or forensic samples might require a permit if they are thought to be pathogenic. Any samples that are being sent for forensic examination or other processes must be packed in accordance with national and international standards as appropriate.

Customs. Customs services may require the services of a forensic expert to verify the identity of imported species against the accompanying documentation. Deliberate misidentification of rare species is common. Dangerous reptiles are also used to disguise consignments of drugs. There are often welfare offenses in illegal consignments, and a veterinary expert may be asked to provide evidence.

Animal Welfare. The need to protect the welfare of captive reptiles and amphibians has long been recognized in Europe. In the UK the classes Reptilia and Amphibia received a level of protection 140 years ago, when they were included in the list of species subject to licensing if they were used for painful experiments in scientific research (Cruelty to Animals Act, 1876). Such protection for them under laboratory and field conditions continues under the UK's Animals (Scientific Procedures) Act 1986 and throughout much of the rest of Europe as a result of (for example) The European Convention for Experimental and Other Scientific Purposes (ETS). Such federal protections are currently lacking in the United States, as reptiles and amphibians remain excluded from the Animal Welfare Act (1966).

The previous comments regarding the variability of legislation are particularly applicable to animal welfare laws. Many animal welfare laws apply to nondomesticated species that are held in captivity, but this and the specific definition of "animal" must be ascertained for each law. Welfare issues for which forensic evidence is required usually relates to designated forms of cruelty or the broader offense of "unnecessary suffering" such as pain, stress, neglect, or starvation. The modern New Zealand, United Kingdom, and some Australian state laws also impose a duty of care on the keeper of an animal to provide for its essential needs.[11,12,14] These principles are based on the widely used "five freedoms" (see http://webarchive.nationalarchives.gov.uk/20121007104210/http:/www.fawc.org.uk/freedoms.htm). These principles can be used as a benchmark in the assessment of the welfare to support expert evidence.

Animal welfare legislation includes the transport of animals that may apply to reptiles and amphibians. The IATA Regulations and the CITES Guideline for Transport are applicable to reptiles.

Reptiles and amphibians may be used in cultural or traditional activities, which may not meet their welfare needs; if the law does not provide adequate protection, education or public awareness may be considered as an alternative.[2] Information on the assessment of welfare of reptiles in captivity is to be found in Warwick et al.[13] Expert herpetologists and/or veterinarians may be able to provide evidence on needs and optimal environmental requirements of a particular species.[15]

Animals in Captivity. Many countries regulate the keeping of reptiles in captivity. Local authorities may license the keeping of reptiles as private pets or restrict the keeping of dangerous species.

Reptile and Amphibian Collections. The law on keeping reptiles and amphibians in captivity are covered in Chapters 183 through 185 and the literature referred to earlier. Situations that may be regulated include keeping animals as pets, as a hobby, for display or entertainment, and for research. Reptiles and amphibians may also be "hoarded," sometimes as part of a well-meaning but poorly executed rescue program. The standards set by law via zoo associations, both national and international, may provide useful criteria for forensic assessments on welfare and management.

Research. Animal research is regulated in many countries and also extends to work in the field where guidelines apply to work funded by the National Institutes of Health.[16] In the UK, new guidance has been issued regarding wildlife research.[17] Again, this may provide a useful benchmark.

Veterinary Treatment. Increasingly there are veterinarians available who specialize in the treatment of reptiles and amphibians and are able to provide expert evidence in the situations discussed earlier that require forensic evidence. Veterinary law restricts the practice of veterinary medicine to duly qualified persons. The British veterinary law expressly includes the treatment of reptiles as reserved to veterinary surgeons (veterinarians), but it is silent on amphibians. Other countries' veterinary laws may or may not be clear whether treatment of such species is restricted to veterinarians, and in many cases wildlife rescue and rehabilitation is often carried out by nonveterinarians. In the United Kingdom anyone may do this (within the bounds of welfare and other laws), but in some countries rehabilitators must be qualified and authorized.

The law on veterinary medicinal products is discussed in Chapters 183 through 185. Expert evidence might be required in cases where drugs for reptiles or amphibians were wrongly prescribed or illegal products were used.

VetBooks.ir

Health and Safety. In countries where occupational health and safety laws are strict, special risk assessments (regarding handling, envenomation) and precautions may be necessary to protect employees and visitors (for example at zoos or petshops) from the hazards posed by some reptile and amphibian species.[18] Expert evidence may be required regarding the animal's health, welfare, biology, behavior, or management in the event of an accident.

Theft. Some reptiles and amphibians are extremely valuable and at risk of being stolen from private or public premises. Expert evidence may be sought regarding identification and origin of species of stolen animals as well as assessment of the time of theft, death or injury, welfare, or other circumstances.

PROVIDING EXPERT EVIDENCE

Experts on reptiles and amphibians may be needed at various stages of a legal process; in particular, when the investigation of a suspected offense requires herpetologic experts on identification or veterinary care (for example, the examination of the premises where reptiles or amphibians are alleged to be illegally kept). Additionally, experts on identification, handling, behavior, and veterinary care of involved species may be required to manage evidence at the crime scene[19] and to provide reports and oral evidence in the event of a prosecution.

Witnesses

A person may be called as a witness in a court case as either:

a. A witness of fact;
b. A professional witness who gives factual evidence but may also be asked to express an opinion;
c. A person with special expertise, who examines evidence, provides a report, and gives evidence in court that can include an opinion.

Quality of Expert Evidence

In Britain, the judiciary has set high standards for experts and their evidence as to quality, integrity, impartiality, and their duty to the court. In the United States, the "Daubert criteria" must be met before an expert is allowed to give evidence in federal courts and those of many states.[20] These provisions are incorporated in the procedural rules of the courts. Many experts now study, attend training or practical courses, and join schemes that verify their standards.[20–22] For more detailed accounts of forensic work relating to reptiles and amphibians and the provision of expert evidence, see Cooper.[7,20,23]

CONSIDERATIONS IN FORENSIC INVESTIGATION

Although many aspects of forensic work with reptiles and amphibians are very comparable to those that apply to work with domesticated animals, there are certain important differences. Some of these relate to the extent to which reptiles and amphibians are subject to legislation, especially in respect of their welfare and ability to "suffer"; the differences in this respect between (for example) the United Kingdom (UK) and the United States (US) are outlined previously.

Another important difference relates to differences in anatomy and physiology. These can be significant in forensic studies, even within groups of mammals and birds[3,24,62] but are particularly important in reptiles and amphibians, not least because all such species are ectothermic. This will influence such parameters as speed of wound healing and response to insults ranging from pathogens to poisons. This may have to be carefully explained to a judge or jury and outlined in written reports.

In addition there are anatomic variations that may be relevant to forensic examination (both clinical and postmortem) and the interpretation of the significance of wounds and other lesions. The herpetologic veterinarian will be aware of these variables but others, including clinicians, pathologists, and laboratory-based personnel who are more familiar with domesticated mammals, may need to be reminded of the basic features outlined in Section 2.

Clinical Investigation

A useful compendium of clinical techniques used in herpetologic forensic work was provided by Mitchell and Hernandez-Divers,[25] who emphasized the range and complexity of methods now available. In all investigations—clinical, postmortem, laboratory—as full a history as possible is desirable. Often in forensic work a comprehensive history is not available because the animal (when found or seized) has clinical signs or is dead, and there may (or may not) be an owner or keeper who can provide background information.

Even if history is supplied, it may not be correct and can even be fabricated, so the clinician has to perform an examination on an animal without knowing the true background. The information offered is the initial context for the examination and analysis of findings but may change as the investigation unfolds.

Certain key details should be recorded when the veterinarian is first contacted regarding a case, by telephone, by text/email, or when the animal is first presented. See Box 186.1, an intake form that is adapted from a document designed for suspected cruelty cases but can be modified to suit other forensic investigations, such as those relating to possible breaches of conservation legislation.

The intake form initiates documentation of the case and continues throughout the case (see Documentation of Examination Procedures). The notes made on the form should be factual; they will be used to produce a forensic report. The veterinarian may need to rely upon them if called to testify, and the notes may eventually be requested by lawyers or the court. The date, time, agency (where appropriate—in Europe there may not be an agency involved), case number, name, and contact information of the person who first contacted the veterinarian should be recorded.

As emphasized elsewhere,[28] information should be obtained regarding the type of reptile or amphibian to be examined, how it is being transported, general details of the alleged crime, what is expected of the veterinarian, and a likely time frame to produce findings. The veterinarian should request from the investigator such documents as incident reports, witness statements, photographs, and videos. The number, condition, and quality of these documents should be noted, and each item recorded in the evidence log (see Box 186.2).[29]

The documentation of information is discussed later, as it applies not only to live reptiles and amphibians but also to dead animals and samples. For the same reason, evidence collection and packaging are covered later.

Regardless of species, the animal should initially undergo a full basic clinical examination, similar to that performed during a (diagnostic) veterinary investigation. This means that the animal is examined systematically, even though there may be an obvious presenting wound or lesion of probable importance (Fig. 186.1). Equipment should be available before the examination begins, and the choice may be influenced by the history or allegation.

Use of a clinical record sheet is essential and, like the necropsy sheet (see later), is often best compiled specially for the forensic case rather than relying upon a standard clinical form, which may or may not permit answers to be given to specific questions of forensic importance.

Descriptions for forensic purposes need to be as accurate as possible (they may be checked by someone else). Measurements are important and some "scoring" system is recommended when there is a need to quantify. Color codes are useful and can also be used to help describe

feces, urine, and so on. Objectivity is enhanced if reference can be made to colors on a chart (such as those used by purveyors of paint). The consistency of, say, feces can be difficult to describe, and it can be helpful to use a grading system (usually 1–5, liquid–solid) advocated by some of the nutritional companies.

If accurate weights and measurements are to be taken, appropriate equipment will be required.

For reptiles, snout-vent length (SVL) and vent-tail length (VTL) are required. A whole-body length is to be discouraged because of the possibility of tail damage (see previous). Care must be taken when straightening the animal (putting the animal into a plastic tube will help).

For tail-less species of amphibians (frogs and toads), SVL is required. For tailed amphibians (newts, salamanders, and tadpoles), SVL and VTL are recommended.

A rule with stop is advisable. Take care as discussed previously.

Defining and assessing "condition" is never easy. The definition and determination of "condition" in nondomesticated species can be difficult.

VetBooks.ir

FIG 186.1 Clinical examination should include careful handling. Poor muscle tone may be an indicator of malnutrition or a toxicosis.

"Condition" is an ambiguous term, because it is commonly used both as an indicator of an animal as a whole and also parts of the body (e.g., "condition of the plumage"). Land tortoises and other chelonians present particular problems in terms of assessing "condition" because of the presence of a protective, often hard, carapace and plastron. There are various methods applicable to different taxa of reptiles and amphibians (see, for example, Hailey[31] on Mediterranean tortoises).

