TABLE 35.1 Hematologic and Serum Biochemical Values of Reptiles—cont'd

Measurement	Carpet Python (*Morelia spilota* ssp.)[2,4,6]	Gopher Snake (*Pituophis catenifer*)[2,4,7]	Indigo Snake (*Drymarchon corais*)[2,4,8]
Phosphorus (mg/dL)	4.1 (0.8–7.9)	3.6 (1.7–7.9)	9.4 (5.8–16.6)[c]
Potassium (mEq/L)	4.9 (3.0–7.1)	4.8 (2.2–7.4)	4.4 (3.2–6.1)[i]
Protein, total (g/dL)	7.2 (5.4–10.3)	6.0 (3.7–8.8)	7.6 (5.2–12.1)[j]
Albumin (g/dL)[b]	2.1 (1.6–2.9)	2.0 (1.1–3.0)	2.4 (1.0–4.3)
Albumin (PEP; g/dL)[b]	—	—	2.3 (1.40–3.27)
Globulin (g/dL)[b]	5.1 (3.7–7.6)	4.0 (1.7–6.3)	—
α-1 (PEP; g/dL)[b]	—	—	0.8 (0.37–1.5)
α-2 (PEP; g/dL)[b]	—	—	1.32 (0.4–2.16)
β (PEP; g/dL)[b]	—	—	1.89 (1.1–3.7)
γ (PEP; g/dL)[b]	—	—	1.09 (0.23–3.73)
A/G Ratio	—	—	0.49 (0.24–0.74)[i]
Sodium (mEq/L)	156 (140–172)	163 (146–180)	167 (158–180)[j]
Triglyceride (mg/dL)	30	27 (16–37)	154 (12–552)[i]
Uric acid (mg/dL)	4.1 (0–9.3)	4.6 (1.9–12.6)	6.7 (1.5–18.3)

Measurement	Corn Snake (*Pantherophis guttata*)[2,4]	Common King Snake (*Lampropeltis getula*)[2,4]	Rat Snake (*Pantherophis obsoleta*)[2,4,9]
Hematology			
PCV (%)	30 (13–50)	31 (9–47)	30 (12–46)
RBC (10^6/μL)	0.88 (0.40–1.60)	0.77 (0.10–1.88)	0.83 (0.23–1.43)
Hgb (g/dL)	11.5 (9.7–13.5)	—	9.8 (2.8–16.2)
MCV (fL)	307 (67–546)	311 (28–618)	354 (73–636)
MCH (pg)	127 (110–143)	—	121 (90–175)
MCHC (g/dL)	35 (32–40)	—	31 (18–45)
WBC (10^3/μL)	5.93 (1.12–16.9)	7.45 (1.55–27.7)	7.83 (1.02–25.2)
Heterophils (10^3/μL)	1.24 (0.23–5.08)	1.01 (0.16–5.50)	1.20 (0.10–3.89)
Lymphocytes (10^3/μL)	2.92 (0.29–11.8)	3.92 (0.35–20.9)	3.89 (0.41–16.1)

TABLE 35.1 Hematologic and Serum Biochemical Values of Reptiles—cont'd

Measurement	Loggerhead Sea Turtle (*Caretta caretta*)[4,45]	Green Sea Turtle (*Chelonia mydas*)[4,46,47]	Hawksbill Sea Turtle (*Eretmochelys imbricata*)[h,4,48,49]
Sodium (mEq/L)	153 (142–164)	139–158	146–159
Triglyceride (mg/dL)	—	492 (124–932)	—
Uric acid (mg/dL)	0.5 (0–1.2)	1.1 (0–2.7)	0.6 (0–1.8)

[a]Listed values are median followed by either min-max or a confidence interval in parentheses depending on reported methods and the authors' judgment from the available evidence, unless there is a single value indicating n = 1, a range enclosed in parentheses indicating min-max, or a range that is not enclosed in parentheses indicating a reported reference interval.
[b]Albumin is measured by colorimetry (e.g., bromocresol green), and globulin value is calculated unless otherwise indicated "PEP" (protein electrophoresis).
[c]Remarkably high reference ranges for Ca (mean, 159 mg/dL; range, 30–337 mg/dL) and P (mean, 35 mg/dL; range, 8–69) have also been reported.[50]
[d]Can be elevated in gravid females.[19]
[e]These data were obtained from iguanas housed outdoors with unfiltered sunlight.
[f]Adults.
[g]Calculated from data.
[h]Juveniles.
[i]Varies between sexes.
[j]Varies between summer and winter.

**Mean ± SD

[a]Hematology is presently of limited diagnostic value because of the lack of normal data and the wide variation in hematologic and biochemical values according to sex, season, and state of hydration.

[b]For leukocyte totals and percentages for various species, refer to the wildlife leukocytes website at wildlifehematology.uga.edu.

[c]Median ± 25% to 75%

Molecular Infectious Disease Diagnostics

James F.X. Wellehan and Stephen J. Divers

Molecular techniques have resulted in rapid advances in both our understanding of the diversity of infectious agents in reptiles and amphibians and our ability to specifically and sensitively diagnose these agents. This has brought a more nuanced understanding of the complex interactions between host, pathogen, coinfections, and environment in causing disease. Conversely, these techniques may not be well understood by the practitioner, leading to misinterpretation of results and bad clinical decisions. It is important for clinicians to understand the basics of molecular diagnostic testing and the potential problems, common errors, and clinical implications of results.

SEROLOGY OR CULTURE COMPARED WITH MOLECULAR TECHNIQUES

When testing for infectious agents, it is first important to determine what information is being sought. Are you looking for a pathogen, such as a virus or bacterium, or are you looking for a reaction to a pathogen, such as an antibody response? The molecular testing emphasized in this chapter tests directly for the presence of a pathogen. Immunologic testing gives evidence that an animal has had an immune response to a pathogen, but does not give information whether the pathogen is currently present. Looking at changes in immune response over time is typically needed to determine the current relevance of an immune response; this requires assaying immune response at more than one time point (e.g., paired rising titers).

For immunologic testing, it is also important to consider whether the patient has had time to develop an immune response to a pathogen. This may take several weeks in reptiles.[1] In acute infections, a specific immune response may not be present. There are large seasonal and temperature effects on the immune response of reptiles, as well as species differences.[2–4] Other factors, including reproductive status and exogenous corticosteroid administration, may also affect development of a measurable immune response.[5,6]

When testing immune response, it is also important to consider what aspect of the acquired immune system is being measured. There are two branches of the acquired immune system, cellular immunity and humoral immunity. A humoral immune response primarily produces antibodies to fight specific pathogens extracellularly. A cellular immune response centers around T-cell receptor recognition of a specific intracellular pathogen presented by a major histocompatibility complex, which are present on all host cells. Cellular and humoral immune responses are often found together but not always. An animal may have a cellular immune response without a significant humoral immune response and vice versa. Most common assays measure humoral immunity. A cellular immune response is typically most protective for intracellular pathogens such as viruses. Many intracellular pathogens elicit a relatively poor humoral immune response. A study of tortoise herpesvirus 3 (TeHV3) in *Testudo graeca* found that only three of four experimentally infected animals developed detectable humoral immune responses, and the responses in the three that did react were relatively transient.[7]

Especially in reptile species, whose pathogen diversity has not been well studied, there is concern of nonspecific cross-reactivity of antibodies against as-yet unstudied but antigenically related species. Although antibody cross-reactivity does correlate with genetic distance,[8] small genetic distances may be clinically significant. For example, *Testudinid herpesvirus 2* (TeHV2) (endemic in California desert tortoises, *Gopherus agassizii*) is distinct from TeHV3 (endemic in Greek tortoises) at a level greater than that seen between *human herpesvirus 1* (causing cold sores in humans, rapidly fatal in marmosets) and *Macacine herpesvirus 1* (causing cold sores in rhesus macaques; rapidly fatal herpes B in humans). It is probable that the clinical significance of the different tortoise herpesviruses in different species is comparable.

Before the diversity of tortoise herpesviruses was understood, a serosurvey of California desert tortoises using what was later shown to be TeHV3 as an antigen found that a number of California desert tortoises were seropositive; this was almost certainly cross-reactivity of antibodies to TeHV2 with TeHV3.[9] Treating diverse herpesviruses as a single entity may lead to inappropriate management decisions. From a population management perspective, it is crucial to know which viruses are endemic in a host species and the pathogenic implications of these viruses in other potential contact species.

Similarly, hemagglutination inhibition assays for ophidian paramyxoviruses in the genus *Ferlavirus* show poor concordance between different assays using different isolates.[10] There has recently been work done expanding the known diversity of the genus *Ferlavirus,* and at least three distinct clades are known.[11] The seroreactivity of samples from different snakes to different paramyxovirus strains differs significantly (Wellehan et al., unpublished data), and this may account at least in part for the lack of concordance seen. Overall, there are few pathogen clades whose diversity in reptiles is well enough understood to be confident of the specificity of a detected antibody. This limits the current utility of serological diagnostics in reptile medicine.

Culture of a pathogen from a diseased reptile has traditionally been utilized for direct identification of infectious agents. Although culture is still important, for some highly significant reptile pathogens such as *Chlamydia pneumoniae* or *Mycoplasma agassizii,* standard culture conditions will not support growth. Successful culture conditions have yet to be determined for the vast majority of microbes. Typically, around 10% of bacterial species can be cultured in a given ecologic niche,[12] and success at culturing viruses or protozoa is even lower.

Even if an agent has been cultured, it is still necessary to identify it. Biochemical methods for bacterial identification have been the standard for the past century. These methods have been best developed for two phyla of bacteria: Proteobacteria, the "typical" gram negatives, and Firmicutes, the "typical" gram positives. However, some of the most medically significant phyla in reptiles, such as Actinobacterium

VetBooks.ir

(containing *Mycobacterium, Devriesea,* and *Austwickia,* and others) and Chlamydiae (containing *Chlamydia* and others) are poorly identified by standard biochemical methods. Molecular methods involving nucleic acid sequencing are superior for identification.[13] The contrast is even more stark in molecular versus classical fungal identification, where identification has been morphologic, missing significant cryptic diversity. The most significant fungal pathogens of reptiles are *Ophidiomyces ophiodiicola* and *Nannizziopsis guarroi.* Although these were commonly called anamorphs of *Nannizziopsis vriesii,* there was no support for this when sequence data from these isolates were examined.[14,15] Sequence-based identification methods should be used to identify any agent where there is reason to question identification by conventional means.

POLYMERASE CHAIN REACTION (PCR)

Polymerase chain reaction (PCR) directly tests for the presence of a specific nucleic acid, in this context from an infectious agent (pathogen). Like other pathogen isolation techniques, this requires that the clinician submit an appropriate sample that contains the actual pathogen. A negative test does not mean that the pathogen is not present elsewhere in the patient. Unlike pathogen isolation, with PCR, the suspected agent does not need to be viable, but nucleic acid needs to be intact. Formalin degrades nucleic acids significantly.[16] The first step in sample processing is nucleic acid extraction. If an RNA template (typically an RNA virus) is to be amplified, the RNA will have to be transcribed into DNA, a process known as reverse transcription.

DNA is composed of two complementary strands oriented in opposite directions (Fig. 36.1A). Primers (short single-stranded segments of DNA) are designed to match the sequence of the two strands of pathogen DNA in a manner such that they face one another. Validation of primers is critical, and labs should provide a peer-reviewed publication on validation of a given primer set for diagnostic use to clinicians for evaluation (required for accreditation by the AAVLD, American Association of Veterinary Laboratory Diagnosticians). The DNA is heated so that the two strands separate (see Fig. 36.1B). The temperature is then decreased to an appropriate temperature for the primers to anneal (bind) with the DNA (see Fig. 36.1C). If the primers do not match with the DNA sequence, they will not anneal, and no product will be formed. The temperature is then increased to an appropriate temperature for thermostable DNA polymerase to extend the primer, making a matching strand for the DNA (see Fig. 36.1D). The amount of DNA between the primers present is thus doubled. The cycle starts over again as the DNA is reheated to separate the strands. The cycle is repeated many times, and the amount of DNA increases geometrically.

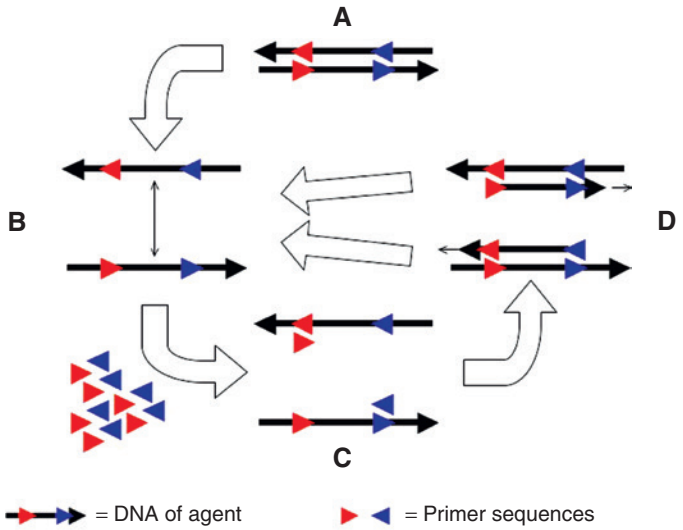

FIG 36.1 (A) DNA is composed of two complementary strands oriented in opposite directions. (B) The DNA is heated so that the two strands separate. (C) The temperature is then decreased for the primers to anneal (bind) with the DNA. (D) The temperature is then increased for thermostable DNA polymerase to extend the primer, making a matching strand for the DNA. The amount of DNA between the primers present is thus doubled. The cycle starts over again as the DNA is reheated to separate the strands. The cycle is repeated many times, and the amount of DNA increases geometrically. (Courtesy of James F.X. Wellehan.)

The PCR product must then be validated, meaning that it must be determined to be the appropriate product and not an accidental binding of the primers to an unexpected site on a different DNA template. Formerly, older validation methods were limited to measurement of the size of the product by gel electrophoresis or restriction fragment length polymorphism (RFLP). These methods are significantly less accurate than modern methods, such as sequencing or probe hybridization, and should no longer be considered acceptable.

The most definitive way to determine the identity of the PCR product is to sequence it. Whereas this was once expensive, with the rapid improvements in sequencing technology that have taken place in the past decade, costs are now minimal. This provides not only the possibility of identifying known organisms but also characterization of novel organisms by comparison to reference sequences and subsequent phylogenetic analysis. Although capable of identifying novel organisms, it is slower and more labor intensive than probe hybridization quantitative (qPCR).

Alternatively, a labeled piece of DNA containing part of the target sequence may be used to probe the PCR product. The probe must be designed to a sequence unique to the pathogen found within the PCR product. When done under the appropriate conditions, binding of the probe to the PCR product indicates that the PCR product is correct. Some protocols, such as probe hybridization qPCR, have the probe incorporated as the PCR is running, and this is discussed in the following section.

PROBE HYBRIDIZATION QUANTITATIVE PCR

Probe hybridization quantitative PCR (qPCR), also known as real-time PCR, is a PCR variant. Similar to standard PCR, primers (short single-stranded segments of DNA) are designed to match the sequence of the two strands of pathogen DNA in a manner such that they face one another. The difference is the addition of a dye-labeled probe that matches and binds to sequences between the two primers. Two dyes, a reporter dye, to be detected by a spectrophotomer during the reaction, and a quencher dye, which absorbs the spectrum emitted by the reporter dye, are bound to the probe (Fig. 36.2A). As before, the DNA is heated so that the two strands separate (see Fig. 36.2B). The temperature is then decreased to an appropriate temperature for the primers and probe to anneal (bind) with the DNA (see Fig. 36.2C). If the primers do not match with the DNA sequence, they will not anneal and no product will be formed. The temperature is then increased to an appropriate temperature for thermostable DNA polymerase to extend the primer, making a matching strand for the DNA (see Fig. 36.2D). DNA polymerase, in addition to extending the primer to match the template DNA, also has exonuclease activity, which means that it will chew up any DNA in front of it that gets in the way as it is extending the primer. If the probe is bound to the template in front of the primer, the polymerase will chew through the probe, releasing the labeled dye. This separates the reporter dye from the quencher dye, and the released reporter dye can be measured with a spectrophotometer.

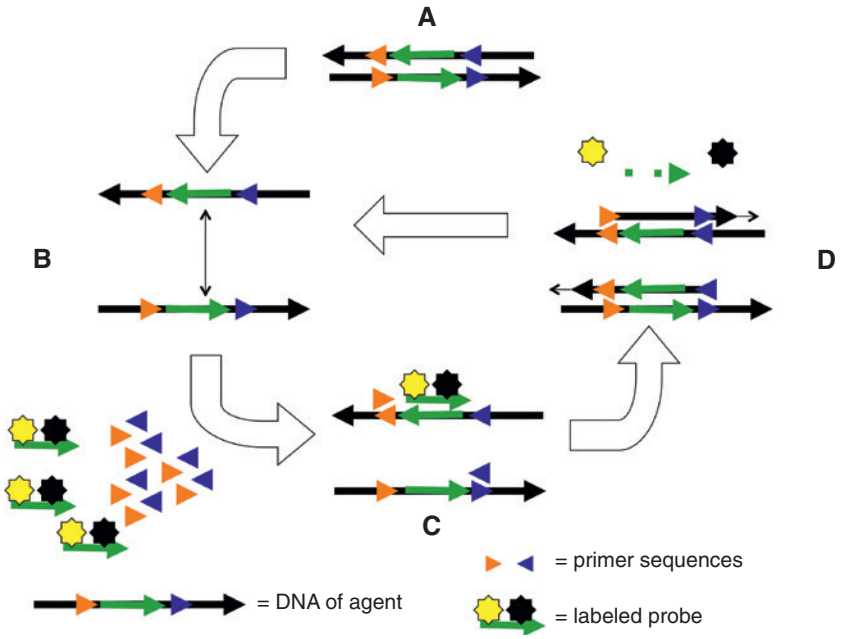

FIG 36.2 (A) Probe hybridization quantitative PCR (qPCR), also known as real-time PCR, is a PCR variant. Similar to standard PCR, primers are designed to match the sequence of the two strands of pathogen DNA in a manner such that they face one another. The difference is the addition of a dye-labeled probe that matches and binds to sequences between the two primers. (B) Two dyes, a reporter dye, to be detected by a spectrophotomer during the reaction, and a quencher dye, which absorbs the spectrum emitted by the reporter dye, are bound to the probe. As before, the DNA is heated so that the two strands separate. (C) The temperature is then decreased to an appropriate temperature for the primers and probe to anneal (bind) with the DNA. If the primers do not match with the DNA sequence, they will not anneal and no product will be formed. (D) The temperature is then increased to an appropriate temperature for thermostable DNA polymerase to extend the primer, making a matching strand for the DNA. DNA polymerase, in addition to extending the primer to match the template DNA, also has exonuclease activity, which means that it will chew up any DNA in front of it that gets in the way as it is extending the primer. (Courtesy of James F.X. Wellehan.)

This has two distinct advantages. First, the validation of the PCR product is rapid. Validation in probe hybridization qPCR is done during the reaction, data output is simple, and no further steps are necessary. Second, the release of dye depends on the amount of template present, providing quantitative information. In Fig. 36.3, a qPCR standard curve is shown. The horizontal axis is number of cycles, and the vertical axis is fluorescence. The arrows drawn on the figure indicate the number of template copies present in the initial reaction. When there are only 10 copies initially present, it takes approximately 37 cycles for the reaction to release enough dye to cross the threshold (green) line. When there are 1,000,000 copies initially present, the threshold is crossed after approximately 19 cycles. This provides a standard to compare samples to and also provides a control to ensure that reactions are working well and efficiently. Quantitative information can be clinically useful to determine whether loads are sufficient to consider as a disease etiology and to follow trends over time to assess response to therapy. A well-designed qPCR is a highly useful tool for specific identification of a known agent. When well designed and properly validated to ensure the assay specifically identifies only the target DNA, probe hybridization qPCR can be a sensitive, specific, rapid, quantitative, and relatively inexpensive test. Proper validation is critical, and labs should provide a peer-reviewed publication on validation of a given probe hybridization qPCR assay for diagnostic use to clinicians for evaluation. There are established guidelines for validation of a qPCR assay.[17]

It is important to realize that there are other assays commonly called real-time PCR that do not involve validation by probe hybridization. The most common of these utilizes SYBR green dye, which is incorporated into DNA as it is synthesized. This methodology does not provide any data on the size or sequence of the PCR amplicon, making it even more prone to false positives than gel electrophoresis. Especially when dealing with diverse host species, as is commonly done in reptile medicine, this methodology should not be utilized.

CONSENSUS PCR TECHNIQUES

Before primers can be designed, the nucleic acid sequence must be known. Some nucleic acid sequences are specific to a given species or even strain. Other nucleic acid sequences have stayed the same through evolution and are found across groups of related organisms. These are known as consensus sequences. Genes that are conserved throughout evolution are typically essential for function of the organism, such as ribosomal RNAs (rRNA) or viral polymerases. Gene choice is critical and depends on the level of taxonomic resolution needed. Within adenoviruses, the polymerase is the most conserved gene, and primers have been designed that will amplify any adenovirus.[18] However, when looking specifically at Agamid adenovirus 1 in bearded dragons, all polymerase sequences obtained to date show minimal variation, and it was necessary to obtain sequence from the hexon gene to differentiate strains.[19] Once consensus sequences have been identified, PCR primers

VetBooks.ir

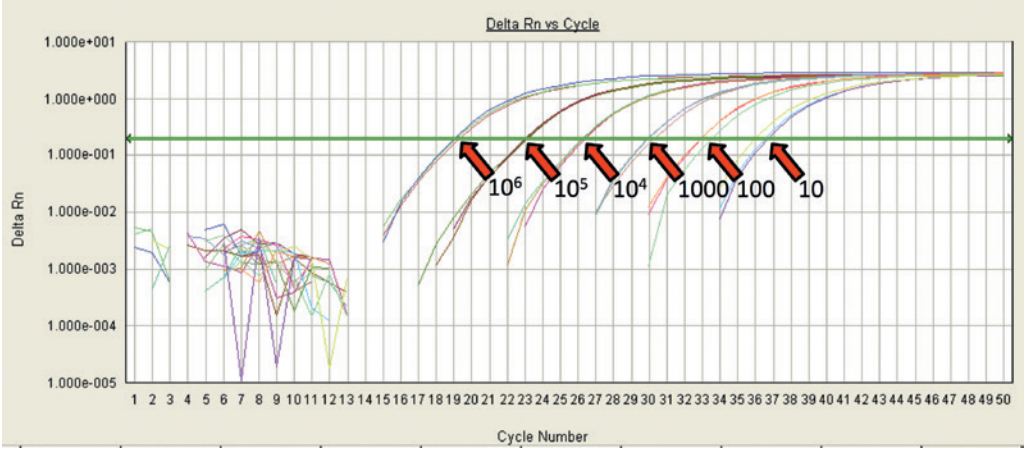

FIG 36.3 A qPCR standard curve is shown. The horizontal axis is number of cycles, and the vertical axis is fluorescence. The arrows drawn on the figure indicate the number of template copies present in the initial reaction. When there are only 10 copies initially present, it takes approximately 37 cycles for the reaction to release enough dye to cross the threshold (green) line. When there are 1,000,000 copies initially present, the threshold is crossed after approximately 19 cycles. (Courtesy of James F.X. Wellehan.)

can be designed in these conserved regions and used to amplify the more variable region between the consensus primers. In reptile medicine, many pathogens remain to be identified. If primers designed to conserved sequences are used in a PCR, the PCR will amplify all organisms containing the conserved sequence, providing the ability to identify novel pathogens in a known clade. Diverse published assays are available for a wide variety of taxonomic levels, ranging from the entire domain of prokaryotes,[20] the class Coccidia,[21] the family Adenoviridae,[18] and the genus *Orthoreovirus*,[22] to allow even more specificity. However, caution is needed. When more than one member of a clade is present in a sample, direct Sanger sequencing of a PCR product will result in mixed sequence that is unreadable. Protocols such as pan-bacterial or pan-fungal PCR are useful for identification of isolated bacteria or fungi, respectively, when ID by conventional methods is questionable. However, application of these methods directly to clinical samples that are likely to have diverse bacterial or fungal flora present, such as oral samples or fecal samples, it is unlikely to result in a product that can be directly sequenced and interpreted. More narrowly targeted assays should therefore be used on such samples (e.g., genus *Mycobacterium*-specific PCR, if that is an important differential) to detect more specific agents of possible concern.

Although consensus sequence PCR is useful for amplification of sequence from novel pathogens, the amplification of novel sequences does not lend itself to specific probe design, eliminating qPCR as an option for this application. Consensus PCR should always be accompanied by sequencing of the PCR product.

ROLLING CIRCLE AMPLIFICATION

Rolling circle amplification (RCA) is a technique for amplification of small circular DNA genomes, as are found in several families of viruses, including papillomaviruses, polyomaviruses, anelloviruses, circoviruses, and tornoviruses. It does not require knowledge of any sequence from the agent. The technique involves a polymerase that moves around the circle as it synthesizes a complementary strand. When the beginning of the circle is reached, the polymerase continues around again, and the new strand is a long series of repeated copies of the circle. This strand is then cut with a restriction enzyme, which recognized specific short 4 to 6 base pair sequences. Since these sequences will be in the same place every time the circle is repeated, the restriction enzymes cut the circle into a set of pieces of specific size. These pieces can then be cloned and used as sequencing template. Because it does not require any known sequence, RCA has proven useful for obtaining sequence templates of divergent agents, such as tornoviruses in sea turtles.[23] However, this technique requires a significant amount of cloning and sequencing and is therefore highly labor intensive, raising costs.

HIGH THROUGHPUT SEQUENCING

Recent years have seen amazing advances in sequencing technology. Costs have been reduced several orders of magnitude. New techniques, including pyrosequencing, Illumina sequencing, PacBio, and SOLiD sequencing are capable of producing millions of sequences in a single run. This has enabled the development of metagenomics, in which nucleic acid representing an entire sample is sequenced, rather than targeted amplification of a specific region. This enables an understanding of the diversity of complex and diverse environments such as the reptile GI tract.[24] The ability to obtain such data sets is a double-edged sword; although it provides the ability to obtain sequences from previously unknown and divergent pathogens, it requires the ability to recognize and sift these sequences out of literally millions of nontarget sequences. This is a major bioinformatics challenge but has already resulted in significant advances in our knowledge of reptile/amphibian infectious disease. Recent discoveries of important reptile pathogens, such as sunshine virus, reptarenaviruses, and ball python nidovirus, have all been based on next-generation sequencing techniques.[25–27] Although costs for metagenomic methods are still considerable, they are decreasing rapidly, and what was a $100,000 project a couple of years ago is a $1000 project now. It is only a matter of time before these techniques become clinically affordable.

SAMPLE COLLECTION FOR NUCLEIC ACID–BASED DIAGNOSTICS

The first thing the practitioner needs to do is open a dialogue with the diagnostic laboratory. It is important first to understand what

VetBooks.ir

methodologies are offered, and ideally, peer-reviewed references describing testing methodologies should be provided to the clinician. Common problems and pitfalls should be discussed in advance, as well as limitations of diagnostic testing.

Histologic evaluation of a necropsy is often one indication that an agent requiring molecular testing is present. As such, although it is critical to collect a complete set of tissues in formalin for histologic evaluation, it is also important to save and freeze another set for further diagnostics if indicated by histology. Frozen tissues should be routinely kept until histologic results are back, and there is no indication for further diagnostics.

Sample choice is critical for nucleic-acid based diagnostics; the agent must be in the sample. This requires an understanding of the common distribution of the agent in the animal. Although plasma has historically been a common sample collected for infectious disease diagnostics (due to the use of serodiagnostics), relatively few infectious agents are themselves commonly found in plasma, making it a suboptimal sample choice for testing for most reptile pathogens. A laboratory with significant clinical experience with a given reptile pathogen may be able to advise on sample choice.

PCR is a highly sensitive technique, and the potential for false-positive results from slight contamination anywhere from collection to laboratory is high. As such, it is critically important that measures are taken to avoid contamination during sample collection and transport and that appropriate controls are run.

Transport is also crucial and needs to be discussed with the laboratory in advance. Agents such as RNA viruses, especially enveloped ones, tend to be significantly less environmentally stable. Media such as RNAlater can be used to preserve viability of nucleic acids. Shipping on ice or even dry ice is often preferable. When same-day transport is not available, overnight shipping is indicated. The laboratory should be notified in advance so that potential problems can be identified and brought up with the shipping service on the same day if a delivery does not arrive.

It is an exciting time in herpetological medicine. Molecular techniques are enabling us to begin to unravel the diversity of pathogens in reptiles and amphibians and detect them in a clinically applicable fashion. An understanding of molecular diagnostic options and their clinical interpretation are essential in modern reptile practice.

HOW TO CHOOSE A LABORATORY

It is important for the clinician to be able to assess the quality of results from the laboratory. The American Association of Veterinary Laboratory Diagnosticians accredits public laboratories, and AAVLD accredited laboratories should be preferred. Any project receiving US federal funding has to use a laboratory meeting GLP (Good Laboratory Practice) standards, but this is not required of private diagnostic submissions. There is no useful accreditation organization for private veterinary diagnostic laboratories in the United States. Important questions that practitioners should ask laboratories include:

1. What protocols are used? Are they from peer-reviewed literature? If so, are they used as in the literature or modified? Practitioners should obtain copies of peer-reviewed literature on protocols used.
2. What controls are used? Nucleic-acid-based testing should have both extraction controls and reaction controls.
3. If PCR-based testing, how are products validated? Acceptable methods include sequencing of products and validated probe hybridization (such as TaqMan). Older, less-specific methods, such as size of a band on electrophoresis, restriction digest fragment size or SYBR green dye incorporation should be avoided. It is important that probe hybridization protocols are properly validated; this should be published in a peer-reviewed journal.

Immunopathology

Elizabeth W. Howerth

Reptiles have a functional and complex immune system that includes innate, humoral, and cell-mediated components. However, the efficiency of the immune system is influenced by a variety of factors, such as health, nutritional status, age, and stress. In addition, environmental temperature, brumation (hibernation) or estivation, and seasonal changes also affect the efficiency of the immune system. Because reptiles are ectothermic, the immune system is dependent on the ability of the animal to maintain adequate core body temperature.

CELLS AND TISSUES OF THE IMMUNE SYSTEM

The tissue components of the reptile immune system include bone marrow, thymus, and spleen, as well as gastrointestinal-, respiratory-, and urogenital-associated lymphoid tissue. In some cases lymph node–like organs are present.[1] Reptiles, unlike mammals, do not have usual lymph nodes and do not form germinal centers, which is where B-cell and helper T-cell interaction, B-cell proliferation, isotype switching, and affinity maturation associated with an adaptive immune response occur in mammals.[1,2] In the reptile, the spleen is thought to be critical for reptilian immune function, assuming the functional role of lymph nodes.[3] Reptiles also do not have a bursa, but a bursalike lymphoid organ is found in the cloacal wall in some reptiles.[4]

The reptilian bone marrow produces both red and white cells, including lymphocytes, and is found in medullary bone throughout the body. In turtles and tortoises this includes the carapace and plastron of the shell.

In general, the thymus of reptiles is bilateral and composed of a variable number of lobulated or nonlobulated glandlike nodules or lobes. Frequently the thymus of each side consists of two small white lobes that are separate from each other. The thymus is located in the cervical region and may be contiguous with or immediately adjacent to the parathyroid glands and next to the ultimobranchial bodies and great arterial vessels and often extends to the base of the heart. It may be embedded in fatty tissue in well-nourished animals and be difficult to identify.

In lizards and tuatara, the thymus is described as nonlobulated, whereas chelonians and crocodilians have distinct thymic lobules.[4,5] Snakes have a spherical, single-lobed, double-lobed thymus immediately anterior to the heart between the thyroid gland and lateral fat body on each side.[5] The sea turtle thymus is an elongated gland on each side of the body, usually within fat, which may be thin and diffuse in chronically ill animals.[6] Crocodiles and alligators have a thymus more like a bird, which is elongated and may be embedded in fat and traverse the length of the neck on both sides of the trachea and into the thorax to the base of the heart.[5,7] In young crocodilians, there may be posterior enlargement of the right and left sides that may meet over the thyroid.[5]

Histologically, the thymus is delimited by a capsule, and the parenchyma is subdivided into a cortex and medulla composed of predominantly small- and medium-sized lymphocytes and a stroma of epithelial cells (Fig. 37.1). Hassall's corpuscles may be present, as well as other cell types such as myoid cells and secretory-like cells.[8]

The spleen produces red and white cells and in most reptiles is spherical, oval, or elongated triangularly and is histologically similar to higher vertebrates being composed of red and white pulp. In some reptiles, the spleen is contiguous with the pancreas, and there may be some admixture of both splenic and pancreatic tissue. This is entirely normal in many chelonians and some snakes, where it is referred to as splenopancreas (Fig. 37.2); in other reptiles the two organs are entirely separate.[4]

The reptilian thymus and white pulp of the spleen exhibit seasonal changes, involuting during the winter and becoming well developed again by the spring (Fig. 37.3).[1] It has been noted in snakes that cortex and medulla of the thymus are poorly defined during winter.[8] Splenic lymphocytolysis may lead to impaired immune function in the winter in some species.[9] Seasonal variation in GALT also has been noted but appears to be species specific.[1]

Lymphoid aggregations composed of lymphocytes and plasma cells occur in the gastrointestinal tract (gut associated lymphoid tissue [GALT]).[8] GALT occurs throughout the intestine, but the most important sites are esophagus, ileum, ileo-cecal junction, colon, and cloaca. These are small nonencapsulated aggregates mainly in the lamina propria, but they may extend deeper in the submucosa. These may reach a large size in certain sites of various reptiles. The lymphoid cloaca complex described in some reptiles may not be related to the bursa of Fabricius

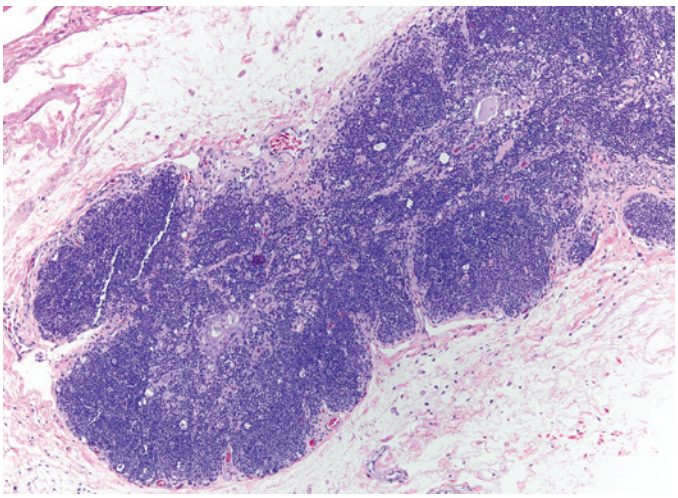

FIG 37.1 Normal lobulated thymus from an alligator (*Alligator mississippiensis*). (H&E, ×10). (Courtesy of Elizabeth Howerth, University of Georgia.)

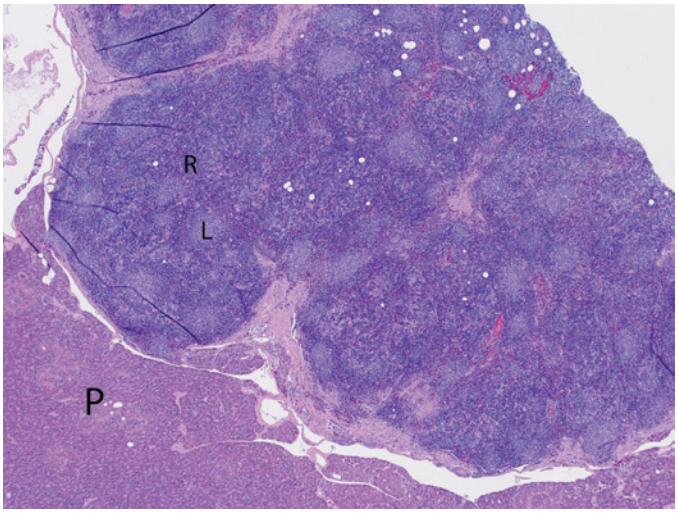

FIG 37.2 Normal splenopancreas from a corn snake (*Pantherophis guttatus*). The spleen is similar to a mammal with red (R) and white (L) pulp. P = pancreas (H&E, ×4). (Courtesy of Elizabeth Howerth, University of Georgia.)

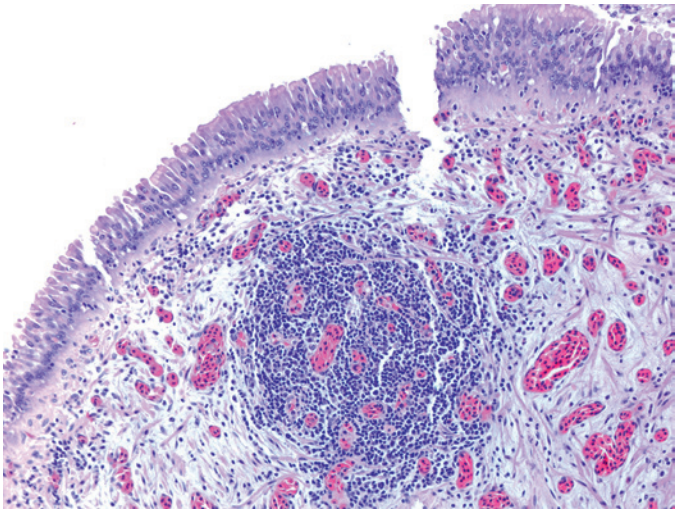

FIG 37.4 Normal urinary bladder from a turtle with typical subepithelial lymphoid aggregate. Similar aggregates occur throughout the gastrointestinal and respiratory tracts (H&E, ×20). (Courtesy of Elizabeth Howerth, University of Georgia.)

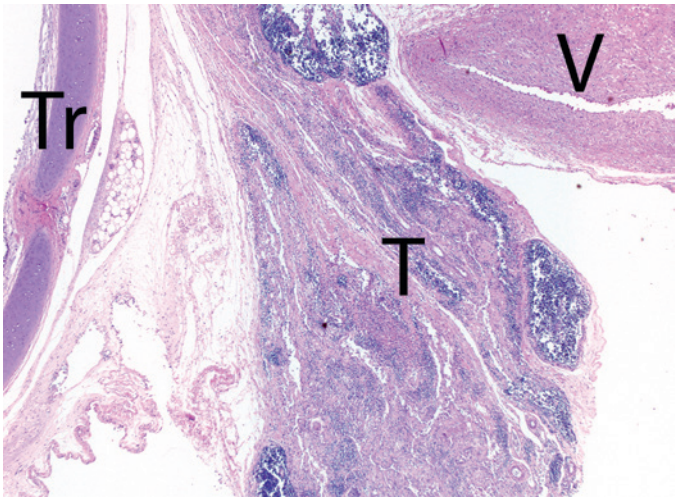

FIG 37.3 Thymic involution in a tortoise. Involution or atrophy can occur for a variety of reasons, including a normal seasonal response, but can also be driven by such things as exposure to estrogenic compounds, high levels of testosterone, or endocrine-disrupting chemicals. T = lymphoid depleted thymus; Tr = trachea; V = cervical vessel (H&E, ×4). (Courtesy of Elizabeth Howerth, University of Georgia.)

of birds because the histology is different. Lymphoid aggregates also occur in the lung, pancreas, urinary bladder, testes, and axillary and inguinal regions (Fig. 37.4). The esophagus of boid snakes has raised ovoid structures with a central cleft referred to as esophageal tonsils. Histologically these are submucosal lymphoid aggregates covered by mucosal epithelium and are important sites for the detection of viral inclusion bodies in boid snakes with arenavirus inclusion body disease.[10] Similar esophageal submucosal nodules have been described in other species of snakes.[11] In some species, small organs similar to lymph nodes have been found in axillary and inguinal areas.[8]

INNATE IMMUNITY

Innate immunity is the first line of defense against pathogens and has a critical role in the activation and regulation of adaptive immunity. The concept of innate immunity being nonspecific to an antigen and lacking memory has evolved into one of a more specific immunity based on pattern recognition receptor molecules (PRRs) and even memory development.[12] In the reptile, the major components include intact epithelial barriers (e.g., skin, gastrointestinal, respiratory, urinary), physiological parameters (e.g., stomach pH, body temperature), and humoral and cellular effector components.[12]

Humoral innate immunity in reptiles includes lysozyme, antimicrobial peptides, acute phase proteins, complement, and certain cytokines.[12] Antimicrobial peptides are known in three of the four orders of reptiles, the testudines, crocodilians, and the squamata, and include members of the cathelicidin and defensin families unlike birds, reptiles also express hepcidins.[13] Reptile heterophils have granules that contain both cathelicidin-like peptides, as well as β-defensin. The β-defensin-like peptides and lysozyme are also found in reptile eggs. The few reptilian antimicrobial peptides that have been isolated and studied demonstrate broad-spectrum antimicrobial and antifungal activity. Expression of these peptides has also been found in wounds, such as when lizards lose their tails.[13]

The acute phase response is an early defense system activated by infection, injury, and inflammation, which results in changes in the concentration of many plasma proteins, known as acute phase proteins (APP), mostly produced by the liver. In reptiles, described APPs are serum amyloid A and fibrinogen.[12] The complement system is composed of serum proteins that react against pathogens through a molecular cascade; however, the molecular makeup of the reptilian complement system remains poorly defined, and only complement protein C3 has been identified.[12] Likewise, information on cytokines in reptiles is sparse, but they appear to have certain cytokines that are well-conserved among vertebrates, such as type II interferons, certain interleukins, and TGF-β.[12]

Cell-mediated innate immunity in reptiles includes intraepithelial T lymphocytes in the intestinal epithelium, phagocytic cells (monocytes-macrophages, heterophils, and dendritic cells), basophils, eosinophils, possibly nonspecific cytotoxic cells, and phagocytic B cells.[12,14] In reptiles, phagocytosis plays an important role in immune response, because it is less influenced by temperature than adaptive immune mechanisms.[12] However, the phagocytic response appears to have seasonal variation.[15,16]

VetBooks.ir

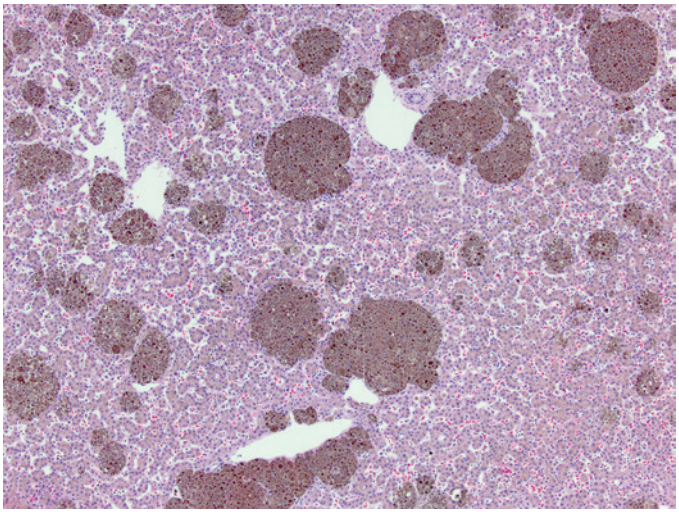

FIG 37.5 Liver from an emaciated Indian star tortoise (*Geochelone elegans*) that had severe pseudogout with an increased number and size of melanomacrophage systems (H&E, ×10). (Courtesy of Elizabeth Howerth, University of Georgia.)

Natural killer cells are an important subset of lymphocytes with the innate ability to kill infected cells without being primed and activated. Although NK cells have not been specifically identified in reptiles, there is evidence of the existence of specific cell types or a functionally similar group of cells in reptiles.[15–18] Reptiles also have circulating monocytes called azurophils due to their azurophilic-staining granules that appear to function similar to mammalian monocytes.[19]

In vertebrates, the "professional phagocytes" recognize senescent cells and microbes by pattern-recognizing receptors (PRRs), including Toll-like receptors and C-type lectin receptors. However, as important as these receptors are and how well-studied they are in other vertebrates, knowledge of PRRs in reptiles is scarce.[20]

The reptilian heterophil is functionally similar to birds, and phagocytosis is its primary function.[21] They are morphologically variable among species but contain two, possibly three, types of granules that contain cationic proteins, lysozyme, acid phosphatases, and acid hydrolases but lack myeloperoxidase, catalase, and alkaline phosphatase. Therefore heterophils depend on a nonoxidative method of killing and do not form pus. Heterophils also contain B-defensins, which have a broad spectrum of activity against infectious agents.[19]

Although eosinophils likely play a role in parasitic infections, little is known about their function.[1] Reptilian basophils are likely to be important in inflammation as they degranulate and release histamine when triggered by an antigen; the release is dependent on antigen concentration and temperature.[1] Aggregates of melanin-containing macrophages (melanomacrophages) normally occur in the liver of reptiles, and with systemic inflammation they can proliferate and even develop in other sites, such as the spleen (Fig. 37.5).[22] In the yellow mud turtle, and most likely in all reptiles, liver aggregations increase in number and size with age.[23] These cells contain melanin granules and also hemosiderin and lipofuscin and are phagocytic. The melanin granules are thought to produce free radicals and therefore may be involved in bacterial killing.[22,23]

ADAPTIVE IMMUNITY

Adaptive immunity occurs following the innate immune response. Current knowledge regarding the function of the reptilian adaptive immune system is poor, although T-cells and B-cells are recognized. The site of origin of reptilian B-cells is unknown, but sites of lymphopoiesis likely include bone marrow, spleen, and other locations in the body.[21] There is evidence that reptilian B-cells possess phagocytic activity.[24] T-cells probably arise from lymphocytes in the bone marrow that colonize the thymus and differentiate into T-cells.[21]

Antibodies in reptiles are considered to be IgM, IgY, IgA, and IgD.[25,26] IgM is probably present in all reptiles as it is conserved across vertebrates, but there is variability among species as to which other classes are present, and in some species more than one form of certain immunoglobulin classes may be present (e.g., sea turtles have three forms of IgM and two of IgY).[27] Immunoglobulins are poorly studied in reptiles, but, in general, the structure of the reptile immunoglobulin is thought to be similar to mammals, although reptile immunoglobulins apparently do not have a hinge.[28] IgM is highest in blood and spleen but is also present in lung and intestine and so may play a role in mucosal immunity.[26] IgY is often considered the functional equivalent to IgG of mammals and expressed in liver and spleen in a T-cell-dependent manner when present.[26] Turtle IgY binds to protein G in contrast to IgY of birds, which does not, so reptile IgY might be more similar to mammalian IgG.[27] IgD may play a role in mucosal protection too.[26] An IgA-like gene is present in some species but lost in others. In gecko and crocodiles, it is expressed in high levels in the intestines and may have a role in mucosal immunity.[26] Reptile immunoglobulins undergo class switch recombination similar to mammals and function similarly to mammals in regard to agglutination, precipitation, and virus neutralization.[26]

Lymphocyte production is affected by stress, temperature, and season (decreased during fall and winter). Both cold and prolonged high temperature can affect antibody production.[29] Pregnancy in viviparous lizards may impair the immune response and is associated with splenic involution.[30] Environmental temperature can affect both antibodies and leukocytes.[26]

Measurement of the humoral immune response in reptiles has typically been measured with an indirect enzyme-linked immunosorbent assay (ELISA).

A variety of cell-mediated immune phenomena similar to mammals are present in a wide range of reptiles, including cutaneous delayed hypersensitivity reaction to tuberculin and alloantigens, allogeneic and xenogeneic graft rejection, phagocytosis, the two-way mixed lymphocyte reaction, and graft-versus-host phenomena.[31] Similar to mammals, the cell-mediated immune response in reptiles can be measured by in vitro cell proliferation assays using whole blood or peripheral blood mononuclear cells cultured with phytohemagglutinin, concanavalin A, or soluble chicken egg white lysozyme.[32]

RESPONSES AND DISORDERS

Sex Hormone–Induced Immunopathology

Physiologically, sex hormones modulate immune function, with both estrogens and androgens impacting immunocompetence. Reptiles, including lizards and turtles, demonstrate immune-related pathologies after estrogen administration. For example, 17β-estradiol (E2) exposure induced thymic atrophy and inhibited thymocyte proliferation in *Hemidactylus flaviviridis*, and injection of 17α-ethinylestradiol, an environmental estrogen often present in sewage-treatment plant effluent, decreased peripheral blood leukocyte and total splenocyte levels in *Sceloporus occidentalis*.[33,34] Testosterone induces lymphopenia in turtles,[35] and high levels of testosterone have been associated with decreased immune function and thymic degeneration in some reptiles.[3]

Endocrine-Disrupting Chemicals

Estrogenic endocrine-disrupting chemicals (EDC), for example, DDT metabolites and PCBs, which may structurally resemble estrogens or

act similarly, can disrupt normal immune homeostasis. Estrogenic EDCs may induce autoimmune susceptibility by way of an overstimulated immune response, while at the same time promoting infection and disease development through specific immune deficiencies. Exposure to environmental estrogens by altering testosterone levels (or the estrogen:testosterone ratio) might result in the mobilization of lymphocytes and an increase in thymic hematopoiesis. This could shift the immune response toward a proinflammatory response, which could enhance responses to self-antigen or even downregulate other immune pathways.[36,37] Exposure to these environmental contaminants appears to result in damage to lymphoid tissue and may be seen as decreased thymic ratio (medulla:cortex) and decreased size of malpighian bodies and lymphocyte sheaths in spleen.[3,38]

Response to Infectious Agents

The typical response to infectious agents, such as bacteria, fungus, and parasites, in reptiles is granulomatous, seen as either a heterophilic granuloma (heterophils accumulate and degranulate and elicit a macrophage response) or histiocytic granulomas (composed mostly of macrophages).[39]

In mycobacterosis, there is a granulomatous lesion often with multinucleated giant cells and variable numbers of other inflammatory cells, heterophils, lymphocytes, and plasma cells. Granulomas range from nodules of viable and degenerate heterophils or nodules with a central core of necrosis surrounded by epithelioid macrophages, multinucleated giant cells (MGCs), and a variable mantel of mixed inflammation to older lesions composed primarily of epithelioid cells and MGCs (Fig. 37.6). These lesions rarely mineralize but will become walled off with fibrous tissue.[40,41]

The response to mycoplasmas, which typically colonize ciliated epithelial mucosa, is somewhat different as these organisms typically cause epithelial hyperplasia with infiltration of heterophils and histiocytes and lymphoid hyperplasia, the latter often being a trigger that a mycoplasma is present (Fig. 37.7).[42]

The response to non-mycobacterial bacteria and fungi is also typically a heterophilic granuloma. For example, lesions in *Ophidiomyces ophidoiicola* infection, which is a fungus, are characterized by central necrosis surrounded by degenerate heterophils, macrophages, and MGCs.[43,44]

Even though reptiles have eosinophils, an eosinophilic response to parasites is rare, and more typically the response is granulomatous.

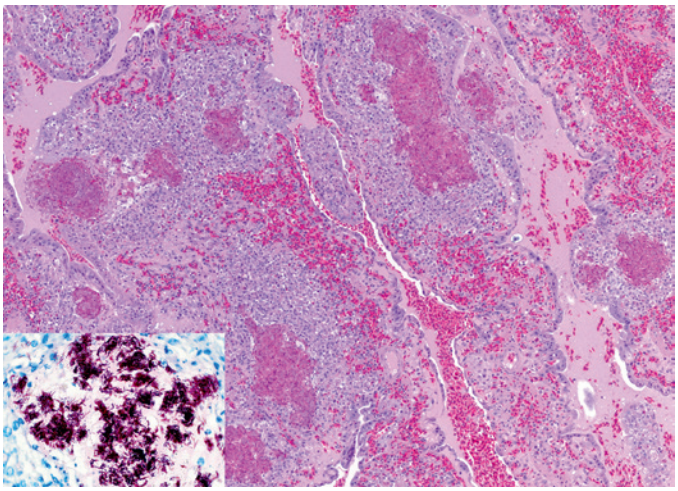

FIG 37.6 Coalescing granulomatous inflammation in the lung of a reticulated python (*Malayopython reticulatus*) with disseminated mycobacteriosis (H&E, ×10). (*Inset*) Acid-fast stain with myriad acid-fast bacilli (Ziehl-Neelson acid fast stain, ×100). (Courtesy of Elizabeth Howerth, University of Georgia.)

Immune Complex-Associated Glomerulonephritis

Glomerulonephritis occurs fairly frequently in reptiles and may range from acute to chronic with glomerular tuft sclerosis (Fig. 37.8).[45] Histologically there may be changes suggestive of immune complex glomerulonephritis, including thickening of capillary membranes due to deposition of hyaline periodic acid Schiff reactive-positive material.[42,45] However, these cases have yet to have been investigated beyond the light microscopic level.

Splendore-Hoeppli Reaction

The Splendore-Hoeppli reaction, characterized by eosinophilic clublike material radiating around an infectious agent, is reported commonly in mammals but only rarely seen in reptiles. Such a response was reported in *Neisseria* sp. infection in two species of iguana.[46]

Hypersensitivity

Except for a type IV hypersensitivity reaction to mycobacteria, there is little evidence to suggest that reptiles have a hypersensitivity response.

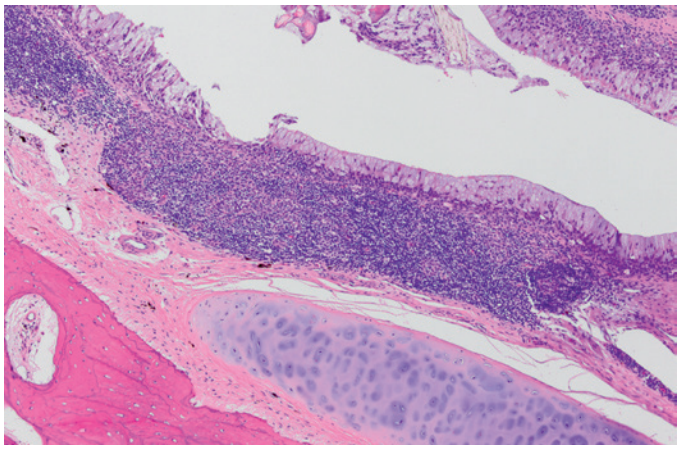

FIG 37.7 Lymphoid proliferation is a common response with mycoplasmosis, as seen in the nasal mucosa of this tortoise (H&E, ×20). (Courtesy of Elizabeth Howerth, University of Georgia.)

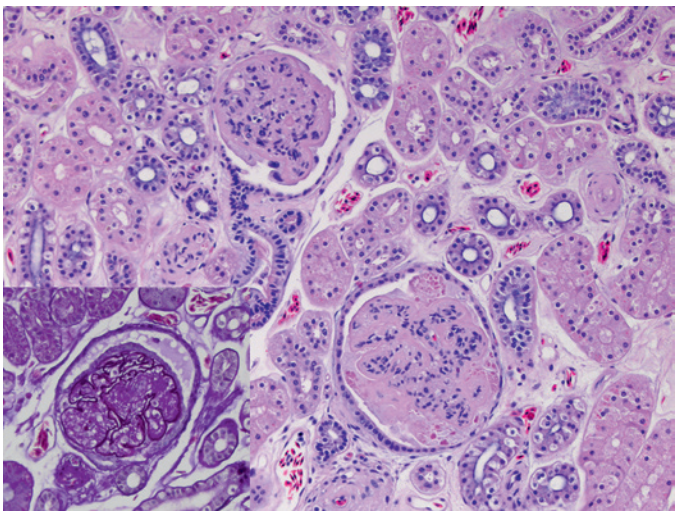

FIG 37.8 Glomerulopathy in an approximately 12-yr-old red diamond rattlesnake (*Crotalus ruber*). Glomeruli are obliterated by a hyaline matrix (H&E, ×20). (*Inset*) The matrix stains purple with a Masson's Trichrome/PAS stain, which is similar to mammals with glomerulosclerosis (×20). (Courtesy of Elizabeth Howerth, University of Georgia.)

VetBooks.ir

However, delayed type hypersensitivity has been used to assess immune function.[47] Although not substantiated, acute hypersensitivity reaction in lungs of *Terrapene carolina* has been reported.[8]

Amyloidosis

In animals, the most common form of amyloidosis is associated with chronic infection and deposits derived from the acute-phase protein serum AA. Although common in mammals and birds, reports of amyloidosis or amyloidlike material in reptiles are few.[45,48,49] Why amyloid deposition is rare in reptiles is unknown. Information about the acute phase reaction and the production of serum amyloid A (SAA) is limited in reptiles, although it has been shown to exist in some reptilian species, for example, the Chinese soft-shelled turtle (*Trionyx sinensis*).[50] Amyloid-like plaques, similar to senile plaques in humans, have been reported in brains of reptiles exhibiting severe neurologic signs.[4]

Neoplasia of the Immune System

Lymphoma, plasmacytoma, and leukemia have been reported multiple times in many families and species of reptiles.[8]

Vaccination

Immunization studies indicate that the humeral response is slow in reptiles, and antigen-specific antibodies may not peak until 6 to 9 weeks postimmunization.[26,51] A prolonged IgM response before switching to another isotype is also reported.[26]

Immunohistochemistry

Immunohistochemistry is widely used in veterinary medicine, mostly in mammalian species, for the identification of tumors. Numerous commercially available antibodies are used for this purpose, but these antibodies are usually against human or mouse antigens, and their use in other mammalian species is based on their ability to cross-react with similar antigens in these species. Immunohistochemistry can also be helpful in determining tumor type in reptiles, but the ability of commercially available antibodies to cross-react in reptiles is often unknown and may vary between reptile species. Vimentin expression was shown in a snapping turtle fibroma (cutaneous fibroma in a snapping turtle, *Chelydra serpentina*),[52] but in other reports vimentin antibodies did not cross-react. Failure to cross-react could be related to species, but it could also be related to the specific vimentin antibody used. Certain cytokeratin antibodies, specifically the pancytokeratin antibodies AE1/AE3 and Lu-5, appear to cross-react in some reptiles and were used to help characterize an undifferentiated ovarian tumor in a corn snake and an esophageal adenocarcinoma in a matamata turtle (*Chelus fimbriata*).[53,54] However, in other reports (referenced in Petterino et al) other specific cytokeratin antibodies were not apparently cross-reactive.[53] While there have been variable results with anti-desmin antibodies, anti-actin antibodies seem more likely to cross-react in reptiles.[53] A variety of antibodies that might be used to differentiate neuroendocrine tumors, including protein gene product 9.5, synaptophysin, gastrin, glucagon, chromogranin, insulin neuron-specific enolase, endorphin, somatostatin, vasoactive intestinal peptide, pancreatic peptide, neurofibromin, have been shown to cross-react, at least in bearded dragons (*Pogona vitticeps*) where they have been used to identify gastric neuroendocrine carcinomas.[55] Melan A was also shown to cross-react in crocodile lizards so might be useful in identifying melanomas in reptiles.[22] Lymphoid tumors have been reported in many species and have sometimes been immunophenotyped. Antibodies to CD3 (T-cell marker) work well in most reptile species,[56] but the common B-cell markers CD79A and CD20 do not seem to be cross-reactive in reptiles (Howerth EW, personal communication, 2017). However, PAX-5 appears to be cross-reactive, at least in snapping turtles, and may hold promise in other species.[56] Cross-reactivity with human factor VIII–related antigen was demonstrated in a cardiac hemangiosarcoma in a Madagascar giant hognose snake (*Leioheterodon madagascariensis*).[57] In conclusion, antibody and species are both important considerations in using immunohistochemistry for tumor identification in reptiles, and a positive control of the same species should always be used.

Cytology

Melinda S. Camus and Corry K. Yeuroukis

Cytology is literally defined as the "study of cells." Cytologic examinations can be performed on body fluids (e.g., blood, urine, synovial fluid, effusions) or on material that is aspirated, scraped, or washed from a solid tissue. Cytology is often preferred to biopsy, at least as an initial diagnostic step, because it is typically less expensive, less invasive, requires less equipment, and has a more rapid turnaround time. Although cytologic examinations can be performed by general practitioners, microscopic interpretation can be challenging and is often best accomplished by a board-certified clinical pathologist. Submission of nondiagnostic samples results in loss of information, difficulties associated with resampling, and ultimately client dissatisfaction. Preanalytic factors including sample acquisition, handling, and submission are critical for optimizing chances of an accurate cytologic diagnosis.

SAMPLE ACQUISITION

Cytologic samples can be collected in a variety of ways, based on the sample location. Collection methods include aspiration, tissue impression, scraping, and swabbing. Regardless of sample type, the desired outcome is acquisition of enough intact cells with minimal contamination to allow for accurate interpretation. Broken cells often become unrecognizable or morphologically altered, which can yield incorrect conclusions. Samples diluted with iatrogenic blood contamination from sample collection contain leukocytes (white blood cells) from the peripheral blood that confound cytologic evaluation. Minimizing cell breakage and sample contamination should be a priority when collecting cytological samples using all methods but should not prevent collection of an adequate number of cells for interpretation. Use of the biggest possible needle while minimizing discomfort and hemorrhage is recommended.

Aspirates

This technique is used for collecting samples from masses, subcutaneous tissues, and internal organs. It is also commonly used in the acquisition of fluid samples. This method can be done in a number of ways. Typically, minimal cleansing preparation to the surface overlying the area of aspiration is desired. For large lesions where central necrosis is suspected, aspiration of the marginal areas may provide a higher diagnostic yield. If a sample is acquired via ultrasound guidance, care should be taken to avoid aspiration through ultrasound gel, as the gel can obscure microscopic evaluation of cells.

The most common aspiration technique involves stabilization of the structure to be aspirated with one hand, while a needle with an attached syringe is inserted into the structure with the other hand (Fig. 38.1). The length of the needle and the size of the syringe should be selected based on lesion size, depth, and character (e.g., hard versus fluctuant). For example, a 1-inchlong, 22-gauge needle attached to a 3-mL syringe should be adequate to aspirate a small, fluctuant subcutaneous mass, with minimal patient discomfort and iatrogenic hemorrhage. Once the needle is inserted firmly into the structure, negative pressure is applied by repeatedly pulling back on the syringe plunger. The needle tip can be redirected within the lesion or multiple aspirates can be performed in an attempt to sample several representative areas. The negative pressure should be released before removing the needle from the lesion to minimize tissue damage and avoid aspirating cells far into the syringe barrel, where they are difficult to retrieve.[1] Once the needle is withdrawn from the aspirated structure, the needle should be removed carefully from the syringe, and the syringe should then be filled with air. The needle is then replaced and the plunger rapidly depressed to disperse all collected sample onto one or more microscope slides. Once the sample is on a slide, an attempt should be made to distribute the cells gently and uniformly before they dry, typically with the weight of a clean "pusher" slide either held horizontally at a right angle to the sample slide or as done when making a blood smear (Fig. 38.2). Diagnostic sample may adhere to the "pusher" slide, which should also be submitted to the laboratory.

FIG 38.1 Aspiration technique. Adequate and appropriate restraint should be used to ensure patient and staff safety. Prepare and isolate the structure to be aspirated. Insert the needle into the lesion with the syringe plunger depressed. Once the needle is seated in the lesion, pull back on the syringe multiple times while directing and redirecting the needle. Make sure the syringe plunger is depressed when removing the needle to avoid aspirating sample contents into the syringe itself. (Courtesy of Stephen J. Divers.)

VetBooks.ir

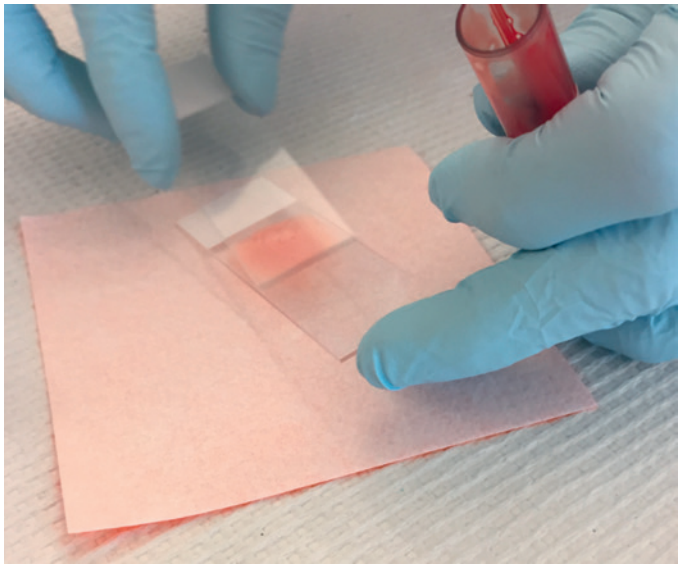

FIG 38.2 Smear preparation. The technique used to prepare well-distributed blood smears may also be utilized for fluid samples. A well-distributed fluid smear will have a curved shape and occupy approximately ¾ of the slide length. (Courtesy of Melinda S. Camus and Corry K. Yeuroukis.)

FIG 38.3 Impression smear. Blot the cut surface of the tissue on clean gauze until tacky and relatively free of blood. Touch the cut surface multiple times along the length of a clean slide. (Courtesy of Melinda S. Camus and Corry K. Yeuroukis.)

Another "aspiration" technique is the "pin prick" method or "stab technique."[1] This method involves using the needle, with or without an attached syringe, and rapidly moving the needle up and down in a vertical motion along the same needle tract in an attempt to "cut" the tissue and loosen the cells. After the sample is collected, an air-filled syringe is attached (if not already present), which is used to rapidly expel cells onto slides, as with the aspiration method. The "pin prick" method works well for vascular samples (e.g., spleen) because it minimizes bleeding and reduces blood contamination that can interfere with interpretation.[2]

Impression Smears

Impression smears are utilized when a solid piece of tissue is blotted onto a slide. This is typically done with (1) biopsy specimens that have been surgically collected and then pressed directly onto a slide to allow for rapid diagnosis; (2) skin lesions that have an ulcerated surface against which a slide can be pressed (Fig. 38.3); or (3) fresh necropsy tissues where a rapid provisional diagnosis may be possible while awaiting definitive histologic results. With all samples, it is essential to blot away any visible blood prior to making the impressions, because blood contamination can obscure the cells, which can make interpretation challenging. Additionally, it is important to realize that only the cells on the imprinted surface are transferred to the slide. Biopsy and necropsy specimens should be transected to allow for imprinting of the cut surface. Limitations of sampling only the surface, rather than deeper tissues, within a skin lesion must be recognized.

Scrapes

Tissue scrapings are often utilized with skin lesions and other surfaces in an attempt to minimize the superficial contamination obtained with the impression technique. A sterile scalpel blade coated in mineral oil is rubbed rapidly against the area to be sampled in an attempt to loosen cells that can be transferred onto a slide for microscopic evaluation. This can be more difficult in reptiles than in other animals due to their tough, keratinized integument. This is most frequently done to obtain tissue cells that would not otherwise exfoliate well.

Swabs

Sterile cotton-tipped applicators can be used to collect tissues and tissue discharges easily and with minimal disruption. Adding a drop of sterile saline prior to gently rolling the swab on or in the sample collection area minimizes tissue trauma and prevents contamination of the slide with cotton fibers. Collected cells are transferred onto a clean slide by gently rolling the swab across the slide's surface. Care must be taken not to press too hard, in an attempt to minimize cell breakage.

SAMPLE HANDLING

Sample handling is a critical component to achieving accurate cytologic diagnoses. Properly collected samples should be handled with care and packaged appropriately for transport to the laboratory to minimize cell deterioration and breakage. Fluid samples and slides have different handling requirements, and any questions regarding best practices for sample handling should be directly addressed to the laboratory prior to collection.

All samples should be labeled with the patient's identifying information and sample location immediately after collection. Slides with a frosted edge allow for easy labeling and are designed for use with a standard number 2 pencil. Slides without a frosted edge should be labeled near one end in an attempt to avoid covering potentially diagnostic material. Identifying information should be written directly on the slide and should not be placed on tape, which can fall off or obscure diagnostic material. Slides should never be labeled with permanent marker, which will wash off during many staining processes. A specific laboratory marker should be utilized to ensure that slides remain properly identified after processing.

Once a cytologic sample has been placed on a slide, a single slide should be stained using a standard Romanowsky-type stain (e.g., Diff-Quik), if possible. Heat fixing slides before staining is unnecessary and may compromise the integrity of the cells. The stained slide should then be examined to ensure that there is adequate cellularity for evaluation. In the event that no cells are seen or all cells are broken or deteriorated beyond recognition, additional samples can be obtained prior to incurring costs and delays associated with sending nondiagnostic

VetBooks.ir

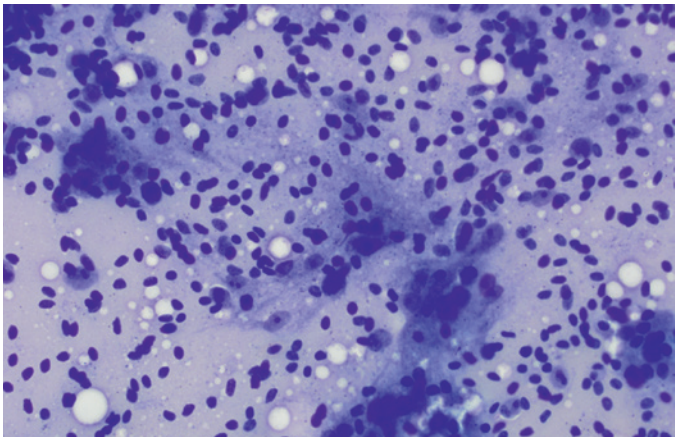

FIG 38.4 Slide examination. Prior to slide submission, stain a representative slide and examine it for sample quality. This slide (a liver aspirate from an iguana taken at 50x magnification and stained with modified Wright's stain) is of poor quality, consisting primarily of numerous free nuclei from ruptured cells in the background, with no microscopic evidence for cytoplasmic borders. The few cells with remaining cytoplasm have indistinct borders and swollen nuclei, which are additional features of ruptured cells. (Courtesy of Melinda S. Camus and Corry K. Yeuroukis.)

FIG 38.5 Recommended items for effective collection of specimens for sample submission and cytologic examination. The use of plastic slide containers for sample transport is ideal to minimize slide breakage. (Courtesy of Melinda S. Camus and Corry K. Yeuroukis.)

slides to the laboratory (Fig. 38.4). All additional slides for submission should remain untouched, with no fixation, including heat, methanol, or formalin. Specifically, extra care must be taken with cytology samples if they are to be used in conjunction with surgical biopsy or necropsy to establish a diagnosis, because formalin cross-links proteins. Exposure of unstained slides to formalin fumes, even when packaged within the same box for shipping, results in poor tinctorial properties due to protein cross-linking and typically precludes an accurate cytologic diagnosis. Submitting unstained slides allows for application of special stains at the discretion of the pathologist, in the event that it is necessary (e.g., for additional characterization of bacterial microorganisms in advance of culture results). All slides (both stained and unstained) should be packaged in a protective container for transport to the laboratory (Fig. 38.5). Many laboratories recycle slide containers and provide them free of charge for laboratory clients on request.

Fluid samples for cytology should be placed into sterile collection tubes. Although a no additive (red top) tube is most desirable to minimize dilutional effects, submission in species-appropriate anticoagulant is occasionally required to prevent sample clotting when large amounts of blood are obtained during sample collection. If culture is desired, or the need is even anticipated, a small amount of fluid should be collected into a separate no additive tube (or culturette with transport medium) at the time of sample collection. All fluid samples should be analyzed as soon as possible, because cellular detail diminishes in fluid suspension. Because even a small delay in time to sample analysis is inevitable, making a direct smear of a fluid sample at the time of sample collection is strongly encouraged. Preparation of the direct smear can be performed with the same technique used to create a blood film, stopping 1/4 inch from the end of the slide to prevent loss of potentially diagnostic samples off the end of the slides. Preparation of a direct smear for diagnostic fluid samples helps preserve cell morphology and may aid the pathologist in interpretation.

SAMPLE SUBMISSION

All laboratory submission forms should be filled out completely and concisely. As context accounts for the majority of interpretation, providing the pathologist with all pertinent medical history and a thorough description of the lesion helps with diagnostic accuracy (Fig. 38.6).[3] A good history includes answers to the questions: (1) Why was the sample acquired?; (2) what are the objective clinical findings (e.g., condition of the patient, duration and severity of the problem, appearance of the tissue, previous treatment or lab results)?; (3) what are differential diagnoses?; and (4) what exactly was sampled? Forms should be typed or written legibly in pen, and all patient information must match exactly what is written on the sample slides themselves. Abbreviations on the form should be limited to those that are standard and well recognized and should be reviewed prior to submission. Highlighting on submission forms should be avoided, because it often blurs text when copied or scanned.

VetBooks.ir

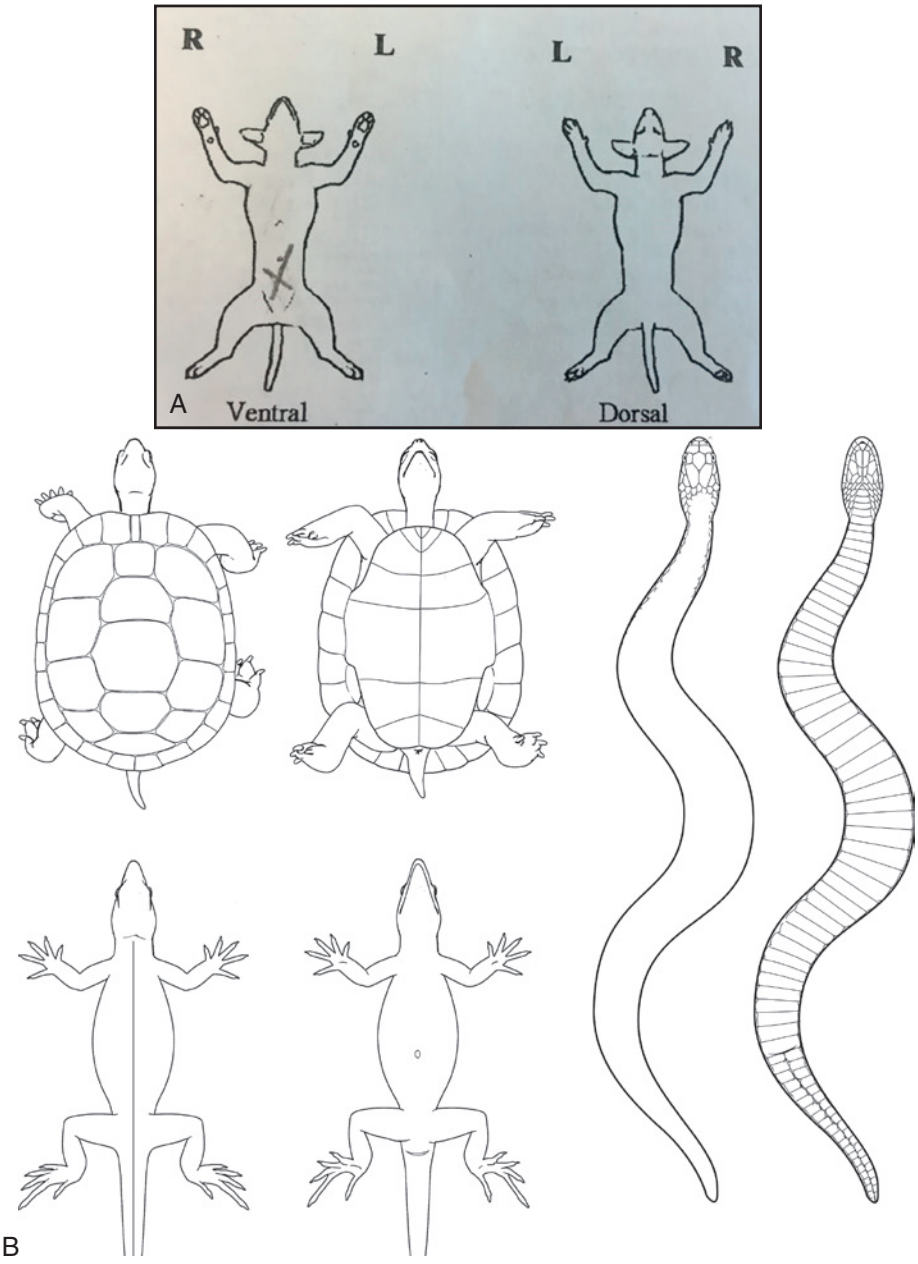

FIG 38.6 (A) Most laboratory submission forms show a picture of a canine patient. This can be utilized or a reptile-specific diagram (see B) can be attached. A visible "X" can be placed on the diagram to indicate the location of the sampled lesion. A thorough description of size, color, texture, and location of the lesion must also be included on the submission form to receive the most complete interpretation possible from the pathologist. The "X" in this image, without an accompanying history, could represent a skin lesion, a bladder aspiration, or a sample of an intra-abdominal structure. (B) Reptile-specific submission form diagram. These figures can be copied and attached to laboratory requests to indicate the location of the sampled lesion. (Courtesy of Educational Resources, University of Georgia.)

Biopsy

Nicole Gottdenker and Wilson Yau

Diagnostic biopsy samples provide clinically relevant information that helps with treatment and management at both individual and population levels. Obtaining and submitting a biopsy that results in a nondiagnostic report can be frustrating. Table 39.1 lists common errors associated with non-diagnostic samples, and steps to optimize sample collection. Fig. 39.1 illustrates some useful biopsy sampling supplies.

A complete medical history, including a summary of supportive diagnostic information such as clinical pathology, specific infectious disease testing (e.g., PCR, ELISA), and diagnostic imaging results, significantly helps the pathologist in providing meaningful diagnoses, comments, and feedback. In addition to patient signalment, pertinent information should include clinical signs and duration, husbandry conditions, and any recent changes or additions, treatments administered, and number of animals affected. In particular, husbandry specifics include type of cage and substrate, temperature, humidity, photoperiod, diets, and nutritional supplementation. Detailed descriptions of the submitted sample should include size, gross appearance, tissues involved and location on the body (Fig. 39.2), and whether the entire lesion has been submitted (incisional versus excisional biopsy).

When infectious or toxic etiologies are suspected, collecting paired samples (fresh and formalin-fixed) is recommended. Although formalin-fixed tissues allow for histopathology and immunohistochemistry, fresh tissues and swabs can be submitted for a wide variety of ancillary testing, such as bacterial and fungal cultures, fluorescent antibody testing, PCR, mineral analysis, and liquid chromatography-mass spectrometry. Fresh tissues stored in Whirl-Pak Bags can be frozen, held, and, if histopathology results indicate, subjected to ancillary testing later. Because some ancillary tests are specific to reptiles and are not widely available, it is important to identify and become familiar with diagnostic laboratories that offer such tests and the associated sample requirements, shipping guidelines, and turnaround times.

Recommended guidelines for submission for veterinary surgical pathology have been published.[1] In brief, most types of biopsy samples should be placed in 10% neutral buffered formalin as soon as possible to minimize tissue artifacts. To ensure adequate fixation, the volume of the formalin should be at least 10 times that of the tissue (10:1 ratio). If surgical margins are of interest, application of surgical ink or placement of sutures is helpful. Ink must dry completely prior to placing the tissue in formalin, which can take up to 10 minutes, and the designated margins should be clearly labeled on the submission form. Use the end of a cotton-tip applicator to minimize the amount of ink applied to the tissue.

Making tissue imprints often allows for quick identification of neoplastic populations and infectious etiologic agents, especially when a mass is identified during surgical exploration or necropsy. If tissue imprints are to be made, the procedure and slides should be made far away from formalin fumes, because the latter can introduce significant artifacts in the resulting imprints. Cut the tissue into a small block, such that forceps can hold onto opposite sides of the block while allowing for the downward-facing surface to be used for imprinting. Blot the surface onto clean absorbent material (such as paper towels) until no wet imprints are left, because excess blood and tissue fluids prevent cells and organisms from sticking onto the glass slide. After the surface is blotted dry, gently press the surface onto a clean glass slide. Depending on the size of the surface, often times multiple imprints

TABLE 39.1 "Dos and Don'ts" That Apply to Procurement and Submission of Biopsies

Do	Don't
Use 10% neutral buffered formalin, 10:1 ratio	Mix samples from multiple sites in the same container without labeling
Handle biopsy sample at margins	Grasp body of biopsy with forceps
Obtain more than one biopsy if possible	Submit the biopsy sample previously used for tissue imprints
Use scalpel or forceps to collect sample	Cauterize the tissue submitted for biopsy
Collect paired samples (fresh and formalin fixed)	Neglect to collect fresh tissues with suspected infectious or toxic etiologies
Double-pack samples & use absorbent liner	Use glass containers or zipper storage bags

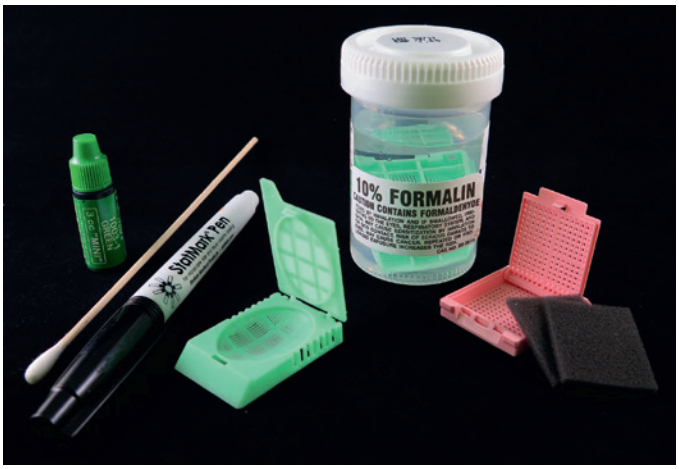

FIG 39.1 Useful biopsy sampling supplies, including formalin-filled jar with screw-top lid, cassette with sponge pads, Vortex cassette, StatMark pen, tissue ink, and cotton-tip applicator. (Courtesy of Wilson Yau.)

VetBooks.ir

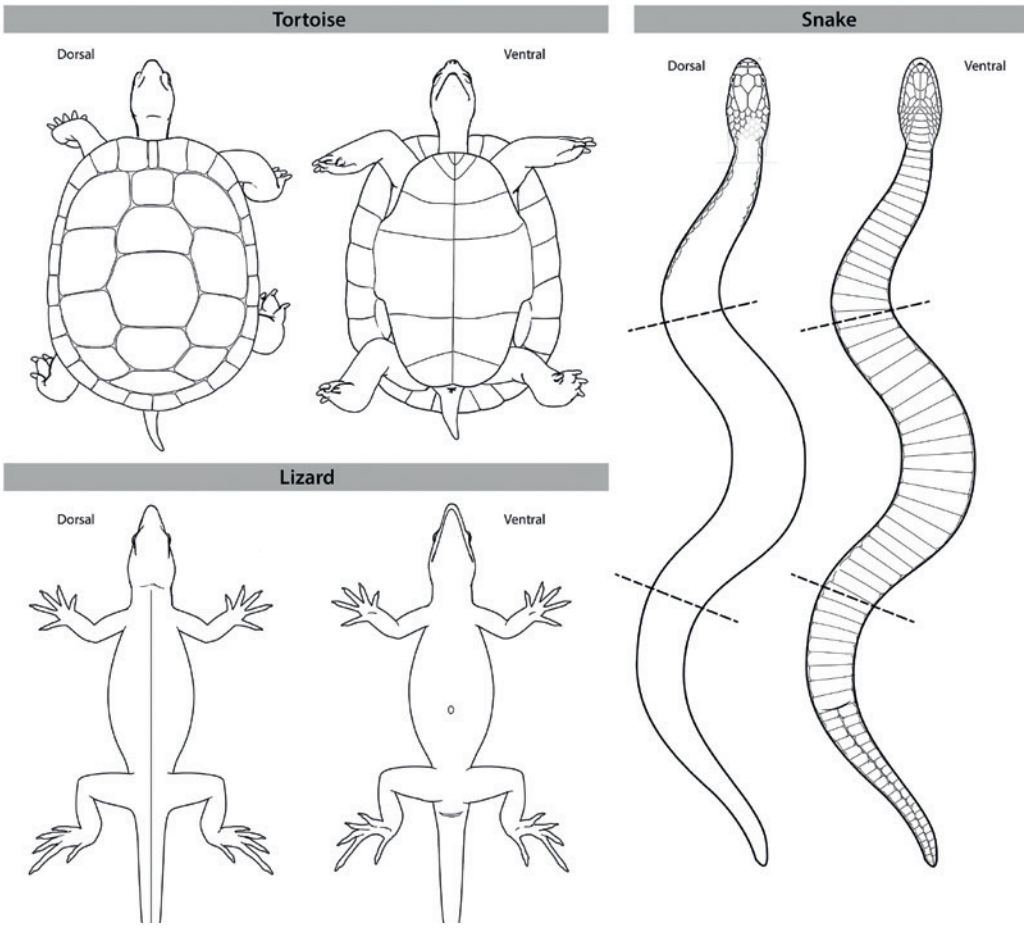

FIG 39.2 Reptile-specific submission form diagram. These figures can be copied and attached to laboratory requests to indicate the location of sampled lesions. (Courtesy of Educational Resources, University of Georgia.)

can be made onto the same slide in a row. Do not drag the tissue along the glass slide, because cells can rupture easily. Allow the glass slide to air dry before staining it with Diff-Quik or another Romanowsky-type stain. Consider making multiple duplicates of unstained glass slides, especially if infectious agents are suspected, in case special stains are indicated. The process of making imprints can distort tissue architecture (especially with kidney, liver, and gut mucosa), such that submission of other pieces of tissue not subjected to imprints is preferred. Endoscopic biopsies have been validated and produce clinically relevant results in lizards, chelonians, and snakes.[2,3] Refer to Chapters 63 and 64 for obtaining endoscopic biopsies. Similar small samples should be placed in screen cassettes and sandwiched between two sponge pads, which helps reduce sample movement and minimize the chance of sample loss or omission. Alternatively, Vortex cassettes eliminate the need for sponge pads. Do not use needles to immobilize tissues, which pose an unnecessary safety hazard to laboratory personnel handling the specimens. When multiple anatomic sites are sampled (e.g., proximal vs distal intestines), it is recommended to use separate cassettes. The cassettes should be labeled with pencils or StatMark pens. Do not use ballpoint pens or other ink markers, because the ink often smudges.

Small, soft tissue biopsy specimens are best obtained using a scalpel or biopsy forceps (crush technique). In contrast, radiosurgery, laser, and cautery techniques can cause extensive coagulation artifacts, which can significantly impede microscopic interpretation at the margins. Because some biopsy sites, such as the oral or nasal cavity, can bleed profusely, the use of hemostatic devices may be required to control bleeding after the biopsy has been obtained. One should avoid the use of tissue forceps directly on the biopsy specimen, because this can cause microscopic crush artifact and impede interpretation. These principles also apply to core biopsies.

Disease processes are generally dynamic, and lesions or parts of lesions may be in different stages of formation or regression. For this reason, obtaining more than one biopsy from different parts of a lesion or from different sites of the same disease process is recommended. This is particularly applicable for multicentric skin lesions and core biopsies of large or nonresectable masses.

Bone biopsies often pose a significant challenge, because the reactive hyperostosis associated with many underlying bone lesions can be more prominent than the primary lesion, and obtaining representative biopsies becomes difficult, particularly with core biopsy techniques.

Because formalin is a hazardous substance that is irritating to the skin and mucous membranes, shipping the samples securely is important to ensure personnel safety. The samples should be placed in formalin-filled, plastic, and leak-proof containers, preferably with wide necks and screw-on lids. Parafilm-M can be used at the bottle neck to further minimize the chance of formalin leakage. The container should then be placed in a sealed plastic bag, surrounded by

VetBooks.ir

absorbent packing material, and shipped in accordance with postal regulations.

GROSS PHOTOGRAPHY

Photographs of gross lesions are extremely valuable, especially to pathologists correlating gross and histologic findings in both biopsy and necropsy cases.

The lesion should be of a magnification that occupies about 70% to 80% of the field, but an attempt should be made to include a margin of surrounding normal tissue to aid in viewer orientation. Including both low- and high-magnification images helps fully illustrate the location and gross features of the lesion. One should obtain more than one image at each magnification, adjusting for each to obtain the best contrast and focus.

For in situ and ex situ lesion photography, framing the lesion in the center of the image is important. For ex situ photography, a black or dark blue background is best to aid in tissue contrast, such as a flat, black rubber mat or a piece of clear glass placed over blue or black cloth. Many backgrounds can be distracting, such as newspaper, paper towels, wooden cutting boards, cage grates, or tile flooring. Fluid seepage and subsequent glare should be minimized by blotting the tissues before final positioning. A ruler is a useful size guide, especially for ex situ tissue photography; however, the ruler should not occupy more than 10% of the image and should not overlap the tissue of interest.

40

Necropsy

Nicole Gottdenker and Wilson Yau

Necropsies provide valuable information for diagnostic and educational purposes and often provide insight into population health management. A carcass can be submitted for necropsy with or without histopathology at a diagnostic laboratory. On the other hand, costs incurred and logistics of transferring whole carcasses can become prohibitive, and in-house necropsies are often performed. In addition, shipping intervals can contribute to autolytic change, postmortem bacterial overgrowth, and pseudomelanosis, which can significantly impede diagnostic evaluation. This chapter describes techniques to effectively perform a gross necropsy, including obtaining fresh and formalin-fixed samples for ancillary testing. Fig. 40.1 shows supplies useful for performing a necropsy.

Consultation with the pathologist regarding the animal's case history before shipping an entire carcass for a diagnostic lab necropsy or shipping formalin-fixed and fresh tissues from an in-house necropsy prevents many errors that arise from inadequate communications. This is particularly important with legal cases or cases that are being shipped on weekends or holidays. To prevent excessive autolysis, carcasses should be submitted with cold packs using the most expedient form of transport possible. Ideally, the carcasses should be necropsied as soon as possible after death. Carcasses waiting to be shipped or necropsied should be placed in a cooler (4°C) to slow autolysis. Avoid freezing carcasses directly, as freezing and thawing introduces tissue artifacts.

Gross pathology alone may not be sufficient to reach a specific diagnosis in many cases, and histopathology is indicated. At the minimum, formalin-fixed tissues of the brain, heart, lung, liver, spleen, kidney, reproductive organs, skeletal muscle, and a long bone should be collected.

FIG 40.1 Useful necropsy instruments and sampling supplies. Formalin-filled container, syringe and needle, scissors, bone rongeur, Whirl-Pak Bag, culturette swab, tissue cassette, ruler, tissue forceps, scalpel blade, knife, blood tube, permanent marker (for labeling bags and containers), StatMark pen (for labeling cassettes), cutting board, Stryker saw, T-bar, and garden shears. (Courtesy of Wilson Yau.)

Tissues should be fixed in 10% neutral-buffered formalin. To ensure adequate fixation, the volume of the formalin should be at least 10 times that of the tissue. Tissue thickness should not exceed 1 cm because formalin takes a considerable time to penetrate into the center of the tissue, and thick sections may not have adequate fixation, leading to autolytic change. Specific tissues may benefit from other types of fixatives. For example, eyes can be fixed in Davidson's solution, whereas tissues affected by gout should be fixed in ethanol instead, as formalin dissolves uric acid crystals. For cases where electron microscopy is anticipated, small vials containing 3% glutaraldehyde jars are ideal. Table 40.1 describes the dos and don'ts of submitting samples for necropsy.

When infectious or toxic etiologies are suspected, collecting paired samples (fresh and formalin-fixed) is highly recommended. Although formalin-fixed tissues allow for histopathology, immunohistochemistry, and in situ polymerase chain reaction (PCR), fresh tissues and swabs can be submitted for ancillary testing, such as aerobic and fungal cultures, fluorescent antibody testing, PCR, mineral analysis, and liquid chromatography–mass spectrometry. In cases suspected of toxins, save large quantities of liver, coelomic fat, kidney, and stomach contents, as certain toxicology tests require substantial amounts of sample to run. Fresh tissues stored in Whirl-Pak Bags can be frozen at −20°C or −80°C, held, and, if histopathology results indicate, subjected to ancillary testing. As some ancillary tests are specific to reptiles and are

TABLE 40.1 "Dos and Don'ts" That Apply to Procurement and Submission of Necropsy Samples

Do	Don't
Use 10% neutral buffered formalin, 10:1 ratio	Overfill container with tissues
Ensure tissues are less than 1 cm thick for formalin fixation	Immerse entire carcasses in formalin without incising the coelom to allow for infusion
Use and label tissue cassettes for very small samples	Overfill a cassette and create "waffle" indentations on the tissue
Obtain multiple representative pieces of lung and liver for fixation	Submit only a single small piece of lung or liver
Call laboratory before sending fresh carcass/tissue	Send fresh tissue and carcasses without calling or on weekend/holiday
Keep extra set of formalin-fixed tissues	Discard tissues before biopsy/necropsy results are known
Collect paired samples (fresh and formalin-fixed)	Neglect to collect fresh tissues for cases with suspected infectious or toxic etiologies

not widely available, it is important to identify and become familiar with diagnostic laboratories that offer such tests, as well as their associated sample requirements, shipping guidelines, and turnaround times.

Although collecting fresh samples using aseptic techniques is ideal, it may not be practical in many situations. Nonsterile equipment can be dipped in alcohol, and the alcohol burned off with a Bunsen burner or lighter. In addition, diagnostic labs often have the ability to sanitize samples to minimize bacterial contamination. Any fresh tissues collected must not touch formalin, as formalin inactivates and destroys microorganisms and cross-links surface proteins, which drastically reduces the value of many ancillary tests.

Making tissue imprints often allows for quick identification of neoplastic populations and infectious etiologic agents, especially when a mass is identified during exploratory or necropsy. If tissue imprints are to be made, the procedure and slides should be made far away from formalin fumes, as the latter can introduce significant artifacts in the resulting imprints. Cut the tissue into a small block, such that forceps can hold onto opposite sides of the block while allowing for the downward-facing surface to be used for imprinting. Blot the surface onto clean absorbent material (such as paper towels) until no wet imprints are left, as excess blood and tissue fluids prevent cells and organisms from sticking onto the glass slide. After the surface is blotted dry, gently press the surface onto a clean glass slide. Depending on the size of the surface, often times multiple imprints can be made onto the same slide in a row. Do not drag the tissue along the glass slide, as cells can rupture easily. Allow the glass slide to air dry before staining it with Diff-Quik. Consider making multiple duplicates of unstained glass slides, especially if infectious agents are suspected, in case special stains are indicated. The process of making imprints can distort tissue architecture (especially with kidney, liver, and gut mucosa), such that submission of other pieces of tissue not subjected to imprints is preferred.

Table 40.2 lists reagents, instruments, and sampling supplies useful to perform a necropsy. Most necropsy equipment can be purchased at the local hardware store, but some equipment, such as dissecting scissors, forceps, and T-bars, may be purchased from medical suppliers (see Fig. 40.1).

Personal protective equipment should be used, as reptiles can carry multiple zoonoses, including salmonellosis, aeromoniasis, campylobacteriosis, mycobacteriosis, and zygomycoses. At minimum, personnel should wear dedicated protective clothing, footwear, and disposable gloves. Other equipment to consider includes safety goggles and facemasks, especially when using power tools (e.g., bone saws to separate turtle plastron and carapace) and high-pressure hoses. In addition, extra care should be exercised when handling venomous species, such as taping the mouth shut prior to handling the head to prevent accidental contact with fangs and subsequent envenomation.

NECROPSY PROCEDURES

Before starting a necropsy, ensure that the animal is indeed deceased (see Chapter 47 for proper euthanasia methods). Euthanasia by prolonged exposure to CO_2 alone often is not sufficient to ensure death of a reptile, such that application of a secondary lethal procedure may be indicated.[1] On the other hand, excessive injectable euthanasia solution, including intracoelomic or intravenous, creates extensive tissue artifacts resembling coagulative necrosis, which can obscure findings.

A necropsy examination must be methodical and complete, because, unlike a clinical physical examination, it cannot be repeated. Table 40.3 is a sample necropsy form that includes a tissue checklist, which should accompany all histopathologic submissions to help the pathologist put findings in context. A necropsy can be broken down into six steps:

1. Obtain signalment and medical history
2. External examination, including body weight
3. Open the body and examine body systems "in situ"
4. Remove and set aside the organs
5. Examine and sample the organs
6. Write the report

1. Obtain Medical History

A complete medical history significantly helps the pathologist in providing meaningful diagnoses and comments. In addition to patient signalment, pertinent information should include clinical signs and duration, husbandry conditions, and any recent changes, treatments administered, number of animals affected, whether the animal died or was euthanized, and any recent additions to the population. In particular, husbandry specifics include diet, type of cage and substrate, temperature, humidity, and photoperiod.

If multiple animals are affected in a die-off, do not necropsy just one carcass. Lesions present at different stages may be present in different individuals in a population, such that performing a necropsy on multiple affected individuals increases the likelihood of reaching a diagnosis. Attached clinical data, including hematology, biochemistry, culture and sensitivity, infectious disease testing (e.g., PCR, ELISA), and diagnostic imaging information, are often tremendously helpful.

2. External Examination

Record the body weight, snout-to-vent length, and total length. Observe for ocular, nasal, vent/cloacal discharge, discoloration, trauma, retained shedding of the skin (dysecdysis), and ectoparasites. In forensic necropsies, imaging techniques are invaluable, especially in detecting the presence of fractures, dislocations, bullets, or pellets that can be easily missed in cases without externally apparent wounds.[2]

Integument and Musculoskeletal System. Skin conditions are common in reptiles, especially trauma, burns, and infectious dermatopathies. A magnifying glass or dissection scope can help with examining small carcasses. Any cutaneous abnormalities or asymmetrical discoloration should be noted and collected in formalin. Photographs should also be taken of any suspected lesions and provided to the diagnostic pathologist (this applies to internal and external lesions). Fresh tissue should also be collected if infectious etiologies are suspected. Distribution and size of the abnormality should be succinctly noted on the necropsy

TABLE 40.2 Equipment Needed for Performing a Gross Necropsy

Reagents and Supplies	Safety Equipment	Instruments	Sampling Supplies
Disinfectant detergent	Protective clothing	Knives, scalpel holders and blades, cutting board	Whirl-Pak Bags, culturette swabs
Neutral buffered 10% formalin solution	Nitrile or latex gloves	Bone rongeur, pruning shears, T-bar, Stryker saw or hacksaw	Needles and syringes, blood tubes
90% ethyl alcohol solution	Goggles, surgical face mask, face shield	Tissue forceps and scissors	Glass slides for imprints
		Ruler, permanent marker, StatMark pen	
		Camera, gram scale, dissecting scope or magnifying glass

†Fresh tissue should be collected.

form (i.e., "random on the back and legs," "confined to ventral aspects of body [or legs]," "tip of nose [or tail]"). For chelonians, this information also applies to the carapace, plastron, and bridges.

The musculoskeletal system provides useful information regarding current and past nutritional status, which can be affected by traumatic, degenerative, and infectious conditions. Palpate the appendicular skeleton for signs of fracture or unusual softness (metabolic bone disease). For carcasses too large to submit whole, an effort should be made to submit the head, a segment of vertebral column, and at least one long bone with the articular surface, such as the femur, tibia, humerus, or radius, especially if degenerative joint diseases or osteomyelitis are suspected. Postmortem radiographs may also be helpful for diagnostic and legal purposes. Peripheral nerves are often incorporated when collecting large muscles. Processing of bone most often requires decalcification, which can add days to weeks of processing time, depending on the thickness of the bone submitted and decalcification reagents used.

Snakes: All snakes possess secretory sacs at the base of the tail (scent glands). They may enlarge as inspissated secretions accumulate.

Crocodiles: Two pairs of musk-producing glands are present, one nuchal and the other cloacal.

Lizards: A single row of femoral pores are present on the ventral aspect of the thighs in many lizards, such as iguanas. Geckos can have both femoral and precloacal pores. Mature males tend to have larger femoral pores. Lizards such as geckos have paired endolymphatic sacs in the ventrolateral cervical region. These sacs often contain chalk-white liquid when normal.

3. Open the Body Cavity

Although many variations among reptile anatomy exist, a general necropsy approach can be applied to all, with modifications made for specific orders and species (Figs. 40.2–40.9). In particular, specific and detailed protocols on groups of reptiles are published, such as sea turtles.[3] Most animals should be placed in dorsal recumbency, while chameleons and other laterally compressed lizards may be better placed in lateral recumbency.

Many reptile specimens are small, which makes necropsy relatively easy. For animals less than 10 cm in length, use scissors to cut through the skin and coelomic wall from cloaca to the intermandibular symphysis,

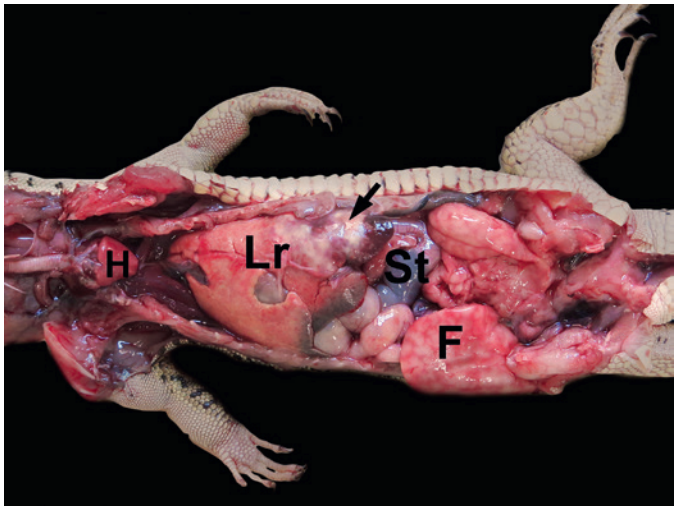

FIG 40.2 Ocellated lizard *(Timon lepidus)* necropsy. The ventrum and ribcage have been removed to reveal coelomic contents. Note the heart (H), liver (Lr), stomach (St), and coelomic fat pad (F). A large granuloma is present on the caudoventral aspect of the liver (arrow). (Courtesy of Wilson Yau.)

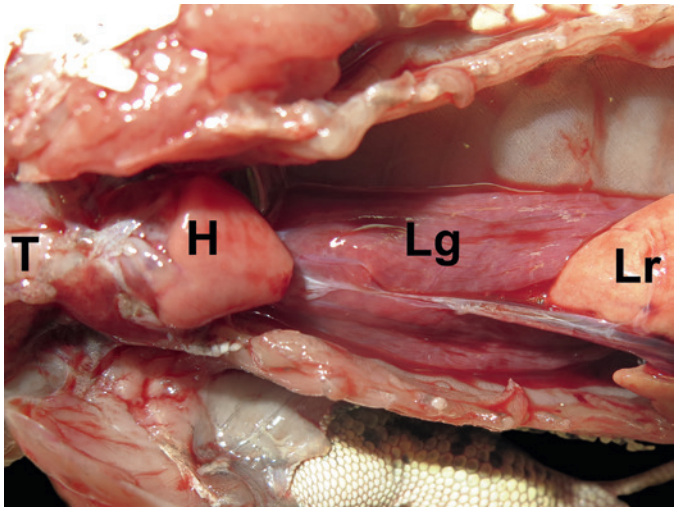

FIG 40.3 Ocellated lizard *(Timon lepidus)* necropsy. Higher magnification of the cranial coelom. Note the trachea (T), heart (H), lung (Lg), and liver (Lr). (Courtesy of Wilson Yau.)

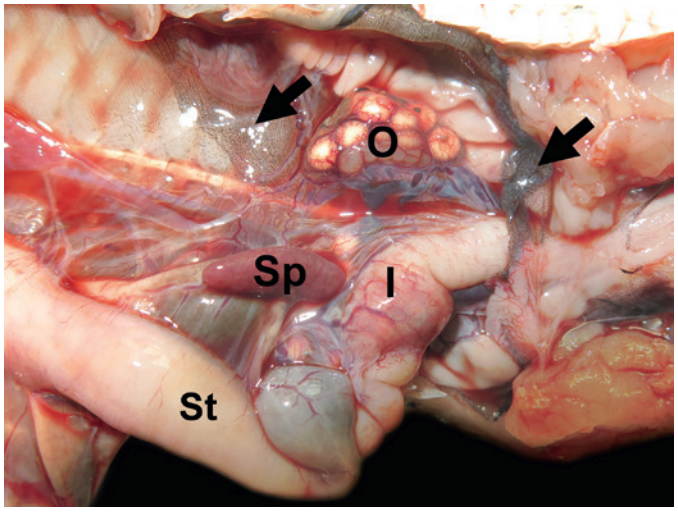

FIG 40.4 Ocellated lizard *(Timon lepidus)* necropsy. Higher magnification of the caudal coelom. Note the normal melanin pigmentation throughout the serosa (arrows), spleen (Sp), stomach (St), intestines (I), and ovary (O). (Courtesy of Wilson Yau.)

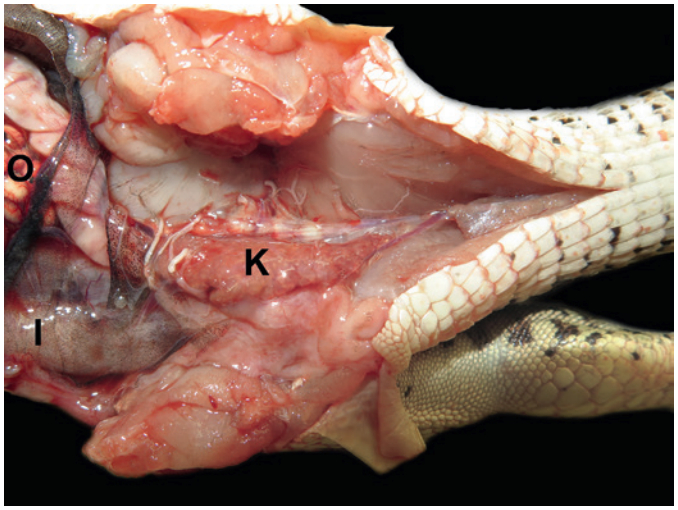

FIG 40.5 Ocellated lizard *(Timon lepidus)* necropsy. The pelvic symphysis has been split to reveal the left kidney (K). Note how caudal the kidney is compared to the ovary (O) and intestine (I). (Courtesy of Wilson Yau.)

VetBooks.ir

FIG 40.6 Chelonian necropsy. Incising the shell bridge with a Stryker saw. The carcass is inverted and angled at approximately 45 degrees. The initial cut is at the extreme caudal or cranial bridge junction, and a straight cut is made to the opposing end. The contralateral bridge is cut in the same manner. Alternatively, a hacksaw may be used if a Stryker saw is not available. (Courtesy of Wilson Yau.)

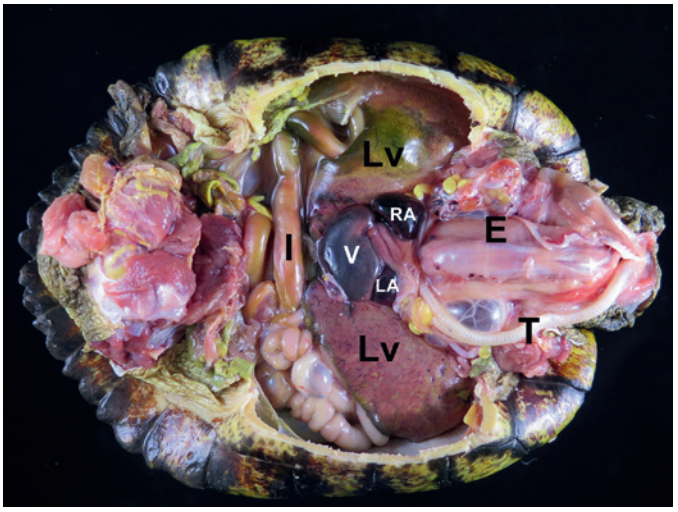

FIG 40.8 Chelonian necropsy. The pectoral and pelvic musculature, ventral coelomic wall, and pericardium have been removed to reveal the left atrium (LA), right atrium (RA), ventricle (V) of the heart, liver (Lv) with bile imbibition of the right lobe clearly visible, intestines (I), esophagus (E), and trachea (T). (Courtesy of Wilson Yau.)

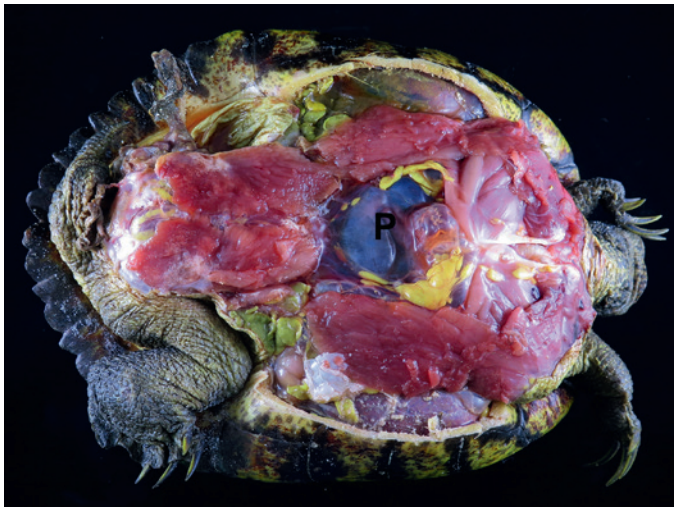

FIG 40.7 Chelonian necropsy. The plastron has been removed to reveal the pectoral and pelvic musculature and pericardium (P). (Courtesy of Wilson Yau.)

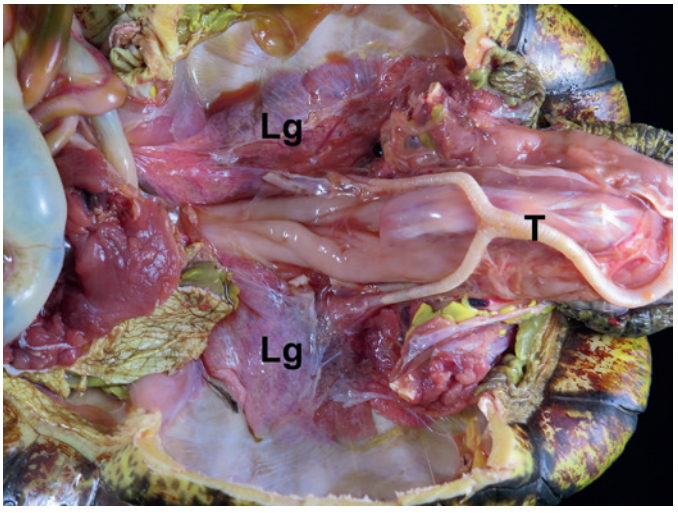

FIG 40.9 Chelonian necropsy. The liver and intestines are removed to reveal the bifurcating trachea (T) and lungs (Lg). The lungs are tightly attached to the ventral aspect of the carapace. (Courtesy of Wilson Yau.)

avoiding the ventral midline vein. Collect fresh tissues and swabs for ancillary testing (refer to the upcoming Step 5). Incise the skin and musculature over the cranium, and expose part of the calvarium using rongeurs, such that formalin can permeate the brain effectively. The entire carcass can then be submerged in 10% neutral buffered formalin. The formalin-to-tissue ratio should exceed 10:1 to ensure thorough fixation.

Larger snakes and lizards: The skin and body wall are gently parted with fingers, forceps, or scissors. When the body is opened, evaluate body condition, evident by the amount of coelomic fat present, and, in some cases, subcutaneous fat (e.g., tail fat storage in leopard geckos). Lizards generally have two paired intracoelomic fat bodies initiating ventrally near the pelvis and growing cranially and laterally as they enlarge with stored fat. Crocodilians have a single intracoelomic fat body on the right side of the coelom caudally. Note the degree of postmortem autolysis, including bile imbibition and pseudomelanosis. Note any effusions present within the coelom or pericardium, including volume, color, and consistency. Observe the visceral arrangement and any apparent displacement of organs. Observe the serosal surfaces for deposition of any abnormal material (such as visceral gout or yolk peritonitis). Some lizards, particularly chameleons and bearded dragons, normally have extensive melanin pigmentation in the mesentery and inner surfaces of the body wall and coelomic fat bodies, and this pigmentation should not be interpreted as a pathologic condition (see Fig. 40.4).

In cases with a high index of suspicion for infectious etiologies, fresh samples should be taken at this point from the lung, liver, and kidney using sterile instruments.

Chelonians: Several methods are used to remove the plastron. In young chelonians or those with significant loss of shell bone, the shells can

VetBooks.ir

be separated at the bridge with stout scissors. For larger animals, separation of the shells with a Stryker saw or hacksaw may be necessary (see Fig. 40.6). In all cases, the chelonian is placed on its back, then tilted laterally to a 45-degree angle. This angle allows gravity to shift the viscera downward, so they are not inadvertently incised during the sawing procedure. This is especially important for obtaining sterile cultures of the viscera and for avoiding a full urinary bladder. With care taken not to go too deeply with the saw, the shell is cut at the junction between the plastron and carapace without damaging the underlying soft tissues. Both bridges are sawed through in this manner. With the animal still in dorsal recumbency, scissors are used to cut through the skin at the front and rear attachments to the plastron. The soft tissue attachments are bluntly dissected from the top of the plastron, from rear to front, exposing the intact coelomic wall. For cultures, a small incision can be made in the coelomic wall to allow access to viscera. This provides access to the liver but not the lungs. The lungs are adhered to the ventral surface of the carapace, extend the full length of the carapace, and can be difficult to dissect from the dorsal body wall.

If sterile access to lungs is indicated in a particular case, then the carapace should also be removed. Use scissors to cut the skin at the junction of the carapace (chelonian still in dorsal recumbency), front and rear. A thick screwdriver, wedge, or T-bar is used to disarticulate the tail vertebrae and the cervical (neck) vertebrae from their attachments to the ventral aspect of the carapace. The chelonian is carefully turned over, and gravity is allowed to pull down on the viscera. The tissues are digitally dissected away from the inside aspect of the carapace, starting from the back and moving forward. The large skeletal muscle bundles in the shoulder and pelvic regions may need to be cut with scissors. The carcass is placed in sternal recumbency on the necropsy table, which allows for sterile access to the lung fields by an incision through the wall. This technique is modified for the giant land tortoises and large sea turtles that are too heavy to suspend during dissection of the carcass away from the carapace.

4. Remove and Set Aside the Organs

After examining the organs in situ, including relatively small frequently overlooked organs such as the thyroid glands, thymus, pancreas, adrenal glands, and spleen, isolate "the pluck" from the body wall to thoroughly examine the organs. The pluck incorporates the tongue and the gastrointestinal tract, heart, respiratory tract, and the cloaca. Some prosectors prefer to remove and set aside the spleen before removing the pluck, as this important organ is often small and difficult to locate after the organs have been manipulated. See below for discussion on hematopoietic organs.

Remove the pluck by cutting the tongue away from its attachments and pulling it through the ventral intermandibular space. While applying caudal traction to the tongue, use scissors or fingers to dissect the soft tissue attachments to the dorsal body wall. This procedure may be difficult in large crocodilians and chelonians, and the tissue collection and inspection may need to be done in situ. For better exposure, some prosectors prefer to incise around the perimeters of the ventral body wall on large lizards and crocodilians (with pruning shears to cut through the ribs), rather than on the ventral midline.

5. Examine and Sample the Organs

To minimize cross-contamination when taking fresh samples, start from the cleanest organs and end with the dirtiest organs. In other words, start with lymphoid tissue (spleen, thymus) and then proceed to brain, lungs and heart, kidneys, reproductive tract, liver, and finally the gastrointestinal tract.

Note any abnormalities in each, including distribution of lesions, color, size, shape, consistency, and the presence of any exudates. Examine both the capsular surface, as well as the cut surfaces. Make serial cuts of the liver, lung, and kidney to check for any focal lesions. Crushing should be avoided when using forceps to take samples. Using a sharp blade and a hard surface (cutting board) can minimize artifacts. When sampling mucosal surfaces, avoid rubbing the mucosa vigorously with fingers or instruments. If particular organs appear enlarged or small, obtain a weight of the organ to calculate percentage body weight (%BW) as an objective measurement.

In-house cytology performed on intestinal contents, masses, and granulomas is inexpensive and can sometimes offer quick insights into infectious or neoplastic etiologies. If tissue imprints are to be made, the procedure and slides should be made far away from formalin fumes, as the latter can introduce significant artifacts in the resulting imprints. The process of making imprints can distort tissue architecture (especially with kidney, liver, and gut mucosa), such that submission of other pieces of tissue not subjected to imprints is preferred (see Chapter 38).

Hematopoietic and Lymphoid Tissues (Spleen, Thymus, Bone Marrow, Peripheral Blood). Most reptiles lack discrete lymph nodes, although extensive lymphatic networks are present. Examination of these tissues provides clues to immune status, anemia, and various infectious and nutritional problems. Evaluation of overall lymphoid cellularity can give a crude estimation of immune status and can also provide evidence of exposure to stress.

The spleen is generally a small ovoid brown/red or tan structure located in the mesentery, off the greater curvature of the stomach, and often close to the gallbladder and pancreas (see Fig. 40.3). The association of these three organs is often referred to as the triad in snakes and is useful in helping to find the organs during imaging, surgery, or necropsy. The spleen can be difficult to find but is important to examine for the presence of infectious disease processes. The thymus is a lobulated structure and variable in location and may be found from the base of the heart to the neck.

Bone marrow can be collected from the medullary cavity of long bones. Crack open a long bone to ensure the presence of bone marrow, and then the whole bone can be placed in formalin. For larger species, bone marrow can be scooped out and placed in a cassette to be fixed in formalin.

Snakes and chelonians: In many species the spleen is fused with the pancreas (splenopancreas). Snapping turtles have lymphoid follicles present in the cloaca. The bone marrow is "trabecular" in nature and may be difficult to collect separately.

Lizards: The bone marrow is normally gelatinous.

Endocrine Organs (Adrenal, Pancreas, Thyroid, Parathyroid, Ultimobranchial, Pituitary, Pineal Glands). The adrenal gland is paired in reptiles but varies considerably in shape and location. Generally, it is a tubular-shaped or an ovoid structure closely associated with the kidneys and gonads. Microscopic changes in the adrenal gland can indicate stress, which can be difficult to evaluate by external observation.

The thyroid is a single structure (except variations in lizards) located at the base of the heart or at the bifurcation of the greater vessels. It is amber and appears multilobulated on cut surfaces. It can be mistaken for an abnormal mass. Examination of the thyroid for evidence of goiter or neoplasia is important. Thyroid size may vary from seasonal changes in follicular diameter, so mild enlargement may be a physiological rather than pathologic event. Also in the region of the thyroid are small lobulated structures that represent the thymus, parathyroid, and ultimobranchial bodies. Normally, ultimobranchial bodies are difficult to locate on gross examination.

VetBooks.ir

The pancreas has both exocrine (digestive) and endocrine functions. Pancreatic examination is important because it develops microscopic changes indicative of nutritional status. Some infectious disease processes have a tropism for the pancreas, such as paramyxovirus and monocercomoniasis in snakes. It is important to be aware of the location of the islet cell tissue in the pancreas of the reptile patient, as much variability exists. It may be best to submit the entire pancreas for histopathology to allow thorough evaluation of endocrine and exocrine tissue.

The pituitary and pineal glands are extremely small structures that are rarely diseased. If examination is warranted, it is recommended to submit the entire head of a necropsy specimen and request their examinations explicitly on the submission form. The head will then be decalcified and serial sectioned to look for these organs.

Snakes and chelonians: The pancreas is often fused with the spleen (splenopancreas) and located in the mesentery next to the gut and gallbladder.

Snakes and lizards: The adrenals are incorporated into the mesorchium of the male and mesovarium of the female.

Crocodilians: The adrenal gland is retroperitoneal, lying dorsolateral to the genital ducts.

Cardiovascular System (Heart, Great Vessels). A broad array of disease processes affects the cardiovascular system, such as atherosclerosis, bacterial endocarditis, endocardiosis, degenerative cardiomyopathy, thrombosis of the greater vessels and their main branches, and mineralization of the greater vessels. If cardiac pathology is of concern in a case, avoid intracardiac injections of euthanasia solution, as this can introduce significant histologic artifacts to the myocardium and vasculature.

Other than crocodilians, all reptiles possess a three-chambered heart, with muscular ridges partitioning the single ventricle. A fibrous attachment is sometimes present, connecting the pericardial sac to the apex of the ventricle (gubernaculum cordis), which is normal. For microscopic examination, routine submission of the entire heart of small reptiles (minus any fresh tissue for cultures) is recommended. For larger reptiles, full-thickness sections of the ventricle, both atria, and sections of the valves of larger reptiles is recommended. Opening the heart during dissection to allow for formalin perfusion is helpful for adequate fixation and may reveal lesions worthy of culture before formalin submersion. If the size of the heart permits, open the heart at the vena cava with blunt-tipped scissors at its insertion in the right atrium, extend the incision through the wall of the ventricle toward the apex, and then back up the left side to the aortic outflow. Reflecting the ventricles after this procedure exposes the valves for visual examination.

Visual identification of the aorta and major branches, and full-length examination of the luminal surfaces, is also recommended, especially if the animal has a history suggestive of thrombosis or vasculitis. A short length of cardiac outflow vessels (greater vessels) should routinely be submitted.

Blood films on slides can be made from heart blood at necropsy, provided the blood is not clotted. Blood collected in blood tubes can be centrifuged, and the resulting serum can be frozen and held for specific tests, such as electrolyte measurements.

Respiratory System (Trachea, Bronchi, Lung, Pseudodiaphragm). Numerous disease processes affect the respiratory tract, especially infectious diseases and mineralization from metabolic or nutritional disorders. Submission of the entire head ensures microscopic examination of the nasal cavity and larynx. Representative sections of the trachea and lung should always be submitted. In reptiles, the lung is a hollow sac with a honeycomb appearance on the inner surface. The anterior portion often has a thick, vascularized wall for respiratory function. The posterior portions are often thin-walled in nature. If size permits, open the trachea in its entirety and extend the incisions into the bronchi to look for parasites, effusions, or reddening of the mucosa. Palpate all lobes, if present, of the lungs for firmness (granulomas or neoplasia). The nasal cavity can be exposed by rongeurs to examine the nasal turbinates. Reptiles do not possess a muscular diaphragm, although tuataras, monitors, and crocodiles have a pseudodiaphragm.

Snakes: In nonboids, the right lung is well developed, while the left lung is generally reduced in size or absent. The lungs continue posteriorly as an air sac and can extend to the most caudal aspects of the coelomic cavity.

Lizards: The tracheal rings are incomplete. Geckos have chambered lungs, while iguanas and chameleons have transitional lungs with a large septum dividing a single chamber. The monitor and beaded lizards have multichambered lungs.

Chelonians: Complete cartilaginous rings are present. In sea turtles, the central bronchus extends throughout the length of the lungs. The lungs are attached to the ventral surface of the carapace, which consists of large, multichambered structures separated by septa (see Fig. 40.9). These can be difficult to dissect and remove from the carapace.

Crocodilians: The extrapulmonary bronchi can be extensive.

Urogenital System (Kidney, Urinary Bladder, Ovary, Uterus, Testes, Phallus/Hemipenes). Common disease conditions in reptiles that involve the urinary tract include chronic renal disease (especially iguanas), gout, urolithiasis (often large stones), nephrocalcinosis, bacterial and parasitic infections, and neoplasia.[4] The kidneys are paired and are generally located in the caudal coelomic cavity. Routine collection of reproductive tissues is important. Common reproductive problems in reptiles and amphibians include bacterial infections, neoplasia, and preovulatory and postovulatory follicular stasis; uterine/oviductal/cloacal disease; and mineralization, impaction, or prolapse of the hemipenes.[4] The urogenital system is similar in most reptiles. Gonads are paired. Females have paired oviducts (salpinx), and males have a paired epididymides and vasa deferentia. Identification of the kidneys, gonads, and adrenals in situ is important so that they are not lost or inadvertently overlooked during prosection. When present, the urinary bladder should be opened to look for cystic calculi, eggs, and parasites.

Lizards: The kidneys are especially caudal and can be missed at necropsy (see Fig. 40.5). The urinary bladder is absent in certain lizards. Lizards possess hemipenes tucked inside the base of the tail. Hemipenal appearance varies in size, shape, and external appearance among species.

Snakes: The kidneys are lobulated, elongated, and resemble an oblique stack of coins. During breeding season, male snakes (and some male lizards) can undergo a renal change and develop a "sexual segment," resulting in a more swollen and pale appearance to the kidney. The urinary bladder is absent, such that ureters directly enter the urodeum. The right gonad is cranial to that of the left. The testes are elongated, lightly colored, and are located between the pancreas and the kidneys. On the other hand, the ovaries are often nearer the pancreas. Snakes possess hemipenes inside the base of the tail, which vary in size, shape, and external appearance among different species.

Chelonians: Similar to lizards, the kidneys are especially caudal, and removal of pelvic bones ventrally is recommended to access and visualize them. Chelonians possess a phallus, while the tuatara do not have any specialized intromittent organ.

Crocodilians: The urinary bladder is absent. Crocodiles possess a phallus.

Liver. The liver is the largest organ in the coelomic cavity (see Figs. 40.2 and 40.8). It is generally bilobed, and all species have a gallbladder. The gallbladder is intimately associated with the right liver lobe in most

VetBooks.ir

lizards and chelonians. Hepatic diseases include infectious processes, neoplasia, toxicosis, lipidosis, cirrhosis, and melanosis.[4] Observe all the lobes for any uneven coloration and palpate for any evidence of friability or firmness. Although the normal liver is brown, abundant melanin can turn it black. A pale yellow to white and fatty liver can be associated with not only overfeeding and obesity but also impaired metabolism, anoxia, and toxins. However, seasonal, metabolic, and often associated reproductive activity can result in normal lipid movement into the liver of females, and this must be differentiated from true pathology (see Chapters 67 and 151). If sections of liver float in 10% neutral buffered formalin, consistent with lipidosis, then this should be noted. The gallbladder should be incised to examine the mucosal surface and look for any choleliths or parasites that may be present.

Snakes: The gallbladder is separated from, and caudal to, the liver, located close to the spleen and pancreas. There is a cystic duct that connects the gall bladder to the duodenum.

Nervous System (Brain, Spinal Cord). Diseases of the nervous system are commonly seen in reptiles and amphibians and are usually manifestations of other visceral disorders, such as gout, neoplasia, intoxication, or infectious disease. For small reptiles, the brain and cord are best examined when the entire head and vertebrae are submitted. For those animals too large for submission of an entire head and vertebral column, prosection of the spinal cord and brain is necessary. Using a knife or scalpel blade, the skin and musculature overlying the atlanto-occipital junction is incised, while moving the head up and down to facilitate separation without having to cut through bone. Exposure of the dorsocaudal aspect of the calvarium is achieved by removing the overlying soft tissue. The skull is removed piecemeal using rongeurs, starting at the foramen magnum and working rostrally, paying attention not to damage the brain underneath. Larger heads may require a Stryker saw or handsaw to cut through the calvarium. The top of the vertebral body (spinal process and lamina) can be removed for access to the spinal cord.

Extra care should be exercised when examining venomous snakes. The mouth should be taped shut so fingers are not impaled on fangs, and the top of the skull should be removed with a Stryker saw or bone rongeur for exposure to the brain. With submission of the head from venomous reptiles, labeling the containers "venomous" is important. Taping the mouth shut is useful when removing the brain, but fixation of the tissues may be impeded if the entire head is placed in formalin.

Gastrointestinal Tract. Disease conditions of the alimentary tract are especially common in reptiles, including a wide variety of bacterial, fungal, viral, and parasitic diseases.[4] Obstruction, plication, or ulceration from luminal passage of foreign bodies, intussusception (telescoping), stasis, and rectal/cloacal prolapse also are occasionally seen. Preferably, the pathologist should examine microscopically all segments of the alimentary tract, including the oral cavity (included with the head), esophagus, stomach, small intestine (duodenum, jejunum, and ileum regions), colon, rectum, and cloaca. Identifying particular segments of the intestines can be difficult histologically, especially when compounded by autolysis. Placing segments of intestines in separate and labeled cassettes can be helpful for the pathologist. If anaerobic etiological agents are suspected, segments of intestines should be tied off (if size permits) before placing into Whirl-Pak Bags. This allows for anaerobic culture of the intestinal contents, which would otherwise be compromised if the lumen is exposed to air. If ingestion of heavy metal is suspected, radiographs can be useful to demonstrate metal within the gastrointestinal tract that can easily be missed on the gross necropsy.

Snakes: Most snakes do not possess a cecum but have cloacal glands that exit at the caudolateral vent margins.

Lizards: Green iguanas *(Iguana iguana)* normally have a darkened tongue tip. They also have a sacculated large intestine.

Chelonians: Turtles lack teeth. Sea turtles have prominent spines associated with the esophageal mucosa, which should normally be directed caudally toward the stomach and are rigid. The intestinal tract is relatively short in carnivores and longer in herbivores.

6. Write the Report

Although formalin-fixed and frozen tissues can be stored for long periods of time, the written report and photographs are the only legal documents and physical evidence that remain once a gross necropsy is completed. Therefore it is critical that the thorough and succinct report includes high-quality photographs and is based on the contemporaneous notes taken during the necropsy examination. Table 40.3 is a sample necropsy form that includes a tissue checklist, which should accompany all histopathologic submissions to help the pathologist put findings in context.

The report should include at least the following information:

- Animal signalment: species, breed, age, sex
- Clinical history
- Died or euthanized, nutritional status
- Findings organized by organ system: external findings and musculoskeletal, lymphoid, respiratory, digestive, urogenital, and nervous systems

AFTER THE NECROPSY

Carcasses should be disposed of according to federal, state, and county regulations. Saved formalin-fixed tissues and Whirl-Pak Bags should be properly labeled and stored. If large amounts of fixed tissues need to be shipped, it may be preferable to thoroughly fix the tissues in formalin (at least 48 hours) and then pour off the formalin and wrap the fixed tissues in formalin-soaked power towels or gauze to be shipped. This avoids the need to ship large jars of formalin. However, proper infrastructure to handle formalin disposal and fumes is required.

ACKNOWLEDGMENTS

We would like to thank Dr. Mike Garner for his work on the previous edition of this textbook chapter, and Dr. Rita McManamon and Dr. Stephen Divers for collecting carcasses to be photographed. Several necropsy protocols, both specific to reptiles and modified from mammals, have been referenced as well.[4–8]

Diagnostic Laboratory Listing

Stephen J. Divers

Below is a list of diagnostic laboratories that have been fully or provisionally accredited through the American Association of Veterinary Laboratory Diagnosticians (AAVLD) (North America). This list is regularly updated and readers are advised to check current listings at http://www.aavld.org/accredited-laboratories.

Additional laboratories that are not accredited through the AAVLD have been included by recommendations from members of the Association of Reptilian and Amphibian Veterinarians, American Association of Zoo Veterinarians, American College of Zoological Medicine, and the European College of Zoological Medicine. It is the responsibility of those wishing to use these labs to ensure that they are satisfied with laboratory quality control and methodology validations.

NORTH AMERICA (ACCREDITED LABORATORIES)

Alabama

Thompson-Bishop Sparks State Diagnostic Laboratory

Medical History and Physical Examination

Stephen J. Divers

The successful diagnosis and treatment of reptile disease requires an ability to properly restrain, examine, and perform a variety of clinical techniques. The principles are similar to those used in domestic companion animal medicine. The ability to perform a thorough physical examination, which depends on adequate restraint, is considered a cornerstone of clinical practice. However, there are herp-specific peculiarities that must be appreciated to avoid potentially serious errors or injuries. The following descriptions include clinical techniques employed for the purposes of diagnosis in pet, zoo, and free-ranging reptiles. Some descriptions are general and apply to most if not all species within a group, while others may be more taxa or even species specific. It is vital that the species is identified prior to clinical interaction so that potential dangers can be appreciated and avoided. Strikes, bites, scratches, crushing injuries, envenomation, and zoonoses are some of the common dangers facing the clinician.

Clinical evaluation starts with a detailed history, and inexperienced clinicians are advised to consult a history form to ensure that no items are overlooked (Table 42.1). The aim of the physical examination is to identify and document any lesions or clinical signs to an organ system or systems and formulate a list of differential diagnoses (Table 42.2). It may be possible to observe calm specimens unrestrained, permitting an assessment of demeanor, locomotion, and obvious neurologic disorders such as lameness, paralysis, paresis, and head tilt.[1] Observation while the animal is in its normal enclosure is particularly valuable, and clients should be encouraged to share smartphone videos whenever possible. Nervous or aggressive species are best restrained at all times using towels, snake hooks, clear plastic containers, restraint tubes, and for larger animals, ropes and snares. Gloves and gauntlets severely reduce the clinician's tactile sensation but may be required when dealing with large pugnacious lizards or small-to-medium aggressive crocodilians.

A systematic examination from rostrum to tail tip is always indicated, whether the reptile is being presented for a postpurchase exam, yearly health exam, presurgical assessment, or because it is clinically unwell.[2–4] The clinicians' senses of sight, sound, smell, and touch are all utilized to examine all accessible areas for abnormalities. When taking the first tentative steps into reptile medicine, it can be invaluable to seek the help of individuals from a local herpetological society or herpetoculturalist for the purposes of examining clinically healthy animals.

A common stress response of many species to handling is the voiding of feces, urine, and urates during the clinical examination (Fig. 42.1). In many cases, material will be deposited on the table or on the clinician. Any veterinarian blessed with an abundance of clinically valuable material should consider immediate collection for possible laboratory investigation, including urine dipstick, fecal wet preparation, and flotation. Microbiologic results must be interpreted with caution when dealing with material collected in such an unsterile manner.

SPECIAL CONSIDERATIONS

Reception and Preparation

Reception staff should ideally be knowledgeable of common species, and many of the best staff have direct experience of keeping reptiles themselves. If the practice also sees domesticated dogs and cats, then consideration should be given to seeing herps at specific times, often at the end of surgery hours when the waiting room is quieter.

Although little specific equipment is required, technicians should prepare examination areas ahead of time, especially with regard to availability of clean towels, mouth speculums, syringes, needles, and specimen containers (see Chapter 1).

Transportation

Herps should be transported in insulated containers, but careful thought should be given to whether supplemental heating is necessary—overheating is more acutely fatal than cooling. No reptile should be unsecured and free-handled in the public waiting area.

Large Dangerous or Venomous Reptiles

Careful consideration should be given to the safety of veterinary staff, curatorial staff, and private owners when dealing with potentially dangerous animals. Some species may be covered by legislation restricting their ownership (see Chapters 183, 184, and 185 on legislation). Venomous snakes (especially front-fanged species), venomous lizards (*Heloderma* spp), crocodilians, and large aquatic turtles can be aggressive and dangerous. Examination of such animals should only be performed by experienced, recognized specialists with due regard to required equipment, practice facilities, and trained staff, as well as legal and liability issues.

Chemical Restraint

In many cases the judicious use of chemical agents can expedite procedures and reduce risks to both herp and human considerably, particularly when dealing with dangerous or venomous animals. Given the improvements in sedation and anesthesia, even reasonably manageable "pet" species may be preferentially sedated or anesthetized for clinical

TABLE 42.1 Reptile and Amphibian History Form

A detailed history is essential to provide the most appropriate veterinary care for your animal. Please complete this form as accurately as possible. If there is anything you are unsure about, you can discuss it in more depth with the veterinary staff during your appointment.

Animal Details

Animal's name or identification: _____ Common or scientific species name: _____

Date of birth: _____ Age: _____ Sex: M ☐ F ☐ Unknown ☐ Neutered/spayed ☐ Origin: captive bred ☐ wild-caught import ☐ unknown ☐

How long have you had this animal? _____

From where did you obtain this animal? _____

Does your reptile have any history of breeding or laying eggs? N ☐ Y ☐ Please give details: _____

_____

When did your reptile last shed? _____ How often has your reptile been shedding? _____

Do you have any other reptiles or pets? N ☐ Y ☐ Please give details: _____

_____

Have you or your reptile had any contact with other reptiles in the last 90 days? N ☐ Y ☐ Please give details: _____

_____

When was the last reptile added to your collection? _____

_____

Reason for Presentation Today

What is the primary complaint or what signs have you noticed? How long have these problems been present?

_____

_____

What health problems has your reptile had previously? _____

_____

When & why did you last see a veterinarian? _____

_____

Has your reptile received any treatment in the last 30 days? N ☐ Y ☐ Please give details (what was used, dosage, how often, duration?): _____

_____

Have you noticed any change in your reptile's behavior? N ☐ Y ☐ Please give details: _____

_____

Have any other animals or persons in the household had any illness in the last 30 days? _____

_____

TABLE 42.1 Reptile and Amphibian History Form—cont'd

Cage Environment

What type of cage is used? arboreal (tall, climbing) ☐ terrestrial ☐ aquatic ☐ Cage size: _____

_____

What is the cage made of? plastic/fiberglass ☐ wooden ☐ metal ☐ glass ☐ other: _____

_____

What is the floor substrate? paper ☐ corn cob ☐ sand ☐ astroturf ☐ bark ☐ other: _____

_____

What décor and furnishings are present? _____

Is there additional ventilation (grills or mesh)? N ☐ Y ☐ Please give size/details: _____

_____

Are bathing facilities provided? N ☐ Y ☐ Please give details: _____

How often is the cage cleaned? _____

What cleaning/disinfectant agents are used? _____

What heating equipment is used?

Ceramic/infrared ☐, power _____ W thermostat control: N ☐ Y ☐

Spot light/bulb ☐, power _____ W thermostat control: N ☐ Y ☐

Heat mat ☐, size: _____ under cage ☐ or inside cage ☐ thermostat control: N ☐ Y ☐

Aquarium water heater ☐, power _____ W thermostat control: N ☐ Y ☐

Other heaters, please give details: _____

Are the heat sources screened from the animals? N ☐ Y ☐ Please give details: _____

_____

Can the animal(s) touch or access the heat source? N ☐ Y ☐ Please give details: _____

_____

Is additional lighting provided inside the cage? N ☐ Y ☐

If yes, what type of light is used? Light bulb ☐ Fluorescent strip light ☐

What is the model and manufacturer? _____

When was the light last replaced? _____

Are the lights screened from the animals? N ☐ Y ☐ Please give details: _____

Can the animal(s) touch or access the lights? N ☐ Y ☐ Please give details: _____

_____

How many hours of light are provided each day? _____

Is there ever access to direct sunlight (not through glass or plastic)? N ☐ Y ☐

If yes, how many hours per day or per week? _____

Do you measure the humidity in the cage? N ☐ Y ☐ If yes, what is the humidity level? _____

_____

What are the day time temperatures? Hottest area, basking area = _____ Coolest area = _____

What are the night time temperatures? Hottest area, basking area = _____ Coolest area = _____

Are these temperatures measured using a thermometer? Y ☐ N ☐

Does anyone in the household smoke? N ☐ Y ☐ Do you use any aerosolized products? N ☐ Y ☐

Have there been changes in the reptile's environment in the last 3 months? N ☐ Y ☐ Please give details: _____

_____

Diet

How often do you feed your animal? _____

Indicate which foods are eaten and in what amounts (by number, weight, or approx volume):

Fresh vegetables ☐ type and amount per feed: _____

Frozen/thawed or processed vegetables ☐ fresh ☐ other ☐ _____

Flowers ☐ type and amount per feed: _____

Fresh fruits ☐ type and amount per feed: _____ Frozen/thawed ☐ fresh ☐ other ☐

Frozen/thawed or processed fruits ☐ fresh ☐ other ☐ _____

Insects: crickets ☐ locusts ☐ mealworms ☐ waxworms ☐ earthworms ☐ other ☐ _____

Mice ☐ type and number per feed: _____ Freshly killed ☐

Rats ☐ type and number per feed: _____ Frozen/thawed ☐

Birds or fish, please give details: _____ Live prey ☐

Do you feed any wild animals to your animal? N ☐ Y ☐, please give details: _____

Any other food items fed? Please give details: _____

Do you use any nutritional supplements? N ☐ Y ☐, if yes what, how much, and how often: _____

_____

What water supply do you provide? tap water ☐ bottled water ☐ rain/river water ☐

How is water provided? bowl ☐ dripper system ☐ spray ☐, how often: _____

How often is the water changed? _____

Do you use any water supplements? N ☐ Y ☐ Please give details: _____

Have you noticed any changes in feeding or drinking behavior? Please give details: _____

Have you noticed any changes in droppings (fecal material, urine and urates)? Please give details: _____

_____

Any other comments or information: _____

_____

_____

procedures that would otherwise take longer to accomplish and cause unnecessary stress or discomfort (see Chapters 48 and 49). When dealing with venomous snakes and other dangerous reptiles, anesthesia should be routinely considered before examination.[5] Potential effects of sedation or anesthesia on clinicopathologic results, especially hematology and biochemistry, should be appreciated even if they cannot be avoided.

Operant Conditioning and Training

An overlooked facet of reptile examination has been the value of operant conditioning and training. Several zoos have instigated such behavioral programs, which can greatly improve the ability to perform physical examinations and collect diagnostic samples from large tortoises, lizards, and crocodilians (see Chapter 14).[6] Even in private practice, this approach deserves further consideration with clients encouraged to desensitize their animals to transportation containers, physical restraint, mouth opening, coelomic palpation, and more.

Zoonoses

Reptiles, like all other animal groups, can be a source of disease in humans. The risks of reptile-borne zoonoses are probably no greater than for other animal groups, and basic personal hygiene after handling patients will reduce these risks to an acceptable, minimal level. The major zoonoses of potential concern include *Salmonella* sp, *Pseudomonas* sp, *Mycobacteria* sp, *Cryptosporidia* sp, *Rickettsia* sp, and pentastomids (arachnid lung parasites). Major public concern centers on the commensal reptile salmonellas, and clinicians are advised to obtain a copy of the statement policy and client brochure on this subject produced by the Association of Reptile and Amphibian Veterinarians (see Chapter 174).

Weight, Length, and Body Condition Score

Every animal must be accurately weighed, because deaths associated with drug overdose, particularly anesthetics and aminoglycosides, are avoidable. Serial weight measurements permit an appraisal of growth and captive management, response to treatment, and disease progression. Relating body weight to length to give an assessment of body condition is valuable but takes practice and experience to master; however, it does promote differentiation between the acutely sick (less common) and terminal presentation of chronic disease (more common). A calculated ratio of weight:length (snout to vent length in lizards and snakes, straight carapace length in chelonians) provides a numerical body condition index, and there are published charts that utilize this ratio for several common species.[7–10] In addition, body condition scoring can be useful, albeit more subjective, and a system from 1 to 5 is practical (1 emaciated, 2 underweight, 3 normal, 4 overweight, 5 obese). Loss of bodily reserves

VetBooks.ir

are usually most obvious around the tail, pelvic, and hind limb areas in lizards and crocodilians. Some species, such as the leopard gecko (*Eublepharis macularius*), store most of their fat reserves within a bulbous tail, and therefore tail size and shape in this species is a good means of assessing body condition. In snakes, the fat reserves tend to be more diffuse throughout the elongated coelomic fat bodies, nevertheless weight loss leads to loose skin folds with pronounced spine and ribs. Obese snakes will often exhibit soft, fatty swellings just cranial to the vent. The snout-vent length of a snake is important to note as organ position and growth can be calculated as a result. Chelonians present more of a problem. The musculature of the limbs and subcutaneous fat stores can be palpated, but the best estimation of body condition relies on relating total weight to carapace length or body volume.

Cloacal Temperature

It may seem a paradox to recommend taking a cloacal temperature from an ectotherm, but in certain situations it can be rewarding. Obviously, small reptiles maintained out of their heated enclosures for prolonged periods will experience changes in core temperature. However, larger reptiles (especially large tortoises, crocodilians, and snakes) that are examined in their home environment or soon after leaving their normal enclosure will not demonstrate dramatic changes in their core temperature if they are transported in an insulated container. Consequently, cloacal temperature may provide an indication of the thermal environment from which the reptile came.

Transillumination

Transillumination of the coelom using a cold light source can be beneficial for visualizing the internal structures of small lizards and snakes and is particularly useful for confirming suspected impactions and foreign bodies in the examination room. The light can be held against the body of a small herp, or lubricated and inserted into the esophagus or cloaca of a sedated animal. Transillumination in a darkened room enables coelomic masses to be identified, and the cardiac shadow can be located for cardiocentesis.

Auscultation

Auscultation is certainly possible, but the use of a standard diaphragm stethoscope does require an absolutely silent consulting room and is often unrewarding. The adventitious sounds produced between the shell or scales and the stethoscope diaphragm may be reduced by placing a dampened swab or towel between the stethoscope and the reptilian integument. More recently, the use of electronic stethoscopes has improved the appreciation of heart and respiratory sounds, although Doppler devices are favored for recording heart rates. In general, auscultation is of limited value.

FIG 42.2 (A) Restrained snakes must have their head and body supported. Aggressive snakes like this boa constrictor (*Boa constrictor*) cannot harm the handler when their heads have been securely grasped and controlled. (B) Nonvenomous snakes that are too nervous to examine properly, such as the rosy boa (*Lichanura trivirgata*), can be sedated by placing them in a clear plastic bag with 5% isoflurane or 8% sevoflurane in oxygen. Once righting reflexes have been lost (typically 5–30 mins) the snake can be removed for examination and will recover within 10 mins. (Courtesy of Stephen J. Divers.)

SNAKES

The head of an aggressive snake or a snake of unknown disposition should be identified and restrained before opening the transportation bag and removing the animal. Venomous snakes should be placed in clear plastic tubes or anesthetic induction chambers and anesthetized using an inhalant prior to examination. In general, the head of the snake is held behind the occiput using the thumb and middle finger to support the lateral aspects of the cranium. The index finger is placed on top of the head. The other hand is used to support the serpentine body (Fig. 42.2A). By restraining the snake's head in this manner, greater support can be given to the cranium-cervical junction, which, having only a single occiput, is more prone to dislocation with rough or inappropriate handling. The largest pythons and anacondas can exceed 5 m and 80 kg and are powerful and potentially dangerous. When dealing with large, even docile boids, an additional handler is recommended for each meter of snake.

Nonvenomous species should be removed from their cloth bag and supported using one or two hands depending on size. An assessment of demeanor can usually be quickly determined. Nervous or aggressive (nonvenomous) snakes can be restrained using clear plastic bags and/or sedated prior to examination (Fig. 42.2B). The docile snake should be permitted to roam over the hands and arms, thereby enabling the clinician to gauge muscle tone, propioception, and mobility. Propioception can be assessed by placing the snake in dorsal recumbency and monitoring the effort and ability of the snake to right itself (Fig. 42.3). Systemically ill serpents will often be limp, weak, and less mobile. The healthy serpent will impart a sense of strength and be active during handling. A healthy individual that is permitted to wrap a coil around

FIG 42.3 (A) Complete lack of righting reflex in a *Boa constrictor* suffering from arenavirus (boid inclusion body) disease (IBD). (B) Loss of righting reflex and opisthotonus in a ball python (*Python regius*). (Courtesy of Stephen J. Divers.)

FIG 42.4 (A) Dysecdysis in a *Boa constrictor*. (B) Blister disease associated with the ventrum of a colubrid snake caused by constant dampness within the vivarium. (C) Thermal burn on the ventrum of a kingsnake (*Lampropeltis* sp), caused by a poorly controlled heat mat. (Courtesy of Stephen J. Divers.)

the handler's wrist while the head is allowed to hang down should be able to raise its head to the level of the tail. Head carriage, body posture, cloacal tone, propioception, skin pinch, withdrawal, and ocular and righting reflexes can be used to assess neurologic function.

The entire integument, particularly the head and ventral scales, should be thoroughly examined for evidence of dysecdysis (poor shedding), trauma, parasitism (especially the common snake mite, *Ophionyssus natricis,* and ticks), and microbiologic infection (Fig. 42.4). If available, the recently shed skin should also be examined for evidence of retained spectacles. Skin tenting and ridges may indicate cachexia or dehydration, whereas ticks and mites may congregate in skin folds, infraorbital pits, nostrils, and perispectacular rims. The infraorbital pits (where present) and the nostrils should be free from discharge or retained skin. The eyes should be clear, unless ecdysis is imminent. In preparation for shedding, snakes produce a lymphlike fluid that creates a white to bluish haze to the eyes. It is this fluid that creates the cleavage zone and facilitates the lifting of the old skin. The spectacles covering the eyes should be smooth, as any wrinkles usually indicate the presence of a retained spectacle. The spectacle represents the transparent fused eyelids, and therefore the cornea is not normally exposed. The subspectacular fluid drains through paired ducts, close to the vomeronasal openings in the maxilla. When blocked, the buildup of fluid causes a subspectacular swelling that often becomes infected, resulting in a subspectacular abscess. Damage to the underlying cornea can result in panopthalmitis and ocular swelling, while retrobulbar abscessation will result in protrusion of a normal-sized globe. Other ocular pathologies can include uveitis, corneal lipidosis, and spectacular foreign bodies, including slivers of wood chip or other vivarium materials (see Chapter 71).

Examination of the oral cavity is often left until the end of the examination, as many snakes object to such manipulation. However, even before the mouth is opened, the tongue should be seen flicking in and out of the philtrum with regularity. The mouth can be gently opened using a plastic/wooden spatula or wood portion of cotton-tip applicators to permit an assessment of mucous membrane color and buccal examination for evidence of mucosal edema, ptyalism, hemorrhage, necrosis, and inspissated exudates (Fig. 42.5). The presence of white deposits may indicate uric acid deposition due to visceral gout.

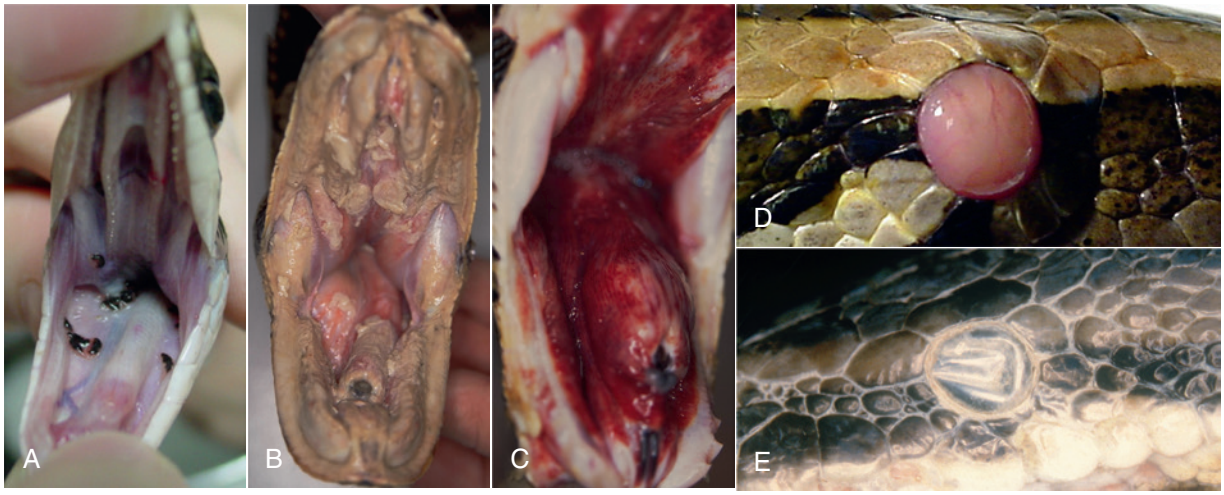

FIG 42.5 (A) Digenic trematodes (*Renifer*) in the oral cavity of a free-ranging black racer (*Coluber constrictor*). (B) Severe bacterial stomatitis in a *Boa constrictor*. (C) Severe buccal erythema and petechiation associated with stomatitis in a boid snake. (D) Subspectacular abscess in a Burmese python (*Python bivittatus*). (E) Retained spectacle in a ball python (*Python regius*). (Courtesy of Stephen J. Divers.)

The pharynx, choana, and larynx should be examined for hemorrhage, foreign bodies, and discharges. It is important to observe the larynx during respiration to differentiate between discharges originating from the respiratory or gastrointestinal tracts. Unfortunately, due to the stress of examination, respiratory rates are often elevated in normal reptiles, and therefore tachypnea may not be considered a definitive indicator of respiratory disease unless observed in the undisturbed snake. However, open mouth breathing is a reliable indicator of severe respiratory compromise. During the oral examination the patency of the internal nares and the state of the polyphyodontic teeth should be noted.

Working from cranial to caudal, the head and body are palpated for abnormal swellings, wounds, and other abnormalities. The position of any internal anomalies, noted as a distance from the snout and interpreted as a percentage of snout-vent length (SVL), will enable an assessment of possible organ involvement (Fig. 42.6).[11] Depending on the musculature, feeding habits, and fat reserves of the snake, it may be possible to palpate the normal heart, stomach, liver, active ovaries, eggs, kidneys, and fecal material. Recently fed snakes will have a midbody swelling associated with the prey within the stomach, and postprandial handling can lead to regurgitation. The clinical examination should differentiate between coelomic (internal) and extracoelomic (subcutaneous) masses. The majority of subcutaneous masses are usually abscesses, but parasitic cysts, blisters, and neoplasia are occasionally seen. Internal masses may represent abscesses, neoplasia, granulomas, obstipation, organ hypertrophy, retained eggs, or ova (Fig. 42.7). The cloaca should have muscle tone, not be gaping, and be free from fecal staining, discharge, and prolapse (Fig. 42.8). Just distal and slightly lateral to the cloaca the paired cloacal scent glands are palpable and should be soft and bilaterally symmetrical. Nervous snakes, especially colubrids, will often expel the contents of these cloacal glands in a defensive reaction to a perceived threat. This foul-smelling material does not represent infection but merely an annoyance, as the smell is difficult to eradicate from clothing. Examination of the cloaca can be carried out using a dedicated otoscope or rigid endoscope. Digital palpation is often overlooked but is a useful technique. In medium-to-large snakes a latex-gloved, lubricated finger can be passed into the cloaca and may allow palpation of eggs, cloacoliths, fecoliths, or abscesses. In the giant constrictors it is possible to insert a lubricated, gloved arm and perform an internal cloacal and even colonic examination. Care is required not to force the colonic examination, because the lower intestinal wall is thin and prone to laceration. Internal palpation often induces defecation and urination and can be useful to aid the collection of samples. Examination of tail length or probing of the hemipenes should confirm gender (Fig. 42.9). The tail length (and the number of subcaudal scales) is always shorter (less) in females than in males; however, this method requires access to published information on tail length and scale counts (which is not available for all species) or the presence of both sexes for simultaneous examination, and thus is a less reliable technique. The hemipenes are entered by directing a blunt, water-soluble lubricated probe, caudally, on either side of midline. In males the probe passes to a depth of 6 to 14 subcaudal scales, whereas in females the probe enters a cloacal gland to a depth of only 2 to 6 subcaudal scales. Some species of snakes such as short-tailed or blood pythons (*Python curtis*) can be difficult to sex with probing, as the probing depths are so similar for males and females (see Chapter 80 for more information on gender identification).

LIZARDS

Lizards vary considerably in size, strength, and temperament, and therefore a variety of handling techniques are required to cover most examination scenarios. The tegus (Teiidae) and monitors (Varanidae) are renowned for their powerful bites, whereas other species, particularly the green iguana (*Iguana iguana*), are much more likely to use their claws and tail to painful effect. The main problem when handling small lizards is restraining them before they flee from an open bag or container. In all cases, the lizard should be transported in a securely tied cloth bag so that the position of the lizard can be identified and held before the bag is even opened. Large lizards are best restrained with the forelimbs held laterally against their cranial coelom and the hind limbs held laterally against the tail base (Fig. 42.10). The limbs should not be held over the spine, as fractures and dislocations may occur. Smaller lizards can be restrained around the pectoral girdle, holding the forelimbs against the cranial coelom, although care is required not to impair respiratory movements. Restricting the vision of these animals is often the simplest way to facilitate handling, and a towel or sock placed over the head will often facilitate examination of the rest of

the body and limbs. Particularly nervous lizards can be wrapped in a towel to aid restraint (Fig. 42.11). A useful restraint technique for iguanid lizards utilizes the vasovagal response: gentle digital pressure is applied to both orbits, and in many cases the lizard will enter a state of stupor for up to 30 minutes or until a painful or noisy stimulus is applied. This technique can be used to calm nervous iguanids and monitors and enables the mouth to be gently opened without the need for excessive force.

If possible the lizard should be observed unrestrained to appreciate any neurologic problems or lameness (Fig. 42.12). Calm lizards may be permitted to walk around the examination table or on the floor. However, if in any doubt, the lizard should be placed in a large plastic enclosure to prevent escape during the observation period. Never grasp a lizard by the tail, because many species can perform autotomy and drop their tails in an attempt to evade a predator.

The integument should be examined for parasites (mites and ticks) and evidence of trauma due to fighting, mating, burns, or repeated escape attempts (Fig. 42.13). Most lizards tend to shed their skin in stages, and therefore retained skin (often dry and brown) must be differentiated from normal piecemeal ecdysis (flexible and transparent). Classically, dysecdysis and skin retention occurs around the digits and tail, causing ischemic necrosis. Extensive skin folding and tenting are indicators of cachexia and possible dehydration.

The head should be examined for abnormal conformation (Fig. 42.14). The mouth can be opened using a blunt spatula or by gently applying pressure to the dewlap. Thorough buccal examination for evidence of trauma, infection, neoplasia, and edema, especially pharyngeal edema, and examination of the choana and larynx are considered routine (Fig. 42.15). In addition, the internal extent of any rostral abrasions can be evaluated. The nostrils, eyes, and tympanic scales should be clear and free from swelling and discharge (Fig. 42.16). The presence of white dried material around the nostrils of some iguanid lizards is normal, as some species excrete salt through specialized nasal glands. The head, body, and limbs must be palpated for masses, swellings, and fractures. Focal soft tissue masses are usually abscesses, whereas more diffuse swellings around the long bones or mandible are likely to be related to metabolic bone diseases. Lizards suffering from severe hypocalcemia and hyperphosphatemia due to nutritional or renal secondary hyperparathyroidism exhibit periodic tremors and muscle fasiculations. The coelomic body cavity of most lizards can be gently palpated. In the normal animal food and fecal material within the gastrointestinal tract, fat bodies, liver, ova, and eggs are usually appreciable. Cystic calculi, fecoliths, enlarged kidneys, impactions, retained eggs or ova, large fat bodies, and unusual coelomic masses are abnormal (Fig. 42.17). An appreciation of species, gender, age, body size, and weight will permit

an assessment of growth and body condition. Auscultation of the heart using Doppler ultrasound is possible, whereas lungs are more challenging.

The cloaca should be free from fecal staining with visual and digital palpation considered routine in larger lizards where enlarged kidneys may be appreciated. The high incidence of dystocia necessitates a need to identify gender in the examination room. Many species of lizards are sexually dimorphic, although sexing juveniles can be difficult. Adult males tend to be generally larger with specifically larger heads; have more well-developed integumental appendages such as tubercules, spines, jowls, and dewlaps; are more colorful; exhibit more courting (head bobbing) and territorial behaviors; and possess paired hemipenal bulges at the tail base and more developed femoral or preanal pores (Fig. 42.18). Hemipenal eversion and probing are techniques that can be used but are generally more difficult to master than in snakes (see Chapter 80 for more information on gender identification lizards).

CHELONIANS

Aquatic species tend to have a formidable bite that may belie an apparently gentle disposition. The major biologic peculiarity of all chelonia is the presence of the shell. The plastron and carapace not only give this group their characteristic structure but also doubles as a barrier to physical examination. Nevertheless, much can still be achieved in the consulting room before resorting to imaging techniques. Small-to-medium tortoises are not difficult to handle, although their strength and uncooperative nature can hinder the examination and cause frustration. A little patience while holding the tortoise head down will often persuade a shy individual to protrude the head from the shell, allowing the thumb and middle finger to then be placed behind the occipital condyles to prevent retraction of the head back into the shell. Alternatively, a long 18- to 20-g hypodermic needle with the terminal 3 mm bent at a 60-degree angle can be inserted into the mouth of a retracted head and used to engage the buccal surface of the upper beak. Sustained traction is often successful at extracting the head from the shell. In the larger species (e.g.,

VetBooks.ir

Centrochelys, Stigmochelys, Geochelone) it may be physically impossible to overpower an individual, and reliance on sedation is often necessary.

Applying steady distractive pressure to the maxilla and mandible can open the mouth, and once open the index finger (in small, gentle specimens) or a mouth gag (in larger or aggressive specimens) can be inserted to prevent closure. This method enables the handler to keep the mouth open using one hand, leaving the other free to examine the head and take samples for laboratory investigation. In aggressive species, open-mouth threat displays provide a good opportunity to examine the buccal cavity with minimal handling. The buccal cavity must always be examined, particularly for evidence of inflammation, infection, gout, and foreign bodies (Fig. 42.19). Stomatitis can quickly lead to a generalized esophagitis, and examination down the pharynx and into the esophagus using a rigid endoscope is advisable. Mucous membrane coloration should be noted and is normally pale pink. Hyperemic membranes may be associated with septicemia or toxemia. Icterus is rare but may occur with biliverdinemia due to severe liver disease. Pale membranes are often observed in cases of true anemia. Pale deposits within the oral membranes may represent infection or urate tophi associated with visceral gout. The larynx may be difficult to visualize, being positioned at the back of the fleshy tongue; however, it is important to check for any inflammation and glottal discharges that may be consistent with respiratory disease. Examination of the head should include the nostrils for any discharge and the beak for damage and overgrowth (Fig. 42.20). The eyelids should be open and not obviously distended or inflamed, and the eyes should be clear and bright. Conjunctivitis, corneal ulceration, and opacities are frequent presentations (Fig. 42.21). The retina can often suffer from degeneration as a consequence of freezing during hibernation, and ophthalmic examination is warranted in every animal. The tympanic scales should be examined for signs of swelling associated with aural abscessation (Fig. 42.22). Verification of a tympanic abscess can often be made by observing exudate emanating from the eustachian tube openings at the lateral walls of the pharynx.

The withdrawn limbs can also be extended from the shell of small-to-medium chelonians by applying steady traction. The coelomic space within the shell is restricted, and therefore gently forcing the hind limbs into the shell will often lead to partial protrusion of the forelimbs and head and vice versa. The more aggressive aquatic species should be held

at the rear of the carapace. Some species (e.g., common snapping turtle, *Chelydra serpentina*) can deliver a rapid and extremely powerful bite, and so great care is required at all times. Certain species also possess functional hinges at the front and/or back of the plastron, and care should be taken not to allow a finger to become trapped. A wedge or mouth gag can be used to prevent complete closure of a hinge, and chelonians will not close a hinge on their own extended appendage. The integument should be examined for parasites, particularly ticks and flies, dysecdysis, trauma, and infection resulting from rodent, raccoon, or small carnivore attacks. Aggressive conflicts and courting trauma must also be considered in the communal environment. Limb fractures are less commonly reported in chelonians than in lizards but are often caused by rough handling and falls, with a greater incidence possible in those individuals suffering from nutritional secondary hyperparathyroidism. The integument should be free of damage and subcutaneous swellings, which if present are often abscesses, myiasis (if housed outdoors), or neoplasia, which is less frequent (Fig. 42.23). Aquatic species appear more susceptible to superficial and deep mycotic dermatitis, especially around the head, neck, and limbs. Grossly swollen joints or limbs are more often cases of fracture, osteomyelitis, septic arthritis, or rarely neoplasia.

The prefemoral fossae should be palpated with the chelonian held head-up. Gently rocking the animal may then enable the clinician to appreciate eggs, cystic calculi, or other coelomic masses. The shell should be examined for hardness, conformation, trauma, and infection (Fig. 42.24). Soft, poorly mineralized shells of juveniles are usually a result of nutritional secondary hyperparathyroidism resulting from dietary deficiencies of calcium, excess phosphorus, or a lack of full-spectrum lighting. Pyramiding of the shell has been linked to reduced environmental humidity and high nocturnal temperatures, although it is likely multifactorial. Shell infection may present as loosening and softening of the scutes with erythema, petechiae, purulent, or caseous discharge and a foul odor. Deep infections usually involve the bones of the shell with resulting osteomyelitis.

Prolapses through the vent are obvious, but it is necessary to determine the structure(s) involved. Prolapses may include cloacal tissue, shell gland, colon, bladder, or phallus (Fig. 42.25). Internal examination using digital palpation or an endoscope is recommended. Male chelonians can be differentiated from females by their longer tails and a more distal position of their vent past the caudal edge of the carapace (Fig. 42.26). Other sexually dimorphism characteristics may also be obvious,

including the concavity of the male plastron in many species and the longer forelimb claws of some male freshwater species. (See Chapter 80 for a thorough review of sex determination.)

CROCODILIANS

Individuals under 2 m in total length can often be handled conscious, albeit with extreme caution. Even the small crocodilians can use both tail and jaw to cause injury. Examination of large crocodilians requires the coordinated efforts of an experienced team, and the mouth should always be taped shut and the tail firmly restrained (Fig. 42.27). A vasovagal-induced torpor can be elicited by gently taping the eyes closed. Examination of the eyes and mouth are carried out at the very end of the examination process, just before the animal is released. Animals may be strapped to a wooden plank to improve physical restraint, but when dealing with animals more than 2 m in length, serious consideration should be given to the routine use of chemical restraint. The physical examination of crocodilians follows a similar pattern to that used for large saurians, as their body patterns are similar. The clinician should pay particular attention to the extremities and integument, which are often traumatized by conspecifics or interactions with poorly designed environments.

Diagnostic Techniques and Sample Collection

Stephen J. Divers

The successful diagnosis and treatment of herpetologic disease requires an ability to properly restrain, examine, and perform a variety of clinical techniques. The principles of such techniques are similar to those employed in domestic companion animal medicine. The following descriptions include clinical techniques that the author has employed for the purposes of disease diagnosis in pets, zoo animals, and wildlife. Some descriptions are general and apply to most if not all species within a group, while others may be more specific. Careful consideration should be given to the context of disease investigation, and zoological veterinarians need to be able to switch perspectives from individual animal (i.e., extensive antemortem diagnostic testing is appropriate) to population health (i.e., when elective necropsy of an affected animal may be more efficient and cost-effective). Definitive diagnosis of nontraumatic issues requires demonstration of both a pathologic response by the animal and etiologic agent. Pathologic responses can be documented by histopathology (often considered the gold standard), cytology (less favored due to loss of tissue architecture), and paired rising antibody titers (of which the few that are available take 6–12 weeks to develop and are more retrospective in value). Demonstration of the etiologic cause typically requires microbiology (culture, PCR), parasitology, toxicology, or again, paired rising titers. As zoological clinicians we need to get past disease diagnosis at the organ level (i.e., kidney disease) and strive for an antemortem definitive diagnosis at a histologic level (e.g., glomerulonephritis due to *E. coli*). The advent of various clinical techniques (especially endoscopic biopsy) have enabled antemortem diagnosis, where previously necropsy was the only means of achieving a definitive answer.[1–7]

DIAGNOSTIC SAMPLE COLLECTION

Blood and Hemopoietic System

Venipuncture and Blood Collection. The ability to collect quality blood samples is essential in any animal class. Complete or selective hematologic and biochemical evaluations are possible, but the accuracy of results is often adversely affected by poor venipuncture, handling, or laboratory skills. The production of poor quality blood data can be useless or, even worse, misleading to the clinician. Likewise, the ability to administer intravenous medications especially anesthetics, or place intravenous catheters also relies on proficient venous access. Venipuncture is generally a blind technique in reptiles. The jugular vein of certain tortoises may be visible particularly following temporary caudal occlusion of the vessel or by positioning the animal in a head-down position; however, anatomic knowledge of the position of reptile veins is vital. It is wise to aseptically prepare the venipuncture site, as infection and abscessation following venous access is a potential complication. Despite a continuous trickle of published blood ranges, there is still a paucity of hematologic or biochemical data for reptiles compared to domesticated animals. The issue is further complicated by variations, often dramatic, associated with species, environment, nutrition, age, gender, breeding status, hibernation, and disease status. Consequently, few, if any, of these published ranges can claim to satisfy the American Society of Veterinary Clinical Pathologists guidelines for reference range production and therefore should be described as observed ranges.[8] Given this variability, published ranges are often of limited value, and clinicians should develop a healthy distrust of such data, which becomes clear when you start comparing clinicopathology to histopathology findings. Greater value should be placed on (i) establishing a healthy individual's observed range by annual or biennial sampling, which should form the basis of identifying abnormalities, and (ii) monitoring the progress of hematologic and biochemical changes during disease rather than relying on a single result. The following descriptions indicate the most humane and practical venipuncture sites. Others have been indicated for completeness but may have reduced clinical application due to increased risk, poor quality sample, or significant welfare and ethical concerns. For example, the use of a toenail clip to obtain blood may result in fecal or urate contamination, elevated tissue enzymes, abnormal hemogram, and electrolyte changes due to the peripheral nature of the sample and the crushing artifact of collection. Of even greater concern are the ethical and welfare issues that surround a procedure that causes more pain and carries a greater risk of post-sampling sepsis.

Approximately 0.4 to 0.8 mL blood per 100 g body weight may be safely collected from healthy reptiles, but when dealing with compromised animals, restricting collection to 0.4 to 0.5 mL/100 g on any occasion is sensible. The established dogma that lithium heparin is the preferred anticoagulant for reptile hematology is simply false. EDTA has been shown to be superior for most, if not all, squamates and even some chelonians.[9–11] Only in the Chelonia are there examples of species-specific, EDTA-induced erythrocyte lysis necessitating the use of lithium heparin.[12] When blood-sampling chelonians of unknown EDTA sensitivity, it is wise to submit both heparin and EDTA whole blood samples and to measure the PCV of both. Only if the PCV of the EDTA sample is lower should the heparin sample be used in preference. When dealing with small chelonians of unknown EDTA sensitivity (where only a single hematology sample is possible), heparin should be submitted. Another misconception is the value of manually preheparinized syringes to prevent clotting and improve sample quality. The use of preheparinized syringes results in significant and inconsistent blood dilution with reductions in PCV and total solids and is not recommended.[13]

Snakes. The two common sites for venipuncture in snakes are the caudal (ventral tail) vein and the heart (Fig. 43.1). The caudal (tail) vein is accessed caudal to the cloaca, between 25% and 50% down the tail. It is wise to avoid the paired hemipenes of males (that may extend up to 14–16 subcaudal scales down the tail), and the paired cloacal musk glands in both sexes (that may extend up to 6 subcaudal scales).

VetBooks.ir

The needle is angled at 45 to 60 degrees and positioned in the ventral midline. The needle is advanced in a craniodorsal direction, while maintaining slight negative pressure. If the needle touches a vertebral body, it is withdrawn slightly and redirected more craniad or caudad. Gravity can be utilized to help with venous blood flow by "hanging" the tail down prior to and during blood collection. This vessel is most easily entered in larger snakes and lymphatic or cerebrospinal fluid contamination is possible.

With the snake restrained in dorsal recumbency, the heart is located approximately 22% to 33% from snout to vent. The heart is palpated and immobilized. The needle is advanced at 45 degrees in a craniodorsal direction into the apex of the beating ventricle. Blood often enters the syringe with each heartbeat. If an initial attempt does not result in blood entering the syringe, the needle should be withdrawn and a new needle and attempt should be made. Do not move the needle laterally "searching" for blood flow as laceration to the ventricle or pericardium may occur and result in severe damage and hemorrhage. It is wise to maintain digital pressure for 30 to 60 seconds following this technique. This technique appears to be safe in snakes of all sizes, although pericardial hemorrhage has been appreciated by the author at necropsy following this technique. Lymphatic or pericardial contamination appears uncommon but pericardial fluid, and it has been used in snakes ranging from 10 g neonates to 100 kg constrictors. Nevertheless, excellent restraint is essential if significant cardiac trauma is to be avoided, and this technique should be reserved for animals that are moribund, anesthetized, or where tail venipuncture failed. The palatine-pterygoid veins are easily visualized in the dorsal aspect of the oral cavity of large snakes; however, difficulties concerning physical restraint, appropriate access, and the prevention of a large hematoma make this technique less acceptable.

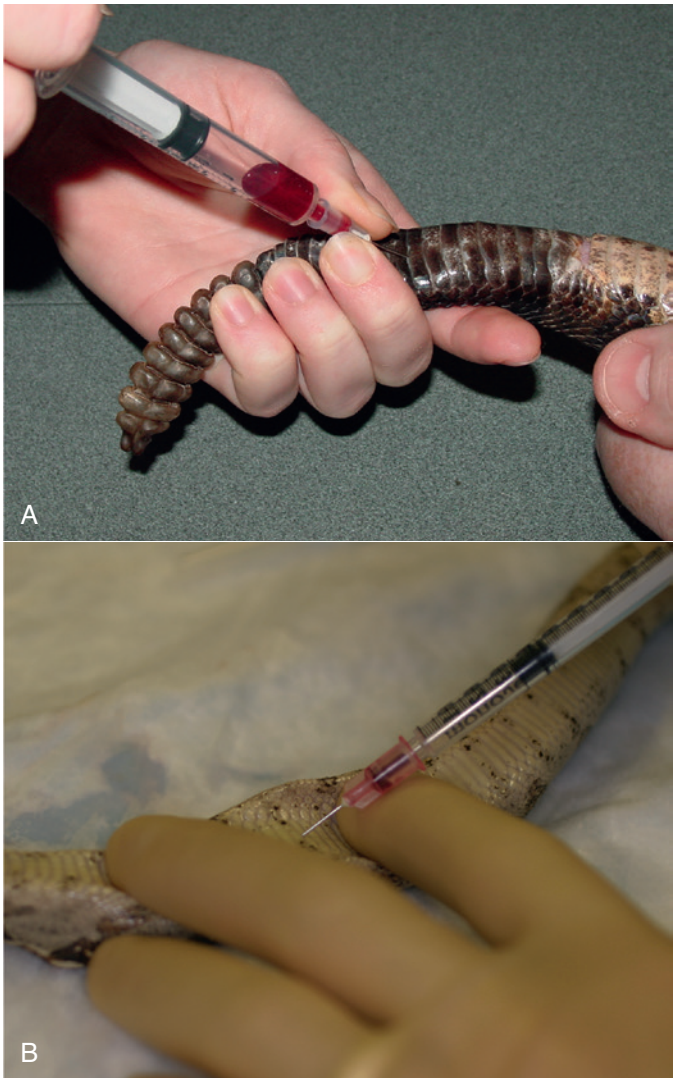

FIG 43.1 (A) Blood collection from the caudal (tail) vein of a rattlesnake *(Crotalinae)*. Note the position of the needle caudal to the cloacal. (B) Blood collection by cardiocentesis in a juvenile *Boa constrictor*. The heart is digitally immobilized prior to introducing the needle. (Courtesy of Stephen J. Divers.)

Lizards. The most clinically useful vessel is the caudal (tail) vein (Fig. 43.2). The needle is positioned in the ventral midline between 20% to 80% down the tail and advanced at 45 to 60 degrees in a craniodorsal direction while maintaining slight negative pressure. If a coccygeal vertebra is encountered, the needle is withdrawn slightly and redirected either further craniad or caudad. An alternative approach that is particularly useful for the larger species is to insert the needle from the lateral midline. The needle is advanced at 45 to 60 degrees in a craniomedial direction, aiming just ventral to the lateral processes of the coccygeal vertebrae. Lymphatic contamination appears more likely with the lateral approach.

Lizards possess a large ventral abdominal vein that runs within a suspensory ligament just below the linea alba. This vessel is most easily entered in the midcoelomic region. The needle is positioned in the ventral midline and advanced in a craniodorsal direction. Apart from the risks of puncturing the gastrointestinal tract or bladder, it is difficult to apply pressure to this vessel, making postvenipuncture hemorrhage a potential complication.

Jugular vein venipuncture is also practical, especially in larger lizards. The jugular veins lie lateral and deep and are seldom visible even when caudally occluded by digital pressure. For most species, the tympanum is a useful anatomic landmark. The lizard is restrained in lateral recumbency, and the clinician should insert the needle in a caudal direction behind the tympanum.

Cardiocentesis in lizards is not as acceptable as it is in snakes, because the heart cannot be stabilized. Other potential sites include the axillary plexus, orbital sinus, and toenail clip. but their use is more problematic, clinically unwarranted, and ethically less acceptable.

Tortoises, turtles, and terrapins. The left and right external jugular veins (also referred to as the left and right dorsal cervical sinuses) are preferred because of the greatly reduced risk of lymphatic or cerebrospinal fluid contamination (Fig. 43.3). The regional anatomy varies with species, but the vessel is generally located laterally and may even be visible by occluding the vessel at the base of the neck or restraining the animal in a 30-degree head-down position. The needle is positioned caudal to the tympanum and directed in a caudal direction. Following venipuncture, the chelonian should be held in a head-up position with pressure applied to the jugular to prevent hematoma formation.

There are variable, species-specific ventral, lateral, and dorsal coccygeal vessels that can be utilized in many chelonia. The dorsal coccygeal vein is probably the most commonly used of the tail veins (Fig. 43.4A). The needle is angled at 45 to 90 degrees and placed, as craniad as possible, in the dorsal midline of the tail. The needle is advanced in a cranioventral direction while maintaining slight negative pressure. If the needle encounters a vertebra, it is withdrawn slightly and redirected more craniad or caudad. The exact position, size, and even presence of this vessel may vary between species, and there is a significant risk of lymphatic or cerebrospinal fluid contamination.

VetBooks.ir

A subcarapacial site is also available and formed by the venous communication between the most craniad intercostal vessels arising from the paired azygous veins and the caudal cervical anastomosis of the left and right jugular veins (Fig. 43.4B). This sinus can be accessed with the chelonian's head either extended or retracted, making it useful for uncooperative or aggressive individuals. Depending on the species and conformation of the carapace, the needle may be bent up to 60 degrees and positioned in the midline just caudal to the skin insertion on the ventral aspect of the cranial rim of the carapace. The needle is advanced in a caudodorsal direction, maintaining slight negative pressure. If a vertebra is encountered, the needle is withdrawn slightly and redirected further craniad or caudad. Lymph, or more commonly cerebrospinal fluid, contamination can occur.

There is a significant postoccipital vessel that lies in the midline, dorsal to the vertebral column. This vessel can be accessed just behind the head (Fig. 43.4C). The needle is inserted from the parietal notch, lateral to the supraoccipital crest, directed at 45 degrees to the midline and advanced in a caudomedial direction. The lateromedial advancement of the needle reduces the chances of trauma to the spinal cord. If unsuccessful, the needle can be inserted in the dorsal midline and aimed ventrally (much like access to the supravertebral sinus of crocodilians); however, excessive penetration can more easily damage the spinal cord, and therefore excellent restraint is necessary. In general, this dorsdal midline approach is reserved for anesthetized or moribund animals where there is a critical need for blood collection and other techniques have failed.

Cardiocentesis is rarely indicated (unless other approaches have failed) or practical due to the obstruction caused by the plastron. In those chelonians with soft shells (e.g., soft-shelled turtles [*Apalone* spp], neonates of most species, and individuals with severe secondary nutritional hyperparathyroidism) a needle can be inserted through the soft plastron directly into the heart. The exact position of the heart varies with species but is generally located just dorsal to the plastron, in the midline at the intersection of the abdominal and pectoral scutes. In hard-shelled animals, a temporary osteotomy over the cardiac point of the plastron also permits access to the heart. Alternatively, the heart may be approached from a soft tissue approach. The chelonian is held in dorsal recumbency and on the right side a point is located midway between the plastron and carapace vertically and between the base of the neck and the shoulder joint horizontally. The needle is inserted at this point and directed toward the junction of the humeral and pectoral scutes.[14]

There are a variety of other venipuncture sites, including the brachial and femoral veins and plexuses, orbital sinus, and toenail clips. Brachial and femoral approaches may be clinically useful in large tortoises, but lymphatic contamination is a concern. Orbital sinus and toenail clips are inappropriate clinically but may have legitimate research applications.

Crocodilians. The most appropriate venipuncture sites are the caudal (tail) vein in small-to-medium crocodilians and supravertebral vein/sinus in medium-to-large specimens (Fig. 43.5). The supravertebral vein is approached with the needle positioned in the dorsal midline, just caudal to the occiput and perpendicular to the surface of the skin. The needle is slowly advanced while maintaining slight negative pressure. Excessive penetration may lead to spinal trauma, but this appears rare in larger animals. The technique for caudal (tail) vein access is as described for lizards. The heart is located on the ventral midline, approximately 11 scale rows caudal to the forelimbs. Cardiocentesis in crocodilians is not as safe as it is in snakes because the heart cannot be stabilized.

Bone Marrow. On occasions it may be necessary to submit bone marrow to permit a more detailed hematologic evaluation. The technique for bone marrow collection depends on the size and nature of the reptile. Diagnostic samples can be collected from the femoral or tibial medullary cavities of most lizards, crocodilians, and large chelonians (although chelonians often have more solid bones and less medullary cavity) (Fig. 43.6A). In these reptiles, a suitably sized spinal needle (or hypodermic needle in very small individuals) can be placed into the medullary cavity of the bone, and gentle-to-moderate aspiration is used to obtain a sample. An alternative site in chelonia is the plastrocarapacial bridge that laterally connects the plastron and carapace, but again the medullary tissue is often limited (Fig. 43.6B). It is generally necessary to drill through the outer layer of keratin and bone and gain access to the medullary cavity and marrow beneath.

In snakes it is often necessary to surgically remove and submit a rib for marrow evaluation. A large midbody rib should be selected. A dorsoventral incision is made in the dorsolateral aspect of the body directly over a rib. The rib is palpated and located before cutting as far dorsad as possible, close to the epaxial musculature. The lateral muscular

FIG 43.5 (A) Blood collection from the caudal (ventral tail) vein of a West African dwarf crocodile (*Osteolaemus tetraspis*). (B) Blood collection from the supravertebral venous sinus of an American alligator (*Alligator mississippiensis*). (Courtesy of Stephen J. Divers.)

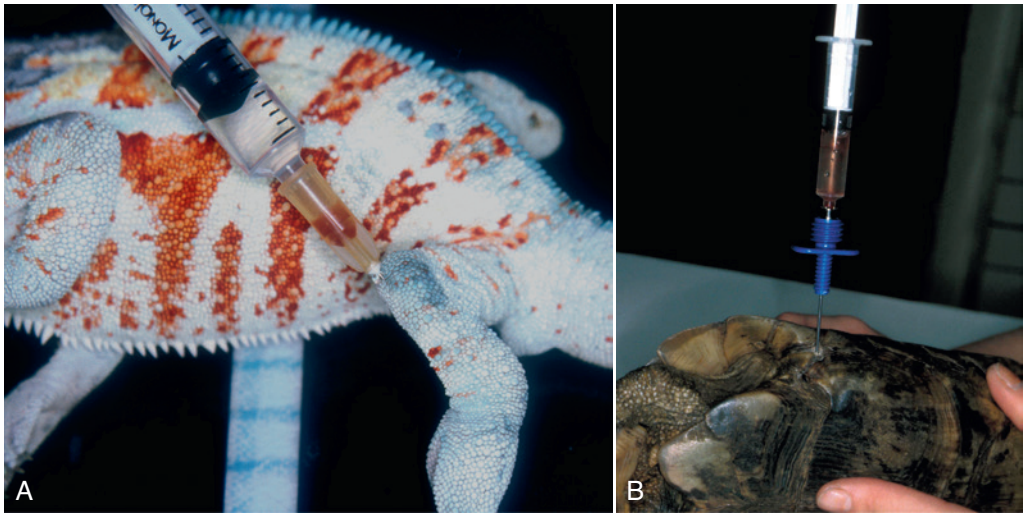

FIG 43.6 (A) Bone marrow aspiration from the tibia of a panther chameleon (*Furcifer pardalis*) using a hypodermic needle. (B) Bone marrow aspiration from the plastrocarapacial bridge of a tortoise (*Testudo sp*). (Courtesy of Stephen J. Divers.)

attachments are dissected free in a dorsoventral direction using scissors. The rib is dissected free and elevated through the skin incision. Hemorrhage has not been a complication, but any damaged intercostal vessels can be sealed using radiosurgery. Depending on the size of the rib and preferences of the histopathologist and hematologist, the entire rib or aspirated marrow may be submitted.

Spleen. The spleen has been cited as an important organ in regard to hemopoietic and lymphopoietic roles, and therefore biopsies or aspirates may be required for further evaluation of hematologic disorders. The spleen varies in size and shape but is usually closely associated with the stomach and pancreas within the dorsal mesentery. In snakes the spleen and pancreas may be combined into a single splenopancreas organ located approximately 60% to 65% from snout-vent. The spleen can be approached and biopsied in two ways: open surgery and endoscopy. Open surgical biopsy requires a standard coeliotomy approach, whereas endoscopic visualization and biopsy is less invasive and quicker to accomplish. Postbiopsy hemorrhage rarely requires intervention but can be controlled with the use of transendoscopic radiosurgery, laser, or a hemostatic sponge.

Cardiovascular Function. There are several means of assessing the cardiovascular system in the exam including the use of visual appearance, palpation, and sensitive electrical stethoscopes. The detection of abnormal rhythm or rate, as well as cardiac murmurs, may be appreciated. Further investigation using electrocardiography, diagnostic ultrasonography, and radiology, are necessary and are dealt with elsewhere (see Chapter 68).

Integument

Dermatologic disease is a frequent presentation, and there are various levels at which the clinician can intervene and collect biological samples. Shed skin, skin scrapes, impression smears, fine needle aspiration, and scale and skin biopsies can all be utilized in the pursuit of a diagnosis (Fig. 43.7A). The skin and associated structures are perhaps the easiest to sample for laboratory analysis due to their accessibility. However, they can also be the most demanding to interpret, as contamination and secondary changes often mask the underlying primary complaint. For example, impression smear cytology and bacterial culture may diagnose *Pseudomonas* sp. dermatitis but miss the underlying burn that caused the initial skin damage and facilitated infection. Alternatively, normal and diseased skin often becomes contaminated from fecal Enterobactereace. It is therefore vital to sample correctly and interpret findings with caution.

Ectoparasites. Various ectoparasites may be clearly seen on the surface of the skin, around nostrils, eyes, and skin folds.[3,7] Mites, ticks, lice, maggots, and flies can often be physically removed and submitted in specimen containers for taxonomic identification. The shed skin of reptiles can be a valuable asset and should be inspected for evidence of parasitism (Fig. 43.7B). Suspected mites can be collected directly using a wet cotton-tipped applicator and transferred to a microscope slide for closer inspection and identification.

Skin Scrapes and Impression Smears. Skin lesions are frequently contaminated, and therefore superficial sampling may not demonstrate the primary cause or agent by the time the reptile is presented. Skin lesions are best cleaned and partially debrided using aseptic techniques prior to the collection of clinical samples.[3,7] Microbiologic swabs should be taken from the periphery of the lesion but deep to any exposed areas. Impression smears can be taken after the lesion has been cleaned with sterile saline and gently dabbed dry with sterile gauze. Skin scrapes may be useful, especially when dealing with drier, more proliferative lesions. Samples may be prepared for immediate microscopy or submitted to an external laboratory.

Scale and Skin Biopsies. Where the clinician requires a skin biopsy, the removal of a single scale may be all that is required, as scales contain both epidermal and dermal elements. A small volume (0.02–0.1 mL) of local anesthetic (e.g., 2% lidocaine) is injected subcutaneously in the area(s) of interest. Using aseptic techniques, a single scale is then elevated and cut close to its insertion using a scalpel blade. If a larger sample is required then a combination of local, regional, or general anesthesia and sharp excision or a skin punch biopsy instrument is effective (Fig. 43.8). A single suture closes the deficit. Biopsy of the chelonian shell requires general anesthesia and cortical biopsy devices (see the sections Bone and Shell Biopsy as well as Musculoskeletal System in this chapter).

Respiratory System

The respiratory system can be conveniently divided into upper and lower respiratory tracts. The upper respiratory tract consists of the nares, buccal cavity, larynx, and trachea, while the lower respiratory tract consists of the bronchus/bronchi, lung(s), and, where present, air-sac(s). There is very little in the way of tubular subdivision into secondary bronchi, bronchioles, and alveoli, as in mammals. The reptilian lung is more reticulated with a large central cavity, although chelonia are an exception because they possess a more three-dimensional, spongelike lung.

Abnormal respiration is a common presentation, and some of these are due to true disease, but many are associated with poor environments that resolve with husbandry improvements. The ability to diagnose pathologic changes within the respiratory system is relatively straightforward if reliance is placed upon the use of lung lavage for the collection of cytologic and microbiologic samples.[3,7] The collection of tissue biopsies requires anesthesia and surgical or endoscopic techniques.

Nares, Larynx and Cranial Trachea. The upper respiratory tract, including the nares, buccal cavity, larynx, and cranial trachea, can be visualized and often sampled directly without a surgical plane of anesthesia. Small-diameter swabs permit the collection of samples, although the greatest concern comes from bacterial contamination by oral commensals. Swabs can be submitted for microbiology or rolled onto glass slides for staining and cytologic evaluation.

Caudal Trachea and Lung Lavage. The simplest method of obtaining a representative sample from the lower respiratory tract is by lavage (Fig. 43.9). Although a lung wash or lavage can be carried out in the conscious reptile, the discomfort of such a procedure warrants sedation or light anesthesia. A sterile catheter of appropriate size is placed through the glottis, taking great care not to touch the oral membranes. The catheter is advanced down the trachea and into the lungs. In snakes the catheter is advanced caudal to the heart (>30% snout-vent), but in large specimens it may not be possible to reach the lung(s), and a tracheal lavage is performed. In lizards the catheter is advanced to a

Gentle rolling and rocking often improves the diagnostic quality of the aspirated sample. (C) Lung lavage of an anesthetized bearded dragon (*Pogona vitticeps*). (D) Microscopic view of a lung lavage sample from a snake indicating multiple, unidentified nematode larvae. (Courtesy of Stephen J. Divers.)

point just caudal to the forelimbs, whereas in chelonia a central position appears most appropriate. In lizards and chelonia the catheter can be preferentially directed into either the left or right lung by inserting a sterile metal stylet down the catheter prior to introduction. The catheter and stylet is then given a gentle bend to facilitate introduction into the left or right lung. Proper positioning of the stylet and catheter can be confirmed by radiography (Fig. 43.10A). Once in place, 0.5 to 1.0 mL of sterile saline per 100 g body weight can be infused. Sample recovery is often aided by rotating the animal and repeatedly aspirating, although in larger reptiles the use of dedicated bronchoalveolar lavage systems that utilize house vacuums are often most rewarding (Fig. 43.10B). In snakes, lifting the head and tail will also help accumulate fluid at the dependent area, near the catheter tip. In chelonia, a unilateral lung wash can also be obtained via a long fine hypodermic needle. The needle is positioned in the dorsocranial area of the prefemoral fossa and directed dorsomedially. Aspiration of air confirms entry into the lung prior to lavage. Similar techniques are possible in lizards and snakes, but anesthesia and lung inflation are usually required. Dependent upon the volume and quality of the sample obtained, material should be divided and submitted as requested by the laboratory. The submission of fresh and fixed material, multiple air-dried smears, and a microbiologic swab permits detailed investigation.

Lung Biopsy. Lavage samples do not permit an appreciation of lung architecture. For this, and many other pathological evaluations, tissue biopsies are preferred. Surgical access to the lung can be achieved using a standard coeliotomy, as there is no functional diaphragm or concern regarding the maintenance of pleural negative pressure in most squamates.[3,7] In snakes, the respiratory active anterior part of the lung is typically located between 35% to 45% snout-vent (i.e., just caudal to the heart). However, there is great species variation with regard to lung anatomy, including the presence of a tracheal lung in some elapids and viperids, both left and right lungs in boids, and only a right lung in most other snakes. Surgical biopsy of the anterior lung commonly results in hemorrhage unless appropriate hemostatic measures are taken. Biopsy of the thinner posterior lung (or air sac) is not complicated by hemorrhage, although closing the thin pulmonary membrane without tearing can be challenging. In lizards the anterior lung is also more highly vascularized than the posterior areas. A cranial coeliotomy, close to the xiphoid process of the sternum, may permit sufficient exposure; otherwise, a lateral approach between ribs may offer better exposure for biopsy of the anterior lung. The tuatara, varanids, and crocodilians possess a significant post-pulmonary membrane that should be respected and, if surgically breached, sutured closed prior to closure of the coelom. In chelonia, the lungs are protected by the carapace, making surgical access more difficult. Creation of a 4- to 5-mm temporary osteotomy in the carapace, over the lung area of interest, does not give sufficient exposure for an excisional biopsy but does permit the collection of a tru-cut biopsy (Fig. 43.11).[15] The osteotomy can then be closed using acrylic or epoxy. Alternatively, an intrapneumonic catheter can be secured in the osteotomy site to permit continued local therapy.[15] A ventral coeliotomy is not recommended in chelonia because the septum horizontale (post-pulmonary membrane) is deep to the coelomic viscera and again should be repaired if surgically incised or penetrated in any way.

Endoscopic Biopsy. The use of small rigid telescopes and fine flexible endoscopes permits access to, and biopsy of, lung tissue in most reptiles. The use of 3- to 5-Fr biopsy instruments permits the collection of tissue samples from reptiles as small as 150 g without deleterious effects. Small biopsies are best submitted in histology filters to avoid loss during

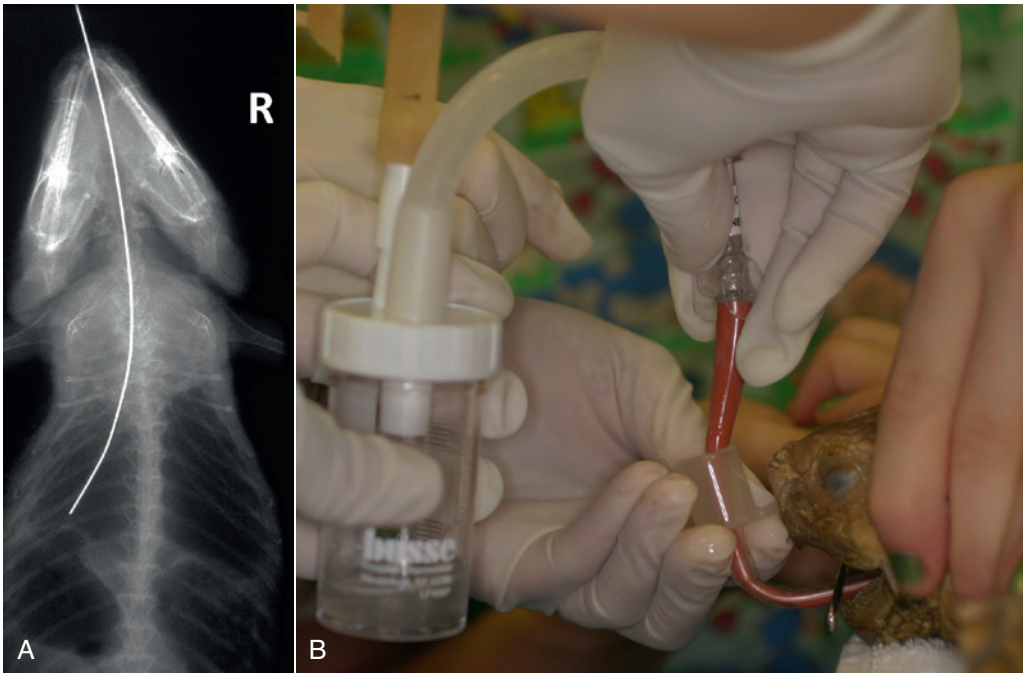

FIG 43.10 (A) By using a curved metal stylet it is relatively easy to ensure unilateral placement of a lung catheter into a specific lung—in this case the left lung of a bearded dragon (*Pogona vitticeps*). (B) For larger reptiles, like this large tortoise, the use of dedicated bronchoalveolar lavage supplies and house vacuums generally provide the most efficient means of sample collection. (Courtesy of Stephen J. Divers.)

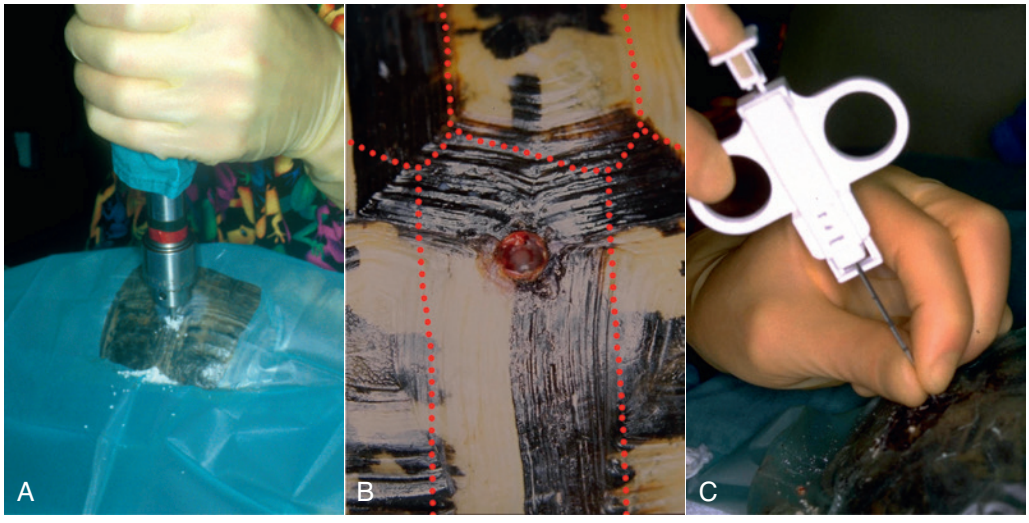

FIG 43.11 Lung biopsy of a tortoise. (A) Drilling a temporary osteotomy in the carapace to gain access to a diseased lung. (B) The general area of interest is determined by radiography or CT, but the osteotomy site should ideally be through a bone plate at the intersection of the keratin scutes and not through the peripheral growth plates (outlined by red dotted line). (C) Needle biopsy via the osteotomy hole. (Courtesy of Stephen J. Divers.)

transportation and processing. The submission of (digitally captured endoscopy) images of the lesion with the biopsies greatly assists the pathologist in histologic interpretation. There are also a variety of other sampling devices available including brush biopsy instruments and remote aspiration needles that can also be used deep within the respiratory system to obtain diagnostic material.

In snakes it may be impossible to reach the lung using a small-diameter bronchoscope via a laryngeal approach. In larger constrictors, a flexible bronchoscope or gastroscope can be inserted via a surgical approach to the lung and passed craniad and caudad to examine the entire lung. The use of a rigid endoscope via a surgical approach to the lungs of boids has also been widely advocated (Fig. 43.12).[7,16] In some lizards, the lungs can be reached via the larynx because the bronchi are often short and easily negotiated. However, in most chelonia the short trachea and long narrow bronchi make access to the chelonian lung extremely difficult via a laryngeal approach, although it is possible in large animals when using fine-diameter flexible bronchoscopes. Endoscopic entry to the lungs can also be achieved via a carapacial osteotomy

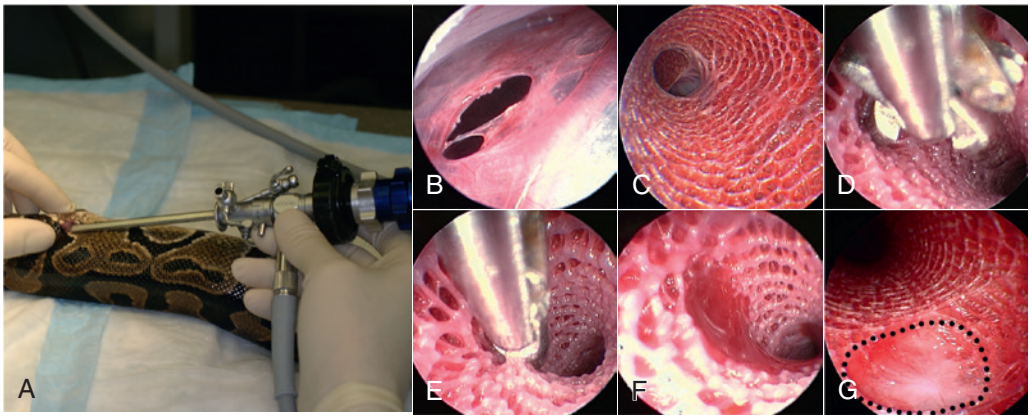

FIG 43.12 (A) Transcutaneous pulmonoscopy in a ball python (*Python regius*). The drape has been removed to facilitate photography. (B) Endoscopic appearance of the perforation into the lung. (C) Endoscopic view of the healthy cranial (faveolar) lung. (D, E, F) Endoscopic lung biopsy. (G) Endoscopic view of a previous lung biopsy site 12 months later (outlined in black dotted line). Note the minimal scarring. (Courtesy of Stephen J. Divers.)

(as described for chelonian lung biopsy) or a prefemoral approach (see Chapter 64). The prefemoral approach to the lungs requires a small incision in the craniodorsal aspect of the prefemoral fossa and identification of the septum horizontale (the membrane that divides the lungs from the remaining viscera). Retaining sutures are placed through this membrane to elevate it close to the skin incision. A small incision in this membrane permits the entry of the endo scope and examination of the lung as far cranially as the bronchial opening. It is important to close the septum horizontale following biopsy to prevent pneumocoelom and emphysema.

Gastrointestinal System

In cases of severe diarrhea or regurgitation, material for laboratory submission will be forthcoming and may be collected and presented along with the animal by well-educated owners or keepers. In addition, many reptiles will spontaneously defecate and urinate when handled during the examination process. It is important to appreciate that, like birds, the stools of reptiles are composed of fecal, urate, and urine components and that the cloaca is a common chamber for the gastrointestinal, urinary, and reproductive systems. For example, watery stools due to polyuria must be differentiated from true diarrhea, and cloacal bleeding may be intestinal, reproductive, or urinary in origin. Fecal material can be submitted for a variety of parasitologic, cytologic, and microbiologic tests. The submission of only fecal material in appropriate sterile containers will prevent further mixing and contamination by urates and urine during transportation and processing. Microbiologic results from deposited feces should be interpreted with caution because contamination from other organ systems can occur in the cloaca prior to elimination, while environmental contamination invariably occurs after elimination. The fresher the material, the more meaningful the laboratory results, although some parasitological investigations (e.g., helminth egg examination) can be performed on refrigerated material up to 4 weeks or more after elimination.

Oral Biopsy. Stomatitis is common, and sampling prior to initiating treatment is important because bacterial, fungal, parasitic, and viral causes are known (Fig. 43.13). Culture of superficial lesions frequently results in culturing commensal gram-negative bacteria and as deeper samples are required, biopsy is preferred. It is critical to submit material for histopathology (or cytology) in addition to microbiology to attribute pathogenicity to any cultured organisms.

Cloacocolonic Lavage. Unfortunately, the slow intestinal transit times of most reptiles often necessitates a more direct approach to obtain material. A cloacocolonic lavage can be performed on most conscious reptiles and provides the clinician with a diagnostic sample (Fig. 43.14A). A sterile lubricated round-tipped catheter is inserted into the cloaca and cranially toward the colon. A relatively large catheter should be used, as this helps prevent kinking of the tube and perforation of the thin intestinal wall. It is important not to force the catheter. Once in place, 0.5 to 1.0 mL sterile saline per 100 g body weight should be gently infused through the catheter and repeatedly aspirated until a sample is obtained. It is possible to infuse an additional 1.0 mL/100 g if no sample is forthcoming. It is surprisingly easy to catheterize the bladder and obtain a feces-free sample. The direct collection of fecal material from the distal colon using a lubricated, gloved hand offers another practical option in giant reptiles.

Gastric Lavage. A similar technique to cloacocolonic lavage can be used to collect samples from the stomach. A relatively large, round-tipped catheter can be inserted into the stomach of most conscious or sedated reptiles. In crocodilians, lizards, and chelonia, it is wise to use a mouth gag to prevent damage to the tube (Fig. 43.14B). The catheter should pass to the midcoelomic region before instilling 0.5 to 1.0 mL sterile saline per 100 g body weight. In large snakes it may not be possible to reach the stomach, in which case esophageal lavage is a more appropriate term. Such samples can be examined as a fresh wet preparation for parasites or stained to demonstrate microorganisms. Microbiological cultures are often worthy, but care is required in their interpretation, as contamination from the respiratory system and oral cavity is possible.

Gastroscopy and Biopsy. For the collection of gastric or intestinal biopsies, standard coeliotomy and excisional biopsies can be undertaken, but endoscopy is much less invasive. In lizards and chelonia endoscopic access to the stomach is straightforward but negotiating the pylorus and entering the duodenum is more difficult (Fig. 43.15). In snakes the small intestine can be readily entered via the gastric pylorus. It is unwise to endoscopically biopsy the large bowel because the intestinal wall is often thin and easily perforated. Even excisional biopsies of the large intestine can be challenging to ensure adequate closure and the prevention of leakage.

Liver Biopsy. Blood biochemistry, diagnostic imaging, and endoscopy may suggest hepatopathy, but they seldom provide the definitive diagnosis.

VetBooks.ir

Liver biopsy remains the most effective tool for conclusively reaching a diagnosis, indicating specific therapies and providing a more accurate prognosis. Correlation between biochemical tests and histopathology are generally lacking, but serial blood sampling and biopsy currently offers the best diagnostic and monitoring approach to hepatic disease.

Biopsies may be collected for histopathology and microbiology. Liver samples may be collected percutaneously (with or without ultrasound guidance), surgically, or endoscopically. Surgical approaches generally rely on a standard coeliotomy approach to the liver, which in snakes usually results in only a small part of the organ being visible and available for biopsy (Fig. 43.16). Biopsies are best collected using large tru-cut needles or biopsy punches, with the defect packed with hemostatic foam to prevent post-biopsy hemorrhage. Wedge techniques can be used for sampling from the periphery in lizards and chelonians. Endoscopic techniques are typically less invasive, permit closer examination of more of the organ, and enable the collection of multiple biopsies

(Fig. 43.17).[2,6] Ultrasound-guided biopsies in snakes and lizards have resulted in serious complications, including gastrointestinal perforation and fatal hemorrhage, and cannot be recommended for most reptiles.[17,18]

Pancreatic Biopsy. Blood glucose values can vary dramatically due to many factors, including stress, metabolic disease, systemic disease, neoplasia, and other extrinsic variables (see Chapters 79 and 155). However, pancreatic disease does exist, and a diagnosis should rely on the histopathologic demonstration of disease following endoscopic pancreatic evaluation and biopsy. Likewise, elevations of blood amylase levels may not be specific for pancreatic disease and should also be viewed cautiously unless disease can be confirmed histopathologically.

Musculoskeletal System

Despite major clinical interest in osteomyelitis and secondary nutritional hyperparathyroidism, there are a variety of other skeletal abnormalities that can affect reptiles. The ability to obtain bone material for histologic and microbiologic interpretation greatly aids our understanding and ability to advise on appropriate treatments for these conditions.