Examination of the forensic case brings with it some extra considerations that may not be part of normal clinical investigation. Record-keeping should be meticulous, and contemporaneous notes are essential (hard copies and/or computerized). Investigations or tests may be carried out that would not form part of a normal standard clinical examination; samples should therefore always be taken (see later). With the exception of special issues of *Applied Herpetology* and the *Journal of Herpetology* mentioned in the references, there are relatively few published texts dealing specifically with the forensic clinical examination of reptiles and amphibians. Standard texts on herpetologic diseases are of relevance, and the "expert" appearing in court should not overlook the fact that some excellent texts are published in languages other than English (see, for example, reference 32).

Any veterinary practitioner may be requested to carry out an initial clinical examination of an animal, including a reptile or amphibian, which might be the subject of a legal case. Under such circumstances the veterinarian, who may well not have any specialist postgraduate training, must do his or her best. Some general rules are as follows:

1. Carry out as full and methodical an examination as possible in the time available and with the equipment that is available.
2. Pay particular attention to any organ systems or parts of the body, which may be particularly relevant to the case.
3. Depending on species, certain structures may be particularly relevant to a forensic case (see earlier). Thus for example, when examining a neotenous amphibian, the gills will need careful inspection.
4. If time, facilities, or the veterinarian's lack of experience of the species in question limits a full examination, this should be stated in the report. It is preferable at an early stage to admit that certain examinations were not carried out (or feasible) rather than for this to come to light during cross-examination in a court case or similar hearing.
5. As in all aspects of forensic examinations, detailed contemporaneous notes should be taken together with, as appropriate, tape recordings (audio and/or video) and photographs.

As stressed earlier, reptiles and amphibians are ectothermic, and therefore all metabolic processes are temperature-dependent; see, for example, the earlier work by Smith et al[33] (1988) on the effect of ambient temperature on healing cutaneous wounds in garter snakes. The clinical investigation of an animal cruelty case was extensively covered by Merck et al.,[34] Munro and Munro,[35] and Tiplady,[36] but these authors concentrated on (mainly domesticated) mammals.

Clinical examination alone is usually only one part of forensic investigation. It can be linked with:

- Hematology
- Clinical chemistry
- Parasitology
- Microbiology
- Histology
- Cytology
- Electronmicroscopy
- Radiology and ultrasonography
- Other advanced imaging (e.g. magnetic resonance imaging [MRI], computed tomography [CT] scan)

It is most important that all observations made during a clinical examination are noted and that they, together with verbal comments made by those present during the work, are added to any letter or certificate. Precision is vital.

Veterinarians are increasingly playing an important role in cases involving animal abuse and domestic violence. This followed in the wake of awareness of "battered-pet syndrome,"[37] similar in a number of respects to "battered-child syndrome" and defined by physical abuse characterized by injuries that are nonaccidental—in other words, they have been inflicted intentionally. Suspicion of "nonaccidental injury" (NAI) is often supported by a number of factors, including unusual distribution or appearance of wounds, untreated lesions, an inconsistent history, and suspicious behavior on the part of the owner. Although most of the focus of debate about NAI has been on dogs and cats, they are not the only species that may be abused. Examples of abuse of captive and free-living reptiles and amphibians include:

- *All species:* Physical assaults (e.g., beating with sticks, gouging of eyes), use of fire, (including fireworks), intentional starving, deprivation of water, neglect.
- *Reptiles:* Disemboweling, cutting/pulling off the tail. Predators, for example, crows, may also cause disemboweling. Some lizards shed their tail as a natural defense process (autotomy).
- *Amphibians:* Disemboweling, removal of/damage to limbs by cutting or treading on them, placing toads in a fire to see them "explode."

Reptiles and amphibians that are alleged to have been starved may be examined/seen alive, necessitating clinical examination, or presented dead, necessitating postmortem examination. In view of the particular importance of the subject in respect of animal welfare, starvation is considered here, as a clinical matter, rather than under postmortem examination. It is important to bear in mind that apparent starvation can be due to a variety of causes, not just omitting food. In captive reptiles and amphibians, it can be the result of one or more of the following):

- Failure of the keeper to provide any food or to provide sufficient food in terms of quantity and quality (see later)
- Failure of the animal to accept food, in part or in whole, despite food being offered; failure of the animal to masticate and swallow food, even though food has been offered and, perhaps, taken initially
- Food not remaining within the stomach (on account of regurgitation or vomiting); food not being adequately digested and absorbed in the intestinal tract (because of malabsorption, increased gut transit time, internal parasites, etc)

VetBooks.ir

FIG 186.2 (A) Investigation of deaths of hatchlings of leatherback turtles (*Dermochelys coriacea*) in Trinidad and Tobago necessitated immediate action before the bodies began to decompose. This meant recruiting students to help and performing "forensic" examinations in situ, with minimal back-up facilities. (B) A vital initial step in such an investigation is to use a hand lens to examine eyes, skin, and orifices before they dry in the tropical heat.

- Food that has been ingested, digested, and absorbed not being utilized because of metabolic or other disorders

The veterinarian should also remember that reptiles and amphibians, especially the larger species, or those that are maintained at low temperatures, can often go long periods (weeks or months) without feeding, even in the wild.

POSTMORTEM INVESTIGATION

Postmortem examination (necropsy) of reptiles and amphibians plays an important part in certain forensic investigations, especially where there is a need for information about the circumstances of death or whether an animal was in poor health, suffered, or was abused during life (Figs, 186.2 and 186.3). Postmortem examination is an important part of herpetologic forensic work but presents many challenges, not least because of the gaps in our knowledge insofar as interpretation of pathological changes is concerned.[39] This applies also to domesticated mammals.[38] Ideally forensic necropsies should be performed by experienced pathologists, but this is not always possible and the veterinary practitioner must be familiar with proper necropsy procedures.

Necropsies need to follow standard protocols and use appropriate equipment (Fig. 186.4). As emphasized earlier, reptiles and amphibians vary in shape, size, and structure, with great differences exhibited by the diverse species, and thus the person performing the necropsy must have some knowledge of the normal features of these ectothermic species and be familiar with the principles of comparative anatomy (Figs. 186.5, 186.6, and 186.7). Sometimes in legal cases only a portion of a carcass is available, or it consists only of bones plus or minus portions of soft tissues that may have become desiccated and "mummified." Such material requires particularly careful handling and the use of special techniques such as slow rehydration to allow proper examination. Other submissions may essentially be a "soup" of autolyzed material, requiring filtering and sequential drying. No material submitted for necropsy should be considered "unsuitable for examination"; at the very least, it can be radiographed to examine for skeletal trauma, bullets, or implants. On occasion the necropsy will entail careful examination of prey items such as rodents or invertebrates.

Supporting laboratory tests may be required, and it is important that material is maintained, both for production in court and as part of a forensic research and teaching collection. Often a dead reptile or amphibian needs to be investigated, with a view to determining the circumstances—cause, mechanism, and manner—of death. A convenient way of doing so is by trying to answer the following questions about the animal:

- How did it die?
- Why did it die?
- When did it die?
- Where did it die?
- Who might have been involved?

FIG 186.3 "Stranded" sea turtles, such as this green turtle (*Chelonia mydas*) in Kenya, should always be considered potential legal cases. Attention to them must bear this in mind and be performed in a forensic manner.

Forensic postmortem examination of wildlife was discussed by Wobeser,[42] and the subject was subsequently reviewed by Cooper and Cooper.[3] There are useful published methods for necropsy (see, for example, Hanley and Hernandez-Divers[43] for reptiles and Pessier[44] for amphibians). Cooper described postmortem techniques for herpetological forensic work,[23] but the diversity in morphology exhibited by diverse species means that the prosecutor must always be innovative

VetBooks.ir

FIG 186.4 A monitor lizard (*Varanus* sp.) is examined postmortem in a simple laboratory in East Africa. One person remains "clean" and serves as scribe.

FIG 186.5 Postmortem examination of this spectacled caiman (*Caiman crocodilus*), which died under suspicious circumstances, revealed no significant internal changes, but a small lesion was detected on the side of the head. Probing indicated a deep stab wound and led to investigation of husbandry methods and interrogation of the keeper.

and adaptable. Radiography or other imaging should be carried out whenever possible before postmortem examination.

The forensic necropsy of embryos, eggs, fetuses, and neonates needs special care because of their size (dissection may need to be carried out using microinstruments, such as ophthalmological scissors and forceps, and employing a loupe or magnifying [hand] lens) and some of their unusual features (e.g., osteoderms, gills).

A suggested format for a necropsy examination is provided in Box 186.3. Sometimes different headings and information may be

FIG 186.6 Assessment of condition of a reptile at necropsy should include detection, palpation, weighing, and histologic examination of internal fat bodies.

FIG 186.7 A red-tailed boa (*Boa constrictor*) is carefully examined externally. The animal died unexpectedly in a zoo and foul play was suspected. Students attend and learn at first hand routine forensic techniques.

needed—and can easily be added to the form—for example, when embryos, tadpoles, or eggs (including spawn) are being examined. In herpetologic forensic investigations examination may take place in a purpose-built postmortem room or, especially in "wildlife crime" cases, require the construction of field necropsy area in the bush or by the side of a river. Field necropsies are discussed in Cooper.[9]

The health and safety (H&S) of those performing the necropsy, or likely to be exposed to it or the samples it yields, is of great importance. In many countries this is a legal requirement (see Chapters 184 and 185). All necropsies carry certain standard risks, but reptiles and amphibians may present some extra dangers—for example, venom from snakes/lizards and skin toxins from amphibians. Hazards presented by reptiles and amphibians during necropsy can be broadly divided into (a) infectious, for example, bacteria that may be acquired from the tissues of the dead animal and (b) noninfectious, such as injuries sustained while attempting to cut through the dorsal bony plates (osteoderms) of crocodiles or the bridge between the plastron and carapace in chelonians.

The interpretation of necropsy findings in reptiles and amphibians requires some knowledge of the normal morphology of reptiles and amphibians, for example, the normal presence of two hemipenes in snakes and lizards and the normal black appearance of the liver

VetBooks.ir

in some amphibians and reptiles due to the presence of melanin (easily confused by inexperienced pathologists during postmortem autolysis).

Some changes in organs and tissues can be of particular significance in forensic cases (e.g., traumatic lesions and degenerative changes suggestive of toxicosis). Others, such as bile-staining and pseudomelanosis, are regularly seen features of postmortem autolysis and can be useful in assessing when a reptile or amphibian died or the sort of environment to which it was exposed after death. Skin wounds, contusion, and scarring may provide information about pathologic processes in the animal antemortem. As stressed earlier, reptiles and amphibians are ectothermic, and therefore all such processes are temperature dependent.[33] After the main necropsy and collection of samples, the skeleton of the animal may need to be prepared and examined for further forensic study.