Bone and Shell Biopsy. Proliferative and lytic lesions affecting the axial and appendicular skeleton are not uncommon. The radiographic interpretation seldom provides a definitive pathologic diagnosis. The use of cortical bone biopsy instruments designed for humans can also be used in reptiles. Care is required not to cause excessive damage and risk fracture, but generally excellent samples can be obtained with only minor surgical exposure (Fig. 43.18A). In very small specimens a hypodermic needle can be used to obtain a core of bone. This bone core can then be expelled from the needle by inserting wire through the needle hub. In cases of vertebral osteomyelitis, where biopsy may be contraindicated due to the proximity of the spinal cord, blood cultures are often useful for identifying the bacterial cause.[19] Septic arthritis is

VetBooks.ir

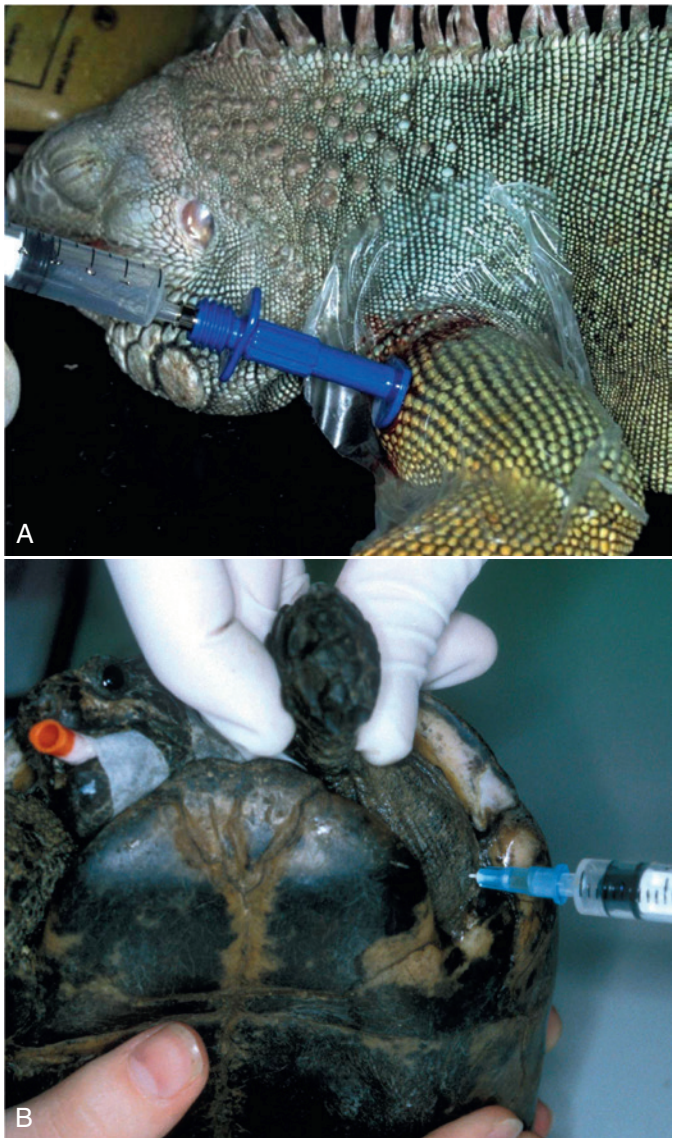

FIG 43.18 (A) Cortical bone biopsy in a green iguana (*Iguana iguana*). (B) Scapulohumeral joint aspiration of a *Testudo* tortoise. (Courtesy of Stephen J. Divers.)

commonly reported following bite wounds to the joints of lizards and tortoises. Following aseptic preparation of the area, fine-needle aspiration will permit the collection of samples for microbiologic and cytologic diagnosis (Fig. 43.18B).

Shell disease of chelonians is also common, and a Michele trephine has been shown to produce diagnostic samples (Fig. 43.19).[20] Diseased bone is often softer and easier to biopsy compared with healthy shell. Care is required to ensure that only a small length of the instrument is exposed so that overly deep penetration into the coelom does not occur. Acrylic or epoxy can be used to seal the biopsy site unless obvious infection is present.

Muscle Biopsy. Most cases of muscle wastage or weakness are related to nutrition or debilitating disease, but, if warranted, muscle biopsies may be collected for histopathologic investigations. The largest affected muscle masses should be selected because many reptiles, especially chameleons and other small lizards, have limited musculature. Surgical exposure of the muscle and longitudinal separation of a number of fibers permits ligation using fine absorbable material at the proximal and distal margins of the biopsy. Sharp excision permits removal of the biopsy. Hemostasis by ligation is preferred over radiosurgery or laser because of the coagulation artifacts that are produced.

Urinary System

Diseases of the urinary system can include the kidneys, ureters, bladder, urethra, and cloaca. In addition to the kidneys, the bladder, cloaca, posterior colon, and remote salt glands can all play important roles in osmoregulation and should be considered part of the osmoregulatory system of reptiles. The clinician may assess the osmoregulatory system by sampling urine and biopsies from the kidney, bladder, and cloaca. Ancillary structures such as salt glands are seldom biopsied, although their secretions can often be collected from the reptile's nares or the glass surfaces of enclosures.

Urine. Urinalysis is less helpful in reptiles than mammals. The reptilian kidney cannot concentrate urine, and so urine-specific gravity is of limited use in the assessment of renal function. Furthermore, renal urine passes through the urodeum of the cloaca before entering the bladder (or posterior colon in those species that lack a bladder). Bladder urine is therefore not necessarily sterile. The clinical picture is further complicated by the fact that electrolyte and water changes can occur across the bladder or cloacocolonic mucosa. Despite these biochemical drawbacks, urine samples are useful for cytologic assessments of inflammation, infection, and for the identification of renal casts (see Chapter 66).

Voided urine. The urinary, genital, and intestinal tracts empty into a common cloaca, and therefore any samples voided from the cloaca may represent material derived from, or contaminated by, any of these systems. Voided urine and urates, although useful for cytology, must be critically evaluated whenever a culture is obtained. Urine microbiology must be even more critically judged if the sample was collected from the floor of the enclosure or the examination table. Fresher urine and urate samples can be collected as a free catch. Many reptiles will spontaneously void urine and urates (often with fecal material) when handled. More stoic individuals may be encouraged to urinate by gentle digital stimulation of the cloaca.

Cystocentesis. A more representative and less contaminated sample may be collected by cystocentesis in chelonia and those lizards that possess a bladder (Fig. 43.20A). However, given the thin, fragile nature of the reptilian bladder, the potential danger of postsampling leakage of unsterile urine into the coelom exists. Given the passage of urine through the cloaca, and the electrolyte and water changes that can occur in the bladder, urine collected by cystocentesis may not be representative of renal urine with respect to electrolyte composition and osmolarity. Such samples are often unsterile, although a heavy, pure microbiological growth should alert the clinician to potential infection.

Catheterization. One means of obtaining bladder urine without puncturing the bladder is by the placement, blind or preferably with the assistance of an endoscope, of a urethral catheter (Fig. 43.20B and C). This procedure has been performed in sedated and anesthetized tortoises and lizards that possess a bladder. Care must be taken not to damage the thin bladder wall. The indwelling catheter can be used to empty the bladder and may then be used to collect fresh urine (Fig. 43.2°C). Collection of bladder urine that has not resided within the bladder for a prolonged period may be more representative of renal urine (i.e., before major post-renal electrolyte changes have occurred across the bladder membrane).

Renal Biopsy. A variety of infectious, degenerative, and neoplastic renal diseases have been reported in reptiles, particularly snakes and

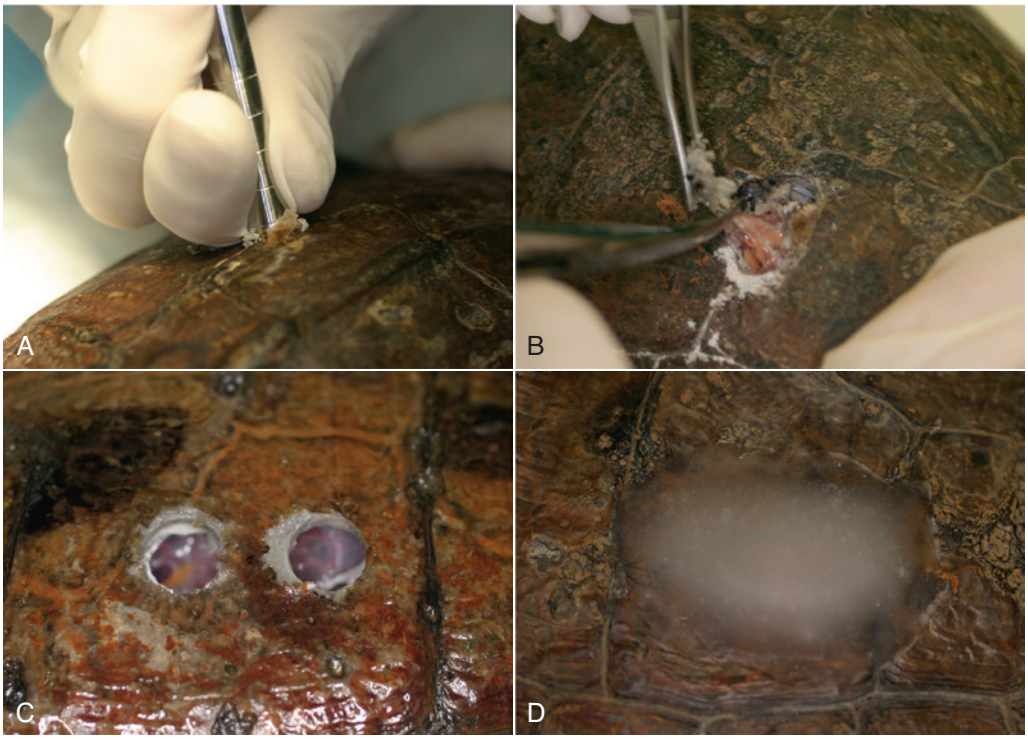

FIG 43.19 (A) Full thickness shell biopsy using a Michele trephine in a map turtle (*Graptemys* sp.). (B) Sharp incision to free the shell biopsy from its underlying attachments. lizards. The poor regenerative capabilities of the kidney make early diagnosis essential. The relatively poor diagnostic value of urinalysis and the late detection of renal disease by blood biochemistry further exemplify the importance of renal biopsy early in the diagnostic process. The cranial tail cut-down and minimally invasive coeliotomy biopsy techniques permit unilateral access to a single kidney. In these cases, cloacal and coelomic palpation, diagnostic imaging (including intravenous urography) can be used to determine whether a left or right approach is most appropriate. Major coeliotomy, ultrasound-guided, and endoscopic biopsy procedures can usually examine and biopsy either or both kidneys.

Coeliotomy biopsy. Where renomegaly is obvious, a coelomic entry and biopsy can be undertaken (Fig. 43.21A and B). A standard midline or paramedian coeliotomy enables both kidneys to be assessed in lizards,

VetBooks.ir

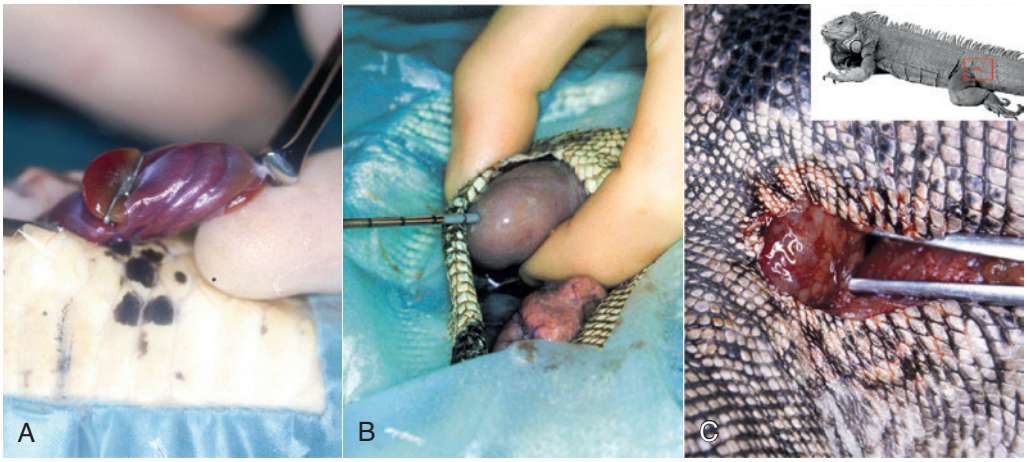

FIG 43.21 (A) Renal biopsy of a *Boa constrictor* following a standard coeliotomy. In this case vascular clips have been used to isolate a small kidney lobule prior to sharp excision. (B) Needle biopsy of an enlarged iguanid kidney during coeliotomy. (C) Cranial tail cut-down procedure to biopsy the caudal pole of an iguanid kidney. Inset: the incision is marked by the red line. (Courtesy of Stephen J. Divers.)

and excisional or tru-cut biopsies can be collected. In snakes, the elongated left and right kidneys overlap for a short distance, and coeliotomy and renal biopsy are readily accomplished. If an enlarged kidney can be palpated it can usually be immobilized just under the skin, permitting the use of a tru-cut needle biopsy or minimally invasive coeliotomy incision directly over the organ. This technique is best suited to the detection of diffuse renal disease, as focal diseases may be missed.

Cranial tail cut-down biopsy. A relatively simple technique for biopsy of the intrapelvic kidneys of iguanas requires a cranial tail cut-down under local or general anesthesia. A small longitudinal incision is made in the lateral midline just below the lateral processes of the coccygeal vertebrae. The incision extends for 1 to 3 cm caudad, starting just behind the hind limb. Blunt dissection between the dorsal and ventral coccygeal muscles permits exposure of the caudolateral aspect of the kidney that can then be sampled (Fig. 43.21C). Hemorrhage depends on the size of the biopsy, but the temporary application of hemostatic dressings or radiosurgery is effective. This technique is particularly valuable when the kidneys are not enlarged, coelomic approaches to the intrapelvic kidneys are more difficult, or shorter anesthesia time is a major advantage. It is limited to unilateral biopsy unless bilateral cut-down procedures are undertaken. Furthermore, as only a small area of kidney can be visualized and sampled from, this technique is best suited for the investigation of diffuse renal disease.

Ultrasound-guided biopsy. Ultrasound-guided biopsies have been performed in dogs and humans but are higher risk for smaller animals, including most reptiles. While ultrasound imaging permits the identification of gross lesions and aids biopsy needle guidance, there are still dangers associated with the voluminous bladder, gastrointestinal tract, dorsal aorta, and renal arteries and veins that must be appreciated and avoided. Depending on the quality of the equipment and skill of the ultrasonographer, multifocal or focal lesions may be missed. Indeed, given the complications encountered with ultrasound-guided biopsies of larger and more accessible organs like the liver, such ultrasound-guided renal sampling is not recommended for most reptiles.

Endoscopic biopsy. The endoscope permits evaluation of the size, color, and shape of both coelomic kidneys via a single surgical entry but is less able to examine intrapelvic tissue. The use of endoscopic scissors and biopsy forceps under direct visual control permits the incision of the renal capsule and collection of quality samples with less risk to surrounding structures (Fig. 43.22). The optics of the telescope also permits an assessment of diffuse, focal, and multifocal disease and the selection of appropriate biopsies that may otherwise be difficult to ascertain without a real-life, color, magnified image.[1–3]

Bladder Biopsy. The bladder performs important osmoregulatory functions in many reptiles and biopsy may rarely be required for an overall assessment of osmoregulation function. Proliferative masses of the bladder can also be biopsied to aid identification and direct treatment plans.

Endoscopic biopsy. Endoscopic entry into the bladder of larger lizards and chelonia has been accomplished with practice. However, endoscopic biopsy of the bladder is not recommended for anything other than grossly proliferative lesions, because there are major risks associated with perforation and leakage of unsterile urine and urates into the coelom.

Excisional biopsy. Surgical excisional biopsy is preferred in most cases due to the importance of preventing postbiopsy leakage. There are no ureteral connections to the bladder, and so bladder biopsies can be collected from almost any site. However, care should be taken to maintain the neural and vascular supplies and avoid the urethra. The technique is similar to that used in mammals, although a double-layer closure can be more difficult due to the very thin nature of the bladder wall. To ensure a waterproof seal the incision should be closed using an approximating continuous or simple interrupted pattern, followed by a second inverting pattern.

Cloacocolonic Biopsy. Biopsies of the cloacocolonic region may rarely be required for a complete assessment of osmoregulatory function, especially in those species that lack a bladder. Due to the intrapelvic position of the coprodeum and urodeum in most reptiles, endoscopic examination and mucosal biopsy is preferred. The cloacal wall tends to be relatively thick and perforation less likely compared to the bladder. Nevertheless, care must be taken not to biopsy or damage the urogenital papillae within the urodeum. Endoscopic biopsy of the colon is not recommended, as the intestinal wall is often thin and prone to perforation.

Reproductive System

Antemortem pathologic assessment of the reproductive system has not been undertaken to a large degree. However, the advent of minimally invasive endoscopic techniques has brought about an increase in obstetric evaluation and sampling.

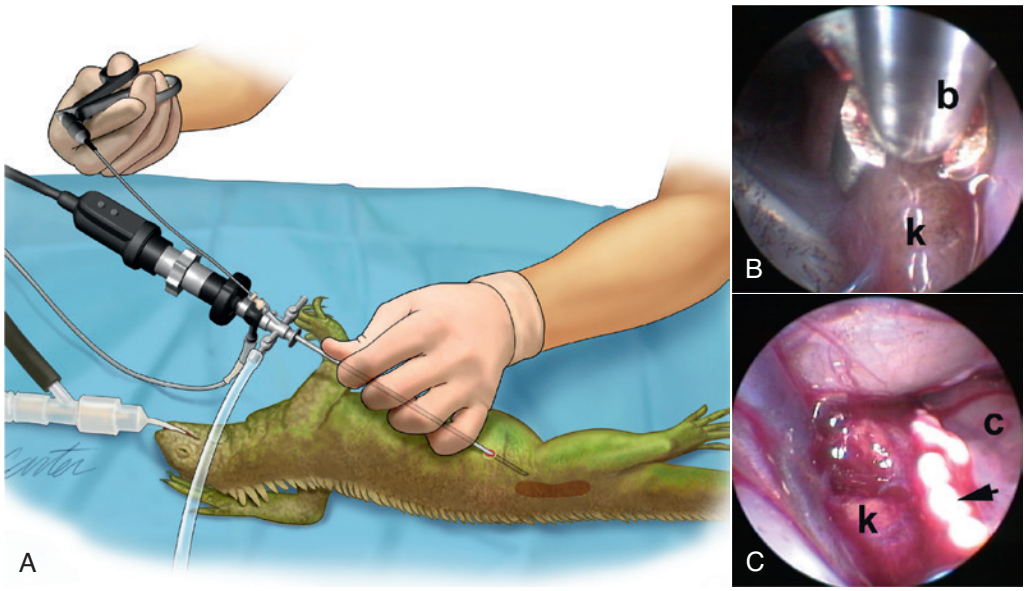

FIG 43.22 (A) Endoscopic evaluation and biopsy of the iguanid kidney. (B) Endoscopic view of an iguanid kidney (k) about to be sampled using 1.7 mm biopsy forceps (b). (C) Postbiopsy view of the same kidney (k) with the intact vas deferens (arrow) and colon (c). (Courtesy of Stephen J. Divers.)

Phallus and Hemipenes. The phallus of chelonians and crocodilians and the hemipenes of squamates may become infected or traumatized. Paraphimosis is not uncommon, and impression smear cytology and culture may indicate primary or secondary infectious causes that need to be addressed once the organ has been replaced. Where the hemipenes are retracted a small sterile lubricated catheter can be inserted into the hemipenal sulcus, and aspiration or lavage procedures can provide material for cytology and cultures. In some cases, there can be such an accumulation of cellular debris that a hemipenal "plug" forms that can be removed from the sulcus using forceps. The cytologic evaluation of hemipenal material may aid the investigation of male infertility by evaluating for the presence of spermatozoa and petroleum-based spermicidal lubricants, which may have been previously used for gender identification by probing.

Cloacal (Musk) Glands. The cloacal or musk glands of snakes connect to the cloaca and may on occasion become impacted and infected (see Chapter 171). Material can often be expressed from these areas manually in the conscious snake, or swabs and lavage techniques can be used for the collection of diagnostic samples.

Oviducts and Vas Deferens. A detailed knowledge of cloacal anatomy and expert proficiency in endoscopic techniques can permit examination of the oviduct. It may also be possible to catheterize the vas deferens, which may aid the investigation of male infertility.

Gonads. The gonads of reptiles can be approached surgically or with endoscopy. The endoscopic identification of gonads has been used as an aid to control reproduction and breeding (see Chapter 64). Testicular biopsy has been used as an aid in the assessment of male infertility in lizards and chelonia. Biopsy of the active ovary is not recommended because of the dangers of yolk leakage and coelomitis. Biopsies have been taken from inactive and diseased ovaries without incident.

Nervous System and Special Senses

The increasing interest in neurological diseases has led to the pursuit of improvements in neurological assessment and antemortem sampling techniques. Previously, cytologic and histopathologic assessment of the nervous system was only possible with necropsy, although investigations in the live reptile are still quite limited.

Cerebrospinal Fluid. Reptiles lack a subarachnoid space, but cerebrospinal fluid (CSF) can be collected from an intrathecal site. Cervical and lumbar tap techniques to obtain CSF samples have been performed in a limited number of cases.[13] It is obviously important to be aware of the potential misidentification and misinterpretation of lymph as cerebrospinal fluid.

The technique is essentially similar to that employed in mammals, with emphasis on proper positioning and accurate anatomic knowledge. The anesthetized lizard is placed in sternal recumbency with the head and neck maximally flexed. Following aseptic preparation of the dorsal neck and lateral retraction of the dorsal crest, the spinal processes of the cervical vertebrae can be palpated. Careful advancement of the needle between C1 and C2 permits the collection of a small volume of CSF. CSF, often blood contaminated, has been collected from the cervical region of lizards, snakes, and chelonians and from the lumbar region of lizards (Fig. 43.23). Strict asepsis is essential, and it is important that either the fluid is permitted to flow from the needle or only very minor negative pressure is applied. The greatest complication with this technique is blood contamination, and concurrent hematologic assessment of blood samples can be helpful in assessing CSF blood contamination and artifact. Cytologic and microbiologic evaluations of CSF would appear to be of value in the assessment of CNS disease.

Eyes. Subspectacular infections in snakes and some lizards occur with some frequency. Surgical wedge resection of the spectacle permits the collection of exudate for cytologic and microbiologic tests (Fig. 43.24A).[3,7] Likewise, proliferative corneal lesions can be carefully scraped and retrobulbar swellings aspirated for further investigation (Fig. 43.24B). Occasionally, eyelid lesions may be seen that can be biopsied using magnification with fine biopsy forceps.

Ears. Tympanic abscessation in chelonians is common, and surgical access to evacuate the inspissated contents also allows the collection of

VetBooks.ir

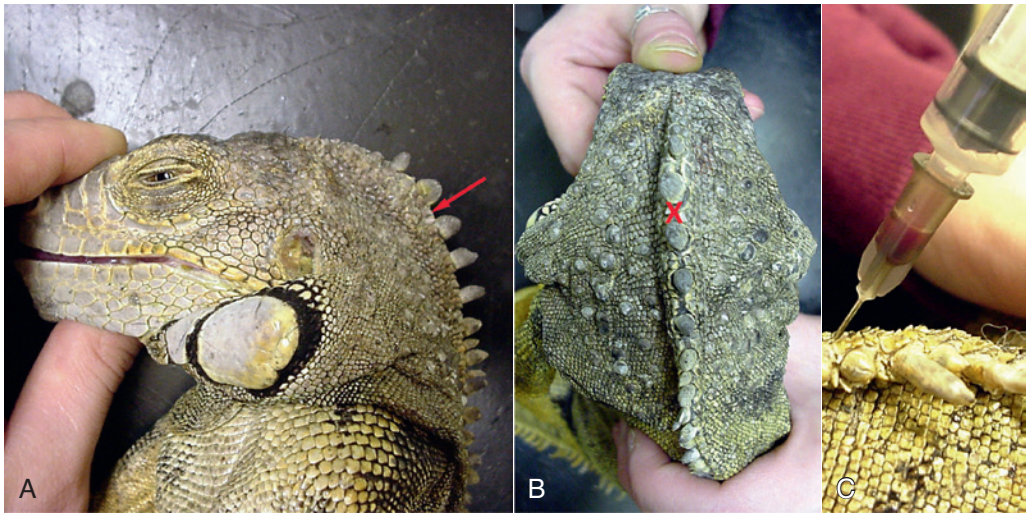

FIG 43.23 Positioning for cerebrospinal fluid tap in an iguana (*Iguana iguana*). (A, B) The head and neck are maximally flexed to improve dorsal access to the spinal canal. The needle is advanced in the dorsal midline; retracting the crest laterally and palpating the dorsal spinal processes aids proper needle placement (red cross and arrow). (C) Note that blood contamination is a common complication. A more caudal approach can also be attempted cranial to the pelvis or along the tail; however, reptiles do not possess a cauda equina, and therefore the potential for spinal damage remains. (Courtesy of Stephen J. Divers.)

appropriate samples. In lizards, tympanic disease appears to be less common, but a variety of infectious causes, including *Cryptosporidia* sp have been identified and may not be appreciated without the collection of aspirates or biopsies. The removal of 25% to 50% of the tympanum facilitates both collection of samples and evacuation of exudates. This procedure does not damage the ear and the tympanum will heal by second intention.

Peripheral Nerve Evaluation and Biopsy. Peripheral neuropathies are seldom reported, but similar techniques to those used in mammals can be employed. Electromyography can be used to evaluate for potential neuromuscular diseases (Fig. 43.25). In most cases gastrointestinal or muscle biopsies often contain neural tissue.

Catheter Placement

Mariana A. Pardo and Stephen J. Divers

Vascular access in reptiles can present unique challenges for clinicians due to their intrinsic and particular anatomy. Peripheral vessels are not readily visualized, with the exception of the dorsal buccal vein in snakes. Because of this, additional visualization techniques such as surgical exposure and ultrasonography have been used to improve vascular access. A combination of appropriate patient restraint, technique, and technical expertise can facilitate venous access. Although vascular catheterization is not required for blood collection or fluid and drug administration, it is considered standard of care when treating critically ill patients. Often these critical reptiles require repeated or continuous drug administration or serial blood sampling. Additionally intravenous (IV) administration of medications are more rapid and reliable and may decrease variables that influence pharmacokinetics when medications and fluids are given through alternate routes to critically ill patients (Fig. 44.1).[1,2]

PERIPHERAL VENOUS CATHETERIZATION

Catheter Types

There are a variety of commercially available catheters. The selection of the appropriate gauge and length of the catheter is dependent on the species and size of the animal, the condition and availability of veins, and the needs of the patient. The maximum flow rate of a catheter is determined by the radius and the length of the catheter. A rapid delivery of large volumes of fluid will require a short, large-gauge catheter. If a slower rate is acceptable, then smaller-gauge catheters may be appropriate.

- Over-the-needle catheter: This is the most commonly used catheter type. They are easy to place and inexpensive. They are available in a variety of sizes and are composed of several materials. The point of the needle is beveled and extends a few millimeters past the catheter tip.
- Through-the-needle catheter: This type of catheter is passed through the lumen of the needle. They are much longer (8–12 inches, 20–30 cm) in comparison to over-the-needle catheters and also come in a variety of diameters. The catheter is covered by a plastic sheath to prevent catheter contamination during placement. Once the catheter is fed through the needle, the needle is withdrawn and removed completely or covered with a needle guard to prevent laceration or damage to the catheter lumen (Fig. 44.2).

Catheter Insertion Sites (Table 44.1)

- Cephalic vein: This is a common site of insertion in lizards and is located running from medial to lateral in a proximal to distal direction across the antebrachium (Fig. 44.3). Using sterile techniques, a superficial transverse cut down, starting from the midmedial antebrachium to lateral, is performed. The vein is superficial; hence, an aggressive skin incision may easily damage the vessel. Blunt dissection may be used to further expose the vein. An appropriately sized catheter can then be placed and secured. An ultrasound-guided technique has been used in turtles under 15 kg.[3] This technique requires ultrasonographic visualization of the cephalic vein and is then used to guide the catheter insertion. Due to skin thickness, this technique may not be adequate in turtles more than 15 kg without previously performing a surgical cut down.[3]
- Ventral coccygeal vein: This is a common site of insertion in lizards, snakes, and crocodilians (Fig. 44.4). Using sterile technique, the transverse vertebral processes are palpated, and the tail is bent laterally. The catheter is inserted horizontally just below the level of the transverse vertebral processes in a proximal direction and then directed toward midline ventral to the vertebral body.[4] Alternatively, the catheter may be placed through the ventral midline approach

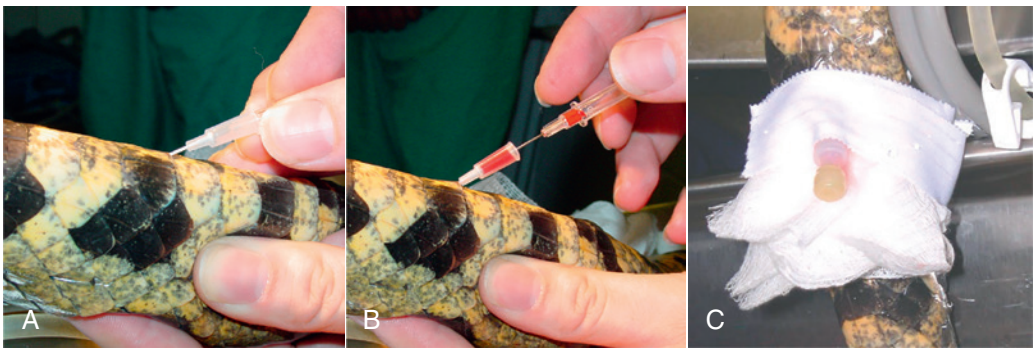

FIG 44.4 (A, B) Ventral coccygeal venous catheter placement in a snake. (C) While bandaging in place helps maintain patency, such catheters are difficult to impossible to maintain in active snakes. (Courtesy of Stephen J. Divers.)

TABLE 44.1 Available Intravenous and Intraosseous Catheter Sites for Reptiles

Species	Catheter Site	Comment
Chelonian	Jugular vein	Right jugular larger than left
	Cephalic vein	<15 kg, requires ultrasound guidance
	Plastrocarapacial bridge	Requires a drilled pilot hole, less effective than long bones
	Humerus/femur	Similar principle to small animals
Crocodilian	Ventral coccygeal vein	Similar principle to blood sampling
	Humerus/femur/tibia	Similar principle to small animals
Lizard	Cephalic vein	Requires a cut down
	Ventral coccygeal vein	Similar principle to blood sampling
	Femur/humerus/tibia	Similar principle to small animals
Snake	Jugular vein	Right jugular larger than left
	Heart	Only for emergency situations in moribund or anesthetized animals

in anesthetized reptiles. This has the advantage of being less likely affected by lateral tail movement or position but cannot be easily maintained in a conscious animal in sternal orientation.

- Dorsal coccygeal vein: This approach can be used in chelonians but is prone to lymphatic or cerebrospinal fluid contamination, is more difficult to maintain, and is therefore restricted to nonmobile or anesthetized animals where other routes prove unsuccessful. Using sterile technique, the transverse vertebral processes are palpated, and the tail is bent ventrally. The catheter is inserted vertically in the dorsal midline, between the spinous processes of the coccygeal vertebrae (Fig. 44.5).
- Jugular Vein: This is a common site of insertion in chelonians and snakes but can also be used in lizards (Fig. 44.6). The right jugular vein may be larger than the left; however, both sides may be used. The vein is located by drawing an imaginary line between the tympanic membrane and the carapace, under which the vein normally runs its path.[5] Ultrasonographic guidance can also aid in locating the vein.[3] A small cut down and blunt dissection is made at least one third of the way back from the tympanum down the neck. The further caudal the catheterization entry site, the more difficult it is to place, but the less likely it will be dislodged by the animal. An

FIG 44.5 Dorsal coccygeal venous catheter in a turtle. Such catheters are difficult to impossible to maintain in active animals. (Courtesy of Stephen J. Divers.)

appropriately sized catheter is placed and secured. Longer catheters can flex when the neck is retracted and produce catheter failure; hence, central venous catheters may be considered instead (see the section Central Venous Catheterization). These catheters are more easily maintained in active animals.

- As in chelonians, the right jugular vein is typically preferred in snakes for placement of an indwelling catheter. The patient is placed in dorsal recumbency, and the heart is located by watching for the beating ventral scutes. Using a sterile technique, a small incision is made 10 scutes cranial to the heart and should be 3 scutes long at the margin of the scutes and the first row of lateral body scales. Using blunt dissection, the jugular vein is exposed; it is superficial and runs medial and parallel to the free margins of the ribs. An appropriately sized catheter is then inserted and directed toward the heart. Sutures will be needed to secure the catheter in place.

INTRAOSSEOUS CATHETERIZATION

Intravenous access can be difficult in dehydrated or hypotensive reptiles, and therefore intraosseous catheters may be placed in lizards, crocodilians, and chelonians. Intraosseous (IO) catheters should occupy between 33% to 67% of the marrow cavity at the thinnest portion. Intraosseous catheters should not be kept in place for more than 72 hours, and they should be replaced by IV catheters when possible. Intraosseous fluid delivery has been shown to be significantly slower than IV administration. The location of the IO catheter can influence delivery, and in desert tortoises, uptake from the shell was significantly lower than for the humerus and femur.[6] Due to the nonexpansive nature of the IO route, administration rates may be limited, with higher rates likely to result in patient discomfort. Contraindications for IO catheters include fractures, neoplasia, osteopenia, burns, and infection of the access site. Complications associated with IO catheters in human patients are <1% but include local cellulitis, osteomyelitis, fracture, IO needle bending, and occlusion. Additionally, extravasation of fluids or medications from an improperly placed catheter or due to the use of excessive force during bolus administration may occur.[7]

Catheter Types

A variety of human commercial intraosseous needles are available, including the Jamshidi needle (Baxter Health Care Corp., McGraw Park, IL) and the Sur-Fast Intraosseous needle (Cook, Bloomington, IN). These may be used in larger reptiles. More frequently, spinal needles are used for intraosseous catheters; however, if not available, hypodermic needles can also be used in small reptiles or amphibians, although they are more likely to become blocked with a bone plug during placement.

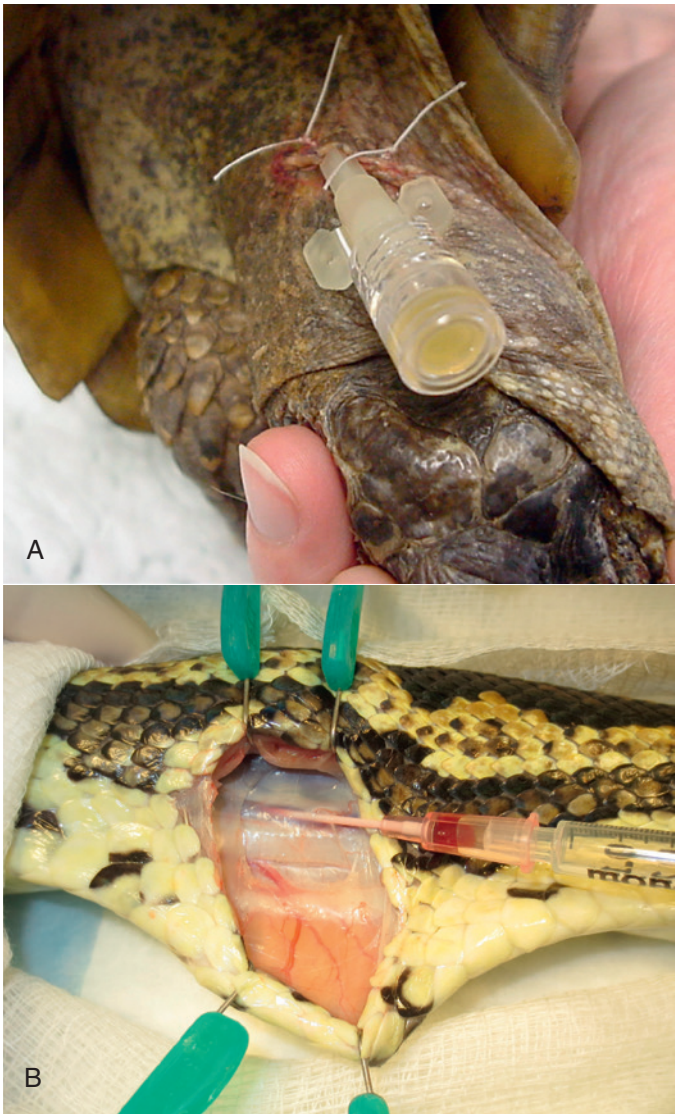

FIG 44.6 (A) Jugular venous catheter sutured in place in a chelonian. (B) Placement of a jugular venous catheter in a snake following a small coeliotomy cranial to the heart. (Courtesy of Stephen J. Divers.)

Catheter Insertion Sites

Intraosseous catheters should ideally be placed with analgesia and, in some cases, anesthesia depending on the patient's condition. Local anesthesia with 2% lidocaine over the placement site may be adequate to reduce pain associated with catheter placement. The site should be aseptically prepared.

- Proximal tibia: This is the most common IO site used in lizards (Fig. 44.7). The tibial crest is localized, and the catheter is introduced at the insertion of the patellar ligament. Penetration into the joint should be avoided. With the proximal tibia firmly grasped, the stifle is flexed while the needle is advanced through the skin and tibial crest while gently rotating the needle, until a subtle give is felt. Care is needed to keep the needle straight. The needle is then advanced within the marrow cavity. Depending on the angle at which the

VetBooks.ir

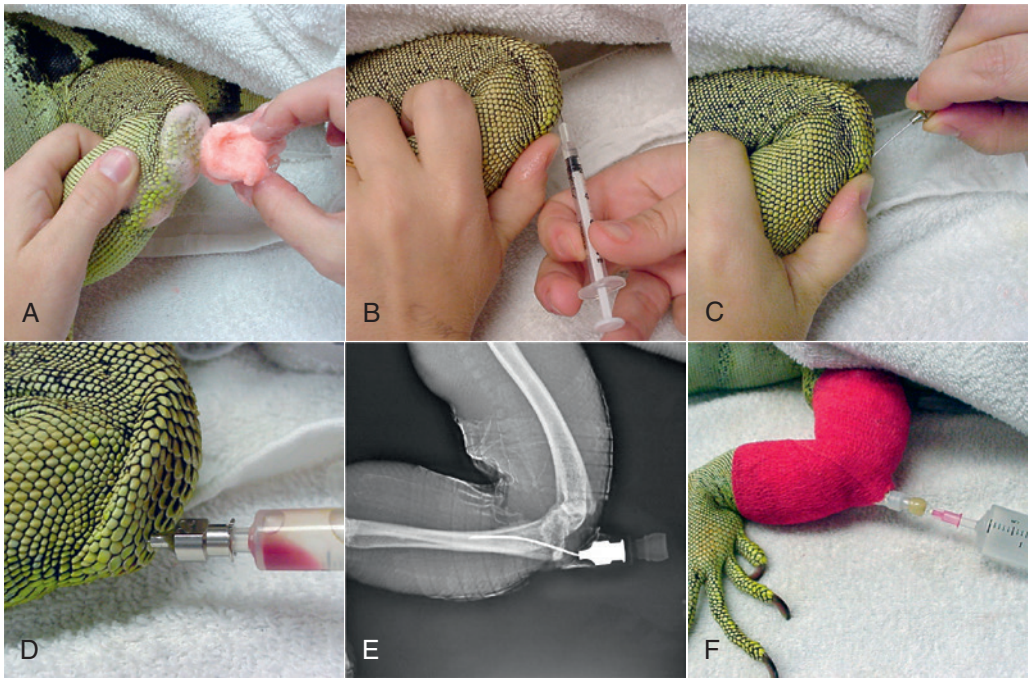

FIG 44.7 Intraosseous catheterization in a green iguana *(Iguana iguana)*. (A) Aseptic preparation of the right proximal tibia. (B) Injection of lidocaine subcutaneously. (C) Insertion of a 22 g 1-inch (2.5-cm) spinal needle. (D) Aspiration of bone marrow confirming correct placement. (E) Radiographic confirmation of intramedullary placement. (F) The catheter has been securely taped using a self-adhesive bandage, and a slow bolus of intravenous fluids is being given. (Courtesy of Stephen J. Divers.)

needle was bored, the catheter can be advanced to its full length in the case of catheters placed parallel to the long axis of the bone. In catheters placed at an angle, the needle is advanced until the tip of the catheter encounters resistance, indicating the opposite bone cortex. Care must be taken not to advance the catheter past this point of resistance because this can lead to penetration through the opposite cortex and extravasation of fluids into soft tissues.[7]

- Proximal humerus/femur: This technique can be used in chelonians, lizards, and crocodilians. The humerus and the femur can be catheterized by grasping the bone and firmly placing one finger along its long axis to indicate the direction of the bone. The needle is then introduced distally by use of a combination of a rotational movement and gentle pressure on the needle. Once the needle passes through the cortex into the medullary canal, a sudden loss of resistance will be detected.[8]
- Plastrocarapacial junction: In chelonians this technique can be used by locating the widest cranial aspect of the most dorsal-lateral scute of the bridge. A small pilot hole is created with a wire driver drill and sterile wire in a parallel plane to the shell in a cranial–caudal direction.[6] The wire is then removed, and the catheter is inserted by hand. Care should be taken to avoid celomic placement, and delivery at this site is less effective than the humerus and femur (Fig. 44.8).

FIG 44.8 Intraosseous fluid administration via a plastrocarapacial bridge catheter in a chelonian. (Courtesy of Stephen J. Divers.)

INTRACARDIAC CATHETERIZATION

In emergency situations where a jugular catheter is unsuccessful, an intracardiac catheter may be placed in snakes (Fig. 44.9). Using sterile techniques, place the patient in dorsal recumbency in the usual manner used to identify cardiac beat. Using an appropriately sized catheter, direct the catheter through the ventral skin between scutes toward the heart. The heart beat will be felt against the catheter. Once a flash is observed, remove the stylet, advance the catheter, and secure appropriately.[5] This technique is generally restricted to anesthetized or moribund snakes due to the difficulties of maintenance in an active animal.

ARTERIAL CATHETERIZATION

Arterial catheterization is important for the evaluation of invasive arterial blood pressure and serial arterial blood gas analysis. Unfortunately, arterial catheterization is invasive and challenging and tends to be restricted to research studies. Femoral artery and carotid catheterization has been successfully performed in iguanas,[9,10] and the vertebral

FIG 44.9 Intracardiac catheterization and intraoperative fluid administration in an anesthetized albino Burmese python *(Python bivittatus)*. (Courtesy of Stephen J. Divers.)

artery has been used in rattlesnakes.[11,12] In snakes, the vertebral artery is accessed by making a ventrolateral incision approximately 3 cm cranial to the heart. The tip of the catheter is then advanced toward the right aortic arch and secured in place with sutures.[11] The left carotid artery has been successfully catheterized in iguanas and used for evaluation of invasive arterial blood pressure.[13] The skin over the lateral neck is aseptically prepared, and the left carotid artery is surgically exposed. The carotid artery is ligated cranially with 5–0 nonabsorbable sutures, and the artery is occluded proximally with a sterile cotton-tipped applicator. An arterial catheter can then be inserted with the tip of the catheter positioned near the aortic arch and sutured in place (Fig. 44.10).

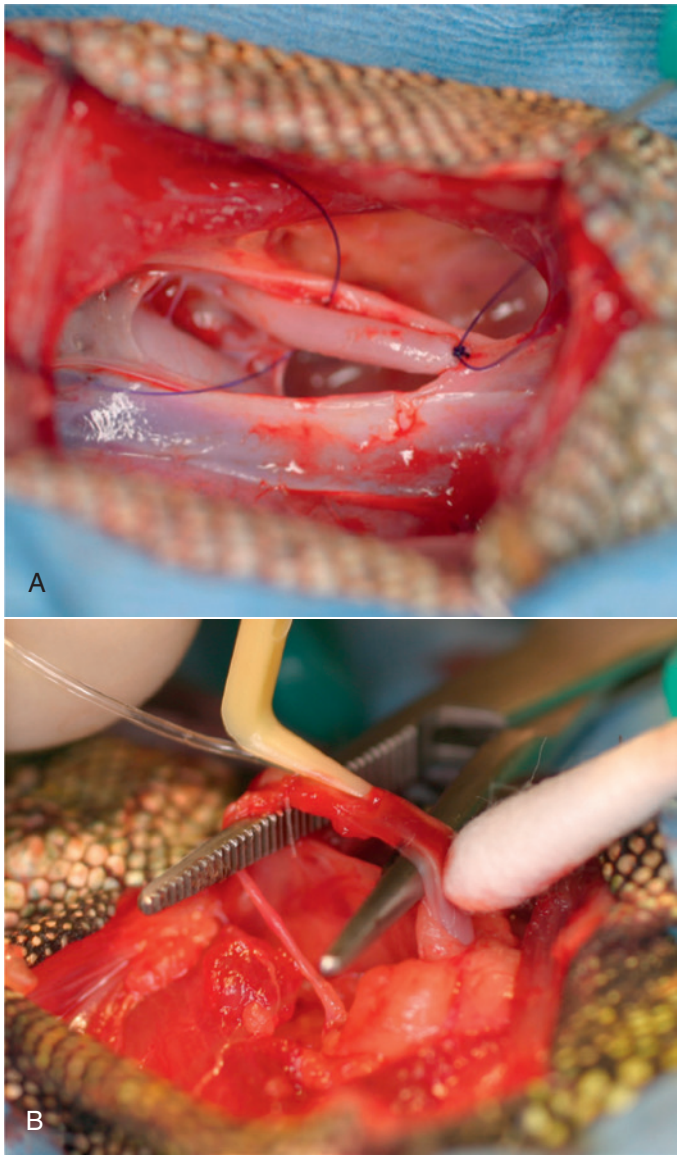

FIG 44.10 Intra-arterial catheterization in an iguanid lizard. (A) After surgical exposure of the lateral cervical region, the carotid artery has been isolated using stay sutures. (B) After small arteriotomy and while occluding the artery proximally, a catheter is being placed into the carotid artery. (Courtesy of Mariana A. Pardo.)

CENTRAL VENOUS CATHETERIZATION

Long-term IV access can be difficult to obtain and maintain; however, it may be critically important for administration of medications, fluids, blood products, and repeated blood sampling in hospitalized patients. Jugular catheterization provides the most rapid and secure route for vascular access, but catheters can be difficult to place, and maintaining catheter patency can be challenging. Central venous catheters have been shown to provide flexibility and sampling access while minimizing catheter displacement in chelonians.[14] Jugular veins have been the most commonly catheterized vessel; however. any vessel capable of supporting the diameter and length of these catheters may be a good candidate.

Catheter Types

Central venous catheters are available in a variety of gauges and lengths and with multiple lumens through Mila International (Florence, KY) and Arrow International (Reading, PA). This selection should be based on vessel diameter and length of catheter required.

- Single lumen catheter: These catheters may be appropriate when there is only one purpose for the central venous catheter, such as serial blood draws or fluid therapy.
- Multilumen catheter: These catheters may have up to four lumens. They are useful in critical care settings; incompatible drugs and fluids can be delivered simultaneously, they serve as a blood sampling line, and assessments such as central venous pressures can be performed. (Fig. 44.11). Dual-lumen catheters have been most commonly used by the authors, with one line for dedicated blood collection and the second for fluid/drug administration.

Seldinger Technique

This technique has been previously described in tortoises and sea turtles.[14,15,16] Under anesthesia or sedation, the jugular site is surgically prepared and draped in a standard fashion, and the patient is placed in sternal recumbency in a 20- to 30-degree head-down position. Ultrasound-guided placement and surgical cut downs have been used to improve success of catheterization.[3] The jugular vein is exposed through blunt dissection and then catheterized with an over-the-needle introducing catheter in a caudal direction. The J-tipped wire is introduced through the catheter, taking care to advance to the level of the proximal humeral plastron scutes and not to the level of the heart. Once the guidewire is placed, the introducing catheter and wire introducer are then carefully removed while keeping the wire in place. The vein dilator is then threaded over the wire and introduced a couple

of centimeters into the vein while applying firm torsion. The dilator is removed and digital pressure is applied to prevent blood leakage. The central venous catheter is then threaded over the guide wire and introduced caudally. The guidewire will then appear through the uncapped distal lumen. Care must be taken to not lose sight of the guidewire as the catheter is introduced. As the catheter is threaded over the wire and into the patient caudally, the wire is slowly removed in the opposite direction. The catheter should be introduced to the desired depth. Air entrapped in the catheter should be removed and then primed with sterile saline. The catheter is then sutured in place; a spacing clamp fastener may or may not be needed depending on patient size (Fig. 44.12).

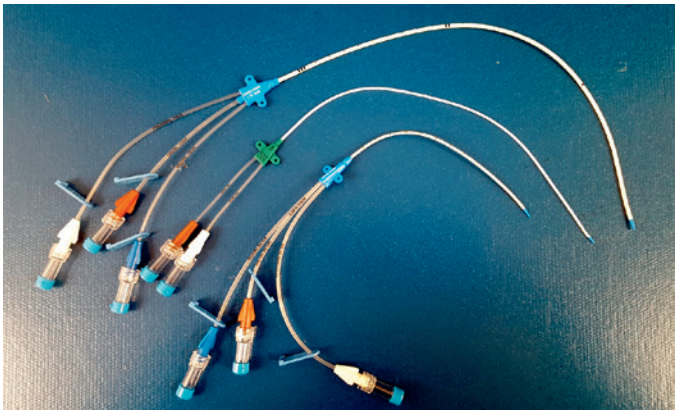

FIG 44.11 Multilumen central venous catheters. Top: triple lumen 7Fr 30 cm central venous catheter (Arrow International, Reading, PA); middle: double lumen 5Fr. 25 cm central venous catheter (Mila International, Florence, KY); bottom: triple lumen 5.5Fr 13 cm central venous catheter (Arrow International, Reading, PA). (Courtesy of Mariana A. Pardo.)

Verification of Placement

Correct placement should be confirmed radiographically; the tip of the catheter should lie anterior to the heart. If the catheter is placed too far into the heart or past it, it should be backed up an appropriate distance until it is located in the desired area.

Rewiring of Catheters

Central venous catheters that are no longer patent or problematic can be replaced through an exchange technique. Catheters should be rewired only when there is no evidence of infection and the insertion site is clean and does not appear inflamed. Sterile techniques should be used as previously indicated. The Seldinger technique is again used by passing the guidewire through the existing catheter and then removing the catheter while keeping the guidewire in place. The replacement catheter is the threaded over the wire and into the vein as previously described.

Catheter Maintenance

Catheter maintenance involves twice daily flushing of the catheter port with sterile saline or heparinized saline if the ports are not being currently used with a continuous infusion. Monitoring of the insertion site for signs

FIG 44.12 (1) Surgical cut down in preparation for jugular catheterization in a chelonian with an over-the-needle catheter. (2) Placement of J-tipped wire through the catheter. (3) Vein dilator placed over the wire. (4) Placement of central venous catheter over the wire. (5) Removal of air from catheter and priming with saline. VetBooks.ir

of infection, thrombosis, and phlebitis should be performed daily. Catheter sites should be gently cleaned of any obvious organic material daily.

VASCULAR ACCESS PORTS

Vascular access ports may be placed in reptiles that require serial blood sampling.[17] The technique has been previously described in iguanas, where arterial blood gases were evaluated.[18] Using sterile techniques, blunt dissection ventral to the external jugular vein is performed to expose the internal and external carotid arteries near their bifurcation. The catheter was inserted into the internal carotid artery and then guided to the common carotid artery. The opposite end of the vascular access port is then tunneled under the skin to a dorsal location near the scapula. Maintenance of the port included flushing twice a week with heparinized saline. Placement of a cardiac port in tortoises has also been described: a hole is drilled at the cardiac level in the plastron, and once the heart is visualized a sterile rubber is custom fitted and sealed in place with epoxy.[19] Myocardial fibrosis was seen in some of these subjects.[18]

CATHETER MAINTENANCE

Regardless of the catheter insertion site, inspection of the catheter site should be performed daily and examined for signs of pain, phlebitis, infection, thrombosis, and subcutaneous infiltration of fluids. Catheters should be removed if any of these signs are observed (Box 44.1).

BOX 44.1 Complications Associated With Catheterization

- Dislodgement
- Mechanical (phlebitis, hematoma, laceration)
- Subcutaneous extravasation
- Infection
- Thrombosis

CONCLUSION

Unhindered access to the vascular compartment of reptiles has huge implications for serial clinicopathologic evaluations and therapy. Just as they have become an essential and integral aspect of human and domesticated animal critical care, they should be utilized in herpetological medicine. In particular, given the slow response of many reptiles, central line catheters have provided a mechanism for serial sampling and IV drug administration over periods of weeks to months. This has revolutionized our management of these cases from inpatient to outpatient, in much the same way that esophagostomy feeding tubes have.

Esophagostomy Tube Placement

Daniel Cutler and Stephen J. Divers

Compared with other veterinary patients, the debilitated reptile often requires an extended period of supportive care and treatment. For this reason the esophagostomy tube has proven especially useful as a method for delivering oral fluid therapy, nutrition, and medications, both in the hospital and on an outpatient basis.

Correction and maintenance of proper hydration is imperative in any sick patient.[1,2] Intravenous, subcutaneous, and intracoelomic routes for providing fluid therapy are utilized in hospitalized patients and particularly in those with dysfunctional gastrointestinal tracts or abnormal body temperatures.[3] However, long-term hospitalization may not be practical or financially viable, and these hydration techniques may not be possible by the caretaker.[1]

Ensuring proper nutrition and caloric intake should not be ignored and is vital to recovery. In addition to nutritional support, various medical therapies may need to be given for an extended period. Therapeutic drugs can be given via intramuscular or subcutaneous routes; however, the owner may not be able to give injections, and drugs that require multiple dosing throughout the day may be stressful to the patient. Depending on the species, oral medications may be easily administered by the owner with minimal stress. Most lizard and snake species are good candidates for oral dosing. Caretakers of such species can be trained to give both oral medications and nutritional supplementation via syringe or gavage needle. However, larger lizards such as monitors or iguanas may not allow repeated restraint and oral administration without putting the caretaker in unnecessary danger, in addition to being stressful to the patient.[4] Also, concurrent pathology of the oral cavity such as severe stomatitis or mandibular fractures may contraindicate giving treatments via the oral route.[2,5] Chelonian's anatomic adaptations make oral medicating and assist-feeding more challenging, if not impossible.

A solution to these challenges is placement of an esophagostomy tube.[4] An esophagostomy tube (E-tube) allows a long-term route for enteral treatments to be given. The E-tube is well tolerated by most reptiles and can be left in place when the patient is discharged from the hospital. Also, the patient is able to eat and swallow with the tube in place. This allows the animal to transition back to eating unaided while weaning off nutritional support. Caretakers can be trained on proper use and maintenance of the E-tube, allowing it to be used and kept in place for weeks to months. Placement of the E-tube is easily performed with sedation and local anesthesia to light anesthesia, and this is virtually identical to methods used in domestic small animal medicine. Removal of the E-tube rarely requires sedation. When the E-tube is removed, the esophagus is allowed to heal by second intention, and the skin typically does not require sutures. Due to the ease in placing and removing E-tubes, when sedating for other diagnostics/procedures, the reptile clinician should consider whether an E-tube may be necessary for ongoing case management.

PROCEDURE

See Table 45.1 for a list of materials needed for E-tube placement. Once the patient is adequately sedated/anesthetized, the tube entry site is aseptically prepared. The location of the tube should allow normal movement of the head (e.g., retraction of the head into the shell) but should not be placed too far forward to allow the front limbs to dislodge the tube. In general, the caudolateral neck is preferred, taking care to avoid the carotid and jugular vessels. The tube should be premeasured so that the end is at the level of the stomach (Fig. 45.1) and marked (with a permanent marker) where the tube would exit the neck. Curved hemostats are directed into the oral cavity and down the esophagus (Fig. 45.2A). The tips of the hemostats are pressed against the wall of the lateral esophagus to tent the skin at the preferred location. The hemostat tip (and ultimately, the tube) should be approximately halfway between the dorsum and ventrum of the neck (i.e., lateral at the 3 or 9 o'clock position) to best avoid any major vasculature. Applying firm pressure of the hemostats against the esophagus and skin helps to create an incision window with the least amount of tissue dissection and minimizes the risk of vascular laceration.

TABLE 45.1 Recommended Materials for E-Tube Placement

- Surgical scrub (e.g. chlorhexidine/povidone iodine and alcohol)
- #15 scalpel blade and handle
- Esophagostomy tube—A soft rubber or feeding tube should be chosen with the appropriate length to reach the stomach as well as adequate lumen diameter to prevent clogging.
- Christmas tree adapter and injection port
- Permanent marker
- Curved hemostats—It is important to ensure that the hemostats selected are long enough to reach the E-tube site and also long enough to direct the tube beyond the E-tube site and down the esophagus. In giant tortoise species, a large, curved Doyen clamp can be used.
- Nonabsorbable suture material (e.g., nylon)
- Needle drivers
- Suture scissors
- Materials for securing tube
  - Chelonians—White tape or duct tape can be used to affix the tube to the shell.
  - Squamates—White tape can be used to make a butterfly bandage and affix the tube to the skin with nonabsorbable suture material.
  - Antimicrobial ointment—Topical antibiotic or antiseptic treatment should be applied at least once daily after cleaning to deter local infection.

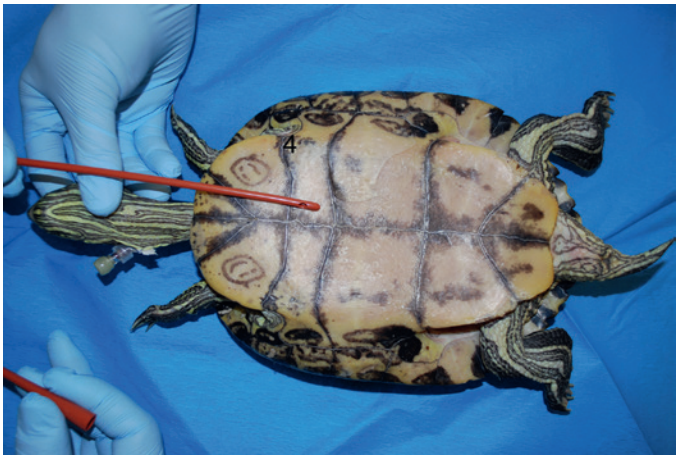

FIG 45.1 Prior to placement, the esophagostomy tube should be premeasured to the level of the stomach and marked at the point where it will leave the neck. In chelonians, the tube can be measured to the level of the pectoral scutes. (Courtesy of Daniel Cutler and Stephen J. Divers.)

Once the hemostats are properly placed, a #15 scalpel blade is used to make a small incision directly over the hemostats (Fig. 45.2B). Continual lateral pressure of the hemostat tips should be applied to cause the hemostat tips to protrude through the incision as soon as it is wide enough. A small incision provides a better seal around the tube and leaves a smaller incision to heal when the tube is removed. With the hemostat tips protruding, an appropriately sized E-tube is placed between the jaws of the hemostats and firmly grasped (Fig. 45.2C). The hemostat and E-tube tip is then pulled into the esophagus and out of the oral cavity (Fig. 45.2D). This step is crucial to prevent subcutaneous placement. The end of the tube is grasped with hemostats; the tip of the tube should be in the same direction as the hemostat tips. The hemostat and tube are then directed into the mouth and down the esophagus (Fig. 45.2E). The hemostat and tube should be pressed against the opposite side of the esophagus as they are directed caudally. This helps ensure that the tube is not directed into the esophageal defect created during the procedure. As the tube approaches and passes the location where the tube enters the neck, it is often helpful to retract and then feed the tube so as not to introduce any kinks. Once the

FIG 45.2 While the anatomy is different between species of reptiles, the steps are similar to those performed on this red-eared slider *(Trachemys scripta elegans)*. (A) Hemostats are inserted into the esophagus and pressed against the lateral side of the caudal neck. (B) An incision is made over the tips of the hemostats. (C) The hemostats are forced through the incision and used to grasp the tube and (D) pull the tube out of the mouth. (E) The tube is then redirected down the esophagus with the hemostats until (F) the premeasured mark is reached. (G) The tube is then secured with a purse-string and finger-trap suture techniques. (H) Following placement, the tube should be secured to allow normal movement but prevent contamination or removal by the patient. In chelonians, this is easily achieved by taping the tube to the carapace. (Courtesy of Daniel Cutler and Stephen J. Divers.)

VetBooks.ir

FIG 45.3 Placement should always be checked prior to giving any fluids via the tube. Contrast material can be given to assist in confirmation of proper placement in the distal esophagus or stomach. (Courtesy of Daniel Cutler and Stephen J. Divers.)

hemostats reach the extent of their reach, their grasp can be disengaged, the hemostats are removed, and the tube is fed until the proper location is reached (Fig. 45.2F). The tube may be palpated through the skin and stabilized to help direct it toward the stomach.

Once the tube has reached the premeasured location, the tube is secured using a purse-string and finger-trap suture pattern with nonabsorbable sutures (Fig. 45.2G). The tube should be checked to ensure that it will not easily move in or out of the neck incision. The tube end is secured with either butterfly sutures or tape, depending on the species (Fig. 45.2H). The end of the tube should be kept closed (e.g., Christmas tree adapter and injection port) when not in use.

Before food, medication, or water is administered through the tube, proper placement should be verified. Radiographic imaging with contrast or endoscopy can quickly verify proper tube placement (Fig. 45.3).

MAINTENANCE AND USE

While in place, the tube entry site should be cleaned with an antiseptic daily and a topical antibiotic ointment applied to the incision site to prevent local infection. Generally, before and after giving medications or food, and at least once per day, the tube should be flushed with a volume of water at least equal to the volume of the tube (Fig. 45.4). Flushing of the tube helps prevent clogging, which may necessitate

FIG 45.4 Delivering medication via an esophgostomy tube in a yellow foot tortoise *(Chelonoidis denticulata)* with minimal restraint. Note the syringe of water on the table, ready to flush the tube. (Courtesy of Stephen J. Divers.)

replacement. Any nutritional support delivered via the tube should be of an appropriate consistency to allow easy passage without excessive force.

Possible complications include secondary infection, blockage of tube, perforation/ulceration of gastrointestinal tract, and removal of the tube by the patient. Most of these can be prevented using the proper technique described above. The latter is the most common complication, especially in tortoises because of the large protective scales on the front limbs. Placing the tube more caudally and wrapping the "keratinized scales" on the front limbs of tortoises with vet wrap or tape can minimize these scales hooking the tube and pulling it out.

REMOVAL

Removal of the tube is a simple procedure and rarely requires sedation, unless the patient is fractious, dangerous, or uncooperative. Once the purse-string suture is cut, the tube can be pulled. The wound is generally left open to heal by second intention. Food can be offered to the patient the day after the procedure.

CONCLUSION

The E-tube is an important tool for the rehabilitation and treatment of sick and debilitated reptiles. The placement is minimally invasive and allows long-term, reliable delivery of fluids, nutrition, and medications. Use of the tube is not complicated and can easily be taught to the client to decrease hospitalization periods. Placement of an esophagostomy tube should always be considered for the sick, debilitated reptile that is likely to require prolonged, oral treatments.

Hospitalization

Daniel Cutler and Stephen J. Divers

The decision to hospitalize a reptile patient can be made for multiple reasons and are influenced by the medical goals and the patient's condition. The great variability in natural histories and physical attributes among reptile taxa makes finding a "one-size-fits-all" solution for hospitalization difficult. It is important to recognize the basic, daily requirements that must be met for each individual patient, along with addressing the reason(s) for hospitalization.[1] Improper hospitalization can exacerbate presenting pathology and patient stress or even create new problems, which can complicate the clinical picture and disrupt therapy.

INDICATIONS FOR HOSPITALIZATION

Proper requirements for hospitalization can vary based on the length of time the reptile patient will be staying.

Short-term hospitalization: A patient may be housed until a diagnostic or elective surgical procedure can be performed within the next 1 to 3 days. Such animals may only require basic amenities to address temperature, humidity, lighting, and security. Several days of stabilization and monitoring are often required for ill or unstable patients. In these cases, ensuring and monitoring the appropriate humidity, photoperiod, weight changes, appetite/caloric intake, and defecation/urination becomes more important.

Long-term hospitalization: If necessary, reptiles may need to be hospitalized for weeks to months. These reptile patients are usually chronically debilitated and require intensive daily care that the owner is unable to perform. Such hospitalization is far less common due to expense, and usually efforts are made to treat such cases on an outpatient basis using esophagostomy tubes and central line catheters. Fullspectrum lighting (including UVB) should be utilized for these long-term patients to prevent secondary nutritional hyperparathyroidism, as well as facilitate normal behaviors and color recognition. It is also increasingly important to ensure that the diet given to long-term inpatients meets all nutritional requirements (not just calories). Acknowledging these components of husbandry and addressing them proactively will allow the presenting complaint to be treated without management-induced complications.

ENCLOSURES AND SECURITY

Besides meeting requirements for proper medical care, hospital enclosures must also be safe and escape proof. Escaped patients can pose significant dangers to themselves, other patients, and staff, notwithstanding the embarrassment and liability if the animal cannot be recovered. For larger reptiles, walk-in kennels used for dogs may be appropriate (Fig. 46.1). Some designs incorporate sloped flooring to provide aquatic areas. Many reptiles are adept climbers, so the cage must be completely enclosed. Such large kennels are more difficult to heat or maintain humidity unless they have dedicated thermostats, heat sources, and humidifiers.

Enclosures and incubators designed specifically for reptiles provide the most security, particularly for smaller species. Purpose-built caging offers the ability for custom designs and sizes for small areas and, although expensive, can create easily controllable and cleanable environments (Figs. 46.2 and 46.3). In general, the ability to divide or combine cage spaces provides more versatility, as does having both terrestrial and arboreal options (Figs. 46.4 and 46.5).

It is advisable to have locking mechanisms for cages because some (especially snakes) are escape artists, whereas others may be especially valuable or dangerous (e.g., venomous snakes). Venomous snake enclosures must be lockable and require special shift boxes integrated into their design (Fig. 46.6) that can be easily disconnected and moved to connect to practice anesthesia machines. It is beneficial to be able to view all enclosures, especially those that contain venomous species, from outside the reptile room. It is also useful for such windows to have integrated blinds to improve animal seclusion. If housing venomous snakes, the veterinarian should review any local, regional, and federal requirements. In addition, protocols for escapes and envenomation incidents should be developed, clearly posted, and periodically reviewed.

FIG 46.1 Dog kennels or runs can be used for reptiles such as large tortoises, lizards, or crocodilians. This walk-in cage was designed with a large drain and sloping floor so that larger turtles could be housed. (Courtesy of Stephen J. Divers and Daniel Cutler.)

FIG 46.2 Custom reptile enclosures like this unit by Habitat Systems Ltd allow more comprehensive and automated control of environmental conditions, including temperature, humidity, and light cycle. Note the arboreal cages at the top with resin branches that can be sterilized. Each cage also has a lock and a separate temperature probe. The large enclosure at the bottom has a divider enabling it to be connected to the adjacent enclosure for large constrictors. There is also a shift box connector for moving venomous snakes (arrow). (Courtesy of Stephen J. Divers and Daniel Cutler.)

FIG 46.3 Reptile enclosures can also have customized furnishings, such as slide-out tables, to allow more convenient cage side treatment. Plastic bins can be incorporated into reptile housing units to provide temporary holding. These bins can easily be removed for disinfection. (Courtesy of Stephen J. Divers and Daniel Cutler.)

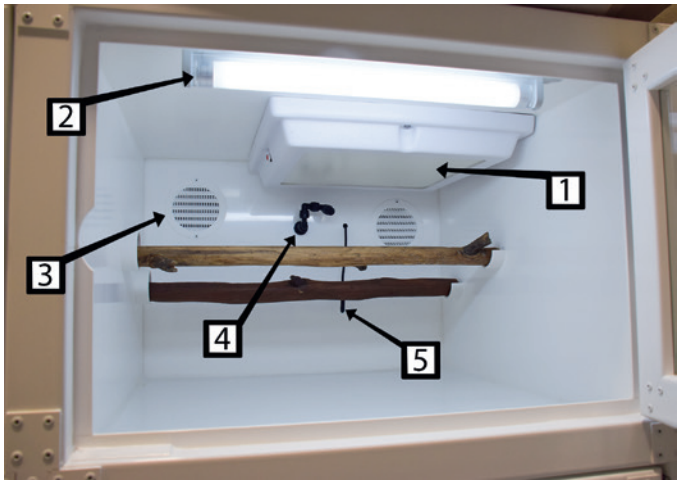

FIG 46.4 Arboreal reptiles, such as chameleons and some snakes, benefit from having suitable perching available. The perches are made of resin and can be easily cleaned and disinfected. Notice also the (1) heating element, (2) light, (3) ventilation panels, (4) sprinkler output, and (5) temperature probe. (Courtesy of Stephen J. Divers and Daniel Cutler.)

FIG 46.5 Caging units with dividers give the clinician more options in providing appropriately sized enclosures for patients (A and B). The access between separate units allows different temperature ranges to be accessible to the patient. (Courtesy of Stephen J. Divers and Daniel Cutler.)

VetBooks.ir

Temperature

As discussed elsewhere (see Section 2), maintaining appropriate temperatures and temperature gradients are imperative for healthy reptiles, with specific temperatures varying from species to species and dependent on natural history.[2] A sick reptile may be unable to ambulate and select an appropriate temperature within a gradient. Therefore moribund or nonambulatory reptiles should be provided with a steady temperature at the upper end of the preferred optimum temperature zone. Failure to provide an appropriate temperature will adversely affect drug absorption, distribution, and elimination. Temperature should be checked with digital instrumentation (not "dial" thermometers). For chelonians, a thermometer can be taped to the carapace to measure the animal's external temperature. An infrared laser thermometer is a convenient tool to measure both enclosure and external body temperatures (Fig. 46.7). Thermal support should be automated using reliable thermostats to ensure consistency, even on weekends. Dimming or proportional thermostats reduce temperature cycling. On-off thermostats cannot be used with lights. For larger chelonians and crocodilians, the general air temperature can be controlled in a small room with dedicated thermostat control (background heating), which is supplemented with a heat lamp suspended inside a large enclosure (basking area). Regardless of the methods used, providing safe, consistent, appropriate, and monitored thermal support is vital.[3]

Humidity

Hospital systems for maintaining appropriate environmental humidity can be simple or complex. Periodic misting of an enclosure can often provide short-term humidity for small enclosures. The humidity of larger rooms can be raised by providing larger water areas and/or allowing water to continually drip. Humidity boxes can also be placed in enclosures and provide microclimates for reptiles to selectively choose to enter. Fogging and misting systems can also be used to greatly elevate the amount of water in the air. These systems can be relatively inexpensive, with no automation, or can be built into an enclosure and controlled via hygrometers and timers (see Figs. 46.2 and 46.8). It is important to periodically disinfect or replace tubing on these fogging, misting, and drip systems, because hydrophilic bacterial growth can result overtime.

Enclosure Substrate

In contrast to the aesthetics of the normal enclosure, the main objectives during hospitalization are monitoring and hygiene. Compared to particulate materials, paper provides an inexpensive, easily replaceable floor cover that allows monitoring for urination, defecation, and vomiting/regurgitation, and reduces the chances of wound contamination. In some cases, particulate substrate may be necessary to promote natural behaviors such as egg laying. Also, aquatic and semiaquatic animals require a water-filled area of the enclosure. Enclosures made of glass or plastics can easily accommodate water. It is important that any substrates can be easily replaced and the enclosure and any utensils cleaned and disinfected. Perches and enclosures made of porous material (e.g., wood) should be avoided or discarded after use.

Nutrition

Appropriate food should be provided based on the medical history and natural history. Foods should be recognizable and presented in accordance with usual husbandry practices. Using dishes and food sources from the animal's home enclosure may be beneficial to a reptile housed in a foreign environment. If a reptile is to be fasted for medical or surgical procedures, then this should be clearly indicated on the cage door and in the medical record.

Some reptiles may require more intensive and calorically dense nutrient sources, especially when debilitated. A liquid diet is a good option as it can be delivered to an anorectic patient via feeding tube or gavage (see Chapter 45). Commercial powdered diets are available and are formulated for herbivorous, omnivorous, and carnivorous animals. When using such products, it is important to ensure that portion size and total daily amount is appropriate for the stomach size of the animal and also meets the daily caloric requirements. Cachectic reptiles that have been rehydrated should initially be fed very small quantities (approximately 10% of metabolic requirements) that are increased slowly over 2 to 4 weeks (see Chapter 122).

Staff

Staff directly involved with animal care and hospitalization must be appropriately trained and supervised, and qualified veterinary technicians and nurses are preferred. When dealing with potentially dangerous species (e.g., venomous snakes, crocodilians, large constrictors), staff must receive specific training, adhere to standard operating protocols, and never work alone. An incident log should be created for recording any mishaps, whether or not they are associated with injury to the patient or staff.

Monitoring

Any hospitalized reptile should receive at least daily examinations, and all observations and treatments must be accurately and contemporaneously recorded (Fig. 46.9). Changes in the environment, if not monitored, recorded, and addressed, can hamper recovery. Reptiles typically exhibit slower and more subtle changes, either positive or negative, which can easily be missed day to day. By regularly monitoring and maintaining a thorough record, changes in the patient's status can be more readily recognized and addressed. At a minimum, a patient's weight, demeanor, appetite, eliminations, environmental temperature, and environmental humidity should be recorded at least once if not twice daily. For more critical or postsurgical patients, more frequent monitoring and recording should be performed. Patient monitoring values can be recorded along with treatments given and case notes (Fig. 46.10).

FIG 46.9 In a busy reptile practice, ensuring accurate and up-to-date records is essential to avoid medical errors. (A) Hanging records adjacent to caging and (B) labeled bins with medications and other supplies decreases the likelihood of confusion between patients. (Courtesy of Stephen J. Divers and Daniel Cutler.)

Euthanasia

Javier G. Nevarez

The word *euthanasia* originates from two Greek words, *Eu* meaning good and *Thanatosis* meaning death. Hence, its literal translation is "Good death." In contemporary terms, euthanasia is defined as ending the life of an individual animal in a way that minimizes or eliminates pain and distress.[1] Within this context, the American Veterinary Medical Association Guidelines for the Euthanasia of Animals (AVMA Guidelines) states that veterinarians carrying out euthanasia have two primary responsibilities: "his or her humane disposition to induce death in a manner that is in accord with an animal's interest and/or because it is a matter of welfare, and the use of humane techniques to induce the most rapid and painless and distress-free death possible."[1] It is further stated, "These conditions, while separate, are not mutually exclusive and are codependent."[1] Whereas in the United Sates the term euthanasia is widely accepted, in some parts of the world, the term killing of animals rather than euthanasia is often used. In these countries, killing of animals is an accepted term regardless of the context within which the life of the animal is terminated (pets, food, etc.). Although the use of the term killing may connote a more negative emotion, it is a literal interpretation of what is effectively being done, which is to terminate a life. As such, the euthanasia of animals carries significant professional, moral, and ethical responsibilities for veterinarians. In veterinary medicine, euthanasia is a tool available to ease the pain and suffering of animals, as well as a necessary part of management of animals for food and textiles. In all instances it must be conducted in the most humane manner possible. Veterinarians must also be sensitive to local customs and perceptions toward this act and perform euthanasia in a manner that conforms to accepted cultural, religious, and societal norms within their country. The human-animal bond should also be a consideration, even when working with herpetological species.

The AVMA Guidelines have long been regarded as the most important reference for euthanasia methods in the United States, and similar recommendations have been published by other veterinary bodies internationally (e.g., British Veterinary Association, Universities Federation for Animal Welfare). Nonetheless, the information contained with respect to reptiles and amphibians has been limited due to the low amount of research on euthanasia of these species. Anatomic and physiological differences of herpetological species add to the difficulties in providing objective data specific to the euthanasia of these animals.

There has been an ongoing debate about whether reptiles and amphibians feel pain and suffer in the same manner as mammals do or if a simple nociceptive response with no central processing in the brain is involved. This debate is a strong point of contention among biologists and veterinarians alike. In the United Kingdom, protection of animals, including reptile and amphibian welfare, has been legally defined and defended by veterinarians since 1911. However, in the United States, it was not until 2011 that the US veterinarians' oath was changed to reflect the need to prioritize animal welfare, and even today, herpetological species remain excluded from the US Animal Welfare Act. As such it is indeed our responsibility as veterinarians to practice under the premise that reptiles and amphibians do feel pain and therefore should be treated with the same humane standards as other species, including providing them with proper analgesics. Sladky and Mans provide a review of clinical analgesia in reptiles.[2]

Concerning euthanasia, the AVMA Guidelines state: "it is often difficult to ascertain that an amphibian or reptile is, in fact, dead."[1] Although this statement has become a paradigm when dealing with euthanasia of herpetological species, the truth is there are methods to ensure reptiles and amphibians are indeed dead, and it is our responsibility as veterinarians to educate ourselves and apply those methods in a manner that respects their welfare.

The AVMA has recently acknowledged the need for establishing separate guidelines that address the euthanasia of animals destined for food. As a result, the AVMA Guidelines for the Slaughter of Animals (AVMA Slaughter Guidelines) was published in 2016.[3] A third AVMA document addressing depopulation is also planned.[3] The AVMA Slaughter Guidelines include recommendations for hoof stock, poultry, fish, alligators, and rabbits. In 2013, the Swiss Federal Veterinary Office (Swiss FVO) published the analysis on humane killing methods for reptiles in the skin trade.[4] This Swiss FVO document aims to establish international standards for the humane slaughter of reptiles. Both of these documents represent the first time that governments have established reptile-specific guidelines and are pivotal in the advancement of the welfare of reptiles. In addition to these guidelines, other resources for information on euthanasia of reptiles include various textbooks and studies, most notably, Cooper's monograph on Euthanasia of Amphibians and Reptiles, which has been considered a gold standard since it was first published.[5-8]

For clarity purposes, the term euthanasia will be used when referring to reptiles and amphibians maintained as pets, zoological specimens, laboratory animals, and more. The term slaughter will be strictly used for animals in the commercial food and textile trade. Anyone performing euthanasia or slaughter has the responsibility to stay up to date on the current methods and recommendations to ensure they are using the most humane techniques available.

EUTHANASIA TECHNIQUES

Regardless of whether dealing with a pet, zoo animal, or laboratory subject, euthanasia should always provide a humane death in the fastest way possible with the least amount of distress to the animal. The first decision to be made is whether a one-step or two-step euthanasia method will be applied (Table 47.1). One-step euthanasia is ideally performed when there is adequate venous access and the animal can be safely restrained without causing additional stress. Injection of euthanasia solution via the intracoelomic route and cardiac puncture

TABLE 47.1 Review of Euthanasia Methods With Routes and Techniques for Their Application

Single Methods	Route/Technique	Species	Comment
Injectable Agents			
Sodium pentobarbital (60–100 mg/kg)	IV	R, A	
MS 222 (>500 mg/L)	IV, ICe, Bath	A	While advocated in reptiles by some, its humaneness is not proven.
Benzocaine hydrochloride (>250 mg/L)	Bath, topical, ice	A	
Physical Methods			
Penetrating captive bolt	Placed over brain	R, A	Due to the force exerted, it will obliterate the head of any species smaller than crocodilians.
Nonpenetrating captive bolt	Placed over brain	R, A	Due to the force exerted, it will obliterate the head of any species smaller than crocodilians.
Firearm	Aim for the brain	R, A	Shot placement is critical for this procedure to be humane.
Blunt force trauma to the head	Aim for the brain	R, A	An adjunct method, such as decapitation or pithing, must be promptly applied to ensure death.
Adjunct Methods			
Decapitation	Atlanto-occipital joint	R, A	Must use sharp instruments and perform in a single swift motion. Facilitated by single occipital condyle.
Pithing	Needle or rod	R, A	Select the largest needle or metal rod possible.
Unacceptable Methods			
Hypothermia		R, A	
Inhalants		R	Because reptiles can hold their breath for an extended period of time, this can prolong death.

A, Amphibian; *ICe,* intracoelomic; *IV,* intravenous; *R,* reptile.

BOX 47.1 Three-Step Approach to Euthanasia of Reptiles to Ensure Death

Step 1

Inject Telazol (Fort Dodge, Inc, Fort Dodge, Iowa), 50 mg/kg IM, SQ, or ketamine HCl, 100 mg/kg IM, SQ.

Step 2

Option A. Once anesthetized, inject pentobarbital 0.5–1 ml/kg IV, IO, intracardiac, intrahepatic, or intracoelomic.

Option B. Once anesthetized, apply a physical method of euthanasia (see Table 47.1).

Step 3

Confirm lack of corneal reflex +/- fixed and dilated pupils. Then perform pithing, decapitation, or freezing.

(in snakes and lizards) is often advocated; however, one must wonder how much pain and discomfort a fully awake and aware reptile experiences with these procedures. In addition, in cases where postmortem evaluation and histopathology will be performed, cardiac puncture may result in mechanical or chemical damage to heart tissue and thus is not ideal. For these reasons, whenever possible, it is strongly suggested that one-step injectable euthanasia should be performed via the intravenous route. When venous access is not easily obtained, or if dealing with large, potentially dangerous, or unrestrainable animals, a two-step euthanasia should be performed. In two-step euthanasia the first step leads to a deep anesthetic plane while the second step results in death (Box 47.1). The authors recommend starting with anesthetics such as Telazol (Fort Dodge, Inc, Fort Dodge, Iowa), 50 mg/kg intramuscularly (IM) or subcutaneously (SQ), or ketamine HCl, 100 mg/kg IM or SQ. At these high dosages, approximately 10 to 20 minutes are needed for the drugs to take effect when the patient is at room temperature (see Box 47.1). Both of these drugs can be administered intramuscularly or subcutaneously, thereby facilitating delivery to a fractious or dehydrated patient or a patient with inaccessible peripheral veins. After the patient has been anesthetized, the second step of the euthanasia procedure can proceed. At this time, an intravenous, intracardiac, intracranial, intrahepatic, or intracoelomic injection of euthanasia solution can be administered (see Box 47.1). Alternatively, a physical method of euthanasia can be applied (see Table 47.1).

Even when performing two-step euthanasia, assessment of whether a reptile is, in fact, deceased can be difficult. This is important because occasionally a client takes the remains home for burial, taxidermy, and so forth. It would behoove the practitioner to make absolutely, positively sure that the pet is deceased before it is released to the owner. The situation can be embarrassing if owners call wanting to know why the animal they just paid to have euthanized is walking around. To prevent this type of medicolegal catastrophe, a third step in the euthanasia process can be performed.

Fixed, dilated pupils combined with lack of corneal reflex are good indicators that the animal is at least unconscious if not dead. After confirming a lack of corneal reflexes, pithing can be performed to ensure the brain tissue is destroyed. This technique also creates minimal external damage that may otherwise be unpleasant for an owner to visualize. Pithing is a technique by which a rigid tool or rod is inserted through the foramen magnum to the level of the brain. Once in the brain cavity, the rod can be rotated in circles 4 to 6 times to ensure destruction of the brain and, hence, death. For pet reptiles, the author utilizes a 14 to 16 g needle. In larger reptiles, a metal rod with a sharp tip can be used. For pithing to be successful, veterinarians must be familiar with the skull anatomy and location of the brain (Figs. 47.1 and 47.2). Pithing should only be performed as part of a two- or three-step euthanasia after an animal has been injected with euthanasia solution and there is a lack of corneal reflexes. In cases where the use of euthanasia solution may affect examination or testing

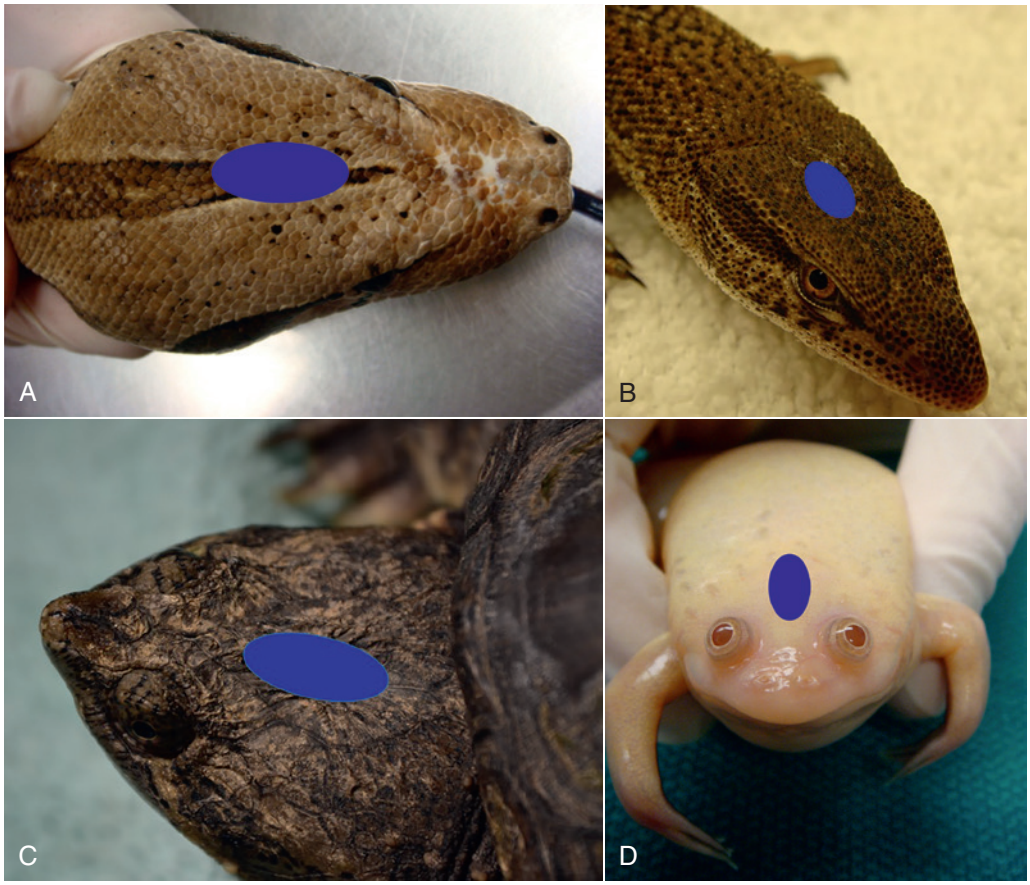

FIG 47.1 Approximate location of the brain (blue oval) in reptiles and amphibians. Proper localization of the brain is essential when applying physical methods of euthanasia to ensure the procedure is effective and humane. (Courtesy of Javier G. Nevarez.)

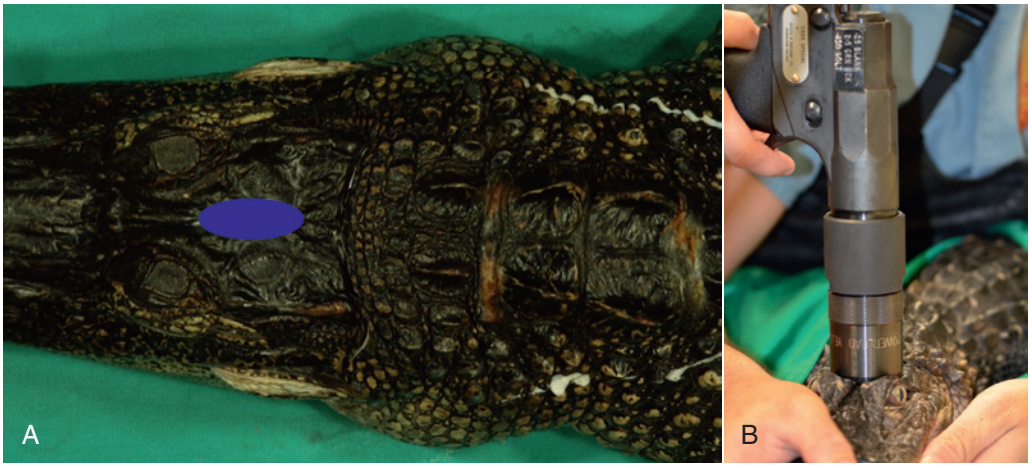

FIG 47.2 (A) Location of the brain (blue oval) in an American alligator. (B) Placement of a nonpenetrating captive bolt on the skull of an American alligator *(Alligator mississippiensis)*, directly over the brain location. (Courtesy of Javier G. Nevarez.)

of tissues (e.g., histopathology), pithing should only be performed in a reptile that is in a deep/surgical level of anesthesia.

An alternative to pithing is decapitation. Decapitation is visually unpleasant and therefore not ideal for reptiles that an owner wants to take home. Also it must be noted that decapitation by itself is not an effective euthanasia technique and must only be performed following complete unconsciousness with absent reflexes. Finally, freezing (only after rendering complete unconsciousness with no intact reflexes) for at least 24 hours before the carcass is released to the owner is another alternative to ensure death.

Assessment of heart rate by electrocardiogram or Doppler blood flow analysis does not provide an accurate determination of death because the heart occasionally continues to beat, even hours after the apparent euthanasia. Movement of the limbs and head should also be interpreted cautiously because this is often normal even after pithing and decapitation. This is due to inherent differences in the nervous

VetBooks.ir

system of reptiles and amphibians, including the presence of spinal ganglia. Nonetheless if movement is present, a thorough assessment of the patient must be performed to ensure it is deceased.

In summary, euthanasia of reptiles is best performed as a two- or three-step procedure (see Box 47.1). First the reptile is sedated or anesthetized; this is then followed with an injection of euthanasia solution. Potassium chloride may also be injected intracardially in fully anesthetized animals.[1] As an added assurance of death or when sending a patient home with the owners, pithing or freezing can be performed. By following a stepwise, two- to three-step (see Box 47.1) approach to the euthanasia of reptiles, death can indeed be confirmed and performed in a humane manner.

EUTHANASIA OF FIELD-COLLECTED ANIMALS

The collection of specimens is an essential part of the advancement of science. This often creates the need for euthanasia of reptiles and amphibians in field situations away from laboratories and under the care of nonveterinarians. Although anesthetics are often not available, in the United States it is possible in some instances to obtain special licenses to possess certain euthanasia solutions. When this is not possible (e.g., working in foreign countries), scientists must utilize physical methods in the most humane manner possible when a veterinarian is not available. Nevertheless, a veterinarian should be consulted during the development of any such scientific study.

SLAUGHTER

A number of reptile species, most notably chelonians and crocodilians, are raised for food and textiles throughout the world (see Chapter 177). The AVMA Slaughter Guidelines provide recommendations for the slaughter of alligators based on the most current scientific information for this species.[3,9] The FVO Analysis on the humane killing of reptiles includes slaughter recommendations that can be applied to various reptile species.[4] The species, size, age of the animals, and personnel safety and training should all be considered before selecting a method of slaughter to ensure it is applied in the most humane manner possible. Specific slaughter recommendations can be found in Table 47.2.

In the United States, reptiles do not fall under the regulation of the Humane Slaughter Act; therefore it is up to the individual states and industries to establish their own regulations. Such legislation often exists elsewhere, including Europe. In alligators, spinal cord severance followed by pithing of the brain and application of a penetrating or nonpenetrating captive bolt is more humane and effective for inducing death, whereas spinal cord severance alone was determined to be inappropriate.[9] In 2016, the Louisiana Department of Wildlife and Fisheries established a regulation that requires all alligator ranchers and farmers to slaughter the animals according to established guidelines by the AVMA and Swiss FVO. Specifically, it includes the use of penetrating or nonpenetrating captive bolt (Fig. 47.2) and spinal cord severance followed immediately by pithing. This regulation had the full support of the Louisiana Alligators Farmers and Ranchers Association and represents the first instance of regulatory governing of slaughter methods for a commercial reptile species in the United States. These guidelines and regulations also acknowledge that methods may be refined as more research becomes available and strongly encourage consultation with veterinarians to ensure that the methods being used are the most humane possible for each species and circumstances.

AMPHIBIANS

The same basic considerations for the euthanasia of reptiles apply to amphibians; however, because of their skin permeability, there are some methods that are unique to this group of animals. External or topical agents, such as tricaine methane sulfonate (TMS, MS-222), may be used to euthanize amphibians (concentrations >500 mg/L). Before using, it is important to ensure that the MS-222 has been buffered with sodium bicarbonate at a 1 : 1 weight ratio or until the solution reaches a pH of 7 to 7.5. The buffered MS-222 can also be injected directly into the amphibian lymph sac or the coelomic cavity. Injection into the coelomic cavity may cause pain or discomfort so that should be a consideration. Benzocaine hydrochloride can also be used for euthanasia at a concentration exceeding 250 mg/L, used either in a bath or in a recirculating system.

In an emergency situation, aquatic amphibians can be euthanized by placing them in water that contains dissolved carbon dioxide (with the addition of sodium bicarbonate powder or Alka-Seltzer tablets to water).[5] Rapid freezing, such as dipping in liquid nitrogen, is approved and effective in reptiles and amphibians of less than 4 g.[1]

A recent study evaluated a two-step process of amphibian euthanasia by first cooling toads in a refrigerator for approximately 60 minutes followed by freezing for 30 minutes.[10] Brain activity as measured by EEG declined through the procedure. Based on this it was suggested that the animals did not feel pain and that this technique should be considered humane. The use of EEG's to assess pain in humans is a complex field with conflicting information. The use of EEGs to assess pain in amphibians has not been validated. In addition this study did not include a control group. Therefore the use of this method should be approached with caution until more data is available that validates the methodology and conclusions of the study.

TABLE 47.2 Acceptable Methods of Slaughter for Reptile Species

Method	Comment
Penetrating captive-bolt	Alone or with an adjunct method (pithing) to ensure death if the brain is not immediately destroyed.
Nonpenetrating captive-bolt	Alone or with an adjunct method (pithing) to ensure death if the brain is not immediately destroyed.
Spinal cord severance immediately followed by pithing	Cord severance by itself is not an acceptable method. This can be accomplished within 3 seconds, but severance would be expected to be painful because the animal would be completely conscious.
Blunt force trauma to the head with a hard implement	In combination with an adjunct method (pithing) to ensure death.
Firearm	Shot placement is critical for this procedure to be humane.
Injection	Meat must be discarded.
Cervical dislocation	With proper technique and followed by another procedure to ensure death. Acceptable in animals under 200 g.
Decapitation immediately followed by adjunct method	Decapitation by itself is not an acceptable method.
Pithing	Adjunct method only. Should only be performed after prior stunning or decapitation and as method to ensure death.

Sedation

Rodney W. Schnellbacher and Molly Shepard

Sedation of reptiles has become an increasingly common strategy to provide immobilization, reduce trauma, and mitigate the stress response caused by physical restraint. Additionally, it facilitates clinical procedures such as physical examination, blood collection, and noninvasive or minimally invasive procedures. Sedatives act to induce the depression of the central nervous system while ideally preserving airway reflexes, hemodynamic stability, and a patient's ability to respond to repetitive or painful stimuli. Depending on patient selection and protocol design, a combination of sedation and local anesthesia can provide a safe alternative to general anesthesia for procedures such as wound care, placement of an intraosseous/intravenous catheter, some diagnostic endoscopy procedures, and minor surgery. Although the basis for sedation is to provide light to moderate narcosis, many sedation drugs also may serve as analgesics or premedications in the context of a general anesthetic event. The reader is directed to subsequent chapters on anesthesia (49) and analgesia (50) for elaboration on these topics.

Drugs used for sedation should ideally be short acting or reversible to avoid prolonged or unpredictable recoveries. Drug selection and administration technique should be determined based on the desired level of narcosis, the general condition of the patient (e.g., signalment, comorbidities, handling risks for personnel safety), environmental factors (facility limitations, weather), the monitoring modalities available, and the diagnostic and/or therapeutic procedures to be performed. Adverse events in the context of a sedation procedure may include compromise of upper airway patency, ventilation, or cardiovascular stability. Dosages should be adjusted according to the condition of the animal, with appropriate dose reduction and other special considerations for debilitated, gravid, pediatric, and geriatric patients, as well as patients in seasonal or metabolic states that may increase their sensitivity to tranquilizers.[1–3] Sedation requirements can vary widely between patients and species. In general, sedation dosages are lower than dosages required for anesthetic induction, and many tranquilizers, regardless of dose, cannot serve as single-agent anesthetics. Due to the paucity of published literature describing reptilian sedation, dosages are frequently extrapolated from other species, and many recommendations are based on anecdotal reports. The authors of this chapter recommend a multimodal approach to sedation, when possible, whereby a variety of injectable tranquilizers and analgesics are administered at subanesthetic doses to minimize the side effects of each agent.

MAINTAINING BODY TEMPERATURE

Due to their ectothermic nature, sedated reptiles should be maintained at temperatures and humidity levels appropriate for their species (their Preferred Optimal Temperature Zone, hereafter POTZ). Pharmacokinetic properties including clearance time and area under the curve (AUC) can be influenced significantly by a reptile's body temperature.[4] Maintenance of the POTZ is therefore crucial for the safety of the patient and reliability of the protocol (e.g. onset, duration and intensity of clinical effects) (see Chapters 49 and 50). Body temperature should be monitored throughout the procedure and can be actively maintained through the use of conductive (heating pads, circulating hot water blankets, heated examination tables, warm lavage fluids), convective (forced air warmers, incubators), and radiative (radiative infant warmers, sunshine) heating strategies. Body heat can also be preserved passively by reduction of evaporative heat loss (e.g., covering the patient after surgical preparation or minimizing surgical time while body cavities are exposed) (see Chapters 49 and 50).

INDUCTION AND RECOVERY

Indicators of sedation depth in reptiles are fairly consistent. Loss of withdrawal reflex and muscle tone is expected to start cranially and move caudally in the following sequence: pectoral limbs, pelvic limbs and neck, loss of the righting reflex, tail and cloaca, and often lastly jaw tone.[5] Reptiles maintain the ability to react to painful stimuli until lingual and palpebral reflexes are absent,[6] which signifies a deeper state of narcosis (anesthesia). In snakes and some lizards, palpebral and corneal reflexes cannot be elicited due to the presence of a spectacle. The reflexes described above allow practitioners to subjectively gauge sedative depth and predict features of recovery.

Recovery time from sedation is variable and depends on the drug protocol and patient condition. Debilitated animals may experience a more prolonged recovery presumably due to changes in hepatic blood flow or metabolic processes. Many drugs used for sedation (e.g., benzodiazepines opioids, and alpha-2 agonists) can be reversed, if necessary. Like induction of sedation, clinical signs of recovery in reptiles are uniform, with restoration of muscle control and withdrawal reflexes typically occurring in a caudal to cranial direction.

In order to improve the safety of sedation, it is necessary to evaluate sedation features, that is, via sedation scoring, which may allow the practitioner to target a sedation depth in a reproducible manner. The authors of this chapter suggest sedation scoring systems based on locomotion, muscle relaxation, and body position.

ROUTES OF ADMINISTRATION

Oral, intramuscular, intravenous, intraosseous, intranasal, subcutaneous, topical, cloacal, and intracoelomic routes are available. Routes of sedative

VetBooks.ir

administration should be selected based on ease of administration, size of animal, reliability of absorption, and rate of metabolism. Although oral, cloacal, intracoelomic, and subcutaneous routes of drug administration have been investigated, these routes are less reliable and characterized by poor absorption, delayed onset of action, protracted clinical effects, and occasionally, lack of clinical effect.[7]

Intravenous (IV) administration is considered the preferred method for sedation in reptiles, whenever possible, due to its predictability of drug action and recovery time. Unfortunately, IV administration can be technically difficult and can increase stress in small or fractious patients, or those difficult or dangerous to restrain. With experience, good technique, appropriate patient selection, and skilled physical restraint it is possible to approach the caudal (ventral coccygeal) vein in most snakes and lizards and the dorsal coccygeal vein, radial sinuses, and jugular vein in chelonians. The subcarapacial sinus is also a common target for IV administration in chelonians but should be approached with caution, due to the possibility of inadvertent intrathecal administration.[8] Lizards have a prominent ventral abdominal vein that can be used for the administration of sedatives. Intracardiac injections should only be given in emergency situations for administration of emergency drugs. However, one study in ball pythons (*Python regius*) showed that intracardiac injection of propofol is safe and only produced mild histopathological lesions to heart tissues.[9] Intraosseous routes of administration may provide a substitute for IV administration in some chelonian and saurian cases.[10,11]

In most reptiles, intramuscular administration of sedative agents is most practical and often effective. Although a renal portal system has been identified in reptiles, the clinical significance of this anatomic feature has little clinical impact on sedatives or analgesics injected into the caudal half of the body.[12] The epaxial muscles provide a suitable injection site in most snakes. In lizards, the muscle mass of the forelimb (triceps and biceps), hind limb (quadriceps, semimembranosus, and semitendinosus), and tail can be used. Caution should be used during handling of species known to autotomize their tails. In chelonians, intramuscular injections are recommended in the proximal pectoral limbs, targeting the triceps or pectoral muscles. However, some chelonian species lack significant muscle mass in this area, and intramuscular injection can inadvertently become subcutaneous.

Intranasal administration of sedatives has been utilized as a safe and effective route for short-term sedation and restraint in veterinary and human medicine.[13,14] Its appeal for reptile practitioners arises from its tendency to be less technically demanding than IV administration, less painful and stressful for patients than intramuscular injections, and its theoretical circumvention of hepatic first-pass metabolism. The nasal mucosa is a highly permeable port of entry for different drugs, presumably due to the relatively large mucosal surface area available for absorption and its proximity to the brain. Recent studies of intranasal sedation in chelonians have yielded variable results. One study of dexmedetomidine/ketamine in yellow-bellied sliders (*Trachemys scripta scripta*) showed positive sedation results[15] (Table 48.1), while another study of intranasal medetomidine/midazolam in the red-footed tortoise (*Chelonoidis carbonaria*) and Indian star tortoise (*Geochelone platynota*) showed little sedation benefit.[16] This administration route may offer a less invasive alternative to IM administration but requires more investigation with a greater range of drug species.

BENZODIAZEPINES

Benzodiazepines produce anticonvulsant and hypnotic effects through their enhancement of the neurotransmitter, gamma-aminobutyric acid (GABA) at the $GABA_A$ receptor, and anxiolytic and muscle relaxant effects through glycine-mediated inhibitory pathways in the brain and spinal cord. Their high margin of safety makes them appealing for use in compromised patients. Benzodiazepines such as midazolam and diazepam have been used alone and in combination with other sedatives to produce mild to deep narcosis in reptiles.

Midazolam has been investigated in many aquatic and terrestrial chelonian species. Intramuscular midazolam 1.5 mg/kg has been shown to produce sedation and muscle relaxation suitable for minor manipulations in red-eared slider turtles (*Trachemys scripta elegans*), with onset of 5 minutes and duration of approximately 80 minutes.[17] Other chelonian studies of IM midazolam sedation have described variable effects ranging from no sedation to profound sedation in the following species: common snapping turtle (*Chelydra serpentina*), red-footed tortoise, and Indian star tortoises.[16-21] Case reports have also described the use of midazolam combined with other agents (e.g., ketamine, medetomidine, dexmedetomidine) to produce standing sedation in the Galapagos tortoise (*Chelonoidis nigra*) and three African spurred tortoises (*Centrochelys sulcata*; see Table 48.1) (unpublished data).[22]

Midazolam appears to provide useful sedation for handling and minor nonsurgical procedures in several squamate species, as described in a recent retrospective study.[21] An average dose of 0.3 mg/kg (range 0.1–1.0 mg/kg) produced median onset time of 10 minutes and median time to maximal effect of 20 minutes (Fig. 48.1). Midazolam 2 mg/kg combined with medetomidine was also used to achieve standing sedation in the komodo dragon (*Varanus komodoensis*) (unpublished data).