Forensic entomology is important in animal forensic investigations,[3,39] mainly in helping to ascertain how long an animal has been dead. Insects are the prime indicators, as they are in human work, but millipedes, spiders, ticks, and mites can be significant. Any invertebrate found on, in, or in association with a dead reptile or amphibian should be collected and identified and (where appropriate) its stage of development recorded (e.g., a nymphal tick or first-instar maggot). Techniques for sampling invertebrates are to be found in standard texts and described in detail by Barnes[45] and Anderson.[46]

Comparable specialized techniques may also be needed when examining other samples found in association with a dead reptile or amphibian. These include the collection for investigation of (a) plant material, including pollen and seeds (forensic palynology) and (b) mineral deposits, such as dust. Sampling for toxicologic analysis can be challenging; Rotstein provides useful guidance.[48]

Determining when an animal died is often very relevant in forensic work but can be far from easy,[3] especially when dealing with reptiles and amphibians, where published data on postmortem interval (PMI, or time since death estimations) are still scant. Some limited information exists, notably by Frye, who described changes that occur after deaths in reptiles and amphibians (Frye, Proc Association of Reptilian and Amphibian Veterinarians, 1999, pp 23–25), and the paper by Cooper, outlining current knowledge and needs as far as the estimation of PMI in these species.[50]

Reptiles and amphibians present a range of challenges in terms of accurately assessing changes due to autolysis and decomposition, owing to their high variability in morphology and lifestyle; in particular, effects due to ectothermy, the different anatomical features of these two groups of vertebrates, the marked variation in body size of diverse taxa of reptiles and amphibians, and seasonal fluctuations in subcutaneous and internal fat content. Eggs, embryos, fetuses, and larval stages in amphibians present particular challenges.

The postmortem examination of reptiles and amphibians can provide useful information in support of a claim that an animal has been ill-treated but, often this evidence has to be linked with other data on (for example) how the animals have been housed, fed, and handled.

LABORATORY INVESTIGATIONS

Laboratory investigations are an important part of many forensic cases and are applicable to cases involving live or dead reptiles and amphibians. Some of the techniques used are almost entirely laboratory-based—for example, histopathology, toxicology, and DNA technology—but in herpetological work, the investigators are likely to be using a combination of such tests and the evaluation, often in the field, of a live or dead animal or its derivatives. "Derivatives" in a herpetological context include samples that are not a feature of standard mammalian forensic work, such as urates, frog spawn, and shed (sloughed) skins (Fig. 186.8). Gross and microscopic examination of these materials, including a range of laboratory tests, can be useful and is noninvasive.[51] Techniques of particular value in herpetologic forensics include investigation for ectoparasites, chemical analysis of sloughs for pesticides,[52] and both morphologic and genetic studies for identification purposes.[53]

Molecular techniques have become a feature of forensic investigations concerning reptiles and amphibians in recent years.[54] Various tissues can be sampled, in both live and dead animals. Fetzner[56] described a simplified method for the extraction of high-quality DNA from shed reptile skins. Care must be taken during postmortem examinations not to spread or mix DNA from different sources (see also later discussion).

The two key factors in laboratory forensic work are (a) chain of custody and (b) quality control. The answer to all procedures is to develop and use protocols, whereby the method to be used is clearly defined and followed and will be adhered to in the same way thereafter. Techniques that may be used for samples from live or dead animals or, in some cases, from their environment, were discussed by Cooper and Cooper.[3,39] While many standard procedures are applicable to reptiles and amphibians, some may need modification; for example, microbiological culture may need to be incubated at 24°C.[55] Frye described methods for sampling and standard laboratory techniques in herpetologic forensic work.[56] It is important to use an appropriately accredited laboratory (veterinary/medical/forensic) whenever possible, as results may be challenged. This is sometimes not feasible, however, especially when dealing with wildlife overseas.

Correct sampling will yield reliable results and in turn facilitate accurate interpretation followed by appropriate action. In "forensic" cases such precision is all-important. Mistakes can occur at various stages of sampling (selection, collecting, packing, transportation, reception, processing). An error, inconsistency, or delay at any point can have adverse effects subsequently and thereby prejudice results.

Laboratory techniques cannot be discussed in detail here. Many, but not all, are similar to those used in mammals and birds. The small size of many reptiles and amphibians means that some specimens, such as tiny geckos and tree frogs, may be best embedded, serially or step-sectioned, and then processed for histologic examination.

FIG 186.8 The shed skin of reptiles—and to a certain extent of amphibians—can be an important source of information in forensic cases. Such material must be handled with gloves and stored correctly.

VetBooks.ir

CRIME SCENES, FIELDWORK, AND IN SITU COLLECTION OF EVIDENCE

Crime scene investigation in animal forensic cases has been discussed in various veterinary texts, most relating to domesticated species. The particular features of the wildlife crime scene investigation, which is often the norm insofar as reptiles and amphibians are concerned, were detailed by Cooper et al.[57] and by Byrd and Sutton.[58] In such circumstances the "crime scene" may range from just the carcass of an animal—or its parts—to terrain that encompasses topography as varied as coastline, forest, or desert. Often, the location of the wildlife crime scene is isolated, with few facilities for proper investigation and collection of evidence.[59] In poorer parts of the world and in countries that are experiencing social unrest, crime scene investigation may present particular challenges. Equipment, investigative techniques, and scientific technology all need to be appropriate to, and the best available in, the circumstances. Effective investigation under field conditions is likely to require a combination of portable and easy-to-use laboratory equipment, coupled with modern methods of data collection and information transmission.[9]

A whole spectrum of evaluation and interpretation may be needed in wildlife crime scene investigation, and often the veterinarian is working as part of a team. His/her responsibilities may include clinical or postmortem examination of reptiles and amphibians, searching for samples of poisons, correct sampling for toxicologic analysis, and investigation of vegetation, soil, or water. Knowledge of natural history is helpful in wildlife forensic work, as the animals involved may range from terrestrial or arboreal lizards to stranded marine turtles. An interdisciplinary approach is essential. Biologists/naturalists and those experienced in health studies, especially epidemiology, can often usefully complement the role of the police, enforcement officials, and crime scene specialists.[62] Such visits may take the forensic veterinarian to locations as diverse as petshops, zoos, homes of hobbyists, and airports, as well as habitats referred to previously.

RECORD-KEEPING AND COLLATION AND ANALYSIS OF FINDINGS

The forensic examination is a process that requires appropriate, accurate, and full documentation. As stressed by Merck and Mader, everything associated with the case is subject to legal scrutiny that includes all notes, correspondence, photographs, radiographs, examination findings, reports, and the handling of evidence.[28] These are all considered evidence and will be reviewed by the investigator, prosecutor, defense attorney, barrister, and judge. The use of forms is extremely useful in forensic cases to ensure procedures are followed completely and to meet the legal standard for evidence; these include chain of custody/evidence log, photo log, and live and necropsy examination.[28]

CHAIN OF CUSTODY

All evidence must be subjected to a chain of custody (COC). COC refers to a process of documentation in which the evidence is accounted for at all times, and there is a record of any alteration or deviation (for example, when testing is performed) (Appendix 3, Evidence Log/Chain of Custody). Evidence is anything collected or recorded from the animal and includes samples, photographs, radiographs, and the animal itself (Fig. 186.9).

All evidence must be properly collected, packaged, and labeled, and each item must be recorded in the evidence log. Evidence should be kept in a locked cabinet with restricted access. If the evidence is transferred to another person, location, or laboratory, this must be recorded in the evidence log with the time, date, and a signature from the sender and/or recipient.

FIG 186.9 In possible legal cases involving necropsy, the packaging material and wrappings must be retained as they may provide forensic evidence and might need to be produced in court.

Whenever evidence needs to be transferred elsewhere, including the transportation of laboratory samples, COC must again be followed. An evidence receipt form should be sent along with the evidence, containing instructions for the receiving agency/person to complete the COC section and return a copy. It should be recorded on any test request form whether the samples are "evidence," "forensic samples," or involve a "criminal investigation." This information may assist the recipient laboratory to implement appropriate handling protocols and to assign the appropriate person(s) to the analyses.[28]

If evidence is removed from storage, it should be documented in the evidence log, including a note of the purpose, if opened, and of any testing or alteration. Evidence must be held until the court case is over. Because additional legal avenues may be pursued after a case is closed, the prosecuting or other appropriate authority should be consulted before disposing of any evidence.[3,28]

PHOTOGRAPHY AND VIDEOGRAPHY

It is desirable that photographic records, together when appropriate with video documentation, should be kept of all forensic examinations on live or dead animals. This may not always be practicable when investigating free-living reptiles and amphibians under field conditions. The type of camera used is important, and some of the particular precautions that must be taken when photographing cases that are the subject of a legal investigation were described by Merck and Mader.[28] To these can be added the challenges of photography in the field, in cases of wildlife crime. Photographing and examining dead animals and other sensitive material at the crime scene is then best carried out without the attention of on-lookers or the press. Privacy screens may be purchased as such or constructed using canvas or sacking and aluminum poles or strong canes. Camera accessories, including tripods, facilitate the photographing of material that is illuminated with blue

light. The use of reflective ultraviolet photography in forensic work is often now standard.

Video documentation is often valuable when examining live reptiles and amphibians, especially when an animal shows difficulty in performing certain functions, such as a snake with neurological or ambulatory signs. In mammals it also helps demonstrate certain types of behavior, such as vocalizing because of pain; these are not usually a feature of herpetological cases, but snakes may hiss or strike or feign death and amphibians secrete excess mucus. Some reptiles and amphibians change color in response to aversive stimuli. If starvation or dehydration is suspected, it is useful to video the animal's response when it is first offered food and water. The same evidence procedures as for photography should be used.[28]

DOCUMENTATION OF EXAMINATION PROCEDURES

When an animal is examined in a forensic case, live or dead, the veterinarian is working on behalf of the court, and there must be full documentation of all the findings, positive and negative. From a legal standpoint, it is likely to be assumed that "it is not documented, it was not done." There should be both written and photographic documentation, but the latter may not always be feasible when investigating free-living reptiles and amphibians under field conditions. It may also be helpful to have a recording device available during examination to permit dictation of findings.

Imaging, including radiography, are important, especially when animal abuse is suspected. Digital radiographs are preferred (although not always possible in poorer countries or under field conditions). If digital radiography is performed, CD copies should be made following the photography protocol advocated by Merck and Mader.[28] Hand-drawn diagrams may be used to document injuries such as bruising and wounds.

Some general considerations should be taken into account for all written documentation.[3] Leaving blank areas on forms should be avoided; *N/A* or a strike through the item should, instead, be used if no entry is required. Editorial remarks on the record should also be avoided. Any errors should be corrected by drawing a single line through the entry, marking it "error," and dating and initialing it.[28]

Details of the headings on the examination form will not be given here as they are featured in Appendix 2, Forensic Necropsy Examination Form for Reptiles/Amphibians.

When a dead animal is received, details of the external and internal packaging are recorded, and photographs should be taken as each layer is removed. Any tears or leakage of the packaging material should be noted, as well as a comment on the degree of decomposition (see PMI). Courier information on the package should be photographed and, if feasible, removed and placed in the case file.[28] All packaging should be retained as possible evidence.

The question of euthanasia is complicated, and the guidelines differ according to the country's laws and veterinary professional regulations.[3] Awareness of the need to relate methods to the specialized features of reptiles and amphibians—for example, the resistance of the nervous tissue of some species to hypoxia—led to guidelines in the UK nearly 30 years ago. Permission for euthanasia may need to be sought. An exception may include a situation in which the animal is in critical condition, and euthanasia is urgently required on humanitarian grounds. These issues, together with the question of the release and disposal of the animal's body, were discussed by Merck and Mader.[28] Specific guidance on forensic record-keeping and the documentation of samples in the context of reptiles and amphibians was given by Hart and Budgen.[60]

THE FORENSIC REPORT

Report-writing has been discussed in various veterinary texts, mainly relating to domesticated species, most recently in the book by Bailey[61] and the chapter by Cooper and Cooper.[62] In the context of reptiles and amphibians it is among topics covered in Chapter 187. Merck and Mader[28] emphasized the importance of the expert's report, stressing that it is written for the whole community: law enforcement agencies, prosecutors, both defense and prosecution lawyers, defendants, judges, and juries.

Merck and Mader stressed that the purpose of the forensic report is to provide a clear understanding of the veterinary evidence.[28] It should include information provided by investigating authorities and/or anyone else involved in the investigation, examination findings, procedures, samples/evidence collected, test submissions and results (medical and forensic), medical diagnoses, treatments and outcomes, and conclusions. Terminology is important in the forensic report, as in the oral presentation of evidence. Some of this relates to medical language, some to the use of words. International differences have to be taken into account, especially in legal cases relating to CITES (see earlier). For example, in most of North America the term "turtle" is used for any chelonian. In Britain, other parts of Europe, Australasia, and some of Africa, a "turtle" is a marine (sea) chelonian, a "terrapin" is a fresh-water chelonian, and a "tortoise" is a terrestrial species.

One issue that deserves further mention here—and which is often a very important point in the forensic report—is the manner or "circumstances" of death.[28] Traditionally, the classifications in humans are homicide, suicide, accident, natural, or undetermined. In animals, the categories often used are nonaccidental, accidental, natural, or undetermined. Alternatively, the questions referred to earlier, under the section Pathology and Postmortem Examinations, can be employed and may prove more intelligible to the court.

THE COLLECTION AND PACKAGING OF EVIDENCE

Appropriate equipment is needed for evidence collection and packaging. Some standard materials are available, such as those in the Animal Cruelty Forensics Kit for veterinarians, available from Tri-Tech Forensics (tritechforensics.com) in the United States. Often, however, especially when investigating possible breaches of conservation or animal welfare law concerning free-living reptiles and amphibians, the veterinarians must fashion their own.[39]

Different types of evidence require different types of packaging and storage. The packaging chosen should be appropriate in size and material for the particular item and should be clean or new to avoid contamination. The goal is to preserve the integrity of the evidence. Clean paper evidence bags and envelopes are preferred over plastic, which may allow moisture to build up over time, thus causing damage. However, plastic storage has been shown not to degrade DNA for up to 3 months (Wilson et al, Proc American Academy of Forensic Sciences, 2010, pp 178–179).

Each item of evidence should be packaged separately. If it is wet or moist, it needs to dry fully. Fragile items should be packed carefully to prevent damage in handling and transport. Gunshot projectiles should be collected with the use of plastic instruments or gloved fingers to prevent damage to any ballistic evidence. They should then be placed in a cardboard box so that damage or marks to the surface are prevented. Small items such as hair or fibers should be placed in coin envelopes or pharmaceutical folds.

Samples from stains of biologic origin may be collected using sterile swabs. For dry stains, a wet–dry technique may be used. Dry swabs may be placed in a paper envelope. If the swab is wet, it should be

VetBooks.ir

allowed to air-dry or be placed inside a swab box, which allows the swab to breathe and dry safely. The entire swab box is then placed inside a paper envelope or bag to protect it from contamination while drying.

Arson evidence requires special packaging to prevent vapors from escaping or being absorbed (as occurs when plastic containers are used). Instead, clean unused metal paint cans or special arson packaging containers (available from evidence collection supply companies) should hold the evidence.

Forensic entomology was briefly discussed earlier (see also Barnes[45]). Properly used, it has the greatest potential to provide an accurate time of death. It may also provide information on the time of injury when maggots are found on live animals (myiasis). The documentation, collection, and packaging of insect evidence differs from that of other types of evidence. Collection should include all the different types of insect evidence, including adults (imagines). The oldest life cycles should always be among those collected, because they probably represent the earliest time of insect arrival and colonization. Detailed information about the collection and storage of dipterous larvae and pupae (puparia) is given by Anderson[46] and Barnes.[45]

DNA testing is commonly performed in forensic cases for species determination or when individualization is needed for a match to a questioned sample. The identification of species is especially important in the illegal trade of animals.[3,59] DNA technology and its applications to herpetologic research and forensic investigations involving reptiles and amphibians were described by McDowall.[54] Genetic methodologies in wildlife crime investigations, many of them applicable to reptiles and amphibians, were described in detail by Robinson.[63]

All evidence needs to be properly sealed, not only to protect it but also to indicate readily if its integrity has been maintained.[64] Evidence tape is made to easily tear and is not meant to hold bags closed or boxes together. Packing tape may be used to seal containers, and evidence tape may then be placed over it. The person who packaged the evidence then signs or places his or her initials and the date across the tape.

The package should be properly labeled with the evidence number, case number, date, collection location, description of the item, time collected, collector's name, and signature. If the evidence contains biological fluids or tissue and/or poses a potential hazard to humans, it should be marked with a biohazard label. Each item of evidence is assigned an evidence identification number, and all of it is recorded in the evidence log (see Box 186.2). Chain of custody procedures should be followed, and any transfer, storage, or transport of the evidence must be documented. Reference should be made to documentation, earlier, and to Frye,[56] who described sampling and standard laboratory techniques in herpetologic forensic work.

RETENTION OF FORENSIC EVIDENCE AND OTHER MATERIAL

As emphasized earlier, the retention of material is wise, sometimes essential, because it is likely to constitute evidence. There are three aspects:

1. the storage of everything received, including wrappings, pending a court case where such evidence may need to be produced;
2. the specific selection of relevant specimens for production as evidence (e.g., a piece of damaged carapace);
3. when circumstances, especially legal considerations, permit, the curating and cataloging of appropriate material, after the court case, as "reference" or "voucher" specimens. Cooper et al.[65] discussed the relevance of such reference collections to zoological medicine and conservation biology.

SERVING AS A WITNESS AND APPEARING IN COURT

This important aspect of forensic work is covered in Chapter 187 on Jurisprudence, Expert Reports, Testimony, and Court Appearance by Lawton.

CONCLUSION

Herpetologists and veterinarians who have special knowledge of, and skills with, reptiles and amphibians can make a valuable contribution to forensic evidence. An understanding of the relevant legislation will both enable them to perform their duties more effectively and to comply with necessary legal requirements in preparing and delivering herpetologic forensic evidence.

Jurisprudence, Expert Reports, Testimony, and Court Appearance

Martin P.C. Lawton

Medical jurisprudence has been defined[1] as the science that applies the principles and practice of the different branches of medicine to the elucidation in judicial proceedings of questions relating to the cause or effect on the legal status of an individual's mental or physical disease or injuries. Despite the age of this definition, it is still pertinent.

Guidance on medical jurisprudence provided to the court is usually by a suitably qualified professional referred to as the "expert witness." Experts were first used in legal matters in the 14th century.[2] The evidence given by medical experts is classed as "opinion" evidence. It consists of the expert providing conclusions (as a scientist) drawn from certain facts, which had been or are supposed to have been proven.[1]

The term "expert" may be misleading, because it means that only by training or experience the witness is qualified to express an opinion, which an ordinary person may not.[2] The acceptance of a witness as an "expert" is ultimately the responsibility of the court (e.g., judge or bench) to decide.

PRINCIPALS OF BEING AN EXPERT WITNESS

A veterinarian may be a witness in a court proceeding in a variety of roles and not always as an expert. A working knowledge and understanding of current regional legislation is advisable when undertaking any potential legal work. Confidence in medical witnesses may be eroded by miscarriages of justice caused by misleading and flawed evidence.[3] Especially true when medical witnesses support conclusions out of synch with their peers or appear to have their own agenda. The roles a veterinarian may be asked to assist with in a court or arbitration include the following:

1. A witness of fact, where the veterinarian may have witnessed an event and be called on to give details of the event. Being a "witness of fact" does not necessarily imply or require the veterinarian to have any special knowledge or experience other than being able to truthfully report events they have witnessed.
2. A professional witness, where a veterinarian is asked to be a witness by virtue of their profession. This does not necessarily require specialist knowledge or experience beyond that expected of a competently qualified veterinarian. The "professional witness" is also a witness of fact and is expected to be able to report on matters experienced but also draw limited conclusions based upon their direct experience only.
3. An expert witness, where a veterinarian may not necessarily have been a witness of fact but by virtue of their qualifications and experience is asked to assess all evidence and draw a conclusion (known as an "opinion") usually in a preprepared report. The expert witness should be prepared to be challenged by the conclusions drawn and be able to defend their assumptions and conclusions under cross-examination.

An expert will most often be called on by either a prosecuting body or, after charges are filed, by the defense team. However, it is important to remember that any expert approached to ultimately assist the court in reaching a decision must remain neutral to either party.[4] Irrespective of what type of witness a veterinarian is when involved in a case, there are a number of golden rules, the most important of which is to not state anything that is not true or is not capable of being supported with argument.

EXPERT REPORTS

The ability to recognize neglect from cruelty can be difficult[5] and will often be the contested issue before the court that requires expert witnesses.

It is standard practice for the expert witness to prepare a detailed report providing information and facts and an "opinion" based on these details to assist the court in understanding scientific facts and to draw a conclusion (verdict). All potential legal cases will require a detailed report, which also acts as a statement of events, findings, and opinions. To prepare a report, further research and consulting with colleagues may be required.[6]

Irrespective of which side calls ("instructs") the expert, they should be nonpartisan[2] and be mindful that they should be working as advisors for the court to help in reaching a fair and correct decision. This is a concept that goes against human nature (not to pick and fight for a side) and must always be forefront in the mind of any expert.[4] Opinions must therefore always be accurate, fair, and, above all, defendable if challenged. A true expert must be able to see matters from both sides and include a weighed opinion in the report, avoiding bias.

All reports prepared by an expert will be subject to legal and critical scrutiny, often with the assistance of another expert ("for the other side"). An important aspect of preparing a report is never to say anything that is either outside of your area of expertise or that you will not be able to later defend and support when challenged.