Midazolam provides a proven benefit for restraint and handling of crocodilians. Routine capture of this species for transport or diagnostic events can cause significant stress, intense muscular exertion, lactic acidosis, and, in worst cases, capture myopathy and postcapture death.[23] Additionally, captive crocodilians frequently display abnormal interactions, basking, and feeding behavior for several days post-handling. One study of juvenile saltwater crocodiles (*Crocodylus porosus*) showed that those administered 5 mg/kg IM midazolam prior to physical examination, sample collection, and translocation had lower heart rates, respiratory rates, blood glucose, lactate, and acidosis during sedation, and faster recovery, compared to crocodiles under manual restraint alone.[20]

TABLE 48.1 Sedation Protocols Commonly Used in Reptiles

	Dose (mg/kg)	Route	Species	Comments	Reference
Chelonians					
Midazolam	0.5–2	IM	Red-eared slider, snapping turtle, red-footed tortoise, Indian star tortoise	Mild to moderate sedation for minor procedures and handling; medium maximum effect 20 mins	17, 21
Dexmedetomidine Midazolam	0.1 1	IM	Red-eared slider, North American box turtle	Mild to moderate sedation, completely reversible; rapid recovery after reversal	*
Dexmedetomidine Midazolam Ketamine	0.1 1 2	IM, SC	Red-eared slider	Moderate sedation, partially reversible; rapid recovery after reversal, suitable for intrathecal injection and endotracheal intubation	7, 22
Medetomidine Ketamine	0.1–0.2 5	IM, IN	Red-eared slider turtle, yellow-bellied slider	Deep sedation, suitable for intubation	15, 27, 29
Medetomidine Ketamine Morphine	0.15 2.5 1	IM, SC	African spurred tortoise	Deep sedation to light anesthesia, partially reversible; rapid recovery after reversal	22
Medetomidine Midazolam Morphine	0.2 2 1	IM, SC	African spurred tortoise	Deep sedation to light anesthesia, completely reversible; rapid recovery after reversal	22
Alfaxalone	10	IM	Red-eared slider	Moderate sedation, suitable for intubation	2, 3
Alfaxalone	10 and 20	IM	Horsfield's tortoise	Moderate to deep sedation, intubation not possible in about half of the tortoises	52
Propofol	2 to 5	IV		Moderate sedation; light anesthesia	11, 29, 42, 43
Lizards					
Midazolam	0.1–2	IM	Bearded dragon, Merten's water monitor, spiny-tailed monitor, frilled lizard, Eastern water dragon, Hosmer's skink, Komodo dragon	Mild to moderate sedation for minor procedures and handling; medium maximum effect 20 mins	21
Dexmedetomidine Midazolam	0.1–0.2 1	IM	Bearded dragon, green iguana	Moderate sedation, completely reversible; rapid recovery after reversal	*
Dexmedetomidine Midazolam Ketamine	0.05-0.1 1 3	IM	Bearded dragon, spiny-tailed lizard, blue iguana	Moderate to deep sedation, partially reversible; rapid recovery after reversal	*
Alfaxalone	10	IM	Green iguana	Light to moderate sedation, maximum effect after approximately 5 min; duration of effect, approximately 10 min	45
Alfaxalone	9	IV	Australian lizards	Induction agent; maintain with gaseous anesthetic	54
Propofol	3–5	IV, IO		Deep sedation to light anesthesia	†
Snakes					
Midazolam	1–2	IM	Black-headed python, carpet python, water python, emerald tree boa, eyelash palm pitviper	Mild to moderate sedation for mild procedures and handling; median time to maximal effect was 20 minutes	21
Tiletamine/ zolazepam (Telazol)	2–5	IM	Large snakes	Mild to moderate sedation, endotracheal intubation	†
Ketamine	5–10	IM		Mild to moderate sedation, endotracheal intubation	†
Propofol	3–5	IV		Moderate sedation to light anesthesia	9†
Crocodilians					
Midazolam	1–2	IM	Juvenile saltwater crocodile	Moderate sedation handling; reduction of lactic acidosis post handing	23
Tiletamine/ zolazepam (Telazol)	1–2	IM	Crocodilians	Mild to moderate sedation	†
Xylazine Ketamine	1–2 50–60	IM	Adult alligator	Partially sedated or no effects	†
Medetomidine	0.15–0.3	IM	Adult alligator	Mild to moderate sedation	†
Propofol	3–10	IV	Alligator	Mild to Moderate sedation to light anesthesia	†

IM, Intramuscular; *IV,* intravenous; *SC,* subcutaneous; *IN,* intranasal.
Atipamezole is used to antagonize medetomidine/dexmedetomidine in 1:1 volume, SC or IM. Flumazenil is used to antagonize midazolam: 0.01 to 0.1 mg/kg SC, IM, or IV. Naloxone is used to antagonize morphine or hydromorphone: 0.04 to 0.2 mg/kg SC, IM, or IV.
*Anecdotal dosages used in practice.
†See Chapters 49 and 50.

VetBooks.ir

Although midazolam at high dosages can provide variable sedation, combinations with other drugs (dissociative agents, opioids, alpha 2 agonists) are recommended to produce stronger and more reproducible results. Midazolam at 2 mg/kg in combination with 20 to 40 mg/kg ketamine, administered to common snapping turtles, provided better sedation than either agent alone or exposure to isoflurane. Combination of midazolam with the lower dose of ketamine produced levels of sedation for extensive manipulation for a minimum of 25 minutes.[18]

Diazepam appears to be an appropriate alternative to midazolam; however, this agent is less frequently used due to a longer anticipated duration of action and its hydrophobic properties, which cause a delay and reduction in IM absorption. Intramuscular diazepam (0.22–0.62 mg/kg) administered 20 minutes prior to IM succinylcholine chloride in American alligators (*Alligator mississippiensis*) resulted in reduced drug volume and decreased stress and lowered the dosage of succinylcholine chloride required for adequate immobilization for the purposes of safe handling.[24]

Flumazenil, an imidazobenzodiazepine derivative, antagonizes the actions of benzodiazepines by competitively inhibiting activity at the GABA receptor. Renarcotization can occur, especially if high concentrations of long-acting benzodiazepines such as diazepam were used, which may necessitate additional doses of this agent for sustained reversal.[21] While the recommended dosages in reptiles range from 0.01 to 0.3 mg/kg IM or IV, there are currently no pharmacokinetic studies of flumazenil in reptiles.

α2-ADRENERGIC AGONISTS

α2-Adrenergic agonists are a class of major tranquilizer drugs that selectively stimulate alpha adrenergic receptors, with sedative effects attributable to their activity in the central and peripheral nervous system and antinociceptive properties attributable to their activity within the spinal cord. α2-adrenergic agonists facilitate handling and synergistically combine with other sedative agents to facilitate short procedures such as abscess debridement, minor repair procedures, and collection of diagnostic samples. In most species, α2 adrenergic agonists initially produce a period of hypertension resulting from receptor activity on vascular smooth muscle and subsequent vasoconstriction. Hypertension is accompanied by bradycardia and decreased cardiac output as a result of reflex vagal activity and α2-mediated inhibition of norepinephrine release in the sympathetic nervous system. The α2 adrenergic agonists produce dose-dependent cardiovascular depression in reptiles. Significant decreases in mean heart and respiratory rates; systolic, diastolic, and mean ventricular pressures; and mean ventricular partial pressure of oxygen have been documented following administration of medetomidine 0.15 mg/kg in desert tortoises (*Gopherus agassizii*).[25] Due to the respiratory depressant effects attributed to these drugs, supplemental oxygen is recommended for extended procedures. While α2 adrenergic agonists may be used as single agents with variable efficacy (see Table 48.1), these agents are more commonly administered in combination with ketamine, benzodiazepines, and opioids to produce safe, reliable, and reversible sedation/anesthesia.

Xylazine, as a sole sedative agent or in combination with other agents, produces more variable clinical results than (dex)medetomidine. Xylazine sedative combinations, however, have been investigated for sedation in reptiles. Red-eared sliders given xylazine 2 mg/kg in combination with ketamine 60 mg/kg produced adequate sedation for minor procedures, however, xylazine appeared to provide no benefit over the group receiving ketamine alone.[19] Giant Amazonian turtles (*Podocnemis expansa*) administered xylazine 1.5 mg/kg IM followed by propofol 5 to 10 mg/kg IV produced deep sedation of approximately 150-minute duration, which provided adequate restraint for physical examinations, venipuncture, and minor surgery.[26]

The use of medetomidine and dexmedetomidine in reptiles has been well documented, primarily by the IM route. In the desert tortoise, medetomidine 0.15 mg/kg IM produced light to heavy sedation within 20 minutes post injection, with leg and neck reflexes significantly slowed. For tortoises given atipamezole at a dose of 0.75 mg/kg, reflexes were considered normal within 30 minutes of reversal.[25] Medetomidine 40 to 300 mcg/kg combined with ketamine 4 to 15 mg/kg IM have been used to produce light sedation followed by inhalation anesthesia in lizards, alligators, sliders, and other tortoises[27,28] (Fig. 48.2).

Yellow-bellied sliders administered dexmedetomidine 0.2 mg/kg and ketamine 10 mg/kg intranasally resulted in moderate to heavy sedation within 30 to 45 minutes post administration, without any adverse effects and with safe, reliable recovery within 19 minutes of atipamezole administration[15] (Fig. 48.3).

PHENOTHIAZINES (ACEPROMAZINE)

Acepromazine is a phenothiazine derivative, antipsychotic drug, which produces sedative effects mediated primarily by blockade of dopamine receptors in the basal ganglia and limbic system. Acepromazine also binds to adrenergic and muscarinic receptors. Systemic hypotension occurring as a result of this drug in mammals is typically attributed to antagonism of α1 adrenergic receptors in the peripheral vessels.

Although acepromazine can be used, little information has been published on its use in reptiles, either for sedation or as a premedicant prior to general anesthesia.[30,31] The irreversible character and prolonged effects of this drug make it less desirable as a tranquilizer in reptiles.

OPIOIDS

Opioid drugs, when administered alone, have variable sedation effects in reptiles. Butorphanol at 2 mg/kg IM in green iguanas did not reduce induction times, and when used as a premedication did not have isoflurane-sparing effects.[32,33] Additionally buprenorphine did not significantly increase iguana hind-limb withdrawal latencies at any time point when compared with saline. However, in chelonians the effects of opioids appear more profound. In a study of African spurred tortoises administered morphine at 2.0 mg/kg and midazolam at 1 mg/kg subcutaneously (SC), adequate sedation was achieved to allow physical examinations and blood collection to be performed.[22] Furthermore, red-eared slider turtles administered a high dose of tramadol at 25 mg/kg orally exhibited limb and neck flaccidity, as well as respiratory depression, within the first 12 hours after administration.[34] Moreover, red-eared sliders administered either butorphanol at 28 mg/kg or morphine at 1.5 mg/kg IM exhibited respiratory depression for 1 to 3 hours.[35] For this reason, oxygen supplementation should be considered for reptilian patients exhibiting reduced respiratory rates under morphine sedation.

SEDATION USING LOW-DOSE ANESTHETIC AGENTS

The following drug classes (dissociatives; sedative hypnotics, e.g., propofol; and steroid anesthetics, e.g., alfaxalone) are described in the literature and are clinically used as sedatives or anesthetics in reptiles. While the purpose of this chapter is to report evidence-based approaches to reptilian sedation, differentiation between sedation and anesthesia is difficult, given the challenges of determining depth of central nervous system depression in any vertebrate species and particularly reptiles. The authors of this chapter ask readers to recognize the inevitable overlap of information regarding protocols for sedation versus anesthesia and refer readers to Chapter 49, which addresses protocol design, monitoring, and other management issues surrounding general anesthesia in reptilians.

Dissociatives (Ketamine, Tiletamine)

Ketamine hydrochloride is a dissociative agent commonly used in sedative or anesthetic protocols for many species. The mechanism of action is by antagonism of the N-methyl-D-aspartate (NMDA) receptor, a glutamate receptor and ion channel protein residing in the central nervous system. It may be administered by IM or IV routes, and while its lower pH has been anecdotally noted to irritate tissue, especially when injected IM into smaller muscle bellies, it remains an important component of tranquilizer combinations for many species. Bienzle et al.[18] demonstrated that IM ketamine 20 to 40 mg/kg combined with midazolam 2 mg/kg provided sedation for physical examination of common snapping turtles, which was superior to that achieved by 5% inhaled isoflurane. Medetomidine 0.1 mg/kg and ketamine 5 mg/kg provided short-term, adequate sedation, with moderate hypoventilation, for minor diagnostic procedures in gopher tortoises (*Gopherus polyphemus*).[36,37] Furthermore, IV administration of atipamazole precipitated severe hypotension in this study population, and IM administration is recommended. Additional studies describing ketamine use in reptiles were described above, in combination with other tranquilizer agents.

A combination of the dissociative anesthetic, tiletamine, and the benzodiazepine tranquilizer, zolazepam, produces sedation, mild analgesia, and muscle relaxation in many mammalian species. Tiletamine/zolazepam is commonly characterized by a prolonged, mildly to moderately dysphoric recovery in mammals compared to recovery from ketamine combinations.[38,39] The clinical efficacy of tiletamine/zolazepam in reptiles, however, can be unpredictable, and recovery from this drug may be prolonged, especially at higher doses.

Sedation in green iguanas is reportedly unreliable, with some animals remaining sedated for up to 16 hours.[40] Similar sedation levels were achieved at all doses investigated (4.4, 22, 33, 44, 66, 88 mg/kg), with the majority never reaching a "surgical" depth of anesthesia. Water snakes administered higher doses in this same study exhibited unreliable, prolonged sedation (>8 hours) or death.[40] Tiletamine/zolazepam can be useful for sedation of large or dangerous species (e.g., crocodilians, large monitor lizards), and although not recommended for routine use in most species, some have reported consistently good results. Doses of 1 to 2 mg/kg have been recommended for crocodilians and produce sedation but responsiveness.[41] Given the irreversible nature and unpredictable response to this drug, caution is required.

Propofol

Propofol (2,6-diisopropylphenol) is a short-acting, lipid-soluble sedative hypnotic used frequently as an injectable general anesthetic in mammals. General advantages of propofol include quick induction and recovery with minimal to no dysphoria. Disadvantages of this drug include a dose-dependent depression of respiratory function. In mammals, it has been shown to cause reductions in cardiac contractility and vascular tone, the latter two properties frequently leading to hypotension.[42] Propofol is not reversible and requires intravascular administration, which may represent a significant limitation in reptile species for whom IV or IO access is difficult. Some formulations are available in multidose bottles with storage for up to 28 days at room temperature.

Propofol has been paired with various tranquilizers for successful and safe reptile sedation.[29] Chelonian species safely sedated with IV propofol include red-eared sliders, giant Amazon turtles (*Podocnemis expansa*), and loggerhead sea turtles (*Caretta caretta*), who develop rapid narcosis and dose-dependent depth and duration of sedation under the influence of propofol.[29,43,44] Both species demonstrated respiratory depression, a common finding among other species. Ball pythons (*Python regius*) administered intracardiac propofol demonstrated rapid sedation but a prolonged recovery when compared to sedation or anesthetic induction with isoflurane gas.[44]

The significance of apnea is controversial in reptiles, particularly for aquatic species that exhibit profound dive reflexes. Intracardiac shunting, which is thought to cause blood to bypass the lungs during a dive, may also occur during times of iatrogenic physiological stress, for example, sedation. Arterial blood is difficult to sample in most reptiles, and in the event that arterial samples are available for blood gas analysis, demonstration of hypoxemia in these samples may not correlate with a systemic state of metabolic distress. Given the logistical difficulties inherent to monitoring oxygenation, manual ventilatory support in apneic reptiles is recommended.

Alfaxalone

Alfaxalone is an injectable anesthetic found in a novel cyclodextrin excipient, which conceals this lipid-soluble compound in a water-soluble exterior, thereby facilitating its absorption following IM injection. Alfaxalone has gained recent popularity as an injectable sedative or anesthetic agent in reptiles due to its smooth induction properties and utility as an IM or IV single agent or part of a combination protocol for minor or noninvasive procedures.[54] The lack of a preservative mandates disposal of a vial after it has been breached.

When administered IM to green iguanas, alfaxalone showed a dose-dependent narcosis, with 10 mg/kg providing light sedation appropriate for examination or venipuncture, 20 mg/kg sufficient for endotracheal intubation, and 30 mg/kg providing surgical anesthesia for durations up to 40 minutes.[46] Another study evaluated 5 mg/kg IV in green iguanas and found this protocol to provide a smooth anesthetic induction prior to intubation and gas anesthesia.[45] While cardiovascular parameters remained stable during sedation in both studies, respiratory rates under IM sedation uniformly decreased; meanwhile, respiratory rates increased during the IV alfaxalone anesthesia.

In red-eared sliders and Horsfield's tortoises (*Agrionemys horsfieldii*), IM alfaxalone provides a smooth induction of dose-dependent sedation, which clinically becomes deeper and longer in duration at lower ambient temperatures.[2,3,53] Alfaxalone 10 mg/kg caused light sedation for shorter periods of time (<20–30 minutes), providing a depth suitable for examinations, venipuncture, and other noninvasive procedures. This drug was reliable when administered IM and also provided a smooth recovery.

Disadvantages of this drug include its apparent lack of (or yet unproven) analgesic properties, high expense, locomotor activity that can occur during recovery (turtles), and the large volumes required (when used as a single agent) that often necessitate multiple IM injections at different locations to administer an adequate clinical dose. Additionally, the lack of a preservative mandates disposal of a vial after it has been breached. In some countries, refrigeration for up to 1 week is acceptable; however, in the United States the FDA has mandated that a vial must be discarded within 6 hours of opening. Unless used extensively alfaxalone is often an expensive agent to work with for a single, small reptile patient.

NON-PHARMACEUTICAL METHODS

Vasovagal Response

Besides pharmaceutical forms of restraint, the vasovagal reflex may also be used for mild sedation for short, nonpainful procedures. Pressure over the eyes of most lizards and crocodilians or placement of the animal in dorsal recumbency can stimulate a vagal response and decrease in heart rate, blood pressure, and activity. This physical sedation can last up to 40 minutes in some species of lizards and can be a useful supplement to chemical restraint (Fig. 48.4).

FIG 48.4 Vagal response for a green iguana (*Iguana iguana*) undergoing radiographs. (Courtesy of Stephen J. Divers.)

Cold Narcosis

Despite its historical use, cold narcosis is not considered an acceptable form of sedation for reptilians. Hypothermia may exacerbate underlying metabolic diseases and weaken the immune system,[47] reduce the ability to respond to nociceptive stimuli,[48–51] and cause tissue injury. Additionally, necrotic changes in the brain have been reported in snakes and turtles restrained with cold narcosis.[51,52]

MONITORING PATIENTS UNDER SEDATION

Recommendations for monitoring sedated reptiles include intermittent measurement and documentation of respiratory rate and effort, heart rate, reflexes, and body temperature until narcosis has decreased to a level allowing ambulation and the return of normal behaviors. At this point, patients are frequently transferred to a heated enclosure for visual monitoring until fully recovered.

General Anesthesia

Christoph Mans, Kurt K. Sladky, and Juergen Schumacher

Historically, managing anesthesia in reptiles has been problematic for three primary reasons. First, there is an enormous diversity of species across the class *Reptilia*, one of the most phylogenetically diverse animal classes with four extant orders (*Crocodylia*, *Testudines*, *Squamata*, and *Rhynchocephalia*) and more than 9600 species worldwide. Second, there is a lack of systematic research dedicated to advancing our understanding of effective anesthetic/analgesic induction and maintenance drugs, dose-dependent effects, duration of drug efficacy, interspecies differences, and potentially fatal drug-related adverse effects, such as cardiopulmonary depression. Lack of funding in support of such research has hampered the field and limited the application of anesthetic/analgesic agents in reptiles when compared with mammals. Third, the reptile literature is rife with anecdotal information, which has persisted and, in many cases, has grown to be widely accepted dogma for clinicians. The diversity of reptiles in terms of natural history, size, anatomy, and physiology presents a unique clinical challenge to the veterinarian.[1] Safe and effective anesthesia of the reptilian patient is a requirement for procedures, including physical examination of large or dangerous species, collection of diagnostic samples, and application of various imaging modalities, as well as for surgical procedures. The anesthetic management of the reptilian patient, including the design of the anesthetic protocol, represents unique challenges due to marked anatomic and physiologic differences between taxa. Responses to frequently used anesthetic agents and dosages are often variable between taxa, and individual differences are also commonly observed. Additionally, anesthetic and analgesic protocols, including monitoring techniques to evaluate cardiopulmonary performance, are often derived from domestic animals and then applied to the reptilian patient. These techniques are often of limited value and should be interpreted by clinicians with caution.

ANATOMY AND PHYSIOLOGY

Thermoregulation and Environmental Temperature

Reptiles differ from mammals physiologically and anatomically, and therefore it is difficult to directly extrapolate from methods used in mammalian anesthesia. Most importantly, reptiles are ectothermic, meaning that their body temperature is directly dependent on environmental temperature and associated behaviors to modify that body temperature. Changes in body temperature significantly affect metabolic rate and many other physiological processes. Therefore the temperature at which one maintains a patient is an important factor in reptilian anesthesia due to the fact that the absorption, distribution, metabolism, and excretion of drugs in reptiles is directly related to environmental temperature.[2–4] Consequently, it is important to maintain the reptile patient within its preferred optimal temperature zone (POTZ) to be able to better predict the physiological effects of anesthetic drugs. POTZ is generally considered to be 20° to 25°C (68°–77°F) in temperate and aquatic species and 25° to 35°C (77°–95°F) in tropical species.[5] In red-eared sliders, the induction, duration, and recovery times after alfaxalone administration (10 and 20 mg/kg IM) were significantly shorter at 35°C (95°F) compared with 20°C (68°F).[6] At 20 mg/kg IM the induction times were 19 ± 6 (20°C, 68°F) and 7 ± 5 minutes (35°C, 95°F), and the plateau phase lasted 28 ± 13 (20°C, 68°F) and 8 ± 5 (35°C, 95°F) minutes.[6] Crocodiles administered medetomidine (0.5 mg/kg IM) for anesthesia were induced significantly faster at higher temperatures (32°C, 90°F) compared with lower temperatures (22 and 27°C, 72° and 81°F), while at 17°C (63°F) no anesthetic effects were observed.[7] In contrast, recovery times following atipamezole administration were not different between animals maintained at different temperatures.[7] In estuarine, but not in freshwater crocodiles, the duration of effect of intravenous alfaxalone was shorter at higher temperatures (32°C, 90°F) compared to lower temperatures (22°C, 72°F).[8] In neotropical rattlesnakes (*Crotalus durissus*) lower body temperature (22°C, 72°F) did not have an effect on induction times following administration of ketamine (80 mg/kg IM) when compared to animals maintained at 30°C (90°F). However, recovery times were significantly shorter at the higher temperatures (3.5 hours) compared to lower temperatures (5.5 hours).[3]

Cardiopulmonary Systems

The reptile cardiovascular system is characterized by several unique anatomic structures and physiological functions. In chelonians (turtles, tortoises), lizards, and snakes, the heart is 3-chambered, composed of a single ventricle and two atria. The two atria are completely separate, and the ventricle is divided longitudinally into two chambers by an incomplete intraventricular septum. The incomplete septum allows mixing of oxygenated and deoxygenated blood and shunting of blood from both left-to-right and right-to-left. All reptiles have two aortic arches, right and left. While cardiac shunting is considered detrimental in birds and mammals, it is an important physiological mechanism in reptiles during apneic periods (e.g., diving). The functional significance of cardiac shunts in reptiles has been the subject of debate for decades and is beyond the scope of this clinical review.[9,10] However, the clinician should be aware that cardiac shunting can play a role in inhaled anesthetic uptake and elimination, potentially causing delayed induction and delayed or an unexpectedly rapid recovery. In addition, cardiac shunts may affect systemic blood pressure and arterial/venous oxygen concentration, which, in turn will impact anesthetic monitoring (e.g., blood pressure, pulse oximetry, expired gases).

Hepatic First-Pass Effect. The hepatic first-pass effect following hind limb administration of anesthetic and other drugs has not received much attention in the literature. However, its pharmacodynamics and pharmacokinetic significance may be more clinically important than that of the renal portal system.[11] The venous blood flow from the hind limb in chelonians, lizards, and crocodilians drains into the ventral abdominal vein(s), which either passes directly to the liver or indirectly

VetBooks.ir

via the hepatic portal vein.[12–14] Hence, any liver-metabolized or excreted drug administered in the hind limb first enters the liver before reaching the systemic circulation, resulting in a hepatic first-pass effect. In turtles and crocodiles, the hepatic first-pass effect following hind limb administration leads to lower bioavailability of drugs, resulting in lower plasma concentrations and/or reduced or no clinical efficacy.[11,15,16] However, despite the published evidence of the clinical significance associated with the hepatic first-pass effect, pharmacokinetic and pharmacodynamic studies continue to be published without taking this anatomic factor into consideration with respect to study design.[15,17]

In leopard geckos (*Eublepharis macularius*), as well as red-eared sliders, hind limb administration of dexmedetomidine-ketamine resulted in significantly less, or no, anesthetic effects compared to administration of the same dosages in the forelimbs (Lahner, Proc AAZV, 2011, p 136).[18] A suspected hepatic first-pass effect was also reported in estuarine crocodiles (*Crocodylus porosus*) following medetomidine administration.[16] In contrast, broad-snouted caimans (*Caiman latirostris*) administered ketamine (30 mg/kg IM) and xylazine (1 mg/kg IM) in both the forelimb and hind limb did not exhibit any differences in sedation scores, induction, recovery, or physiological and behavioral responses.[19] In ball pythons (*Python regius*) the subcutaneous administration of alfaxalone in the caudal body half, just cranial to the cloaca, had significant less cardiovascular and sedative effects than administration in the cranial body half, at the level of the heart (Yaw, Proc ARAV, 2017, p 145). Since many drugs commonly used in reptiles, particularly analgesics and anesthetics, undergo hepatic metabolism and/or excretion, one must consider the hepatic first-pass effect, since the majority of venous blood from the hind limbs and caudal body half drains directly into the liver before entering the systemic circulation.[11,14] Therefore it is advised to avoid administration of anesthetic drugs by intramuscular or subcutaneous injection in the caudal body of reptiles. Intravenous administration of anesthetics in the coccygeal (caudal ventral tail) vein of lizards does not result in an hepatic first effect, because it drains directly into the caudal vena cava.[13] In turtles the venous drainage from the tail is less consistent, with some blood entering the ventral abdominal vein and some entering the caudal vena cava.[14]

Respiratory Anatomy and Physiology. The structure and function of the reptilian respiratory system not only differs considerably from mammalian and avian species, but differences are also apparent between reptile orders and families.[7,8] All reptiles lack a functional diaphragm, and the force to move air during inspiration and expiration comes from movement of skeletal muscles, resulting in changes of intrapulmonary pressure. Chelonians use pelvic and pectoral muscles, which are functionally analogous to a mammalian diaphragm. Snakes use a combination of smooth muscle in the lung walls, as well as intercostal muscles, while lizards use lung smooth muscle, intercostal, pectoral, and abdominal muscles for respiration. The glottis of snakes is located rostrally, and air enters through the external nares, the nasal sinuses, and the internal nares.[9] The trachea consists of incomplete cartilagenous rings and bifurcates into short bronchi at the level of the heart. The lungs are elongated saclike structures lined with respiratory epithelium. Most snakes have a vestigial left lung and a functional right lung, which ends distally as an airsac that is lined with nonrespiratory epithelium. Boid snakes have functional right and left lungs (although the left tends to be smaller) and distally caudal air sacs.

The glottis of carnivorous lizards is located more rostrally when compared to herbivorous species, where it is commonly found at the base of the tongue. Lizards have incomplete tracheal rings, and the trachea bifurcates approximately at the base of the heart. The lungs of most lizard species are single-chambered organs that extend caudally into an air sac. Some iguanids, varanids, and chameleons have multichambered lungs that consist of an anterior and posterior chamber.

In chelonians, the glottis is located at the base of a fleshy tongue. The trachea has complete tracheal rings, is relatively short, and bifurcates into a left and right intrapulmonary bronchus at the level of the thoracic inlet. Turtles and tortoises have paired, multichambered, relatively rigid lungs. In crocodilians, the glottis is located behind the epiglottal (gular) flap. The lungs of crocodilians are complex and multichambered, and the bronchi branch into multiple internal lobes.

Physiologically, reptiles have lower metabolic, cardiac, and respiratory rates because of their lower oxygen demands. Reptilian respiration is controlled by hypoxia, hypercapnia, and environmental temperature. Specific receptors increase ventilation during periods of low O_2 and high CO_2. In most reptiles, hypercapnia causes an increase in tidal volume, and hypoxia increases respiratory rate. In reptiles, the stimulus to breathe comes from low oxygen concentrations. Respiratory rate has been shown in tortoises to increase during hypercapnia but decrease during hypoxia. The higher demand for oxygen during increased temperature, or after prolonged dives in aquatic species, is met by increasing the tidal volume and not the respiratory rate. In an oxygen-enriched environment, reptiles decrease ventilation, characterized by a decrease in respiratory rate and tidal volume. Intrapulmonary shunts, which represent the portion of pulmonary blood bypassing gas exchange, reduce the efficiency of gas exchange in the lungs and result in a reduction of arterial oxygen concentrations (PaO_2).

PREANESTHETIC EVALUATION

A thorough and complete evaluation of the patient should be conducted to design an effective anesthetic and analgesic protocol. A complete history and critical review of husbandry practices, including diet, temperature, and humidity, should be obtained since they will provide valuable information on the health status of the patient. The medical record of the patient, including past anesthetic episodes, should be reviewed, followed by a complete visual and physical examination. Specific attention should be paid to evidence of systemic disease, as well as signs of cardiovascular or respiratory compromise, which will affect the patient's performance under anesthesia.

Diseases of the respiratory tract are commonly observed in reptiles and may affect both the upper and lower respiratory tract.[20] Most commonly, a viral or bacterial etiology is identified, and the patient may require effective antimicrobial therapy prior to induction of general anesthesia. Determination of respiratory rate and effort will provide limited information on the presence of respiratory tract disease. Imaging modalities such as radiography or computed tomography, as well as collection of diagnostic samples, will assist in identifying the severity and etiology of respiratory tract disease.

Assessment of cardiovascular performance should be part of the physical examination. Unfortunately, few studies have determined normal cardiovascular performance (e.g., heart rate, arterial blood pressures) in reptiles. Although reference values for various cardiac parameters need to be established in common reptile species, determination of heart rate and rhythm, and radiographic evaluation of cardiac morphology, as well as echocardiography will give valuable information on cardiac performance and abnormalities.[21,22]

Diagnostic samples such as fecal screens, hematology, and plasma biochemistries should be collected, before anesthesia if possible, to determine the health status of the reptile. Reference values for common reptile species have been published and should provide important information on organ function and presence of infectious and noninfectious disease processes. Imaging modalities such as radiography,

VetBooks.ir

ultrasonography, and computed tomography are performed as indicated by medical history and physical examination findings.

Some attempt should be made to objectively classify and document patient anesthetic risks, and the following physical status classification system created by the American Society of Anesthesiologists (ASA) can be useful.

ASA 1: A normal healthy patient
ASA 2: A patient with mild, systemic disease
ASA 3: A patient with severe systemic disease
ASA 4: A patient with severe systemic disease that is a constant threat to life
ASA 5: A moribund patient who is not expected to survive without the operation

It is useful to calculate all possible intraoperative and emergency drug requirements prior to premedication and induction. A simple spreadsheet can, after inputting the reptile's weight, produce a printable list of all potential emergency drugs. This should be attached to the anesthesia record and be constantly available during the premedication, induction, maintenance, and recovery phases.

Supportive Measures

Many reptiles require supportive care prior to anesthesia due to underlying chronic disease processes and dehydration, often identified during preanesthetic evaluation. Elective procedures should be delayed until underweight, dehydrated, or debilitated animals have received treatment to improve their condition. For nonelective procedures, dehydration and electrolyte imbalances should be corrected prior to anesthesia (see Chapter 87). Even the most moribund dystocic reptile will usually benefit from stabilization for 24 to 48 hours before embarking on general anesthesia. In the authors' experience, reptiles that fail to stabilize prior to surgery tend to succumb intraoperatively or postoperatively. Effective fluid therapy is indicated to correct fluid and electrolyte imbalances and return the patient to a normovolemic state. Intravenous or intraosseous fluid therapy are most effective and should be administered as a constant rate infusion if vascular or intraosseous access has been established (Fig. 49.1). Intravenous catheters can, following surgical cut-down, be placed percutaneously in the jugular veins of chelonians; jugular, cephalic, ventral abdominal vein, or ventral tail veins of lizards; and cranial vena cava or jugular vein of snakes. In lizards, the tibia or femur are common sites for intraosseous catheterization when IV access is not possible (see Chapter 44).

In cases of suspected or confirmed bacterial and fungal infections, effective antimicrobial/antifungal therapy should be initiated following the collection of material for culture and prior to the anesthetic event if possible. Particular attention should be paid to signs of respiratory or cardiovascular compromise, since compromise of these systems will affect the anesthetic plan, including selection of drugs, dosages, monitoring equipment, and requirement of supportive care measures during anesthesia.

INJECTABLE ANESTHETIC AGENTS

Prior to administration of any anesthetic or sedative drugs, reptiles should be maintained within their preferred optimal temperature zone (POTZ), and the core body temperature should be monitored throughout the anesthetic period. A variety of agents representing different classes of drugs are frequently used, either alone or in combination, depending on the desired level of sedation or anesthesia. It is recommended to avoid administration of high dosages of a single anesthetic agent (e.g., ketamine, alfaxalone), and instead, consider protocols in which multiple drugs are combined with synergistic actions, thereby requiring lower dosages for each drug. Additionally, using readily reversible drug protocols

FIG 49.1 Intravascular access in reptiles. (A) Intravenous catheter in the jugular vein of an African spurred tortoise (*Centrochelys sulcata*). (B) Intraosseous catheter in the left tibia of a red tegu (*Tupinambis rufescens*). Correct intraosseous catheter placement is confirmed by aspiration of hemorrhagic aspirate (needle hub), consistent with bone marrow. (C) Intravenous catheter placement in the tail vein of a green anaconda (*Eunectes murinus*). (C, Courtesy of Stephen J. Divers.)

VetBooks.ir

will provide for more rapid recoveries. Since most deleterious side effects (e.g., prolonged recovery, cardiopulmonary depression) associated with anesthetic and sedative drug administration are dose dependent, individual drug dosage reduction and reversibility will result in fewer complications and improved recoveries. Similar drugs and drug combinations can also be chosen for premedication/sedation prior to induction of general anesthesia. If the patient is scheduled for a painful procedure, it is recommended to include an analgesic agent such as an opioid in the preanesthetic protocol. Many injectable protocols in reptiles include the administration of an α-2 agonist (e.g., [dex]medetomidine) with ketamine and/or midazolam. A μ-opioid receptor agonist (e.g., morphine, hydromorphone) should be added to the protocol if additional analgesia is required in chelonians and lizards. One must keep in mind that many factors (e.g., site of injection, underlying disease, dehydration, body temperature, gravidity, etc.) may affect the onset, recovery, and efficacy of anesthetic drugs.[2–4] Therefore an individualized approach in selecting appropriate drug combinations and dosages should be considered.

Injectable agents alone can be used to facilitate a variety of short diagnostic and surgical procedures, as well as for induction of general anesthesia. Maintenance of a surgical plane of anesthesia for prolonged, invasive procedures is frequently based on administration of an inhalational agent, such as isoflurane or sevoflurane. In aquatic freshwater turtles and terrestrial chelonians, injectable protocols containing (dex) medetomidine-ketamine, with or without opiates and local anesthetics, were successfully used to induce and maintain surgical anesthesia, without the need of gas anesthesia (Tables 49.1 to 49.4), and these protocols are preferred by the authors.[23–26]

Routes of Parenteral Drug Administration

While historically the intramuscular route of drug administration is recommended in reptiles, it is considered more painful, and less

TABLE 49.1 Anesthetic Protocols Reported in Tortoises and Freshwater Turtles

Protocol	Species	Dosage (mg/kg)	Route	Comments
Alfaxalone	Red-eared slider (*Trachemys s. elegans*)[56]	5	IV	Surgical anesthesia for 30 ± 15 minutes, following induction within 22 ± 8 seconds. Intubation possible in 100%. Recovery by 34 ± 5 minutes at 25°–30°C.
	Macquarie river turtle (*Emydura macquarii*)[15]	9	IV	Deep sedation to light anesthesia for 14 ± 5 minutes. Intubation possible in 100%.
	Red-eared slider[6]	10	IM	Moderate sedation within 16 ± 8 (20°C) and 5 ± 2 (35°C) minutes. Duration of maximum effect 13 ± 12 (20°C) and 8 ± 5 (35°C) minutes. Intubation possible in 80% (20°C) and 0% (35°C). Recovery by 105 ± 22 (20°C) and 41 ± 8 (35°C) minutes.
		20	IM	Anesthesia within 19 ± 6 (20°C) and 7 ± 5 (35°C) minutes. Duration of maximum effect 28 ± 13 (20°C) and 8 ± 5 (35°C) minutes. Intubation possible in 100% (20°C) and 30% (35°C). Recovery by 105 ± 22 (20°C) and 41 ± 8 (35°C) minutes.
	Russian tortoise (*Agrionemys horsfieldii*)[58]	10	IM	Moderate sedation within 15 ± 5 minutes. Duration of maximum effect 46 ± 23 minutes. Intubation not feasible. Recovery by 116 ± 39 minutes at 25°C.
		20	IM	Moderate to deep sedation within 14 ± 6 minutes. Duration of maximum effect 99 ± 74 minutes. Intubation possible in 56%. Recovery by 187 ± 30 minutes at 25°C.
Alfaxalone + medetomidine	Russian tortoise[58]	10 (A) + 0.1 (Me)	IM	Light anesthesia within 15 ± 5 minutes. Duration of maximum effect 99 ± 74 minutes. Intubation possible in 67%. Recovery by 223 ± 85 minutes at 25°C after administration of atipamezole at 60 minutes. Use cautiously—cardiovascular depression reported.
		20 (A) + 0.05 (Me)	IM	Light anesthesia within 13 ± 4 minutes. Duration of maximum effect 103 ± 49 minutes. Intubation possible in 89%. Recovery by 275 ± 108 minutes at 25°C after administration of atipamezole at 60 minutes. Use cautiously—cardiovascular depression reported.
Dexmedetomidine + ketamine	Red-eared slider[34]	0.1 (D) + 10 (K)	IM, SC	Light anesthesia. Suitable for intubation. Rapid recovery after reversal with atipamezole.
Dexmedetomidine + ketamine + midazolam	Red-eared slider[34,35]	0.1 (D) + 2 (K) + 1 (Mi)	SC	Light anesthesia, rapid recovery after reversal with atipamezole and flumazenil.
	Gopher tortoise (*Gopherus polyphemus*)[44]	0.075 (D) + 8 (K) + 1 (Mi)	IM	Light-moderate anesthesia within 22 ± 5 minutes. Recovery after low-dose atipamezole 93 ± 6 (10–266) minutes.
Dexmedetomidine + ketamine + morphine	Herman's tortoise (*Testudo hermanni*)[23]	0.1 (D) + 10 (K) + 1.5 (Mo)	IM	Surgical anesthesia induced within 30 minutes, cystoscopy in hatchlings, reversal with atipamezole (0.5 mg/kg IM) and naloxone (0.2 mg/kg IM). Recovery after reversal: 3–21 minutes.
Isoflurane	Most species	1%–4%		Maintenance agent. Not suitable for induction by mask in chelonians. Prolonged recovery possible, which can be shortened by administration of epinephrine 0.1 mg/kg IM.[74]

VetBooks.ir

TABLE 49.1 Anesthetic Protocols Reported in Tortoises and Freshwater Turtles—cont'd

Protocol	Species	Dosage (mg/kg)	Route	Comments
Medetomidine + ketamine	Gopher tortoise[41]	0.1 (Me) + 5 (K)	IV	Light anesthesia.
	Red-eared slider[24]	0.1 (Me) + 5 (K)	IM	Light anesthesia, suitable for intubation, recovery by 60 minutes after reversal.
		0.2 (Me) + 10 (K)	IM	Surgical anesthesia, recovery by 60 minutes after reversal.
	Galapagos tortoise (*Chelonoidis nigra*)[43]	0.1 (Me) + 10 (K)	IV	Anesthetic induction within 11 ± 8 minutes. Required propofol (1.7 ± 1 mg/kg) in 50% for intubation. Maintained on isoflurane. Recovery by 120 ± 53 minutes after reversal.
Medetomidine + ketamine + morphine	Map turtles (*Graptemys* spp.)[a]	0.15 (Me) + 10-20 (K) + 1.5 (Mo)	IM	Surgical anesthesia by average induction time of 42 minutes. Reversal with atipamezole and naloxone. Naloxone at 0.02 mg/kg was insufficient and recovery was >3 hrs. Renarcotization noticed.
	Red-eared slider[26]	0.1 (Me) + 10 (K) + 1 (Mo)	IM	Surgical anesthesia by average induction time of 12 minutes. Reversal with atipamezole and naloxone (0.2 mg/kg). Mean recovery time 6 minutes.
		0.15 (Me) + 15 (K) + 1 (Mo)	IM	Surgical anesthesia by average induction time of 9 minutes. Reversal with atipamezole and naloxone (0.2 mg/kg). Mean recovery time 10 minutes.
	Chinese box turtles (*Cuora flavomarginata*)[25]	0.1 (Me) + 10 (K) + 1.5 (Mo)	IM	Surgical anesthesia, coelioscopy in hatchlings. Median reversal time 6 (0–21) minutes following administration of atipamezole and naloxone (0.2 mg/kg IM).
Medetomidine + hydromorphone + ketamine + midazolam	African spurred tortoise[76]*	0.15 (Me) + 0.5 (H) + 10 (K) + 0.5 (Mi)	SC	Light surgical anesthesia, maintain with gaseous anesthetic if necessary.
Midazolam + Ketamine	Common snapping turtle (*Chelydra serpentine*)[45]	2 (Mi) + 20-40 (K)	IM	Light anesthesia recovery up to 210 minutes without flumazenil administered.
Propofol	Most species[36,37]*	2–10	IV	Induction agent; use lower dose in large tortoises.
	Common snapping turtle[74]	5	IV	Induction agent.
	Red-eared slider[49]	10	IV	Light anesthesia within 1.7 ± 2.4 minutes. Duration of maximum effect 41 ± 20 minutes. Intubation possible in 70%. Recovery by 63 ± 24 minutes.
		20	IV	Surgical anesthesia within 0.9 ± 1.4 minutes. Duration of maximum effect 53 ± 32 minutes. Intubation possible in 100%. Recovery by 91 ± 32 minutes.

Atipamezole is usually dosed at 10 times the amount of dexmedetomidine or 5 times the amount of medetomidine in mg. Lower doses of atipamezole have been reported in reptiles. Recommended dose of flumazenil is 0.05 mg/kg in most cases. Lower dose (0.01 mg/kg) should be considered in large animals to reduce injection volume. Naloxone is used to antagonize morphine or hydromorphone: 0.04–0.2 mg/kg SC, IM, or IV.
*Information based on limited number of animals reported in case reports or based on anecdotal information.
[a]Hernandez-Divers SM, Proc ARAV, 2007, pp 34–35.
SC, Subcutaneous; *IM*, intramuscular; *IV*, intravenous.

space is provided in small muscle bellies for larger drug volumes when compared to the subcutaneous route. Recommended injection sites are summarized in Table 49.5. In snakes, the epaxial muscles are used, while in lizards and chelonians, muscles of the front limbs are a common intramuscular injection site but provide only limited space to administer anesthetic drugs (Fig. 49.2). The intramuscular injection of anesthetics may result in more rapid and less variable onset times compared to subcutaneous injection, depending on the drug administered. However, in red-eared sliders *(Trachemys scripta elegans)* administered dexmedetomidine-ketamine, the depth of anesthesia was not significantly different (~45 minutes) after either IM or SC injection.[1] In leopard geckos, the administration of alfaxalone-midazolam by subcutaneous injection resulted in first anesthetic effects within 5 to 10 minutes.[27] Furthermore, subcutaneous opioid absorption has been shown to be rapid in red-eared sliders.[1] Therefore the subcutaneous administration of anesthetic and analgesic drugs offers several advantages over intramuscular injection, including access to a variety of subcutaneous sites requiring minimal manual restraint or patient manipulation, suspected less discomfort on injection, and the capability of administering larger volumes in a single location (Fig. 49.3).

FIG 49.2 Red-eared slider turtle (*Trachemys scripta elegans*) demonstrating injection sites in the front half of the body. The SC (subcutaneous) site highlights the skin between the forelimb and neck. The IM (intramuscular) site highlights the muscle bellies of the forelimb.

TABLE 49.2 Anesthetic Protocols Reported in Lizards

Protocol	Species	Dose (mg/kg)	Route	Comments
Alfaxalone	Bearded dragon (*Pogona vitticeps*), Chinese water dragons (*Physignathus cocincinus*)[77]	5	IV	Induction agent, allows for endotracheal intubation in all animals. Loss of righting reflex within 12–45 seconds.
	Veiled chameleon (*Chamaeleo calyptratus*)[a]	5	IV	Surgical anesthesia within 2 minutes. Duration of maximum effect 5–10 minutes. Intubation possible in 100%. Recovery by 20 ± 5 minutes. Animals received butorphanol (2 mg/kg IM) prior to induction.
	Australian lizards[55]	9	IV	Moderate sedation—light anesthesia in most species; duration of effect <30 minutes, intubation possible, apnea reported, maintain with gaseous anesthetic if needed.
	Green iguana (*Iguana iguana*)[78]	5	IV	Surgical anesthesia within <1 minute. Duration of maximum effect 2–9 minutes. Intubation possible in 100%. Recovery by 14 ± 4 minutes.
	Green iguana[54]	10	IM	Light-moderate sedation within 8 ± 2 minutes. Duration of maximum effect 11 ± 4 minutes. Intubation possible in 40%. Recovery by 29 ± 36 minutes at 28°C–32°C.
		20	IM	Light anesthesia within 5 ± 2 minutes. Duration of maximum effect 22 ± 7 minutes. Intubation possible in 100%. Recovery by 45 ± 8 minutes at 28°C–32°C.
		30	IM	Surgical anesthesia within 4 ± 1 minutes. Duration of maximum effect 39 ± 12 minutes. Intubation possible in 100%. Recovery by 68 ± 9 minutes at 28°C–32°C.
	Leopard gecko (*Eublepharis macularius*)[27]	10–20	SC	Light-moderate sedation, inconsistent effects.
	Bearded dragon (*Pogona vitticeps*)[b]	20	SC	Light anesthesia within 5–10 minutes. Righting reflex lost and intubation possible. Maintained spontaneous respiration. Duration of maximum effect for ~30–45 minutes. Recovery by ~60 minutes at 25°C.
Alfaxalone + midazolam	Leopard gecko[27]	15 (A) + 1 (Mi)	SC	Moderate sedation, intubation possible in 33%, prolonged recovery (56 ± 29 minutes) after reversal with flumazenil at 26.0°C–28.0°C.
Dexmedetomidine + ketamine	Bearded dragon[b]	0.1 (D) + 20 (K)	SC	Light—surgical anesthesia within 5–20 minutes. Righting and limb withdrawal reflexes lost. Spontaneous breathing maintained. Reversed after 45 minutes. Recovered by 10–20 minutes after reversal at 25°C.
	Leopard gecko[18]	0.1 (D) + 10 (K)	IM/SC	Light anesthesia within 5–10 minutes. Righting reflex absent. Reversed after 45 minutes. Recovery by ~ 15 minutes at 26.0°–28.0°C.
Dexmedetomidine + midazolam	Bearded dragon[b]	0.1 (D) + 1 (Mi)	SC	Moderate sedation within 10–20 minutes. Righting reflex maintained, intubation not consistently possible.
	Leopard gecko[27]	0.1 (D) + 1 (Mi)	SC	Moderate sedation, intubation possible in 33%, completely reversible; rapid recovery by 6.1 ± 2.2 minutes after reversal with flumazenil + atipamezole at 26.0°–28.0°C.
Dexmedetomidine + ketamine + midazolam	Bearded dragon[b]	0.1 (D) + 10 (K) + 1 (Mi)	SC	Light—surgical anesthesia within 10–20 minutes. Righting and limb withdrawal reflexes lost. Spontaneous breathing maintained. Reversed with flumazenil and atipamezole after 45 minutes. Recovered by 10–20 minutes after reversal at 25°C.
	Bearded dragon, Uromastyx, blue iguana[76]*	0.05–0.1 (D) + 3 (K) + 1 (Mi)	SC	Deep sedation–light anesthesia, intubation possible, partially reversible; rapid recovery after reversal. Righting and limb withdrawal reflexes lost.
Isoflurane	Green iguana[59,60]			MAC: 2.0% ± 0.6 %, 1.8% ± 0.3%
	Dumeril's monitor (*Varanus dumerilii*) [79]			MAC: 1.54% ± 0.17%
Propofol	Green iguana[37,80,81]	5–10	IV, IO	Induction agent, apnea common, requires intubation and IPPV.
Sevoflurane	Green iguana[59]			MAC: 3.1% ± 1.0%
	Dumeril's monitor[82]			MAC: 2.51° ± 0.46%
Zolazepam-Tiletamine (Telazol)	Green iguana [83]	10.5 ± 4.2	IM	Light anesthesia, induction by 6.5 ± 0.7 minutes, intubation possible, initial excitement phase, long recovery times
	Large lizards[81]	5–10	IM	Premedication

Atipamezole is usually dosed at 10 times the amount of dexmedetomidine or 5 times the amount of medetomidine in mg. Lower doses of atipamezole have been reported in reptiles. Recommended dose of flumazenil is 0.05 mg/kg in most cases. Lower dose (0.01 mg/kg) should be considered in large animals to reduce injection volume. Nalaxone is used to antagonize morphine or hydromorphone: 0.04–0.2 mg/kg SC, IM, or IV.

TABLE 49.5 Preferred Anesthetic and Analgesic Injection Sites in Reptiles

Chelonia

SC drug administration sites include the skin between the neck and forelimbs.

IM drug administration sites include the forelimb and pectoral muscles.

IV access recommended includes the jugular vein, brachial vein, or ventral coccygeal vein.

Lizards

SC drug administration sites include the dorsum, overlying the epaxial muscles. Stay in the cranial half of the body.

IM drug administration sites include the forelimb and epaxial muscles in the cranial half of the body.

IV access includes the ventral coccygeal vein (i.e., ventral tail vein), jugular vein, ventral abdominal vein, and cephalic vein.

IO administration requires catheterization of the distal femur or proximal tibia.

Snakes

SC drug administration sites include the dorsum, overlying the epaxial muscles. Stay in the cranial half of the body.

IM drug administration sites include the epaxial muscles in the cranial half of the body.

IV access includes the ventral coccygeal vein (i.e., ventral tail vein) and the palatine veins in the oral cavity of larger species.

IM, Intramuscular; *IO*, intraosseous; *IV*, intravenous; *SC*, subcutaneous.

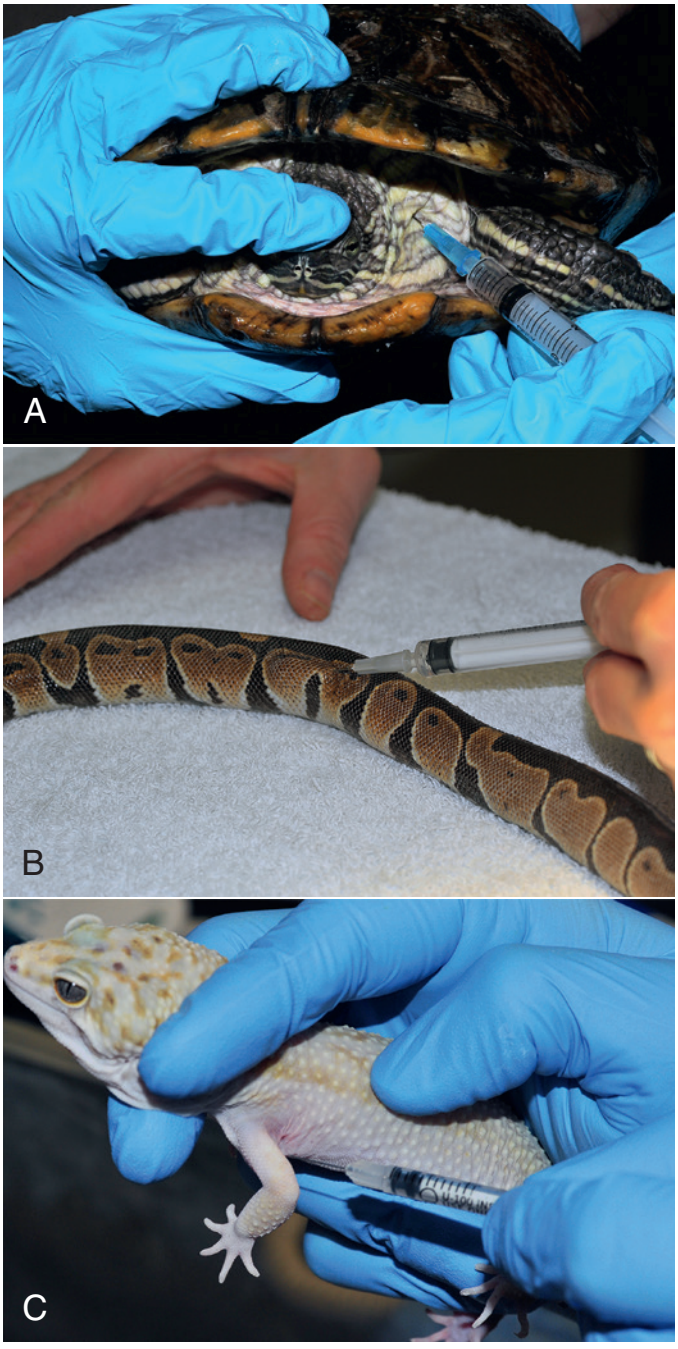

FIG 49.3 Subcutaneous drug administration in reptiles: (A) Red-eared slider (*Trachemys scripta elegans*), (B) ball python (*Python regius*), and (C) leopard gecko (*Eublepharis macularius*).

The intravenous route offers an excellent route of administration for anesthetic agents and results in rapid onset of anesthesia. However, depending on the species, patient size, and level of cooperation, intravenous access may be challenging or impossible to obtain, making the subcutaneous or intramuscular route more feasible. In lizards, intravenous injections are most commonly administered into the caudal (ventral tail) vein (Fig. 49.4). In most tortoises and nonmarine turtles, the jugular vein is preferred for intravenous drug administration, but the brachial plexus is also practical. The subcarapacial sinus and dorsal coccygeal vein cannot be recommended for intravenous drug administration in chelonians due to the risk of accidental administration of anesthetic agents into the intrathecal space, which may lead to severe neurologic complications including permanent paralysis and death.[28,29] In addition, the dorsal coccygeal vein is not consistently developed across chelonian species, and while present in red-eared sliders, it is absent or poorly developed in several tortoise species. Therefore it should be assumed that a well-developed dorsal coccygeal vein is the exception, rather than the rule, among chelonians. Hence, the authors advise against drug administration into the subcarapacial sinus or the dorsal tail vein in chelonians. Intravenous injection sites in snakes are limited to the caudal (ventral tail) vein and the jugular vein following a cut-down procedure. Intracardiac administration of propofol has also been reported in snakes and results in rapid onset with no significant complications reported in a controlled study.[30] However, cardiac tamponade after cardiocentesis in snakes has been reported, and the increased risk of intracardiac injections should be considered.[31]

Intranasal administration of anesthetic agents has been investigated in chelonians.[32,33] Intranasal administration of dexmedetomidine (0.2 mg/kg) and ketamine (10 mg/kg) only induced mild to moderate sedation in yellow-bellied sliders (*Trachemys scripta scripta*) at dosages that would result in surgical anesthesia if administered IM or SC.[33] In red-eared sliders, the complete intranasal delivery of dexmedetomidine (0.1 mg/kg) and ketamine (10 mg/kg) was not possible due to the exhibited defense behavior of the turtles, and anesthesia was not induced (in contrast to IM or SC injection of the same doses of drugs). However, for administration of atipamezole in anesthetized red-eared sliders the intranasal route has been shown to be as effective as the IM or SC routes. In large chelonians in particular, large volumes of the anesthetic agent are a limiting factor.

As mentioned above, all IM or SC injectable anesthetic or analgesic agents should be administered in the cranial body half in order to avoid

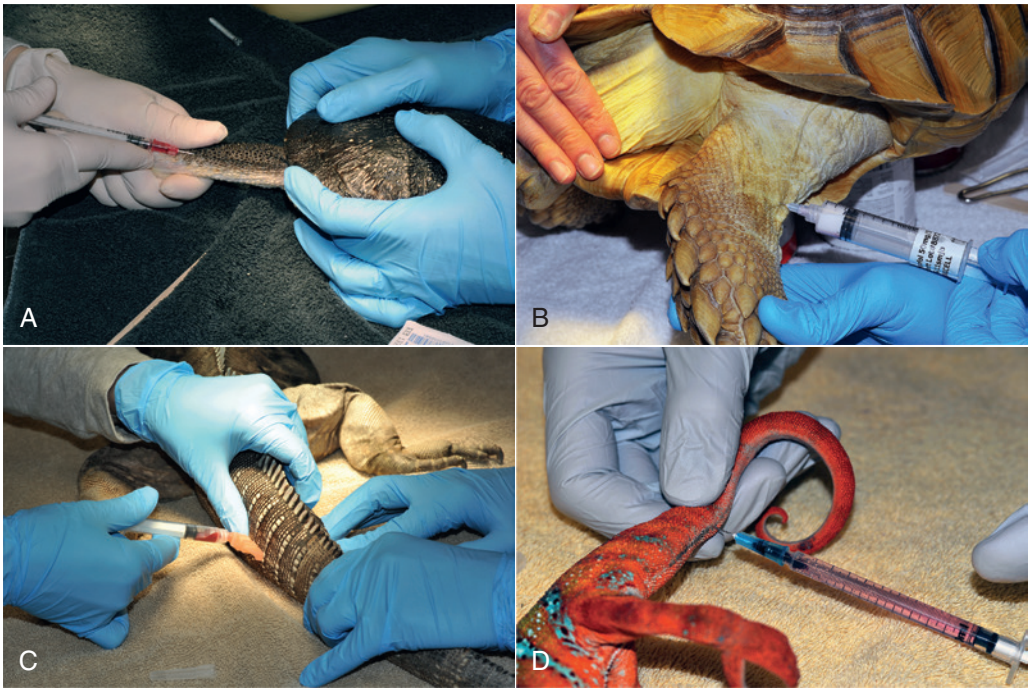

FIG 49.4 Intravenous drug administration in reptiles. (A) Intravenous injection in the left jugular vein of a side-necked turtle (Pleurodira). (B) Intravenous propofol administration in the left brachial plexus of a sedated African spurred tortoise (*Centrochelys sulcata*). a hepatic first pass effect and reduced or lack of anesthetic/analgesic effects.[16,18]

Drugs

Ketamine, a dissociative agent with dose-dependent anesthetic, sedative, and analgesic properties, is frequently used in reptile anesthesia. However, when administered alone, muscle relaxation is considered inadequate and recoveries excessively prolonged, especially when high dosages (>50 mg/kg) are used. Administration of an α-2-adrenergic agonist (e.g., dexmedetomidine) and/or a benzodiazepine (e.g., midazolam), in conjunction with ketamine, allows for reduction of ketamine dose. Additionally, these protocols have the benefit of partial reversibility, leading to more rapid recoveries and increased safety (see Tables 49.1 to 49.4). Even at lower, subanesthetic dosages (<5 mg/kg), ketamine can provide additional sedation and analgesia if combined with other anesthetic drugs.[34,35]

Tiletamine/zolazepam is a commercially available drug combination, which is composed of the dissociative anesthetic, tiletamine, and a benzodiazepine, zolazepam. Dosages of 2 to 10 mg/kg have been recommended for sedation, induction of general anesthesia, or facilitation of intubation.[36-38] The anesthetic efficacy of tiletamine/zolazepam can be unpredictable and recovery may be prolonged. In dehydrated patients, or those with underlying renal or metabolic disorders, the use of this drug combination is contraindicated.[37] Tiletamine/zolazepam is also useful in large or dangerous species (e.g., crocodilians, large monitor lizards, etc), especially when remote darting techniques are required (see Tables 49.1 to 49.4).

α-2-adrenergic agonists, such as medetomidine and dexmedetomidine, provide sedation, muscle relaxation, and analgesia in reptiles. Dose-dependent cardiovascular depression was documented in reptiles after α-2 agonist administration.[18,39–41] α-2-adrenergic agonists are commonly used in combination with ketamine, especially in chelonians, for safe, reliable, and reversible anesthesia, but can also be combined with benzodiazepines for procedural sedation.[24,25,27,42,43] Combining ketamine with medetomidine, or dexmedetomidine, allows reduction of both drug dosages, and reversibility of the α-2-adrenergic agonist with atipamezole will lead to faster and more predictable recoveries. Morphine or hydromorphone can be added to α-2 adrenergic agonist plus ketamine protocols in cases in which analgesia is needed. [23,25,26,44] If morphine is used, reversal with naloxone (0.04–0.2 mg/kg, SC) should be considered if respiratory depression persists after termination of the anesthetic procedure or recovery is delayed. In gopher tortoises anesthetized with dexmedetomidine-ketamine-morphine, administration of naloxone was not necessary, and animals recovered within ~90 minutes after administration of atipamezole.[44] Concentrated formulations of medetomidine (e.g., 20 mg/ml, Zoopharm Inc) are available and are more suitable for giant species, such as large chelonians, crocodilians, and komodo dragons (*Varanus komodoensis*).

Benzodiazepines, such as midazolam and diazepam, have sedative and muscle-relaxant properties. Midazolam is water soluble; can be administered SC, IM, and IV; and is considered a more appropriate choice than diazepam, which is not recommended for IM or SC injection.[9] Midazolam, used alone, is anxiolytic and provides mild, but highly variable, sedation, which may be sufficient for minor clinical procedures.[45–47] Midazolam, combined with ketamine and/or an α-2-adrenergic agonist, reduces all drug dosages and attenuates the dose-dependent cardiovascular depressant effects and prolonged recoveries commonly observed with high dosages of ketamine. Midazolam (1 mg/kg) has also been combined with alfaxalone (15 mg/kg) for subcutaneous administration in leopard geckos, and provides improved anesthesia, instead of using alfaxalone alone at higher doses (see Table 49.2). The effects of benzodiazepines can be antagonized using flumazenil (0.05 mg/kg, SC, IM),

VetBooks.ir

which shortens recovery from sedation or anesthesia.[27,48] Concentrated formulations of midazolam (e.g., 50 mg/ml, Zoopharm Inc) are available and are more suitable for administration of midazolam in giant reptile species.

Propofol, a short-acting, nonbarbiturate anesthetic agent can be administered intravenously or intraosseously to provide short-time anesthesia, facilitating procedures such as placement of an esophagostomy tube or abscess debridement, or to induce general anesthesia and allow for endotracheal intubation and maintenance of anesthesia with an inhalational agent. Respiratory depression is more profound when propofol is administered rapidly.[37,49] Since propofol does not accumulate in tissues and is rapidly metabolized, recovery can be expected with assisted ventilation in cases of overdose. Propofol requires intravascular administration, which can be challenging. Recently, published reports have described complications secondary to accidental extravascular injection of propofol intrathecally and into the subcarapacial sinus or the coccygeal vein of chelonian species.[28,29] Complications associated with intrathecal propofol injection included fore and hind limb paralysis, coma, and spinal necrosis.[28,29] In addition, complications with propofol in sea turtles were reported, which included respiratory arrest and death several hours post anesthesia (Mader: Pers. comm.). Two different formulations are available. The original preservative-free formulation should be discarded within 6 hrs of first use, while a newer formulation, containing 2% benzyl alcohol, can be used for up to 28 days after initial use.

Alfaxalone is a short-acting steroid anesthetic, which is labeled for induction of anesthesia in dogs by intravenous administration. However, alfaxalone can be administered by either the intramuscular or subcutaneous route at higher doses. Alfaxalone is rapidly cleared and its metabolism is independent of organ function; however, pronounced temperature-dependent difference in anesthetic induction, plateau, and recovery times have been reported.[6] Similar to propofol, alfaxalone administration is associated with dose-dependent cardiovascular and respiratory depression in mammals.[50–52] Recovery from alfaxalone induced anesthesia is dose-dependent, and at high dosages, prolonged recoveries are to be expected.[27,53] The major advantage of alfaxalone over propofol is that it can be administered intramuscularly as well as subcutaneously, in addition to the intravenous route.[6,27,50,54,55] Due to the high dosages needed for nonintravenous administration in chelonians and lizards, the resulting drug volumes are usually inappropriately large due to the low concentration of the available alfaxalone formulation (10 mg/mL). Therefore the authors recommend SC injection if large volumes of alfaxalone are to be administered. The subcutaneous administration of alfaxalone in reptiles has been associated with rapid induction times. In the United States, the USDA mandates that, following initial use, any unused drug must be discarded after 6 hours and cannot be stored.

The intravenous administration of alfaxalone in green iguanas (*Iguana iguana*) (10 mg/kg) and red-eared sliders (5 mg/kg) resulted in rapid induction of light to surgical anesthesia, which allowed endotracheal intubation.[55,56] Alfaxalone can be administered by subcutaneous administration, which results in comparable onset of effects as after intramuscular injection (see Table 49.2). Since large volumes usually need to be administered, the subcutaneous route should be used. The effects of intramuscular administration of alfaxalone was investigated in red-eared sliders, Russian (Horsfield's) tortoises (*Agrionemys horsfieldii*), and green iguanas (see Tables 49.1 and 49.2).[6,54,57] Induction times ranged between 5 to 15 minutes following intramuscular alfaxalone administration.[6,54] The induction times after intramuscular administration in green iguanas were short (approximately 5–10 minutes at 24°–27°C, 75°–81°F) and recovery was smooth. The induction and duration of effect following intramuscular administration were significantly shorter at 35°C (95°F) compared with 20°C (68°F) in red-eared sliders.[6] At 20 mg/kg IM, the induction times were 19 ± 6 (20°C, 68°F) and 7 ± 5 minutes (35°C, 95°F), and the plateau phase lasted 28 ± 13 (20°C, 68°F) and 8 ± 5 (35°C, 95°F) minutes.[6] Recovery times following intramuscular administration were prolonged, in particular at room temperature, lasting approximately 60 to 90 minutes following 10 mg/kg IM and 2 hours or longer after 20 mg/kg IM at room temperature.[6,54] Increasing body temperature to 35°C (95°F) significantly shortened recovery times in red-eared sliders by >50%.[6] Green iguanas maintained at 28° to 32°C (82°–90°F) body temperature displayed a dose-dependent recovery between approximately 10 to 30 minutes after intramuscular administration of alfaxalone (10–30 mg/kg).[54]

Alfaxalone has been used in other species in combination with other drugs such as butorphanol, dexmedetomidine, and midazolam. In reptiles, the combined use of alfaxalone with medetomidine (0.1 mg/kg) was evaluated in Russian (Horsfield's) tortoises and resulted in deep anesthesia and cardiovascular depression (severe if combined with high doses of alfaxalone).[58] In leopard geckos, alfaxalone (15 mg/kg), in combination with midazolam (1 mg/kg), given by subcutaneous injection was evaluated.[27] This combination resulted in deep anesthesia with no clinically significant cardiovascular depression and allowed for use of lower alfaxalone doses, since 10 and 20 mg/kg of alfaxalone did not result in consistent chemical restraint in this species.[27] However, compared to dexmedetomidine-midazolam (0.1 + 1 mg/kg SC) the alfaxalone-midazolam protocol resulted in much longer recovery times.[27]

Inhalational agents, such as isoflurane and sevoflurane, can be used for both induction and maintenance of anesthesia. Both agents offer the advantages of relatively fast induction and recovery times, as well as limited organ toxicity, especially in patients with renal or hepatic impairment. Sevoflurane is commonly used in human and domestic animal anesthesia, has a low blood solubility, and a rapid increase in alveolar concentration can be observed during induction with this agent. The low blood solubility allows for rapid changes in anesthetic depth. Investigations of sevoflurane in various reptile species have shown variable results, with some species not achieving a surgical plane of anesthesia. Few studies have investigated comparative cardiopulmonary effects of sevoflurane versus isoflurane in reptiles. Administration of inhalational agents follows similar principles as those established for domestic animal anesthesia. Following induction of anesthesia, the trachea should be intubated with an appropriately sized endotracheal tube, which should be connected to a nonrebreathing (body weight <10 kg) or rebreathing system. Intermittent positive pressure ventilation should be performed in all reptiles. The concentration of the inhalational agent necessary to maintain a surgical plane of anesthesia depends on the health status of the patient. Minimum anesthetic concentrations (MAC) of isoflurane and sevoflurane were determined in green iguanas and are 1.8% to 2.1% and 2.1% to 4.1%, respectively.[59,60] Maintenance requirements for a surgical plane of anesthesia were reported to be 2% to 3% for isoflurane and 3.5% to 4.5% for sevoflurane.[36] Both isoflurane and sevoflurane have a dose-dependent, depressive effect on the cardiovascular system. Isoflurane was shown to significantly reduce blood pressure in green iguanas and ball pythons.[61,62] Therefore significant cardiovascular depression can occur with normal maintenance concentrations of isoflurane. No significant differences were detected between sevoflurane and isoflurane in cardiopulmonary function of green iguanas.[63] However, use of sevoflurane resulted in faster induction and recovery compared with isoflurane.[63]

Due to right-to-left cardiac shunting in some reptiles, reduced lung perfusion can occur, and therefore concentrations of inhalant anesthetic gases in the lungs do not necessarily reflect the concentrations in the blood or brain.[9] Sudden changes in shunting directions can lead to

sudden changes in inhalant anesthetic blood concentration, which can lead to significant changes in anesthetic depth, evidenced by slow induction, sudden arousal from anesthesia, inability to deepen a lightly anesthetized reptile, or prolonged recovery from anesthesia.[1] In lizards and snakes, changes in gas concentration can be used to control anesthetic depth, but in chelonians, particularly aquatic turtles, a change in gas concentration will not lead to measurable changes in anesthetic depth as a function of cardiac shunting, breath-holding ability, and ventilation-perfusion mismatch.[1]

GENERAL ANESTHESIA

Induction

Induction of anesthesia can be accomplished with injectable or inhalational agents. In patients with established, reliable vascular access, slow administration of propofol (3–10 mg/kg IV, IO) or alfaxalone (5–10 mg/kg IV) will induce rapid induction of anesthesia (see Fig. 49.3 and 49.4). Alternately, intramuscular or subcutaneous administration of various combinations of ketamine, midazolam, α-2-agents, alfaxalone, and opioids will induce a dose-dependent plane of anesthesia adequate for endotracheal intubation and maintenance with an inhalational agent, if required. Mask or chamber induction with an inhalational agent can be used in snakes and lizards, and for handler safety reasons these are particularly useful in venomous species (Fig. 49.5). Mask or chamber inductions require high concentrations of gas anesthetic, which is associated with environmental contamination and can contribute to unpredictable and prolonged induction times. In monitor lizards, induction times of >10 minutes were noted following isoflurane and sevoflurane delivery by mask.[64] In reptile species that are able to breath-hold for extended periods, in particular semiaquatic and aquatic turtles and crocodilians, induction times will be prolonged and/or induction with inhalant agents may be ineffective.

Endotracheal intubation is relatively easy to perform in most snakes and lizards. In these species, the glottis is located rostrally in the oral cavity, and the trachea can be intubated with an appropriate-sized endotracheal tube (Fig. 49.6). Most chelonians have a fleshy tongue, and the glottis is located at the base of the tongue, thus making visualization difficult. Good muscle relaxation is necessary to open the mouth wide enough to visualize the glottis and intubate the trachea. Care should be taken not to intubate the left or right primary bronchus since the tracheal bifurcation is cranial in some chelonians. In crocodilians, the glottis is located behind the epiglottal (gular) flap, which has to be reflected ventrally to visualize the glottis and allow for intubation (Fig. 49.7). The reptile glottis is only opened during active respiration and is therefore likely to remain closed for prolonged periods following induction. A stylet may help in advancing the endotracheal tube through the closed glottis.

Securing the endotracheal tube is critical (Fig. 49.8) to avoid accidental extubation during anesthesia and excessive movement, which could lead to irritation of the tracheal mucosa. In some species, a mouth gag should be used to protect the endotracheal tube (see Fig. 49.1A) and

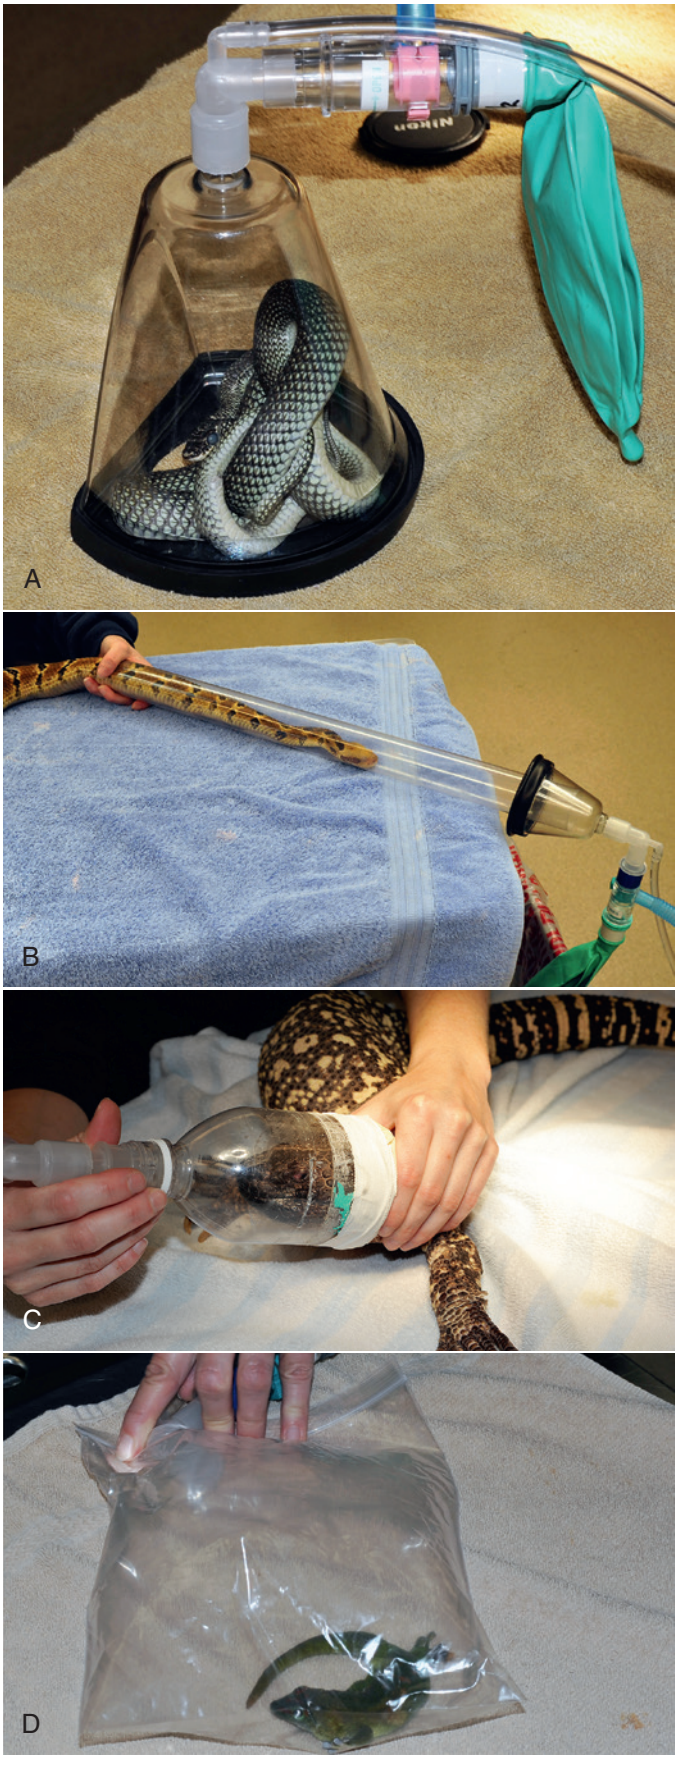

FIG 49.5 Anesthetic chamber and mask induction in reptiles. (A) Anesthetic induction of a snake using a canine face mask. facilitate placement of monitoring devices (e.g., pulse oximeter probe). The trachea in chelonians has complete cartilaginous rings, while in lizards and snakes the cartilaginous rings are incomplete. Uncuffed endotracheal tubes are recommended in chelonians and in small lizards and snakes. In larger squamates, cuffed tubes can be used. It is important to use the widest endotracheal tube possible, especially in smaller reptiles, to reduce airway resistance ($Resistance \propto 1/r^4$) and anesthetic gas leakage.

Maintenance

During maintenance of anesthesia the patient should be monitored regularly for depth of anesthesia, cardiopulmonary performance, and evidence of pain. If indicated, the anesthetic level should be adjusted and additional analgesic therapy may be warranted. Similar to domestic animals, cardiopulmonary depression is dose dependent in reptiles, and a decrease in heart rate and arterial blood pressure will be observed, although blood pressure monitoring is difficult and frequently impractical.

All reptiles require intermittent positive pressure ventilation (IPPV) at a surgical plane of anesthesia to maintain $EtCO_2$ between 10 and 25 mm Hg. Overventilation (decreased $EtCO_2$) causes respiratory alkalosis and delays return to spontaneous ventilation during recovery. Ventilation can be performed manually or more accurately with a mechanical ventilator (Fig. 49.9). Any anesthetized reptile that is breathing spontaneously is light. Pressure-driven ventilators are commercially available (e.g., SAV04 Vetronic Services, Ltd, UK, http://www.vetronic.co.uk/products/article/sav04; Small Animal Ventilator, Vetronics, BASi US, https://www.basinc.com/products/vetronics/products/smvent), which will accurately ventilate even small reptilian patients. To avoid overinflation of the lungs and air sacs, inspiratory pressure should not exceed 12 cm H_2O. While anecdotally, it has been recommended to ventilate anesthetized reptiles at 4 to 6 breaths per minute, the rate of IPPV needs to be adjusted to each individual patient based on the preanesthetic examination and $EtCO_2$ values. For example, in anesthetized neotropical rattlesnakes (*Crotalus durissus)* five breaths per minute lead to respiratory alkalosis and was considered excessive, while 0.67 breaths per minute led to mild hypercapnia and mild respiratory acidosis. Therefore a

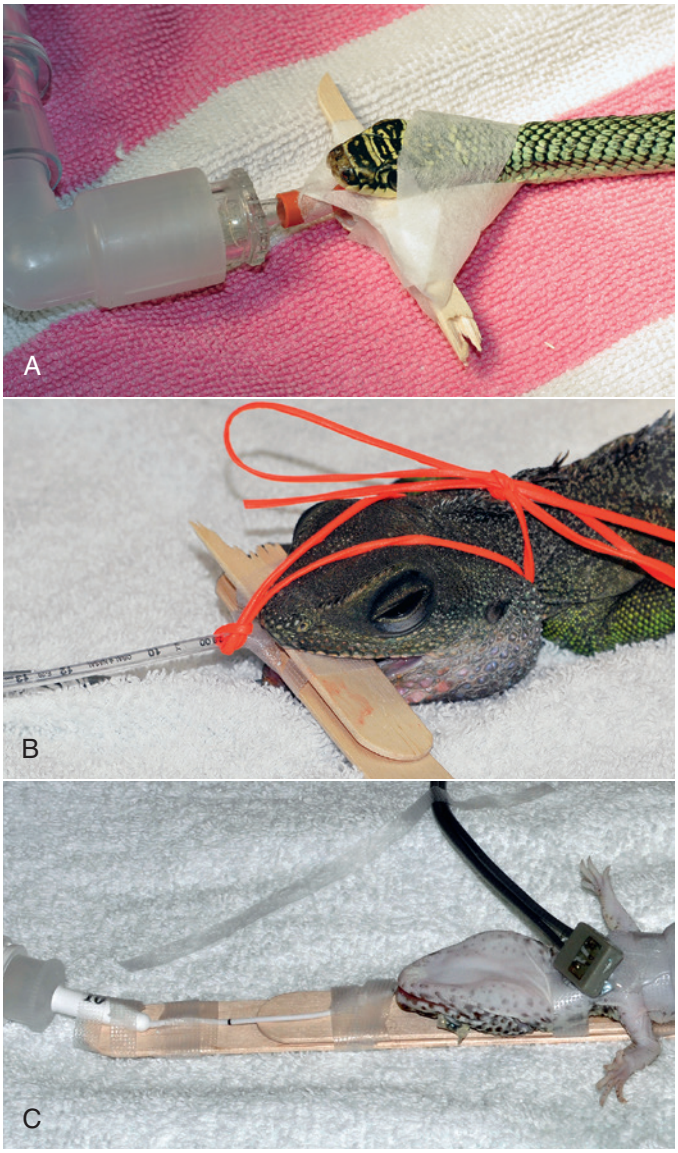

FIG 49.8 Securing endotracheal tubes in small reptile patients. (A) Tongue depressors are used (as with this colubrid snake) to protect the tube and to allow for application of tape, instead of placing it directly around the tube. (B) Tie-in technique for securing an endotracheal tube in a Chinese water dragon (*Physignathus cocincinus*). (C) In small lizards (such as this leopard gecko, *Eublepharis macularius*) and snakes a tongue depressor can be used to secure the patient and the endotracheal tube to avoid accidental extubation during anesthesia.

FIG 49.9 (A) The small animal ventilator (SAV4) offers accurate, consistent, uncomplicated pressure-cycled ventilation for reptiles from 35 g to 80 kg. The unit features main power and battery back-up for mobility; inspiratory time, respiratory rate, and pressure displays; overpressure and apnea alarms; and respiratory rate ranging from 1 to 120 breaths per minute with expiratory phase ranges of 0.1 to 60 seconds. (B) Large, anesthetized *Cyclura* lizard intubated (1) and connected to the SAV4 ventilator (2) with mainstream capnography and pulse oximetry unit (3); Doppler monitoring (4) with the probe placed close to the heart (5); mobile, passive scavenging of anesthetic gases using activated carbon (6); and intravenous cephalic catheterization (7) with connection to a syringe pump (8) for fluid support throughout the anesthetic event. (A, Courtesy of Keith Simpson, Vetronics Services Ltd; B, courtesy of Stephen J. Divers.)

respiratory rate of one to two breaths per minute at a tidal volume of 30 ml/kg was recommended for this species.[65]

Intraoperative fluid therapy : Following standard practice in human and domestic animal anesthesia, intraoperative fluid therapy is recommended and anecdotally infusion rates of 3 mL/kg/hr are often suggested for reptiles, which are lower than those used for mammals (5–10 mL/kg/hr). Rates of balanced isotonic crystalloids are most frequently used (e.g., lactated ringer's solution), although specific solutions, colloids, and even blood products may be used with justifications similar to that of human and domesticated animal fluid therapy.

Depth of anesthesia: Depth of anesthesia should be evaluated regularly, and adjustments should be made if the patient is determined to be too deep or too light (Table 49.6). Response to a painful stimulus, such as movement and increase in heart rate, should be followed by an increase in the concentration of the inhalant anesthetic agent, or additional systemic or regional analgesic should be administered.

Body temperature: Response to anesthetic and analgesic agents is dictated by body temperature, and the reptile should be maintained within the preferred optimum temperature range prior, during, and after anesthesia.[6] A hypothermic reptile will have compromised metabolic function, and recovery from the anesthetic event will be delayed. It was demonstrated in several studies that body temperature has a profound effect on respiration, blood gases, and acid-base status in reptiles.[66,67] In freshwater turtles (*Chrysemys picta bellii*), oxygen uptake increased disproportionately when compared with pulmonary ventilation, with increasing temperatures.[66] Body temperature should be measured and recorded with an esophageal or cloacal temperature probe, not a mammalian rectal thermometer. Every effort should be made to maintain the patient in its optimal temperature range during anesthesia and the recovery period. Heat lamps, circulating water blankets, warm air blankets, and other equipment is available to accomplish this.

MONITORING TECHNIQUES

Accurate monitoring of anesthetic parameters is essential to safely and effectively anesthetize the reptilian patient. An accurate anesthesia record,

VetBooks.ir

TABLE 49.6 Assessing Anesthetic Depth

Stage of Anesthesia	Behavior	Respiration	Cardiovascular Function	Response to Painful Stimuli	Depth	Muscle Tone	Reflex Response
Stage I	Disorientated	Breath hold, normal, or rarely hyperventilating	HR unchanged, may be hypertensive	Struggle	Not anesthetized	Good	All present
Stage II	Excitement, struggling	Irregular, breath hold, or hyperventilating	HR may increase, often hypertensive	Struggle	Not anesthetized	Good	All present, may be exaggerated
Stage III plane 1 (light)	Immobile	Normal, regular, or decreased	HR normal, normotensive	May respond with movement	Light	Good	Righting absent Palpebral present may often be slowed Limb and tongue withdrawal present Cloacal reflex present Corneal reflex present
Stage III plane 2 (surgical)	Immobile	Apnea	HR decreased, strong pulse, increasing hypotension	HR and blood pressure may increase	Moderate (surgical)	Relaxed	Righting absent Palpebral absent Limb and tongue withdrawal absent Cloacal reflex may be present but greatly reduced Corneal reflex present
Stage III plane 3 (deep)	Immobile	Apnea	HR decreased, pulse strength reduced, significant hypotension	None	Deep	Greatly reduced	Righting absent Palpebral absent Limb and tongue withdrawal absent Cloacal reflex absent Corneal reflex reduced or absent
Stage III plane 4	Immobile	Apnea	HR decreased to basal level, pulse weak, severe hypotension	None	Overdose	Flaccid	No reflex activity Pupils often dilated
Stage IV	Immobile	Apnea	Cardiovascular collapse to slow intrinsic, basal HR, peripheral pulse often not appreciated	None	Dying	Flaccid	No reflex activity Pupils widely dilated

HR, Heart rate.

including preanesthetic findings, anesthetic techniques and drugs, cardiopulmonary parameters, and recovery data, should be completed. Application and interpretation of many monitoring techniques in reptiles is in its infancy, and some devices and techniques may only be of limited value.[68] Monitoring of cardiopulmonary performance in the anesthetized reptilian patient presents challenges, and further work is needed to establish reference data for common reptile species. One should be familiar with the applications and limitations of various monitoring devices developed for human and veterinary anesthesia. Anesthesia-monitoring techniques such as pulse oximetry, arterial blood gas analysis, and capnography are commonly used in human and veterinary anesthesia, but not all have been validated for use in reptiles. In addition, reference values for common reptile species and common anesthetic protocols are scant. Therefore knowledge of the anatomy, physiology, and pathophysiology is essential. Also, the pharmacology of sedative and anesthetic agents being used, as well as their effects on cardiopulmonary performance and organ function, must be known. To accurately interpret cardiopulmonary performance, there is a need for normal values in conscious reptiles; however, few studies have investigated normal cardiopulmonary parameters in conscious, nonanesthetized reptiles. Most published reports have collected data on cardiopulmonary function from anesthetized animals. Comparison of data requires consideration of the different effects of the anesthetic agent used. A study in green iguanas determined selected cardiopulmonary values in conscious animals including respiratory rate, heart rate, and direct arterial blood pressures, as well as arterial and venous blood gas parameters.[69] In addition, the effects of 100% oxygen inspiration were measured. Comparison was also made between arterial blood gas analysis and pulse oximetry readings in conscious green iguanas. It was shown that oxygen saturation, as measured by pulse oximetry, underestimated saturation calculated by arterial blood gas analysis.[69]

Determination of the degree of sedation and depth of anesthesia is commonly performed by assessment of the presence or absence of reflexes such as head or limb withdrawal, righting reflex, palpebral and corneal reflexes, and toe/tail pinch reflex, as well as cloacal tone. However, significant anatomic differences exist between snakes, chelonians, and

VetBooks.ir

lizards. The corneal and palpebral reflex is present and useful in many reptiles but cannot be assessed in snakes and most geckos (one exception being leopard geckos), due to lack of eyelids and presence of spectacles. The righting reflex should be absent in snakes and lizards during a surgical plane of anesthesia but is not as useful in turtles and tortoises.[36] Assessment of head withdrawal and neck tone may provide useful information in turtles and tortoises. Snakes tend to lose muscle tone from head to tail during induction and regain muscle tone from tail to head during recovery.[37] In general, a surgical plane of anesthesia, including effective analgesia, is determined when there is no response to a painful stimulus, such as a skin incision and, consequently, no changes in cardiopulmonary parameters such as tachycardia, hypertension, or increase in respiratory rate. A classification system to determine anesthetic depth is provided in Table 49.6.

Cardiovascular Monitoring

Monitoring of cardiovascular performance is challenging in reptiles. Heart rate can be influenced by a variety of factors, including environmental temperature, metabolism, and presence of noxious stimulation.[70] Many parameters commonly recorded in mammalian species are either impractical to determine in reptiles, or reference values have not been established. Assessment of mucous membrane color and capillary perfusion time are inaccurate in reptiles, and measurement of cardiac output has limited clinical applications. The most accurate assessment of cardiac output in reptiles is determination of heart rate. An esophageal stethoscope or Doppler can be used in most reptiles for direct measurement of heart rate under anesthesia. Both tachycardia and bradycardia can decrease cardiac output and reduce flow of blood to peripheral tissues. A baroreceptor reflex has been demonstrated in conscious green iguanas.[69]

Ultrasonic Doppler flow devices are the most useful and reliable monitoring devices in reptile anesthesia and allow for noninvasive recording of heart rate and rhythm in both conscious and anesthetized animals. Values derived from the conscious patient prior to induction of anesthesia should be used as reference values during anesthesia. Flat and pencil probes are available (Figs. 49.8C and 49.10). The ultrasonic Doppler probe can be placed over the heart in snakes and lizards or over the carotid arteries in lizards and chelonians. In lizards, the heart is located cranially between the forelimbs (except in monitor lizards, Fig. 49.10B), and the probe can either be positioned ventrally on the cranial coelom or in the axillary region. In chelonians, the placement of a Doppler probe for heart rate measurement can be more challenging. Placing a flat or pencil probe on either side of the neck, at the coelomic inlet, can be effective in detecting the pulse rate via the carotid artery. If a Doppler device is not available, echocardiography, using an appropriate-sized probe/clip/needle, can serve as an effective way to monitor cardiac function and measure heart rate.

Electrocardiography (ECG) can be performed to monitor cardiac function (Fig. 49.11).[22] Unfortunately, limited data are published to establish reference parameters in commonly maintained species. The reptilian ECG is similar to a mammalian ECG with a P, QRS, and T wave, and, in some species, an SV wave is present before the P wave. Low electrical amplitudes may make interpretation of a reptilian ECG challenging. In snakes, electrodes should be attached two heart lengths cranial and caudal to the heart. In larger species, an esophageal ECG can be placed. Factors influencing heart rate, such as environmental temperature and painful stimuli, should be considered when interpreting a reptilian ECG. However, persistent baseline ECG and heart rate can also be detected in reptiles following CNS death, and therefore ECG

FIG 49.10 Placement of an ultrasonic Doppler flow device at the level of the heart in (A) an anesthetized green iguana (*Iguana iguana*) and (B) a black tree monitor (*Varanus beccarii*). Note that in monitor lizards the heart is located more caudad compared with other lizards, and therefore the Doppler probes are placed at different levels in these two animals. (C) Placement of an ultrasonic Doppler pencil probe in the coelomic inlet in a common map turtle (*Graptemys* spp.). (D) Placement of an ultrasonic Doppler flat probe ventrally over the heart in an anesthetized snake.

alone to monitor cardiac activity of anesthetized reptiles is of limited value, especially at a low basal rate.

Indirect blood pressure measurements are possible in many species of reptiles but have poor correlation with values obtained via direct blood pressure measurements.[61,71] Arterial blood pressure is a function of heart rate, blood volume, stroke volume, and arterial compliance. All anesthetic agents will compromise cardiovascular homeostasis to varying degrees. Direct arterial blood pressure measurements were reported in both conscious and anesthetized reptiles. Baseline arterial pressures were established in conscious green iguanas and gray rat snakes.[69,71,72] Green iguanas had lower baseline arterial blood pressures (MAP: 62 ± 12 mm Hg to 79 ± 13 mm Hg) than those reported for mammals. Direct arterial blood pressure measurements require surgical exposure of an artery, is time consuming, and therefore is largely impractical for clinical practice; however, these techniques are certainly of value for research purposes. Even though accurate pressure monitoring is not possible clinically, it is important to appreciate that reptiles maintained using inhalants are likely hypotensive. For example, compared to conscious mean arterial pressures of 79 ± 13 mmHg, iguanas anesthetized using 1.5% and 3% isoflurane were profoundly hypotensive at 47 ± 2 and 32 ± 10 mmHg, respectively.[71] Increasing blood pressure with dopamine and dopbutamine has been shown to be ineffective, but norepinephrine at 0.4 µg/mL/min resulted in normotension in anesthetized iguanas; however, clinically a more cautious rate of 0.1 µg/mL/min is used routinely (Divers, unpublished data).

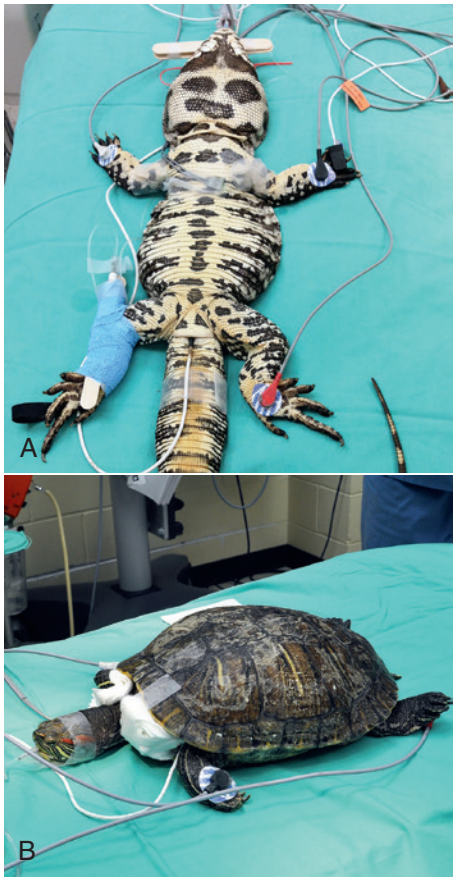

FIG 49.11 Electrocardiographic (ECG) monitoring in reptiles. (A) Argentine black and white tegu (*Salvator merianae*). Note the placement of the Doppler probe over the heart and pulse oximetry probe in the cloaca. (B) Red-eared slider (*Trachemys scripta elegans*).

Respiratory Performance

Determination of respiratory rate and effort prior to induction of anesthesia will provide valuable information with respect to the respiratory status of the patient, including evidence of underlying respiratory disease processes, and will provide baseline values for the rate of ventilation during anesthesia. Respiratory movements of the body wall in snakes and lizards can be easily visualized and measured in breaths/min if transparent drapes are used for surgery. In chelonians, movement of the skin overlying the prefemoral fossae, and at each side of the coelomic inlet, can be observed and measured during the respiratory cycle. The mean baseline respiratory rate of healthy green iguanas is 28 ± 6 breaths/min.[69] Supportive measures, such as administration of antimicrobial agents for confirmed infections, tracheal suctioning, and administration of oxygen should be initiated prior to anesthesia, if indicated. Once the reptile is anesthetized, monitoring of respiratory performance is limited to pulse oximetry, venous blood gas analysis, and capnography. Unfortunately, most devices have not been validated for reptiles but can provide valuable information on respiratory trends and metabolic status of the patient. Pulse oximetry was validated in green iguanas.[69] Inherent respiratory rate and effort cannot be determined because all reptiles require assisted ventilation during surgical anesthesia, either by means of manual ventilation or a mechanical ventilator. While the accuracy of these monitoring modalities have yet to be validated in reptiles, investigations were performed in some reptile species, mainly green iguanas, to determine usefulness and accuracy.[69]

Pulse oximetry is a noninvasive technique routinely used in mammalian patients to calculate relative arterial oxygen hemoglobin saturation (SpO_2). Accuracy of pulse oximetry is influenced by poor tissue perfusion, as well as pigmentation of the skin. In reptile anesthesia, use of pulse oximetry is associated with several concerns and potential erroneous readings (see Fig. 49.10A and 49.11A). Skin thickness and pigmentation often reduces signal strength, and the reported values should only be recorded if there is a good pulse wave. Pulse oximeters are calibrated based on the human oxygen hemoglobin dissociation curve, and SpO_2 values are calculated. High levels of methemoglobin have been reported for reptiles and will affect pulse oximeter readings. A further concern is the pronounced difference in respiratory physiology and function among reptile species. Therefore reference values derived from one taxa may be of limited value in other taxa. Reflectance pulse oximeter probes are most useful and can be placed into the oral cavity (Fig. 49.12), the

FIG 49.12 Anesthetized green iguana (*Iguana iguana*) with placement of an esophageal pulse oximeter probe connected to a pediatric mainstream capnography device.

esophagus at the level of the carotid artery, or in the evacuated cloaca (see Fig. 49.11A). In sevoflurane-or isoflurane-anesthetized green iguanas, a comparison of arterial blood oxygen saturation, as determined by pulse oximetry (SpO_2) versus arterial blood gas analysis (SaO_2), showed no significant differences between the two monitoring modalities over time. Although not significant, SpO_2 values were lower than SaO_2 values at all time points in isoflurane-anesthetized iguanas.[63] A study in conscious green iguanas showed that oxygen saturation, calculated by pulse oximetry (86% ± 6%), was lower than the SaO_2 (92% ± 5%) measured by arterial blood gas analysis.[69] Baseline SaO_2 values in conscious iguanas were reported to be >90%.[69]

Blood gas analysis: It has been well established in human and veterinary anesthesia that arterial blood gas analysis allows for accurate assessment of pulmonary function, including ventilation, oxygenation, and acid-base status. Venous blood gases will give an assessment of metabolic status. Venous blood gases are affected by local tissue metabolism and low blood flow, but in humans venous blood gas analysis can predict arterial blood gas values for pH, PCO_2, and bicarbonate concentrations. Baseline venous blood gas values in green iguanas are similar to those reported in humans and domestic animals.[69] In reptiles, collection and interpretation of arterial blood gas parameters is challenging due to poor accessibility and lack of normal reference values, as well as physiological features such as intracardiac shunting, the ability to tolerate varying degrees of hypoxia, and the capability to convert to anaerobic metabolism. Intrapulmonary shunts will bypass gas exchange in the lungs. In reptiles, many factors will influence arterial blood gas composition, including taxonomic differences (e.g., aquatic vs. terrestrial species), inspired concentration of oxygen, and temperature. At present, application of mammalian arterial blood gas values to reptiles is considered inappropriate because reptiles are more tolerant to changes in arterial partial pressures of oxygen and carbon dioxide. As mentioned above, intracardiac shunting and ventilation/perfusion mismatching in reptiles may also result in inaccurate interpretation of arterial blood gases. In green iguanas premedicated with butorphanol and maintained with sevoflurane or isoflurane, arterial blood oxygen saturation, as determined by arterial blood gas analysis, was >90% throughout the anesthetic event.[63] In the same study, significant decreases in pH values were observed over time. A study in conscious green iguanas demonstrated that $PaCO_2$ values (32 ± 7 mm Hg) were similar to those reported in mammalian species.[69] Arterial blood gas values were similar to mammalian species; however, baseline SaO_2 values were lower than in a similar study in gray rat snakes.[72] Circadian changes in arterial PO_2 and SaO_2 were reported in green iguanas, with values being significantly lower in the morning than in the afternoon. In most studies, blood gas values are determined at 37°C (98.6°F) and corrected for the body temperature of the reptile.[69]

Capnography is used in mammals as a noninvasive tool to determine concentrations of CO_2 in expired air and assess ventilation. In reptiles, capnography is associated with several limitations, which may provide erroneous results. End-tidal CO_2 concentrations will provide an estimate of arterial CO_2 tension; however, this technique needs to be validated for reptiles.[63] Right-to-left intracardiac shunts can make $EtCO_2$ difficult to interpret in reptiles. Another concern in small reptiles relates to the use of side-stream units with high sampling rates, which are likely to produce inaccurate, diluted results. Portable side-stream capnography units are available with low sampling rates adequate for even small patients, while pediatric mainstream units avoid the complication of side-stream dilution altogether (see Fig. 49.12). In green iguanas maintained with either sevoflurane or isoflurane, $EtCO_2$ decreased over time, but no differences were observed between groups.[63] $EtCO_2$ concentrations, in both isoflurane and sevoflurane anesthetized green iguanas, reflected $PaCO_2$ values at the beginning (10 minutes) of the anesthetic event. However, over time $PaCO_2$ values were significantly higher than $EtCO_2$ concentrations. Therefore $EtCO_2$ appears to underestimate $PaCO_2$ but is a useful tool to monitor trends in arterial CO_2 tension.

Further studies are indicated to validate the aforementioned monitoring modalities in other species. In the meantime, it is recommended that values obtained with the use of pulse oximetry, arterial, or venous blood gas analysis and capnography should be interpreted with caution. However, all the above-mentioned techniques will provide information on trends in respiratory and metabolic performance so that corrective and supportive measures can be initiated.

ANESTHETIC EMERGENCIES

The principles and techniques of managing anesthetic emergencies, established in domestic mammalian veterinary medicine, also apply to reptiles. While topics such as effective fluid therapy, cardiopulmonary support techniques, and administration and selection of emergency drugs have been reported for reptiles, currently there is still a need for further investigation into effective drugs and dosages. The preoperative calculation and printing of an emergency drug sheet helps improve the speed and accuracy of emergency treatments. The need for effective cardiopulmonary resuscitation may arise in any anesthetized reptilian patient, especially in critically ill animals undergoing diagnostic or surgical procedures. The same concepts established for domestic animals apply, and the reptile should be assessed for respiratory status and cardiovascular status. The principles of airway (A), breathing (B), and circulation (C) apply. An airway should be (re)established immediately, and respiratory support should be provided, either by manual ventilation or a mechanical ventilator. Devices to monitor cardiac and circulatory function should be utilized, including ECG and Doppler flow device, and vascular access should be (re)established. If venous access is not possible, an intraosseous catheter can be placed to administer emergency drugs and fluids, while intratracheal administration can be used if no IV/IO access is possible. Unfortunately, little information is available on effective dosages of emergency drugs commonly used in mammalian species. Atropine is indicated during episodes of severe bradycardia and should be administered intravenously or intraosseously. Doxapram is a respiratory stimulant and should also be administered via the intravenous or intraosseous route to be most effective. Doxapram administration may result in reduced CNS oxygen delivery and long-term brain damage if the patient is hypoxic; therefore the use of doxapram is not recommended for cerebral-pulmonary resuscitation. In the rare case of true cardiac arrest, epinephrine is the drug of choice and can be administered either intravenously, intraosseously, or diluted with sterile saline via the endotracheal tube. Supportive measures such as effective fluid therapy and provision of heat and oxygen should accompany resuscitation efforts.

RECOVERY

Following cessation of the procedure, inhalant anesthesia should be discontinued and reversal drugs administered (taking care to provide alternative analgesia if using naloxone). Room air administered with an Ambubag (Fig. 49.13), instead of 100% oxygen, has, historically, been recommended for ventilation of reptiles during recovery. It was suggested that high oxygen concentrations in the lungs delay return to spontaneous respiration.[36] However, recent studies could not demonstrate any statistical or clinical significant difference in recovery times in monitor lizards or bearded dragons ventilated with 100% oxygen, compared with animals ventilated with room air during recovery from gas anesthesia.[64,73] As is standard protocol for domestic animals, fluid

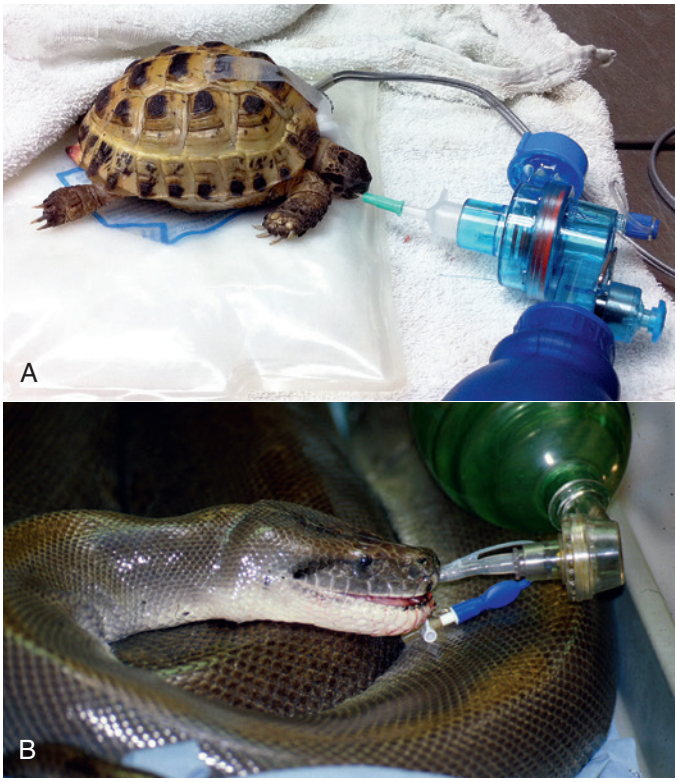

FIG 49.13 Use of an Ambubag during anesthetic recovery in reptiles. (A) Russian tortoise (*Agrionemys horsfieldii*) intubated with an intravenous catheter. (B) Burmese python *(Python bivittatus)* intubated with a cuffed endotracheal tube.

therapy and pain management should be continued during the recovery period, and additional analgesia should be provided as necessary.