The most important thing to remember when preparing a report is that it will contain your views and it is what you will be questioned on if the matter comes to court. Your report will be used to establish your "Evidence in Chief." In court you will have access to your reference material, any contemporaneous notes, records, photographs, or other items that you used to formulate your report. This is helpful because it is not unusual for the final court hearing to be many months to years after the original matter or your report was written.

In structuring the expert report, it is standard to include the following:

1. Your full name, qualifications, and details of experience pertinent to the case.
2. A brief curriculum vitae (CV) showing your general experience and supporting why the court should accept you as an expert.
3. Details of the instructions (from the solicitor or attorney), including any specific points on which you have been asked to address or comment or any scenario that you have been asked to consider (especially common when called by the defense).

4. A list of the information (evidence) with which you have been provided (e.g., other witness statements, photographs, videos, laboratory reports, contemporaneous records of interview, etc.).
5. A statement as to whether you have examined the animal(s) involved and details of your involvement and assessments.
6. Conclusions (opinions) drawn from the information provided to you or that can be reasonably drawn from the circumstances of the case.
7. A "statement of truth" and that the conclusion and opinions drawn are within your knowledge. You should also state the facts you have relied on if not already stated.
8. A copy of any references utilized in the making of the report.

The use of technical terms and abbreviations should not be used (unless clearly explained) because the report should be written for a lay audience.[4]

EXAMINATION OF ANIMALS

Although it is not necessary for the expert to have actually examined any of the animals involved in a case, it is always desirable that there be a veterinary report of an examination that can be referred to later. The veterinary examination of live animals should be prompt and as near to the dates of the potential offense as possible. When there is a body(s) involved, a postmortem examination may be delayed or performed at a more convenient time as long as correct storage is maintained to preserve forensic material.

The examination of live or dead reptiles should be thorough and information recorded at the time of evaluation. Recorded information may be written, in a bound notebook (to prevent the accusation of pages being removed or replaced), or digitally recorded (analog is also acceptable) either as a voice recording or a video recording. If the examination is being video recorded, it is important for the clinician to demonstrate what they are doing and point out any abnormalities found so these can be recorded. The video or voice recording may well be presented in court as evidence, and it is import to be mindful that any comments made are appropriate and descriptive and not open to criticism. The recorded examination (in whatever format) will be considered as contemporaneous notes and can be referred to both in the preparation of a report (usually copies are appended to this) and later in court. Any examination records, even if not actually used in court, will need to be provided and disclosed to the other party in case they wish to introduce them as evidence.

In addition to the standard examination covered elsewhere in this book, the veterinarian should always be mindful of the additional requirements necessary in undertaking a forensic examination. For example, it is important to not just record abnormalities but also describe the body systems examined, or not examined, and list any samples taken or additional investigations performed. It is important when recording numerical information, such as lengths, weights, temperatures, and more, to describe with what degree of accuracy this information was collected and detail any equipment used (and if that equipment has been calibrated recently) (Fig. 187.1). If a video recording is not utilized then photographic records of any pertinent findings are important so that reference can be made to this within the report. When taking photographs, it is also important to have identification data such as the case number, specimen number, date, and often a form of measurement in clear view in the images (Figs. 187.2) (especially useful for postmortem examinations or when an abnormality is being recorded).

When samples (blood, feces, swabs, body tissues, etc.) are taken and submitted to an outside laboratory, it is important that there is an effective and unchallengeable "chain of custody." This will start with the veterinarian or technician giving each sample a unique code (usually the initials of the person taking the sample followed by a number and sometimes the time and date), which is recorded on an "exhibits list" with a description of the sample and method of preservation (if any) that will be appended to the final report. The unique sample number should be used thereafter in any laboratory request form, delivery, and receipt, and should appear on any laboratory report subsequently produced. The method of transporting the sample (courier, in person, or recorded post) should be documented and signatures obtained from all those involved in the process, including the acceptance and processing at the laboratory. It is advised to make contact with a laboratory before the samples are sent to make sure they are aware it is a legal (or potentially legal) case and that they should follow chain of custody protocols.

REPTILE WELFARE AND SUFFERING

A useful summary of many of the laws affecting zoo and wild animals in the United States and elsewhere[7] are given in Chapters 183, 184, and 185.

The involvement of animals in legal situations has been previously considered,[8,9] but a reptile may be either the direct object of the criminal action or the indirect object involved in a nonassociated criminal activity.[4] The direct involvement may be associated with the intrinsic value of the reptile, its rarity (including export or import restrictions and Convention and International Treaty in Endangered Species [of Wild Fauna and Flora] [CITES] requirements), or the potential dangerous nature of the animal and legal restrictions in ownership.[4] However, the

VetBooks.ir

largest categories in which a veterinarian as an expert witness will become involved are the welfare and "unnecessary suffering" categories of the various Animal Welfare Acts (where or if they exist).

The use of reptiles and amphibians indirectly in crimes is often encountered when there is a potentially "dangerous" or "fearsome" animal that can be used to reduce the possibility of a certain area (usually the vivaria) being fully searched as part of a criminal investigation (e.g., for stolen goods or drugs),[4] It is rare, but a reptile may also be used as a "dangerous" weapon to cause harm or even death to another human being. The legislation that restricts the ownership of venomous or dangerous reptiles in many countries substantially reduces the risk of the latter being realized, but it is always a possibility.

The welfare categories may not be a deliberate act of neglect or cruelty but have resulted by a lack of understanding the proper care of a reptile; this is known in legal terms as a "failure to meet the needs of that animal." Keeping reptiles or other ectotherms in captivity, compared with mammals and birds, requires an exacting environment and sometimes unusual nutritional requirements often not provided by the owner, leading to suboptimal health and welfare concerns.

Animal welfare legislation set the minimum standards that are expected for the care and treatment of "protected animals."[7] The legal definition of "protected animals" is varied, and, for example, in the United Kingdom, it must be either (1) commonly domesticated in the British Islands; (2) under the control of humans whether on a permanent or temporary basis; or (3) is not living in a wild state.[10] The regional definition of what is a "protected animal" is therefore very important because, in effect, animal welfare legislative requirements (including preventing unnecessary suffering) may not always apply to wild reptiles. Whether the reptile involved is a "protected animal" or not may be an argued point of law, and the veterinarian should always be prepared to be able to make an appropriate argument regarding this.

The welfare categories are linked to the "five freedoms," which are listed as follows:

1. **Freedom from hunger and thirst.** Provided by a ready access to fresh, clean water and a suitable diet appropriate to maintain health and vigor.
2. **Freedom from discomfort.** Provided an appropriate safe environment, including appropriate temperature, humidity, shelter, and a comfortable resting area.
3. **Freedom from pain, injury, or disease.** Provided by frequent checking (ideally daily) and examination of the animal and promptly seeking veterinary advice or treatment as required.
4. **Freedom to express normal behavior.** Provided by appropriate housing, including keeping in suitable and compatible groups such that the animals can act normally or as near to normal as possible.
5. **Freedom from fear and distress**. Provided by appropriate housing away from predators, dominant or noncompatible cage mates and appropriate human/animal interactions.

The unnecessary suffering categories of the various animal welfare legislations are often an important area in which the veterinarian will be asked to define, confirm, and sometimes argue for or against. Questions often posed in courts that the expert may have to answer include whether reptiles do or do not suffer or how they can suffer when they are considered a "lower" vertebrate. Or another argument, less commonly encountered, but just as important: "Do reptiles experience pain?" In both situations, veterinarians typically discuss the scientific literature (e.g., various volumes of *Biology of the Reptilia*) and how these confirm that the nervous pathways of reptiles have been extensively studied and shown to be similar to those of mammals, and thus reptiles can suffer and feel pain. However, the question of what is "pain" may arise and may need to be discussed in court. The accepted definition of pain is "a physiological state caused by any unpleasant sensory or emotional disturbance associated with actual or potential tissue damage." It has been an all too regular defense, especially in chronic neglect cases, that because there may be no pain involved, then there could not be any suffering, thus implying that there cannot be suffering without pain. The legal definition (set by precedent as a ruling in a higher court in the United Kingdom) is that unnecessary suffering "imports the idea of the animal undergoing, for however brief a period, unnecessary pain, distress or tribulation"[11] and clearly sets out that although pain can be part of suffering, suffering can still occur without the involvement of pain. Morton and Griffiths[12] have prepared guidelines on the recognition of pain, distress, and discomfort that may be referred to in support of an expert's argument and conclusions.

The proof of "unnecessary suffering" can sometimes be more difficult to establish, because this requires not only a deliberate act of causing harm to a reptile but the understanding by the perpetrator that such an action will, or would be likely to, result in pain, discomfort, or lasting harm (e.g., suffering). The ability of a person having the understanding of the likelihood of suffering to have occurred or be likely to occur is known in legal terms as malfeasance, and the state of mind of knowing the consequence of particular actions is referred to as "mens rea," which is translated as guilty knowledge or intention to commit a prohibited act. The court often looks to the veterinary expert to qualify any, or the degree of, suffering, and whether it was anticipated or avoidable and thus was unnecessary or not.

COURT APPEARANCE AND TESTIMONY

It is the authors' experience that a court appearance to support the opinions and facts stated in the "expert report" are required in less than 10% of the cases instructed. Once an expert report has been prepared and examined by both parties it may be decided that:

1. there is insufficient evidence for there to be a case (charges) to answer;
2. there is a case to answer but there is an acceptable reason to be offered in mitigation (defense);
3. that the evidence and expert's report is accepted such that the person(s) culpable of the offense (PCO—defendant) offers a plea of guilty ("no contest"); or
4. that charges are laid and the defendant pleads not guilty and a court/tribunal hearing is required.

It is only for the last point (4) that the expert is likely to be called to make a court appearance and give testimony. There are rare situations when even at this point, the expert may not need to attend court, because the expert's report may be "accepted" by both sides and will be put to the court untested (or with agreed redactions). The latter is usually where there are mitigating circumstances raised by the defense that will be argued in court that do not need the involvement of the expert.

Preparation before any court case is required, including taking any pertinent references or text books. The expert may also need to produce secondary or rebuttal reports, depending on any new evidence or other expert reports that are disclosed during the lead-up to the court hearing.

In court, an expert may be asked their opinion on facts established or hypothesized based upon the evidence.[2] It is important for the expert to:

1. Be professional in appearance and during communication at all times.
2. Have a firm opinion and be firm about that opinion.
3. Admit freely if there is room for argument or an alternative opinion.
4. Be concise if possible.
5. Use nontechnical language (without sacrificing accuracy of phrase).
6. Give ground with honesty and good grace.

VetBooks.ir

An unbending expert who is argumentative will often fail to impress the court and carry a lower "weight" in deliberations compared with an expert who is fair and reasonable. However, be wary of the opposing advocate's questions and interruptions. Always listen carefully to the entire question before replying, consider your answer, and then respond. If the question was a series of questions, then state this and that you will deal with each question in turn. Make all replies directly to the judge (or bench) and not to the advocate; the physical movement of your body from facing the advocate to facing the front of the court also reduces the possibility that the advocate will interrupt your reply midflow, as they have lost your attention. It is not unusual for an advocate to ask basically the same question in several different ways. This is known as "testing the evidence" and requires experience to recognize and not be contradictory to answers you have already supplied. Above all else, remember that the expert is there to assist the court in reaching their decision and do not be afraid to reply, "I cannot properly answer that question" or "That matter is beyond my expertise."

Broad-snouted caimans *(Caiman latirostris)*
embryos exposed to bisphenol, 1423
hematologic and serum biochemical values of, 333*t*–348*t*
hepatic first-pass effect in, 448
UVB requirement for, 197
Broad-spectrum antibiotics, 974, 1002
Bromethalin, toxicity, 826, 982–983
Bronchi, necropsy of, 374
Brown tree snake *(Boiga irregularis)*, 1422
Brumation, 150. *See also* Snakes
Buccal cavity, 410
Bufagenin, toxicity, 986
Bufodienolides, toxicity, 986
Bufotoxins, 986
Bulbus lamelle, 675
Bullous spectaculopathy, 733
Bunyaviridae, 267
Bunyaviruses, 267
Buoyancy disorders, in sea turtles, management of, 1387
Bupivacaine, 475
Buprenorphine, 471–472
for amphibians, 485
Burkholderia, 240
Burmese python *(Python bivittatus)*, 50, 1422
3D reconstruction of, 563*f*
anorexia, weight loss, coelomic mass, 829*f*
chronic constipation, lateral radiograph of, 829*f*
cloaca, metastatic lesion in, 829*f*
coelomic fat bodies, 829*f*
gastroscopy, 608*f*
heart, 676*f*
hematologic and serum biochemical values of, 333*t*–348*t*
inclusion body disease (IBD) and, 266*f*
localized pneumonia, 567*f*
MRI
brain anatomy, 580*f*
sagittal/parasagittal, 579*f*
pericardial sac, 672*f*
pneumonia, 567*f*
renal adenocarcinoma, 829*f*
Burns
in chelonian shell, 719–720, 720*f*
skin, 708–709, 708*f*
thermal, 1351–1352, 1351*f*
Bush vipers *(Atheris squamigera)*, infected with ferlaviruses, 264*f*
Buspirone HCL, adverse consequences, 1246
Butcher's paper, usage of, 117
Butorphanol, 485
Butorphanol tartrate, 469–471

C

Cachectic reptile, urine, 635*f*
Cage-mate aggression, 1004
Cages
accessory, change, impact of, 129
changing, impact of, 129
furniture, 156–157
outdoor enclosure in, 125*f*
shapes, 122
size and orientation, 155, 156*f*
for snakes, 145–147, 146*f*–147*f*, 146*t*
traps, for wild amphibians and reptiles, 1367*t*
Caicos rock iguana *(Cyclura carinata)*, ontogenetic change, 160
Caiman lizards *(Dracaena guianensis)*, mollusc-eating, 69
Caiman pox virus, in crocodilians, 257*t*
Caimans
length of, 75
of reptile farming, 1396–1397, 1396*b*, 1396*f*
semitransparent third eyelid in, 722*f*
Calcidiol, 841, 842*t*
Calcium, 330
deficiency, 1326
homeostasis, 840–843
ionized, values of, 841*t*
supplements, 206–210, 210*t*
Calcium edetate (CaEDTA)
allometric scaling formulary of, 1187*t*–1188*t*
toxicity, 984
Calcium gluconate
for sea turtles, 1386
Calcium pyrophosphate dihydrate (CPPD), crystals of, 1333
Calculi, cystic, 1355–1356, 1355*f*–1356*f*
Caliciviridae, 268
Caliciviruses (CVs), 268
California kingsnake *(Lampropeltis getula californiae)*
discharge associated with cloacitis, 782*f*
hepatic melanomas in, 668*f*
intestinal adenocarcinoma, 830*f*
metastatic lesions, 830*f*
neoplastic lesion, 830*f*
vertebral osteomyelitis, 818*f*
Cameras, in diagnostic endoscopy equipment, 593, 593*f*
Campylobacter, 242, 1362
Canadian Council on Animal Care (CCAC), 1414
Canadian federal regulations, 1462
Canadian Veterinary Journal, 1415
Cancer
describing prognosis with statistics, 832, 832*t*
diagnosis of, 827–830
staging of, 831–832
treatment of, 832–834
suitability of patient for, 830–831
Candida, 279–280
Candida albicans, 279–280
Candidatus Neoehrlichia mikurensis, 1365
Candoiinae, 54
Cane toad *(Rhinella marina)*, 1422
husbandry requirements, 229*t*–231*t*
Canine acupoints, transposition of, 1241, 1242*f*
Cannulae, 595–596, 596*f*
Capillary refill time, 968–969
Capnography, for general anesthesia, 462*f*, 463
Captive breeding, 865–870, 1425, 1425*f*
conservation issues in, 1425, 1425*f*
Captive care, for sea turtle, 186
Captive populations, sustainable, management for, 1399
Captive reptiles
common stressors of, 105, 106*b*
for display, 1452–1453
European legislation for, 1449–1453
for exhibition, display, and entertainment, 1452–1453
general, 1449
as pets, 1449–1452
protected species of, 1452
scientific research in, 1453
nonadaptive stress response, 106
requirements for, 112–129, 129*f*–130*f*
bioactive substrates, usage of, 126
cage size and construction, 118–123, 119*t*–120*t*, 120*f*–121*f*
cleaning and disinfection, 123
closed collection, control of disease transmission in, 124
environmental enhancement and outdoor enclosures, 125–126
examination, 123–124
feeding, 127–129, 127*f*
humidity and ventilation, 116–117, 116*f*–117*f*
measuring and monitoring, 118, 118*f*–119*f*
multi-individual and multispecies enclosures, 124–125, 125*f*
parasite control, 124
photoperiod and light quality (lighting), 115–116, 115*f*
POTR for, 114*f*
quarantine, 123
stress, 129
substrate, usage of, 117–118
temperature, 111*t*, 113–115, 114*f*–115*f*
temporary housing or hospitalization, 112–113, 113*f*–114*f*
water, availability, 126–127, 127*f*
scientific research in, 1453
stress of, 105–108
captivity, 106–107, 107*f*
important to reptile medicine, 107
recognizing, 107–108
on various body systems, effects of, 105–106
stress response, physiology of, 105
Captive reptiles *(Continued)*
welfare of, 105–108
impacts on, 107–108, 108*f*
needs, assessing, 107
Captive-born lizards, 74
Captivity
behaviors particular to, 99
feeding habits in, 927
in forensics, 1465
stress in, 925–926
stress of, 106–107, 107*f*
Capture techniques
for wild amphibians, 1366, 1367*t*
for wild reptiles, 1366, 1367*t*
Carapaces
scutes, nomenclature of, 40*f*
solid, formation of, 713
Carapacial pankinesis, of Malayan softshell turtle, 714
Carbamates, 825
toxicity, 981–982
clinical signs of, 981
Carbapenems, 1145
Carbaryl powder
for mite infestations, 1169*t*
Carbenicillin
allometric scaling formulary of, 1187*t*–1188*t*
Carbon dioxide (CO_2)
insufflation, 594, 594*f*
laser, 1016, 1019*f*–1020*f*
Carboplatin
as chemotherapy agent, 1180*t*
Cardiac diseases, 692–696
Cardiac glycosides, plants containing, 989
Cardiac shunting, 447, 680–682
Cardiac silhouette, 687*f*
Cardiac size, 669–672
Cardiac troponins, 683–684
Cardiocentesis
for collection of hematologic samples, 997–998
in lizards, 406
in tortoises, turtles, and terrapins, 408
Cardiology, 669–698
anatomy and physiology in, 669–682
diagnostic tools in, 682–692
Cardiomegaly, in snakes, 1249–1250
Cardiomyopathies, 692–695
Cardiopulmonary cerebral resuscitation, 970
Cardiopulmonary systems, general anesthesia and, 447–448
Cardiotoxin, 162–163
Cardiovascular system
of amphibians, 88
function, assessment of, 409
of lizards, 493–494, 494*f*
necropsy of, 374
radiography of, in chelonians, 516
of snakes
radiography of, 504–506, 506*f*
signs in, 1249–1250, 1249*f*
ultrasonography of, 547
Carettochelyidae, 33*f*
Caribbean tree frog *(Eleutherodactylus coqui)*, 1422
Carnivores, 216–220
Carotenoids, 939
Carpet python *(Morelia spilota variegata)*, 52*f*
heart swelling (radiograph), 687*f*
hematologic and serum biochemical values of, 333*t*–348*t*
Carprofen, 1162–1163, 1163*t*
allometric scaling formulary of, 1187*t*–1188*t*
Caryospora, 284–287
Caryospora chelonae, in sea turtles, 1383
Caseous conjunctivitis, 734
Cassette, for radiography, 486
Castor bean intoxication, 989
Casts, observation, 636–637
Cataracts, 735
in amphibians, 1287
in snakes, 1251, 1251*f*
surgery, 1027
Categorical data, statistical flowchart for, 29*f*
Catheterization, 416, 417*f*
Catheters
maintenance of, 423*t*, 427–428
placement of, 422–428, 422*f*
complications associated with, 428*b*

Catheters *(Continued)*
rewiring of, 427
types of, 426
Caudal coelom (abdomen), in crocodilian radiography, 530, 531*f*
Caudal coiling syndrome, 824, 824*f*
Caudal pole, kidneys (fusion), 626*f*
Caudal trachea, diagnostic sample collection from, 410–411
Cava communicate, 66
Cavum dorsale, 673
Cavum pulmonale, 673
Cavum venosum, 675–676
Cayman Turtle Farm, mariculture at, 1389–1392
Cedar shavings, 826
Cefoperazone, 1143
Cefovecin, 1145
Cefquinome, 1145
Ceftazidime, 1143
allometric scaling formulary of, 1187*t*–1188*t*
Ceftiofur, 1145
Ceftiofur crystalline-free acid, 1145
Ceftiofur sodium, 1145
Celioscopy, of amphibian soft tissue surgery, 1098–1099
Cell-mediated innate immunity, 357–358
Cellular immunology, 918
Cellular inclusions, in reptile and amphibian, 317–318, 317*f*–318*f*
Cellulitis
abscess and, 706, 706*f*
pharyngeal and submandibular, 750, 750*f*
Central American legislation, 1456–1463
Central nervous system (CNS), membranes of, 978
Central venous catheterization, 426–428
catheters for
maintenance of, 423*t*, 427–428
rewiring of, 427
types of, 426
Seldinger technique in, 426–427, 427*f*
verification of placement in, 427
Cephalexin
allometric scaling formulary of, 1187*t*–1188*t*
Cephalic flexure, 805
Cephalic vein
as catheter insertion site, 422–424, 423*f*
in lizards, 971
Cephalosporins, 1143–1154, 1144*t*
Cephalothin
allometric scaling formulary of, 1187*t*–1188*t*
Ceramic heaters, 132
Cerebral cortical pathways, 466–467
Cerebrospinal fluid (CSF)
analysis, 815–816, 816*f*
diagnostic sample collection of, 419, 420*f*
Cervical aneurysm, 750
Cervical spondylomyelopathy (CSM), 1110
Cestoda, 290–292, 290*f*–292*f*
Cestodes, 696, 1006, 1167–1168, 1168*t*