Prolonged anesthetic recoveries are common in reptiles, especially if high dosages of nonreversible injectable drugs are administered (e.g., tiletamine/zolazepam). Isoflurane anesthesia in chelonians is also frequently associated with slow recoveries, which is suspected to be due to hypotension, right-to-left shunting, and reduced lung and tissue perfusion.[10,74] Administration of epinephrine (syn. adrenalin, 0.1 mg/kg IM) in common snapping turtles *(Chelydra serpentina)* significantly reduced time to return of spontaneous breathing and complete recovery following isoflurane anesthesia.[74] It was demonstrated that an increase in adrenergic tone of the pulmonary vasculature leads to shunting of blood away from the pulmonary circulation during episodes of apnea in turtles and that, by increasing the sympathomimetic tone of the systemic vasculature through administration of epinephrine, pulmonary shunting is reduced, leading to accelerated recovery in turtles anesthetized with isoflurane.[74,75] Stimulation of the acupuncture point GV-26 also hastens snapping turtle recovery from isoflurane, comparable to the administration of epinephrine.[74]

FIG 49.14 Postanesthetic recovery of a green iguana (*Iguana iguana*) in an incubator to ensure the patient is maintained within its preferred optimal temperature zone.

During recovery the patient should be kept in a temperature-controlled environment (Fig. 49.14). For most reptilian patients, dedicated reptile or small animal incubators are ideal since they are designed for accurate temperature maintenance. It is not recommended to exceed the species-specific POTZ, since this will result in an increased metabolic rate and oxygen demand. Reptiles recovering from general anesthesia will be in a state of respiratory compromise, and it may be difficult to meet the increased demand of oxygen by spontaneous respiration. During the recovery period, it is essential to assess respiratory status of the patient and continue assisted ventilation until the patient is breathing spontaneously, has regained reflexes, and can be extubated.

Spontaneous breathing and ambulation are reliable indicators of anesthetic recovery. Reptiles should be extubated once spontaneous breathing is observed and oropharyngeal reflexes (e.g., jaw tone, tongue movement) have returned.[36] If spontaneous breathing has not returned, IPPV should be continued. Even following extubation, monitoring should continue, as it is not unheard of for a spontaneously breathing reptile to slip back into unconscious apnea.

Analgesia

Kurt K. Sladky and Christoph Mans

Veterinary clinical medicine typically lags behind human clinical medicine by several decades. Veterinary analgesia is one such discipline. While the focus in human analgesia is on chronic and neuropathic pain, as well as the molecular mechanisms associated with pain, the focus in veterinary medicine continues to be associated with whether reptiles experience pain, the measurement of pain, analgesic drug efficacy, duration of drug action, and appropriate routes of administration. Our current understanding of reptile pain and analgesia has advanced considerably in the last 5 to 10 years; however, there is much to be learned. Many veterinary clinicians still continue to debate whether reptiles experience pain and how best to treat pain in different reptile species.

To put the issue into historical perspective, less than 4 decades ago it was routine for human physicians to forego administering analgesic drugs to human infants, even after undergoing invasive surgical procedures. Before the late 1970s, clinical and empirical research on human pain and pain management focused entirely on adults. Pain management for infants and young children was nonexistent, and surgery was typically performed with only paralytics on board. For example, one of the most common surgical procedures performed on premature babies was thoracotomy for ligation of a patent ductus arteriosus, which most surgeons and anesthesiologists believed was best accomplished using oxygen and pancuronium as the sole anesthetic regimen.[1] At the time, it was hypothesized that human infants had an immature central and peripheral nervous system, which was neither structurally nor functionally capable of receiving and processing noxious stimuli. Because infants were nonverbal, measurement of pain was considered difficult, if not impossible. The thinking was that analgesic drugs would not only be ineffective, but that they contributed to deleterious physiological side effects, which further jeopardized the recovery and, ultimately, the health of the child. During the 1980s and 1990s, clinical analgesia research focusing on human full-term and premature babies blossomed, and we now understand the following: nociceptive neural pathways are fully developed and in place in humans by 22 to 24 weeks' gestation[2]; and nonverbal human infants can respond to pain using vocalizations, facial expressions, body movements, changes in respiratory and heart rate, changes in skin color, and metabolic changes. With this in mind, is it any wonder that we are just beginning to understand nonhuman mammalian pain and analgesia? The acceptance of nonverbal human infants being able to perceive and express pain was a breakthrough and a prelude to a new focus on veterinary analgesia.

Many veterinary clinicians continue to argue that the administration of analgesics is risky to the patient and may mask behavioral signs of pain, which are considered evolutionarily adaptive for survival. This remains particularly true when nonmammalian patients are considered. This issue was expressed in a survey of members of the Association of Reptile and Amphibian Veterinarians.[3] Most respondents (98%) believed that reptiles were capable of experiencing pain, but relatively few clinicians administered analgesics to reptiles under conditions in which they would administer analgesics to mammals. The implication from the survey data collected was that there were too many unknowns; recognition of pain was difficult, there was concern about detrimental side effects from analgesic administration, dosages and duration of effect were anecdotal, no pharmacokinetic data were available, and, at the time of the survey, published efficacy data were uncommon. Since that survey, we now recognize that, at some level, reptiles experience pain, and while there is interest in treating pain in reptile patients, we remain unsure if the chosen drugs, dosages, or duration of administration are effective or whether the chosen analgesic will have deleterious consequences. Added to this, the diversity of the class *Reptilia* makes it difficult to extrapolate analgesic efficacy from one species to the next. Regardless, veterinarians have an ethical obligation to treat painful conditions in all animals. Effective pain management reduces stress-induced disruption to homeostatic mechanisms and can decrease morbidity and mortality associated with trauma or surgery. Therefore the primary objective of this chapter is to describe and highlight the most current information with respect to pain and analgesia in reptiles.

REPTILE NOCICEPTION OR PAIN?

Do reptiles feel pain? Can we recognize pain in reptiles? Is the perception of pain by a reptile equivalent to that of a mammal? Does it make anatomic or physiological sense that the ability to perceive and respond to an aversive stimulus is evolutionarily limited to mammals? We will never be able to objectively answer these questions because reptiles simply cannot tell us. However, like nonverbal human infants or nonhuman mammals, should the inability to communicate dictate whether pain is being perceived or whether an analgesic drug should be administered? We would argue, emphatically, NO. By anthropocentric definition, the word "pain" implies higher level cortical processing of information, and therefore nociception and antinociception are used when referring to pain and analgesia in most nonmammalian species. This stems from the controversy concerning whether or not nonmammalian species have the appropriate central and peripheral nervous system structures and pathways, capable of "receiving and processing" noxious stimuli and responding appropriately. In other words, can nonmammals "experience" pain, or are they merely capable of demonstrating a "reflexive" response to a noxious stimulus, that is, nociception? Based on published neuroanatomic, neurophysiologic, and behavioral data, there is plausible evidence to suggest that, structurally and functionally, reptiles have the capacity to experience pain. Therefore as clinicians, it is our contention that, because of limited understanding of pain and analgesia in reptiles, we should err on the side of reptile patient well-being and assume that conditions considered painful in humans and other mammals are painful across all other vertebrate species, including reptiles.

Neuroanatomic and Neurophysiological Evidence

Nociceptive Pathways. It is adaptive for all animals to avoid aversive stimuli in the environment as an ultimate mechanism for survival, and therefore all vertebrates have specialized sensory receptors, nociceptors, which are capable of detecting noxious stimuli (e.g., thermal, mechanical, chemical receptors) and afferent pathways relaying this information to the central nervous system. Efferent pathways exist to initiate a response, typically a movement away from the noxious stimulus. Therefore for any vertebrate organism to "perceive" a painful stimulus, there must be the following: a peripheral sensory receptor (e.g., nociceptor), a sensory pathway to the spinal cord, initial processing of the painful stimulus within the spinal cord dorsal horn, ascending pathways to the brain, processing of the painful stimulus by the brain, and descending pathways, which exert control over the withdrawal, escape, or defensive or immobile responses. Like mammals, reptiles have all of the anatomic structures considered critical for the recognition of pain: peripheral nociceptors, appropriate central nervous system structures and pathways, opioid receptors and endogenous opioids, reduction of nociceptive response with analgesics (although data are sparse), pain avoidance learning, and suspension of normal behavior with pain.[4–6] Recent research in fish, amphibians, reptiles, and birds has demonstrated that the transmission of peripheral sensory signals, via the spinal cord, to midbrain and forebrain regions are homologous to mammalian cortical and limbic structures.[7–10] Thus the physiological and anatomic requirements for pain and analgesia appear to be remarkably similar among all vertebrate species.

Nociceptors. Although peripheral nociceptors have not been identified, specifically, in reptiles, nociceptors are highly conserved across phyla, from invertebrates to fish, amphibians, birds, and mammals.[9,11] Nociceptors have been identified in aquatic and terrestrial invertebrates, teleost fish, amphibians, and birds.[9,10] The only reason nociceptors have not been specifically identified in reptiles is, simply, because nobody has looked.

Functionally, all nociceptors do not respond to the same stimuli. Some may be specifically mechanoreceptors, chemical receptors, or thermoreceptors, and some nociceptors may be multimodal and respond to a variety of different noxious stimuli. Unfortunately, the Reptilia are among the least studied taxa with respect to presence of nociceptors, nociceptive pathways, and central nervous system involvement. In pit vipers, touch, thermosensitive, and thermomechanosensitive nociceptive neurons were identified in the trigeminal ganglia.[12] Mechanonociceptors were identified in the cutaneous plantar nerve of the alligator, *Alligator mississippiensis*, and some of these mechanoreceptors also responded to a noxious thermal stimulus (>40°C) as well.[13]

Ascending (Afferent), Cerebral Cortical, and Descending (Efferent) Pathways. We know from the mammalian literature that noxious sensory information is initially detected by cutaneous afferents, the cell bodies of which are in the dorsal root ganglia of the spinal cord, and can be separated into two main groups according to axon caliber and myelination: large-diameter, myelinated A-fibers and small-diameter, unmyelinated C-fibers.[9] As with mammals, fish, amphibians, and reptiles have myelinated and unmyelinated afferent fibers running together in sensory nerves: large, myelinated A fibers (Aβ); small, myelinated A fibers (Aδ); and small, unmyelinated C fibers (C).[10,14] In amphibians, small, slowly conducting fibers (Aβ and C) transmitted the majority of all impulses induced by noxious heat, pinching, pin pricks, and the application of dilute acetic acid to the skin.[14] There are limited published data for reptiles. In pit vipers, Aβ-fibers were shown to respond to nonnoxious mechanical stimuli and to have larger somata, whereas Aδ-fibers responding to noxious mechanical stimulation have smaller somata.[12]

Sensory information detected by nociceptors, and carried by the cutaneous afferents, is transmitted to the dorsal horn of the spinal cord and continues to the brain to activate systems responsible for producing the sensation of pain and the motivational-affective responses that accompany the experience of pain. In mammals, substance P, a peptide that is present in small primary afferent nerves and in the dorsal and ventral horns of the spinal cord, is expressed in direct association with painful stimuli. Substance P is highly conserved in mammalian and nonmammalian species, including invertebrates, fish, amphibians, reptiles, and birds. Specifically, in reptiles, substance P is present in the nervous system of several turtle species.[15,16]

Transmission of sensory information moves from spinal cord to brain. In mammals, pain-related activity detected by the thalamus spreads to the insular cortex (believed to process the feelings that distinguish pain from itch, for example) and by the anterior cingulate cortex (believed to control the motivational element of pain). The transmission of nociceptive information from peripheral to central nervous system is likely the function of several different ascending pathways originating from neurons located within the spinal cord gray matter. The axons of these neurons travel within the spinal cord white matter, and they terminate in higher centers, including several parts of the thalamus and the brain stem reticular formation.[17] In mammals, the ascending tracts in the anterolateral quadrant of the spinal cord that seem most likely to mediate pain are the spinothalamic, spinoreticular, and spinomesencephalic tracts.[18] Neurons belonging to these pathways project chiefly contralaterally, and recordings in mammalian experiments have demonstrated the presence of nociceptive neurons among the cells of origin of all of these pathways.[18] It was hypothesized that the sensory aspects of pain are mediated primarily by the spinothalamic tract and that the motivational-affective aspects result from activity in all three of these pathways. In reptiles, while the same basic ascending sensory pathways for the visual, auditory, and somatosensory systems are present, they involve fewer cell groups or subdivisions of cell groups in the thalamus and pallium compared with homologous pathways in birds and mammals.[19–23]

The telencephalon of reptiles, birds, and mammals consists of two major subdivisions: the pallium and the subpallium. The subpallium, also called the basal ganglia, is further divided into two main subdivisions: the striatum and pallidum. The striatum and pallidum are also thought to contribute to the septum and subpallial amygdala (central and medial nuclei). The subpallial components are relatively con-served in its organization among amniotes.[24,25] The neocortex of mammals, as a derivative of the dorsal pallium, is homologous as a field only to the hyperpallium of birds and the dorsal cortex of lizards/turtles. The dorsal pallium is present in all amniotes and shares a number of similar cell types and connections across phyla.[26] The organization of the reptile pallium is not yet as well-defined, but it consists of the dorsal cortex and the dorsal ventricular ridge (DVR), as well as olfactory, hippocampal, and pallial amygdala regions. The reptile anterior dorsal ventricular ridge (ADVR) is a large intraventricular protrusion in the reptilian forebrain, which receives information from many different sensory modalities, and, in turn, projects massively into the striatum. The ADVR possesses functional similarities to the mammalian isocortex and may perform complex sensory integrations. The ADVR in lizards is composed of three longitudinal zones, which receive visual, somatosensory, and acoustic info. These projections are relayed by the thalamic nuclei.[8] The posterior part of the dorsal ventricular ridge (PDVR) is considered an associative center that projects to the hypothalamus, thus being comparable to the amygdaloid formation. Evidence suggests that the PDVR and neighboring structures constitute the reptilian basolateral amygdala and

indicate that an emotional brain was already present in the ancestral amniote.[27]

The descending motor pathways from the hypothalamus and brain stem to the spinal cord in the quadrupedal reptiles studied (turtles, *Pseudemys scripta elegans*, and *Testudo hermanni*, and the lizards, *Tupinambis nigropunctatus* and *Varanus exanthematicus*) appear to show remarkable similarities to pathways in mammals as regards their cells of origin as well as their spinal cord trajectory.[28] In the reptiles studied, the presence of interstitiospinal, vestibulospinal, and reticulospinal pathways could be demonstrated. The crossed reticulospinal tracts regulate the sensitivity of flexor responses to ensure that only noxious stimuli elicit the responses. A crossed rubrospinal tract has been shown in the turtles and in the lizard but could not be demonstrated in the python.[29] A small rubrospinal tract was demonstrated in a colubrid snake species (water snake).[30] The nonexistent or reduced rubrospinal tract in snake species is believed to be associated with limblessness. In the large *Psammodromus* lizard, efferent fibers from the dorsal cortex reach the rostral midbrain tegmentum, and it was suggested that this was the reptilian representation of the sensorimotor cortex.[31] A similar corticoefferent pathway was described in turtles after lesions in the general cortex.[31] In gecko species, anterograde-labeled fibers were observed in the same tegmental area after a tracer injection into different locations of the dorsal cortex.[31] Although axon terminals were not described in the gecko (*Gekko gekko*) midbrain tegmentum, thus far, reptile data strongly suggest the presence of a cortico-reticulospinal motor pathway. This pathway originates from the rostral dorsal cortex, and it may represent the anatomical substrate for a motor pallium in reptiles, which is comparable to the avian "motor pallium," both topologically and with respect to the organization of efferent pathways.[31] In addition, in pond turtles (*Pseudemys scripta elegans*), the determination of a descending pathway linking cortical regions with the red nucleus via the hypothalamus suggested indirect cortical control of the reptilian rubrospinal system.[32] Altogether, these findings suggest that the presence of functionally segregated thalamocortical projections is a conserved feature of brain organization among amniotes.

Opioid Receptors and Endogenous Opioids. The opioid receptor gene family is highly conserved across multiple vertebrate orders (e.g., bovids, chickens, bullfrogs, and teleost and elasmobranch fishes),[11] but there is limited information on opioid receptors in reptiles. The three main opioid receptors, μ, δ, and κ, were cloned and sequenced in three nonmammalian vertebrates: the zebrafish, the Northern grass frog, and the rough-skinned newt.[33–35] In aquatic turtles, μ- and δ-opioid receptors are located throughout the brain, and δ-opioid receptors are more abundant than μ-opioid receptors.[36] However, results of our study did not determine the location and distribution of μ- and δ-opioid receptors in the spinal cord (where nociceptive inputs enter the CNS) of turtles, nor were κ-opioid receptors examined anywhere in the CNS. With respect to endogenous opioid-related neurotransmitters, proenkephalin-derived peptides are present in turtles with a distribution similar to that in mammals and birds.[37] In addition, the reptilian brain (aquatic slider turtles, American alligators, and anole lizards) was found to contain large quantities of endogenous enkephalins, also known as endorphins (Met-enkephalin, Leu-enkephalin, and Met-enk-Arg-Phe or MERF).[38]

MEASUREMENT AND QUANTIFICATION OF PAIN AND ANALGESIA IN REPTILES

Measuring pain in any species, particularly reptiles, is the most difficult hurdle in the study of pain and analgesic efficacy. For example, as veterinarians, do we assume that this bearded dragon and sea turtle are experiencing some level of pain and should we attempt to provide an analgesic to make them more comfortable (Figs. 50.1 and 50.2)? In mammals, it is well established that perioperative pain management facilitates recovery and healing, reduces morbidity and mortality, and contributes to more rapid return to normal behavior.[39–41]

Why not consider this as salient in nonmammalian species? If measuring pain in mammals is challenging, how do we begin to decipher pain-related behavior in reptiles? An objective understanding of normal behavior of a particular species and the ability to differentiate the presence of abnormal behavior indicative of discomfort are critical to the study of pain and analgesia. Therefore one must first have an understanding of normal species-specific behavior within the environmental context in which that behavior is being displayed or observed, in order to be able to discriminate behavior associated with pain. For example, observing the postovariectomy behavior of an adult female green iguana in its own home cage may be different than behavior of the same animal under the same postovariectomy conditions observed in a hospital setting. This is certainly true in some mammalian species.[42] Methods for assessing and measuring pain in reptiles have been described previously.[41] Ideally, a combination of appropriate behavioral and physiological parameters might best be employed to measure pain and analgesia in reptiles. Along those same lines, the development of a species- and context-specific

FIG 50.1 Bearded dragon (*Pogona vitticeps*) with complete skin sloughing of the right side of the face due to *Chrysosporium* anamorph of *Nannizziopsis vriesii* (CANV) infection. (Courtesy of Kurt K. Sladky.)

VetBooks.ir

ethogram for each species being evaluated would provide the best method for distinguishing normal versus abnormal (e.g., painful) behaviors. Most commonly, animal pain, or lack thereof, is assessed before and after some invasive procedure, such as a surgical procedure. This method requires the development of a behavioral ethogram, which, in turn, requires the observer to become well versed in subtle behavioral differences through many hours of observation and analysis (videotaped or live observation). Behaviors must be operationally defined, which will provide objectivity and reproducibility (Table 50.1). For example, in a recent study, our laboratory developed a behavioral ethogram to evaluate preoperative and postoperative behavioral responses to food intake, willingness to swim, and breathing in red-eared slider turtles following a unilateral orchidectomy.[43] We were able to compare postoperative behavior in turtles with and without analgesic administration using morphine, butorphanol, and saline. Our hypothesis was that preoperative behaviors would return to normal more rapidly in those turtles receiving a mu-opioid receptor agonist analgesic. We demonstrated that those turtles receiving morphine and undergoing unilateral gonadectomy returned to normal preoperative behavior more quickly than those receiving saline or butorphanol. An alternative to studying postsurgical pain is to measure pain under strictly controlled laboratory conditions using established behavioral models during which noxious stimuli (e.g., mechanical, thermal, chemical) are applied to an anatomic location on the reptile subject.[44–48]

TABLE 50.1 Behavioral and Physiological Parameters Associated With Pain in Reptiles

1. Absence of normal behavior
2. Hunched posture
3. Increased aggression with manual manipulation
4. Rubbing/scratching affected area (e.g., incision site, wound, etc.)
5. Skin color changes, especially general darkening
6. Head extended away, and ventrally directed, from body, especially obvious in chelonians
7. Lameness: graded as 0 (no lameness), 1 (barely perceptible lameness), 2 (lameness always perceptible), and 3 (non-weight-bearing lameness)
8. Changes in consumptive behavior (food consumption):
   a. Scored as % of total food consumed in a 24-hour period
      i. Food intake can be quantified based on quantity or weight of food source within a given time limit (e.g., number of pellets consumed/number of pellets offered within 24 hours in aquatic turtles).
9. Lack of activity:
   a. Duration (in seconds/minutes) of spontaneous and voluntary movement within the tank during each observation period
      i.) Active versus complete reluctance to move
   b. Location within the enclosure during each observation period
10. Interactive behavior: immediate response to approaching observer/object
    a. Oblivious to environment, nonresponsive to interaction
    b. Partial retreat: attempted movement away from observer/object
    c. Full retreat: unambiguous movement away from the observer/object
11. Rate of respiration: scored as number of breaths per minute at each observation period
12. Heart rate: Not particularly useful in reptiles. Scored as beats per minute using a stethoscope or Doppler flow probe, although handling may confound the results.

Analgesic drugs can be administered and the response compared with baseline responses. The application of a noxious thermal stimulus provides a well-established behavioral model for assessing pain and analgesia in rodents.[49] In our own studies, we have successfully adapted this classic thermal nociception model developed for use in rodents and determined that reptiles show unambiguous, easily quantifiable withdrawal responses indistinguishable from rodents.[6,44–46] The thermal hind limb withdrawal latency model uses a noxious thermal stimulus applied to the plantar surface of the hind limb or the ventral surface of the body (e.g., snake species) of different reptile species (Figs. 50.3 and 50.4). A withdrawal latency is automatically determined when the animal withdraws its limb or tail from the noxious stimulus. This model has many advantages over other noxious stimulus paradigms, including rapid application and decay of the noxious stimulus (thereby not causing long-lasting inflammation), instant latency quantification, and unambiguous behavior after stimulus exposure (either the animal does or does not withdraw its limb). Most importantly, the animal can escape the noxious stimulus by simply withdrawing its limb. While some might argue that a withdrawal response to a noxious stimulus is not equivalent to pain, there is evidence in a variety of species that noxious thermal stimulation caused molecular and cellular changes in the central nervous system.[50–52] As a qualification to the noxious thermal, some have suggested that reptiles are prone to thermal burns, and therefore they are less likely to respond to a noxious thermal stimulus. While our understanding of thermal burns in reptiles is inadequate, there is no doubt that all reptile species studied in our laboratory perceive and respond to the focal heat source in an identical manner as a mammal. In fact, of the hundreds of healthy reptiles across multiple species subjected to a noxious thermal stimulus applied to either the plantar surface of the hind limb or various areas of the ventral body surface of limbless snakes in our laboratory, we have observed 100% response rate to this stimulus paradigm.

Physiological changes have been used to quantify stress and pain in mammals, and this approach has been adapted for reptiles as well.[53,54] For example, heart rate significantly increased in ball pythons after subcutaneous capsaicin administration.[54] In this study, opioid analgesic drugs did not alter this physiological response.

The bearded dragon has the plantar surface of its right hind limb placed directly over the infrared heat source. Note the circular region at the center of the "X" in the corn snake image, just in front of the snake's head, which is the focal infrared heat element. (Courtesy of Kurt K. Sladky.)

ANALGESIC DRUGS

Methods of Administration

It is difficult to describe the most appropriate methods for administering analgesic drugs in reptiles because analgesic pharmacokinetic and/or pharmacodynamic data in reptiles are scarce. Whether an analgesic drug is administered intravenously (IV), intramuscularly (IM), subcutaneously (SC), orally (PO), or transcutaneously (TC) is partially dependent on the size and temperament of the individual reptile. Anatomic location is another consideration, because there is pharmacologic evidence that drug administration to the hind limbs or tail of a reptile may cause rapid clearance by the renal portal system or, in the case of opioids, the hepatic first-pass effect.[41,55] However, whether this more rapid clearance has any implication for efficacy remains unknown.

Historically, and anecdotally, intramuscular administration was the preferred route for most analgesics and anesthetics in reptiles.[41,56,57] Many veterinarians believed that the subcutaneous space of reptiles was not well vascularized and therefore drug absorption would be prolonged. However, advantages associated with SC drug administration include access to a variety of subcutaneous sites requiring minimal manual restraint or patient manipulation and therefore increased safety and the capability of administering larger volumes in a single location. Currently there are no published data demonstrating that intramuscular administration results in superior analgesic efficacy compared with SC administration, and results from our laboratory indicate that drug effects can be measured rapidly after SC administration.[43–46] We determined that meperidine, an opioid analgesic with rapid absorption and excretion in humans, administered SC in red-eared slider turtles causes measurable behavior changes within 30 minutes of administration.[44] Therefore the authors routinely administer analgesic drugs and their antagonists SC in chelonians, lizards, and snakes, particularly if larger volumes of anesthetic drugs need to be injected.

Other routes of administration are also useful in reptiles. Transdermal fentanyl patches have been applied to two reptiles species for pharmacokinetic analysis, and plasma concentrations were detectable in both species.[58,59] Recently, our laboratory has evaluated the efficacy of transdermal fentanyl patch (12.5 mcg/hr) administration in ball pythons and corn snakes and determined that fentanyl patches may be the most promising analgesic approach for use in some snake species (Gutwillig, et al, Proc ARAV 2012, p 66). A new form of transdermal fentanyl, Recuvyra topical solution, is available for dogs and cats, has a 96-hour duration of effect, and may be a useful fentanyl application for reptiles in the future. Oral administration is an uncommonly used method for analgesic administration in reptiles, because there is concern that a potentially slow gastrointestinal transit time will delay onset, peak efficacy, and clearance. However, we have found just the opposite in our laboratory. Tramadol and metabolite plasma concentrations can be detected within hours of oral administration in loggerhead sea turtles,[61] and thermal hind limb withdrawal latencies increased in red-eared slider turtles within 4 hours of oral tramadol administration.[6] Table 50.2 summarizes commonly used analgesic protocols in reptile species.

Opioids and Opioidlike Analgesics

Opioids, the most effective drugs for controlling pain in mammals, are classified according to receptor subtypes—μ (mu), κ (kappa), and δ (delta) (Table 50.3). The μ, δ, and κ opioid receptors, abbreviated MOR, DOR, and KOR, mediate the analgesic effects of opioids, while the role of the fourth type of opioid receptor, the nociceptin or orphanin FQ receptor (ORL), is less clear.[62,63] For pain management in mammals, many clinicians prefer administering either a μ-opioid receptor agonist (e.g., morphine, fentanyl, hydromorphone, etc.); a partial μ-opioid receptor agonist (e.g., buprenorphine); or a mixed-opioid, κ-receptor agonist–μ-receptor antagonist (e.g., butorphanol). For exogenous opioids to be effective analgesics in reptiles, opioid receptors must be present. The gene family for opioid receptors (μ, κ, and δ) is highly conserved across multiple vertebrate orders.[11] Two snake species have endogenous brain opiates,[64] and red-eared slider turtles have both proencephalin-derived peptides and functional μ- and δ-opioid receptors in the brain.[36,37]

Although opioid receptors are expressed in reptiles, we are just beginning to understand the efficacy of commonly used opioid drugs. Butorphanol tartrate was considered to be the most commonly administered analgesic drug in reptiles.[3] In a published survey of veterinary medical clinicians, the applied reptile dosage range for butorphanol varied from 0.02 mg/kg to 25 mg/kg.[3] However, there were no clinical data to substantiate that butorphanol was an effective analgesic drug in reptiles. Butorphanol was, and still is, being used as a primary analgesic in reptiles because everyone was reporting that it worked. In 2005, our laboratory began to ask the first question: How do we know that butorphanol has analgesic properties in reptiles? Using our own noxious thermal stimulus paradigm, and through a series of controlled

TABLE 50.2 Analgesic Protocols for Use in Reptiles

	Dosage (mg/kg)	Route	Frequency	Comments
Opioids				
Buprenorphine[47,55,72]	0.075–0.1 0.02–0.1 0.1–1.0	SC, IM	q24h	No evidence of analgesic efficacy; plasma concentrations equivalent to those effective for analgesia in mammals; respiratory depression not studied
Butorphanol[43,45–48,65,66]	1.0–20.0 0.4–8.0	SC, IM	NDA	No evidence of analgesic efficacy; significant respiratory depression in RES (>10 mg/kg NOT RECOMMENDED)
Hydromorphone[72]	0.5	SC, IM	q24h	Good analgesic efficacy in RES; respiratory depression not studied, but thought to be significant
Fentanyl (Gutwillig, et al, Proc ARAV 2012, p 66)[58,59,71]	12.5 mcg/hr 2.5 mcg/hr	TC	One patch for 24–72 h	Transdermal patch; provided antinociception in ball pythons and corn snakes; plasma concentrations detected in ball pythons and prehensile-tailed skinks
Meperidine (pethidine) (Sladky K, unpublished data)[67,68]	1.0–5.0 10.0–50.0	SC, IM	q2-4h	Analgesic efficacy short-lived in RES; respiratory depression not studied
Methadone (Vaughan, personal communication)[102]	3.0–5.0	SC, IM	q24h	Good analgesic efficacy in RES; administered without evidence of efficacy in Australian Krefft's river turtle; anecdotal evidence in lizard species; respiratory depression not studied
Morphine[43–47,68–70,87]	1.0–5.0	SC, IM,	q24h	Good analgesic efficacy in RES & bearded dragons; unknown efficacy in snakes; significant respiratory depression (>5 mg/kg NOT RECOMMENDED)
	0.1–0.2	IT		Antinociceptive for >24 h in red-eared sliders
Naloxone[43–46]	0.04–2.0	IM, SC		All species; antagonizes μ-opioid agonists (e.g., morphine)
Oxymorphone (Sladky K, unpublished data)	NDA			As a μ-opioid agonist, analgesia presumably achieved, but no dosage information
Tapentadol[80,81]	5.0	IM		Analgesic efficacy in yellow-bellied sliders; pharmacokinetics indicated 10 h duration of effect
Tramadol[6,61,79]	5.0–10.0	PO	q48-72h	Good analgesic efficacy with relatively long duration when administered PO in chelonians; less respiratory depression than other opioids in RES, YBS; in loggerhead sea turtles, 10 mg/kg PO q 48–72 h
NSAIDs				
Carprofen[5,41]	0.1 1.0–4.0	SC, IM	NDA	No data regarding analgesic efficacy, safety, nor phamacokinetics/pharmacodynamics in any reptile species
Ketoprofen (Norton, Harms, personal communication)[99]	2.0	PO, SC, IM	NDA	Pharmacokinetic data in green iguanas; no evidence of analgesic efficacy in any reptile species, but an NSAID frequently used by sea turtle clinicians as an antiinflammatory due to apparent safety
Meloxicam[66,92–98,103,104]	0.1–0.5	IV, SC, IM, PO	NDA	Pharmacokinetic data in loggerhead sea turtles at 0.1 mg/kg; did not reach plasma concentrations indicative of analgesia in mammals; not recommended at these dosages; pharmacokinetic data in green iguanas at 0.2 mg/kg IV; no evidence of analgesic efficacy in any reptile species; no physiological changes in ball pythons administered postoperatively; aquatic turtles (0.2–0.4 mg/kg) IM, IV; ball pythons (0.3 mg/kg) IM; pharmacokinetic data in RES
Local Anesthetics				
Lidocaine (1% or 2%)[87,89]	1–2 (keep <5.0) 4.0	SC, IM IT	NDA	Appears to be a good local nerve block and effective IT in chelonians
Bupivicaine (0.5%)[87]	1.0 (keep <2.0) 1.0	SC, IM IT	NDA	Appears to be a good local nerve block and effective IT in chelonians
Mepivicaine (2%)[13]	1.0	SC	NDA	Used as a mandibular nerve block in alligators
Proparacaine Ophthalmic Solution (0.5%)[105–107]		Topicalcorneal	NDA	Blocked corneal sensitivity within 1 min of application with duration of effect at least 45 min. in Kemp's ridley turtles; green iguanas; bearded dragons; caiman

TABLE 50.3 Opioid Receptor Subtypes, Exogenous and Endogenous Opioids

Receptor Subtype	Exogenous Opioid Agonist	Endogenous Opioid Agonist	Exogenous Antagonist
Mu (μ)-opioid receptor (MOR) agonists	Morphine, hydromorphone, fentanyl methadone, oxymorphone, experimental drugs (DAMGO)	Endorphins (enkephalins), endomorphins	Naloxone, naltrexone
Kappa (κ)-opioid receptor (KOR) agonists	Butorphanol (kappa-agonist/μ-antagonist), nalbuphine (kappa agonist/ partial mu antagonist), experimental drugs (U50488, U69593)	Dynorphin A	Naloxone, naltrexone
Delta (δ)-opioid receptor (DOR) agonists	Only experimental drugs (DADLE, DPDPE, deltorphan II)	Endorphins (enkephalins)	Naltrindole, naloxone, naltrexone

DAMGO-[D-Ala 2, MePhe 4, Gly(ol) 5]enkephalin; DPDPE-[D-Pen 2, D-Pen 5]enkephalin; DPDPE-[D-Pen2,5]Enkephalin, [D-Pen2,D-Pen5] Enkephalin; U50488-trans-(-)-3,4-Dichloro-N-methyl-N-[2-(1-pyrrolidinyl)cyclohexyl]benzeneacetamide hydrochloride; U69593-N-methyl-2-phenyl-N-[(5R,7S,8S)-7-(pyrrolidin-1-yl)-1-oxaspiro[4.5]dec-8-yl]acetamide.

experiments, we determined that butorphanol had no analgesic efficacy in red-eared slider turtles when administered at dosages of 2.8 and 28 mg/kg SC or in bearded dragons when administered at dosages of 2 and 20 mg/kg SC.[44–46] Our butorphanol data in corn snakes was too variable to make any firm conclusions, but an unfortunate consequence of that publication[46] was that several clinicians decided to administer butorphanol (20 mg/kg) to debilitated snakes, which had fatal consequences in some cases. Consistent with our turtle and bearded dragon data, butorphanol administered IM at a dosage of 1 mg/kg had no analgesic efficacy (determined by use of a thermal noxious stimulus method)[48] and no isoflurane-sparing effect in green iguanas.[65] In ball pythons, butorphanol administered at 5 mg/kg IM had no effect on physiological parameters compared to saline.[66] Conversely, one study demonstrated that butorphanol may provide analgesia in green iguanas exposed to a noxious electrical stimulus.[47] On the other hand, morphine sulfate was an effective analgesic in bearded dragons (1 and 5 mg/kg) and turtles (1.5 and 6.5 mg/kg) using the thermal noxious stimulus method, but data were not as clear in corn snakes, even when administered morphine at a dosage of 40 mg/kg.[46] Similarly, morphine (5, 7.5, 10, and 20 mg/kg) and pethidine (10, 20, and 50 mg/kg) provided analgesia in Speke's hinged tortoises *(Kinixys spekii)* exposed to formalin administered into a limb, which was reversible after naloxone administration.[67] In further support of morphine analgesic efficacy in reptiles, morphine increased limb withdrawal latencies in crocodiles[68,69] and increased tail flick latencies in anole lizards.[70] Related to morphine, hydromorphone is a semisynthetic, μ-opioid receptor agonist, which was demonstrated to provide analgesia in red-eared sliders using the thermal hind limb withdrawal nociception model at 0.5 mg/kg SC for up to 24 hours.[71]

Fentanyl is a μ-opioid receptor agonist, with 75 to 100 times the potency of morphine, which can be administered either transcutaneously as an impregnated patch or intravenously (Figure. 50.5). Two separate studies have evaluated the pharmacokinetics of fentanyl in two reptile species. In ball pythons, fentanyl plasma concentrations reached 1 ng/ml within 4 hrs of application of a transdermal fentanyl patch (12.5 mcg/hr)[59] and were detectable by 4 to 6 hours and for greater than 72 hours in the plasma of prehensile-tailed skinks (fentanyl dose was applied at 10% exposure of total surface area of a 25 mcg/hr patch for 72 hours).[58] It remains unclear whether there is any biologic significance to these plasma fentanyl concentrations. A recently completed study in our laboratory evaluated the efficacy of transdermal fentanyl patch (12.5 mcg/hour) administration in ball pythons.[72] The results demonstrated that the mean latency associated with withdrawal from a noxious thermal stimulus was not statistically different after fentanyl patch application compared to controls without a fentanyl patch. We also confirmed that fentanyl was readily absorbed through the skin of the snakes and remained at very high plasma levels during patch application. In the same study, we determined that fentanyl patch application decreased respiration in the same snakes, so we know that fentanyl is biologically active in the snakes, even though we cannot definitively determine analgesic efficacy.

Buprenorphine is an effective analgesic in many mammalian species and used extensively due to its longer duration of action compared with other opioids. Buprenorphine has partial agonist activity at the

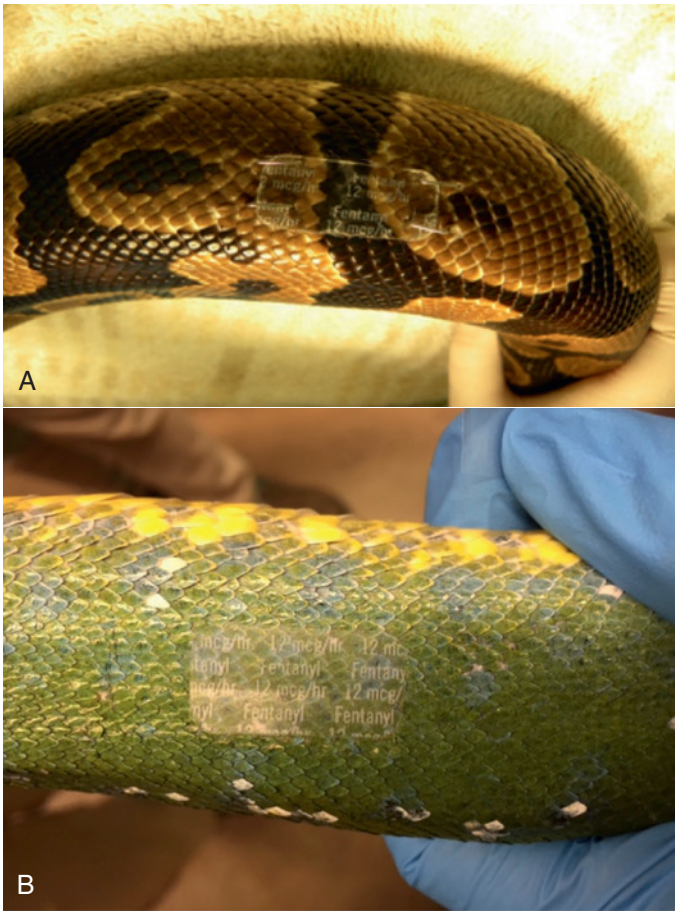

FIG 50.5 Fentanyl patch (12.5 mcg/hr) application on the skin of (A) a ball python (*Python regius*) and (B) a green tree python (*Morelia viridis*). (Courtesy of Kurt K. Sladky.)

μ-opioid receptor, partial or full agonist activity at the δ-opioid receptor, and antagonist activity at the κ-opioid receptor. Buprenorphine pharmacokinetics in reptiles were determined after SC administration in red-eared slider turtles, and effective dosages ranged from 0.075 to 0.1 mg/kg, which provided plasma concentrations at those associated with analgesic efficacy in humans for approximately 24 hours.[55] Interestingly, plasma concentrations of buprenorphine were reduced by approximately 70% when the drug was administered in the hind limb compared to the forelimb, indicating a significant hepatic first-pass effect. The analgesic efficacy of buprenorphine has not been demonstrated in reptiles. Buprenorphine did not alter responses to an electrical noxious stimulus in green iguanas.[47] Similarly, in our laboratory, buprenorphine (0.1, 0.2, and 1.0 mg/kg, SC) provided no analgesic efficacy in red-eared slider turtles exposed to a noxious thermal stimulus.[71]

Tramadol has become a widely used analgesic alternative to other opioids in veterinary medicine, because it can be administered orally and due to its relatively long duration of action. Tramadol and its major active metabolite, O-desmethyl-tramadol (M1), produce analgesia in mammals by activating μ-opioid receptors, but also by inhibiting central serotonin and norepinephrine reuptake.[73,74] Parent tramadol has μ-opioid activity, but O-desmethyl-tramadol, the active metabolite of tramadol, has up to 200 times greater affinity for μ-opioid receptors.[75] Overall, tramadol binds μ-opioid receptors with 6000 times less affinity than morphine,[75] thus having the potential for producing fewer μ-opioid–induced side effects. In fact, tramadol does not appear to alter breathing in humans[76] and produces significantly less respiratory depression than morphine in cats and dogs.[77,78]

In mammals, the analgesic effects of tramadol typically begin within 30 minutes after oral administration and last for 6 hrs. In contrast, tramadol (5.0 mg/kg; PO) administered to turtles significantly increased withdrawal latencies for 12 to 24 hours postdrug administration and 6 to 96 hours after administration of the higher tramadol dosages (10 or 25 mg/kg; PO or SC).[6] In loggerhead turtles (*Caretta caretta*), plasma concentrations of tramadol and O-desmethyl-tramadol remained above the target concentration of ≥100 ng/mL for approximately 48 hours at a dose of 5 mg/kg PO and for 72 hours when tramadol was administered at 10 mg/kg PO.[61] Subjectively, appetite, swimming, and general activity level did not change after drug administration. Most human and nonhuman mammalian studies consider the tramadol target analgesic plasma concentration to be 100 ng/mL. Recently, tramadol pharmacokinetics and efficacy were evaluated in yellow-bellied slider turtles (*Trachemys scripta scripta*) after a single intramuscular dose (10 mg/kg) administered in either the hind limb or forelimb.[79] Using a thermal hind limb withdrawal latency test, antinociceptive efficacy appeared to last approximately 48 hours regardless of whether the tramadol was administered in the forelimb or hind limb, and tramadol and O-desmethyl-tramadol (M1) remained above an atypically high target plasma concentration (1 μg/mL or 1000 ng/mL) for approximately 48 hours.[79] Of interest was that the pharmacokinetic trends were similar for tramadol administration in forelimbs and hind limbs, but the concentration of M1 was approximately 20% higher in the plasma of the group receiving tramadol in the hind limbs compared with those receiving tramadol in the forelimbs.

With respect to deleterious side effects, respiratory depression associated with tramadol administration in red-eared slider turtles was approximately 50% less than that measured after morphine administration.[6] Therefore tramadol appears to be a promising analgesic alternative to traditional opioids in reptiles. As mentioned, one of the significant deleterious side effects associated with tramadol, and all opioid drug administration in mammals, is respiratory depression. This problem is paralleled in reptile studies. Our laboratory determined that both butorphanol and morphine caused profound respiratory depression in turtles,[45] whereas respiratory depression was significantly less when turtles were administered tramadol. The bottom line is that it is imperative that clinicians continue to monitor respiration during and after procedures in which any opioid drugs are administered to reptile species.

Tapendatol, similar mechanistically to tramadol, is a human drug that shares μ-opioid receptor activation and norepinephrine reuptake inhibition with tramadol, but tapendatol has only weak serotonergic reuptake and has more potent opioid properties without an active metabolite. Tapendatol was administered to red-eared and yellow-bellied slider turtles to determine analgesic efficacy using a thermal noxious stimulus model and pharmacokinetics.[80,81] After intramuscular administration (5 mg/kg), tapendatol plasma concentrations were detectable for approximately 24 hours, and the duration of antinociceptive effects was approximately 10 hours in both turtle species.[80,81] The shorter duration of antinociceptive efficacy, compared with tramadol, may be due to the lack of an active metabolite. Although respiratory depression has not been investigated after tapendatol administration in reptiles, in humans it is thought to cause less respiratory depression compared with commonly administered μ-opioid agonist drugs.

Parenteral Anesthetics

There are no published data demonstrating analgesic efficacy associated with administration of anesthetic drugs, such as ketamine, dexmedetomidine, medetomidine, midazolam, or propofol in reptiles. Combinations of these drugs are excellent for sedation and induction of anesthesia, but one can only extrapolate from the mammalian literature with respect to analgesic efficacy. In mammals, for example, there is interest in

the fact that low-dosage ketamine provides analgesia.[82] Ketamine has an antagonistic effect on N-methyl-D-aspartate (NMDA) receptors, decreasing the wind-up effect and central sensitization, especially for chronic pain.[83] These receptors have been demonstrated in chelonians.[84] Unfortunately, nothing is currently known about ketamine as an analgesic in any reptile species. Combining ketamine with an alpha-2-adrenergic agonist (e.g., medetomidine, dexmedetomidine) increases the level of sedation in reptiles, as in mammals. Although such combinations provide analgesia in mammals, it can only be speculated that the same is true in reptiles, as no data are available.

Local Anesthetics as Analgesics

Local anesthetics can be used alone or as part of a multimodal anesthetic/analgesic approach. These include lidocaine, bupivacaine, and mepivacaine, which block peripheral nerve transmission to the dorsal horn by inhibiting sodium influx into the neurons and therefore blocking the nociceptive signal from traveling along the nerve fibers.[85] For all local anesthetics, the pain transmission is blocked as long as the local anesthetic nerve block lasts, but inflammation and pain will still develop at the site of injury and will be transmitted to the central nervous system after the effect of the block has ceased. Because of its significant analgesic effect, any local block that is correctly executed will significantly decrease the required amount of other anesthetic agents, but additional analgesia is warranted for postoperative pain management in certain cases. The limitations associated with local anesthetic administration include a focal nervous block and short duration of action.

With respect to local anesthetics, there is only one published reptile study, in which mepivacaine was used as a mandibular nerve block in an alligator.[13] In this study, a nerve locator was used to facilitate the procedure. Lidocaine (2%) (up to 5 mg/kg total dose) can be used for local ring blocks or line blocks. Lidocaine may be diluted with bicarbonate or sterile water at a 1 : 1 ratio or greater to decrease the pain of injection and allow increased volume to be infused without reaching a toxic dose. In addition, topical lidocaine (4%) is commonly administered directly to wounds before and after debridement for local analgesia, particularly in chelonian species. Proparacaine was demonstrated to be effective in blocking corneal sensitivity in Kemp's ridley turtles for up to 45 minutes, with a 1-minute onset to effect.[86] Similarly, intrathecal analgesia was reported in chelonians.[87] Intrathecal administration is useful for surgical procedures of the tail, phallus, cloaca, and hind limbs.[87] Lidocaine (2% at 4 mg/kg; <1 hour duration), bupivacaine (1 mg/kg; 1–2 hours duration) or preservative-free morphine sulfate (0.1–0.2 mg/kg; duration of up to 48 hours) can be administered intrathecally between the coccygeal vertebrae of turtles. For example, bupivicaine (0.1 mL for each 10 cm of carapace) was administered intrathecally in order to facilitate surgical excision of fibropapillomas from the posterior flippers of a green sea turtle.[88] In a different study, 2% lidocaine (1 mL/20–25 kg) was administered intrathecally in hybrid Galapagos tortoises prior to phallectomy surgery.[89] Coelioscopic orchiectomy was performed on adult male desert tortoises, and intrathecal lidocaine (2 mg/kg), in combination with morphine sulfate (0.1 mg/kg) were administered intrathecally prior to the surgical procedure.[90]

Nonsteroidal Antiinflammatory Drugs (NSAIDs)

While not as potent as the opioids, nonsteroidal antiinflammatory agents are used widely in reptile clinical practice as analgesics, as well as for their antiinflammatory properties. Nonsteroidal antiinflammatory drugs provide analgesia in mammals by blocking the binding of arachidonic acid to cyclooxygenase enzyme (COX), preventing the conversion of thromboxane A2 to thromboxane B2 (TBX), thus preventing production of prostaglandins (PG), potent mediators of inflammation.[91] Nonsteroidal antiinflammatory drugs are often classified based on their relative specificity. There are two COX enzymes, COX-1 and COX-2, that participate in renal and gastric protection and inflammation, respectively.[91] The NSAID ketoprofen is equipotent against both isoenzymes, although carprofen is slightly more COX-2 specific and meloxicam is COX-2 specific.[91] Therefore the degree of efficacy and side effects may vary with each of the three NSAIDS selected.

Although many NSAIDS appear to be relatively safe when used in reptiles, there is only one published study with respect to analgesic efficacy.[92] Ball pythons administered meloxicam (0.3 mg/kg, IM) prior to a surgical placement of an arterial catheter showed no physiological changes (e.g., heart rate, blood pressure, plasma epinephrine, and cortisol) indicative of analgesia. With respect to the pharmocokinetics of NSAIDS in reptile species, plasma concentrations of meloxicam (0.2 mg/kg, PO) administered as a single dose to green iguanas were at levels considered analgesic in mammals, and these levels were measurable out to 24 hours postadministration.[92] In loggerhead turtles, meloxicam (0.1 mg/kg) administered both IM and IV did not reach plasma concentrations consistent with analgesia in humans, horses, or dogs, and the half-life was short.[93,95] In a pharmacokinetic study in which meloxicam (0.2 mg/kg IM and IV) was administered to red-eared slider turtles, the IM dose provided a therapeutic concentration range necessary for meloxicam to provide analgesic and antiinflammatory effects equivalent in mammals for approximately 48 hours.[96] In a different study evaluating the pharmacokinetics of meloxicam (0.2 mg/kg PO, ICe, and IM) in red-eared slider turtles, only the ICe and IM routes, but not the PO route, provided mean blood concentrations of meloxicam that were above those considered effective to induce antiinflammatory effects in mammals for approximately 8 hours (IM) or 12 hours (ICe).[97] Ketoprofen (2 mg/kg, IV), administered to green iguanas, had a long half-life (31 hrs) compared to ketoprofen phamacokinetics in mammals, but the bioavailability after IM administration was 78% with a relatively short half-life (8.3 hours).[98]

Since no efficacy data and few pharmacokinetic data are available with respect to NSAID administration in reptiles, appropriate dosages and frequency of administration can only be extrapolated. Additionally, clinicians should be aware of the deleterious side effects documented in avian and mammalian species (e.g., renal impairment, gastrointestinal ulceration/inflammation, hematological abnormalities), and assessment of suitability for this class of drugs for the individual patient is prudent.

Acupuncture

Although acupuncture has been used as an analgesic across a variety of domestic species, including equine, canine, and rodent patients, systematically derived data collected under controlled conditions have not been described. The analgesic efficacy of acupuncture applied to nondomestic species has not been well documented. Electroacupuncture involves application of an electrical stimulus to peripheral nerves via acupuncture needles applied to specific acupuncture points.[99] Electroacupuncture-induced analgesia is attributable to stimulation of mu, sigma, and kappa receptors in rats.[100] However, little to nothing is known about the efficacy of electroacupuncture as an analgesic technique in reptiles. One study effectively transposed canine acupuncture points to a red-footed tortoise in order to successfully treat a locomotor disability associated with an injury.[100] In bearded dragons, morphine is considered to be the most effective antinociceptive agent, and μ-opioid agonists appear to be the most effective antinociceptive agents across many reptile species.[44,46] Since electroacupuncture also acts on μ-opioid receptors, electroacupuncture may be a promising method for providing analgesia (i.e., antinociception) to bearded dragons. The Chi institute of Traditional Chinese Veterinary Medicine in Florida has effectively treated bearded dragons for a variety of ailments such as malnutrition and anorexia with electroacupuncture (Sladky K, personal communication). In our

laboratory, we recently completed a study in which bearded dragons were subjected to electroacupuncture, followed by application of a thermal noxious stimulus to determine whether electroacupuncture provided thermal antinociception (Fig. 50.6). Preliminary data suggest that the bearded dragons relaxed under the influence of electroacupuncture and demonstrated a trend toward delayed limb withdrawal after exposure to a thermal noxious stimulus. However, the data are not statistically different from controls.

Multimodal Analgesic Approaches

In reptiles, multimodal drug paradigms may be the best approach for managing pain. Multimodal analgesia refers to the administration of multiple drugs, which have analgesic efficacy at different levels in the central and peripheral nervous system. For example, opioids will have greatest efficacy at opioid receptors in the central and peripheral nervous systems, whereas NSAIDs administered at the same time as the opioid will have greatest efficacy as antiinflammatory agents at the peripheral tissues.[101] Local anesthetics can enhance multimodal analgesic protocols by blocking the initial pain cascade at the peripheral level. In concert, all of these drugs have the potential to minimize transmission of pain signals to the brain, especially when administered preemptively, before a potentially painful procedure is established.

CONCLUSION

While our understanding of reptile pain and analgesia has advanced significantly during the past 10 years, there is a great deal of theoretical and clinical research to conduct, and our ability to extrapolate across orders and species remains a major limitation. In other words, an effective analgesic drug administered to a leopard tortoise may not have the same efficacy in a ball python. Our inability to have a "one size fits all" model for reptile analgesics stems from the fact that the class *Reptilia* is incredibly diverse. Continued research focusing on effective analgesic drugs, dose-dependent effects, duration of drug efficacy, interspecies differences, and potentially detrimental drug-related adverse effects will advance the field and begin to reinforce, or abolish, the perpetuation of anecdotal information, which remains pervasive in the reptile clinical medicine literature.

Butorphanol tartrate (a κ-opioid receptor agonist), administered at mammalian-derived dosages, was once believed to be the most effective analgesic drug for use in reptiles. More recently, however, our systematic investigation into pain and analgesia in a variety of reptile species has demonstrated that μ-opioid receptor agonists, such as morphine, hydropmorphone, fentanyl, or tramadol, provide effective analgesia, while butorphanol appears to be no more effective than saline. Extrapolation of analgesic efficacy across orders and species remains a major limitation, and there is a clear need for evaluating analgesic drugs across a variety of clinical situations, particularly as they apply to postsurgical pain. We believe that objectively derived methods for evaluation of pain in animals are critical, but these methods must be species and context specific. In addition, determining pharmacokinetic parameters, duration of drug efficacy, species-specific requirements, and deleterious side effects of opioid drugs in different reptile species remains critical to continue to advance the field of reptile analgesia.

Regional Anesthesia and Analgesia

Christoph Mans, Paulo Steagall, and Kurt K. Sladky

Regional anesthesia and analgesia are currently underutilized in reptile medicine but offer significant benefits, for example, in the ability to reduce injectable, inhalant anesthetic and sedative drug requirements and to produce preemptive analgesia in the perioperative period without deleterious side effects, such as respiratory depression. In addition, drugs used for regional anesthesia are widely available and often do not fall into controlled drug categories (e.g. Drug Enforcement Agency scheduling in the USA). Finally, in mammals, local anesthetics have the potential to blunt a surgery-induced neuroendocrine (stress) response. Knowledge of anatomic landmarks and basic pharmacology of local anesthetics is required for safe and effective nerve blocks. Regional anesthesia can be used as a sole anesthetic modality in manually restrained or sedated reptiles for minor surgical procedures (Fig. 51.1A and B). Common indications for the use of local anesthetics as part of an anesthetic protocol include distal limb surgery, cloacal procedures (e.g., prolapse), phallectomy, and celiotomy. Local anesthetics can be administered as part of topical or incisional (infiltration) anesthesia, peripheral or cranial nerve blocks, or neuraxial (intrathecal, spinal) anesthesia.

MECHANISM OF ACTION

Local anesthetics are expected to have a similar mechanism of action among reptiles as they have in other vertebrates. Local anesthetics block neuronal, voltage-gated Na^+ and voltage-dependent Ca^{2+} and K^+ channels. This results in a blockade of generation and propagation of electrical impulses in a reversible manner. These drugs will produce loss of sensory, motor, and autonomic function. Clinical experience shows that autonomic responses are inhibited before sensory (loss of sensation, pain, and light touch) and motor blockade. Resolution of blockade occurs in the reverse order. Local anesthetics have a pKa (dissociation constant) between 7.5 and 9 and are formulated as hydrochloride salts. When local anesthetics are injected into body tissues with a physiologic pH (7.4), the nonionized lipid-soluble form will prevail. This allows local anesthetics to cross biological membranes. In inflammation, the ionized form prevails due to acidic pH, and these drugs may not produce an appropriate anesthetic effect ("patchy" block).

Clinical experience demonstrates that local anesthetics have similar onset and duration of action in reptiles when compared with mammals. Dosages, volumes, and concentrations of local anesthetics are crucial in determining the magnitude and quality of the anesthetic block. High concentrations are preferred, but sufficient volume of tissue distribution should be considered. Site of injection will be an important factor in inducing the onset of block. For shorter onset of anesthesia, local anesthetics should be administered as close as possible but not directly into a nerve. Physical and chemical characteristics of the local anesthetic explain the slow onset, but some lipophilic drugs (e.g., bupivacaine) provide a long duration of action.

ADVERSE EFFECTS

Local anesthetics can produce irreversible or reversible nerve damage. Neurotrauma occurs during intraneural injections. A local anesthetic should never be injected if resistance to injection is observed. Systemic toxicity is produced by accidental intravascular injection of local anesthetics. Toxic dosages associated with adverse effects have not been determined in reptiles, but maximum dosages used in mammals, particularly in small reptiles, should be used as a guide. Adverse effects can include seizures, cardiorespiratory depression, and death. Only preservative-free drug formulations should be used for intrathecal injections.

LOCAL ANESTHETICS

Lidocaine

Lidocaine (2%) is an amino-amide local anesthetic that is commonly used in reptile medicine. Dosages associated with toxicity were reported to be between 5 to 20 mg/kg in mammals.[1] In reptiles, lidocaine was administered at up to 4 mg/kg intrathecally without side effects (Table 51.1).[2] Concentrations of 0.5% and 1% are also available. In addition, a commercial mixture of lidocaine (2.5%) and prilocaine (2.5%) in gel preparation (EMLA cream) is available and used for venipuncture in small animals. Its use was reported in turtles and tortoises undergoing phallectomy, with a dose of 1g/10 cm^2 applied to the phallic mucosa.[3] Onset of action was approximately 20 minutes and other anesthetic-analgesic techniques should be used in combination.[3] Infiltration of the prefemoral fossa in chelonians with lidocaine has been reported and is frequently used by biologists for coelioscopy. However, it has been documented that this technique using 1 mg/kg of lidocaine results in insufficient anesthesia and analgesia compared to general anesthesia and is therefore not recommended.[4]

Bupivacaine

Bupivacaine is a highly lipophilic, amino-amide local anesthetic that produces significant cardiotoxicity when injected intravenously. It is not clear what dosages will produce these deleterious effects in different reptile species, but negative aspiration of blood into the needle hub is always recommended prior to bupivacaine administration. Bupivacaine was used for tissue infiltration in garter snakes during cloacal procedures, for the study of mating behavior, and by the intrathecal route of administration in turtles (see Table 51.1).[2,5]

LOCAL ANESTHETIC TECHNIQUES

Tissue Infiltration (Incisional Anesthesia)

Local anesthetics are used for incisional anesthesia and can be infiltrated in the subcutaneous tissue in association with a surgical field, for example,

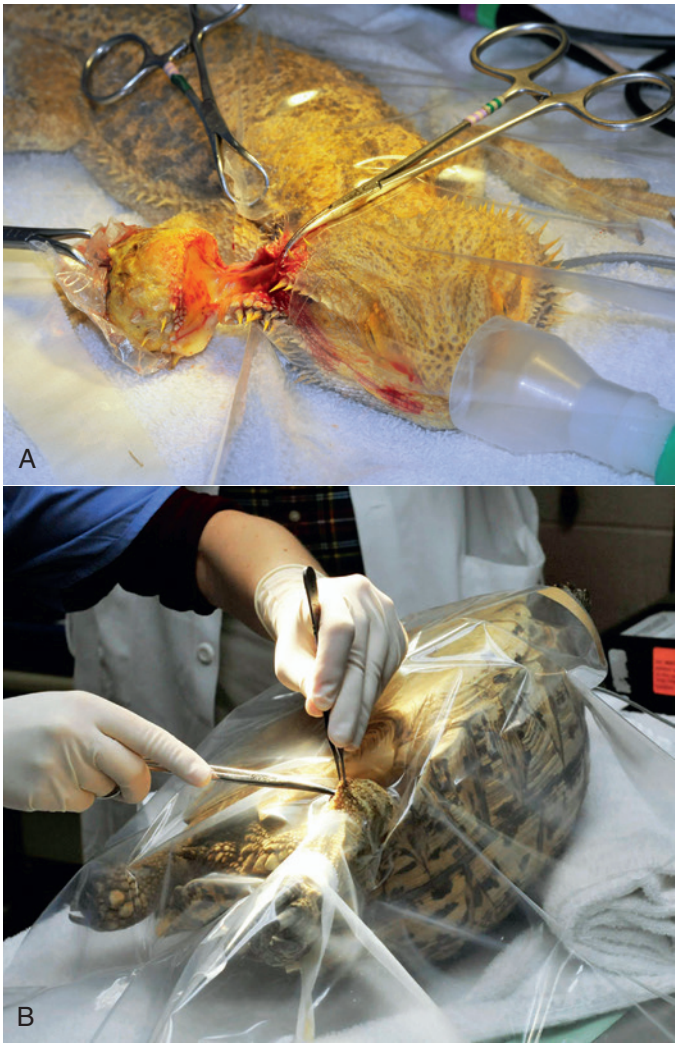

FIG 51.1 Regional anesthesia combined with procedural sedation in reptiles. (A) Bearded dragon (*Pogona vitticeps*) undergoing removal of a facial mass. Lidocaine was locally infiltrated after moderate sedation was induced with the administration of dexmedetomidine and midazolam. The skin mass was surgically excised. The animal continued breathing spontaneously and recovered without complications. (B) Sedated leopard tortoise (*Stigmochelys pardalis*) undergoing subcutaneous abscess removal, following the local infiltration of the surgical site with lidocaine.

prior to celiotomy ("line block"), skin biopsies, or laceration repair. However, local anesthetics should not be administered in proximity to neoplastic tumors, since the process can spread neoplastic cells. In small animals, this technique is used most frequently before laparotomy and as part of a multimodal analgesic approach, during which NSAIDs are also administered systemically. Aseptic techniques are always employed.

Nerve Blocks

Local anesthetic techniques of the head and limbs are not commonly reported in reptile literature. This is likely due to the large number of reptilian species and paucity of information on their specific neuroanatomy and the efficacy of locoregional techniques.

In crocodilians, dental blocks can be used as part of the clinical investigation, for tissue biopsies, draining abscesses and surgery, and to improve anesthetic recovery.[6] An electrical nerve locator was attached to an insulated needle and generated an electric field in the tissues surrounding a target nerve; in this particular case, the mandibular nerve.[6] This resulted in depolarization and muscle contractions that are used to confirm correct needle placement before drug administration. Theoretically, the use of a nerve locator reduces the dose of a local anesthetic required for an effective block and increases the rate of success. In large crocodilians, the positive electrode of the nerve locator is attached to an area of softer skin immediately behind the front leg. The external mandibular foramen is palpated, and after aseptic preparation, the needle attached to the negative electrode is inserted from a lateral approach into the cranial aspect of the external mandibular foramen. Alternatively, a different technique can be used when the needle is inserted (attached to the negative electrode) ventrocaudally along the lingual surface of the mandibular ramus toward the mandibular foramen. In crocodilians, the mandibular nerve branches travel past the cranial aspect of the external mandibular foramen. The nerve locator is set to deliver an initial current of 2 mA with frequency at two pulses per second. Higher currents may produce pain in the conscious patient. Movement of the intermandibularis muscle, during stimulation, is considered to be the end point. Mepivacaine 2% (1 mg/kg per side) was injected when responses were observed at 0.5 mA but not at 0.2 mA (risk of intraneural injection). Negative aspiration of blood should be confirmed before injection.[6] The use of nerve locators has great potential for reptile medicine, and further studies are warranted using this technique for locoregional anesthesia.

For surgical procedures involving the forelimbs, a nerve block should be considered. In an eastern box turtle *(Terrapene carolina)* a nerve block was used to perform an incisional biopsy of a forelimb digit swelling (Grioni et al, Proc ICARE, 2015, p 284).

Spinal Anesthesia

Spinal (also referred to as *intrathecal* or *subdural*) anesthesia offers substantial advantages, if used as part of a balanced anesthetic protocol, by reducing injectable and volatile anesthetic requirements needed to perform surgery. Consequently, the dose-dependent cardiorespiratory depressant effects of general anesthetics are reduced, and analgesia of longer duration can be provided. Local anesthetics are injected intrathecally (subdurally), which results in autonomic, sensory, and motor blockade. Opioids are commonly combined with local anesthetics for spinal analgesia. In this case, they bind to opioid receptors in the spinal cord and reduce release of excitatory neurotransmitters and hyperpolarize cell membranes, blunting nociceptive afferent input. Opioids do not produce motor blockade or impair proprioception and will increase duration of action providing sustained postoperative analgesia. In mammals, possible indications for spinal (or epidural) anesthesia include surgical procedures caudal to the diaphragm, including the tail, perineum, external genitalia, hind limbs, and caudal abdomen.[8,9]

Spinal anesthesia and analgesia of the spinal cord is currently in its infancy in reptiles and has only been reported in turtles and tortoises (see Table 51.1).[2,10–12] In chelonians, epidural anesthesia is not possible due to the lack of a sufficiently developed epidural space. However, a well-developed intrathecal (subdural) space, which directly surrounds the spinal cord and is filled with cerebrospinal fluid (CSF), has been reported (Fig. 51.2) and allows for intrathecal administration of various anesthetic and analgesic drugs.[2] The presence of the carapace, and the fusion of the vertebral column to the carapace, limits access only to the cervical and coccygeal intrathecal space in chelonians, but only intrathecal injections in the coccygeal region are of clinical interest.[2]

In turtles and tortoises, the cloaca, external genitalia, and hind limbs are innervated by caudal branches of the sacral plexus and coccygeal nerves.[13,14] The sacral plexus arises from spinal nerves XVII through XXI, located at the last dorsal and sacral vertebrae.[13,14] Within the sacral

TABLE 51.1 Spinal Anesthesia Studies Performed in Turtles and Tortoises

Species	Gender	Body Weight (kg)	N	Indication	Sedation	Drug(s) Used	Dose (mg/kg)	Duration of Effect	Comments
Galapagos tortoise *(Chelonoidis nigra)*[10]	Male	32–97	15	Phallectomy	No	Lidocaine 2%	0.8		No effects on hind limbs
Red-eared slider *(Trachemys scripta elegans)*[2]	Female	0.5–1	15	Experimental	Yes	Lidocaine 2%	4	76 ± 46 minutes	57% success after 1st injection, 83% success after 2nd injection of same dose
Red-eared slider *(Trachemys scripta elegans)*[2]	Male	0.5–0.8	13	Experimental	Yes	Lidocaine 2%	4	67 ± 24 minutes	60% success after 1st injection, 90% success after 2nd injection of same dose
Red-eared slider *(Trachemys scripta elegans)*[2]	Male	0.5–0.8	13	Experimental	Yes	Bupivacaine 0.5%	1	121 ± 57 minutes	
Red-eared slider *(Trachemys scripta elegans)*[2]	Male	0.5–0.8	20	Experimental	Yes	Morphine 0.1%	0.1–0.2	Up to 48 hours	Administered with lidocaine (4 mg/kg).
Black-bellied slider *(Trachemys dorbigni)*[11]	Female	1.1 ± 0.4 kg	10	Experimental	No	Lidocaine 2%	3	81 ± 10 minutes	

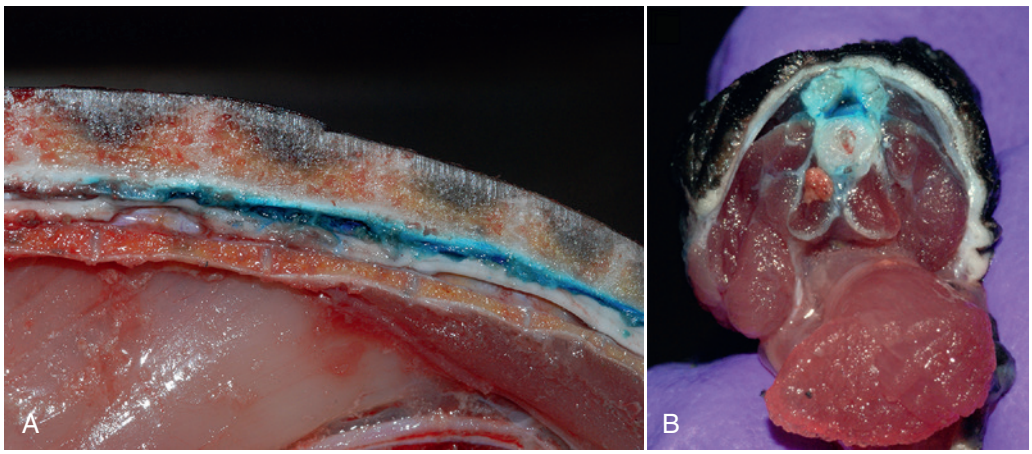

FIG 51.2 Methylene blue injection in the intrathecal (subdural) space of the spinal canal in red-eared slider (*Trachemys scripta elegans*) carcasses: (A) longitudinal view of the dorsal segment of the spinal canal, and (B) cross-section of the proximal tail base. Note the close proximity of the skin overlying the neural arch dorsally.

plexus, the nerves interconnect and subdivide several times before terminating in the inguinal, pelvic, and hind leg muscles.[13,14] Therefore the temporary desensitization of these nerves by intrathecal injection of local anesthetics and analgesics can provide regional anesthesia and analgesia sufficient for a variety of surgical procedures involving the cloaca, urinary bladder, genitals, and hind limbs in turtles and tortoises. More cranial spreading of intrathecally administered anesthetics will lead to desensitization of spinal nerves located more cranially, which supply the prefemoral fossae and caudal coelomic organs and may allow for surgical procedures via the prefemoral approach. A head-down body position should be avoided during and following intrathecal drug administration to avoid excessive cranial spread of the injected drugs.

Spinal anesthesia techniques are used, clinically, in a variety of turtles and tortoises. In conscious, male Galapagos tortoises (*Chelonoidis nigra,* body weight 32–97 kg), 3-cm hypodermic needles were placed in the mid to distal dorsal coccygeal region after aseptic preparation (Fig. 51.3A).[10] Needle placement was performed through an intervertebral space, which had been identified by palpation. Correct intrathecal needle placement was confirmed by aspiration of CSF before intrathecal injection of 2% lidocaine at an average dose of 0.8 mg/kg (0.04 mL/kg body weight or 1 mL of 2% lidocaine per 20 to 25 kg body weight). In all 15 animals, the level of regional anesthesia was graded as excellent and allowed for successful completion of phallectomy in all tortoises. At the reported dosage, no hind limb paralysis was induced, and no side effects were reported.

In a green turtle (*Chelonia mydas*), spinal anesthesia was used to facilitate the surgical removal of a cutaneous fibropapilloma from the posterior flipper. In this case report, bupivacaine (0.5%), at a dose of

0.1 mL per 10 cm of carapacial length, was administered following induction of anesthesia with midazolam and propofol.[12]

Black-bellied slider (*Trachemys dorbigni*) turtles were evaluated after the spinal administration of lidocaine in an observational study, without a control group using saline.[11] Ten healthy female animals, with an average body weight of 1.1 ± 0.4 kg, were used for this study, in which lidocaine, without epinephrine (3 mg/kg, 2%, or approximately 0.2 mL of lidocaine for each 10 cm of carapacial length), was administered while turtles were in dorsal recumbency. Motor and sensory block of the tail, cloaca, and hind limbs was successfully induced in all turtles. Onset times of spinal anesthesia were 0.4 ± 0.1 minutes for the cloaca and tail, and 2.6 ± 0.4 minutes for the hind limbs. The average duration of motor and sensory block was approximately 80 minutes for analgesia and muscle relaxation. Responses to toe pinch returned approximately 100 minutes after drug administration.[11]

In red-eared sliders (*Trachemys scripta elegans*), the feasibility of spinal anesthesia using lidocaine or bupivacaine was systematically evaluated.[2] Spinal anesthesia was successfully induced in turtles of both sexes, with body weights ranging from 0.5 to 1.0 kg. Injections were performed in sedated turtles, which allowed for proper restraint of the tail and correct intrathecal administration at the level of the mid-to-proximal coccygeal vertebrae. The turtles were positioned in ventral recumbency, and the tails were aseptically prepared before insertion of 28-g needles, attached to 0.5-mL insulin syringes (Fig. 51.4).[2] After penetration of the neural arch, the needle was advanced into the intrathecal space, and careful aspiration was performed. If significant amounts of blood were aspirated, the needle was inadvertently placed in the prominent intravertebral venous plexus surrounding the intrathecal space. The needle position was readjusted until no aspiration of blood occurred, followed by administration of anesthetic and analgesic drugs over approximately 3 to 5 seconds. Successful intrathecal injection and induction of spinal anesthesia was confirmed by complete motor block (relaxation) of the tail, cloacal sphincter, and hind limbs. The onset to motor block ranged from 1 to 5 minutes. Following the initial injection of either preservative-free lidocaine (4 mg/kg, 2%) or bupivacaine (1 mg/kg, 0.5%), spinal anesthesia was successfully induced in approximately half of the turtles. In turtles showing no evidence of spinal anesthesia after the initial injection, a second intrathecal injection, of the same drug and dosage, was administered approximately 15 minutes after the first. The repeated intrathecal injection increased the overall success rate to approximately 80% to 90%.[2] In male and female red-eared sliders, the duration of motor block of the tail, cloacal sphincter, and hind limbs was approximately 1 hour following intrathecal lidocaine administration (4 mg/kg, 2%).[2] Intrathecal bupivacaine injection (1 mg/kg, 0.5%) in male red-eared sliders caused motor block of the tail, cloacal sphincter, and hind limbs, which lasted approximately 2 hours.[2] There was a large variation in duration of spinal anesthesia in turtles of both genders. A possible explanation for this variability was associated with the well-developed and prominent intravertebral venous plexus, which is located within the spinal canal directly overlying the intrathecal space, both dorsally and laterally. Therefore in some cases, a shorter duration of spinal anesthesia was attributed to a partial intrathecal dose delivery, secondary to an inadvertent IV administration into the intravertebral venous plexus. Consequently, care should be taken with needle placement within the intrathecal space by means of repeated aspiration before, and during, intrathecal injection.

In addition to the administration of anesthetic drugs, drugs with primary analgesic properties can also be administered intrathecally for provision of long-term spinal analgesia. Intrathecally administered morphine relieves somatic and visceral pain by selectively blocking nociceptive impulses without interfering with sensory and motor function or causing sympathetic nervous system blockade, which may lead to hypotension. Morphine is a highly hydrophilic drug that tends to induce long duration of action after intrathecal administration because of delayed systemic absorption and longer maintenance in the spinal cord.[15,16] In male red-eared sliders, intrathecal administration of preservative-free morphine (0.1–0.2 mg/kg, 4 mg/mL) and lidocaine (4 mg/kg, 2%) resulted in thermal antinociception of the hind limbs for up to 48 hours.[2] Sedation was not observed after intrathecal morphine administration. This drug combination has the advantage of providing intra- and postoperative analgesia since lidocaine has short anesthetic onset and duration of action, whereas morphine induces prolonged onset and duration of analgesia due to its physicochemical properties. Postoperative analgesic requirements are commonly reduced in this case. It is currently unknown if intrathecal morphine contributes to respiratory depression in turtles, as has been documented for systemically administered morphine.[17]

In summary, spinal anesthesia and analgesia are clinically feasible techniques in turtles and tortoises. However, significant anatomic differences exist, particularly the presence of a prominent intravertebral venous plexus in turtles. This makes general recommendations regarding technique and dosages across chelonian species challenging. Furthermore,

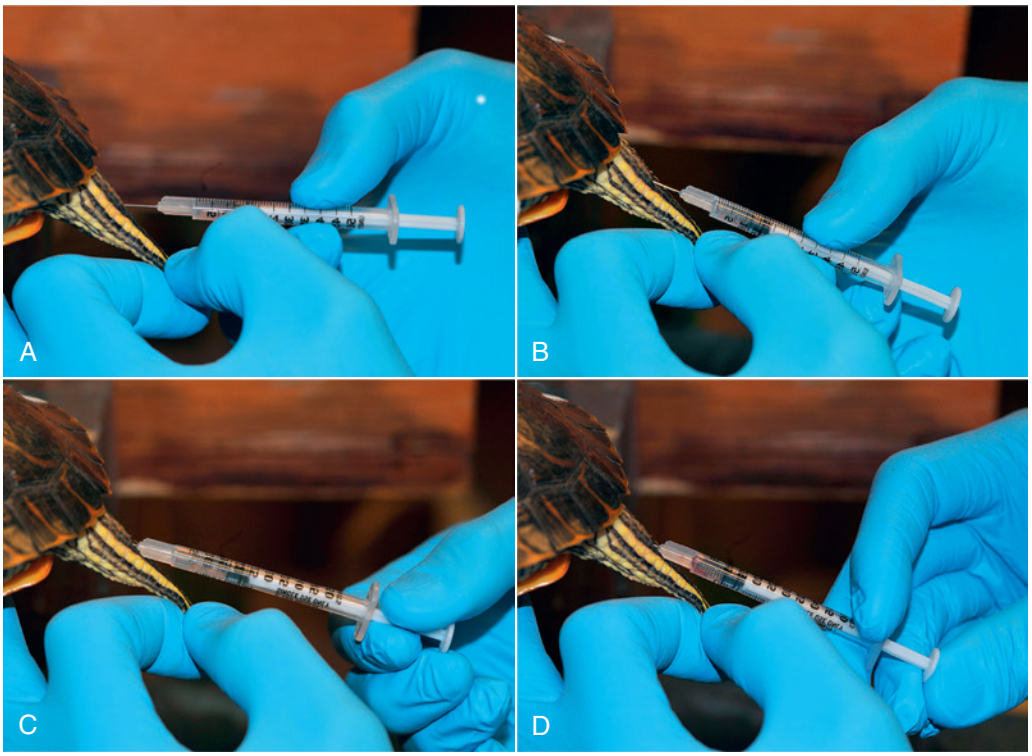

FIG 51.4 Intrathecal administration of anesthetic agents to induce spinal (intrathecal) anesthesia and analgesia in a red-eared slider (*Trachemys scripta elegans*). (A) Penetration of the skin and neural arch with the needle in approximately a 45-degree angle. (B) Advancement of the needle into the spinal canal at about a 20-degree angle. (C) Aspiration is performed to ensure correct placement in the intrathecal place. If an excessive amount of blood is aspirated the needle is repositioned until no further blood is aspirated. (D) Injection of the drug into the intrathecal space over 5 to 10 seconds.

the quantity of drug administered intrathecally will affect the extent of the sensory and motor block. Therefore different procedures will require different volumes of anesthetics and analgesics to be administered intrathecally. The technique may have to be repeated depending on the outcome of the first dose administered. Strict aseptic techniques should be used to avoid iatrogenic complications, and only preservative-free drugs should be administered into the intrathecal space, so that spinal toxicity and secondary neurologic complications are avoided. In contrast to mammals, in which the spinal cord terminates in the distal lumbar or lumbosacral region, the spinal cord in chelonians extends caudal to the last coccygeal vertebrae, and a cauda equina is not present.[18] Therefore intrathecal needle placement in chelonians can potentially lead to iatrogenic mechanical trauma of the spinal cord in the coccygeal region, with accompanying neurological deficits. Sedation, prior to intrathecal drug administration, is recommended so that the tail is sufficiently restrained and immobilized and the caudal scratch/kick reflex is reduced. This reflex is commonly observed in chelonians and can make intrathecal injections in conscious turtles and tortoises challenging.

Amphibian Anesthesia

Izidora Sladakovic and Stephen J. Divers

Amphibians represent a vast and varied taxonomic class, with more than 6000 species occupying many ecological niches, including adaptations for both aquatic and terrestrial life. Amphibians are the "coal mine canaries" of the current times and are frequently evaluated as markers of ecosystem health. The changes that have occurred in the natural world, along with emergence of certain diseases, has seen amphibian populations decline dramatically. To provide a high level of care and to better understand and conserve these sentinel species, there is a need to deliver safe and effective anesthesia and analgesia. Anesthesia may be required for evaluating a patient not amenable to physical restraint or to perform various diagnostic and therapeutic procedures, including surgery.

ANATOMY AND PHYSIOLOGY

Amphibian anatomy and physiology is described in greater detail in Chapter 12. Aspects relevant to anesthesia will be briefly mentioned here. Amphibians are divided into three orders: anurans (frogs and toads), urodeles (salamanders, newts, and sirens), and caecilians. Amphibians are unique in their respiratory anatomy and physiology, between species and between life stages as they go through metamorphosis. Respiration can occur via four modes: lungs, skin, buccopharyngeal mucosa, and gills. The presence and extent of these modes contributing to respiration varies between species. In general, all amphibians utilize skin for respiration to varying degrees. The permeable and highly vascular skin of amphibians is unique in its ability to function as an organ for gas exchange and play a vital role in water and electrolyte homeostasis. Some amphibians have structural adaptations of the skin that increase its surface area, which maximize its ability to efficiently carry out multiple functions. All larval forms utilize gills for respiration. Adult anurans and most adult caecilians rely on lungs and buccopharyngeal mucosa. Pedomorphic urodeles retain gills in adulthood and rely on them for respiration, whereas in metamorphic urodeles, gills are resorbed and lungs develop to varying degrees. In some aquatic urodeles, both gills and lungs are present. Some species of urodeles lack lungs completely and rely on cutaneous respiration as a primary mode of gas exchange. Gas exchange also occurs across the highly vascularized buccopharyngeal mucosa via gular pumping, which has a higher rate of pumping than lung inflation. The mode of respiration should be researched and considered for a species when devising an anesthetic plan, particularly as there are many exceptions. For example, species that rely primarily on cutaneous respiration, such as hellbenders (*Cryptobranchus alleganiensis*), require a lower concentration of immersion agent. In lunged species, the trachea is composed of complete cartilaginous rings and is generally short in anurans, and the lungs are simple and delicate. Therefore care must be taken with intubation and ventilation to avoid bronchial intubation, tracheal trauma, and overinflating the lungs because rupture can occur.[1,2]

ANESTHETIC AGENTS AND MODES OF ADMINISTRATION

Most studies on amphibian anesthesia have been performed using research species, predominantly African clawed frogs (*Xenopus laevis*) and leopard frogs (*Rana pipiens*), with less data available on other frog species and urodeles. At this time, the author could locate no peer-reviewed studies on anesthesia in caecilians. Therefore caution should be exercised when extrapolating the literature to the different species within the class Amphibia. Amphibians are a highly varied group of animals with great divergence time gaps between species, and marked differences have been observed between species using the same anesthetic agents and doses. When faced with an unfamiliar species for which peer-reviewed literature is lacking, the veterinarian is encouraged to reach out to colleagues with experience of the species in question.

Due to their multiple modes of respiration, delivery of anesthetic agents in amphibians has been investigated via various routes. Administration of anesthesia via immersion has traditionally been the method of choice for anesthetizing amphibians due to their permeable integument. There is ongoing research in this field, with agents designed for parenteral or inhalational administration being investigated as both immersion agents and via the route for which they are intended.

Tricaine Methanesulfonate

Tricaine methanesulfonate (MS-222) is one of the most commonly used anesthetic agents in amphibians. MS-222 is available in many countries through various suppliers but is banned in some countries due to toxicity reports. Depending on the country, it is licensed for use in amphibians. It is a water-soluble benzocaine derivative that blocks the sodium channels. Although it is a local anesthetic, when administered as an immersion it results in depression of the central nervous system compatible with anesthesia.[3] It comes as a white powder that is dissolved in water and administered as an immersion. It is buffered to a neutral pH with sodium bicarbonate to offset its acidity, which is irritating to the patient, and to aid absorption. Induction with MS-222 can range from a few minutes to approximately 30 minutes, during which time erythema of the ventral skin, agitation, and leaping may be observed (Fig. 52.1A). Respiration often slows, and by the time induction is achieved, respiration often ceases completely. Once the desired level of anesthesia is achieved, the patient is removed from the immersion, rinsed, and kept moist with anesthetic-free water. Induction with MS-222 often provides a surgical plane of anesthesia of approximately 30 minutes or longer depending on the dose and species. Time to induction and recovery is also dependent on the dose used. Higher concentrations

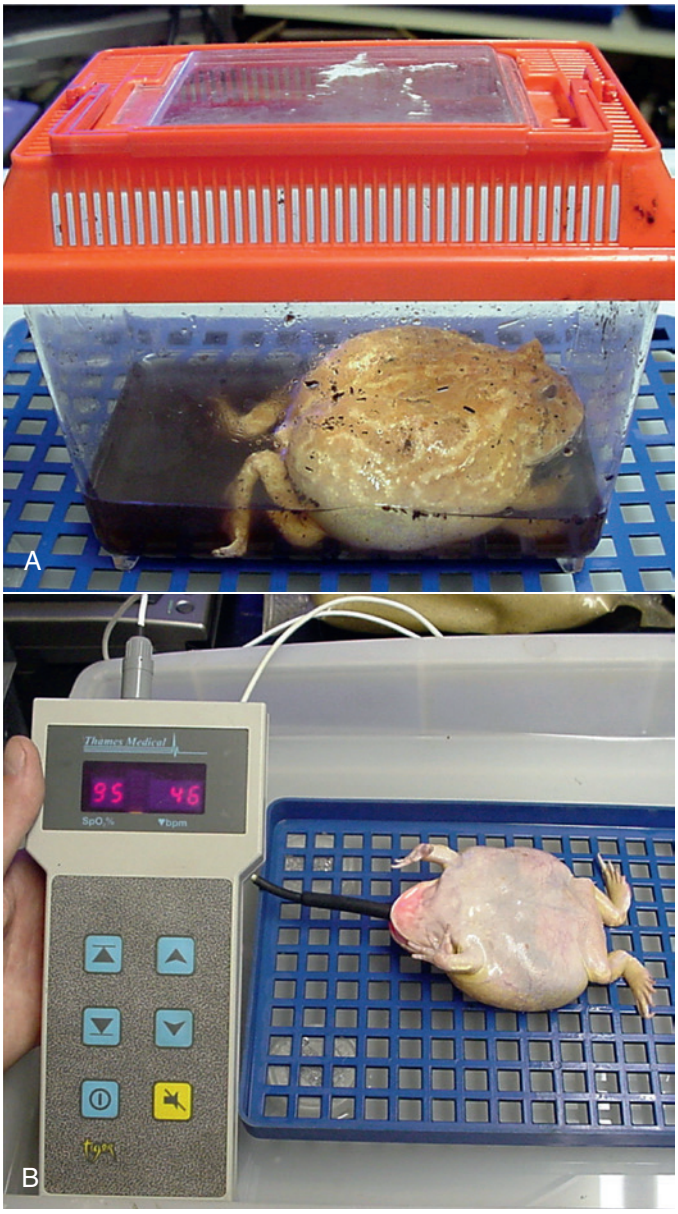

FIG 52.1 (A) Induction of an albino Argentine horned frog (*Ceratophrys ornata*) using an MS-222 immersion. The frog defecated during the excitatory phase of induction and contaminated the water. (B) Same frog after induction. The animal has lost righting and withdrawal reflexes. The intraoral reflectance probe and pulse oximeter indicates a pulse of 46 bpm and a spO_2 of 95%. Although the spO_2 values should be viewed sceptically, a robust waveform provides confidence in the pulse rate. (Courtesy of Stephen J. Divers.)

result in a shorter induction time but a longer recovery time. If ongoing anesthesia is required, the desired anesthetic depth can be achieved by partial immersion or trickling of MS-222 on the patient at half or less than the induction concentration.

In some studies a buffer is not used, which should be taken into consideration when interpreting the results. The dose of MS-222 per liter of water required varies with the life stage and species. Tadpoles, gilled species, and species that rely primarily on cutaneous respiration generally require lower doses than adult frogs. In leopard frogs, a 1 g/L immersion resulted in a surgical plane of anesthesia, with apnea and an average of 18% decrease in heart rate. No deaths occurred in the study.[4] In African clawed frogs, 1 g/L and 2 g/L immersions resulted in a surgical plane of anesthesia for 30 and 60 minutes, respectively, with marked respiratory depression. The heart rate dropped significantly in the 1 g/L group but was unaffected in the 2 g/L group. Excess struggling in the 1 g/L group occurred prior to anesthesia, and it is suspected that stress tachycardia occurred as baseline mean heart rate was significantly higher than in the 2 g/L group. No histologic lesions were observed in euthanized frogs.[5] Heart rate reduced with MS-222 at concentrations of 400 mg/L in leopard frogs, but in this study the frogs were kept anesthetized for 4 hours at this dose, which is unlikely to occur in a clinical setting.[6] It is often stated that toads require higher doses of MS-222 due to their thicker and less permeable integument. In cane toads (*Rhinella marina*), a dose of 3 g/L was used, and mean time to induction was 40 minutes. No deaths were reported.[7] However, in Sonoran desert toads (*Bufo alvarius*), a dose of 1 g/L resulted in a mean time to induction of 20 minutes and surgical depth of anesthesia.[8] In Fowler's toads (*Bufo fowleri*), the use of unbuffered MS-222 at a dose of 0.5 g/L resulted in a 12% mortality rate. In this study, many of the toads urinated during handling prior to anesthesia, and it is speculated that in response to this water loss, the toads absorbed excess amount of the anesthetic agent through the pelvic patch.[9] Terrestrial anurans have a hypervascularized ventral pelvic region and increased skin surface area over this region;[1] therefore when using MS-222 immersion, higher doses may not be required for all species of toads and may result in excess depth of anesthesia, particularly if the patient is in negative water balance prior to immersion. In a study investigating surgical implantation of coelomic radio transmitters in Chinese giant salamanders (*Andrias davidianus*), 0.6 g/L immersion of MS-222 was sufficient to induce a surgical plane of anesthesia, and a 0.1-g/L shallow bath was sufficient for maintenance. Higher doses resulted in prolonged recoveries.[10] In hellbenders, 0.25 g/L of MS-222 is sufficient to induce anesthesia.[11] Within species, smaller individuals are often more rapidly induced, and a greater anesthetic effect is observed due to a larger surface area to body weight ratio.[4,10,12]

Eugenol

Eugenol, the active ingredient in clove oil, is also commonly used as an immersion agent. It acts by blocking sodium channels, vanilloid receptor TRPV1, and activating GABA A channels.[13] There are different formulations of clove oil with other ingredients often present, so the percentage of eugenol can differ between products. As far as the authors are aware, eugenol is not licensed for use in amphibians. No buffering is required for eugenol. An Aqui-S meter is available for accurately monitoring the concentration of anesthetic. This device is expensive but may be worthwhile for large institutions.

In leopard frogs, 255 mg/L immersion resulted predominantly in immobilization, with some frogs reaching light and deep levels of anesthesia. Apnea was observed in some of the frogs, and bradycardia was observed in all the frogs.[4] In African clawed frogs, 350 mg/L immersion resulted in a surgical plane of anesthesia lasting 30 minutes, with respiratory depression but no effect on the heart rate. There were no histologic lesions in euthanized frogs.[14] This is in contrast to a study where the same dose of the same formulation of eugenol resulted in renal tubule apoptosis and pulmonary hyaline membranes after a single anesthetic episode, and hepatic necrosis after three consecutive daily anesthetics.[15] Topical application of eugenol in African clawed frogs has also been reported to cause cutaneous necrosis.[16] Gastric prolapse and vomiting have been reported in leopard frogs and African clawed frogs, respectively, with the use of eugenol immersion.[14,17] In cane toads, 0.3 ml/L immersion resulted in 30% mortality rate, respiratory distress, and noncardiogenic pulmonary edema on necropsy.[7] In tiger salamanders (*Ambystoma tigrinum*), a 10-minute immersion at 450 mg/L resulted in a surgical plane of anesthesia in 67% of the animals. Bradycardia

VetBooks.ir

was observed, but there was no change in respiration and no other adverse effects were noted.[18] Isoeugenol was used to anesthetize tadpoles of the southern brown tree frog (*Litoria ewingii*). Three concentrations were used (10 µl/L, 20 µl/L, and 50 µl/L) and all were effective. No mortalities or adverse effects were noted, and 20 µl/L concentration was most suitable.[19]

Inhalant Agents

Anesthetic effects of inhalant agents have been investigated using the conventional route, immersion, bubbling vaporized inhalant through water, topical application, and parenteral administration. Inhalational induction in lunged amphibians can be used to induce anesthesia, however, the time to induction can be excessively long,[20] and during this time desiccation of skin can occur. In a study investigating effects of isoflurane in African clawed frogs, the frogs showed avoidance behavior when isoflurane was bubbled through water. None of the frogs became anesthetized when isoflurane was bubbled through water or delivered in air.[21] If using inhalational anesthesia for induction, the procedure should be stopped if the patient is showing signs of discomfort and an alternative anesthetic plan followed. In the same study, parenteral administration (intracoelomic, subcutaneous, and intramuscular) produced highly variable results, including mortalities with intracoelomic and subcutaneous administration. Topical application, using a pad with a vapor-barrier backing saturated with liquid isoflurane and placed on the frog's back, produced the most reliable results, with rapid induction, consistent recovery times, and no mortalities.[21] Isoflurane and sevoflurane mixed with water-based jelly and water creates a gel that reduces vaporization and increases skin contact time. In *Xenopus* and *Bufo* species, isoflurane gel provided consistent levels of surgical anesthesia (Stetter, unpublished data). However, in the American green tree frogs (*Hyla cinerea*), higher isoflurane doses caused unacceptable mortality levels when applied to the ventrum.[22] In addition to the higher dose, *Hyla* frogs have granular skin on the ventrum, increasing surface area available for absorption, which may have contributed to increased absorption of the isoflurane jelly.[1] In the same study, sevoflurane gel caused a rapid loss of the righting reflex and no mortalities.[22] In cane toads, sevoflurane gel applied to the dorsum of the toads resulted in a reliable and rapid loss of the righting reflex.[23]

Cotton balls soaked with isoflurane and placed in a porous pill vial, which is then placed in a plastic induction chamber, has been used to induce anesthesia in Australian green tree frogs (*Litoria caerulea*) (Fig. 52.2). Induction was achieved within 5 to 10 minutes, and signs of discomfort or excitation were not observed. Once induced using this method, the frogs retained gular respiration (Simpson S: Pers. comm.). It is possible that this method provides a higher percentage of isoflurane in the chamber due to lack of air flow, therefore ensuring a more rapid induction time while reducing the discomfort associated with fresh flow of dry anesthetic gas. Lack of direct topical application of jelly-based mixture may also avoid inhibition of cutaneous respiration. Isoflurane or sevoflurane can also be used for anesthetic maintenance in intubated patients (Fig. 52.3), which is discussed further in the Maintenance section of this chapter.

The risk to personnel needs to be considered when using inhalants, and all such procedures should use sealed chambers and have a scavenging system in place.

Injectable Agents

Various injectable agents, including propofol, ketamine, tiletamine/zolazepam, and medetomidine have been administered intracoelomically, intramuscularly, and/or as immersion agents. The results of these studies have produced variable results, however, extensive investigation of different dosages and in different species is lacking. In frogs, propofol

FIG 52.2 An Australian green tree frog (*Litoria caerulea*) in a plastic induction chamber. The chamber is lined with moistened paper towels. A pill vial lid is porous and contains isoflurane-soaked cotton balls. (Courtesy of Shane Simpson.)

as an immersion and as an intracoelomically administered agent has shown to have a narrow safety margin, with mortalities reported.[24,25] In tiger salamanders, intracoelomically administered propofol was found to produce a surgical plane of anesthesia; however, time to surgical anesthesia was prolonged.[18] Prolonged recoveries have also been reported with injectable agents.[7,8,18] There has been increased research on the use of alfaxalone in amphibians. While the agent has shown promise as an alternative to MS-222 and eugenol immersion and inhalant induction, the results appear to be species specific. Doses of 20 mg/kg and 30 mg/kg administered intramuscularly produced sedation and light anesthesia in three species of *Litoria* frogs.[26] Doses ranging from 10 mg/kg to 17.5 mg/kg administered intramuscularly immobilized bullfrogs (*Lithobates catesbeianus*), while immersion at 2 g/L was ineffective.[27] Conversely, immersion at 200 mg/L immobilized oriental fire-bellied toads (*Bombina orientalis*) but did not provide a surgical plane of anesthesia.[28] The addition of dexmedetomidine to the immersion did not increase the depth of anesthesia.[29] Topical application of a pad saturated with 1 ml of 10 mg/ml alfaxalone and placed on the dorsum of African clawed frogs, weighing on average 27 grams, resulted in loss of the withdrawal reflex (surgical plane of anesthesia) in 75% of the frogs (Fiddes, unpublished data). The use of alfaxalone was reported

FIG 52.4 Intravenous administration of propofol into the ventral abdominal vein of an albino Argentine horned frog (*Ceratophrys ornata*). (Courtesy of Stephen J. Divers.)

in a case report as an intramuscularly administered induction agent, which resulted in sedation in a bullfrog. This was followed by a lidocaine block, allowing for surgical removal of a nuptial pad.[30] Alfaxalone immersion, followed by branchial and transcutaneous irrigation of additional alfaxalone, was used successfully in an axolotl (*Ambystoma mexicanum*) undergoing exploratory coeliotomy.[31] Although there are no studies evaluating intravenously administered agents, anecdotally alfaxalone and propofol administered intravenously have been effective in some species (Fig. 52.4).

Miscellaneous Drugs

Various other agents have been through trials with mixed results. Benzocaine cream (Orajel) used topically was effective in immobilizing leopard frogs,[4] and when used as an immersion was effective in anesthetizing Northern cricket frogs (*Acris crepitans*), mole salamanders (*Ambystoma talpoideum*), and northern dusky salamanders (*Desmognathus fuscus*).[9] However, it caused unacceptable mortality rates in Fowler's toads, presumably due to excessive anesthetic uptake after water loss from urination during handling.[9] Lidocaine:prilocaine cream (EMLA) resulted in a high mortality rate when used topically in leopard frogs.[4] Metomidate in leopard frogs failed to produce surgical anesthesia and prolonged recoveries were observed.[32]

MONITORING

Anesthetic depth classification system has not been clearly defined in amphibians as it has in domestic animals, and there is inconsistent use of terminology in the literature with regard to defining depth of anesthesia. This may be in part due to the different mechanisms of action of anesthetic agents and the variety of species in this taxa. In addition, much of the available monitoring equipment is either impractical or unable to be used in amphibians. Nevertheless, direct assessment of the patient can yield vital information and ensure that the patient remains under the appropriate level of anesthesia.

Cardiopulmonary Parameters

Monitoring respiration can be difficult in amphibians because many species become apneic under anesthesia. On induction, pulmonic (coelomic) respiration often disappears first, followed by buccal (gular) respiration. In some cases, gular respiration remains. During periods of apnea, the patient relies on skin for gas exchange. Although the skin is capable of ventilating off carbon dioxide, it is a less effective means of oxygen uptake and the blood pH can drop, presumably due to metabolic acidosis from anaerobic metabolism.[33] Some species are physiologically adapted to cope with this as they undergo naturally occurring periods of apnea (such as during torpor). It should, however, be mentioned that anesthesia can suppress these cardiopulmonary adaptations. In cane toads, a significant drop in PaO_2 and an increase in $PaCO_2$ levels occurred during anesthesia.[34] Although these toads were presumed healthy and all recovered after the experiment, in a clinical setting unhealthy individuals may have reduced compensatory abilities, and oxygenation and ventilation support may be warranted.

The heart rate is often the most useful parameters that can be easily monitored during anesthesia in amphibians. It can be monitored by visually observing the cardiac impulse or using an ultrasonic Doppler flow detector placed over the heart. A resting heart rate should be obtained prior to anesthesia. Depending on the anesthetic protocol used, some agents will cause bradycardia once the patient is anesthetized, however, with most agents, the heart rate will remain unaffected. A slowing heart rate compared to baseline (more than 20% decrease) or loss of cardiac impulse is a sign of excessive anesthetic depth and should prompt lightening of anesthesia or resuscitation efforts.

Pulse oximetry has not been validated for use in amphibians and its usefulness is questionable (see Fig. 52.1B). A pulse oximeter was used in a study on MS-222 in African clawed frogs, and percentage saturation remained unchanged from baseline, despite marked respiratory depression, including apnea.[5] However, in an investigation of blood gases in anesthetized cane toads, apnea resulted in a decrease in PaO_2 to below 30 mmHg. Once breathing resumed, PaO_2 increased.[34] Arterial cannulation for blood gas monitoring has been performed in experimental studies and may be applied to a clinical setting, however, due to large physiological fluctuations of blood gases in amphibians, interpretation may be challenging.[34]

Reflexes

Assessing reflexes is useful in determining the depth of anesthesia in amphibians. The righting reflex is assessed by placing the animal on its back and observing its ability to correct its position. This is often the first reflex to disappear, and the patient is usually defined as being immobilized or sedated if the reflex is lost or delayed. Withdrawal reflex is assessed by pinching the toe of the patient. If the withdrawal reflex is lost, the patient is defined as being at a surgical plane of anesthesia. Reduced withdrawal reflex and lack of righting reflex is often classed as a light plane of anesthesia.

The presence and absence of the corneal reflex appears to vary between studies. The loss of corneal reflex is usually associated with excessive depth of anesthesia across species; however, in amphibians this is often cited as a feature of a light plane of anesthesia. It is possible that the use of MS-222 causes loss of corneal sensation due to its topical, local anesthetic effects, and that the lack of corneal response is merely a local effect unrelated to the anesthetic depth. However, loss of corneal reflex has also been observed with the use of intracoelomic propofol in Sonoran Desert toads under a surgical plane of anesthesia.[8]

Some studies have reported a transient darkening of skin color while the patient is sedated or anesthetized (Fig. 52.5).[14,26,27]

ANESTHETIC PROCEDURE

Preparation

A complete history should be collected and a physical examination performed, paying particular attention to the cardiopulmonary and integumentary systems. Obtaining an accurate weight and baseline parameters are essential. It is preferable to obtain a resting heart rate with

VetBooks.ir

FIG 52.5 Two green and golden bell frogs (*Litoria aurea*). The sedated individual's skin is significantly darker. (Courtesy of Robert Johnson.)

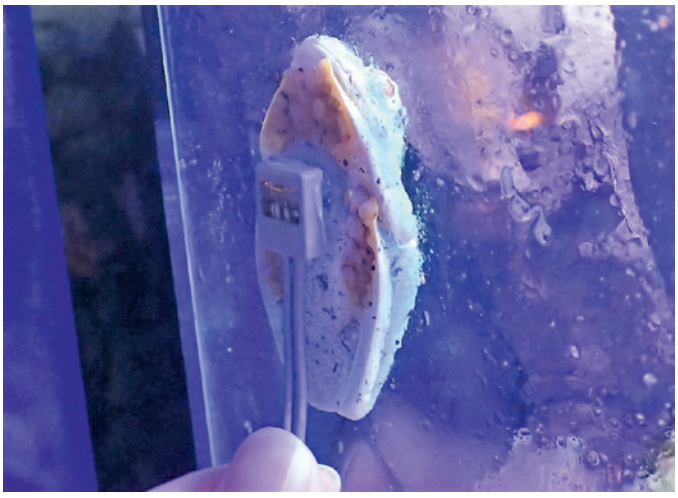

FIG 52.6 A red-eyed tree frog (*Agalychnis callidryas*) resting in its enclosure. A baseline heart rate being obtained through the wall of the enclosure to minimize stress-induced tachycardia. (Courtesy of Izidora Sladakovic.)

no or minimal handling (Fig. 52.6), because tachycardia can occur with holding, affecting interpretation of heart rate during anesthesia compared with the baseline.[5] Dermatologic diseases are common in amphibians and may affect the stability of the patient by interfering with osmoregulation, cutaneous respiration, and the uptake of immersion anesthetic agents.

Gloves should be worn when handling amphibians for the health and safety of both the patient and personnel. Rinsed and moistened nonpowdered gloves are recommended for adult amphibians. Tadpoles are particularly sensitive to gloves, with deaths observed after handling with latex, nitrile, and vinyl gloves. Although all gloves can potentially be toxic to tadpoles, well-rinsed vinyl gloves appear to be least harmful.[35]

Aspiration does not appear to be a risk factor for amphibians under anesthesia because their larynx remains tightly closed; however, they are able to vomit, and therefore fasting should be considered if the need for anesthesia is not urgent. The length of the fasting period depends on the species. The authors recommend skipping one meal as a general guide.

Plastic bags (such as disposable ziplock bags) and plastic containers are ideal induction chambers. These must be clean and free of chemicals and toxins that may be harmful if absorbed across the skin by the patient. They should be enclosed and padded to prevent injury if an excitation phase of anesthesia occurs. If working with inhalant agents, a scavenger or a fume hood should be used for personnel safety.

Chlorine-free, toxin-free water at the animal's preferred temperature is essential for use in the induction chamber, as are rinsing and keeping the animal moist during anesthesia. It is ideal to use water from the animal's environment if available, as long as the water quality parameters are acceptable. A water parameter testing kit is required to assess water quality and ensure appropriate buffering if using MS-222. Oxygenation can be provided by bubbling oxygen through water or via an anesthetic machine in an intubated patient. Uncuffed tubes, such as Cole tubes, and intravenous catheters can be used to intubate amphibians. Due to their tendency to remain apneic during the surgical plane of anesthesia, a ventilator is required.

Induction

For induction using an immersion agent, ziplock clear plastic bags provide an ideal induction chamber, because they are disposable and provide a cushion during the excitatory phase of anesthesia. The bag should be partially filled with an induction agent, enough to cover the ventrum of the animal is sufficient and not too deep as to cover the nostrils in lunged species. During induction, the animal should be monitored continuously because drowning is a risk in lunged species. Once the animal has reached the desired plane of anesthesia, it is removed from the immersion container and rinsed with anesthetic-free water. Lengthy immersion at MS-222 can result in excessive depth of anesthesia, even at low doses.[6]

For parenteral drug administration, intramuscular injections can be given in the thigh muscles of anurans or epaxial muscles in urodeles. To avoid damaging the integument, use gentle restraint with gloved hands and moistened cloth or net/plastic bag if required.

Maintenance

Mode of anesthetic maintenance is dependent on the type and length of the procedure and on the species. Animals induced with MS-222 can remain anesthetized for approximately 30 to 60 minutes. If additional length of anesthesia is required, the solution can be trickled over the animal, generally at 10% to 50% of the induction concentration. Lunged species can be intubated and maintained on an inhalant agent, delivered via an intermittent positive pressure or volume cycle ventilator. Lunged amphibians generally have a short trachea, so the endotracheal tube should not be placed too far as to intubate a bronchus. The lungs are saclike and delicate, so ventilator pressure should be set low, initially starting at 2 to 4 cmH_2O. There are no studies evaluating this mode of anesthetic delivery, although it is often utilized by practitioners. In an axolotl, anesthesia was successfully maintained by dripping alfaxalone over the gills and skin.[31] If the patient is partially immersed in water, it is ideal to bubble oxygen through the water to provide additional oxygenation.

During anesthesia, the skin needs to be kept moist. This ensures the skin does not desiccate and also maintains cutaneous respiration. Water-based lubricants should not be used to keep the skin moist, because this can impede cutaneous respiration.

Recovery

On completion of anesthesia, the patient should be rinsed with anesthetic-free water (Fig. 52.7), monitored until all reflexes and cardiopulmonary parameters have returned to normal, and kept in a moist environment at the preferred temperature for the species.

ANALGESIA

Literature on nociceptive pathways in amphibians is available and advocates that there are no major differences between amphibians and mammals.[36] The most widely used pain model in amphibians is the

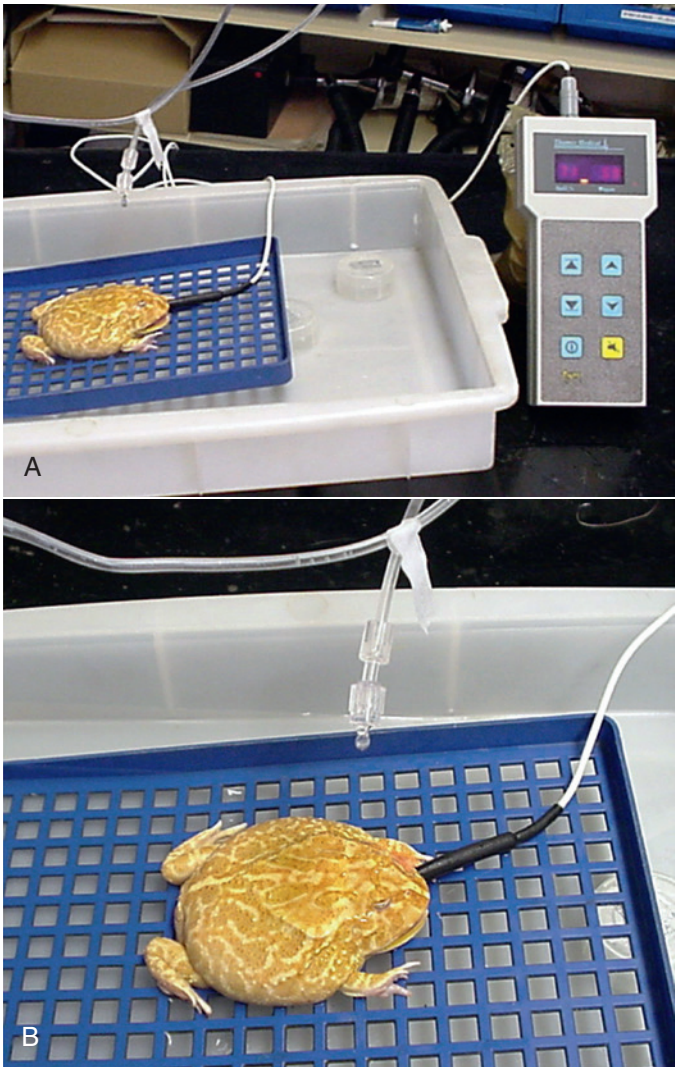

FIG 52.7 (A) Albino Argentine horned frog (*Ceratophrys ornata*) recovering from MS-222 anesthesia. (B) Close-up demonstrating an IV infusion set slowly but continuously dripping fresh water onto the frog's dorsum to speed anesthetic excretion and recovery, and keep the skin moist. (Courtesy of Stephen J. Divers.)

acetic acid test, in which acetic acid is applied cutaneously, on the thigh, and the area observed for a wiping response with the hind limb. Using this model, increased nociceptive threshold has been demonstrated for various opioid and nonopioid analgesics, with doses often being much higher than those used in mammals.[36]

There are few studies in amphibians evaluating analgesia using surgical pain. Buprenorphine and butorphanol were evaluated for analgesic effect by assessing food consumption and behavior following bilateral forelimb amputation in eastern red-spotted newts (*Notophthalmus viridescens*). Buprenorphine at 50 mg/kg administered intracoelomically at completion of surgery, and at 24 and 48 hours postsurgery, and butorphanol at 0.5 mg/L administered as an immersion both resulted in significant recommencement of normal behavior compared with the control group for 72 hours postoperatively.[37]

FIG 52.8 Use of a light source inserted through the mouth to transilluminate the heart (white arrow) of this green tree frog (*Litoria* sp.). This is a useful and rapid technique for visualizing the heart in emergent situations and where intracardiac injection is necessary. (Courtesy of Stephen J. Divers.)

A study in bullfrogs demonstrated a reduction in circulating serum PGE2 levels induced by surgical injury following intramuscular administration of meloxicam 0.1 mg/kg.[38] Flunixin meglumine injected into the dorsal lymph sac at 25 mg/kg significantly increased the nociceptive threshold in African clawed frogs using the acetic acid and Hargreaves (thermal stimulus) tests; however, the results after surgical oocyst harvest were equivocal. One frog died, and kidney congestion was observed on histopathology.[39]

EMERGENCIES

In the event of an anesthetic-related complication, principles of cardiovascular and respiratory support may be extrapolated from other species. Bradycardia may be responsive to atropine. Cardiac compressions should be performed in the event of asystole. Exogenous catecholamines may be administered for cardiovascular support, although there are no studies evaluating these agents in amphibian resuscitation. Although some references suggest doxapram for treatment of apnea, this has fallen out of favor in human and domestic animal medicine due to its side effects and worse long-term outcomes. In the event that respiratory support is required, the authors suggest endotracheal intubation and ventilation in lunged species. For gilled species, ventilation can be provided by flowing anesthetic-free water over the gills. Skin should be continuously rinsed of any anesthetic agent. Oxygenation can be provided by increasing ambient oxygen level, bubbling oxygen through water, or via an endotracheal tube in an intubated patient. Useful sites for gaining venous access are the ventral abdominal vein, femoral vein, axillary venous plexus, and lingual venous plexus in anurans. In tailed species, ventral tail vein can be used. Transillumination can be used to visualize the vein or the heart (Fig. 52.8). Cardiocentesis and intraosseous access are also options when peripheral venous access cannot be achieved. Intratracheal administration of emergency drugs at higher doses can also be considered in intubated patients.

Radiography—General Principles

Shannon P. Holmes and Stephen J. Divers

This chapter will focus on the production of radiographic images of reptiles, including equipment and interpretation principles. The individual radiography chapters on lizards, snakes, chelonians, and crocodilians provide species-specific information with respect to indications for radiography, radiographic positioning, standard views, radiographic anatomy, and interpretation.

In reptiles, as is true for all other species, radiographic diagnostic imaging is universally available and the most common first-line diagnostic imaging test performed. However, radiography is underused in reptile clinical practice compared with its use in dogs and cats.[1] Although this imaging modality can contribute greatly to the medical and surgical management of reptiles, there are numerous important factors that can affect its use and must be considered. Clinician comfort is undoubtedly one of the biggest factors, not just in interpreting radiographs but also in obtaining them. Specific training and experience with reptile radiography as a veterinary student is more limited compared with other species, and there are fewer accessible reference materials. The concern for sources for interpretation of reptile radiographs can be minimized in this age of digital radiology (DR) and teleradiology.[2] Numerous teleradiology groups offer specialists in this area for interpretation of these examinations. An additional benefit of DR is proven superior performance in avian reptiles and presumed extrapolation to non-avian reptiles.[2,3] Another challenge is the different interpretation principles that must be employed because reptiles possess a coelomic cavity rather than a distinct thorax and abdomen.[1,4] The most common radiographic feature of the coelom is its inherent poor tissue contrast, which can be displeasing to view and frustrating to interpret.[1] It also can lead to the erroneous assumption that poor coelomic detail will limit the diagnostic value of radiography to the extent that it will be of no diagnostic benefit. In spite of its limitations, the benefit of radiography as a first-line diagnostic should be appreciated over the subsequent chapters, as its applications are numerous.

RADIOGRAPHIC EQUIPMENT

Most radiographic units used routinely in clinical practice for mammalian species can be adapted to reptile radiographic procedures. The tube stand and design of the radiology area are important. Ideally, there is sufficient space around the X-ray unit to allow all personnel to work around the patient safely and move in and out of the room to minimize exposure (Fig. 53.1A).[5] A particularly important feature for X-ray units utilized in reptile radiography is the ability to rotate the X-ray tube 90 degrees to obtain horizontal beam radiographs (see Fig. 53.1B). These are a component of every standard reptile radiographic examination, whereas they are rarely performed in other small animal species.[1,6–9] The rotation of the X-ray tube to a horizontal projection results in the X-ray beam being directed parallel to the table top and toward a film-screen cassette or DR plate, which is stabilized in a cassette stand or other device.[1,4,10] Wall-mounted and table-mounted cassette holders are available. The cassette can also be supported in the vertical position with tape and radiolucent objects. When using technique chart values for mAs and kVp, it is important to maintain the distance between the radiograph tube and the cassette or DR plate at a focal film distance of 100 cm (40 inches). Some of the DR systems do not have the ability to do horizontal beam radiographs, because the DR plate has been permanently built into the table. Fluoroscopy units offer another form of diagnostic radiography studies (see Fig. 53.1C and D). These are primarily used in interventional procedures in small mammalian species but are more commonly used in reptile species to assess an anatomic area in a dynamic manner.

There are three options for making radiographs of reptiles. Previously, high-quality radiographs relied on film-screen systems. A few practices still use these systems and as a result their radiographic studies are viewed on a light box. Digital radiographic systems are currently more commonplace in most general and all specialty practices.[11] These systems include computer radiography and direct digital radiography; the end product of both is a digitized radiograph that is viewed on a computer monitor.[2,10,12] The ideal DR system for reptiles has a sufficiently large detector plate, spatial resolution (defined by pixel size) of 5 line pairs per millimeter, and high detector quantum efficiency (DQE).[2] A third option is limited to radiography of smaller patients or smaller anatomic areas, which can be imaged with dental radiography units. These can be either film or digital format.

The equipment used must be adjusted appropriately for the species and size of the patient. DR techniques will perform better than film-screen in adapting the technique charts developed for mammalian species to a reptile application.[2,13] With film-screen techniques, the exposure setting for a certain thickness of mammalian tissue will need to be adjusted to account for the thick shell of a tortoise, as an example, because the shell will more greatly attenuate the X-ray beam. In contrast, DR systems can produce diagnostic images over a wider range of exposure values than film-screen and therefore adjustment of the technique chart values may not be necessary.[2,3] This is not to say that exposure errors are not an issue in DR, but the number of retake images is significantly

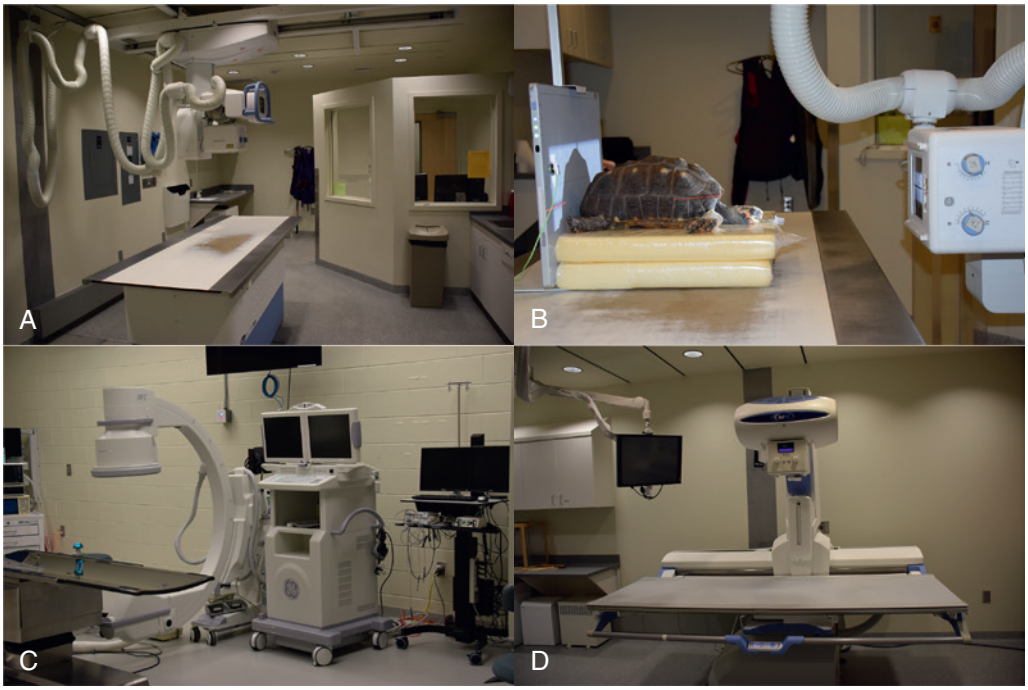

FIG 53.1 Small animal digital radiology (DR) suite with a moveable tube head capable of vertical (A) and horizontal (B) X-ray beams and protected technician control area. Such facilities are suitable for the vast majority of reptiles and amphibians, but giant chelonians and crocodilians may require equipment designed for large domesticated species. Fluoroscopy units come in different forms. C-arm units (C) are increasingly being used for interventional radiography and intraoperative assessments (e.g., orthopedic implants). Some units are capable of both fluoroscopy and digital radiography (D). Both have the ability to rotate to obtain horizontal beam or oblique images. Reptile fluoroscopic techniques are most useful for dynamic assessments of gastrointestinal, vascular, and urinary studies. (Courtesy of Stephen J. Divers.)

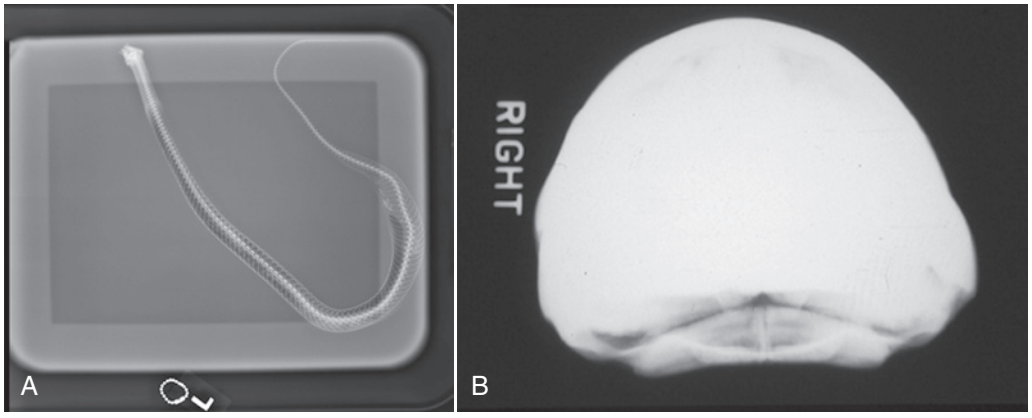

FIG 53.2 Examples of poor radiographic technique. (A) Dorsoventral vertical beam radiograph of a snake that has been constrained in a transparent plastic box, which partially attenuates the X-ray beam. Positioning is poor and evaluation for anything other than a large foreign body or egg is futile. (B) Craniocaudal horizontal beam radiograph of a tortoise. This radiograph is severely underexposed, such that the shell has essentially attenuated the X-ray beam and no internal anatomy is distinguishable.

reduced.[10,11] Underexposure of the aforementioned tortoise in film-screen system will result in less film blackening and potentially further reduced detail of the coelomic cavity (Fig. 53.2). Correcting over- and under-exposure in film-screen systems is important to optimizing image quality and follows specific rules for changing the milliampere/second (mAs) or kilovolt potential (kVp).[10] If your practice performs numerous reptile studies and uses film-screen systems, it may be beneficial to develop a species-specific technique chart. DR systems have more limited technique charts because of sensitivity to X-rays, conversion of information to digital format, and postpossessing techniques. Underexposure in digital

VetBooks.ir

films results in an image having a grainy, diffuse appearance superimposed on the anatomy and background. Overexposure will result in black areas that are described as saturated; there is no manipulation to the appearance of the image that can be made to retrieve the image anatomy in saturated areas.[2,14–16] It is beyond the scope of this chapter to thoroughly review all components of a DR systems that affect image quality. More comprehensive reviews of the application of DR systems with comparison to traditional screen-film systems, some focused on exotic pet radiography, are available and should be considered before purchase of a DR system.[2,3,10,11]

It is important to consider the internal or external anatomical areas of interest when planning a radiographic study. Reptile radiography generally follows the standard radiographic convention mandating that two orthogonal radiographs are necessary for anatomy depiction (see Fig. 53.2). The orthogonal radiographs remove summation of anatomy from different angles and give depth and spatial location information.[1,4,10] Single image studies are rarely indicated, as can be seen in Table 53.1. For example, the chelonian lungs are best evaluated in the craniocaudal projection, which allows comparison of the right and left lungs for degree of aeration versus abnormal accumulation of soft tissue representing pathological change. A lateral radiograph of the chelonian respiratory system can also be made to evaluate the spatial distribution of the lungs from cranial to caudal, given that this cannot be assessed on the craniocaudal view. In contrast, a single lateral projection of the respiratory system may be useful in snakes with only a right lung, because it allows complete system evaluation of the trachea through their saclike lungs with minimal superimposed anatomy.[1] However, when dealing with boas and pythons that possess both left and right functional lungs, the dorsoventral view is also essential to differentiate between left, right, and bilateral disease. Species-specific considerations for radiographic positioning, including restraint techniques, will be discussed in subsequent chapters.

IMAGE INTERPRETATION

Some of the same principles of image interpretation that are used in mammalian species can be used in reptiles. For example, there are only five radiographic opacities that can be depicted; these include metal, bone, soft tissue, fat, and air.[10] However, reptiles generally have minimal diffuse fat located around their visceral organs; instead, most is localized within discrete fat bodies.[1,4,6,7] Diffuse peri-organ fat in mammalian species provides radiographic contrast; thus mammalian abdominal fat facilitates distinction, shape, and margination evaluation of organs. Radiographs of reptiles are often characterized by poor coelomic contrast (Fig. 53.3). The poor contrast in reptiles is exacerbated by close anatomic proximity of internal organs (increased silhouetting of structures), a coelom rather than separated body cavities (i.e., thorax and abdomen), and image degradation that is associated with their often heavily keratinized skin, scales, or osteoderms.[1] Similar to mammalian interpretation, increases in soft tissue within the coelom can produce a mass effect and further reduce regional serosal detail. This is an example of a mammalian radiographic interpretation principle that can be used

[a]Boas and pythons have two functional lungs, and therefore a dorsoventral view is essential to differentiate between left and right pulmonary disease. The dorsoventral view is less valuable for most other snakes that only possess a functional right lung.
[b]Orthogonal views of the limbs are required, particularly if any lesions are identified on the dorsoventral view.

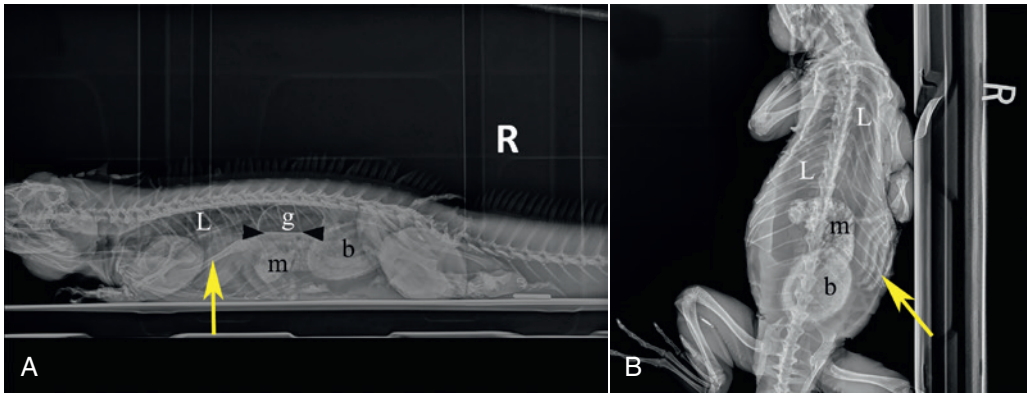

FIG 53.3 (A and B) Grand Cayman iguana (*Cyclura lewisi*). The poor inherent tissue contrast commonly seen in reptiles is demonstrated. Four radiographic opacities are shown: metal opaque label (R) in the dorsoventral image, skeleton and mineral opaque amorphous material (m) in the mid and caudal coelom, coelomic soft tissue caudoventral to the lungs and gas opacity within the aerated lungs (L), and nondependent area of the stomach (g). This degree of poor serosal detail in the caudoventral coelom is normal. In this case it makes it difficult to definitively localize the abnormal mineralized material. The caudal portion was suspected to be in the urinary bladder (b) based on the shape, but there was concern that the more cranial mineral material could be within the gastrointestinal tract because it extends cranial to the stomach that has a gas-fluid line (black arrowheads). Surgery confirmed all mineral material was within the urinary bladder. Note also the suboptimal positioning of the right pectoral limb (yellow arrow); it is superimposed on the coelom but more significantly over the area of interest on the lateral image. (Courtesy of Christine Fiorello, Albuquerque BioPark.)

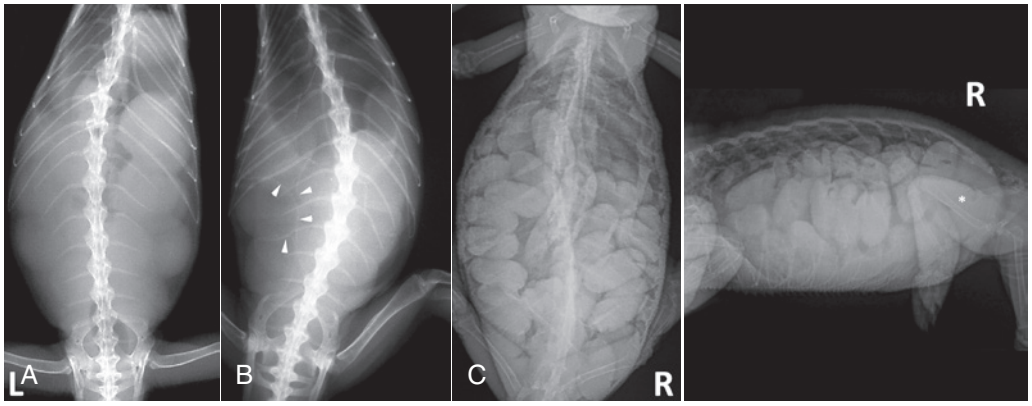

FIG 53.4 (A) Dorsoventral (screen-film) radiograph of a green iguana (*Iguana iguana*) demonstrating multiple, spherical, soft tissue densities consistent with preovulatory follicles. The ova produce a mass effect that further reduces serosal detail in the coelom. (B) Another green iguana dorsoventral (screen-film) radiograph demonstrating multiple soft tissue densities; however, note that the structures are more oval and surrounded by thin shells (arrows), indicating that they must be postovulatory eggs. (C) Dorsoventral and right lateral radiographs of a gravid old-world chameleon (Chamaeleonidae) made with a digital radiography system. The contrast resolution can be enhanced with postprocessing techniques, which explains why the shelled eggs are better seen with digital systems. (A and B, Courtesy of Stephen J. Divers; C, courtesy of Shannon P. Holmes.)

in reptiles but also requires knowledge of baseline poor coelomic detail (Fig. 53.4).

A systematic approach is critical for all radiographic interpretations. Because whole body radiographic examinations are more common in reptiles than focused system examinations routinely done in mammalian studies, the systematic approach used must be adapted. It is best to approach the coelom in anatomic components, such as cardiovascular, pulmonary, gastrointestinal, coelomic organs (liver, pancreas, and spleen), urogenital, and musculoskeletal systems, with each area more specifically evaluated similar to mammals. The evaluation of the respiratory system, for example, could include oral cavity, nasal cavities, trachea, and lungs. Accurate radiographic interpretation requires a strong understanding of anatomical and physiological variations in different species, as these produce different radiographic appearances. For example, the chelonian lung contains muscular bands of tissue throughout, whereas the snake lung is divided into vascular (faveolar) and avascular (saccular) regions.[1,6,17] The alveolar, pleural, and bronchial patterns used in mammalian radiographic interpretation are not applicable to reptiles. Capturing anatomy in certain states is also critical for accurate interpretation, and evaluating inspiratory lungs is important. Artifactual increased opacity of deflated lungs can be misinterpreted as pathologic change (Fig. 53.5). It is important to assess the quality of the radiographic

VetBooks.ir

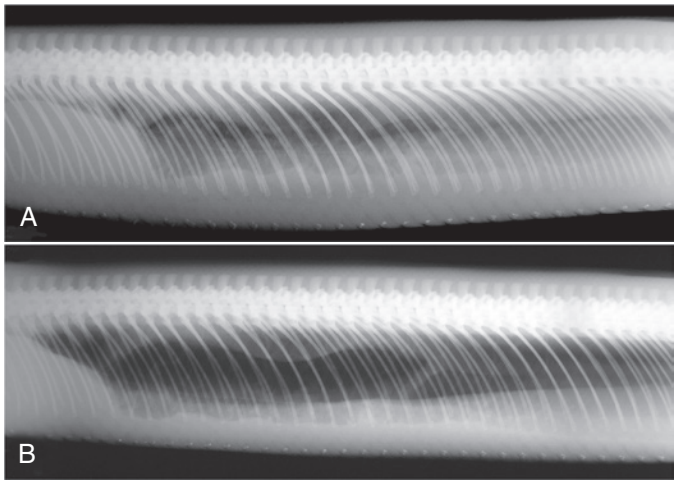

FIG 53.5 Boa constrictor (*Boa constrictor*). The radiograph (horizontal beam, lateral view) was made with the patient during expiration (top) and at peak inspiration (bottom). The lungs are more lucent and expanded on the inspiratory radiograph. This greatly improves the ability to evaluate the lungs for pathological change and is the reason general anesthesia and positive pressure ventilation is recommended for assessing the respiratory system. The cardiac silhouette on the left of the images serves as a point of reference.

study for the body system of interest, as this will impact the systematic approach. General considerations include extent of superimposed pectoral limbs that may interfere with assessment of the heart; degree of inspiration for evaluating the lungs; presence of ingesta in the gastrointestinal tract producing opacities that superimpose the coelomic anatomy to be evaluated; or detectable changes in mineralization of skeletal structures versus inappropriate technique.

Radiography—Lizards

Shannon P. Holmes and Stephen J. Divers

Radiography offers clinicians a minimally invasive tool to look inside their reptile patients using equipment that is readily available in virtually all veterinary practices. As with any diagnostic imaging test, there are benefits and limitations. A major benefit of radiography is that it is inexpensive relative to other diagnostic imaging tests. In lizards, one limitation that can significantly affect interpretation is the inherently low soft tissue contrast within the coelom. The resulting radiographs can be challenging to evaluate and successful diagnostic ability will be governed by the interpreter's knowledge of lizard anatomy, physiology, and pathological conditions. These factors differ significantly from mammalian species, and interpretation principles must be adapted to these unique lizard patients.

RESTRAINT AND POSITIONING

Restraint is a necessity in all aspects of diagnostic imaging. Motion is a major source of image quality degradation. Lizards can be radiographed while conscious with appropriate restraint of their limbs.[1–3] A self-adhesive bandage can be used to secure the pectoral and pelvic limbs away from the area of interest, often to create an uninhibited view of the coelom (Fig. 54.1).[2] It is important to consider the area of interest when securing the limbs to avoid superimposition.[1] This technique is feasible in patients with low activity. Incorporation of slight pressure over the closed eyes to induce a vasovagal response can also be effective in some lizards, especially iguanids.[6] Radiographic accessories can also aid in acquiring radiographs in conscious lizards.[1,4,5] These can include using radiolucent tubes or troughs for smaller lizards to positioning sponges and plexiglass positioners for larger animals. Chameleons will often remain motionless if permitted to perch on a rod or stick.[4] Care must be taken when using positioning aids so that any device extends the length of the area of interest to avoid additional variations in radiopacity that hinder interpretation. It is important that none of these accessories affect the patients' position relative to the cassette or detector. Specifically, none should be abnormally thick to cause the patient to be positioned further from the cassette or detector; this causes magnification and image degradation through blurring.[1,7] This can be a greater issue with the horizontal beam projections.

In those patients with higher activity level or requiring special radiographic views, chemical restraint is likely needed. Although greater preparation time and sedation/anesthesia risks are considerations, the increased efficiency in the radiographic room is beneficial through improved image quality, less retake radiographs, and ease for positioning the patient to obtain specific images.[1,8] The latter is most commonly encountered when the axial or appendicular skeleton of the lizard needs to be imaged and requires positioning in an abnormal posture and/or with limb extension.[8] Specifics on chemical restraint techniques that can be used are available in Chapters 48 and 49. Chemical restraint considerations for radiographic procedures should include the expected length of the procedure, if additional tests are to be performed or if dynamic studies are needed. When general anesthesia is required for other diagnostics, it is best to plan radiographic procedures to precede these and be performed under premedication/sedation if possible. If general anesthesia is required, radiographs should be acquired immediately following induction, because they can often be taken under light anesthesia, with anesthetic depth subsequently increased in preparation for surgery or more invasive procedures. Some drugs can interfere with gastrointestinal motility in mammalian species and therefore should be avoided in reptilian gastrointestinal contrast studies. To date, the effects of drugs on reptile GI motility and radiographic studies have not been investigated.

The ideal radiographic study of most systems consists of dorsoventral vertical x-ray beam and lateral horizontal x-ray beam images.[1,2] Optimal radiographic technique has the lizard positioned as close to the cassette or detector as is possible. The tabletop is as close as possible for systems that have the cassette or detector built into the unit. Otherwise, patients can be placed directly on the cassette or detector for the dorsoventral view (Fig. 54.2). For the lateral horizontal beam image, positioning the cassette or detector close to the patient is hampered if the laterally protruding extremities are not extended cranially or caudally (see Fig. 54.1). For machines that cannot perform horizontal beam imaging, the vertical beam lateral radiograph will be needed and requires greater restraint (Fig. 54.3). This will alter the confirmation of the coelomic structures from the typical published appearance (Fig. 54.4), and this

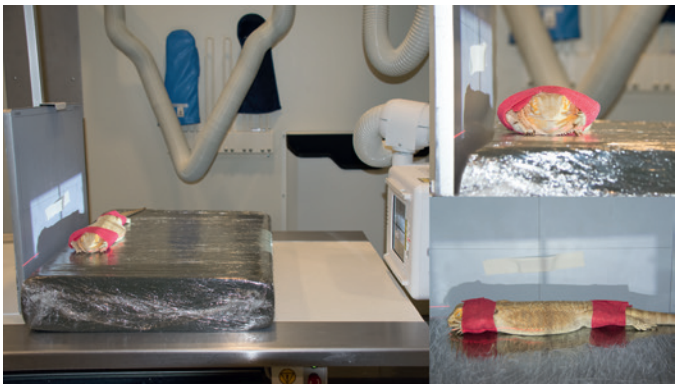

FIG 54.1 Positioning a sedated bearded dragon (*Pogona vitticeps*) for a standard right lateral, horizontal beam radiograph. This is the preferred positioning for lateral radiographs, because visceral displacement is avoided and fluid lines can be appreciated. The limbs have been taped to provide an unobstructed view of the coelom. Radiolucent positioning devices must often be used to elevate the patient from the table and center the x-ray beam. (Courtesy of Stephen J. Divers.)

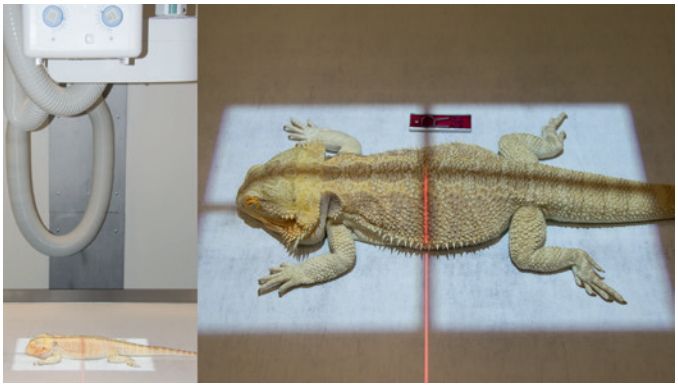

FIG 54.2 Positioning a sedated bearded dragon (*Pogona vitticeps*) for a standard dorsoventral radiograph. (Courtesy of Stephen J. Divers.)

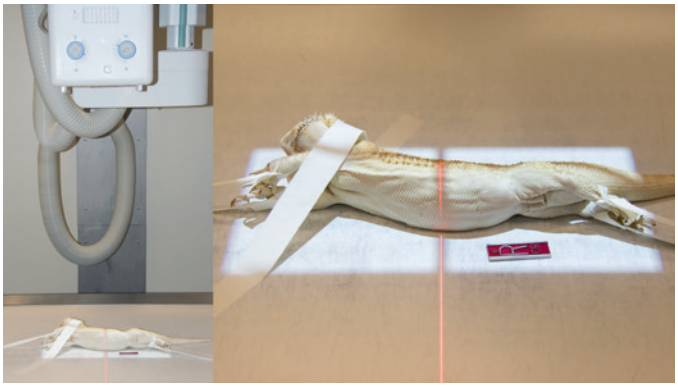

FIG 54.3 Positioning a sedated bearded dragon (*Pogona vitticeps*) for a right lateral vertical beam radiograph. Such positioning is not advised because of the displacement of visceral structures. (Courtesy of Stephen J. Divers.)

FIG 54.4 Right lateral radiographs of the same bearded dragon (*Pogona vitticeps*) comparing (A) vertical beam, (B) horizontal beam without limb retraction, and (C) horizontal beam with limb retraction to avoid superimposition. Lung definition is poor in the vertical beam radiograph due to visceral displacement by gravity, whereas limb retraction provides a superior view of the cranial and caudal aspects of the coelom without superimposition of the limbs. With the lizard in sternal recumbency, there is some compression of the coelomic contents. (Courtesy of Stephen J. Divers.)

FIG 54.5 Common difficulties encountered in lizard radiology. (A) Small patient size, as demonstrated by this 55 g leopard gecko (*Eublepharis macularius*), may be overcome by using magnification, either by raising the lizard on a perspex platform above the radiographic plate or magnifying the image after acquisition. It should be remembered that detail may be sacrificed with any magnification process. (B) Most reptiles store fat in discrete coelomic fat bodies (1) rather than diffusely around visceral organs, which results in poor serosal detail. (C) Heavy scalation and osteoderms, as demonstrated in this helodermatid lizard, often obscure other radiographic details. (Courtesy of Stephen J. Divers.)

is a less ideal technique.[2,9] The positioning of the limbs must be considered with respect to the area of interest. Extension of the limbs cranially is important for evaluation of the heart and lungs, whereas the limbs may be preferably left in a neutral position or extended caudally to examine the head and neck region (see Fig. 54.4). In larger lizards, both right and left lateral views are recommended for respiratory tract evaluation; the lung and any pathology will be best resolved when it is closest to the cassette or detector.[1] Similarly, superimposition of the pelvic limbs over caudal coelom and pelvic girdle can hamper evaluation of these areas on the horizontal beam images. Extending the pelvic limbs caudally minimizes this effect.

There are some additional challenges in lizard radiography that cannot be overcome with technique. Some patients are extremely small (Fig. 54.5A). This is less of an issue with good-quality digital systems given that magnification of the resulting image is feasible.[10,11] Lesser-quality systems can limit the extent to which a radiograph can be magnified before pixilation is evident. With film-screen systems, it is ideal to use slower speed film to optimize resolution.[1,4] An air-gap technique has also been described to "enlarge" the patient, but this magnification technique can result in image blurring. For smaller body parts, such as the oral cavity or a distal extremity, dental film or digital systems can be used (Fig. 54.6). Another challenge is the inherent low serosal detail in the coelom of lizards (see Fig. 54.5B), which is attributed to the localization of fat in the coelom.[1,2,12] Minimal fat exists between or around organ systems, and fat between serosal surfaces is necessary to provide radiographic contrast between different soft tissue opaque structures.[7] There are typically more discrete fat bodies within the caudolateral coelom. Their location does not aid in providing contrast; rather, it will tend to compress the organs together more, and this can worsen soft tissue contrast resolution regionally in the coelom. Fat body

size is useful for evaluating body condition. Finally, it can be difficult to see the coelomic structures with radiopaque or dense scales or cutaneous osteoderms. Osteoderms have mineral deposits in the cutaneous or dermal layers that will obscure the internal anatomy on radiographs to varying degrees (see Fig. 54.5C).

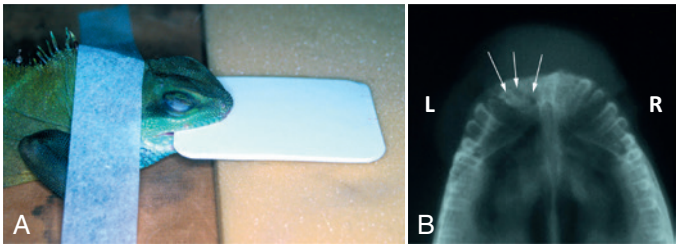

FIG 54.6 Dental radiography units and intraoral films often provide superior detail of oral structures, as they are designed for high-resolution output of smaller structures. In this Chinese water dragon (*Physignathus cocincinus*), small focal areas of osteolysis (*arrows*) are visible. In reptile practice, they can also be used to take survey radiographs of small reptiles or anatomical regions. However, care should be taken to ensure sufficient anatomy can be included for interpretation purposes. (Courtesy of Stephen J. Divers.)

CARDIOVASCULAR SYSTEM

The cardiac silhouette is positioned in the most cranioventral aspect of the coelom in most lizards, except for monitor lizards where it is more caudally positioned.[1,2] The heart can easily be obscured on the horizontal lateral view if the pectoral limbs are not taped forward. The heart and greater vessels are best visualized on this horizontal lateral image, but there are areas of the heart that may remain poorly visualized, including apex, base, and cranial margin.[13] Generally, the heart is poorly seen on the dorsoventral radiograph due to its close proximity to the coelomic inlet and the summation affect associated with the pectoral musculature and superimposition of the spine, ribs, and sternum. The cardiac silhouette of most lizards does not normally have discrete borders, especially on the dorsoventral image, because it is not surrounded by aerated lungs that typically provide margin contrast in mammalian species. The lungs efface the dorsal and, in some species, the caudal contour of the lizard cardiac silhouette (see Fig. 54.4C and 54.7A). Changes in the relationship of the trachea and lungs can be used to evaluate cardiac size (see Fig. 54.7D).[1] Typically, the width of the cardiac silhouette is increased with enlargement, or there is more soft tissue filling the cranioventral coelom. Because the normal cardiac silhouette has indistinct margins, increased marginal conspicuity due to greater

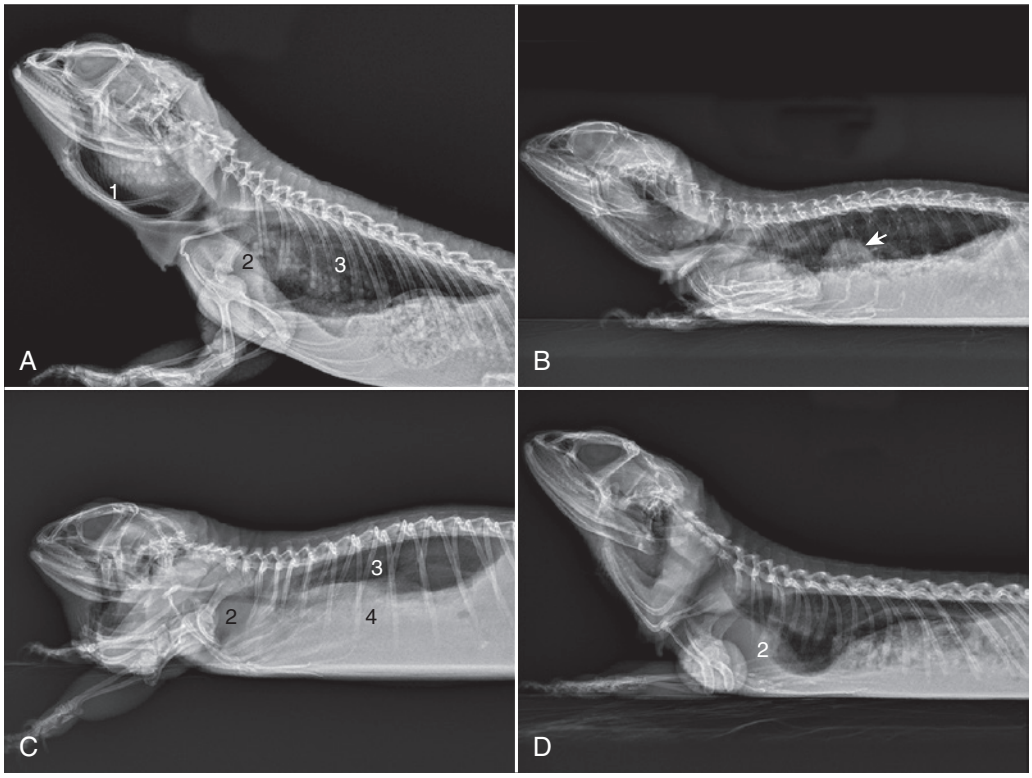

FIG 54.7 Horizontal beam, right lateral radiographs of four bearded dragons (*Pogona vitticeps*) that presented with respiratory signs. (A) Normal radiographic anatomy with unremarkable trachea (1), heart (2), and lungs (3). The apparent soft tissue densities within the cranial lungs are due to superimposition of large keratinized scales and dermal projections. The respiratory signs in this case were determined to be of environmental etiology. Note the effect of pectoral limb superimposition and how the cardiac silhouette is obscured in the cranioventral coelom. (B) Focal soft tissue density in the midventral pulmonary region (arrow). Possible differential diagnoses include abscess, granuloma, or extrapulmonary mass associated with the stomach or liver. (C) Possible enlargement of the cardiac silhouette (2) or increased soft tissue seen in the space between the heart and liver, causing compression of the lungs (3) and dorsal displacement of the trachea due to soft tissue mass effect within the cranioventral coelom (4). Ultrasonography indicated gross obesity and associated coelomic changes of hepatomegaly due to hepatic lipidosis, enlarged fat bodies, and increased pericardial fat. (D) Enlargement of the cardiac silhouette (2) was subsequently identified as ventricular enlargement due to bacterial endocarditis. (Courtesy of Stephen J. Divers.)

VetBooks.ir

FIG 54.8 (A) Dorsal ventral view of a bearded dragon (*Pogona vitticeps*) with increased soft tissue in the area of cardiac silhouette, indicative of cardiomegaly or pericardial effusion. Fluid within the heart (H) (i.e., blood) cannot be distinguished from fluid around the heart because both silhouette or efface the same radiopacity (i.e., the soft tissue muscle of the heart). The ultrasound examination confirmed pericardial effusion was responsible for radiographic appearance. The fluid was aspirated (3 mL of cloudy yellow fluid) and was found to be inflammatory in nature, but no infectious organisms were identified. (Courtesy of Sam Silverman.)

effacement with the lungs can indicate enlargement of the silhouette (Fig. 54.8).[1,14] Enlargement in lizards is most commonly due to pericardial effusion or structural heart disease. Echocardiography provides the most specific structural and functional information about the heart (see Chapter 68).[13,15]

RESPIRATORY SYSTEM

The radiographic appearance of the lungs is highly influenced by the degree of inspiration or ventilation (see Fig. 53.4).[7] If the respiratory system is a primary concern, general anesthesia in stable patients may be elected, since positive pressure ventilation can be used to optimally inflate the lungs during exposure.[2] Because ventilation affects pulmonary radiopacity, it is important to use consistent pressure levels during inflation, especially when doing serial examinations. Overinflation of the lungs could be misinterpreted as a positive response to therapy.[1]

The lungs of lizards may be more radiolucent than mammalian species due to their larger air spaces (see Fig. 54.7A). Others, specifically more advanced lizards like many skink species, have more faveolar parenchyma in addition to the chambered lungs.[2,16] The radiolucency of the lungs should be uniform aside from pulmonary vasculature. The airways caudal to the trachea are not easily detected.[1] Lizard lungs are most easily evaluated on the lateral horizontal beam images. If the patient's coelom exceeds 6 cm in width, right and left lateral views are recommended.[1] The utility of dorsoventral vertical beam radiograph is hampered due to summation with the other coelomic structures, but it is the only view in which the right and left lungs can be individually evaluated. Hoey reported a unique presentation of unilateral lung hyperinflation in a New Caledonian giant gecko (*Rhacodactylus leachianus*) due to pulmonary-tracheobronchial prolapse that demonstrated the value of obtaining the dorsoventral image in addition to the lateral.[9]

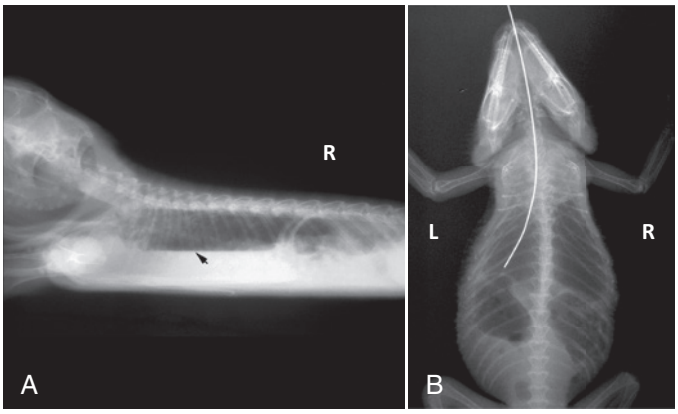

FIG 54.9 (A) Horizontal beam right lateral view of the cranial coelom of an adult bearded dragon (*Pogona vitticeps*) with an acute history of dyspnea. A distinct fluid line (arrow) can be seen. This is possible in lizards because of the more saclike conformation of the lungs. (B) Dorsoventral view of the same lizard following the introduction of a catheter with wire stylet and aspiration of lung exudate. (Courtesy of Stephen J. Divers.)

Radiographic examinations can be performed to investigate all portions of the respiratory tree. Infectious pneumopathies, including abscesses and granulomas, can produce areas of soft tissue consolidation(s) (see Fig. 54.7C).[16] These cannot be distinguished from neoplasia on radiographs. Pneumonia is uncommon in lizards but will also manifest as increased soft tissue opacity or in some cases as fluid accumulations.[2] Due to the saclike or chambered conformation of the saurian lung, fluid can accumulate and will be dependent on the horizontal beam radiograph (Fig. 54.9) producing a distinctly marginated gas-fluid line. This anatomical variation and the appearance of a lung cavity with gas and fluid differ greatly from the appearance of similar cavitations within mammalian lungs and may be misinterpreted if mammalian interpretation principles are applied. As in other species, computed tomography (CT) is a superior diagnostic modality for respiratory tract evaluation of reptiles (see Chapter 59).[7,16,17]

DIGESTIVE SYSTEM

The digestive system is more spread apart on the dorsoventral image, whereas the caudal coelomic anatomy is often dorsoventrally compressed (especially under sedation/anesthesia) on the lateral horizontal beam image. Therefore the spatial relation of the digestive tract is better visualized on the dorsoventral image.[1] Anatomically, the lizard digestive tract is reactively short (especially in carnivorous and insectivorous species) compared with mammals, but the transit time of ingesta is generally much longer. Some lizards are hindgut fermenters (i.e., green iguanas, chuckwallas [*Sauromalus* spp.]) and will therefore have large colons that may contain much fluid and/or gas.[2] Since there is no diaphragm, the relationship of the lungs and the stomach is dynamic. With lung hyperinflation, the stomach can be seen between the caudal aspect of the lungs (Fig. 54.10A and B). The duodenum extends from the pylorus in a caudal to cranial path between the stomach and the cecum. This is a unique variation of the lizard digestive tract that should be considered in interpretation.[6] The visibility of the gastrointestinal tract is highly influenced by the presence or absence of luminal content. An empty digestive tract, as well as the liver and pancreas, are poorly visualized on survey radiographs due to the low inherent soft tissue contrast within the coelom.[1,3,6] The introduction of coelomic gas (i.e., negative contrast coelomography) has been reported as a method to increase detail but is rarely utilized.[18] The presence of gas (often aerophagia) or ingesta aid in identifying the stomach. Therefore fasting

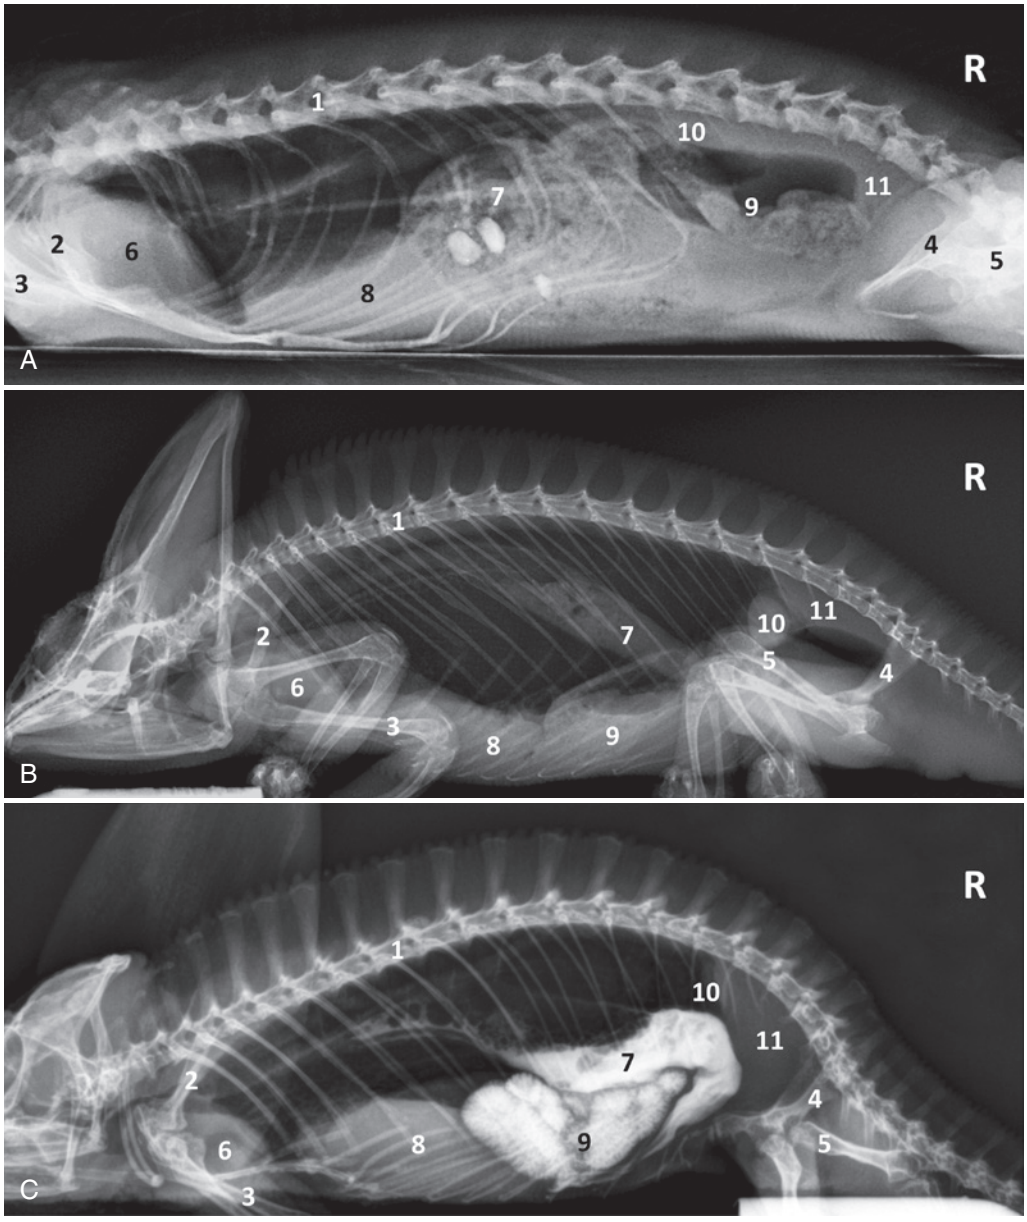

FIG 54.10 Right lateral horizontal beam radiographs of (A) green iguana (*Iguana iguana*), (B) veiled chameleon (*Chameleo calyptratus*), and (C) panther chameleon (*Furcifer pardalis*) following oral barium administration. Visible structures include the spine (1), scapulae (2), humeri (3), pelvis (4), femurs (5), heart (6), stomach (7), liver (8), intestinal tract (9), gonads (10), and kidneys (11). The contrast study demonstrates a variation from mammalian anatomy that is seen in lizards; the stomach extends caudally in the mid coelom, and the intestines largely occupy the ventral coelom rather than being positioned caudal to the stomach in the midcentral and midventral abdomen as is seen in mammals. (Courtesy of Stephen J. Divers.)

before radiography is not considered as important in lizards in that it improves visibility of the digestive tract. However, interpretation can be more challenging, since it requires decisions on the appropriateness of the food and its location in the gastrointestinal tract. The administration of barium or iodinated contrast can also be used to delineate the gastrointestinal tract (see Fig. 54.10C).

Radiographic examinations of the digestive system include the esophagus to cloaca. Disease processes commonly investigated with radiography include obstruction, foreign body ingestion, gastroenteritis, constipation, hepatomegaly or hepatic masses, and renomegaly, which can affect the gastrointestinal tract function.[2,3] Lizards often have mineral opaque bodies (such as rocks, gravel, or sand) in their digestive tract, which in moderation is noted as an incidental finding. Large volumes of these materials can result in impaction. Gastrointestinal dilation should be evaluated in terms of generalized versus segmental ileus.[7] When generalized (e.g., enteritis), a functional problem is more common and disrupts motility, resulting in progressive distention (Fig. 54.11). Segmental dilation is suggestive of obstruction and is characterized by orad enlargement of the digestive tract. This is most common with foreign body ingestion.[2,19] A variety of objects have been reported (including substrate) and tend to be dependent on accessibility within their habitat. Coins or other metallic items and gravel/sand accumulations are readily identified with radiography (Fig. 54.12A and B), but soft tissue opaque foreign bodies such as textiles can be more challenging (see Fig. 54.12C). Radiolucent objects or those having the appearance similar to ingesta are masked, and combinations of diagnostic imaging

VetBooks.ir

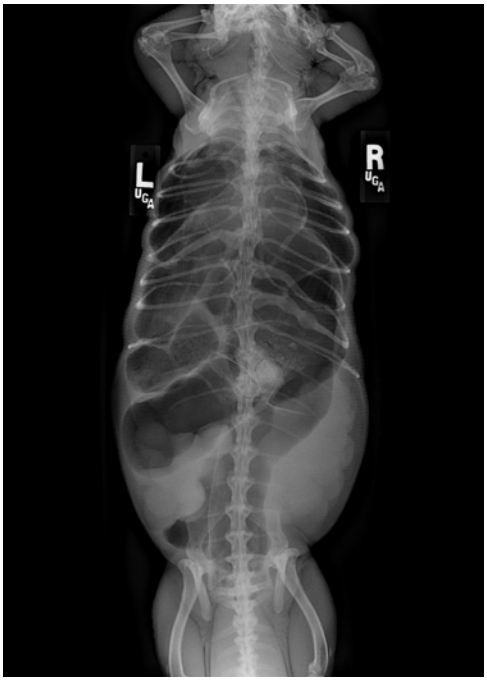

FIG 54.11 Dorsoventral radiograph of the coelom of a female green iguana (*Iguana iguana*) demonstrating extensive gastrointestinal gas from stomach to cloaca, as well as early ovarian activity. There is no evidence of a foreign body, and severe ileus secondary to bacterial gastroenteritis was later confirmed. (Courtesy of Stephen J. Divers.)

modalities have been advocated in these cases.[3,12,20] An obstructive gas pattern is not always seen and one must rely on knowledge of anatomy to determine whether a portion is inappropriately enlarged (see Fig. 54.12C). Sites to interrogate for foreign objects (i.e., where they become lodged) include the gastric lumen, intestines, or cloaca (see Fig. 54.12B). Masses in the saurian gastrointestinal tract follow similar interpretation rules as mammals. Identification of a mass effect is more difficult in lizards because of the poor serosal detail. Displacement of adjacent structures and abnormal gas foci are indicators of a soft tissue mass (Fig. 54.13). Depending on the origin of the mass, an obstructive pattern may also be present.

Numerous digestive tract radiographic contrast procedures have been discussed to improve contrast and anatomy identification, as well as to diagnose intestinal obstruction, foreign bodies, masses, and ileus. These procedures are time consuming because of the prolonged gastrointestinal transit times (which can take multiple days or even weeks) and the need to ensure that any delayed movement is indeed abnormal. Careful planning of these studies is important since it is not possible to remove the contrast once administered. These include positive (barium or iodinated) or negative (air) contrast. The most commonly performed contrast study is an upper gastrointestinal positive contrast study.[1,6,12,21,22] Typically, barium (25% weight/volume) is administered via an oroesophageal tube, and 25 mL/kg is administered. Alternatively, the volume of contrast medium administered should be similar to the volume used to tube feed a particular patient. It is important to sufficiently distend the stomach to initiate normal gastric reflexes for motility studies. These tests are preferred for evaluating motility or detecting obstruction; however, this volume of barium can mask gastric foreign material. Gastric masses or foreign bodies are better assessed with a double contrast study, using barium and air to distend the stomach. Since this improves contrast, it is reported that the study can be continued antegrade for intestinal evaluation as well.[1] If the issue involves the

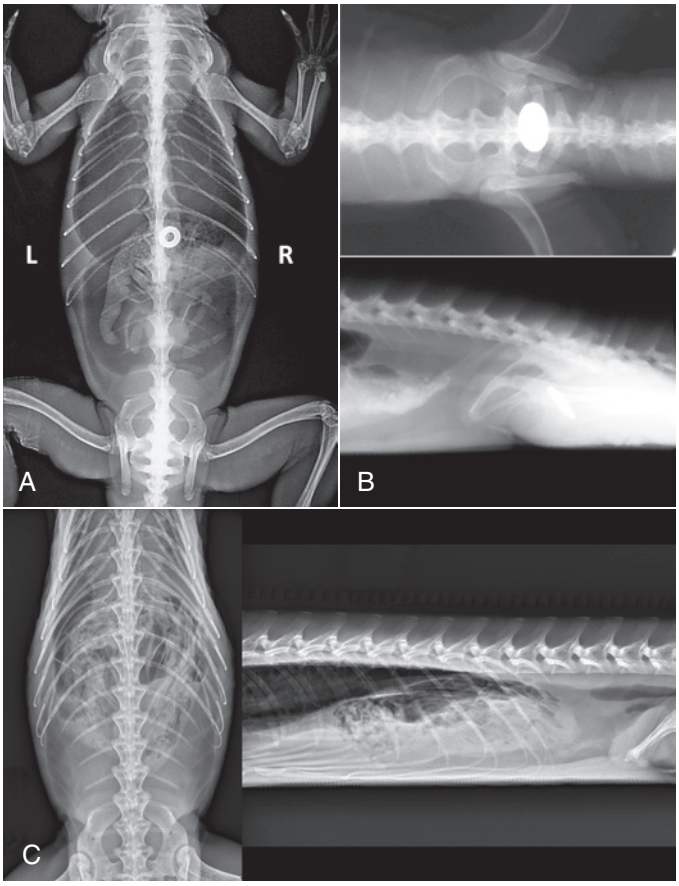

FIG 54.12 (A) Dorsoventral radiograph of a green iguana (*Iguana iguana*) after ingestion of a metal washer. Based on its position and the size of the foreign object, it is likely a gastric foreign body. (B) Green iguana (*Iguana iguana*) with intermittent signs of obstruction over several months. The foreign body (penny) is present in the cloaca of the lateral projection, but it is more obvious on the dorsoventral. (C) Dorsoventral and right horizontal beam lateral coelomic radiographs of a rock iguana (*Cyclura* sp.) that ingested a sock. The heterogeneous and fibrous nature of the textile can be appreciated, but it could be easily confused with fibrous food material. (A and C, Courtesy of Stephen J. Divers; B, courtesy of Sam Silverman.)

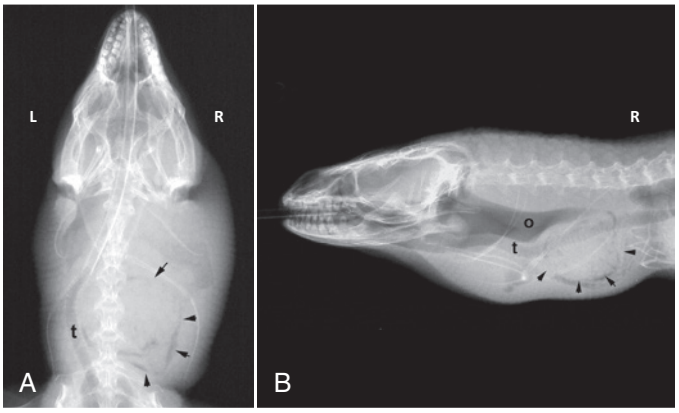

FIG 54.13 Dorsoventral (A) and right lateral (B) radiographs of a savannah monitor (*Varanus exanthematicus*) demonstrating a soft-tissue mass with intermixed and heterogeneous surrounding gas foci that is located within the right caudal cervical area (black arrows). Note that the trachea (t) is displaced to the left around this mass and the esophagus (o) is gas-filled, and the gas ends in a tapered manner around the craniodorsal aspect of the mass. Surgical exploration confirmed this mass to be an esophageal abscess. (Courtesy of Stephen J. Divers.)

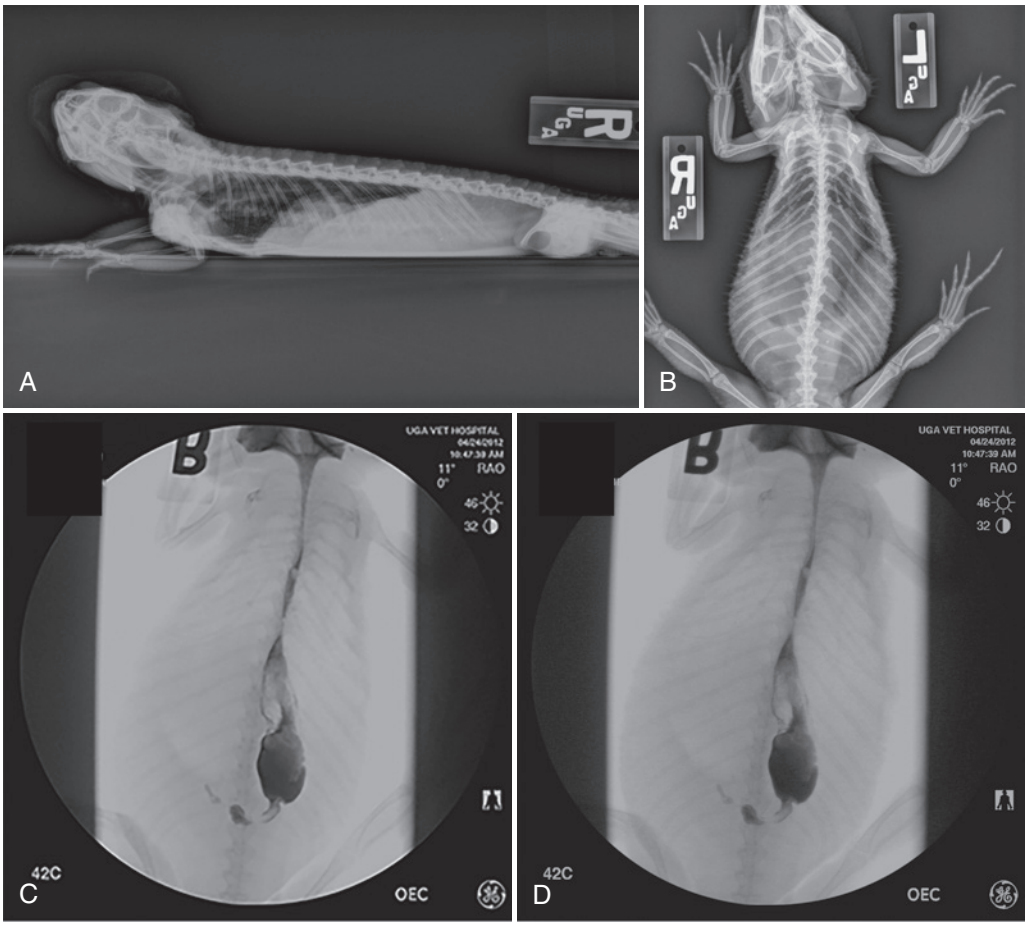

FIG 54.14 Orthogonal whole-body radiographs (A, right lateral horizontal beam; B, dorsoventral) of a bearded dragon (*Pogona vitticeps*) and two nonconsecutive fluoroscopic dorsoventral images (C and D) made after per os barium administration. There is a convex soft tissue opacity seen at the midcaudal aspect of the lungs, which is essentially midline on the dorsoventral image. It is seen in the area of the liver and stomach, and the lungs in this area are normal. In the positive contrast study, a persistent eccentric filling defect is present in the right lateral aspect of the stomach, which was confirmed to be a mural gastric mass. The remainder of the soft tissue in this area is enlarged liver with infiltrative nodules. Contrast is also seen in the first part of the duodenum. It should also be appreciated that respiration in lizards does not alter coelomic anatomy; the stomach is unchanged between end expiration (C) and end inspiration (D). (Courtesy of Shannon P. Holmes, Animal Cross-Sectional Imaging Specialists.)

cloaca, it is better to instill the contrast into the cloaca directly. Double contrast cloacograms, made following the instillation of nonionic iodinated contrast and air into the cloaca, have been used to define radiolucent cloacal foreign bodies or masses. These techniques can also be used with CT imaging to improve delineation of the digestive tract.

Contrast gastrointestinal studies have been described in a limited number of lizards. The normal appearance and transit times have been reported in the green iguana (*Iguana iguana*), bearded dragon (*Pogona vitticeps*), and partially in the common tegu (*Tupinambis teguixin*).[3,6,21] Radiographs are sufficient for upper gastrointestinal studies in lizards; however, fluoroscopy can also examine motility or persistence of a gastrointestinal abnormality, such as a mass or foreign body (Fig. 54.14). It is important that a large volume of barium contrast does not persist in the distal digestive tract given that it could, in rare instances, cause constipation.[1] Nonionic iodinated agents can be used; these have been shown to move through the gastrointestinal tract faster in other reptiles but have not been reported in lizards.[12,22,23]

In the age of ultrasonography and CT, the use of radiographs and contrast studies has diminished in the evaluation of the digestive system. However, there are important aspects to consider in continuing to use radiography and contrast. Radiographs offer a more global assessment of the coelom and can be easily sent in digital format for second opinions, compared with ultrasonograms. Contrast studies provide more longitudinal temporal information that is not possible with plain radiography, ultrasonography, or CT. The benefit of both ultrasonography and CT is not just in removing superimposition, but the parenchyma of the digestive organs (liver and pancreas) and the mural appearance of the gastrointestinal tract can be more thoroughly evaluated. As discussed previously, there is often great value in a multimodal imaging approach.

REPRODUCTIVE SYSTEM

Evaluation for gravidity (pregnancy) and dystocia are the most common reason for radiography of the reproductive system. This includes monitoring gravidity, detecting issues related to dystocia, or other conditions. Follicular stasis appears more common in lizards than other reptiles.[5] Normal developing ova are seen as spherical, soft tissue opacities in the caudal coelom bilaterally (Fig. 54.15).[5] They will summate or overlap and resemble a cluster of grapes.[1] Following ovulation, ova

develop thin mineralized shells and become eggs. These eggs may develop a more ovoid appearance and fill the caudal coelom to displace the intestines cranially. It is important to accurately describe the appearance of the eggs; abnormally large, irregularly shaped, or inappropriate mineralization is indicative of an issue that merits further investigation and possibly surgery.

Radiography can also be used for sex identification in lizards. Specifically, positive contrast introduced through the vent can be used to delineate the presence or absence of hemipenes.[24] Monitor lizards may have mineralized hemipenes and can be seen without contrast.[2] Case reports of radiography used in the clinical diagnosis of reproductive disorders include an ovarian teratoma and follicular torsion.[25] In both cases, radiography was the first line diagnostic imaging modality, and soft tissue masses or a mass effect were identified. Ultrasonography provided more specific details of the anatomy contributing to the radiographic appearance. Like the digestive tract, assessment of the reproductive tract benefits from a multimodal approach, especially where poor radiographic detail hampers the imaging diagnosis.

URINARY SYSTEM

Normal green iguana kidneys may be difficult to visualize as they are located within the pelvis; however, most lizard kidneys are located within the dorsocaudal coelom. The bladder (if present) may be difficult to identify because of poor coelomic detail.[1–3] Both kidneys and bladder should exhibit soft tissue opacity. A caudodorsal coelomic mass effect can be seen with renomegaly.[1,18] The cranial aspect of enlarged iguanid kidneys become visible cranial to the pelvis (Fig. 54.16A). Mineralization of the renal parenchyma makes identification of the kidneys easy

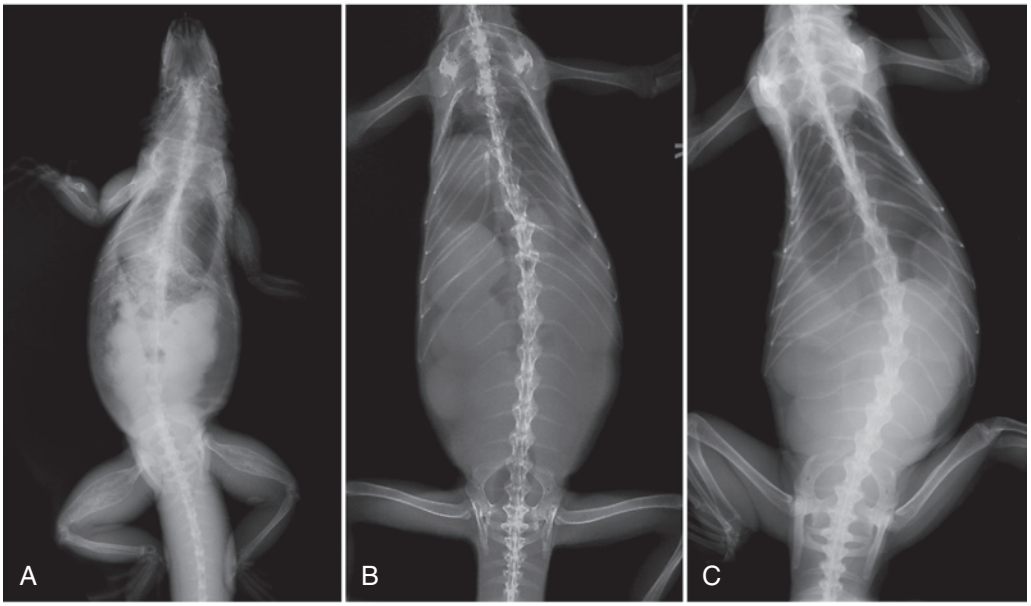

FIG 54.15 Dorsoventral radiographs of reproductive stages in iguanid lizards. (A) Early ovarian development and folliculogenesis with multiple small, rounded, soft tissue densities within the caudal coelom. Note the femoral changes consistent with nutritional secondary hyperparathyroidism, which is often unmasked when a female becomes reproductively active with increased calcium demands. (B) Preovulatory follicles are larger, spherical soft tissue densities that can occupy most of the coelomic cavity. (C) Postovulatory, thinly shelled eggs. (Courtesy of Stephen J. Divers.)

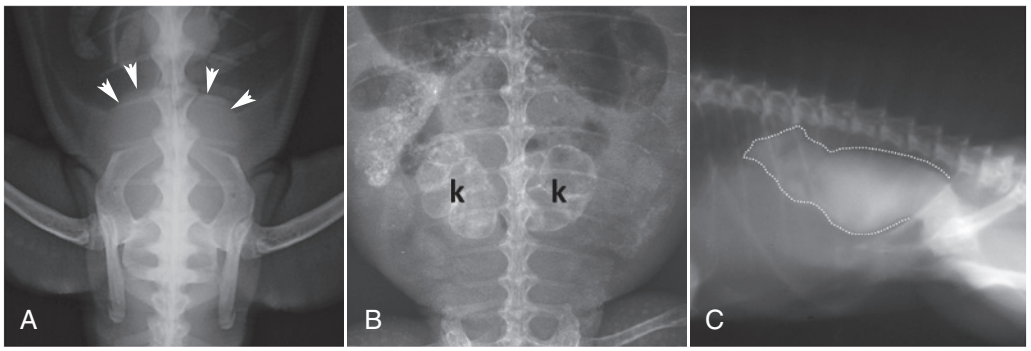

FIG 54.16 (A) Dorsoventral radiograph of the caudal coelom of a green iguana (*Iguana iguana*) demonstrating protrusion of the renal silhouettes (*arrows*) cranial to the pelvic rim, suggestive of renal enlargement. (B) Dorsoventral radiograph of the caudal coelom of a spiny-tailed lizard (*Uromastyx aegyptius*) demonstrating mineralization of both kidneys (*k*). (C) Lateral radiograph (excretory urogram) of a Chinese water dragon (*Physignathus cocincinus*) demonstrating an irregular cranial margin to the renal silhouette (dotted line) after intravenous iohexol administration. (Courtesy of Stephen J. Divers.)

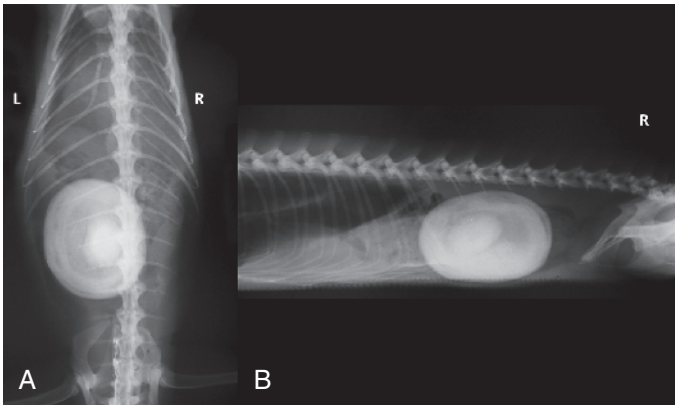

FIG 54.17 Dorsoventral (A) and right horizontal beam lateral (B) radiographs of an adult male green iguana (*Iguana iguana*) with a large urinary calculus. The calculus is composed of uric acid and mineral complexes, and the concentric rings of deposition can be appreciated. (Courtesy of Stephen J. Divers.)

(see Fig. 54.16B).[2] The visibility of the renal silhouettes can also be enhanced with negative contrast cloacography or excretory urography. The intravenously administered iodinated contrast will opacify the renal silhouettes to increase their conspicuity (see Fig. 54.16C).[18] An important consideration in the interpretation of renomegaly in iguanids is its effect on the lower intestine; these cohabitate in the pelvic canal, and enlargement of the kidneys can cause extramural compression of the colon.[26]

Urinary bladder calculi are not uncommon. Potassium or calcium salts are typically complexed with uric acid, making them radiographically detectable.[27] The presence of calculi can indicate dietary issues (e.g., excessive protein, dehydration), urine retention, or bacterial infection. When calculi are present, they can be more cranially positioned within the coelom than would be expected if extrapolating from mammals (see Fig. 53.3). They are typically irregularly marginated in shape or have an irregular, lamellated appearance and an irregular, rounded shape (Fig. 54.17).

Cloacal calculi are occasionally seen in lizards. After gentle irrigation and evacuation of the cloaca with warm saline solution, a radiographic double contrast cloacogram can be performed to identify masses, foreign bodies, strictures, and perforations.[1] The use of nonionic iodinated contrast media is preferred, because introduction of barium into the ureters or kidneys should be avoided. Contrast medium in a volume equal to 50% of the estimated cloacal volume is infused first, followed by infusion of room air in a volume equal to 100% to 200% of the estimated cloacal volume. Sometimes introduction of additional volumes of air between radiographic studies is necessary.

MUSCULOSKELETAL SYSTEM

The musculoskeletal system is one of the most common radiographic examinations in lizards. Radiographs are excellent for evaluating bones and, to a lesser extent, the associated soft tissues. They are most commonly used to evaluate for metabolic bone diseases (especially nutritional secondary hyperparathyroidism), trauma, infection, and neoplasia. The normal radiographic appearance of the musculoskeletal system in the green iguana, bearded dragon, common tegu, and leopard gecko (*Eublepharis macularius*) have been reported and are excellent references to have when embarking on interpretion.[28,29]

Metabolic bone diseases are common.[2] Oversupplementation with vitamin D_3 and calcium or renal disease can result in soft tissue

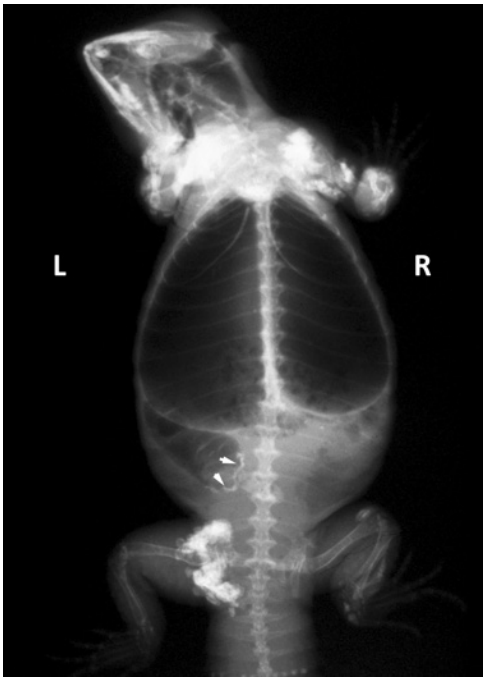

FIG 54.18 Dorsoventral radiograph of a spiny-tailed lizard (*Uromastyx* sp.) with hypervitaminosis D_3 due to excessive oral supplementation. Note the soft tissue calcification associated with the musculature of the pectoral girdle, forelimbs, left thigh, and gastric wall (*arrows*). There is also greater heterogeneity in the mineral opacity of the medullary bone, and the endosteal contours are irregular, which is most notable in the femurs. (Courtesy of Stephen J. Divers.)

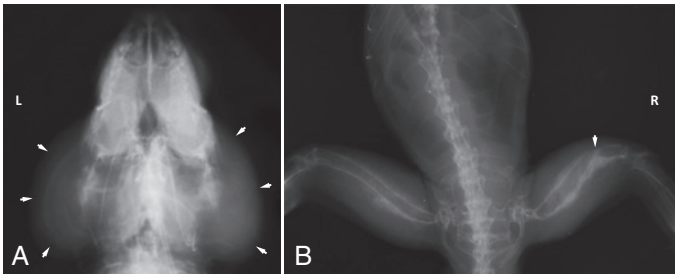

FIG 54.19 (A) Dorsoventral skull radiograph of a green iguana (*Iguana iguana*) with nutritional secondary hyperparathyroidism. Note the pronounced periosteal and fibrous proliferations associated with the mandibles (arrows), as well as generalized skeletal demineralization. (B) Dorsoventral radiograph of the pelvis and hind limbs of the same iguana. Note the poor skeletal mineralization, femoral periosteal reactions and fibrous changes seen as areas of soft tissue enlargement, and pathological folding fracture of the distal right femur (arrow). (Courtesy of Stephen J. Divers.)

mineralization (Fig. 54.18). Decreased mineral opacity of the skeleton is more common and frequently encountered as a consequence of poor diet or inadequate lighting (Fig. 54.19), or less commonly due to renal secondary hyperparathyroidism (Fig. 54.20).[1,2,27] This will affect both the axial and appendicular skeleton, but will be most obvious in the long bones (that normally exhibit distinct corticomedullary regions), pelvis, and spine. In addition to decreased bone opacity, the radiographic features of metabolic bone disease can include soft tissue enlargement associated with fibrous proliferation, thinned cortices, long bone bowing, and pathological fractures.[1,4,30] In contrast to mammalian species, the

VetBooks.ir

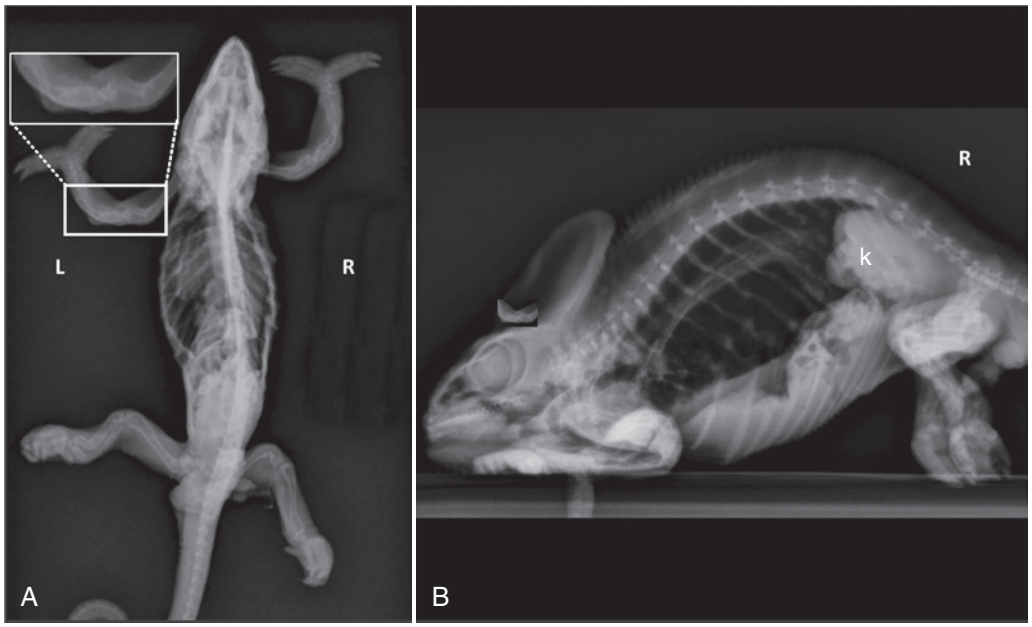

FIG 54.20 Dorsoventral (A) and right horizontal beam lateral (B) radiographs of a veiled chameleon (*Chameleo calyptratus*) with generalized skeletal demineralization, thin cortices, and pathological folding fractures of the long bones. There is increased soft tissue presence in the caudodorsal coelom in the region of the kidneys (k), suggestive of renal enlargement. Renal biopsy confirmed severe pathology and therefore the skeletal changes were associated with renal secondary hyperparathyroidism. (Courtesy of Stephen J. Divers.)

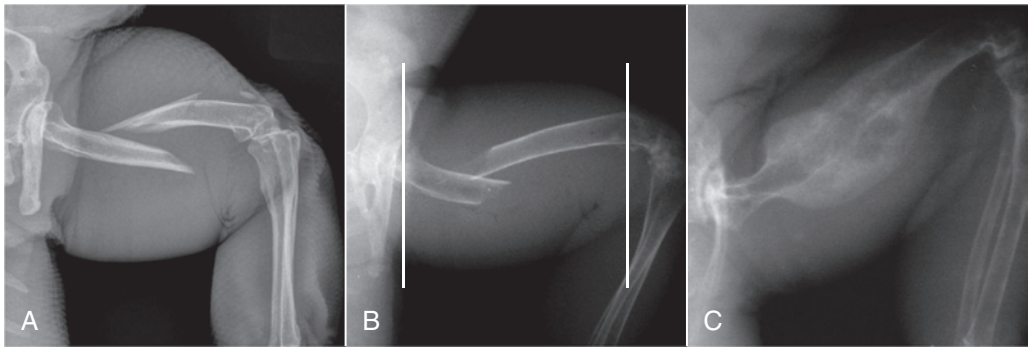

FIG 54.21 (A) Dorsoventral radiograph of an adult varanid lizard demonstrating a middiaphyseal fracture of the right femur. The fracture is comminuted and appears closed. The sharp fracture ends suggest an acute trauma and bone quality is suitable for internal fixation. (B) Lateral radiograph of a juvenile green iguana (*Iguana iguana*) demonstrating a middiaphyseal fracture of the right femur. There is no comminution, and the fracture appears closed. However, although the fracture ends are sharp, indicating an acute trauma, the thin cortices and reduced bone mineralization are consistent with nutritional secondary hyperparathyroidism, and external coaptation is more suitable. (C) Lateral radiograph of the same iguana's right femur 4 months later. The pronounced callus formation and remodeling is common after external coaptation. The appearance of the bone margins are smooth, indicating a healed fracture. Neither the periosteal proliferation nor the internal radiolucent areas are associated with infection in this case. (Courtesy of Stephen J. Divers.)

periosteal reaction seen in lizards with metabolic bone disease appears to be a unique reptilian manifestation.[1] With sufficient demineralization, angular limb deformities or pathological fractures develop due to bone softening. Clinical correlation in assessing metabolic bone diseases is important, since radiographic differentiation between different metabolic diseases and between active vs inactive disease can be challenging. With treatment, an increase in bone opacity and cortical thickness occurs, but the bones often have a decreased trabecular pattern and indistinct cortical borders compared with normal.[1]

Trauma can result in soft tissue injury, joint subluxation/luxation, or bone fracture. Digital luxations occur commonly and often require radiographs for detection, since they can be missed on physical examination.[1] Fractures are the most common traumatic injury evaluated radiographically. They can involve the appendicular or axial skeleton, but the former is more common. Initially, the fracture fragment edges have distinct margination (Fig. 54.21). If internal or external stabilization is performed, immediate postoperative radiographs are essential and will establish the baseline.[7] The alignment, apposition, apparatus, and activity of the bone ("the four A's") should be compared over recheck examinations. The appearance of healing bone, however, differs in lizards compared with mammalian species.[1] Bone healing involves the formation of a mixed fibrous and mineralized callus.[1] Thus, clinical healing usually

VetBooks.ir

precedes radiographic healing. This healing process should also be considered when performing recheck radiographic examinations. Initial recheck radiographs are sometimes recommended to assess if a change in the fracture following surgical intervention has occurred in the patient after recovery from anesthesia. Osteomyelitis is a common complication and radiographic evaluation 2 to 6 weeks after surgery is recommended. To assess fracture healing, longer postoperative periods are recommended, such as 8 to 16 weeks after the injury/repair (as opposed to mammalian recheck examinations after 4–8 weeks). This is to allow sufficient time for detectable mineralized callous formation in addition to the fibrous callous. A third set of radiographs can be acquired at 30 weeks.[1] Radiographic confirmation of complete bony healing may not be evident for more than 6 months.[31] It is also noted that lucent areas at or around the fracture site may be visible in a completely healed fracture (see Fig. 54.21C). This is not seen in normally healed mammalian species and is attributed to the mixed fibrous and mineral callous formed in lizards.[1,7] Trauma can also produce fractures in the skull and spine (Fig. 54.22). The clinical significance and possible therapeutic options are difficult to estimate from radiographic examinations. Therefore CT or magnetic resonance imaging (MRI) examinations could be considered (see Chapters 59 and 60). In lizards, it has also been noted that an exuberant periosteal response occurs with any insult (trauma or infection) on the vertebrae or ribs, compared with mammals (Fig. 54.23).[1,29] As a result, focal or diffuse regions of spinal rigidity may be identified clinically, with dramatic radiographic changes. The radiographic changes are often more dramatic than the clinical signs. The vertebral hyperostosis in lizards may secondarily occlude blood vessels, and some cases of tail necrosis from vascular occlusion have resulted.[1]

Since the osteoproductive component can have a similar appearance between prior trauma and infection/inflammatory bone disease, identification of vertebral lysis or irregularly contoured widened disc space(s) is more indicative of infection or inflammation. Skull infections are most commonly localized to the cranial maxillary or mandible (unless there is another cutaneous defect) and are often associated with cage-associated trauma. With mandibular and maxillary infection, there is progressive cortical and medullary bone lysis, consistent with osteomyelitis (Fig. 54.24). Periosteal new bone production and soft tissue enlargement are other features. Expansile deformities appear more common in the mandible, and teeth are frequently lost.[1] Appendicular osteomyelitis and infectious arthritis also produce aggressive and progressive lytic changes (Fig. 54.25).[2] Similar to fracture healing, bone healing

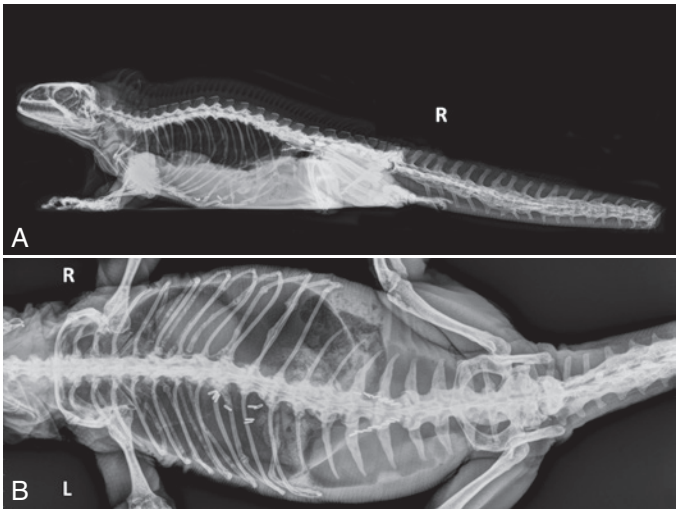

FIG 54.23 Horizontal beam right lateral (A) and dorsoventral (B) radiographs of an adult, spayed female green iguana (*Iguana iguana*) that presented with a rigid tail and reduced locomotion. The proliferative, expansile, and osteolytic changes associated with the caudal spine are characteristic of chronic osteomyelitis. In this case, the disease process has advanced into the caudal coelomic spine. (Courtesy of Stephen J. Divers.)

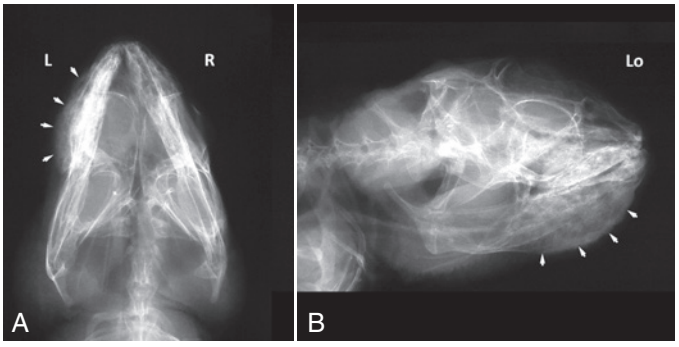

FIG 54.24 Dorsoventral and left lateral oblique radiographs of an iguanid with left mandibular osteomyelitis. Note the osteolysis, proliferative changes (*arrows*), and loss of definition associated with the left mandible. (Courtesy of Stephen J. Divers.)

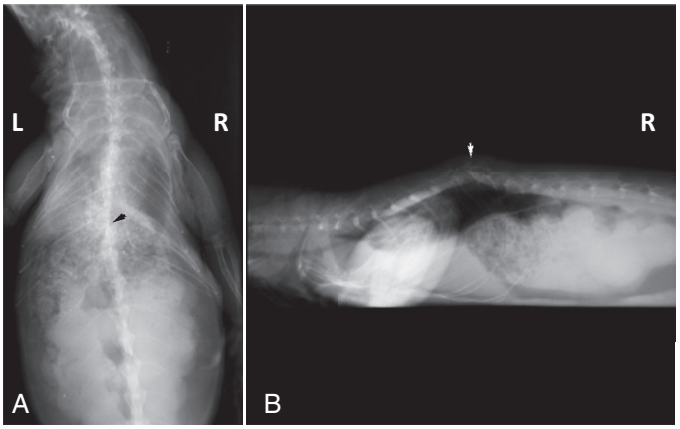

FIG 54.22 Dorsoventral (A) and right lateral horizontal beam (B) radiographs of an iguanid lizard with a vertebral fracture (arrows). There is evidence of generalized reduction in bone mineralization, which, given the obvious ovarian activity, is likely secondary to the increased calcium demands of reproduction. (Courtesy of Stephen J. Divers.)

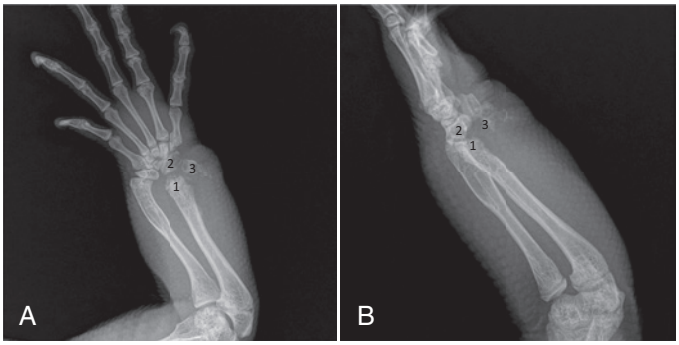

FIG 54.25 Dorsopalmar (A) and lateral (B) radiographs of the right forelimb of a green iguana (*Iguana iguana*) demonstrating osteolysis associated with the distal ulna (1), ulnar metacarpal bone (2), and accessory carpal (or pisiform) bone (3). There is also pronounced soft tissue swelling associated with the carpus. These radiographic findings are consistent with osteomyelitis and septic arthritis, but cytology or biopsy and culture are required for confirmation. (Courtesy of Stephen J. Divers.)

VetBooks.ir

after osteomyelitis can have persistent lucent defects; this can make determination of resolution more challenging radiographically, and clinical correlation is essential. This lucency can be a focus of inflammation or nonossified fibrous tissue without infection or sequestration. Septic arthritis is also a largely lytic process in lizards (Fig. 54.26). Lysis is seen in the subchondral bone plate predominantly and extending into the epiphysis. Concurrent detection of synovial effusion, proliferation, intraarticular fibrous proliferation, or joint distention is dependent on accurate joint assessment. For example, it is difficult to detect intracapsular changes in the glenohumeral joint because of its position, whereas soft tissue enlargement of the distal joints is easier to detect due to the lack of adjacent anatomy.

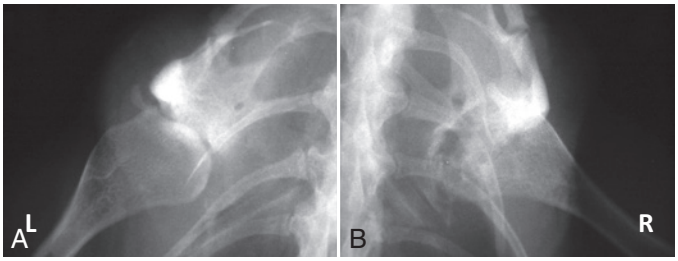

FIG 54.26 Dorsoventral radiographs of the left (A) and right (B) scapulohumeral joints of a green iguana (*Iguana iguana*) that presented with right forelimb lameness. Note the obvious irregularities and articular losses associated with the right humeral head and glenoid cavity. Joint aspiration confirmed septic arthritis. (Courtesy of Stephen J. Divers.)

MISCELLANEOUS

Abscess formation is common in lizards, and radiography is a critical step before surgical debridement in most cases.[2] Primarily, radiographs are used to evaluate involvement of regional tissues, such as detection of osteomyelitis. The extent of an early abscess might also be delineated with iodinated contrast injection into the abscess, although the inspissated nature of chronic forms renders this technique ineffective.

Radiography—Snakes

Jessica R. Comolli and Stephen J. Divers

Diagnosing internal disease in snakes can be challenging even for experienced veterinarians. Clinical signs are often subtle, and physical examination findings are seldom pathognomonic. Radiography is an essential tool; however, a thorough knowledge of snake anatomy, physiology, and pathology is required for proper acquisition and correct interpretation of images. The large number of snake species and the considerable morphologic and anatomic variability that exists contributes to the challenge.[1] Moreover, there is a relatively small amount of published information regarding imaging techniques and interpretation and a lack of clear guidelines for normal and abnormal radiographic parameters for these species. Additionally snakes have poor radiographic visceral contrast related to the close anatomic proximity of internal organs, the lack of periorgan fat (which is localized into discrete fat bodies), the absence of a clearly demarcated thorax and abdomen, and image degradation from heavily keratinized scales.

Fortunately, with a recent increase in published imaging information and studies, and now more affordable and improved digital radiology technology available, practitioners are capable of producing high detail images that can be electronically shared. The goals of this chapter are to describe proper techniques for radiographic positioning, illustrate normal radiographic anatomy, and discuss the principles of radiographic interpretation in snakes.

RESTRAINT AND POSITIONING

When conscious, snakes are relatively difficult to position and restrain for radiographic examinations. General anesthesia or heavy sedation is typically required (see Chapters 48 and 49). When relaxed, positioning is easier and eliminates spinal curvatures associated with normal muscular contractions. Furthermore, if detailed examination of the skeletal, respiratory, and digestive system is desired, the snake must be fully extended (Fig. 55.1). Radiographs of a coiled snake are not recommended because the internal organs are distorted and symmetry of the spine and ribs is compromised. However, if the purpose of the examination is to confirm a specific structure (e.g., radiodense foreign body or eggs/fetuses), then a coiled positioning study may be acceptable.

Unanesthetized snakes may be taped to a padded board or restrained with sand bags; however, care should be taken to avoid scale damage or bruising, and most snakes will still distort and create positional artifacts. Alternatively, the snake can be placed inside an acrylic tube, although this may also produce radiographic artifacts, and positioning will rarely, if ever, be ideal (see Fig. 55.1). A slight increase in the kilovolt peak to compensate for the acrylic's filtration of the radiograph beam may be necessary. The diameter and wall thickness of the tube should be as small and as thin as possible to minimize the object-film distance

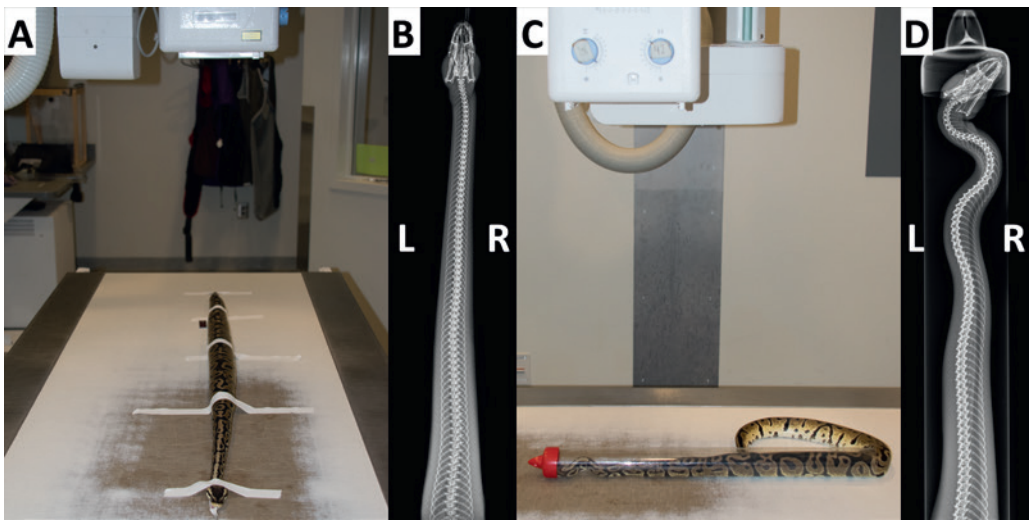

FIG 55.1 Positioning and corresponding dorsoventral radiographs of an anesthetized (A and B) and conscious, tubed (C and D) adult female ball python (*Python regius*). Although the use of plastic, radiolucent tubes does permit radiography of conscious snakes, positioning is still less than ideal. In this case the conscious snake radiograph exhibits significant spinal rotation to the left, and the cervical spine is not straight. (Courtesy of Stephen J. Divers.)

and to immobilize the patient effectively. The acrylic tube should not have perforations or other openings over the radiographed area, because these may produce image artifacts.

Radiography of most snakes requires the acquisition of serial films of the whole body or can be limited to a region of interest (e.g., the respiratory tract, stomach, kidneys). Familiarity with internal anatomy is essential for localization of the radiograph beam (Fig. 55.2).[2] Localization of the cardiac apex motion on the ventral abdominal wall can be used as a reference point for the beginning of the lung tissue in most snakes (Fig. 55.3). Accurate labeling of serial films is essential to relate a radiographic lesion with a specific body region or organ. Radiopaque markers can be taped to the skin, and metallic number markers are ideal for this purpose.[3] The numbers are attached to the skin in a sequential manner so that the contiguous segments can be identified on the multiple images.

Orthogonal views are recommended for evaluation of major organ systems, with dorsoventral projections obtained using vertical x-ray beams and lateral projections using horizontal beams. Lateral views are best taken using a horizontal beam to avoid displacement artifact of the viscera and to more accurately detect fluid lines (Fig. 55.4). Unlike most other reptiles, when positioning snakes for horizontal radiograph beam studies, their bodies can be placed very close or even in direct contact with the radiograph cassette, thus increasing radiographic detail and decreasing magnification. However, standard (vertical beam) lateral views can still be useful where horizontal beams are not possible or safe to undertake, but these technique details must be shared with the interpreter. The interpretations of dorsoventral views are hindered by the spine and ribs but are still useful when dealing with obvious structures, such as eggs, or pathology, such as mineralized masses or bony lysis.