Chaetothyriales, 277–278
Chain of custody, in forensics, 1467*b*, 1473
Chamaeleonidae, 63
Chameleon
gravid, radiograph of, 489*f*
lungs, CT, 564*f*
NSHP in, 936*f*
Chelidae, 31*f*, 32*t*, 33*f*
Chelonians, 31
acclimatization for, 172
adenoviruses (AdVs) in, 249
annual examinations for, 171
antibody detection of viruses in, 250*t*–251*t*
cardiopulmonary system of, 447
cloacal anatomy of, 776–777
common pathogens of, 1403*t*
diseases identified postmortem in, 1411, 1412*f*
dystocia in, 1306, 1306*f*
endoscopy, 610–612, 611*f*–612*f*
endosurgery in, 618–620, 618*f*–619*f*
oophorectomy in, 619, 619*f*
orchiectomy in, 620, 620*f*–622*f*
epidural anesthesia and, 476
female reproductive surgery for, 1086–1089
ferlavirus in, 264, 264*f*
glottis of, 448
Chelonians *(Continued)*
gravid females, 175
handling of, 168, 169*f*
heart of, 677*f*
blood flow through, 679*f*–680*f*
visualization of, 689*f*
herpesviruses in, 254–256, 255*f*
hibernation of, 168–170
identification for, 171–172, 171*f*
internal fertilization in, 44–45
intranasal administration
of anesthetic agents, 454
of sedatives, 442
intraosseous catheterization of, 424
intravenous administration in, 442
lighting for, 168
limbs amputation of, 1112
liver, 649, 650*f*–651*f*
male reproductive surgery for, 1078–1079, 1079*f*
musculoskeletal anatomy of, 900–901
nasal discharge, abnormality, 1270, 1273*f*
necropsy of, 372*f*
neurologic disorders of, 1322–1325, 1322*f*
NSHP in, 934*f*, 937*f*–938*f*
open-mouthed breathing in, 1274*f*
ovaries in, 551–553
papillomaviruses in, 261
pelvic girdle of, 36
penile prolapse in, 1268
phallus of, 45*f*, 419
physical examination of, 399–404, 400*f*–403*f*
plastron shape, 859, 860*f*
predators of, 170–171, 170*f*–171*f*
prefemoral coeliotomy of, 1054–1056
craniocaudal skin incision, 1055*f*
patient positioning of, 1054–1055, 1054*f*–1055*f*
preparation of, 1054–1055, 1054*f*–1055*f*
surgical technique of, 1055–1056, 1055*f*–1056*f*
prefemoral window for, 546*f*–547*f*
radiography of, 514–527
cardiovascular system, 516
gastrointestinal system, 517–521, 520*f*–521*f*
musculoskeletal system, 523–527, 524*f*–527*f*
reproductive system, 521–522, 522*f*
respiratory system, 516–517, 517*f*–519*f*
restraint and positioning in, 514–516, 514*f*–516*f*
urinary system, 522–523, 523*f*–524*f*
ranaviruses on, 258*f*
renal portal systems in, 48
respiratory tract of, 448
anatomy of, 788–790, 789*f*–790*f*
history and physical examination of, 791–792, 792*f*
percutaneous lung lavage in, 796
physiology of, 791
scutes in, 713–714
age determination and, 715
anomalies of, 715
development of, 713
growth of, 715
sex identification, 858*t*
sexual dimorphism in, 46–47, 46*f*–47*f*
shell
anatomy of, 712–715
ankylosis in, 715–716
in anoxia tolerance, in freshwater turtles, 715
bacterial shell dermatitis/osteomyelitis in, 717–718, 717*f*–718*f*
burns in, 719–720, 720*f*
clinical diseases in, 715–720
dermal bones in, 713
dyskeratosis in, 719, 719*f*
embryonic development of, 712
fontanels in, 714, 715*f*
frostbite in, 720
hinges in, 36
kinesis in, 714
mycotic shell dermatitis/osteomyelitis in, 719
neoplasia in, 720
physiology of, 715
plastral peculiarities in, 714–715
plastron, formation of, 713
pyramiding in, 716
rib growth mechanisms of, 712–713, 712*f*
secondary hyperparathyroidism in, 716–717, 717*f*
sexual dimorphism in, 715
Chelonians *(Continued)*
softening of, in juvenile herbivorous tortoises, 716, 716*f*
solid carapace, formation of, 713, 713*f*
skin of, 700–701
small intestines of, 761
sonographic windows for, 546
special senses and salt glands of, 49
species interactions, 179
tail
amputation of, 1115
enlargement, 860, 860*f*
teeth, lack of, 42
temperature of, 168
thyroid gland of, 835–836
transplastron coeliotomy of, 1057–1061
patient positioning of, 1057, 1057*f*
preparation of, 1057, 1057*f*
surgical technique of, 1057–1061, 1058*f*–1061*f*
Chelonid alphaherpesvirus 5 (chHV5), in chelonians, 250*t*–251*t*, 254

physical examination of
in lizards, 398*f*
in snakes, 392
of snakes, 1251, 1251*f*
ultrasonography of, 557, 558*f*

F

Facial masses, 1035–1036, 1036*f*–1037*f*
Facial nerve (CN VII), 811
"Failure to thrive syndrome", 952
Fair prognosis, of shell trauma, 1116
Famciclovir, 1160
Fat body, ultrasonography of, 550, 550*f*
Fat-soluble vitamin A palmitate, 1316–1317
Faveolar lung parenchyma, in lizards, 788
Febantel
allometric scaling formulary of, 1187*t*–1188*t*
Fecal flotation, 764*t*
for reptile parasitology, 281–282
Fecal production, reduced, in amphibians, 1285–1286
Fecundity, 854, 892–893
low, 892–893
Feeding
behavioral issues related to, 926–928, 928*f*
of crocodilians, 198
of lizards, 159–161
Feeding *(Continued)*
of snakes, 148–150, 148*f*
of tuatara, 200
Feline Clinical Care Liquid
oral supplementation, 999
Female crocodiles, reproductive system of, 79
Female reproductive tract, 850–852, 851*f*
Femoral pores, 701, 701*f*
Femur
chelonian, 901
proximal, as catheter insertion site, 425
Fenbendazole, 1167
allometric scaling formulary of, 1187*t*–1188*t*
for nematodiasis, 764
toxicity, 978
Fentanyl, 471
patch, on skin of a ball python, 472*f*
Ferguson zones, 136, 137*f*
Ferlaviruses, 263–265, 1328, 1328*f*
in chelonians, 250*t*–251*t*, 264, 264*f*
detection of, 264–265, 265*f*
identification of infection, 264–265
serology of, 265
in squamates, 252*t*, 263–264, 264*f*
Fertilization, 855
FESSA (Fixateur Externe du Service de Santé des Armées), 1014–1015
Fiber-related disorders, 950
Fibriscesses, 1288–1289
Fibromas, 1010
Fibropapilloma-associated turtle HV (FPTHV), in chelonians, 250*t*–251*t*
Fibropapillomatosis
herpesvirus infection and, 255, 255*f*
in sea turtles, 1383, 1383*f*
Fieldwork, forensics and, 1473
File snake *(Acrochordus arafurae)*, 60
Film-screen techniques, 486–488
overexposure in, 486–488
underexposure in, 486–488
Filobasidiella, 274
Fine needle aspirate cytology, 660, 660*f*
Fipronil
for acariasis, 1291
for mite infestations, 1169*t*
Fire ants, 986
Fire salamander *(Salamandra salamandra)*
conservation issues in, 1424
husbandry requirements, 229*t*–231*t*
Firefly ingestion, 826
Firefly toxicosis (toxicity), 986–987
Firmicutes, 238–239
Fish, nutrition of, 217*f*
Fitzroy River turtle *(Rheodytes leukops)*, 42
"Five freedoms," welfare categories in, 1478
Five-lined skink *(Plestiodon [Eumeces] fasciatus)*, 64–65
Fixation, fracture, 1105*f*–1106*f*
Flaccid paresis, 1275
Flakes, in lizards, 1258–1259
Flank (lateral) coeliotomy, 1049–1053, 1050*f*–1052*f*
Flatback sea turtles, 184*f*
Flaviviridae, 268
Flaviviruses, 268
Flexible endoscopes, 591–592, 592*f*
Flexible instrumentation, 595, 595*f*
Floating, unevenness, 1272, 1274*f*
Florfenicol, 1148
Florida king snake *(Lampropeltis getula floridana)*
fluctuant cutaneous lesion in, fine needle aspiration of, 410*f*
MRI, beam lateral radiographs, 582*f*
Florida pine snake *(Pituophis melanoleucus mugitus)*, 58*f*
Flotation methods, for fecal parasitology, 763, 763*f*, 764*t*
Flowers, consumption of, 128
Fluconazole, 1156
allometric scaling formulary of, 1187*t*–1188*t*
for fungal infections, 1386
Fluid administration
enteral, 1131*f*
intralesional therapy, 1136
long-acting (depot) formulations, 1137
nebulization, 1135–1137, 1136*f*
osmotic pumps, 1136–1137
Fluid administration *(Continued)*
parenteral, 1130–1135
intracardiac, 1135
intracoelomic, 1132, 1133*f*
intramuscular (IM), 1132, 1133*f*
intraosseous, 1133–1134, 1135*f*
intrathecal, 1134–1135
intravenous (IV), 1133, 1134*f*–1135*f*
subcutaneous, 1131–1132, 1132*f*
programmable infusion pumps, 1137
routes of, 1130–1138
topical, 1137
transdermal therapy, 1136
vascular access ports, 1137
Fluid attenuation inversion recovery (FLAIR) sequences, 573
Fluid therapy, 970–974, 1385
for renal disease, 1336
Fluid-filled blisters, in lizards, 1259
Fluids
compositions, 972*t*
replacement, 1130
samples, for cytology, 363
Flukes, 288–290
Flumazenil, 444
Flunixin meglumine, 1163, 1163*t*
allometric scaling formulary of, 1187*t*–1188*t*
Fluorescein dye, 726*f*, 728, 730
Fluorescent bulbs, usage of, 116
Fluoroquinolones, 1150–1154
for mycoplasmosis, 747*t*, 1353–1354
Fluoroscopy, intraoperative, 1020
Flurbiprofen, 1163, 1163*t*
Flushes, cloacocolonic, 763, 763*f*
Fly River turtle *(Carettochelys insculpta)*, 33*f*
Follicular development, 852
Follicular stasis, 880–881, 881*f*
Fontanels, 714, 715*f*
Food chains, 1430–1431
Foods, FDA definition, 1247
Forebrain, 922
Foreign bodies
in conjunctival fornix, 734
gastroenterology and, 759–760, 759*f*
intestinal, 770–773
clinical presentation of, 770–771, 771*f*–772*f*
clinical significance of, 770–771
diagnostic testing and confirmation of, 771, 772*f*–773*f*
prevention of, 773
prognosis for, 773
therapy for, 773
Forelimb amputations, 1111
Forensics, 1464–1475
animal health and, 1465
animal welfare and, 1465
captivity, animals in, 1465
chain of custody in, 1473
clinical investigation for, 1466–1469, 1467*b*
conservation and, 1465
considerations in, 1466–1469
crime scenes and, 1473
customs and, 1465
evidence for, 1466
collection and packaging of, 1468*f*–1470*f*, 1472*f*–1473*f*, 1474–1475
quality of, 1466
retention of, 1475
examination procedures for, documentation of, 1474
findings in, record-keeping and collation and analysis of, 1473
general legal principles of, 1464
judicial systems in, 1464
law in, 1464
health and safety, 1466
international trade/movement and, 1465
laboratory investigations for, 1472
legal considerations for, 1464–1466
pathology and postmortem examinations for, 1469–1472, 1471*b*
photography in, 1473–1474
relevant law in, 1464–1465
report, 1474
reptile and amphibian collections and, 1465
research and, 1465