CARDIOVASCULAR SYSTEM

Depending on species, the heart generally lies between 20% to 36% snout-to-vent length (SVL); however, it has been found to be more cranial in some arboreal snakes and caudal in aquatic snakes due to

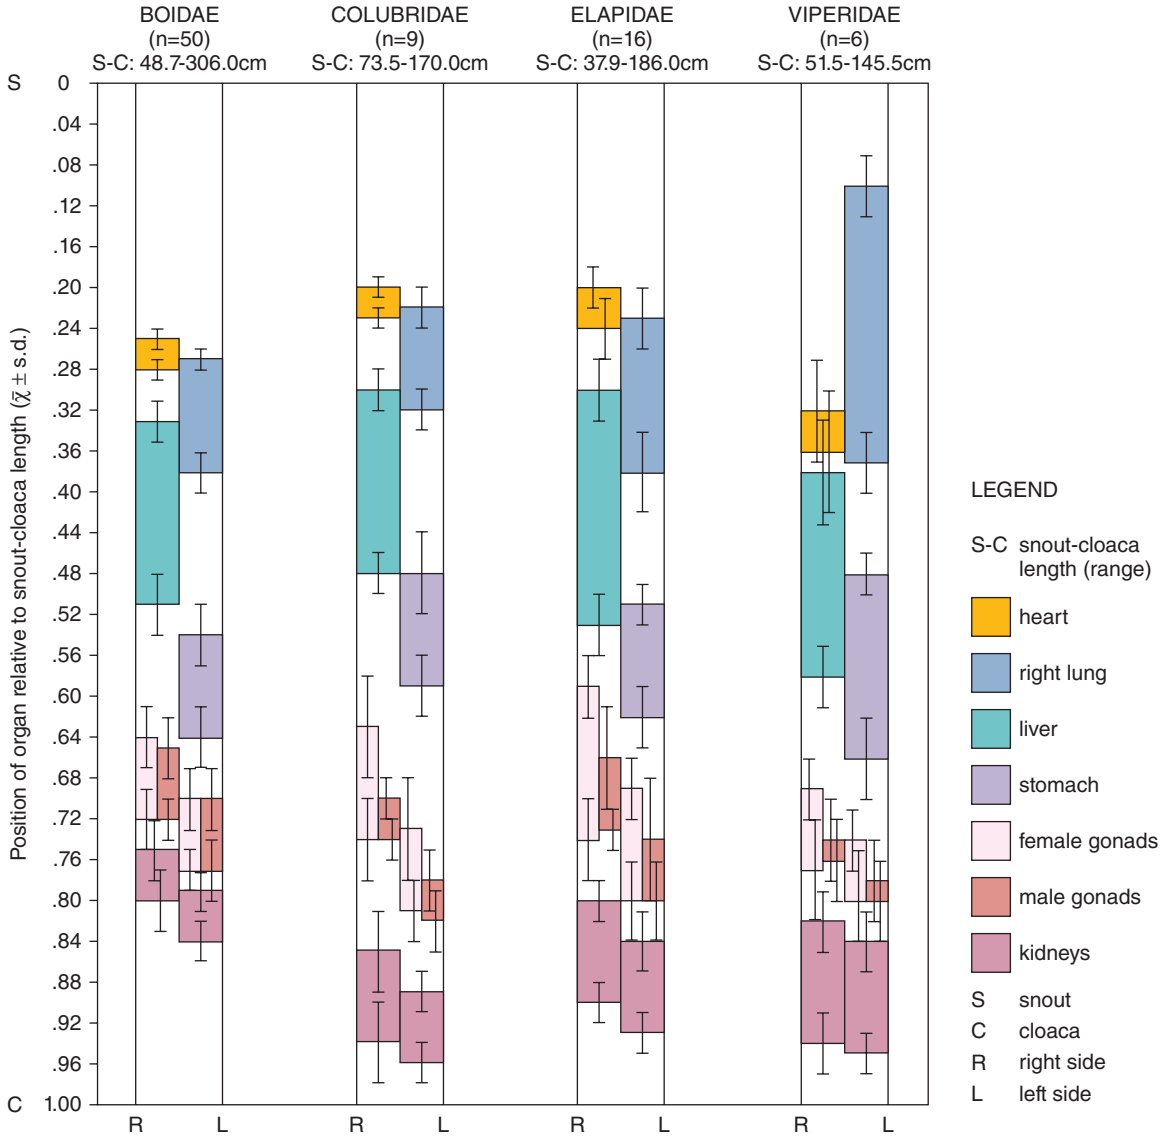

FIG 55.2 Position of internal organs relative to body length; family mean data. (Adapted with permission from McCracken HE. Organ location in snakes for diagnostic and surgical evaluation. In Fowler ME, Miller RE, eds. *Zoo and Wildlife Medicine: Current Therapy,* 4th ed. Philadelphia: WB Saunders; 1999;243–248.)

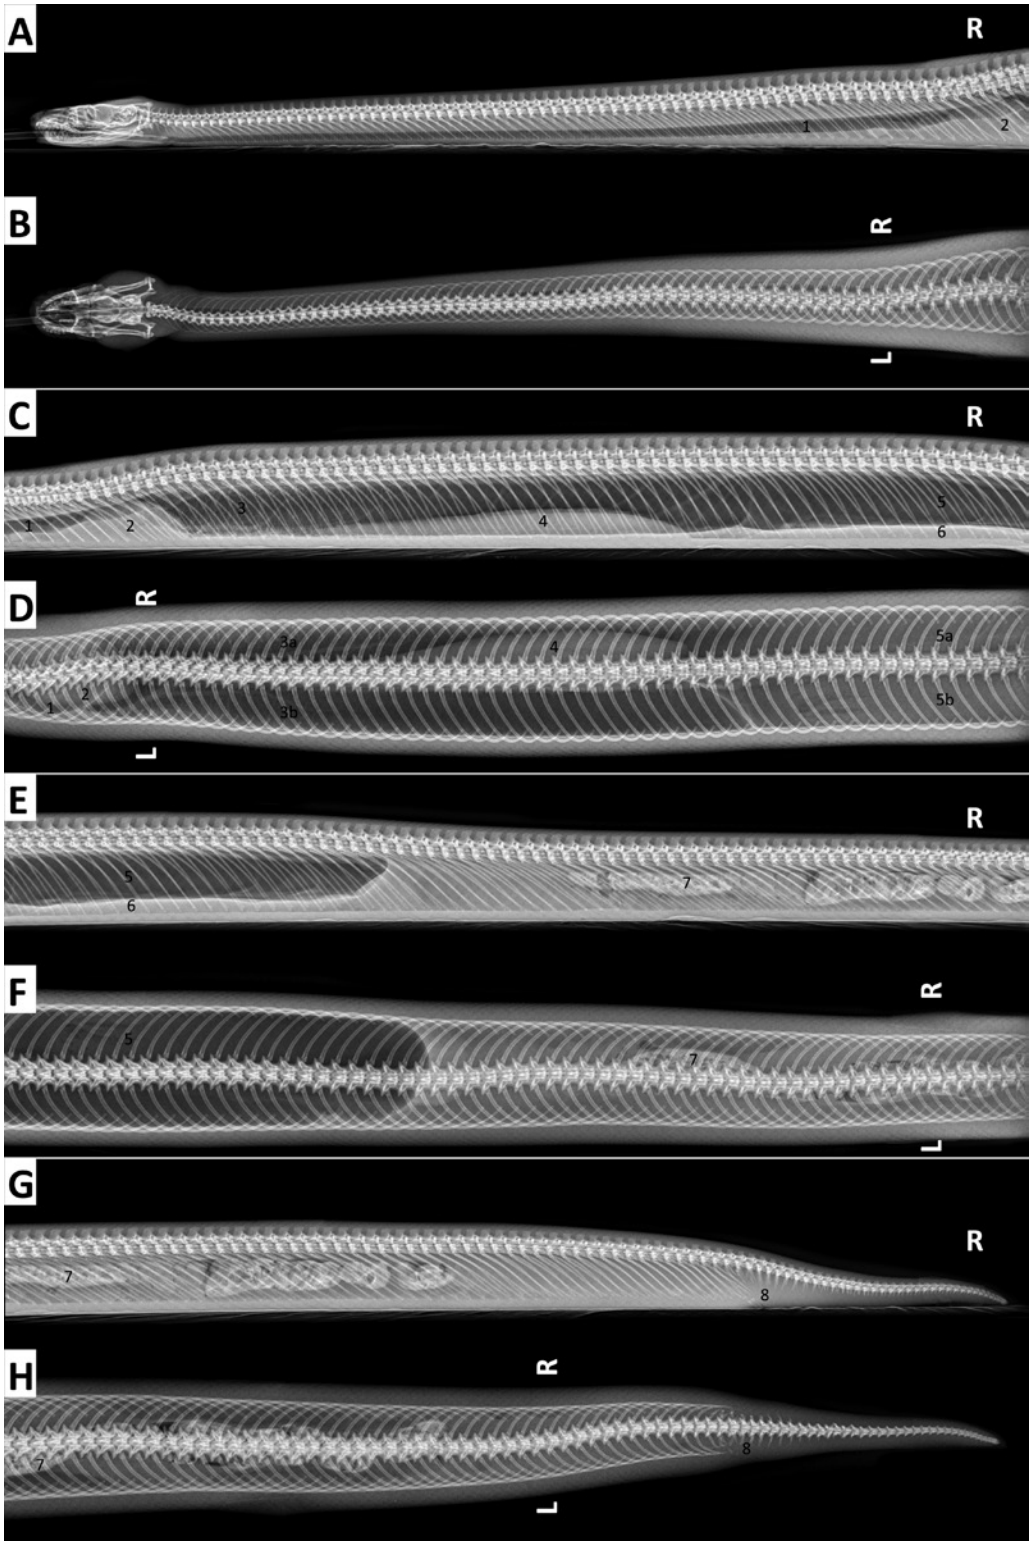

FIG 55.3 Horizontal beam right lateral (A, C, E, G) and corresponding dorsoventral radiographs (B, D, F, H) of a clinically healthy, fasted, adult female ball python (*Python regius*); (1) trachea, (2) heart, (3) vascular lungs (a right, b left), (4) liver, (5) saccular lungs (5a right, 5b left), (6) empty stomach, (7) feces within large intestine, and (8) cloaca. FIG 55.4 Positioning and corresponding horizontal beam (A and C) and vertical beam (B and D) right lateral radiographs of an anesthetized ball python (*Python regius*, 25%–65% snout-to-vent length). Note the displacement of the liver (1) and stomach (2), which has resulted in an apparent reduction in the size of the vascular (3) and saccular lungs (4). Visceral displacement and an inability to detect fluid lines are the primary reasons for recommending horizontal beam lateral views over the more usual vertical beam technique used in small animal practice. (Courtesy of Stephen J. Divers.)

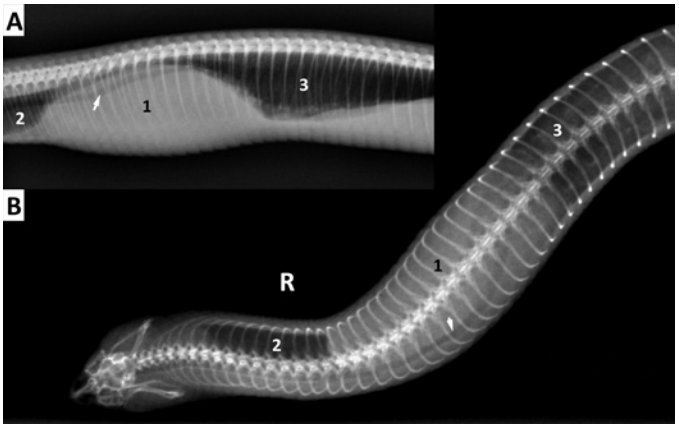

FIG 55.5 Right lateral (A) and dorsoventral (B) radiographs of a western hognose snake (*Heterodon nasicus*), centered over the heart (25% snout-to-vent length). The trachea (arrow) has been displaced dorsad and left laterad by a gross enlargement of the cardiac silhouette (1), which is bordered by an air-filled esophagus (2) and the primary faveolar lung (3). Enlargement of the cardiac silhouette can be associated with pericardial effusion, cardiomegaly, or other soft tissue masses adjacent to the heart. (Courtesy of Stephen J. Divers.)

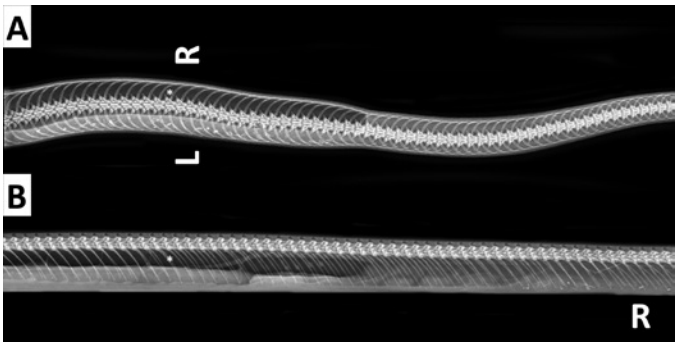

FIG 55.6 Dorsoventral (A) and horizontal right lateral (B) radiographs of a corn snake (*Pantherophis guttatus*, 50%–85% snout-to-vent) demonstrating the single, right lung (*) typical of most snakes. (Courtesy of Stephen J. Divers.)

gravitational effects and evolution in these species (see Fig. 55.2).[4–7] Radiographically, the heart is not usually well visualized on the dorsoventral view unless grossly enlarged but can be consistently evaluated on the lateral view (horizontal X-ray beam preferred) (see Fig. 55.3). Air within the trachea and cranial lung usually provide good contrast for the dorsal and caudal margins of the cardiac silhouette. Enlargement can indicate pericardial effusion or cardiomegaly. Cardiomyopathy, congenital etiologies, neoplasia, and congestive heart failure have been reported to cause cardiomegaly in snakes (Fig. 55.5).[8–15] Echocardiography is recommended after radiographic identification of enlargement of the cardiac silhouette. Postprandial concentric cardiac hypertrophy has been reported in boids and should be considered in species that consume large, infrequent meals.[16,17] Metastatic mineralization of large blood vessels around the heart can also be seen radiographically due to the negative contrast associated with the adjacent lungs.

RESPIRATORY SYSTEM

The lung(s) of snakes generally lie caudal to the heart at approximately 25% to 60% SVL in most species; however, in those species with tracheal lungs, the pulmonary tissue may start as cranial as 6% SVL (see Fig. 55.2). Most snakes, with the exception of boas and pythons, have only a single functioning right lung, with the left either absent or vestigial (Fig. 55.6).[3,18] Radiographically, snake lung(s) are visualized on the lateral view, and horizontal beams are again preferred to detect fluid lines and avoid organ displacement changing the appearance of the pulmonary

VetBooks.ir

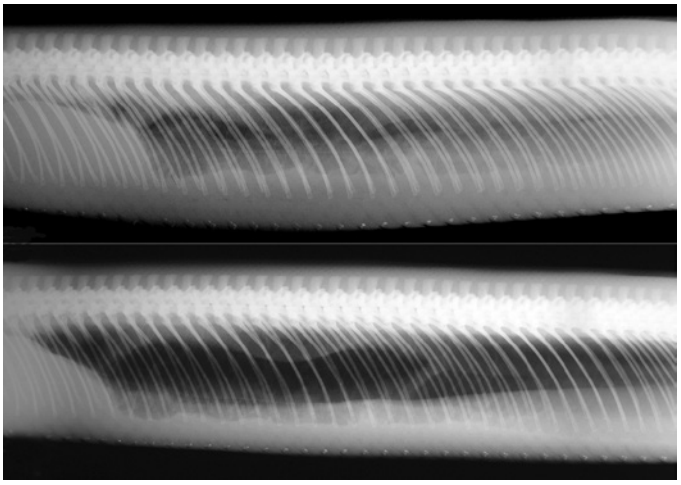

FIG 55.7 Boa constrictor (*Boa constrictor*). The radiograph (horizontal radiograph beam, lateral view) was made with the patient during expiration (top) and at peak inspiration (bottom). The lungs are more lucent and larger on the inspiratory radiograph. The cardiac silhouette on the left of the images serves as a point of reference.

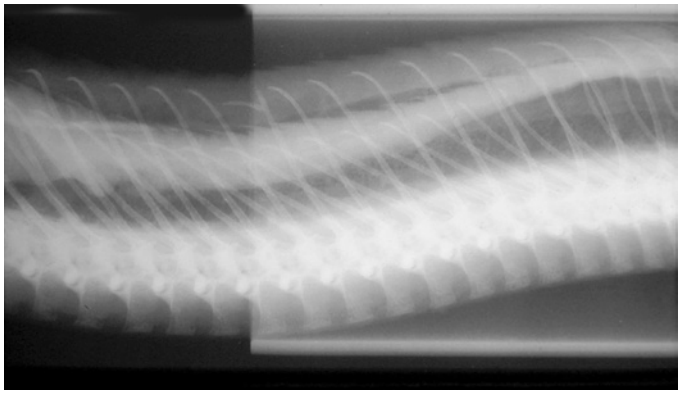

FIG 55.8 Acrylic positioning devices (right side) can increase radiopacity and decrease image detail.

structures. If the patient's diameter exceeds 6 cm, both right and left lateral views are recommended.

The trachea can be visualized as a radiolucent line in the cranial third of the body extending from the head to the cardiac silhouette (see Fig. 55.3). Tracheal masses can often be appreciated if present. The lung becomes a thin-walled saccular structure caudally and may extend close to the level of the cloaca in some species. Overlap of other organs such as liver and stomach over the lung fields can make the radiographic interpretation of respiratory disease challenging, especially with vertical beam lateral views.

The phase of the respiratory cycle at which the radiographic exposure is made is critical and ideally should coincide with the peak of inspiration (Fig. 55.7). Endotracheal intubation and positive pressure inflation of the lungs (10–15 cm of water) for radiography are highly recommended; however, positive pressure ventilation does influence the radiographic appearance of the lungs. The volume of the lungs can be increased with positive pressure ventilation far in excess to what is present with spontaneous respiration. A subsequent diffuse decrease in pulmonary radiopacity has been seen with hyperinflation and in positive pressure studies (see Fig. 55.7). Thus care must be taken when evaluating these films, as they can be misinterpreted as an indicator of a positive response to therapy. The effect of positioning devices on lung opacity and detail must also be considered (Fig. 55.8). Additionally, radiographic studies should not be performed in close proximity to feeding, as distention of the digestive tract often compromises pulmonary inflation, and the radiopacity of the ingesta may obscure detail of superimposed structures.

Common indications for evaluating the respiratory system are rhinitis, stomatitis, and suspected neoplastic and infectious disorders of the trachea and lungs, as well as abscesses or granulomas (Fig. 55.9; also see Chapters 76 and 162).[19–21] As in other reptiles, because the structure of snake lungs (faveolar and saccular) differs greatly from mammals, the standard radiographic patterns (i.e., alveolar, interstitial, bronchial, pleural) used to describe the radiographic appearance of the mammalian lung are not applicable. Snake lungs have a relatively homogeneous radiopacity with more prominence to the pulmonary structure in the cranial vascular region. Airway markings are generally indistinct to indistinguishable throughout, but the intrapulmonary bronchus can sometimes be appreciated. The radiographic manifestation of consolidative pulmonary disease (e.g., pneumonia) is increased pulmonary opacity, either diffuse (most common), focal, or multifocal.[22] Exudate or fluid accumulation may be appreciated as a fluid line on horizontal beam lateral views. Radiographic appreciation of respiratory disease may be limited, however, as changes may not become obvious until advanced.[1,18] Further examination by endoscopy, computed tomography (CT), or magnetic resonance imaging (MRI) may be indicated for snakes with less-advanced disease (see Chapters 59, 60, and 64).

GASTROINTESTINAL SYSTEM

The snake digestive tract is relatively short in length but has a longer transit time than mammals.[23] Snakes are ectothermic with low metabolic rates, and intervals between feedings are much longer than in mammals and many other reptiles. Many gastrointestinal diseases can affect snakes. Most etiologies are related to husbandry (e.g., improper temperature, inappropriate nutrition); gastrointestinal parasitism; gastroenteritis; or intestinal obstructions caused by foreign bodies, impaction, intussusceptions, or tumors.[24–26] Common clinical indications for evaluating the digestive system include chronic regurgitation and any coelomic swelling (e.g., hypertrophic gastritis, foreign body ingestion/impaction, constipation, hepatomegaly and hepatic masses, and other intracoelomic masses) (Fig. 55.10).

The digestive tract and the accessory organs (i.e., liver and pancreas) are poorly visualized on survey radiographs. Poor tissue contrast and serosal detail is seen because of the close apposition of internal organs and the paucity of periorgan fat. The stomach can be easily identified if gas-filled (usually from aerophagia) or radiopaque food was recently ingested, but there is often superimposition of the liver cranially and the gonads caudally. The appearance of the digestive tract is significantly affected by the time of previous feeding, the nature of the ingesta, and the species of the patient. In snakes, ingesta can often be identified as a bolus of material that produces a regional enlargement of the digestive tract. As the ingesta becomes more digested, the bolus becomes less distinct and is more diffusely distributed. Fecal material can often be identified by its heterogeneous presence due to the hair within.

The esophagus extends from the oral cavity to the stomach and is not normally visualized unless gas or contrast material is present. The stomach is located in the middle third of the body, approximately 45% to 65% SVL (see Fig. 55.2 and Fig. 55.3). Often, the radiodense skeletal remains of recently ingested prey can be visualized in the stomach. Ingesta of varying opacities can be observed in the small and large intestines in the caudal third of the body (positioned approximately 65%–100% SVL). Large

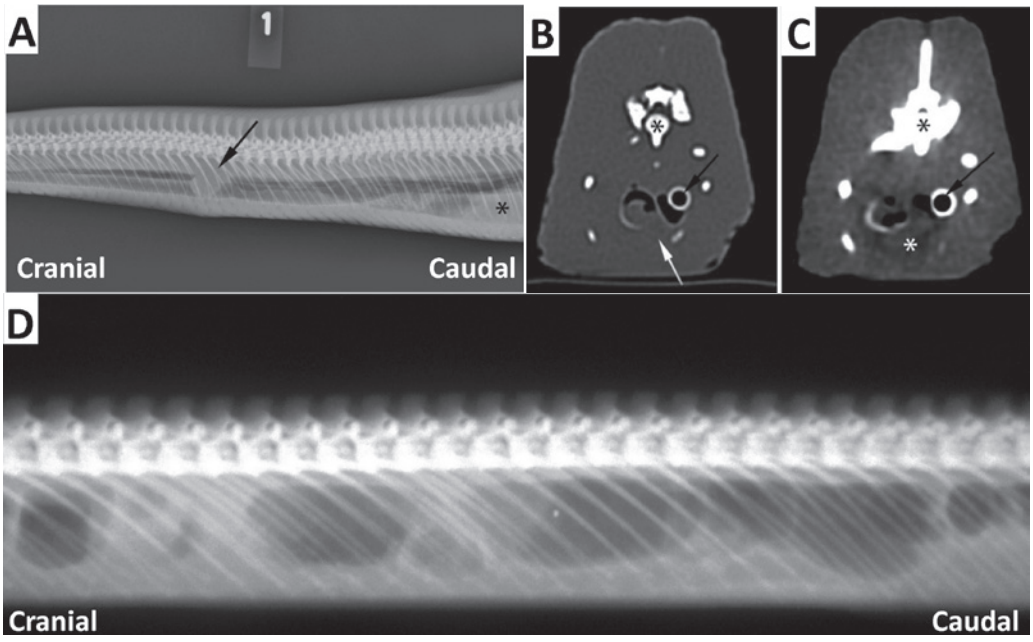

FIG 55.9 (A) Right lateral radiograph of the tracheal region of an 8-year-old boa constrictor (*Boa constrictor*). A round, soft-tissue mass (black arrow) is invading the tracheal lumen at the level of the midtrachea, cranial to the heart (asterisk). (B and C) Transverse computed tomography images of the cervical area of a boa constrictor in a lung algorithm (B) and soft-tissue algorithm (C) revealed a soft tissue mass partially obstructing the tracheal lumen (white asterisk). The mass extends ventrally and medially beyond the tracheal wall (white arrow), close to the esophagus (black arrow). A rubber tube has been inserted into the esophagus to delineate this structure during image acquisition (black arrow). The black asterisk indicates the cervical vertebrae. (D) Horizontal beam, right radiographic view of the cranial coelom (30%–50% snout-to-vent length) of a ball python (*Python regius*) demonstrating multifocal areas of increased soft tissue density throughout the vascular lung due to mycobacteriosis. (A–C, Reproduced with permission from Summa NM, Guzman DS-M, Hawkins MG, et al. Tracheal and colonic resection and anastomosis in a boa constrictor *[Boa constrictor]* with T-cell lymphoma. *J Herp Med Surg.* 2015;25:87-99; D, courtesy of Stephen J. Divers.)

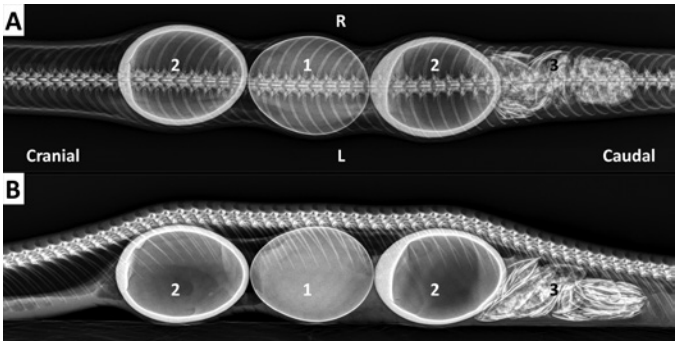

FIG 55.10 Dorsoventral and horizontal beam right lateral radiographs (40%–65% snout-to-vent length) of an eastern black rat snake (*Pantherophis alleghaniensis*) that was found poorly responsive with a pronounced midbody swelling. Note the normal chicken egg (1) along with two artificial ceramic eggs (2) and additional collapsed chicken eggs caudad (3). Gastric foreign bodies are not uncommon in snakes and often require endoscopic or surgical removal. (Courtesy of Stephen J. Divers.)

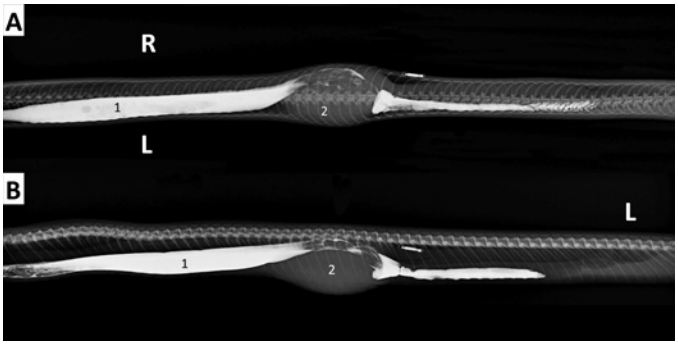

FIG 55.11 Dorsoventral (A) and vertical beam left lateral (B) radiographs of a speckled king snake (*Lampropeltis getulua holbrooki,* 45%–65% snout-to-vent). The snake presented with a midbody swelling and films were taken after barium administration. Note the barium within the stomach (1) and the gastric compression by a soft tissue mass effect (2). A microchip is also visible. The mass was confirmed as a gastric leiomyosarcoma. (Courtesy of Rodney W. Schnellbacher, Dickerson Park Zoo.)

intestinal gas, if present, is often the only contrast visible in plain films of the caudal coelom. The cloaca lies at the level of the last pair of ribs.

Although orthogonal projections are recommended in all cases, the lateral view provides the best visualization of the digestive tract in snakes. Digestive tract radiographic contrast procedures can be helpful for documentation of gastroenteritis and gastric hyperplasia and are often necessary for intestinal obstruction and foreign bodies. In addition, contrast material in the gastrointestinal tract can often outline and help determine the origin of nonspecific intraluminal or extraluminal intracoelomic masses (Fig. 55.11).

CONTRAST RADIOGRAPHY

Contrast media can be used in many instances to increase the yield of radiographic diagnostic information. Gastrointestinal studies with contrast agents enable detection of partial or complete obstructions,

VetBooks.ir

intraluminal masses originating from the digestive tract, enhancement and differentiation of extraluminal masses, and the evaluation of the digestive transit time.[24] For gastrointestinal contrast studies in snakes, standard orthogonal views should be routinely used, although oblique radiographs may be needed to assess a particular abnormality (Fig. 55.12).

Contrast agents include barium products (suspension and impregnated markers) and organic iodinated liquid (low and high osmolality). Barium sulfate is a noniodinated compound that is the standard agent for routine contrast studies of the upper and lower gastrointestinal tract. Barium is ideal in that it provides excellent detail of the gastrointestinal structures, is readily available, and inexpensive.[27] However, it can become desiccated in the digestive tract and result in intestinal obstruction, especially if a large volume of contrast medium is used and remains in the digestive tract for a long time. Although this is not a common complication, it should be considered in patients with preexisting ileus or dehydration. If a large volume of contrast medium is present in the distal colon or cloaca after completion of the study, it should be gently massaged out with external digital pressure. Alternatively, it can be evacuated by cloacocolonic catheterization and lavage using sterile saline. In mammalian radiography, barium sulfate is contraindicated if gastrointestinal perforation is suspected because of the risk of severe peritonitis.[28,29] Although not evaluated in snakes or other reptiles, alternative water-soluble iodinated agents should be used in cases of suspected perforation and intestinal adhesions, as they are known to be quickly absorbed from the peritoneal cavity with little to no adverse effects in mammals.[30,31]

Iodinated contrast water-soluble agents can be separated into two groups: ionic (high osmolarity) or nonionic (low osmolarity). Iodinated agents have a more rapid gastrointestinal transit time, which may be beneficial in patients where a faster diagnosis is required.[32,33] Ionic iodine-based contrast media consists of agents such as diatrizoate sodium and diatrizoate meglumine (Gastrografin). Due to its hyperosmolarity (1900 mOsm/L), it can draw interstitial fluid into the intestinal lumen, and therefore should not be used in young, dehydrated, hypovolemic, or renal-compromised patients.[3,33,34] Furthermore, these agents should not be used in patients with an increased risk of aspiration, as they cause chemical pneumonitis.[35] Nonionic, iodinated contrast mediums such as iohexol (Omnipaque™) have a lower osmolality (520 mOsm/L) and are preferentially used when other contrast media are contraindicated. Although often more expensive than barium sulfate, iohexol provides excellent mucosal detail in birds and mammals, even if partially diluted.[31,36,37]

Gastrointestinal transit times can vary greatly in snakes due to many factors, including their ectothermic nature, species, environmental factors such as temperature and season, food composition, metabolic factors, and stage of digestion.[3,24,27] Comprehensive studies have been conducted on the digestive physiology of snakes; however, few studies have evaluated contrast gastrointestinal radiography. A study in ball pythons (*Python regius*) evaluating gastrointestinal anatomy, normal digestive transit time, and contrast radiographic quality of three different concentrations (25%, 35%, and 45% [w/v]) of barium sulfate concluded that the 35% concentration of contrast medium yielded the best imaging quality.[24] Similarly in bearded dragons (*Pogona vitticeps*), good-quality images were obtained with a concentration of 35% w/v.[27] Ball pythons had an average esophageal transit time of 6.89 ± 6.74 hours, onset of gastric filling time of 0.94 ± 0.54 hours, gastric emptying time of 40.67 ± 14.92 hours, onset of small intestine transit of 2.05 ± 1.70 hours, small intestine transit time of 50.82 ± 12.34 hours, and onset of large intestine transit of 28.94 ± 21.70 hours. However, interpretation of results may not translate well in other species due to anatomic and physiological differences.[24]

Snakes should be maintained at their species-specific preferred optimum temperature zone to ensure that contrast will pass through the gastrointestinal tract at an appropriate rate.[38,39] The contrast medium should be warmed to the approximate body temperature of the patient before administration (often 27°C–29°C, 80°F–85°F). Dose rates have not been determined for all species, but the volume of contrast medium administered should not exceed the volume that would be used to tube-feed the patient. In small animals, a dose of 6 to 16 mL/kg of barium is recommended.[31] Doses of 5 to 20 mL/kg have been suggested in reptiles.[40] In the study mentioned previously, a dose of 25 mL/kg of barium was administered to ball pythons based on the unique capacity for the distention of the gastrointestinal tract in snakes. Four of 18 ball pythons regurgitated immediately after administration, however, possibly indicating that this dose could be excessive and should be reduced, although no additional complications were observed.[24]

Double-contrast upper and lower gastrointestinal radiographic studies can be useful to document mucosal disease, foreign bodies, strictures, and partial or complete obstruction in the esophagus, stomach, and intestines (Fig. 55.13). The procedure uses a smaller volume of positive contrast agent and allows for a more rapid evaluation of the digestive tract, because the gas used propels the positive contrast medium rather than relying on peristalsis. In small animals, double-contrast studies produce superior radiographic mucosal detail over single contrast studies; although in humans, a study comparing diagnostic accuracy in both techniques indicated that the two methods were equal and complemented each other.[41,42] In upper double-contrast studies, a tube is passed into the stomach, and 100% barium sulfate or nonionic iodinated contrast is infused into the stomach at a volume estimated to be one third to

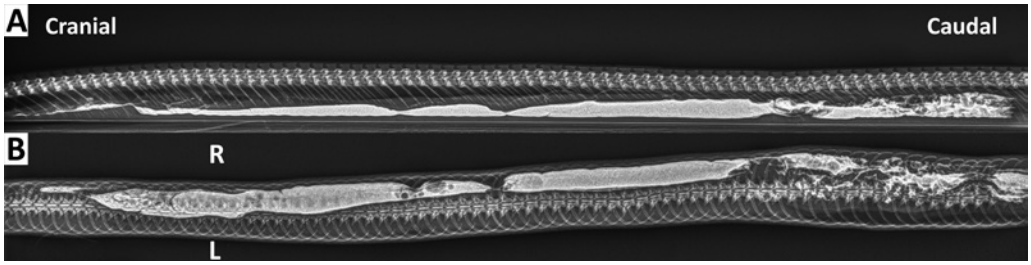

FIG 55.12 Right lateral (A) and dorsoventral (B) radiographs of a colubrid snake at 50% to 90% snout-to-vent length during a barium gastrointestinal study. Gastrointestinal contrast can be useful for evaluating motility, transit, partial obstructions, and coelomic soft tissue mass effects that may be impinging on intestinal function. Transit times are often prolonged requiring repeated radiography over several days or even weeks. (Courtesy of Stephen J. Divers.)

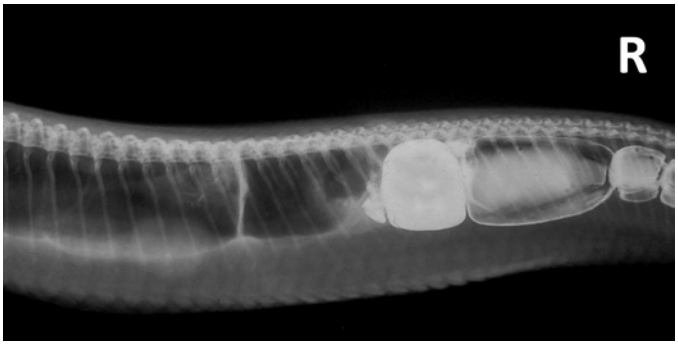

FIG 55.13 Emerald tree boa (*Corallus caninus*) with chronic abdominal distention. The retrograde double contrast study shows an angular constriction caused by an intestinal adenocarcinoma.

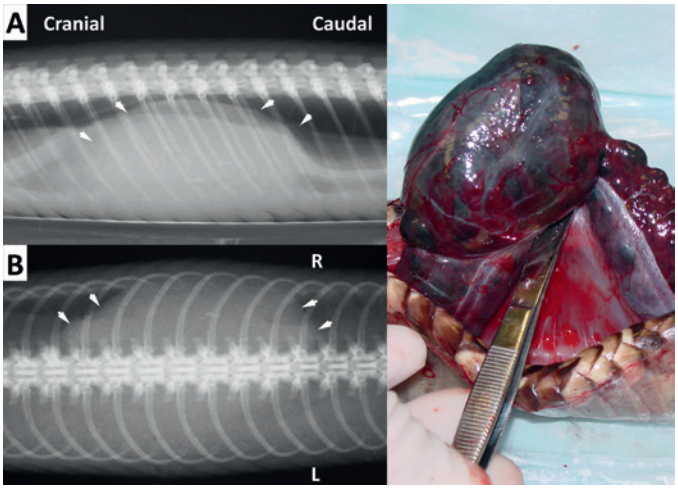

FIG 55.14 Right lateral (A) and dorsoventral (B) radiographs of a king snake (*Lampropeltis getula*) centered at 45% snout-to-vent length. (C) Surgical exploration confirmed a large hepatic mass, as well as numerous smaller nodules throughout the liver. (Courtesy of Stephen J. Divers.)

one half of the gastric volume. Room air is then infused into the stomach in an amount equal to the normal gastric volume. Contrast medium equal to one fourth of the gastric volume is infused into the esophagus as the tube is slowly retracted. When the distal tip of the catheter is in the cranial esophagus, an equal volume of air is infused into the esophagus (one-fourth the gastric volume). The catheter is then removed, and radiographs are taken.

If the intestines, especially the colon and cloaca, are the primary region to be evaluated, a retrograde study should be performed. These procedures usually require anesthesia because the intestinal distention stimulates peristalsis. A flexible catheter is introduced into the cloaca and advanced into the distal colon. Contrast medium is administered until resistance is encountered. A potential but infrequently encountered complication of retrograde studies is accidental introduction of the contrast medium into the ureters and subsequently the kidneys. This could represent a problem with barium sulfate if ureteral or renal concretions develop, especially in dehydrated patients.

Although contrast radiographic studies are helpful for documentation of mucosal disease, ultrasonography can also be useful in the diagnosis of gastrointestinal tract disease, especially if mural thickness is abnormal and the intestines are not filled with gas or fecal material. Endoscopic evaluation of the gastrointestinal tract may be superior in the diagnosis of mucosal disease, providing direct visualization and biopsy capability of the affected area (see Chapters 58 and 64).

LIVER

The liver in snakes is an elongated, poorly lobed organ that usually varies in color from pale tan to black depending on species and other external factors. It is the largest organ of most snakes, comprising of 3% to 4% of body weight, which can fluctuate by season, nutritional status, and reproductive activity.[43] It is located approximately 30% to 60% SVL and may be superimposed upon the heart cranially and stomach caudally (Figs. 55.2 and 55.3). Hepatomegaly, microhepatica, and discrete liver masses can have a variety of etiologies and are often difficult to differentiate from the gastrointestinal tract without contrast or ultrasonography (Fig. 55.14).[44–46] Nevertheless, the hepatic silhouette is often appreciable using horizontal beam techniques (see Chapter 67 for a more in-depth discussion of hepatic disease in snakes).

REPRODUCTIVE SYSTEM

Radiography is often helpful for diagnosing reproductive issues of snakes, especially if shelled eggs or developed embryos are present.[47] The gonads typically lie approximately 60% to 80% SVL (see Fig. 55.2). In oviparous species (and some viviparous species) late gestation can be appreciated on radiographs with the identification of rounded, soft tissue opacity structures in the caudal coelom that are arranged in a linear overlapping pattern resembling a clumped string of pearls (Fig. 55.15A). They are bilateral in location. The ova can be well visualized and may have poorly mineralized calcified shells.[48] As the eggs develop, they enlarge and fill the caudal coelom, compressing the intestines. Radiographic evaluation for the presence, morphology, calcification, and abnormalities of eggs can be useful, especially in combination with ultrasonography.[47,48] Retained eggs can appear more radiopaque due to increased calcification. In viviparous species, fetal skeletons become visible as they mineralize late in gestation (see Fig. 55.15B). Common indications for evaluating the reproductive system include dystocia, apparent infertility, and reduced fecundity. It is important to note that it is usually not possible to diagnose dystocia with radiography alone. A detailed history, clinical signs, and other diagnostic techniques including ultrasonography are often necessary.[48–50]

The hemipenes of some species may appear mineralized and can be detected on radiographs. Contrast has also been used to radiographically highlight the hemipenes of snakes for gender identification.[51] A discrete soft tissue swelling at the level of the cloaca may also indicate cloacitis, abscessation, or fat deposition.

Neoplasia of the reproductive tract is common in snakes, with various tumors observed affecting the ovary, oviduct, and testes.[48] Clinical signs may include infertility, coelomic swelling, cloacal bleeding, and extramural intestinal obstruction. Caudal coelomic radiographs and contrast gastrointestinal studies (oral or per cloaca) are often useful in demonstrating soft tissue mass effects outside of the intestinal tract (Fig. 55.16). Ultrasonography is often preferred for reproductive evaluation and should be used along with radiography (see Chapter 58).[1]

URINARY SYSTEM

The kidneys of snakes are located dorsal to the intestinal tract in close association with the intracoelomic fat bodies, in the caudal coelom approximately 75% to 95% SVL (see Fig. 55.2). They are not always radiographically evident, unless enlarged or mineralized (Fig. 55.17). Disease processes that can cause renomegaly include renal gout infection, and neoplasia (also see Chapter 66). Secondary signs of renomegaly

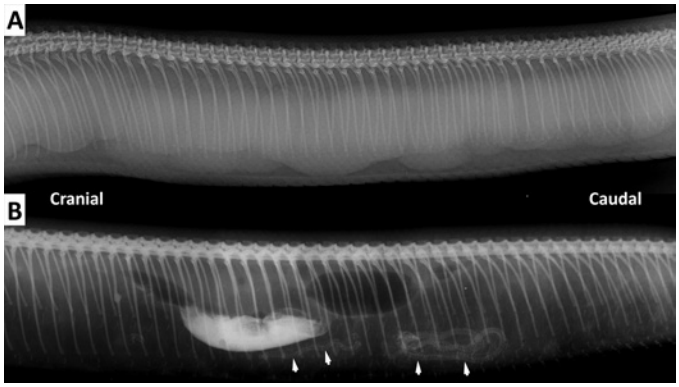

FIG 55.15 (A) Right lateral radiograph of the caudal coelom (65%–80% snout-to-vent length) of an adult female boa constrictor (*Boa constrictor*). The numerous, coalescing, soft tissue masses are consistent with ova, although it can be challenging to differentiate ovarian follicles from ovulated eggs as shells are poorly mineralized in oviparous snakes; in viviparous species, such as this boa constrictor (*Boa constrictor*), fetus development may not yet be evident. (B) Right lateral radiograph of the caudal coelom (70%–90% snout-to-vent length) of a Kenyan sand boa (*Eryx colubrinus*) demonstrating two retained fetuses (arrows). Barium can also be seen within the large intestine. (Courtesy of Stephen J. Divers.)

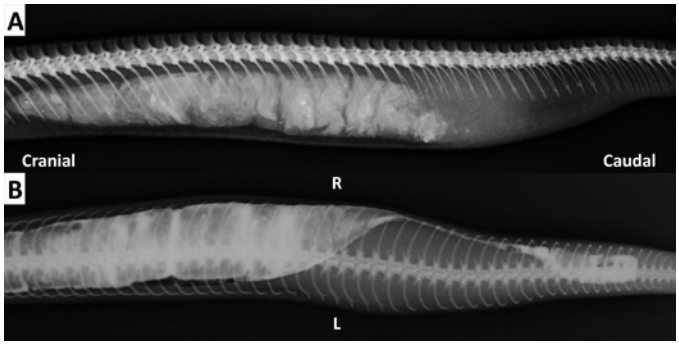

FIG 55.16 (A) Right lateral radiograph (65%–100% snout-to-vent length) of an adult female corn snake (*Pantherophis guttatus*) that presented with constipation. Note the indistinct increase in soft tissue density caudal to the fecal accumulation. (B) Dorsoventral radiograph of the same area after a barium enema. Note that the distal colon has been displaced and compressed by an extraluminal mass effect. Surgical removal was curative, and histopathology confirmed a granulosa cell tumor. (Courtesy of Stephen J. Divers.)

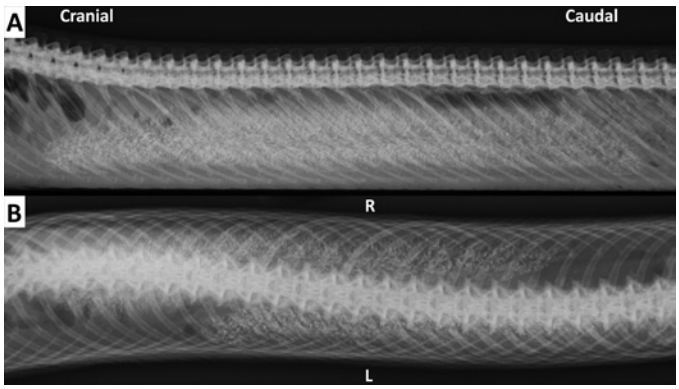

FIG 55.17 Dorsoventral (A) and right lateral (B) radiographs of a hyperuricemic boa constrictor (*Boa constrictor*) at 70% to 90% snout-to-vent. Note the radial, star-burst mineral pattern associated with the left and right kidneys. Although uric acid is radiolucent, chronic renal gout and mineral complexes resulted in increased radiopacity. (Courtesy of Stephen J. Divers.)

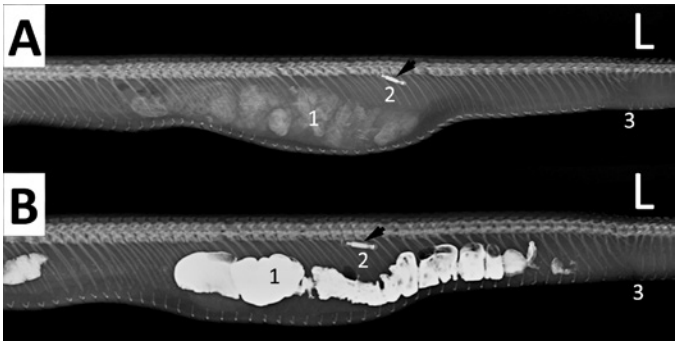

FIG 55.18 Vertical beam left lateral radiographs of a California king snake (*Lampropeltis getula californiae,* 70%–100% snout-to-vent). Noncontrast (A) and gastrointestinal barium contrast (B) radiographs demonstrating constipation (1) cranial to a dorsal coelomic soft tissue mass effect (2). The position of the vent (3) has been indicated and a microchip is also visible (arrow). The mass was identified as a renal mass on exploratory surgery and, after surgical removal, was confirmed as a tubuloepithelial tumor. (Courtesy of Rodney W. Schnellbacher, Dickerson Park Zoo.)

may be constipation or dystocia due to extramural compression. Contrast gastrointestinal studies might be useful in demonstrating renal involvement and location of mass effects (Fig. 55.18). Ultrasonography and advanced diagnostic imaging such as CT and MRI may be needed to further investigate and localize renal lesions.

MUSCULOSKELETAL SYSTEM

Musculoskeletal or, more specifically in snakes, spinal disease is a common indication for radiographic examination. Traumatic fractures, spondylitis/spondylosis, osteomyelitis, neoplasia, and congenital abnormalities are potential issues. Musculoskeletal deformities caused by nutritional secondary hyperparathyroidism have not been reported in snakes fed whole vertebrate prey. Exceptions may be found among insectivorous snakes (e.g., rough green snake, *Opheodrys aestivus*) fed unsupplemented invertebrates. In humans, an estimated 30% decrease in bone mass density is necessary before changes in radiographic bone opacity are recognized.[52] This has not been substantiated in reptiles, but it does emphasize the magnitude of disease necessary to produce radiographic changes. Evaluation of bone radiopacity in snakes is based on rib radiopacity as a reference point.

Traumatic skeletal fractures are common and are usually assessed by plain radiography. Fracture stability usually occurs before radiographic healing is evident due to a mixture of fibrous tissue and osseous callus during the bone healing process.[1,53] Displaced rib fractures with no sign of radiopaque calluses are common but are usually incidental findings. The edges of the fracture fragments may be rounded, and distortion of the fracture end is another sign of chronicity. Variable distortion, proliferation, and osteolysis can also be features of osteomyelitis.

Proliferative spinal osteopathy has been described in snakes and is characterized by proliferative segmented spondylosis, with adjacent vertebrae fused dorsally, ventrally, or laterally by foci of irregular proliferative bone. It is a radiographic description, not a definitive disease diagnosis. Bacterial osteomyelitis has been confirmed in a number of cases, but other possible etiologies include trauma, viral infections, dietary deficiencies, prolonged inactivity, and neoplasia (Fig. 55.19).[54] The radiographic appearance of osteomyelitis can be variable and include osteolysis, proliferative changes, and a loss of normal corticomedullary distinction.[54–56] These changes are not dissimilar to those seen in cases

of bone neoplasia or osteitis deformans.[1,57–59] Therefore radiographic changes should not be considered pathognomonic for any of these particular bone diseases. Ultimately biopsy is required, but, in cases of suspected spinal osteomyelitis, blood culture may be more practical (see Chapter 81 for more information). Advanced imaging, such as CT and MRI, which can create three-dimensional reconstructions, can be especially helpful for further evaluation of complex fractures, as well as the extent of osteomyelitis and neoplasia, especially in the skull (see Chapters 59 and 60).

Soft or hard tissue swellings of the face and oral cavity are common indications for skull radiography. Radiographic examination is also performed in cases of suspected fractures, osteomyelitis, inflammation, or neoplasia. A variety of tumors have been identified in the oral cavity in snakes, including squamous cell carcinoma, fibroma, melanoma, and ameloblastoma (Fig. 55.20)[60–63] Radiographs can be useful in determining whether oral lesions in snakes have underlying bony involvement.

The serpentine skull is complex with the fixed regions comprised of the snout and neurocranium. The palatomaxillary apparatus (homologous to the maxilla), along with the supratemporal, quadrate, articular, suprangular, dentary, coronoid, and splenial bones, are mobile (Fig. 55.21). The two sides of the mandible are divided and lack a mandibular symphysis. Snakes have the most teeth of any reptile. The teeth are generally located on the mandibles and the maxillae, palatines, pterygoids, and premaxillae of the upper jaw. Venomous snakes also have fangs.[23] Obtaining symmetrical radiographs of the head of snakes can be difficult due to the flexible joints between the supratemporal, quadrate bones and the mandible. Therefore symmetry is best evaluated by centering the radiographic beam over the snout and neurocranim due to their fixed position.[64] Chemical restraint is typically required to obtain straight, orthogonal views. Lateral and dorsoventral should be standardized diagnostic views; however, oblique radiographs may be necessary to highlight areas of concern. For smaller snakes, digital dental radiographic systems may be necessary to obtain sufficient detail.

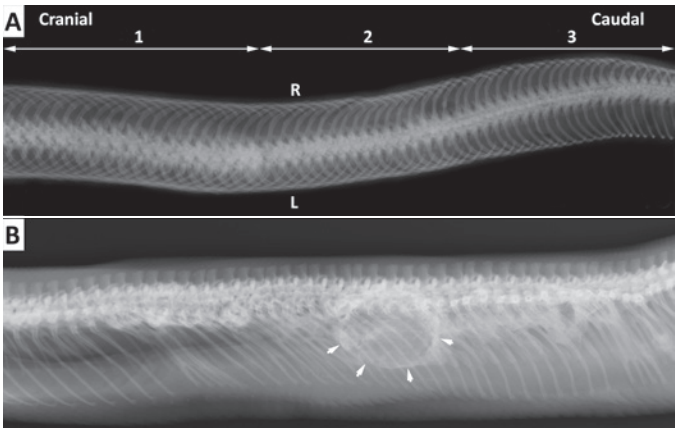

FIG 55.19 Dorsoventral radiograph of a boa constrictor (*Boa constrictor*) at 40% to 60% snout-to-vent length demonstrating moderate (1) and mild (2) spinal osteopathy, with normal spine (3) for comparison. (Courtesy of Stephen Divers, UGA.) (B) Right lateral radiograph of another boa constrictor (50%–70% snout-to-vent length) demonstrating more profound proliferative and osteolytic changes of the spine, with an aggressive expansile lesion also evident (*arrows*). These lesions are typically associated with chronic bacterial osteomyelitis. (Courtesy of Nancy Harrington, All Pets Animal Hospital.)

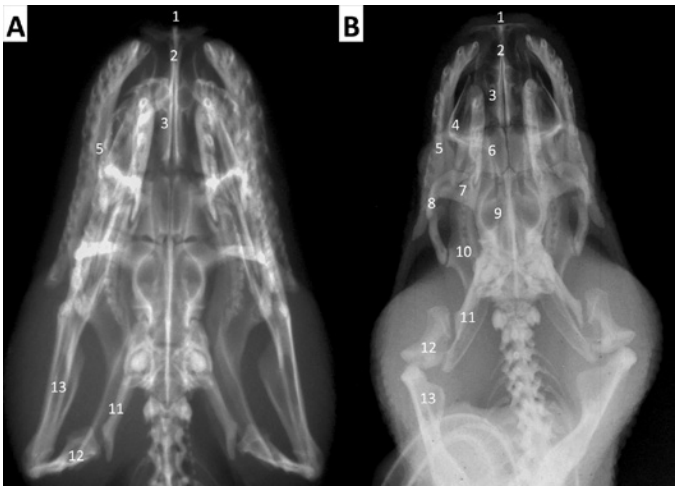

FIG 55.21 Whole skull dorsoventral radiograph (A) and open-mouth ventrodorsal view of just the maxilla (B) of a healthy boa constrictor (*Boa constrictor*) illustrating the major bones: (1) premaxillary, (2) vomer, (3) nasal, (4) prefrontal, (5) dentary, (6) frontal, (7) postfrontal, (8) transpalatine, (9) parietal, (10) pterygoid, (11) supratemporal, (12) quadrate, and (13) articular. (Courtesy of Stephen J. Divers.)

FIG 55.20 A free-ranging eastern black rat snake (*Pantherophis alleghaniensis*) presented with a 3-cm in diameter solid mandibular mass that was partially ulcerated. Lateral (A), dorsoventral (B), and oblique (C) radiographs demonstrated an ill-defined, lobular mass with amorphous intralesional mineral arising from the soft tissues and irregular margins with partial osteolysis and mild periosteal reaction of the adjacent mandible (arrow). Histopathology confirmed ameloblastoma. (Courtesy of Stephen J. Divers.)

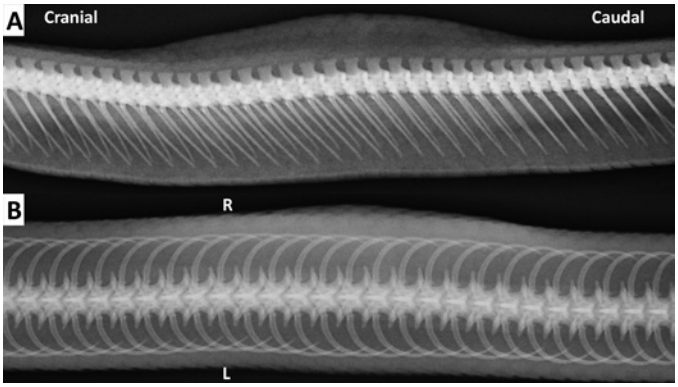

FIG 55.22 Right lateral (A) and dorsoventral (B) radiographs of a black rat snake *(Elaphe obsoleta)* at 50% to 70% snout-to-vent length. A diffuse, fat density can be appreciated dorsal to the spine and right of the midline. Surgical removal and histopathology revealed an infiltrative lipoma. (Courtesy of Stephen J. Divers.)

MISCELLANEOUS

The presence of any physical abnormality can be an indication for radiography. Abscesses, which can either be extracoelomic or intracoelomic and associated with a specific organ or the coelomic wall, are common findings in snakes. Steatitis (inflammation of fat) may be visualized radiographically as an increase in both size and density of the fat bodies. Cutaneous and subcutaneous tumors including lipomas and soft tissue sarcomas have also been reported and may be identified radiographically (Fig. 55.22).[65,66]

Radiography—Chelonians

Shannon P. Holmes and Stephen J. Divers

The hard shell typical for most chelonians will limit the clinician's ability to examine the coelom even more so than other reptilian species. Therefore radiography may be one of the only noninvasive mechanisms for clinicians to "look below the shell." Radiology units and the clinicians' comfort using them is more ubiquitous than other imaging modalities. Ultrasound equipment is also common in practice, but the shell limits these examinations to specific areas that can be visualized from the openings for the appendages. In practice, computed tomography is also becoming more popular, although the added expense may not be acceptable to some clients.

RESTRAINT AND POSITIONING

Acquisition of radiographs is generally easier to perform in chelonians, because the shell aids in patient restraint and positioning. The shell (and visceral structures within) can be positioned and remain motionless in conscious patients for the majority of radiographic exposures. The patient may retract the head and limbs into the carapace, which is suboptimal for image evaluation due to superimposition. We have found elevation of the chelonian by placement of the plastron on an appropriately narrow lucent structure, referred to as a central plastron stand, will encourage the head and limbs to extend and hang ventrally, even in conscious animals (Fig. 56.1). This does not hamper lateral image acquisition but can degrade acquisition if used for the dorsoventral radiograph. Securing the patient to the table or using lucent positioning devices are also helpful.[1–3] If the area of interest is the head or limbs, general anesthesia will be needed to obtain diagnostic images. Manual restraint with adhesive tape around the limb for retraction during radiography has also be described in loggerhead sea turtles; this technique may be feasible given the patient size.[4] However, sedation or general anesthesia may also be elected if multiple procedures are to be performed, and at least one of those procedures requires anesthesia. Generally, similar to other reptiles, radiography of chelonians is easier and more efficient with anesthesia.[2] Therefore, developing a plan for the radiographic examination is an important first step before entering the radiography suite.

In order to obtain high-quality radiographs of chelonians, they must be positioned as close to the cassette or detector as possible. The carapace edge of chelonians is rounded so when the lateral edge is adjacent to the detector, there are internal structures that are more distant. This increased object-film distance detracts from radiographic detail in the lateral and craniocaudal images. Structures further away will be magnified or blurred, which is a greater issue for larger chelonians. Therefore obtaining right and left lateral images is helpful, especially for larger animals.[1]

Following radiographic standards, orthogonal radiographs should be obtained for all chelonian body systems (see Table 53.1). The shape of the shell and internal anatomy necessitates a horizontal radiographic beam for both lateral and/or cranial caudal images (Fig. 56.2), in addition to the dorsoventral vertical beam images (Fig. 56.3). For all radiographs,

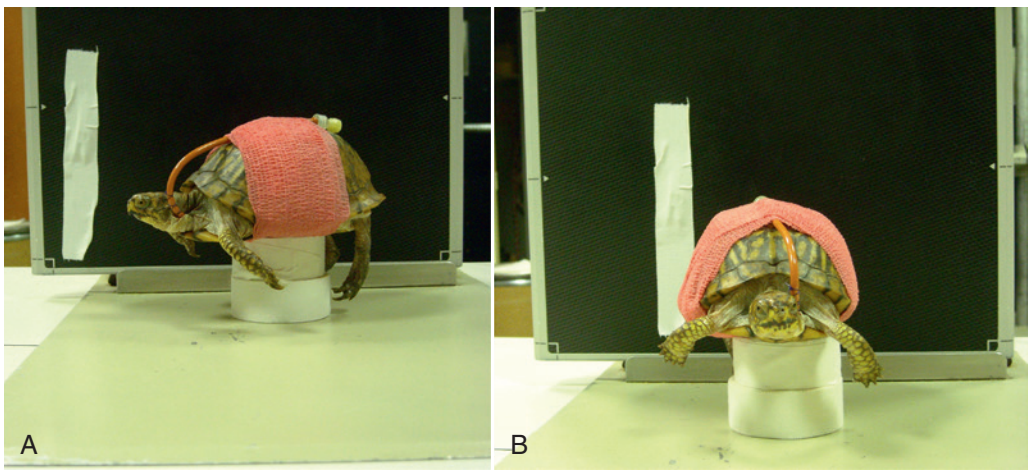

FIG 56.1 Suspended positioning of an eastern box turtle (*Terrapene c. carolina*) to facilitate extension of the limbs and head out of the shell. The additional advantage of this technique is the head and limbs can be better evaluated because they are not superimposed. Orthogonal horizontal beam lateral (A) and craniocaudal (B) radiographs of the carapace will effectively produce lateral and craniocaudal images of the limbs with this positioning technique and patient cooperation by extending limbs ventrally. (Courtesy of Shannon P. Holmes.)

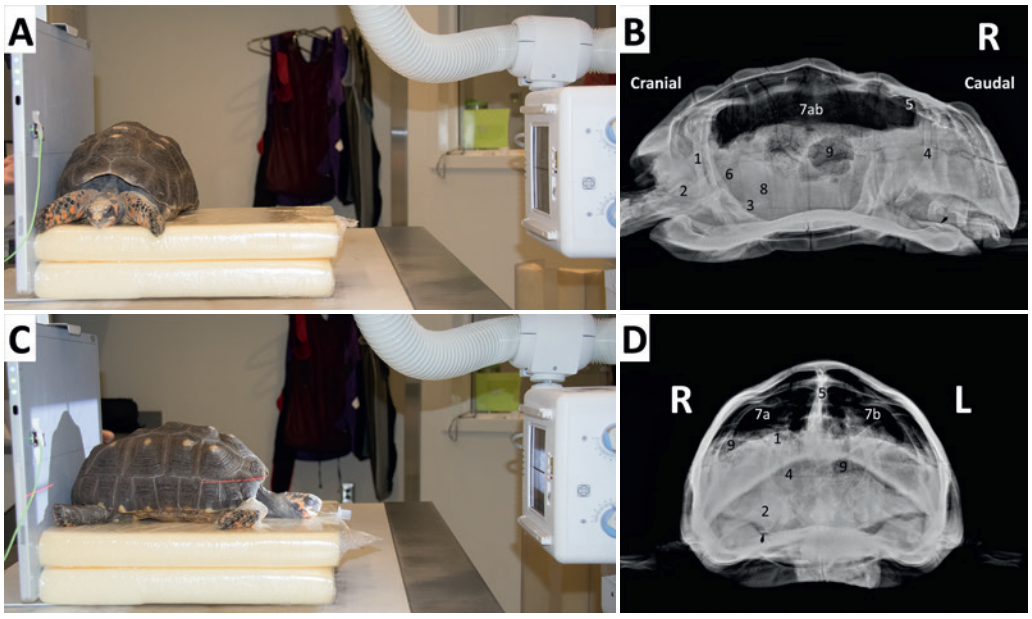

FIG 56.2 Positioning and corresponding horizontal beam right lateral (A and B) and craniocaudal radiographs (C and D) of an adult red-footed tortoise (*Chelonoidis carbonaria*), demonstrating the scapulae (1), humeri (2), coracoids (3), ilia (4), spine (5), trachea (6), right lung (7a), left lung (7b), cardiohepatic silhouette (8), gastrointestinal tract (9), and microchip (arrow). Note the poor serosal detail throughout the ventral coelom; however, these radiographs are most useful for evaluation of the lungs. (Courtesy of Stephen J. Divers.)

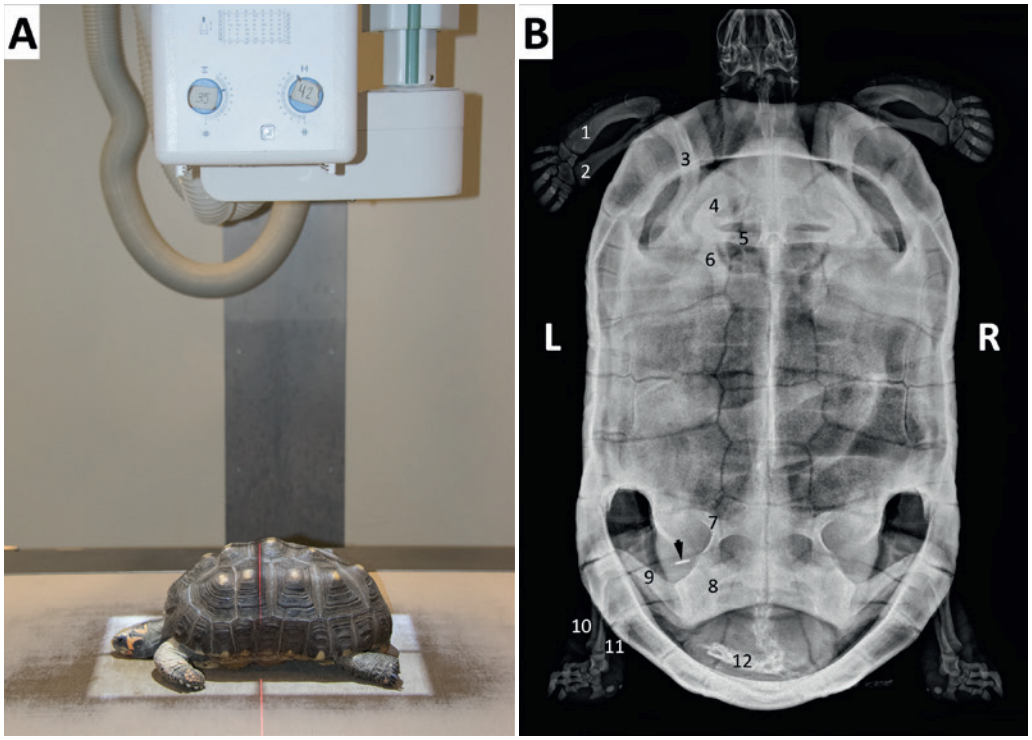

FIG 56.3 Positioning (A) and dorsoventral radiograph (B) of an adult red-footed tortoise (*Chelonoidis carbonaria*) demonstrating the major skeletal structures, including left radius (1), ulna (2), humerus (3), acromion process (4) of the scapula (5), coracoid (6), ilium (7), pubis (8), femur (9), tibia (10), fibula (11), and caudal vertebrae of the tail (12). Note the poor serosal detail throughout the coelom, gas within the gastrointestinal tract that is superimposed on the lungs, and the microchip (*arrow*). (Courtesy of Stephen J. Divers.)

VetBooks.ir

FIG 56.4 Cooter (*Pseudemys* sp.). Coelomic fluid is present from coelomitis and pneumonia. The ventrodorsal radiograph was made with the patient in the erect position with a horizontally directed radiograph beam. The straight gas–fluid interface level is helpful to evaluate the volume of coelomic fluid.

it is easiest, and least stressful to the patient, to position them in sternal recumbency or the prone position.[1,2] As outlined in Table 53.1, the anatomy of an organ system of primary interest, suspected pathological change, presence of coelomic fluid, degree of digestive tract distention, and the contents of the female reproductive tract determines the radiographic images needed. For example, evaluation of the chelonian lungs requires horizontal beam images of both craniocaudal and lateral radiographs. The dorsoventral radiograph does not provide the best evaluation of the lung due to the superimposed digestive tract anatomy. However, it does facilitate evaluation of the craniocaudal length of the right and left lungs individually. The craniocaudal horizontal beam also allows for comparison of the right and left lungs, but the cranial right lung is summated with the caudal right lung tissue. Finally, the right and left lungs are superimposed on the lateral horizontal beam image, such that a lateralized soft-tissue pulmonary focus cannot be localized without an orthogonal image. Determination of the needed radiographic images and radiograph beam orientation is dictated by the goal of minimizing superimposition of nonessential anatomy over the area of interest and to effectively recreate three-dimensional anatomy using two-dimensional radiographs. It is sometimes possible to move or redistribute obscuring structures through changing the patient's position from the standard. An example is the redistribution of coelomic fluid via erect positioning (i.e., as if the chelonian were vertical and resting on the tail and caudal shell) and horizontal beam orientation (Fig. 56.4). The fluid will become gravity dependent, and there will be less superimposition in the cranial coelom, resulting in improved aeration and visibility of the pulmonary parenchyma craniad. These can also be useful for estimation of the volume of coelomic fluid.[1]

One other technical consideration when planning chelonian radiographs is the effect of the shell. A prescribed radiographic technique developed for mammals assumes a soft-tissue body wall and adjusts the technique (i.e., kVp and mAs) according to patient thickness. The shell, and the density of the tissue of which it is composed, will cause greater attenuation of the x-ray beam relative to a mammalian patient of similar thickness. Therefore initially increasing mAs to account for the shell would be beneficial; this will increase the number of x-rays penetrating the shell.

CARDIOVASCULAR SYSTEM

Radiography is not commonly used as a diagnostic tool to evaluate chelonians for heart disease. The heart is poorly visualized due to indistinct borders. It rests on the plastron in the cranial third of the coelom.[2] The location of the heart can be identified as the soft-tissue opaque structure ventral to the tracheal termination.[1] In the loggerhead sea turtle (*Caretta caretta*), the triangle formed by the scapula and coracoid bones was determined to be an extracoelomic landmark.[5] Evaluation of cardiac size, chamber volume, and contractility are best performed with echocardiography.

RESPIRATORY SYSTEM

Evaluation of the respiratory system, especially the lungs, by radiography is a common application. The chelonian lung is an arborized structure characterized by small airways terminating in spongy (edicular) air spaces.[6] Another unique feature is the adherence of the dorsal lung to the carapace parietal serosa.[1,6] As a result, the lungs should never become ventrally displaced or collapsed ventrally. This also means that dorsal carapace trauma will often be complicated by pulmonary involvement. The shell, in addition to the digestive tract or other coelomic content such as coelomic fluid or eggs, will limit the expansibility of the lungs.[1] Muscular fibrous bands are interspersed throughout the parenchyma; these are typically not distinctly seen but contribute to the soft-tissue opacity of normal chelonian lung. The pulmonary vasculature should be visible in normal chelonian lungs, and loss of visibility can be used to confer pulmonary pathological change. Collateral pulmonary vasculature may also be identified.[5]

There are three standard radiographs needed to evaluate the lungs; the craniocaudal horizontal beam, lateral horizontal beam, and dorsoventral views. Some radiographic units are not capable of orienting the x-ray beam horizontally. In this instance it is important to be aware of the changes that result with laterally recumbent lateral radiographs. The lungs are most affected by coelomic organs moving dependently to cause pulmonary compression (Fig. 56.5). It is less intuitive that the head and limb position are important considerations in pulmonary interpretation, but retraction of the appendages will further reduce coelomic volume and increase lung compression. Therefore limb extension is important, and optimal lung inflation is crucial for accurate pulmonary interpretation.[2] Positive pressure ventilation can be used to inflate the lungs, and due to the unique chelonian anatomy, there is less risk of misinterpreting overinflation as absence of disease compared with snakes and lizards.

A wide variety of diseases can affect the respiratory system, including infection (viral, bacterial, fungal, or parasitical), trauma, or neoplasia.[6] Virtually all pulmonary pathological changes in chelonians will result in some degree of increased pulmonary soft-tissue opacity. With the exception of cold-stunned Kemp's ridley sea turtles (*Lepidochelys kempii*), distribution and pattern of pulmonary infiltrates have not been reported with disease/condition specificity as they have with mammals. The aforementioned Kemp's ridley turtles had pulmonary changes, but the most consistent (and normal) finding was a reticular or honeycomb pattern that conformed to the lung trabeculae and ediculae.[7] Changes consistent with disease processes like pneumonia tend to appear as focal, multifocal, or diffuse areas of increased soft-tissue opacification.[1,8] However, it is not possible to reach a definitive pulmonary disease

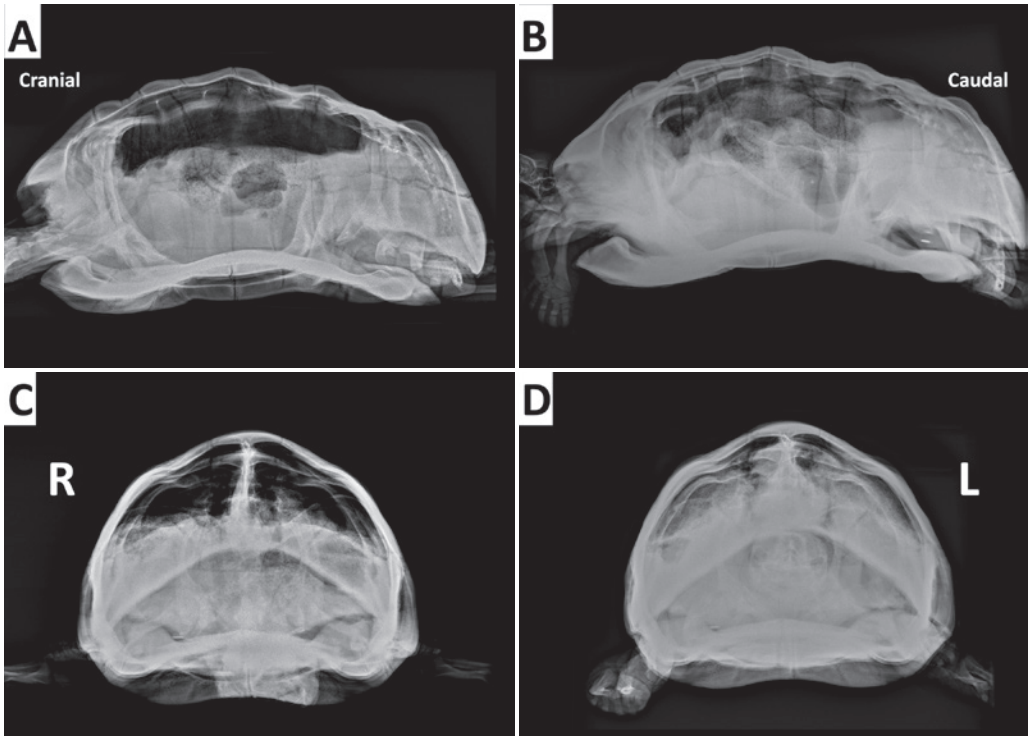

FIG 56.5 Comparison between right lateral (A and B) and craniocaudal (C and D) radiographs using horizontal (A and C) versus vertical (B and D) x-ray beams in an adult tortoise. Note the significant visceral displacement associated with rotating the animal to use a vertical beam, and the subsequent reduction in lung volume (B and D). Consequently, horizontal beam techniques (A and C) are recommended for lateral and craniocaudal radiographs. (Courtesy of Stephen J. Divers.)

diagnosis with radiography alone; clinical correlation and sampling for cytology/histopathology and microbiology are crucial for planning further diagnostics and devising appropriate treatment strategy.[2]

Infectious pneumonopathies are the most frequently encountered in clinical practice. A common feature with pulmonary infection is focal or multifocal ill-defined areas of pulmonary consolidation (Fig. 56.6). The localization of abnormal pulmonary soft tissue is best seen on the horizontal beam images. To accurately estimate the extent of lung involvement, all three radiographic projections are important. A differential diagnosis for a diffuse or multifocal soft-tissue pulmonary pattern could be fibrosis.[2] Solitary or more discrete soft-tissue lesions can also be seen. In this instance the differential diagnosis would include focal/consolidated pneumonia, granuloma, abscess formation, or neoplasia. The distinct margination of these lesions is an important identifier for a pulmonary location and is created by the gas–soft tissue interface. Apart from gas-distended segments of intestine, this would not be seen with other coelomic masses protruding dorsally. The ventral margin of these lesions may not be discrete. These are often better visualized on the dorsoventral image than on the horizontal beam; it is likely the soft tissue–gas interface is more tangential to the x-ray beam, which increases margin conspicuity (Fig. 56.7). Radiographs represent an important diagnostic assessment in monitoring response to therapy for pulmonary disease (Fig. 56.8). The initial radiographs form the baseline for comparison. Direct comparison and accurate interpretation are more reliable if all imaging parameters are kept constant through serial studies, such as the radiographic technique prescribed (mAs and kVp), patient positioning, and conscious free breathing versus anesthetized and ventilated. Computed tomographic (CT) studies are the optimal diagnostic technique for respiratory tract evaluation of reptiles (see Chapter 59). This is especially true for solitary lesions, because these can have distinguishing features in contrast-enhanced CT examinations.

GASTROINTESTINAL SYSTEM

Radiographic evaluation for digestive disease investigations are common in clinical practice. It can be a challenging system to evaluate due to the poor serosal detail in the coelom, which can limit the value of survey radiographs.[9] Radiographic evaluation is further complicated because factors such as temperature, nutritional status, time since last meal, and diet must also be considered.[2] In mammalian imaging, fasting is commonly recommended before imaging, but the presence of ingesta in the gastrointestinal tract aids in its identification in chelonian studies. However, the reviewer must decide if the ingesta is normal in appearance, which is why the previously mentioned factors must be considered. The inherent low contrast in chelonians is mostly due to minimal periorgan fat but is exacerbated by the limited space within the shell and greater effacement of coelomic structures.[1] Regardless, survey radiographs remain a first-line diagnostic step in clinical practice. These must be performed and serve as a baseline, even if contrast studies are needed to increase contrast within the digestive tract.

The standard radiographic images acquired for evaluation of the digestive system include dorsoventral vertical beam and lateral horizontal beam images. Radiograph units that are unable to make horizontal beam images will likely result in radiographs that will affect interpretation of the gastrointestinal system and can lead to misinterpretation when organ displacement obscures the mass effect of a

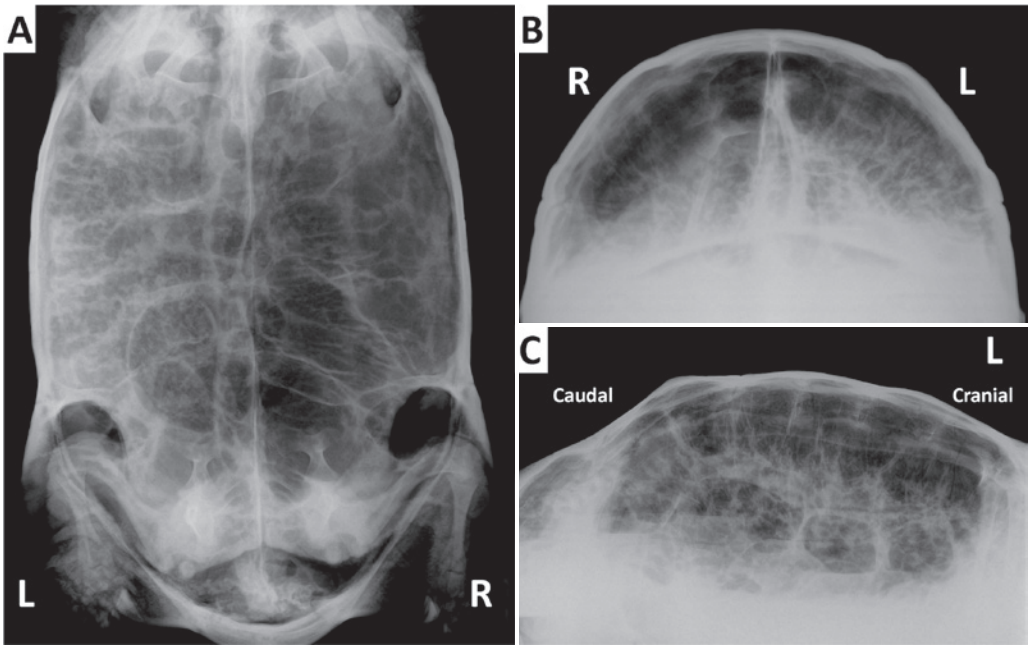

FIG 56.6 Dorsoventral (A), horizontal beam craniocaudal (B), and left lateral (C) radiographs of an adult male box turtle (*Terrepene*) with poorly defined areas of increased soft-tissue opacification of both lungs. The left is more affected, which can be seen on the craniocaudal image, but the extent throughout the left lung is better appreciated on the dorsoventral radiograph, even with the other coelomic structures superimposed. There are no obvious fluid lines. These changes are consistent with pneumonia. (Courtesy of Patrick Leadbeater, Douglas Chang, and Emma Kaiser, Kahala Pet Hospital.)

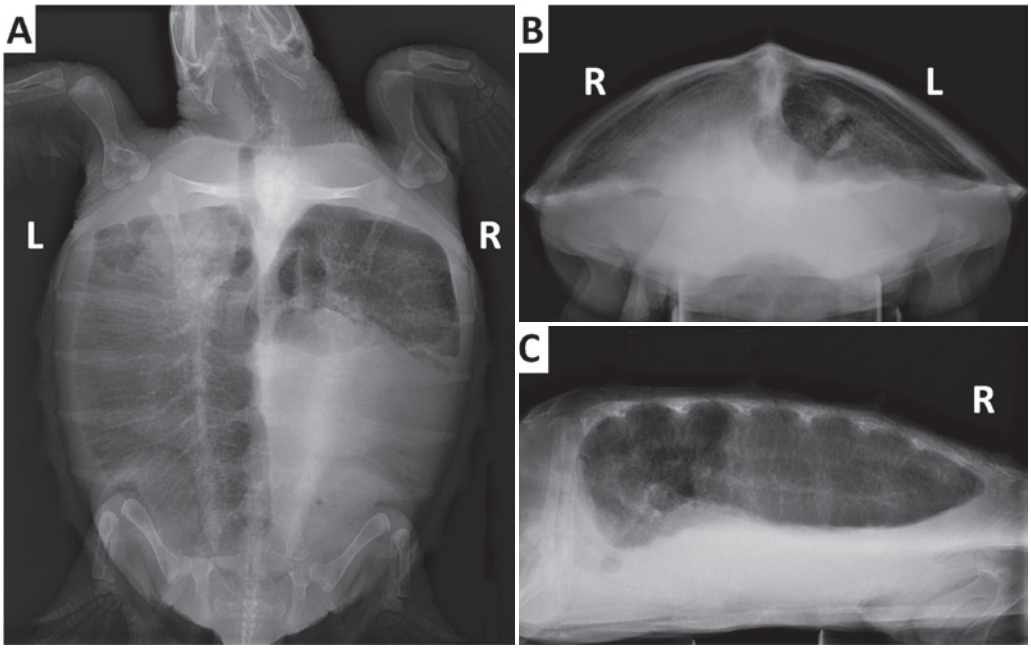

FIG 56.7 Dorsoventral (A), horizontal beam craniocaudal (B), and right lateral (C) radiographs of a juvenile loggerhead sea turtle (*Caretta caretta*). There is a well-defined increase in soft-tissue opacity occupying the mid to caudal right lung. Endoscopic biopsy confirmed a fungal granuloma. (Courtesy of Stephen J. Divers.)

lesion.[10] Generally, the gastrointestinal tract is better visualized on dorsoventral radiographs due to less superimposition. The stomach is located in the left midportion of the coelom on survey radiographs, and the large intestinal luminal contents often have a heterogeneous mixed soft tissue and gas appearance or a more granular look. In our experience the gastrointestinal tract is uncommonly empty in normal chelonians, which is associated with dietary behaviors and the slow transit time. Additionally, in the normal chelonian, minimal gas should be present in the stomach. Increased gastric gas is usually indicative of aerophagia, fermentation, or obstruction. Visualization of the

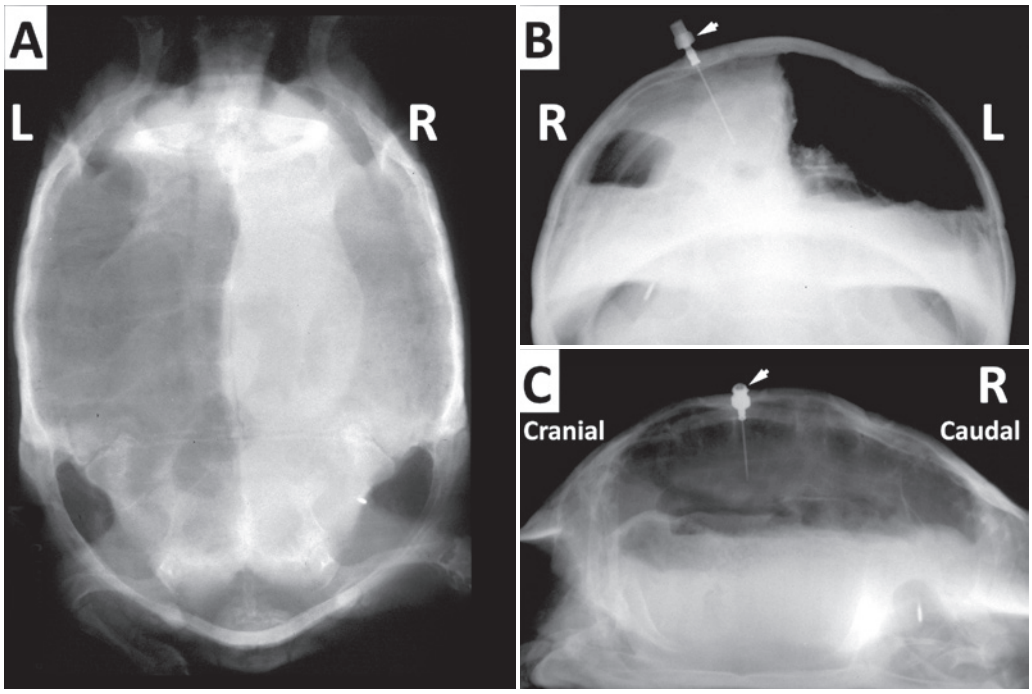

FIG 56.8 Dorsoventral (A), horizontal beam craniocaudal (B), and right lateral (C) radiographs of an adult Greek tortoise (*Testudo graeca*) with mycotic pneumonia. There is an obvious and distinctly marginated solitary soft tissue mass-like focus in the right lung (A and B). It is less opaque on the recheck examination made 4 weeks after the institution of intralesional therapy (C) via an intrapnuemonic catheter (arrows). This increased radiolucency of the right lungs indicates partial resolution. (Courtesy of Stephen J. Divers.)

intestines is more difficult to evaluate than the stomach or lower portions of the digestive tract.

The administration of radiographic contrast agents to delineate the gastrointestinal tract has been investigated and is used frequently in clinical practice. It is necessitated by the low contrast of the coelom. Complete evaluation with ultrasonography is also more difficult (than in squamates) because of the shell. For positive-contrast upper gastrointestinal studies (Fig. 56.9), barium sulfate and iodinated-based contrast are common. Barium sulfate studies have been reported in the red-eared slider (*Trachemys scripta elegans*), leopard tortoise (*Stigmochelys pardalis*), Geoffroy's side-necked turtle (*Phrynops geoffroanus*), yellow-spotted river turtle (*Podocnemis unifilis*), and Arrau river turtle (*Podocnemis expansa*), whereas iodinated contrast studies have been reported in the red-eared slider and Greek tortoise (*Testudo graeca*).[9,11–15] The barium sulfate dose used in the red-eared slider was 30% weight/volume (w/v) and 8 mL/kg at a temperature of 26° to 28°C and in the leopard tortoise was 5 mL/kg at 29°C. For other chelonian studies 70% w/v and a 10 mL/kg dosing rate was administered in mineral oil at a temperature of 26° to 28°C.[13] Di Bello used 60% barium sulfate and iodinated contrast mixed with saline to investigate foreign body obstructions.[14] The addition of food will influence transit time but can be useful for this purpose. For the iodinated contrast studies, Gastrografin (Diatrizoate Meglumine and Diatrizoate Sodium Solution—water-soluble iodinated radiopaque contrast medium for oral or rectal administration) has been used consistently. This contrast is rarely stocked in most veterinary practices in comparison to other iodinated contrast agents such as Iohexol (Nycomed Inc, Princeton, NJ). However, because these papers established transit times, it is important to strictly follow the technique outlined for each species.[16] The transit times were long for barium sulfate, ranging between 72 to 192 hours in the red-eared slider, 144 to 166 hrs in the leopard tortoise, 72 to 156 hours in Geoffroy's side-necked turtle, 365 to 480 hours in the yellow-spotted river turtle, and 360 to 696 hours in the Arrau river turtle. For Gastrografin, the red-eared slider transit time was 48 to 192 hours versus 1.5 to 24 hrs for the Greek tortoise. The effect of temperature was nicely demonstrated in the Greek tortoise study, with faster times in patients maintained between 27° to 34°C. The contrast agent comparison study performed in the red-eared slider also demonstrated the differences in these contrast agents. In addition to faster transit with iodinated contrast agents, there is also poorer mucosal coating and dissipation of the contrast as it transits the gastrointestinal tract.

Contrast studies should be considered as an adjunct to survey radiographs that are inconclusive. It is also important to ensure proper administration of contrast into the alimentary system, because respiratory administration can be fatal. Ensuring successful passage beyond the upper esophageal sphincter and gastroesophageal sphincter is critical. Gastric gavage is used and fluoroscopic guidance is valuable in ensuring correct placement, along with placement of other therapeutic devices (Fig. 56.10).[14] In addition to upper gastrointestinal studies, the double contrast and cloacograms discussed in the taxa-specific chapters can also be performed.

With respect to clinical diagnosis of digestive disease, foreign body ingestion and/or obstruction is among the most common applications (fig. 56.11A–C). Examination of the esophageal area is important in free-ranging chelonians, because fish hooks are one of the more common foreign objects ingested.[17] Identification of an obstructive pattern consisting of orad distention of the gastrointestinal system is made more challenging because the gastrointestinal tract is shorter in length, especially in carnivorous species. Determination of distention due to obstruction versus generalized ileus is important, because surgical intervention is likely needed in the former and not in the latter. Generalized distention, referred to as ileus, can be due to progressive accumulation of ingesta in chelonians (see fig. 56.11D) or due to abnormal motility

VetBooks.ir

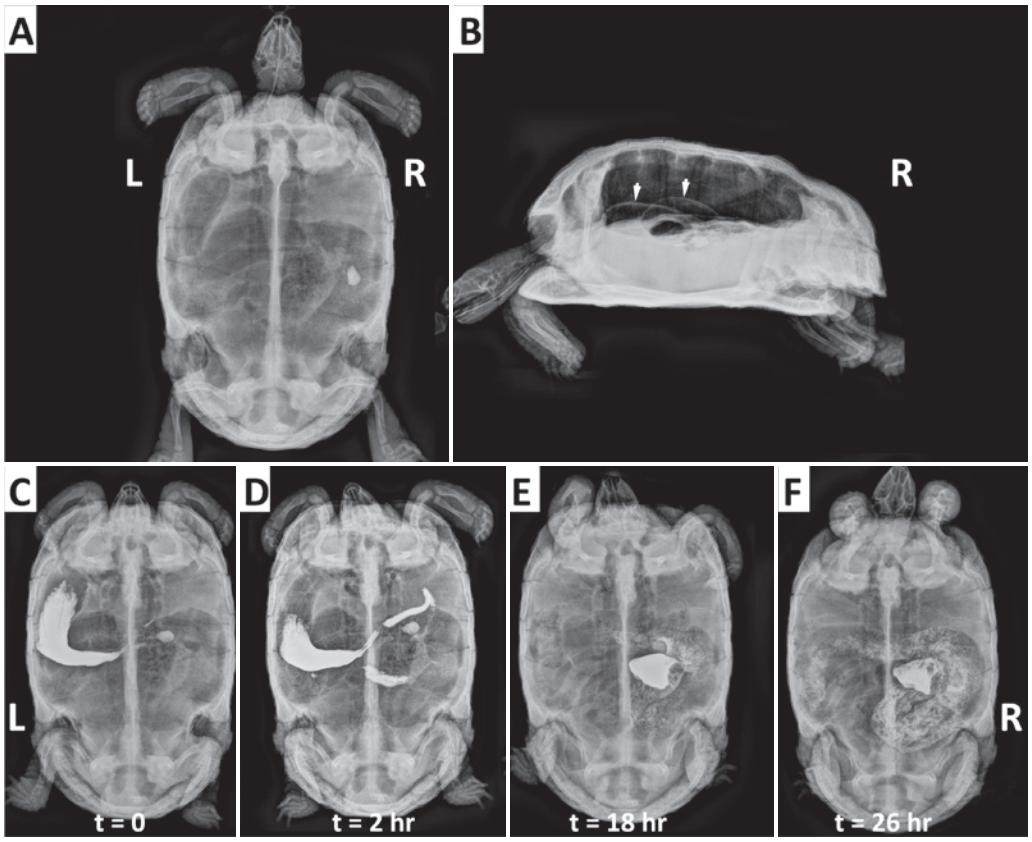

FIG 56.9 Dorsoventral (A) and horizontal beam right lateral (B) radiographs of a red-footed tortoise (*Chelonoidis carbonaria*) with gaseous distension of the gastrointestinal tract but without obvious obstruction. Note the gas-filled intestine impinging dorsally into the lung fields (arrows). Dorsoventral radiographs of the same tortoise immediately after the administration of oral barium (C), and 2 hours (D), 18 hours (E), and 26 hours (F) later. Barium progress is unimpeded, and there is no evidence of an obstruction. Gastrointestinal barium studies can take several days or even weeks to complete. (Courtesy of Stephen J. Divers.)

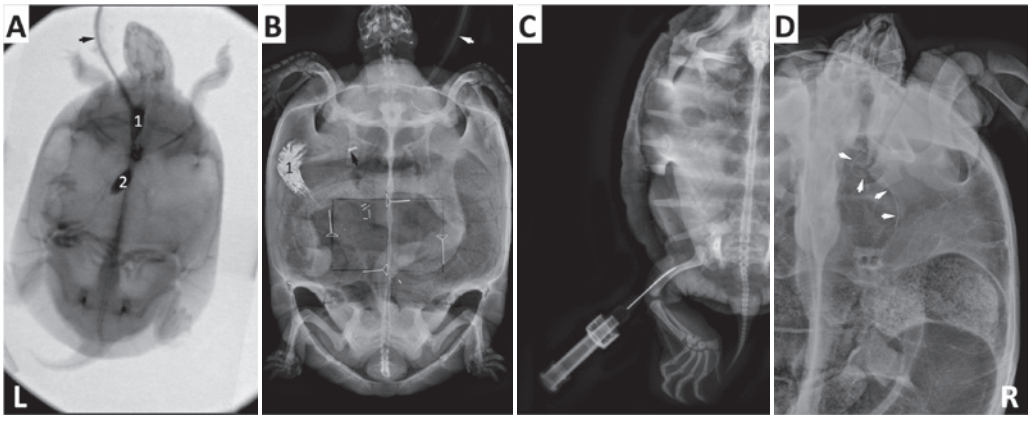

FIG 56.10 (A) Dorsoventral fluoroscopic image of an aquatic slider (*Trachemys*) after the placement of an esophagostomy tube (arrow). The initial test administration of barium (1) indicated that the tube was in the esophagus and was therefore advanced to enter the stomach (2). (B) Dorsoventral radiograph of a tortoise (*Gopherus*) after transplastron surgery and placement of an esophagostomy tube (arrows). Note the test administration of barium entering the stomach, metal vascular clips within the coelom, and the wire suture closure of the replaced section of plastron. (C) Dorsoventral radiograph of a diamondback terrapin (*Malaclemys terrapin*) to confirm placement of an intraosseous catheter into the left femur. (D) Dorsoventral radiograph of the cranial right coelomic quadrant of an aldabra tortoise (*Aldabrachelys gigantea*) to confirm correct placement of a central venous line in the right external jugular. (Courtesy of Stephen J. Divers.)

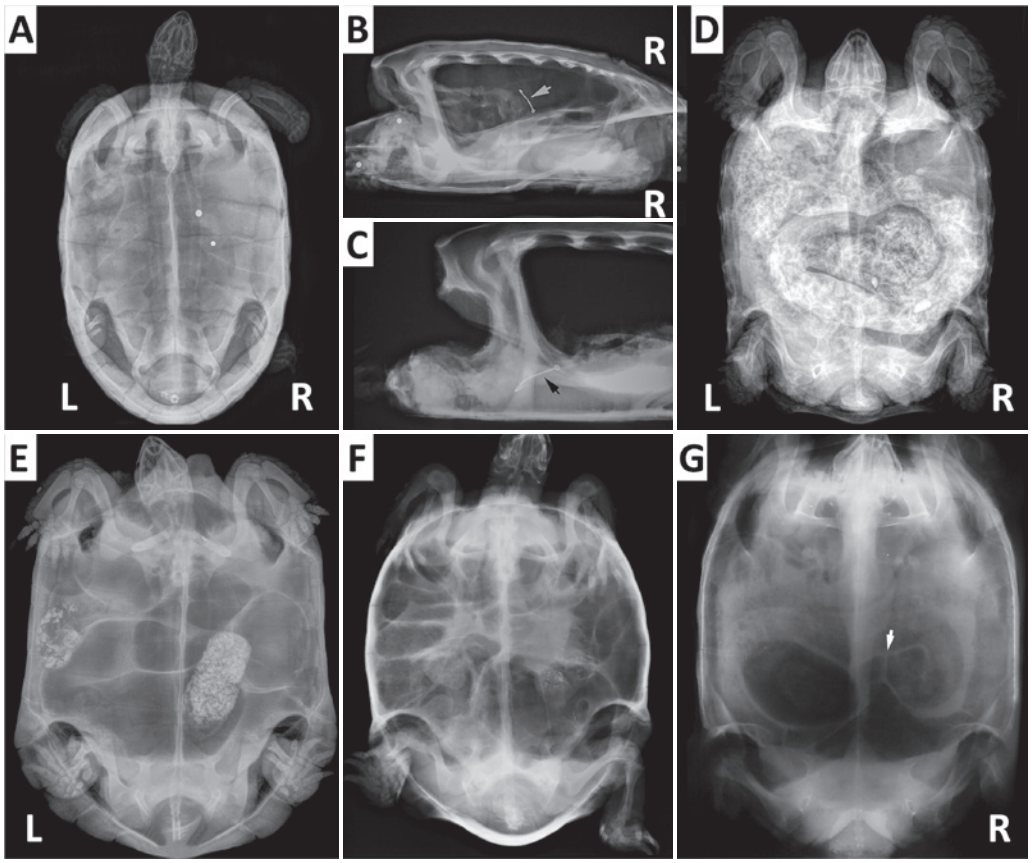

FIG 56.11 (A) Dorsoventral radiograph of a tortoise that ingested two spherical metallic objects. Given their location on the right of the coelom, they are unlikely to be in the stomach. (B and C) Horizontal right lateral radiographs of a free-ranging snapping turtle (*Chelydra serpentina*) that has ingested a fishing hook (*arrows*). The hook is closely associated with the cervical vertebrae, and when the head of the anesthetized turtle is extended (C) the hook moves position, confirming location within the esophagus. (D) Dorsoventral radiograph of an African spurred tortoise (*Centrochelys sulcata*) with severe constipation but without evidence of complete obstruction. (E) Dorsoventral radiograph of a desert tortoise (*Gopherus agassizii*) with a focal area of constipation. The gaseous distension is concerning and can indicate obstruction. (F) Dorsoventral radiograph of a Greek tortoise (*Testudo graeca*) demonstrating severe gas accumulation throughout the gastrointestinal tract. There is no evidence of an obvious obstruction and ileus due to gastroenteritis or generalized ileus is more likely. (G) Dorsoventral radiograph of an African spurred tortoise (*Centrochelys sulcata*) with gaseous distension of the large intestine and a visible stricture aborad (arrow). Surgical exploration revealed an intussusception. (A, Courtesy of S. Shaw, Broadview Animal Hospital; B–G, courtesy of Stephen J. Divers.)

that results in progressive gas distention (see fig. 56.10F). Severe gas distention with obstruction within the more distal portion of the small intestine is the most challenging to distinguish from a generalized pattern. A wide range of conditions are reported in which radiography and/or contrast studies were part of, or pivotal in, the diagnostic process and directed therapeutic intervention; these include foreign body obstructions, lead poisoning, coelomitis due to perforation, hematochezia with constipation, volvulus, and strictures.[18–22] Additionally contrast studies are valuable in detecting a persistent abnormality over serial studies in a manner that is not possible with other imaging modalities.[19]

REPRODUCTIVE SYSTEM

Radiographic examinations of the reproductive tract require dorsal and lateral horizontal beam images, with the dorsal image generally considered most useful. This is commonly performed for reproductive monitoring and conditions such as dystocia. Radiographic examination is limited regarding detection of follicles and ova due to the poor detail in the coelom.[23] Ultrasonography and CT provide a more thorough evaluation of the entire reproductive tract and can be employed as a second line diagnostic, especially if any pathologic change is suspected in the ovaries, salpinx, or testes.[23–25]

Since late-stage eggs have a variably mineralized shell, they are readily identifiable on radiographs in spite of poor coelomic detail (Fig. 56.12).[1,23] It is important to critically evaluate the shape, thickness, continuity, and uniformity of the mineralized egg shell, distribution of eggs within the coelom, uniformity in the size of eggs, and the presence of abnormal soft tissue associated with the egg or the reproductive tract. Before mineralization, follicular enlargement can produce a midcoelomic mass effect and compress the lungs craniodorsally.[23] The radiographic signs of dystocia include enlarged eggs, fractured egg shells, follicular stasis, or normal eggs outside of the reproductive season.[23] Eggs with increased but even shell mineralization and smooth shells are typically associated with prolonged retention within the lower reproductive tract. However, thickened and rough shells are often an indication of uric acid and mineral deposition on the shells of eggs that have been retained within the urinary bladder.

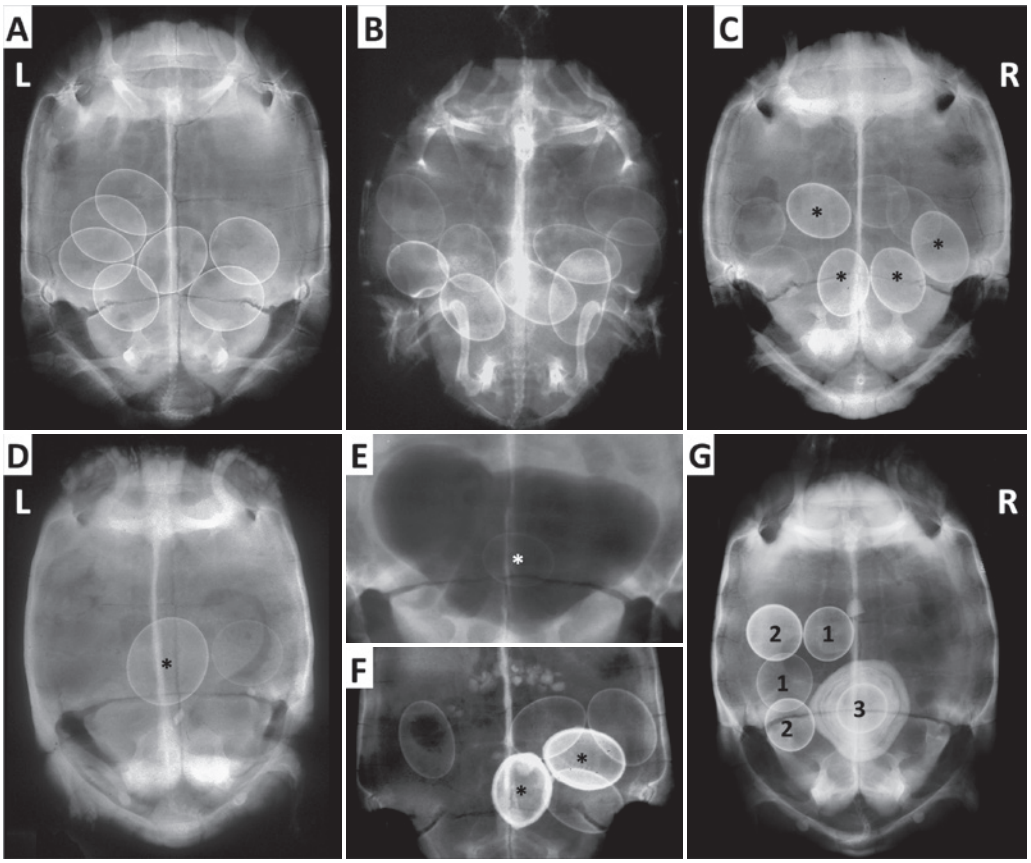

FIG 56.12 (A) Dorsoventral radiograph of a Greek tortoise (*Testudo graeca*) demonstrating normal eggs during the reproductive season. (B) Dorsoventral radiograph of a red-eared slider (*Trachemys scripta elegans*) demonstrating normal eggs during the reproductive season. Note the more elongated appearance of the eggs in this species. (C) Dorsoventral radiograph of a Greek tortoise (*Testudo graeca*) demonstrating normal (thin-shelled) eggs and abnormal eggs (*) with increased, even shell thickness consistent with prolonged retention within the oviduct. (D) Dorsoventral radiograph of a *Testudo* tortoise exhibiting a normal egg (in terms of size and shell thickness) and a significantly larger egg with increased shell thickness (*). Although some species of chelonian naturally produce a few large eggs, this is abnormal in *Testudo*. (E) Dorsoventral radiograph in a tortoise demonstrating a poorly mineralized egg (*) within the bladder by pneumocystography. (F) Dorsoventral radiograph of a Greek tortoise (*Testudo graeca*) demonstrating four normal (thinly shelled) eggs and two abnormal eggs (*). In this case the shells are irregularly thickened, which is commonly associated with eggs retained in the bladder and acting as a nidus for uric acid deposition. (G) Dorsoventral radiograph of a *Testudo* tortoise demonstrating two relatively normal eggs (1), two eggs with increased shell thickness (2), and a third egg (3) that has been retained in the bladder and acted as a nidus for a large calculus. (Courtesy of Stephen J. Divers.)