Forensics *(Continued)*
in situ collection of evidence in, 1473
theft and, 1466
trade and, 1465
veterinary treatment and, 1465
videography in, 1473–1474
witnesses for, 1466
in court, 1475
Formaldehyde, 140*t*
Formalin, 366–367
concentration, 764*t*
Fornicata, 287
Foveae, 726
Fox snakes *(Pantherophis vulpinus)*, outdoor enclosures of, 125
Fractures, 907–908, 908*f*
in crocodilians, 1280, 1280*f*
fixation, 1105*f*–1106*f*
arthrodesis, 1106–1107, 1107*f*
bone grafting, 1104–1106
physical therapy, 1107–1108
iatrogenic mandibular, 1109
repair, complication of, 1106
skull, 1109–1110, 1109*f*
in snakes, 1253
spinal, 1110
Free-ranging reptiles, European legislation for, 1448–1449
fieldwork that involves, 1449
general, 1448
national laws, variation in, 1449
prohibited or controlled activities relating to, 1449
protected species of, 1448–1449, 1450*t*–1452*t*
Freeze damage, 824
Fresh tissues, 365
Freshwater crocodile, hematologic and serum biochemical values of, 333*t*–348*t*
Freshwater turtles
anesthetic protocols reported in, 450*t*–451*t*
nutritional biology of, 222
radio telemetry for, 1374–1376, 1376*f*
Frilled lizard *(Chlamydosaurus kingii)*, 64*f*
Frog virus 3 (FV3)-like
in chelonians, 250*t*–251*t*
in squamates, 252*t*
Frogs, restraint of, 224
Frostbite, in chelonian shell, 720
Fruit
nutritional value, limitation of, 128
seeds, impact, 989
Full thickness shell biopsies, in shell damage, 1339
Functional redundancy, 1430–1431
Functional Scoring System, in reptiles with possible spinal cord injuries, 1233*t*
Funduscopy, 728
Fungal infections, 1363
enteritis, 768–769, 768*f*
in sea turtles, 1386
of spectacle, 730–731, 731*f*
Fungal keratitis, 735
Fungal pneumonia, 801, 802*f*
Funnel traps, for wild amphibians and reptiles, 1367*t*
Fusarium, 279
Fusarium fujikuroi, 279
Fusarium incarnatum, 279
Fusarium oxysporum complex, 279
Fusarium proliferatum, 279
Fusarium solani complex, 279
Fusiform testes, recrudescence of, 60*f*
Fusobacteria, 246
Fusobacterium necrophorum, 246

G

Gadolinium, 572–573
Galapagos tortoise *(Chelonoidis nigra)*
hematologic and serum biochemical values of, 333*t*–348*t*
intracorporeal oophorectomy in, 619, 619*f*
intrathecal injection of lidocaine in, 478*f*
mycotic granuloma and partial glossectomy in, 1034*f*
spinal anesthesia techniques for, 477
GALT (gut associated lymphoid tissue), 356–357
Gamma-aminobutyric acid (GABA), 825, 978
Gastralia, 1062–1063, 1062*f*
Gastric lavage, 413, 414*f*
Gastric overload or impaction, 1000–1001
Gastric prolapse, 1010
Gastritis, 756
Gastroenterology, 752–774, 752*f*
anatomy and physiology in, 752–754, 761–762
clinical diseases related to, 756–758
clinical investigation in, 754–756
clinical pathology, 755
endoscopy, 755–756
history, 754–755
imaging, 755, 755*f*
physical examination, 754–755
foreign bodies and, 759–760, 759*f*
maldigestion and, 759, 759*f*
malnutrition and, 759
neoplasia and, 760
reproductive system, 775–785
Gastrointestinal (GI) disease, drug therapy for, 1185
Gastrointestinal (GI) emergencies, 976, 976*f*
Gastrointestinal (GI) impaction/foreign bodies, in amphibians, 1284, 1285*f*
Gastrointestinal (GI) surgery, 1068–1070
biopsy, 1069
hepatic biopsy/partial hepatectomy, 1069–1070
perioperative care of, 1069
principles of, in reptiles, 1068–1069, 1068*f*
Gastrointestinal (GI) system
of amphibians, signs in, 1285–1286
diagnostic sample collection for, 413–415
radiography of, in chelonians, 517–521, 520*f*–521*f*
of snakes
radiography of, 507–508, 508*f*
signs in, 1250
of tuatara, 84
Gastrointestinal (GI) tract
lower, enterostomy of, 1069
necropsy of, 375
ultrasonography of, 550, 551*f*
Gastrointestinal (GI) transit time, 43
Gastroscopy, 413, 414*f*, 607, 607*f*–608*f*
Gavage feeding, for stomatitis, 1346
Gecko *(Gekko gekko)*, descending pathways in, 467
Gecko retained "eye caps", 1026, 1026*f*
Gekkonidae, 64
parietal eye (absence), 721
Gender determination
in chelonians, 403*f*
of snakes, 396*f*
Gender identification, 857–865
General anesthesia, 447–464
anatomy and physiology in, 447–448
anesthetic emergencies in, 463
body temperature and, 459
cardiopulmonary systems and, 447–448
depth of, 459, 460*t*
drugs for, 455–457
exploratory coeliotomy (open reduction), 1092
hepatic first-pass effect in, 447–448
induction of, 457–458, 457*f*
injectable anesthetic agents for, 449–457
injection sites for, 454*t*
intranasal administration of, 454
intraoperative fluid therapy for, 459
intravenous route of, 454, 455*f*
maintenance of, 458–459
monitoring in
cardiovascular, 461–462
of respiratory performance, 462–463
techniques for, 459–463
parenteral drug administration and, routes of, 450–455
preanesthetic evaluation in, 448–449
protocols for, 450*t*–453*t*
recovery from, 463–464, 464*f*
reflexes in, 460–461
respiratory anatomy and physiology and, 448
supportive measures in, 449
thermoregulation and the effect of environmental temperature in, 447
Genomics, 1426
Genotyping (DNA/molecular sexing), 864–865
Gentamicin, 1142
allometric scaling formulary of, 1187*t*–1188*t*
for mycoplasmosis, 747*t*
toxicity, 979
Geoemydidae, 35*f*
Geophagy, 948–949
Geriatrics, 960–966
definition of, 963
palliative and hospice veterinary care of, 966
senescence, 961*f*–964*f*
shell distortion and hyperkeratosis in, 962*f*
veterinary care, 963–966, 964*f*–965*f*
Gerrhopilidae, 51
Gerrhosauridae, 64–65
Gestation, 97–98, 868–870, 868*t*, 869*f*
Giant New Caledonian gecko *(Rhacodactylus leachianus)*, hemipenis prolapse in, 878*f*
Giant waxy tree frog *(Phyllomedusa bicolor)*, corneal lipidosis in, 1287*f*
Giardia, 287, 287*f*
Gila monsters *(Heloderma suspectum)*
hematologic and serum biochemical values of, 333*t*–348*t*
venomoid surgery, 1041, 1041*f*
Gilatoxin, 986
Gingivitis, 1329
Glass, avoidance in enclosures, 925, 925*f*
Glenoid, 898
Gliosis, 819
Globe, 724
congenital abnormalities of, 734
infection of, 734
Glomerular filtration rate (GFR)
determination, 640, 641*t*
reports, 641
Glomeruli, development, 630–631, 630*f*
Glomerulonephritis, 645–646
Glomerulonephrosis, 644–645, 645*f*
Glomerulosclerosis, 644–645
Glossal prolapse, 1033
Glossal repair, 1033
Glossectomy, partial and complete, 1033
Glossitis, 1033
Glossopharyngeal nerve (CN IX), 812
Glottal tube, of snakes, 786–787, 786*f*
Glottis
diagnostic sample collection from, 410
of lizards, 788, 788*f*
physical examination of, 392–393
of snakes, 786–787, 786*f*
Glucocorticoids, 846, 847*t*, 1163–1164
Glucose, 656
amphibian, 329
analysis, 635–636
in reptiles, 329
Glutaraldehyde, 140*t*, 141
Glycogenolysis, 649–650
Glycopeptides, 1145
Glycoprotein, 630–631
Glyptemys HV1, in chelonians, 250*t*–251*t*
Glyptemys HV2, in chelonians, 250*t*–251*t*
Goggle, 722
Goiter, 949
Golden bell frogs *(Litoria aurea)*, sedated, 484*f*
Golden coin turtle, hematologic and serum biochemical values of, 333*t*–348*t*
Golden mantella *(Mantella aurantiaca)*, husbandry requirements, 229*t*–231*t*
Golfo Dulce poison dart frog *(Phyllobates vittatus)*, husbandry requirements, 229*t*–231*t*
Gonads
diagnostic sample collection from, 419
ultrasonography of, 550–554, 552*f*–556*f*
Good Practice Guide for the Use of Animals in Research Testing and Teaching, 1416
Google scholar, 9–10
Gopher snake, hematologic and serum biochemical values of, 333*t*–348*t*
Gopher tortoise, hematologic and serum biochemical values of, 333*t*–348*t*
Gout, 823, 910–911, 910*f*, 947, 1308–1309, 1308*f*
clinical presentation, 643
clinical significance, 642
in crocodilians, 1280, 1281*f*
diagnostic testing and confirmation, 643
etiological cause, 642–643
prognosis and prevention, 644
treatment, 644
Gradient-recalled echo (GRE), 573–575