Abnormal soft tissue accumulation associated with the reproductive tract should produce areas of further reduced coelomic detail, which can be an interpretative challenge. It is important because these soft-tissue changes are sentinel indicators of disease processes such as follicular stasis or yolk coelomitis. For example, follicular stasis can be inferred from radiographic examinations when a soft-tissue-mass effect is persistently seen in the mid coelom.[2]

URINARY SYSTEM

When radiographically evaluating the chelonian urinary bladder, it is important to remember that it is extremely expansive in volume and bilobed in shape. It can extend into the midcranial coelom (Fig. 56.13) and can be in close proximity to the stomach. In a normal state, the urinary bladder is indistinct and difficult to identify, because the soft tissue is effaced by adjacent organs and there is poor coelomic detail.[2] Similar to the remainder of the coelom, the standard examination of the urinary system consists of dorsoventral and lateral horizontal beam images. Contrast studies can also be used to improve visualization.

Radiographic examinations of the urinary tract are most commonly performed to evaluate for urinary calculi. Urate calculi are the most common in chelonians, and although urate is radiolucent, these calculi are typically visible on radiographs because of their size, density, and deposition of additional mineral complexes over time (Fig. 56.14).[2] The calculi tend to occur with greater frequency in the left lobe of the bladder.[1,26] They have an irregularly lamellated appearance and an irregularly rounded shape. Obstruction of the urinary bladder due to calculi is uncommon, but obstruction at the level of the cloaca can cause ureteral obstruction. Severe urinary bladder distention due to a spinal fracture has been reported; this demonstrates the importance a systematic review of whole body examinations because both of these conditions are clinically significant, but the urinary issues may require more emergent intervention.[10] Contrast cystography (Fig. 56.15) is an option to define the urinary bladder, as well as for detection of other

VetBooks.ir

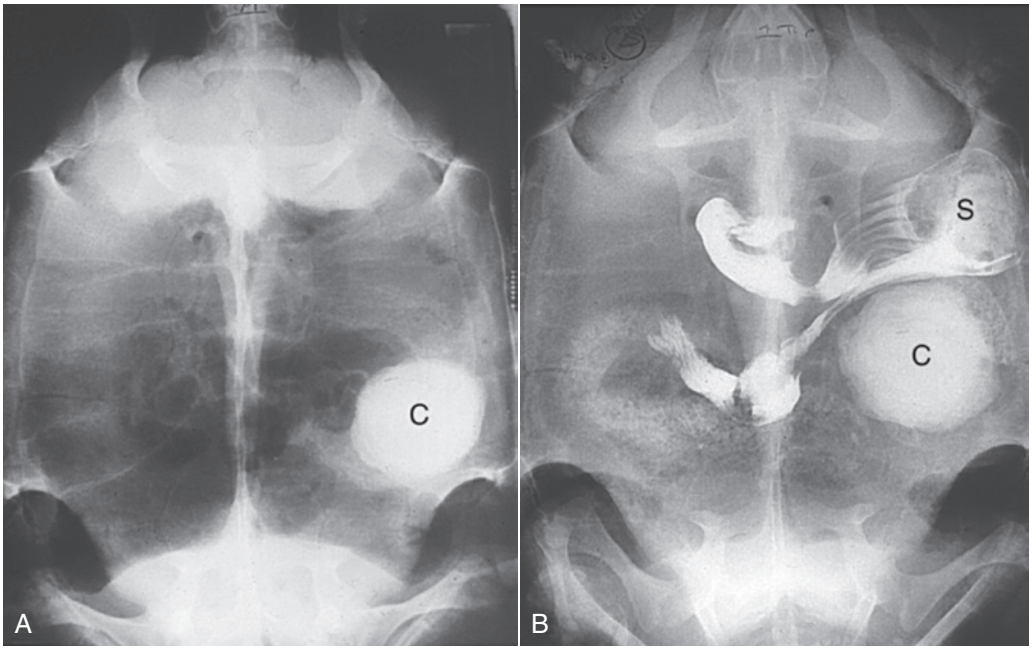

FIG 56.13 Desert tortoise (*Gopherus agassizzi*). (A) A large mineral, opaque, rounded structure is seen in the mid right lateral coelom. It is located in a position that should be considered for a urinary calculus based on the degree of expansion that is possible in the chelonian urinary bladder. It is positioned near the caudal contour of the stomach based on the presence of fine amorphous soft tissue that is likely ingesta. The appearance is also suspicious, because calculi in chelonians are typically highly radiopaque, irregularly marginated, and can have a lamellar internal architecture. (B) In radiographs made 4 years later, the calculus is slightly larger. Its position adjacent to the stomach is better seen with the positive contrast in the gastric lumen, which was administered to rule out the possibility of a gastrointestinal foreign body. (Courtesy of Sam Silverman.)

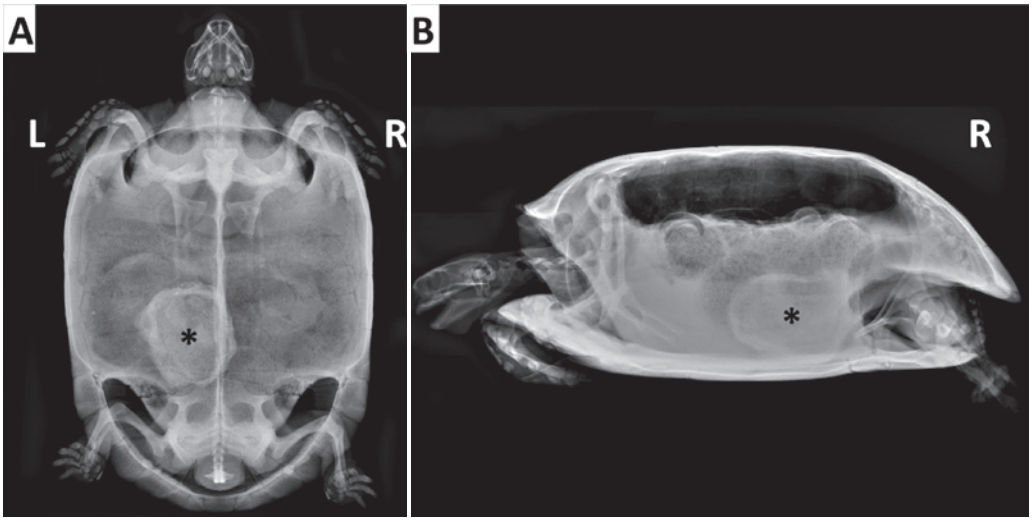

FIG 56.14 Dorsoventral (A) and horizontal beam right lateral (B) radiographs of a gopher tortoise (*Gopherus polyphemus*) demonstrating a large mineralized structure (*) in the caudoventral coelom that was confirmed as a urinary calculus by ultrasonography. (Courtesy of Stephen J. Divers.)

pathological conditions like small, radiolucent urate calculi, rupture, herniation/displacement, or masses (granuloma or neoplasia).

In survey radiographs, the location of the kidneys in the dorsocaudal aspect of the coelom severely limits their visibility.[2] Renal calcification is not commonly seen in chelonians, but increased opacity would increase their visibility. Similarly, intravenous iodinated contrast can be administered to evaluate the kidneys and ureters.

MUSCULOSKELETAL SYSTEM

Evaluation of appendicular skeleton and shell in chelonians may be necessary to investigate disease processes like trauma, osteomyelitis or septic arthritis, metabolic bone diseases, or neoplasia (Fig. 56.16). Of the systems discussed, radiography is particularly useful in chelonians, because the shell and bones are the most opaque structures in the body.

VetBooks.ir

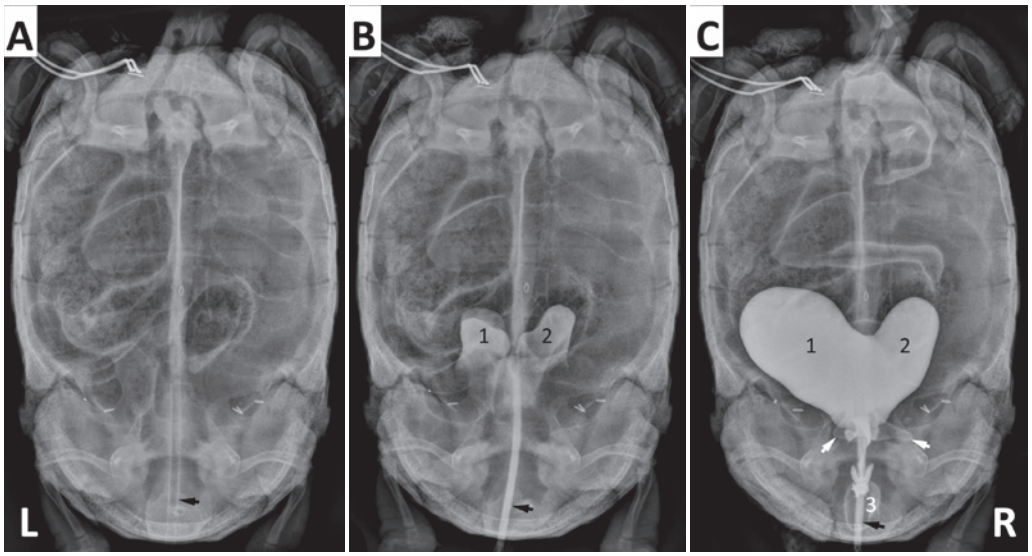

FIG 56.15 Serial dorsoventral radiographs demonstrating positive contrast cystography in a red-footed tortoise (*Chelonoidis carbonaria*) using a 12Fr red rubber catheter (black arrows) and iohexol. (A) Immediately after catheterization of the bladder. (B) Initial infusion of contrast demonstrates the left (1) and right (2) lobes of the bladder. (C) Submaximal infusion demonstrates greater distension of the bladder (1, 2), with contrast also backflowing into the accessory bladders (white arrows) and proctodeum (3). Cystography can be used to evaluate for possible bladder rupture, radiolucent calculi, bladder masses/neoplasia, and anatomical defects or displacements. (Courtesy of Stephen J. Divers.)

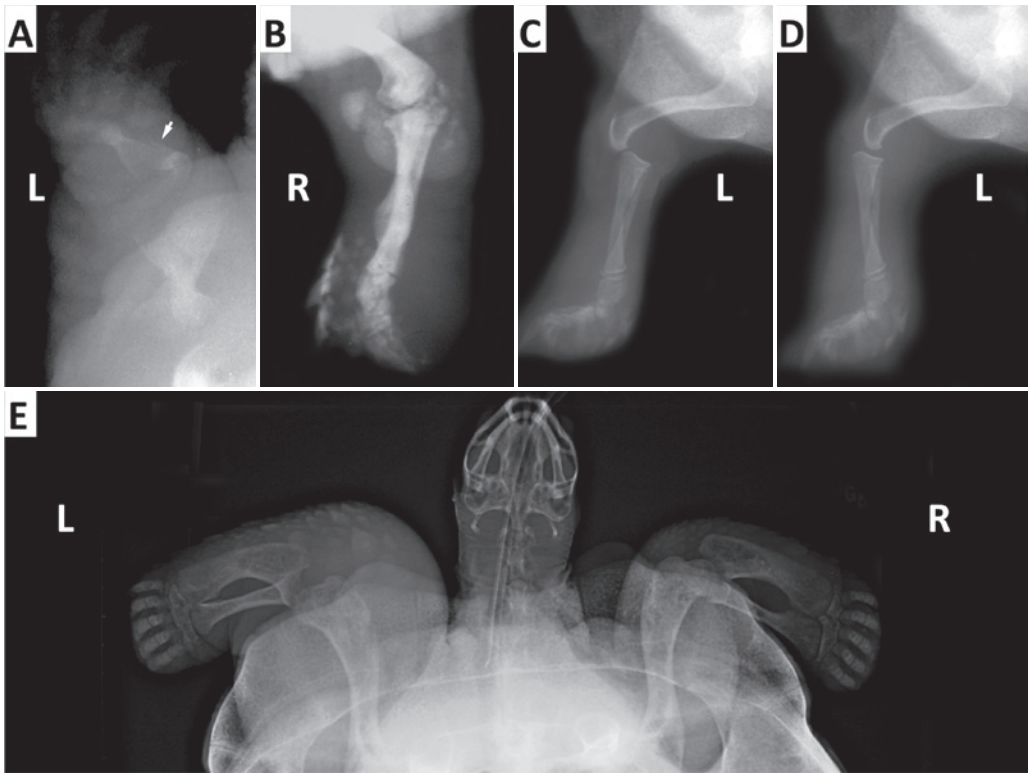

FIG 56.16 Dorsoventral radiographs (lateral view of limbs) of chelonians. (A) Reduced bone mineralization and pathological fracture of the left radius (arrow) associated with nutritional secondary hyperparathyroidism in a juvenile snapping turtle (*Chelydra serpentina*). (B) Effusion, swelling, and osteolysis associated with the right stifle of a *Testudo* tortoise due to septic arthritis and osteomyelitis. (C) Left stifle luxation in a *Testudo* tortoise that was associated with struggling against straw wrapped around the limb. (D) The same limb after cruciate ligament repair and joint imbrication. VetBooks.ir

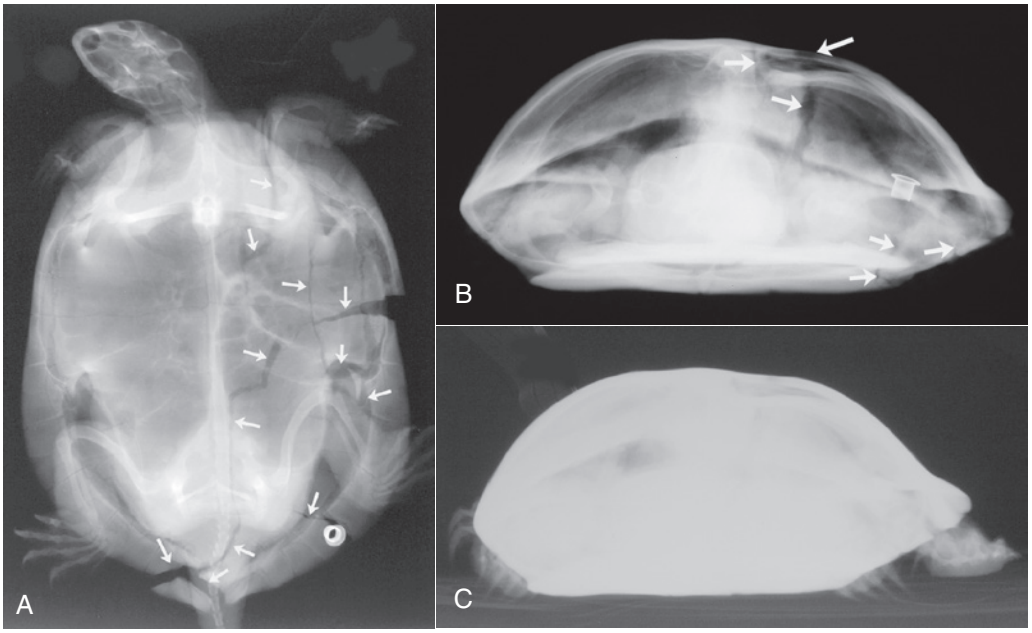

FIG 56.17 Multiple carapacial fractures with varying degrees of displacement (arrows) are present. The value of images with different image orientations noted as well. The slight depression of the carapace lateral to the near midline fracture is only seen on the craniocaudal. The effect of image quality is also demonstrated in this examination. The dorsoventral image (A) is the most appropriate exposed image. The craniocaudal image (B) is diagnostic as well, and fractures are more easily seen in the areas of the lungs and are superimposed over coelomic soft tissue; more critical evaluation is needed in this area since the human eye is best at detecting lesions on a black background. These are film-screen images, which would almost necessitate different exposures for the dorsal aspect of the patient compared with the ventral part. In contrast, digital radiography better corrects for these differences through postexposure processing. The lateral image (C) is severely underexposed to the extent that the fractures are barely visible. (Courtesy of Sam Silverman.)

Interpretation principles used in mammalian species are also more easily extrapolated, with a few notable additions. Obviously, systematic review of the shell is critical in chelonians. The long bones should have distinction between the cortical and medullary bone areas, but the transition between these is less distinct than is seen in normal mammal long bones.[1] In chelonians, the opacity of the pectoral girdle is used as a reference point in evaluating the quality of the radiograph and the bones; pectoral girdle bones should be clearly visualized with sharp margins, a small medullary canal, and a homogeneous cortical radiopacity.

Injuries to the chelonian shell are common. Because these are often visible on examination of the patient, the role of radiography is to document the degree of displacement and extensiveness of shell trauma, as well as to investigate for concurrent soft-tissue abnormalities associated with the injuries, especially pulmonary involvement.[3] Detection of minimally displaced fractures can be challenging if the x-ray beam is not tangential to the orientation of the fracture through the carapace or plastron. A complete examination of the carapace and plastron for fractures includes the dorsoventral, horizontal beam lateral, and horizontal beam craniocaudal images (Fig. 56.17). Additional oblique radiographs may be needed for detection of non- or minimally displaced fractures. This is more commonly needed in larger chelonians or those with greater carapacial curvature. CT can be extremely helpful in documentation of such injuries. Radiographs are also frequently utilized for serial postoperative evaluations (Fig. 56.18). However, monitoring healing of the shell is challenging, because healing occurs primarily through a fibrous callus, and the fracture lucent line can persist for years. It has been recommended that radiographs be repeated 10 to 20 weeks after stabilization, but complete healing and remodeling may take 12 to 18 months.[2] If the carapace fracture crosses midline, concurrent spinal fracture should be expected, because the spine is intimately associated with the ventral surface of the carapace. CT, myelography or magnetic resonance imaging would be needed to evaluate the integrity of the spinal cord.[27]

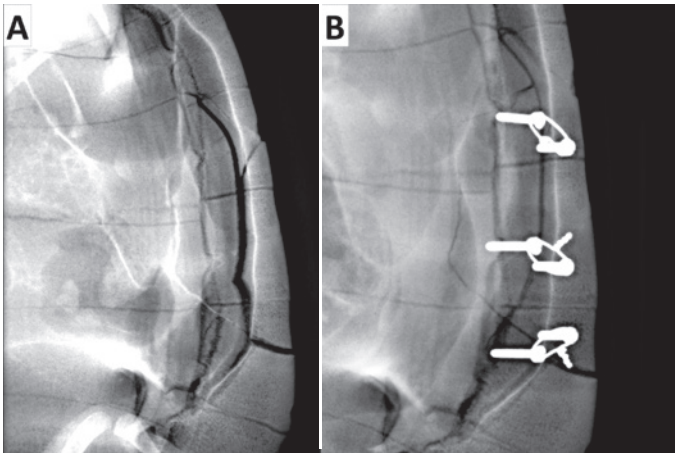

FIG 56.18 Dorsoventral radiographs of the fractured right plastrocarapacial bridge in an aquatic turtle before (A) and after repair (B). Note the radiolucency around the screws, which in this case is a software artifact and not indicative of osteolysis. (Courtesy of Stephen J. Divers.)

Musculoskeletal trauma can result in fractures, luxations, subluxations, or soft-tissue injury (i.e., tendon/ligament tearing or muscle strain/

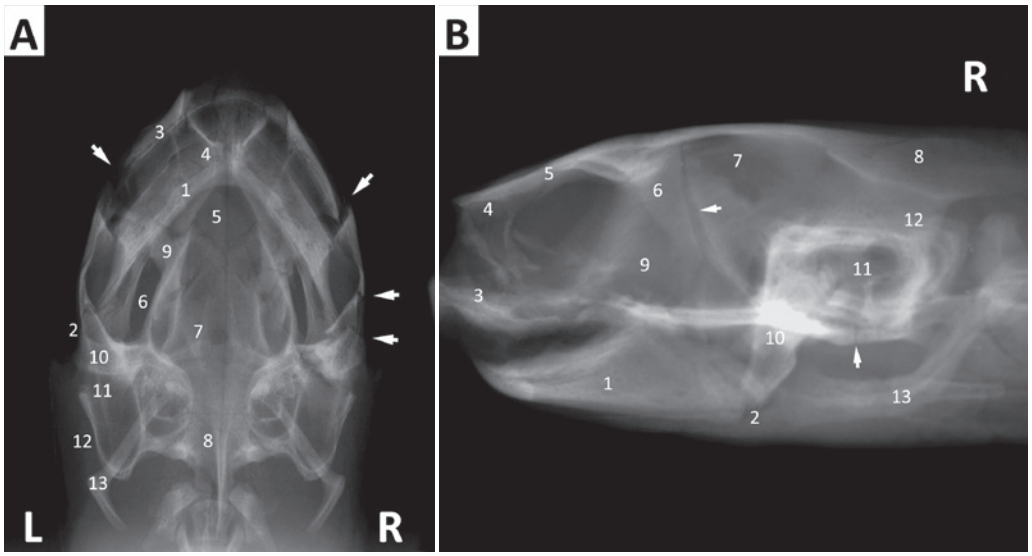

FIG 56.19 (A) Dorsoventral and right lateral radiographs of a *Testudo* tortoise skull demonstrating multiple fractures (*arrows*) and the major bones and structures including mandible (1), temporomandibular joint (2), maxilla (3), prefrontal (4), frontal (5), postorbital (6), parietal (7), supraoccipital (8), jugal (9), quadrate (10), auditory canal (11), squamosal (12), and ceratobrachial of hyoid apparatus (13). (Courtesy of Stephen J. Divers.)

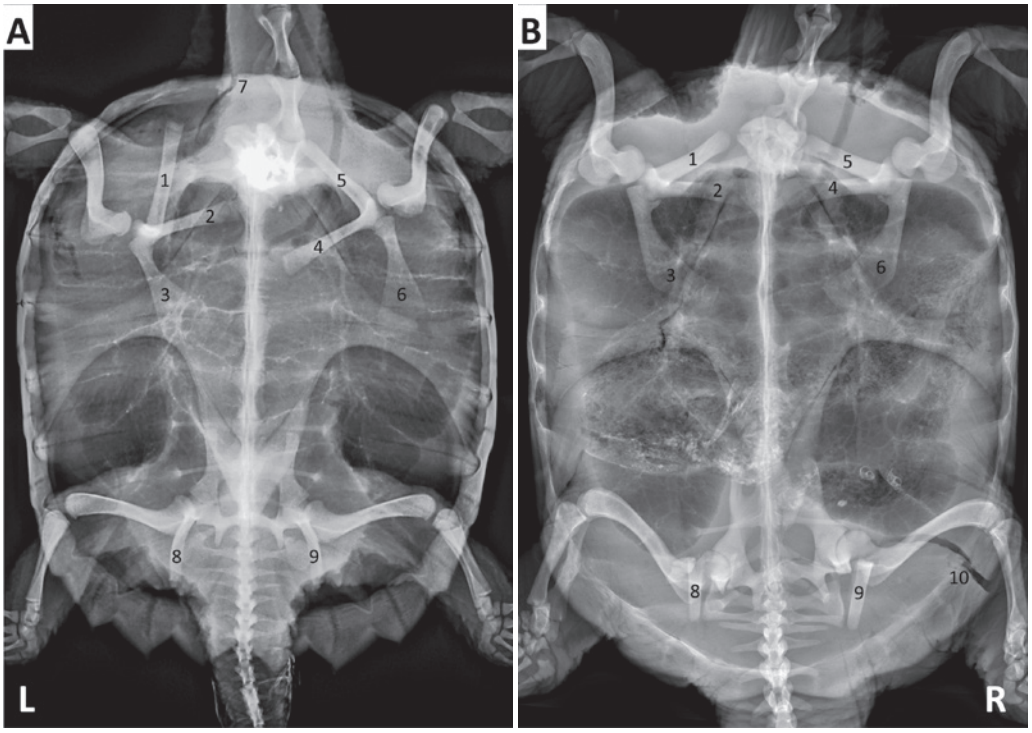

FIG 56.20 Dorsoventral radiographs of two traumatized snapping turtles (*Chelydra serpentina*). (A) The left acromion process (1) has fractured and is overriding the scapula (2) near the scapulohumeral joint. The left coracoid is unremarkable. The right scapula (4) has luxated from its normal attachment to the first fixed vertebra and has rotated caudad. Consequently, although the associated acromion process (5) and coracoid (6) retain their normal anatomical relationship with the scapula, they have also been rotated medially and laterally, respectively. A fracture of the cranial carapace is also visible (7). These injuries are commonly associated with a dorsoventral compressive force applied to the cranial carapace. The same pectoral structures in their usual positions have been labeled in (B) for comparison. (B) There are bilateral fractures of both left and right ilia (8 and 9), and an obvious fracture of the right caudal carapace (10) is present. These injuries are commonly associated with a dorsoventral compressive force applied to the caudal carapace. The same pelvic structures in their usual positions have been labeled in (A) for comparison. (Courtesy of Stephen J. Divers.)

VetBooks.ir

sprain). Orthogonal radiographs of the limb(s) are needed for evaluation of the appendicular anatomy, consisting of lateral and craniocaudal/dorsopalmar/dorsoplantar images. The axial skeleton should be evaluated with dorsoventral and horizontal beam lateral images (Fig. 56.19). General anesthesia is needed for positioning the limb in extension and away from the carapace but should also be considered in traumatic cases for patient comfort. Fractures in the long bones are more easily seen than fractures involving the pectoral or pelvic girdles (Fig. 56.20). It is helpful to have a normal comparison series of radiographs of different species, especially for the interpretation of these more complex anatomical areas. CT can also be helpful in identifying fractures but can also aid in surgical planning. In chelonians, CT has also been shown to better define abnormalities that correlate with clinical presentation and were underestimated by radiography.[28] Dislocations or luxations can be encountered in chelonians in association with mishandling or predation. Similar to fracture detection, scapulohumeral or coxofemoral luxations may be more difficult; the addition of a horizontal beam craniocaudal radiograph may be beneficial in evaluating these areas.[2] Radiography is repeated for monitoring treatment of musculoskeletal disease in chelonians, similar to other species.

Osteomyelitis and septic arthritis are common. The radiographic features of osteomyelitis may include lytic and osteoproliferative changes in the affected bone(s). In contrast to mammalian species, the degree of lytic changes is greater, especially relative to periosteal reaction.[1,3] It is often accompanied by caseous abcessation.[2] Soft-tissue enlargement is prominent and causes regional distortion of anatomy. In the early stages, soft-tissue changes may be the only abnormality associated with osteomyelitis or septic aarthritis.[3] In the author's experience, critical evaluation of soft tissue is often skipped in musculoskeletal interpretation; it should be conceptualized as directing one's attention to an area that may not have osseous changes and therefore may be the most important to critically evaluate in the absence of bone changes.

Metabolic bone disease, specifically nutritional secondary hyperparathyroidism, is commonly seen in chelonians due to husbandry-related issues. Evaluation for nutritional secondary hyperparathyroidism requires good-quality radiographs to prevent erroneous diagnosis associated with bad technique (i.e., overexposure to reduced contrast). It also requires clinical experience with the expected degree of skeletal mineralization seen in different species at different ages (neonates and juveniles often exhibit reduced mineralization for up to the first year). Assessment of the pectoral or pelvic girdles provides the best assessment of skeletal mineralization. Diffusely decreased opacity of the bones is the primary abnormality (Fig. 56.21). Cortical bone thinning, shell, and less commonly, limb thickening due to fibrous proliferation and pathological fractures can further support the radiographic diagnosis.[2,3] Soft-tissue mineralization, mineralized gout tophi, or pseudogout represent other metabolic diseases that are often associated with nephropathy or excessive dietary protein.

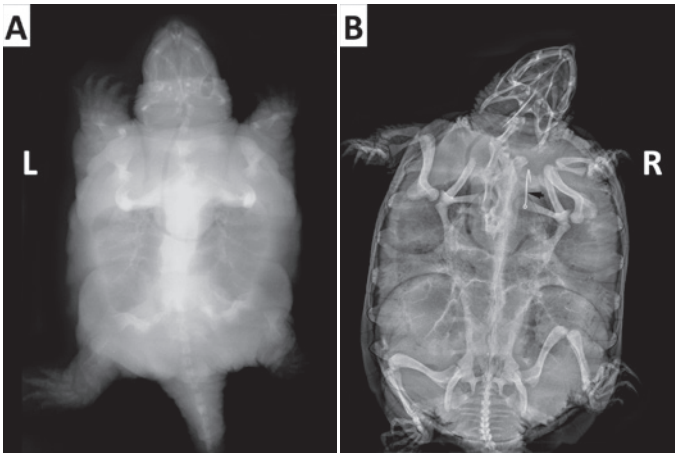

FIG 56.21 Dorsoventral radiographs of a juvenile common snapping turtle (*Chelydra serpentina*) with nutritional secondary hyperparathyroidism (A) and comparison to a normal animal of the same species (B). The generalized decrease in skeletal mineralization and reduced contrast between bone and soft tissues are characteristic of this condition. (Courtesy of Stephen J. Divers.)

Finally, degenerative joint disease is an increasingly encountered abnormality in radiographic examinations of older animals or those with previous musculoskeletal trauma.[2] This is partly associated with their lifespan, as they are some of the longest living animals encountered in veterinary practice. The radiographic features include periarticular mineral proliferation, forming osteophytes.[29] With advanced disease, there is more extensive soft-tissue mineralization around the joint, which is not a common feature in mammals. This can limit range of motion. Grossly, dense fibrous tissue accompanies this proliferation. Infrequently, in cases of severe coxofemoral degenerative joint disease femoral head and neck arthroplasty, can be performed as a salvage procedure.[30] Degenerative joint disease can be an age-related issue but can also be seen in association with prior disease processes like septic arthritis that have subsequently resolved. It should be noted that it can be difficult to distinguish active septic arthritis from degenerative changes in the early stages.

Radiography—Crocodilians

Nathalie Rademacher and Javier G. Nevarez

Standard equipment such as digital or computer radiography (DR or CR) can be used in crocodilians to acquire standard orthogonal views. In field situations, portable x-ray tubes are feasible, however, that will depend on the size of the animal. Depending on the history and clinical presentation, each body part can be radiographed with a similar technique and positioning used in small animals and will be described in more detail below. Radiation safety principles are the same as for small animals, and positioning devices such as foam pads or wedges, radiolucent tape, paper towels, sandbags, and PVC pipes should be used whenever possible with proper collimation for correct positioning to obtain high-quality diagnostic radiographs. Keep in mind that sandbags are of mineral opacity and need to be collimated out of view.

RESTRAINT, PREPARATION, AND POSITIONING

Crocodilians can be powerful animals, even at a small size. Proper restraint is essential for safety of the personnel and the animals, and sedation or anesthesia may be required to obtain the best views. Manual restraint should include keeping the mouth taped shut and the legs tied together. Even with the mouth taped, some teeth remain exposed and can inflict damage to personnel, so care must be taken when working with the head. Taping the eyes closed and inducing a vasovagal response is often effective.

In preparation for imaging, make sure the animal is clean, dry, and free of debris. In general, a minimum of two orthogonal views of each body part should be obtained. Additional views may be obtained as needed. Positioning for standard orthogonal views is similar to other animals. Based on the size of the animal and indication for performing the study, multiple views may be necessary for certain body areas or the whole body can be included in one image. The region of interest must be centered in the image, with proper collimation being used. Patient identification and directional markers must be clearly incorporated, not handwritten on the finished radiograph.

WHOLE BODY

Whole body imaging generally includes all structures except the tail, skull, and distal part of the limbs, although in small animals it may encompass most body structures. For the lateral projection, the crocodilian is placed in sternal recumbency with the legs in a neutral position or restrained away from the coelom and a horizontal beam directed through the patient (Fig. 57.1A). In crocodilians, a traditional lateral projection with the animal in lateral recumbency is also acceptable because the organs are compartmentalized and will not shift within the coelomic cavity as in other reptile species. For the dorsoventral (DV) or ventrodorsal (VD) projection, place the animal in sternal or dorsal recumbency (see Fig. 57.1B). These views are generally used to assess injuries after trauma or to assess bone density in cases of metabolic bone disease (e.g., nutritional secondary hyperparathyroidism) (Fig. 57.2). These studies should not be used when evaluating specific areas, such as cranial coelom, caudal coelom, or the skeleton, due to technique differences as well as x-ray beam divergence that will result in improper centration.

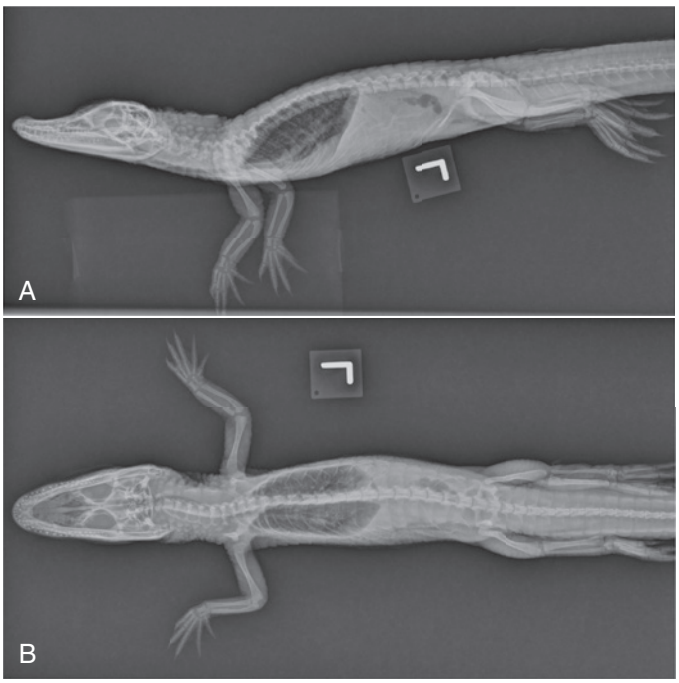

FIG 57.1 Whole body radiographs of an alligator (*Alligator mississippiensis*) brought in for head tilt and circling. (A) Left lateral (vertical beam) radiograph was acquired with the legs in neutral position. (B) VD projection with the patient in dorsal recumbency. Alternatively, a DV view with the patient in sternal recumbency can be acquired as well. No abnormalities were seen. (Courtesy of Natalie Rademacher.)

CRANIAL COELOM

Orthogonal views, including right (and potentially left) lateral(s) (Fig. 57.3A) and DV (and potentially VD) views (see Fig. 57.3B), are recommended. The front limbs should be extended cranially to avoid superimposition with the lungs in the lateral view. In some cases, both

VetBooks.ir

FIG 57.2 (A) Lateral and (B) dorsoventral views of the skull of an alligator (*Alligator mississippiensis*) that presented with a hunched posture and stiff legs at 1 week duration. (C) Dorsoventral whole body view. Overall, severe decreased bone opacity with thin irregular cortices is noted. Moderate folding of multiple long bones, most pronounced in the left radius as well as the tibias and fibulas bilaterally. Moderate leftward and rightward angulation of several caudal vertebral bodies throughout the length of the tail. Diagnosis of a nutritional secondary hyperparathyroidism was made with multiple chronic folding fractures. (Courtesy of Natalie Rademacher.)

VetBooks.ir

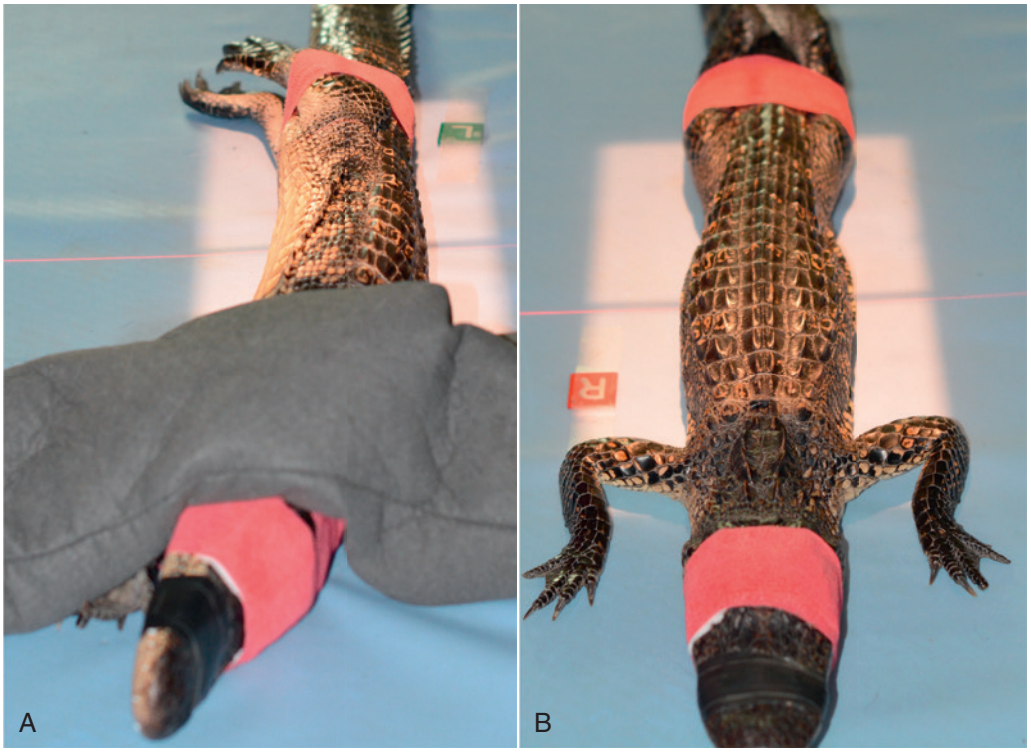

FIG 57.3 Photographs demonstrating positioning for coelomic and spinal projections in an alligator (*Alligator mississippiensis*). (A) Left lateral recumbency. A sandbag has been placed over the cranial half to stabilize the animal in lateral recumbency, and the legs have been secured with tape (not shown). Additionally, vet wrap has been placed over the eyes to calm the animal down. Care must be taken to align the alligator perpendicular to the tabletop in order to acquire straight radiographs. This positioning can be used to acquire total body, coelomic, and/or abdominal radiographs with a shift in the center of the field of view and collimation. (B) Sternal recumbency to demonstrate positioning for the DV view for total body, coelomic, abdominal, or spinal radiographs. Due to the shape of crocodilians, the DV view is usually easier to acquire. (Courtesy of Natalie Rademacher.)

lateral radiographs might be useful for evaluation. Respiratory motion artifacts are not usually a problem. If the patient is large, multiple views of the area of interest may be needed. Exposure at peak inspiration is ideal to maximize contrast by increased aeration. Care must be taken to include all pulmonary boundaries (Fig. 57.4).

CAUDAL COELOM

Right lateral and DV radiographic views are standard, with similar positioning for the cranial coelom (Fig. 57.5). Hind legs can be left in neutral positions or taped caudally along the tail base, out of the coelomic field as shown in Fig. 57.3. Exposure should be acquired at expiration (see Fig. 57.4). In large animals, multiple views will be needed for a complete evaluation.

SKULL

Lateral and VD or DV views are the minimum required projections to evaluate the skull. Given the lack of mobile soft tissues, vertical beam laterals are acceptable. Care must be taken for optimal and accurate positioning of the skull to obtain symmetric diagnostic radiographs. For the lateral projection, place the animal in left or right lateral recumbency with front legs against the body and away from the head. The head is extended in a 90-degree angle perpendicular to the tabletop. A thin foam wedge or paper towels are placed to elevate the tip of the nose so its perpendicular to the tabletop (Fig. 57.6A). The mandibles should be superimposed with each other to check for symmetry (see Fig. 57.6C); however, this might be difficult in cases of mandibular or maxillary trauma. The orthogonal view can be acquired in either the DV or VD projection, depending on specific area of interest (see below) (see Fig. 57.6B and D). Foam wedges or paper towels should be used to elevate the tip of the nose so it is parallel with the table or cassette when in dorsal recumbency, whereas it is not necessary when placing the animal in sternal recumbency, making this view easier to acquire.

Open-mouth images are acquired with the use of a mouth gag (Fig. 57.7A and C) for separation and evaluation of the dental arcades. In cases of trauma and more specifically suspected fractures, the use of mouth gags must be done carefully to prevent injury. Oblique images are acquired in right and left lateral recumbency with rotation of the head by 20 to 45 degrees (see Fig. 57.7B), which highlights the left maxillary and the right mandibular arcades (see Fig. 57.7D). Fig. 57.7E depicts the contralateral maxillary and mandibular arcades and should be acquired for comparison. A case example of a traumatic injury to the right maxilla, also affecting the dental arcade, hard palate, and nasal bone that extends over to the right side, is shown in Fig. 57.8.

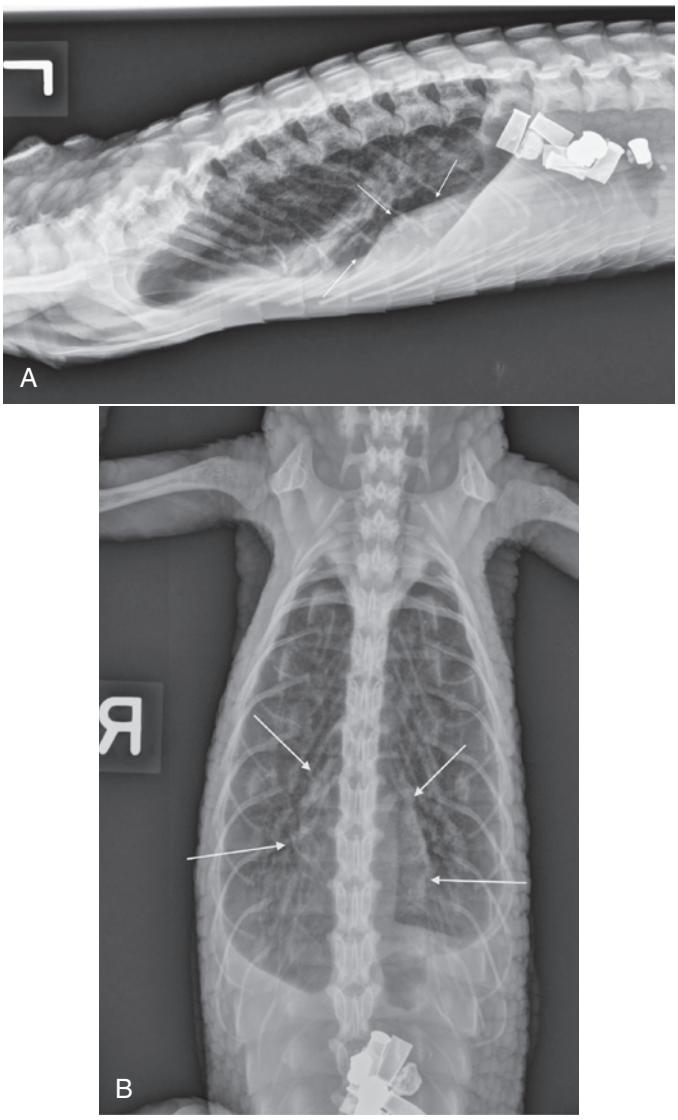

FIG 57.4 (A) Left (vertical beam) lateral and (B) DV cranial coelomic radiographs are shown from the same alligator (*Alligator mississippiensis*) as in Fig. 57.3. The front legs have been positioned out of the field of view cranially to avoid superimposition with the cranial coelom to allow identification of the most cranial part of the lungs. The cardiac silhouette (arrows) is indistinct and silhouettes with the diaphragmatic muscle at its caudal border. The alligator ingested multiple bullets and bullet casings. (Courtesy of Natalie Rademacher.)

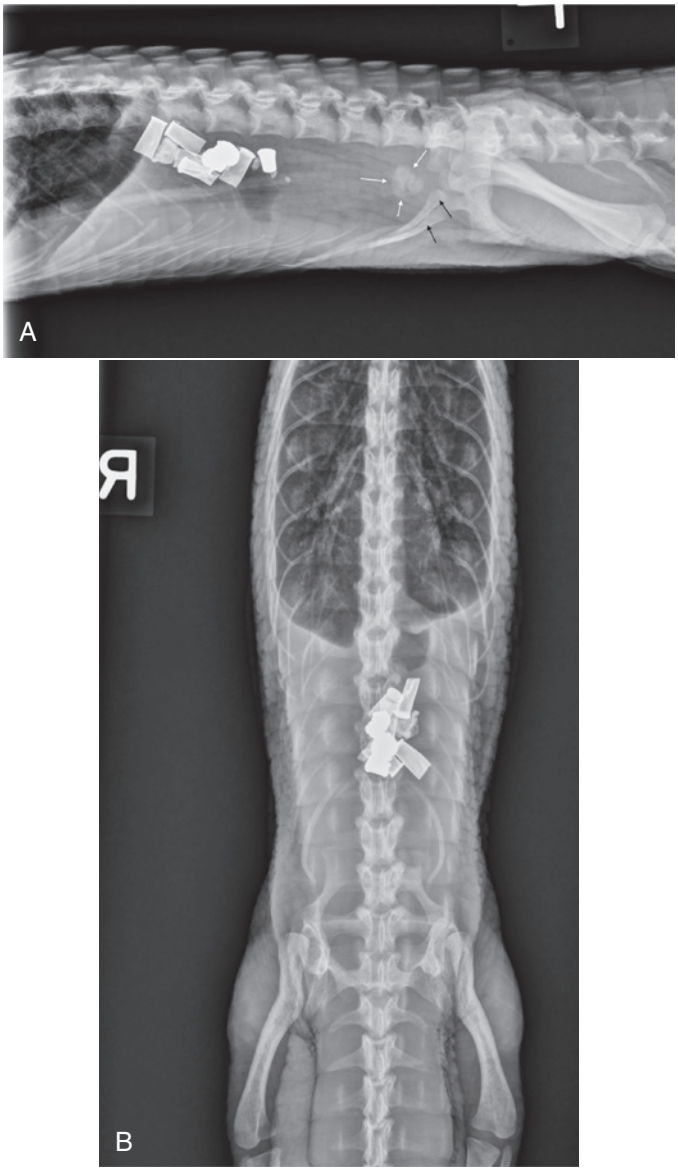

FIG 57.5 (A) Left lateral and (B) DV caudal coleomic radiographs of the same alligator (*Alligator mississippiensis*) shown in Figs. 57.3 and 57.4. The hind legs have been pulled and taped caudally to avoid superimposition with the caudal coelom. Note the multiple bullets and shell casings in the stomach. A well-defined, round mineral opacity is present in the caudal coelom (white arrows) with differentials of a urolith or bates body (calcified fat). The black arrows are pointing at the elongated pubic bone that is characteristic of crocodilians. (Courtesy of Natalie Rademacher.)

SPINE/TAIL

Lateral and VD/DV views are the minimum required projections to evaluate the spine. For the cervical spine, the front legs should be positioned caudally to prevent superimposition and allow evaluation of the entire cervical region (Fig. 57.9A, B, and D). The reminder of the spine must be acquired in separate segments to avoid beam divergence and are acquired in a similar position as shown in Fig. 57.3 (see Fig. 57.9C, E, and F). The total number of radiographs will depend on the size of the animal and available detector size. Fig. 57.10 shows positioning for tail radiographs. Additional views may be needed depending on lesion localization and suspected underlying disease process. As with the skull, care must be taken for optimal and accurate positioning to obtain symmetric diagnostic radiographs.

LIMBS

Lateral radiographs can be acquired either in sternal (Fig. 57.11A and B) or dorsal recumbency (see Fig. 57.11C and D). With the animal in lateral recumbency, the affected limb is placed down and the contralateral limb is pulled caudally away from the field of view to avoid superimposition (see Fig. 57.11A). Joint studies should include the proximal and distal third to the joint, whereas long bone studies should include the proximal and distal joints. Front or hind limb overview studies can be acquired for trauma evaluation or to rule out a lytic process. If lameness

is present and can be localized to a specific joint or bone, or if a soft tissue swelling or skin defect/laceration is present, collimated views of affected areas should be acquired (Fig. 57.12). Contralateral radiographs of the unaffected side should be acquired for comparison. The orthogonal craniocaudal or caudocranial views are best acquired in dorsal recumbency (Fig. 57.13) with the leg angled away from the body to avoid superimposition with the body wall. This is important for the evaluation of soft tissues, as otherwise soft tissue swelling can be missed.

PELVIS

Proper evaluation of the pelvis requires good positioning and collimation of orthogonal views (Fig. 57.14). Evaluation of the pelvis and femur should be done with the limbs extended and in neutral positions (see Fig. 57.14).

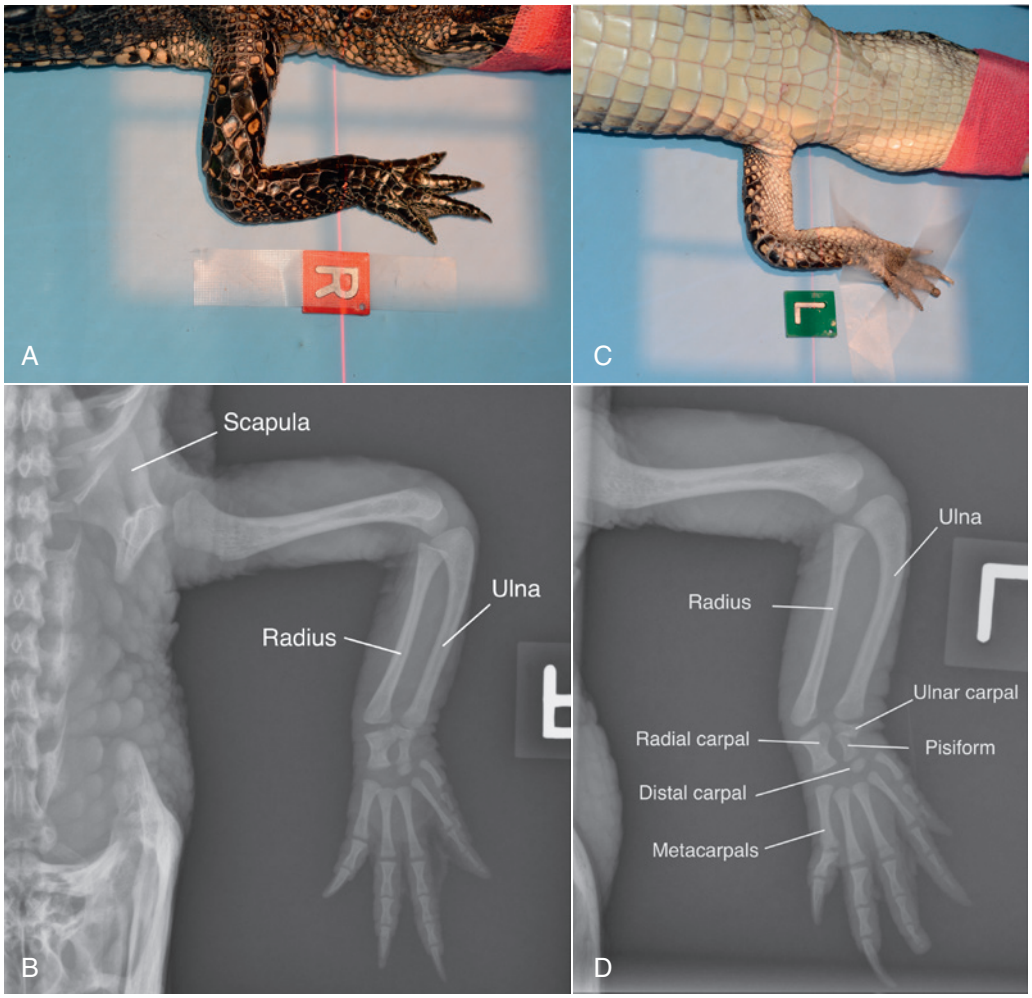

FIG 57.11 (A and B) Positioning and radiograph of the lateral projection of the right front leg with the alligator (*Alligator mississippiensis*) in sternal recumbency. Alternatively, the animal can be placed in lateral recumbency, as shown for the left front leg (C and D). The contralateral leg has been taped caudally along the body wall to avoid superimposition, and the foot has been secured with radiolucent tape to the table. The resulting views are the same and are good overviews of the skeletal structure of the front leg. Note that while a lateral view of the radius and ulna is acquired, the foot is in a dorsopalmar position. The same approach can be used for the hind limbs. (Courtesy of Natalie Rademacher.)

Ultrasonography

Claudia Hochleithner and Ajay Sharma

Ultrasonography has been used in small animal medicine routinely for more than 25 years. It has become a valuable imaging technique. Early sonographers of reptile patients adapted established small animal imaging techniques to the special anatomic features encountered within the wide range of animals in this class.[1–7] With continuing advances in ultrasound machines and transducers, the often small size of reptilian or amphibian patients is less of an obstacle. It is possible to perform ultrasonography even in small geckos or chameleons, with transducer frequencies of 10, 12, or even 18 and higher MHz. However, several unique considerations still must be kept in mind during ultrasonography of these species and will be discussed.

EQUIPMENT

Given the advances in ultrasound technology and equipment over the last several decades, good-quality scanners with high-frequency transducers are available for a reasonable price. A single, all-encompassing transducer does not exist because of the wide range of anatomic situations that may be encountered. Relatively inexpensive portable ultrasound units are now available, and selection should be based on image quality and intended use. Transducer selection is equally important and is based on patients' body shape and size. Three commonly used transducers are linear, microconvex, and convex probes (Fig. 58.1). The name refers to the shape and footprint of the transducer and is often associated with the frequency. Typically, linear transducers have flat surfaces and high frequencies (12–18 MHz); microconvex transducers have small curved surfaces and midrange frequencies (8–11 MHz) and convex transducers have large curved surfaces and low frequencies (1–5 MHz). Sector transducers have largely been replaced by modern electronic transducers. The range of frequencies varies with manufacturer. For snakes and lizards the linear transducers are generally recommended (Fig. 58.2). In lizards, alternating between linear and microconvex transducers may be required to evaluate the cranial coelomic cavity and liver due to the convexity of the rib cage. For chelonians, a microconvex transducer or convex transducer with a small footprint is advantageous because it fits in the curved contours of the small sonographic windows cervical and axillary to the thoracic limbs and cranial to the pelvic limbs. The frequency of the transducer depends on the size of the animal to be examined. High-frequency transducers have the advantage of superior spatial resolution, yielding excellent detail of superficial structures but have limited depth of penetration. Lower frequency transducers, although lacking in fine anatomic resolution, have the ability to penetrate deeper. Therefore, in smaller lizards high-frequency transducers (12–18 MHz) yield the best results. In larger lizards, such as iguanas, (8–11 MHz) linear or microconvex transducers are recommended. For larger patients such as giant tortoises, frequencies from 2.5 to 5 MHz are recommended.[1–3, 8–18]

SPECIAL CONSIDERATIONS

Not only must the equipment and sonography suite be adapted to the special requirements of reptiles, but the practitioner must also be aware of the wide variation in norms among the various species that may be encountered. There is a tendency to overinterpret normal structures in unfamiliar species. Whenever possible, known standards should be consulted, whether it be a different animal of the same or similar species or a published description of normal findings in that species.[1–20]

It is difficult to accumulate expertise and perform a thorough evaluation when sonographic evaluations are limited by the short periods of time typically available between appointments. Ultrasonography, especially in unfamiliar species, is not a quick procedure. Therefore the examination room and furniture should be ergonomically comfortable

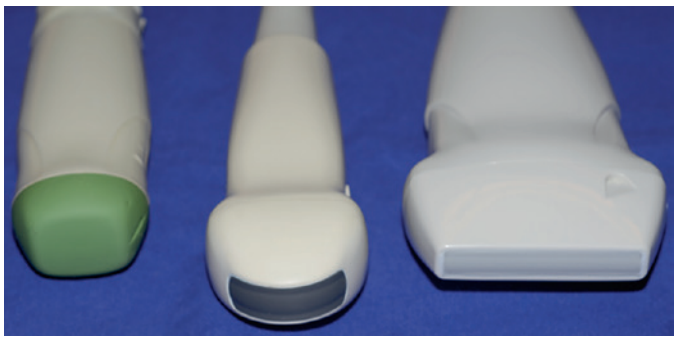

FIG 58.1 Ultrasound probes from left to right: phased array probe 5 to 7.5 MHz; microconvex probe 5 to 8 MHz; linear probe 10 to 18 MHz from Haslauer-Medizintechnik/Esaote Europe.

VetBooks.ir

for the sonographer and the client, as well as for the persons handling the patient. A dim but not completely darkened room provides the best environment for viewing the monitor during the examination.

Proficiency in reptile ultrasonography is not easily acquired. Basic technical ultrasound skills needed to use the equipment and accurate interpretation of the findings are necessary. It is advantageous to have training/experience in small animal ultrasonography in order to gain familiarity with the scanning technique and operation of the machine. Small animal patients are, in general, easier to evaluate and have a more uniform, familiar anatomy.[1–7] When the sonographer has accumulated this basic knowledge, the more variable anatomy and unique sonographic appearances of reptile organs are more easily interpreted. Published literature in peer-reviewed journals and material acquired from books, seminars, conferences, and laboratories can be invaluable.[1–3] To improve image interpretation skills, one may also evaluate the organs of postmortem specimens in a water bath (Fig. 58.3). This reduces artifacts caused by skin, scales, and other surrounding tissues and allows a more thorough evaluation of the viscera. Any abnormalities detected should ultimately be correlated with surgical, necropsy, and histopathological findings (Fig. 58.4A and B) to clarify the etiology of the disease process.

INDICATIONS

Ultrasound is often used as a tool for further imaging of a suspected abnormality; although, in many circumstances, ultrasonography has a clear advantage over radiology or endoscopy and may be chosen as the primary imaging modality.

Coelomic enlargements of unclear origin (e.g., tumors and ascites), along with reproductive monitoring, are the most common indications for ultrasonography. Any kind of enlargement on the animal's body can be scanned and interpreted to better characterize the nature of the swelling. Ultrasound-guided aspirates and biopsies may also be performed, but the need for these procedures should be evaluated in conjunction with possible risks such as organ perforation and hemorrhage.[15,16] Reptile echocardiography is a relatively young field, but with improving equipment and continuing publications, the practical clinical utility of this ultrasound application will continue to increase.

PATIENT PREPARATION

Positioning of the patient must be adapted to what the patient will tolerate while allowing access to the anatomic regions of interest. Typically, dorsal recumbency is the most useful position, but an upright position may also be helpful, especially in weak lizards and in iguanas (Fig. 58.5). Large snakes need more personnel to hold them comfortably for this procedure. In aggressive reptiles, sedation should be used to minimize the stress for the animal and the risk to the patient and veterinary staff. Sedation or anesthesia can facilitate positioning and reduce movement artifacts.

It is important to develop a routine scanning technique that allows evaluation of all typically detectable organs so that an important sonographic finding is not missed. Whenever possible, each organ should be scanned in two planes: usually transverse and sagittal/longitudinal. Oblique scanning planes are also frequently used to evaluate organs and pathology of variable shape and anatomic location. The probe

FIG 58.5 Upright positioning for weak patients. A bearded dragon (*Pogona vitticeps*) is held while ultrasonography is performed.

FIG 58.6 Positioning of the probe in a longitudinal view of a bearded dragon (*Pogona vitticeps*).

should always be held in the same fashion such that the sonographer is oriented to the spatial relationship between the tissues being scanned and their appearance on the screen.[8–12,16,17,18] Standard convention dictates that when the patient is in dorsal recumbency, the head is on the left side or facing away from a right-handed sonographer, and the transducer is gripped so that the indicator of the probe shows either cranially or to the right side of the patient's body (Figs. 58.6–58.9). When this technique is used, the left side of the image on the monitor is cranial in a longitudinal/sagittal view and represents the patient's right in a transverse view (Fig. 58.10). Ample coupling gel must be applied to the skin surface. A gel bottle warmer should be used to prevent cooling of the patient. Better images can be obtained if the skin is moistened with warm water before the coupling gel is applied, because contact is improved and trapped air bubbles that can attenuate the sound beam are reduced. In smaller patients, a stand-off pad to fill the space between the skin and the transducer surface may be helpful. An examination glove filled

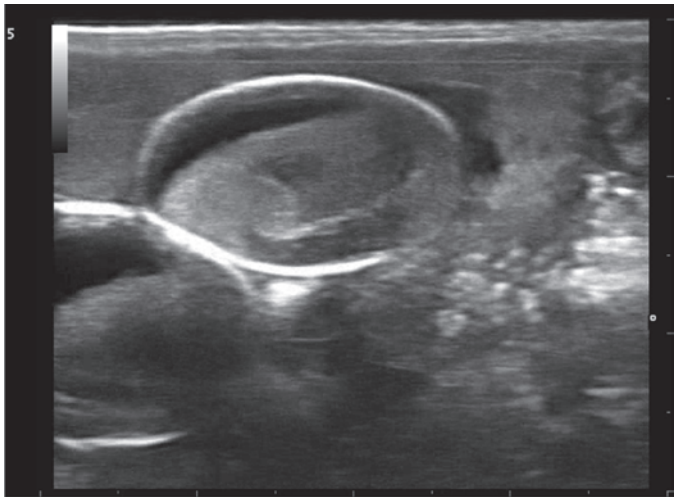

FIG 58.7 Sagittal plane image of an egg in the bearded dragon (*Pogona vitticeps*) from Fig. 58.6. The hyperechogenic oval structure is the shell, the hypoechoic part is the albumin, and the rest of the content is the developing vitellogenic mass shortly before laying.

VetBooks.ir

with warm water is a useful substitution for an expensive stand-off that can easily conform to the desired shape (Fig. 58.11). Coating the standoff pad with coupling gel further enhances the image quality.

If the pressure of the probe on the patient's body is excessive, artifacts and inaccurate findings may result; excessive transducer pressure can result in compression and displacement of organs from their normal position, especially in snakes.

Although ultrasonography is an excellent tool to investigate the organs of the coelomic cavity, some circumstances can complicate this procedure. Patients undergoing or soon to be undergoing ecdysis are poor candidates, because air between the layers of the skin attenuates the majority of the sound waves, resulting in poor penetration of deeper tissues. Some species with ossified scales (e.g., *Tiliqua* spp. and *Heloderma* spp.) are also poor candidates, because the ossified scales hinder penetration of the ultrasound beam. Additional limitations may be associated with increased intestinal gas or coelomic gas due to recent surgical or laparoscopic procedures.

FIG 58.10 In dorsal recumbency, the head of the reptile is on the left side or facing away from a right-handed sonographer, so the indicator of the probe shows either cranially (in this picture) or to the right side of the patient's body.

SCANNING PATTERN

The geometrically simple shape of the snake lends itself to the most straightforward method of sonographic examination.[19] The heart is a useful starting point for establishing appropriate depth and settings on the machine. Blood in the vessels and chambers should be relatively hypoechoic to the cardiac muscle, and the valves should appear as hyperechoic lines. The body must to be scanned in sagittal, transverse, and dorsal (coronal) views caudally to the level of the cloaca (Fig. 58.12).

In lizards, the liver and the gallbladder should be evaluated first. Adjustments should be made to the machine at this time to optimize image quality before proceeding with the rest of the examination. Next, the examination should move cranially to investigate the heart and then back again caudally with transverse and longitudinal views to investigate the fat bodies, gastrointestinal tract, gonads, urinary bladder (if present), and, finally, the kidneys.[18,20]

Chelonians, except for soft-shelled species, are more challenging because they only have three useful acoustic windows to the coelomic cavity.[12] The three accessible sonographic windows are cervico-brachial (between the forelimb and caudal neck to investigate the heart and the liver); axillary (between the caudal aspect of the forelimb and the cranial margin of the plastrocarapacial bridge for the heart and the liver); and prefemoral (between the caudal margin of the plastrocarapacial bridge and the cranial aspect of the pelvic limb to assess the intestine, reproductive, and urinary systems (Fig. 58.13). In soft-shelled chelonians (e.g., *Apalone* spp.), it is possible to scan the coelomic viscera through the plastron. This is occasionally also possible in neonates or diseased chelonians with poorly mineralized plastrons (Fig. 58.14A and B).

Organs are evaluated by measuring size, shape, and margination. Changes in echogenicity, either focal or diffuse, should be visualized and recorded. The gastrointestinal tract is investigated as in small

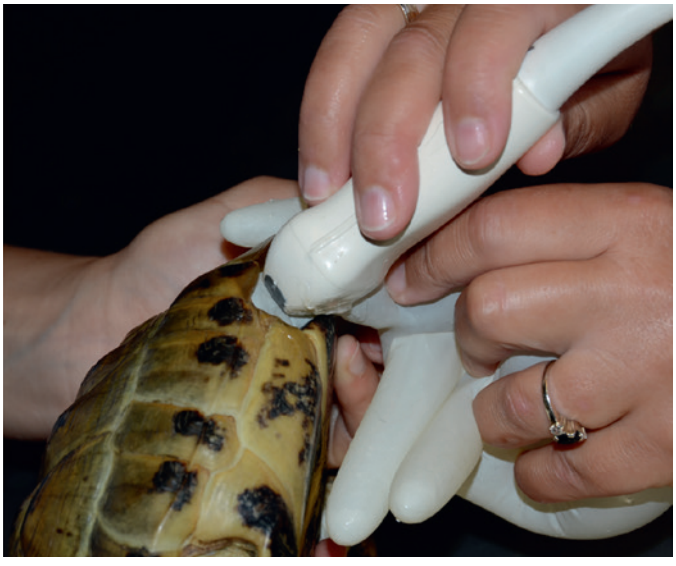

FIG 58.11 In tortoises, an examination glove filled with warm water can be used as a standoff pad in the prefemoral window.

FIG 58.12 The simple shape of the snake lends itself to the most straightforward method of sonographic examination from cranial to caudal. All three planes should be scanned: sagittal, transverse, and dorsal.

FIG 58.13 Prefemoral window to assess the intestine, urogenital tract, and the bladder in chelonians.

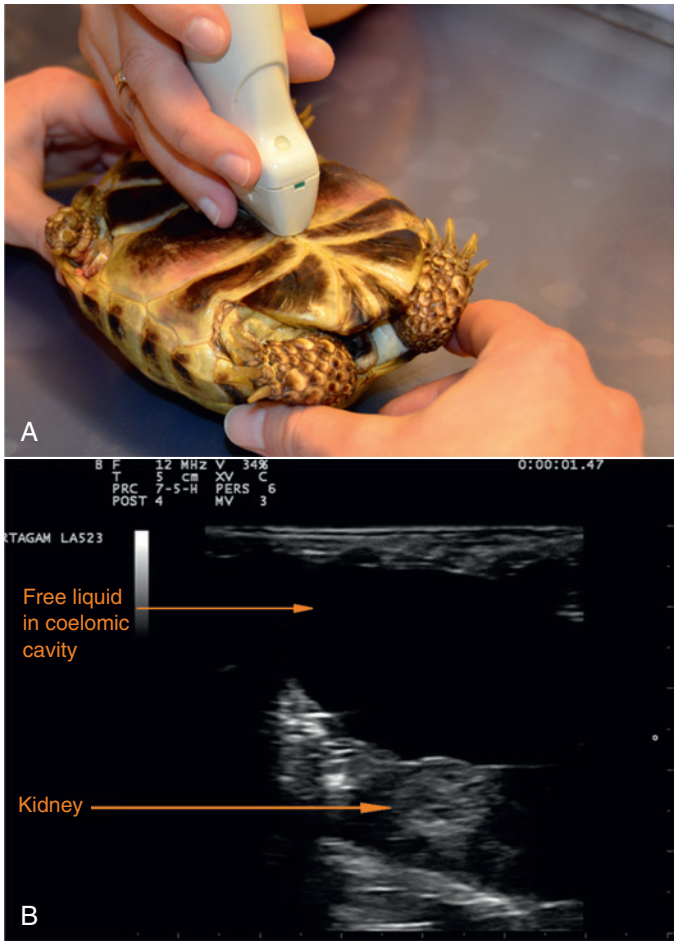

FIG 58.14 (A) In diseased tortoises, it may be possible to scan the coelomic viscera through the plastron. (B) Ultrasound image of the coelomic cavity of a diseased tortoise (histologic findings in Fig. 58.4B) with renal failure due to secondary nutritional hyperparathyroidism.

animals for motility, mural thickness, patency, and foreign content. With high-frequency transducers, intestinal wall layering can be appreciated (Fig. 58.15).

The gonads are evaluated for size and shape to interpret the reproductive stage in both sexes. The kidneys are assessed for size and changes in echogenicity. The urinary bladder, when present, should be investigated for foreign material (e.g., calculi or ectopic eggs). Free coelomic fluid can be detected and assessed for echogenicity, amount, and cellular or presence of flocculent material.

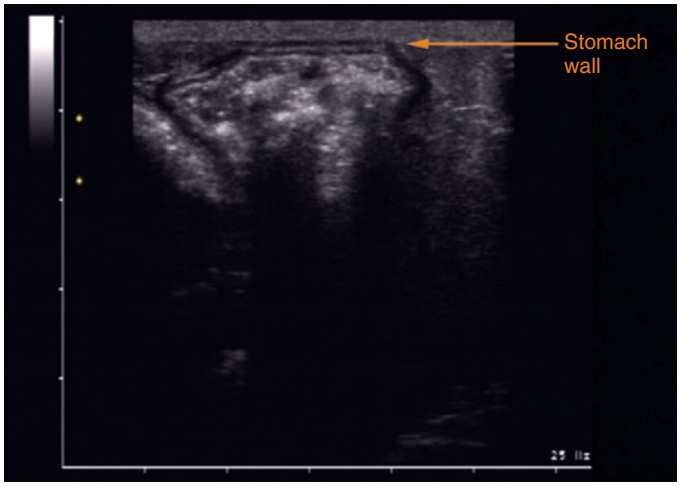

FIG 58.15 Ultrasound image of the different layers of the wall of the stomach of a Savannah monitor (*Varanus exanthematicus*). The first layer is the small hyperechoic line of the serosa, followed by the low echogenic muscularis layer; next is the higher echogenic submucosa, then the less echogenic mucosa, and the last layer is the highly echogenic mucosal surface, beneath which is seen the content of the stomach as a heterogeneous mass, with some parts showing distal attenuation of the ultrasound beam (gas).

CARDIOVASCULAR SYSTEM

Ultrasonography can also be helpful for identifying blood vessels and guiding cannulation. Real-time ultrasound needle guidance with an in-plane/long-axis technique optimizes the probability of catheter placement. Ultrasound guidance can be used not only for central venous cannulation but also in peripheral and arterial cannulation.[17] For echocardiography, see Chapter 68.

THE LIVER

The liver is characterized by a homogenous relatively hypoechoic appearance compared to the fat body, and with anechoic vessels. Anechoic vessels. In lizards and chelonians, the liver is bilobed. The anechoic gallbladder is attached to the right lobe[1–3,11,18] (Fig. 58.16). With proper equipment, the portal vein, hepatic veins, and the caudal vena cava can be individually assessed (Fig. 58.17).

In snakes, the liver extends caudally from the level of the lungs, where it occupies approximately the middle third of the length of the body. Two large vessels (the hepatic portal vein located dorsally and the ventral hepatic vein ventrally) run from cranial to caudal through the length of the organ (Figs. 58.18 and 58.19). The anechoic gallbladder is not associated with the hepatic parenchyma as it is in lizards and chelonians. Rather, the gallbladder is separate, caudal to the liver, and is visible as an anechoic round or slightly oval structure[8,9] (Fig. 58.20). The liver can usually be easily differentiated from the fat body (Fig. 58.21 and 58.22).

Size and echotexture of the liver should be assessed; changes can be either focal, multifocal (see Fig. 58.21), or diffuse throughout the organ. These changes can be distinctly or indistinctly marginated, which can give a hint to the underlying process. Hyperechogenicity and enlargement

of the liver are seen with fatty liver degeneration (Fig. 58.23). A heterogeneous pattern of the liver parenchyma with anechoic areas is common with focal necrosis or inflammation (Fig. 58.24). Anechoic round or oval structures can be visualized in connection with cystic change (Fig. 58.25). Hyperechoic particles in the gallbladder can be visualized as signs of thickening of the bile. Hyperechoic and heteroechoic lesions, usually focal and occasionally attached to the gallbladder, may represent abscessation[14] (Fig. 58.26).

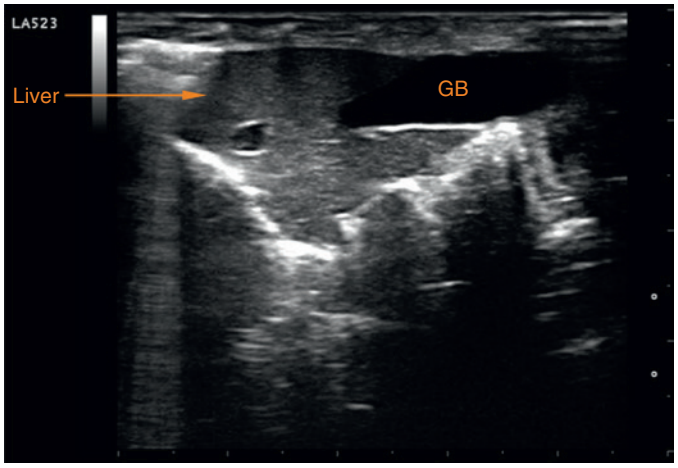

FIG 58.16 Ultrasound image of the homogenous hypoechogenic texture of the liver with the anechoic gallbladder (GB) attached to the right lobe in a green iguana (*Iguana iguana*).

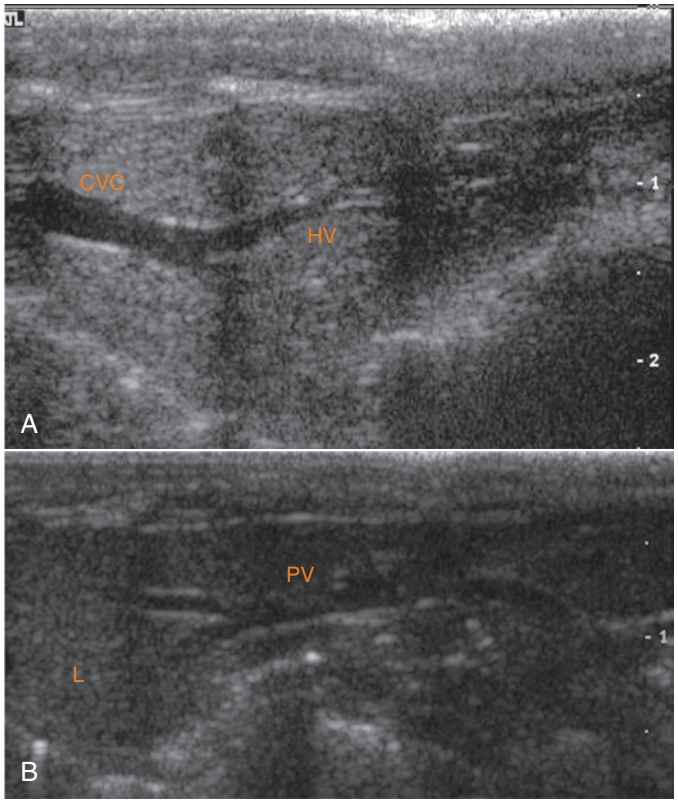

FIG 58.17 (A) Oblique plane ultrasound image showing a hepatic vein (*HV*) entering the caudal vena cava (CVC) within the liver of a healthy green iguana (Iguana iguana). (B) Sagittal plane ultrasound image showing the portal vein (PV) in a healthy green iguana originating in the caudal coelom and arborizing into the liver (L) on the left side of the image. (Courtesy of Mason Holland).

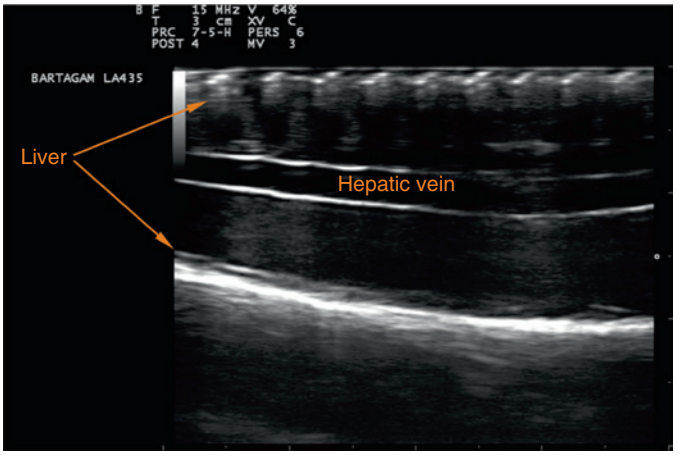

FIG 58.18 Sagittal plane image of the homogenous hypoechoic liver with the central hepatic vein in a ball python (*Python regius*). In this image, only the ventral vein is seen as the probe is held slightly paramedian.

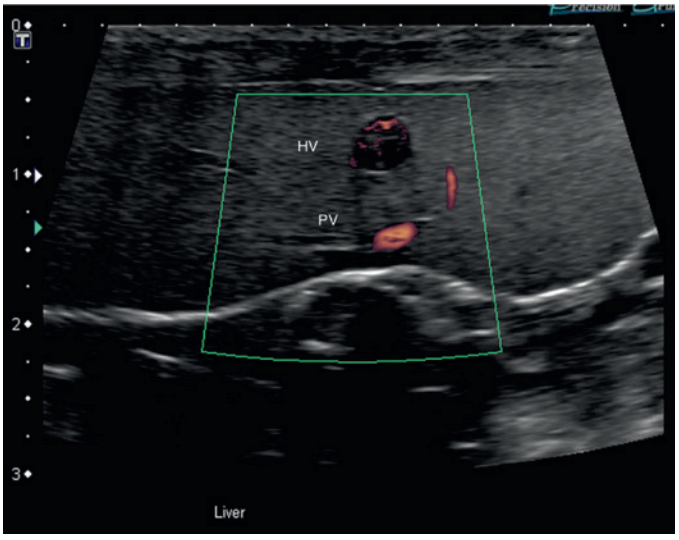

FIG 58.19 Transverse image of a liver showing two large vessels (the hepatic portal vein located dorsally and the vena hepatica ventrally) in a timber rattlesnake (*Crotalus horridus*).

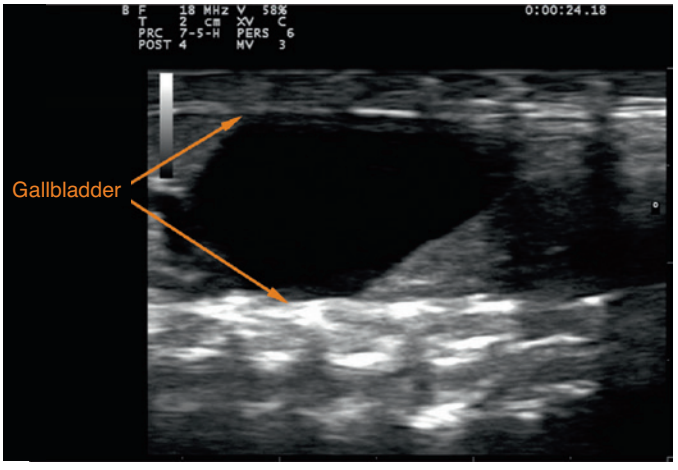

FIG 58.20 The gallbladder of snakes, here a western hognose (*Heterodon nasicus*), appears as a round to oval anechoic structure caudally separated from the liver.

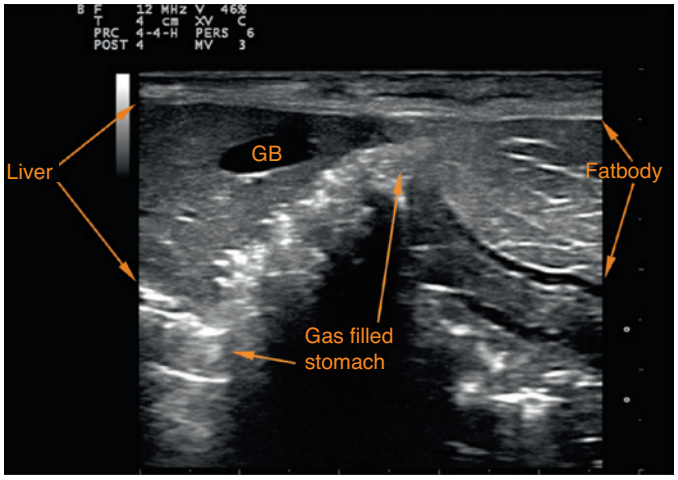

FIG 58.21 Ultrasound image of the echotexture of the liver in comparison with the higher echogenicity of the fat body and the characteristic hyperechoic lines in between the fat in a green iguana (*Iguana iguana*). Between the liver and the fat body is the gas-filled stomach, causing distal attenuation of the ultrasound beam. GB, Gall bladder.

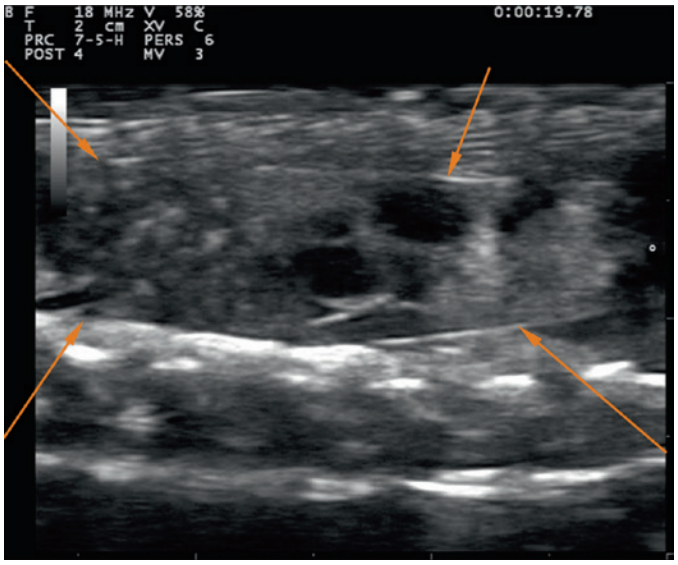

FIG 58.22 Ultrasound image of the liver (margins indicated with *arrows*) of a western hognose (*Heterodon nasicus*) showing a highly heterogeneous pattern throughout the whole liver with round to oval anechoic structures, characteristic of cystic change. Histopathology confirmed liver carcinoma with cystic abnormalities.

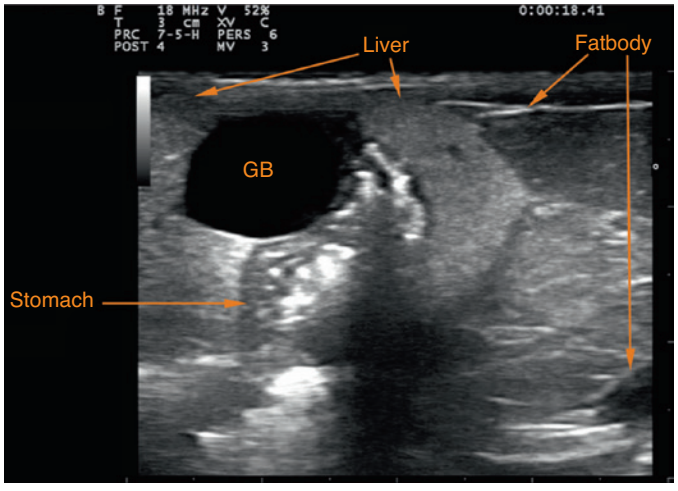

FIG 58.23 Sagittal plane image of fatty liver degeneration in a bearded dragon (*Pogona vitticeps*). The liver shows greater echogenicity than the fat body. In the middle of the figure, deep to the gallbladder (GB), the stomach filled with ingesta and gas is visible.

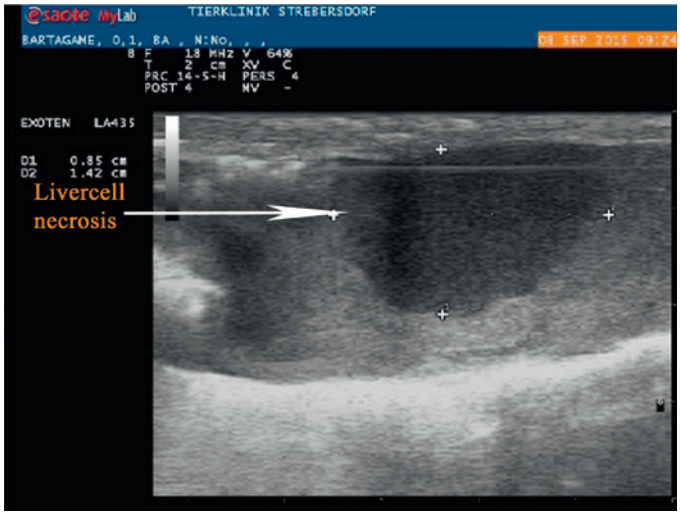

FIG 58.24 Sagittal plane image of the liver in a bearded dragon (*Pogona vitticeps*) with focal anechoic areas in the parenchyma diagnosed by cytology as focal necrosis.

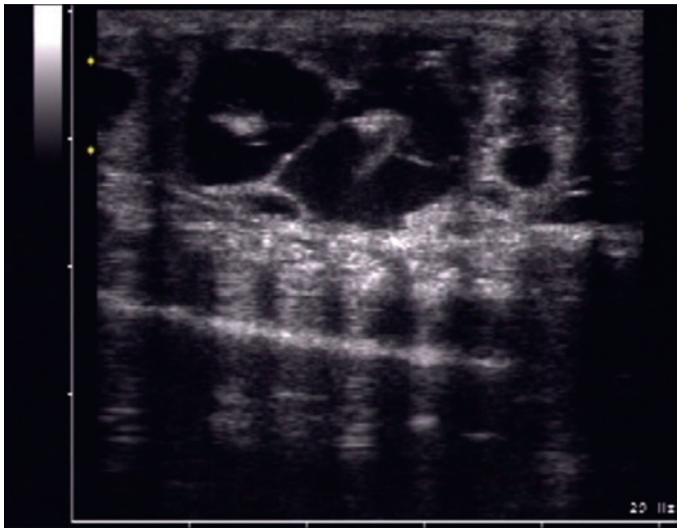

FIG 58.25 Ultrasound image of multiple anechoic structures in the liver of a kingsnake (*Lampropeltis* sp.) consistent with cysts (sagittal plane). Histopathology confirmed hepatic cystic adenocarcinoma.

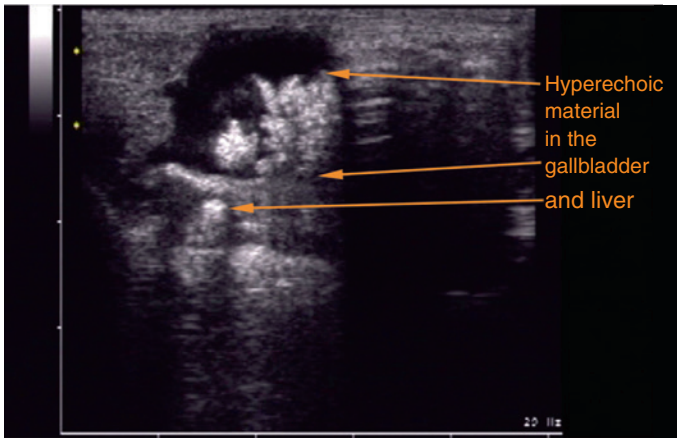

FIG 58.26 Ultrasound image of hyperechoic material in the lumen of the gallbladder and the surrounding liver tissue secondary to an abscess in a bearded dragon (*Pogona vitticeps*).

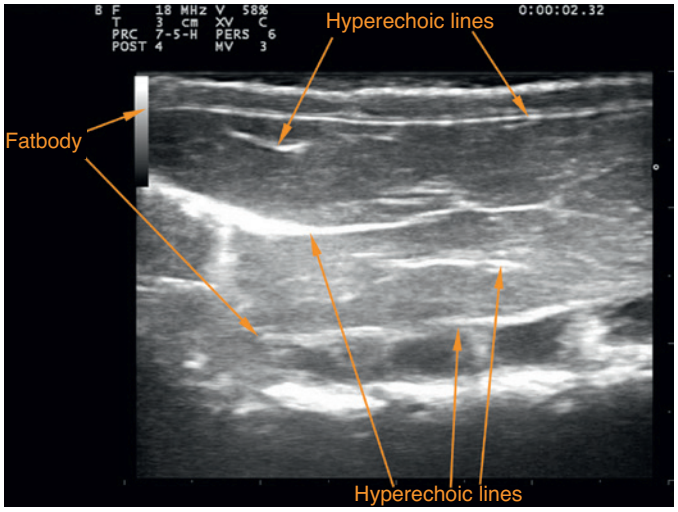

FIG 58.27 Ultrasound image of the fat body in a bearded dragon (*Pogona vitticeps*) with normal hyperechoic lines in between the fat.

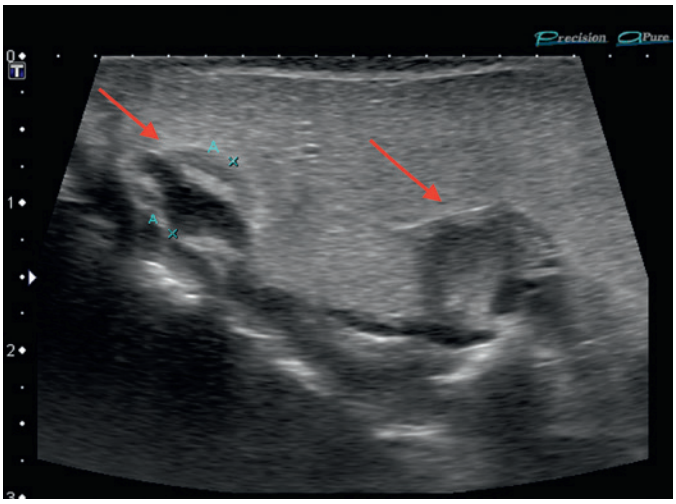

FIG 58.29 Sagittal image of heterogeneous cavitary nodules (*arrows*) in the fat body of an 8-year-old bearded dragon (*Pogona vitticeps*).

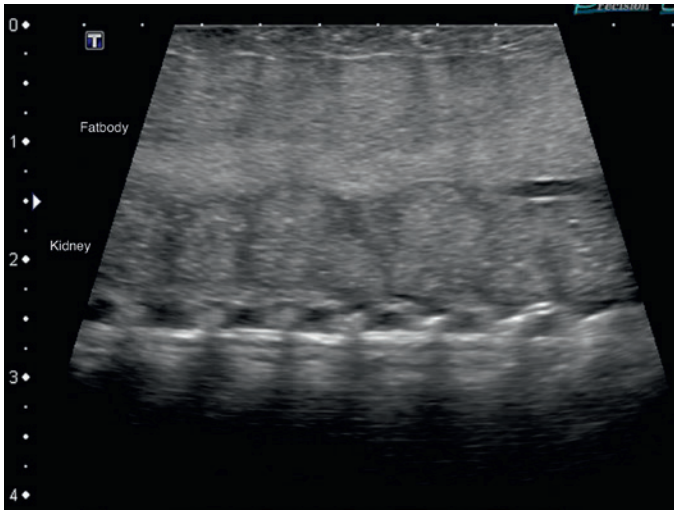

FIG 58.28 Sagittal image of the fat body (near field) and kidney (far field) in a timber rattlesnake (*Crotalus horridus*).

THE FAT BODY

The fat body varies in size, shape, and location depending on the species and body condition of the patient. Normally, they are paired structures that lie laterally within the coelom, extending cranially from the caudolateral coelom. They are hyperechoic to the liver and contain curvilinear hyperechoic septae between fat lobules (Figs. 58.27 and 58.28). Internal vasculature of the fat bodies will be less than that seen within the liver, which is useful to differentiate these two structures. The size of the fat bodies can provide a general assessment of the body condition of the animal (from emaciation through obesity). If a small amount of free fluid is present in the coelomic cavity (a common, normal finding), the fat bodies are easily distinguished. Abscesses, granulomas, or neoplasia (Fig. 58.29) can be visualized as round, sometimes hyperechoic, sharply delineated structures with central hypoechoic/anechoic regions. Dystrophic mineralization or crystal formation in the fat pads are discernible by evidence of hyperechoic foci.

GASTROINTESTINAL TRACT

The gastrointestinal tract and the relationship between the size of the different portions varies greatly depending on dietary classification (whether herbivore, omnivore, or carnivore). In carnivorous reptiles, the stomach is large, and longitudinal folds can be visualized; the intestine is smaller and shorter compared with herbivores. In herbivores, the stomach is smaller and has a thin wall, and the intestine (especially the large intestine) is elongated and often voluminous with mucosal folds. Depending on the size of the animal and the frequency of the transducer, intestinal wall layering can be visualized, similar to mammals and birds (Fig. 58.30A and B). Changes in motility, foreign bodies (Fig. 58.31), and large amounts of gas (Fig. 58.32) or impacted ingesta (such as sand impaction) can be visualized. Intestinal gas typically results in complete reflection of ultrasound waves, preventing assessment of deeper structures. This is especially true in herbivorous species.

Ultrasonography is often used after radiography, but it should be undertaken before gastrointestinal barium studies. Barium has the same effect as gas or stones in the gastrointestinal tract, absorbing and reflecting the sound waves and limiting evaluation. Iodinated contrast media is, however, typically sonolucent.

THE SPLEEN

The spleen is difficult to visualize because the organ is often located deep to the intestine, and evaluation is frequently limited by the presence of intestinal gas. Depending on the species, it is round to elongated and of variable, generally small size; the texture is homogenous with medium echogenicity and fine granular echotexture similar to the testes.[8–13,16,18,19,20] (Fig. 58.33) In male green iguanas (*Iguana iguana*) during breeding season, the spleen may be more easily seen because much of the adjacent intestine is displaced by hypertrophy of the adjacent testes (Fig. 58.34).[18]

THE GONADS

Ultrasonography is the noninvasive imaging modality of choice for evaluation of reproductive function, stage, and disease in (sub)adults

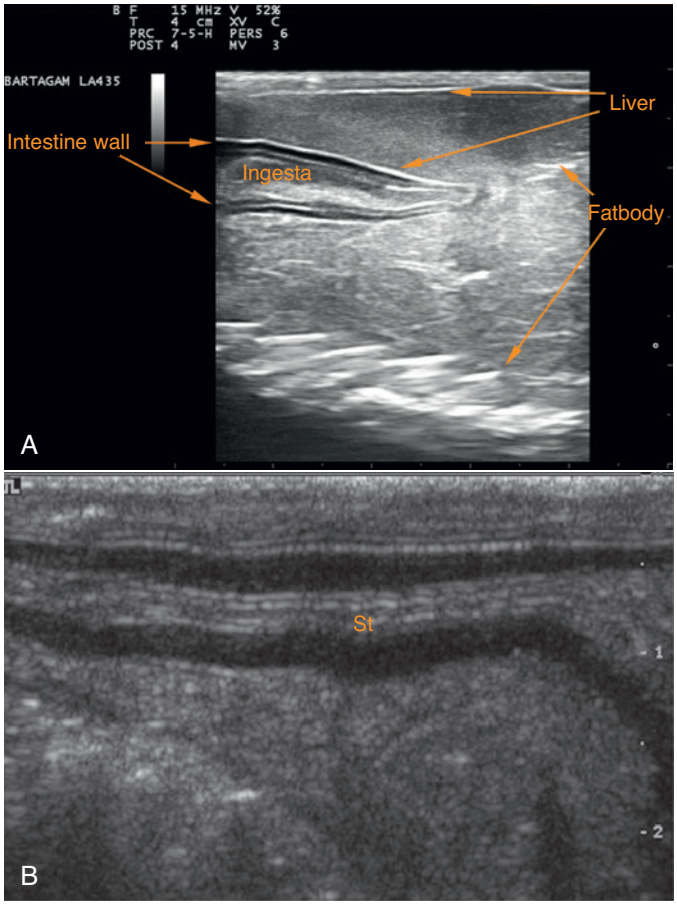

FIG 58.30 (A) Sagittal plane image of a portion of the intestine in a bearded dragon (*Pogona vitticeps*) filled with ingesta. Intestinal layering is visible. The first small hyperechoic layer next to the liver is the small line of the serosa, followed by the low echogenic muscularis layer; next is the higher echogenic submucosa, the low echogenic mucosa, and the highly echogenic mucosal surface, beneath which is seen the contents of the intestine (ingesta) as an heterogenous mass. Below the ingesta is the intestinal wall: small highly echogenic line of the mucosal surface, the low echogenic pattern of the mucosa, and the higher echogenic submucosa, followed by the low echogenic muscularis layer; next to the fat body, as the last outside layer, is the small hyperechoic line of the serosa. (B) Sagittal ultrasound image of the pyloric portion of a nondistended stomach (St) in a normal green iguana *(Iguana iguana)* showing prominent wall layering. A thick hypoechoic muscularis layer is present. Orad is to the right of the image.

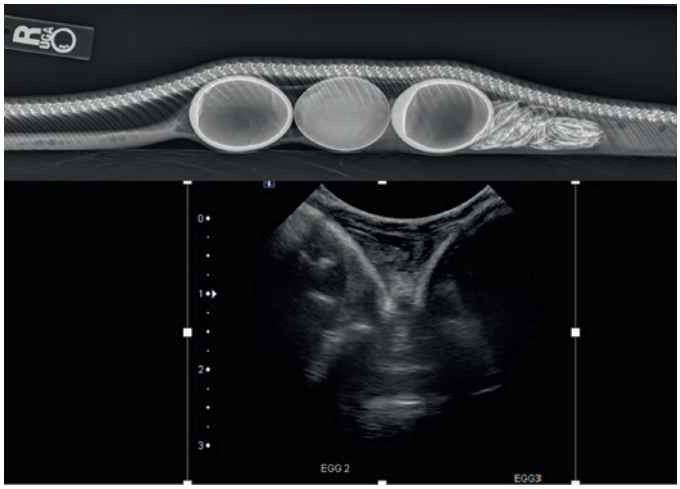

FIG 58.31 Sagittal image of the intestinal tract of a wild black rat snake (*Pantherophis obsoletus*) showing a natural egg (egg 2, echogenic contents) and a ceramic egg (egg 3, clean distal acoustic shadowing) and comparative radiography.

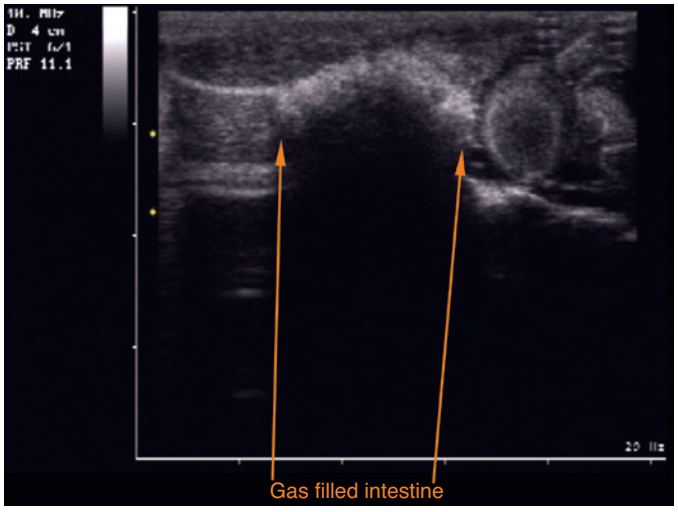

FIG 58.32 Ultrasound image of gas in the intestines with (distal) attenuation of the ultrasound beam in a bearded dragon (*Pogona vitticeps*).

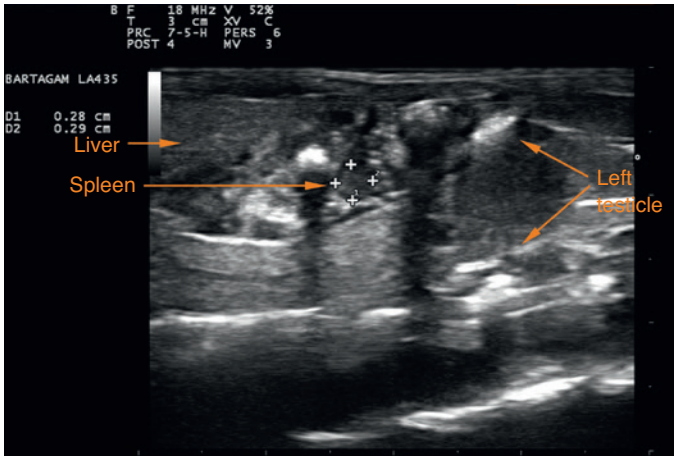

FIG 58.33 Ultrasound image of the spleen (+) in a bearded dragon (*Pogona vitticeps*) with adjacent intestine, liver, and left testis.

and adults. Other applications include gender determination, evaluation of reproductive potential, and directing and assessing the efficacy of therapeutic interventions.[18–25]

Juvenile gonads are poorly visualized because they are obscured by the intestines and are frequently small in size (Fig. 58.35). The gonads lie in the caudal third of the coelom lateral to the aorta, with the right gonad slightly cranial to the left. Depending on the age of the patient and stage of reproductive cycle, the testes are ovoid and vary in size from barely visible to large and obvious; they are especially pronounced in bearded dragons (*Pogona vitticeps*) and green iguanas during breeding season (Fig. 58.36A–D). They show a fine, granular, homogenous echogenicity and are isoechoic to slightly hyperechoic to the liver.

The ovaries may be visualized, depending on their size. At the beginning of the reproductive cycle, the follicles are round and anechoic

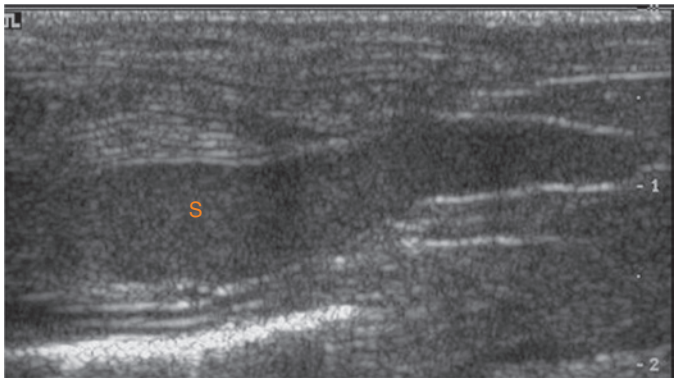

FIG 58.34 Sagittal image of the spleen (S) in a healthy male green iguana (*Iguana iguana*). Physiologically enlarged testes have displaced overlying intestine but are not visible in this image because they were displaced from the plane by transducer pressure.

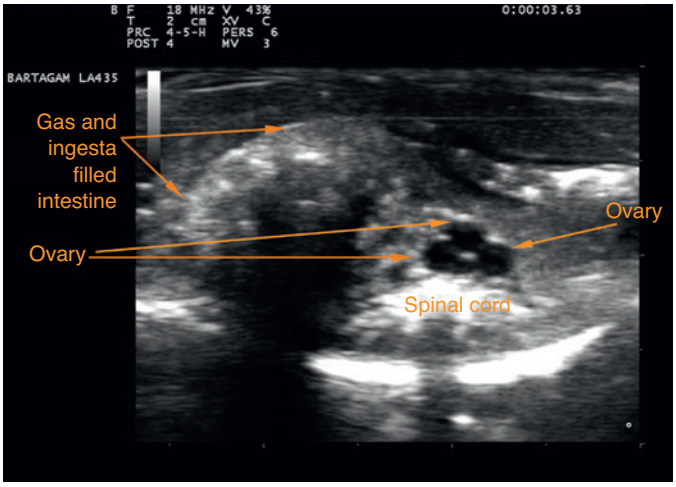

FIG 58.35 Ultrasound image in a transverse plane of the ovary as round anechoic structures ventral and lateral to the spinal cord in a 9-month-old Rankins dragon (*Pogona henrylawsoni*).

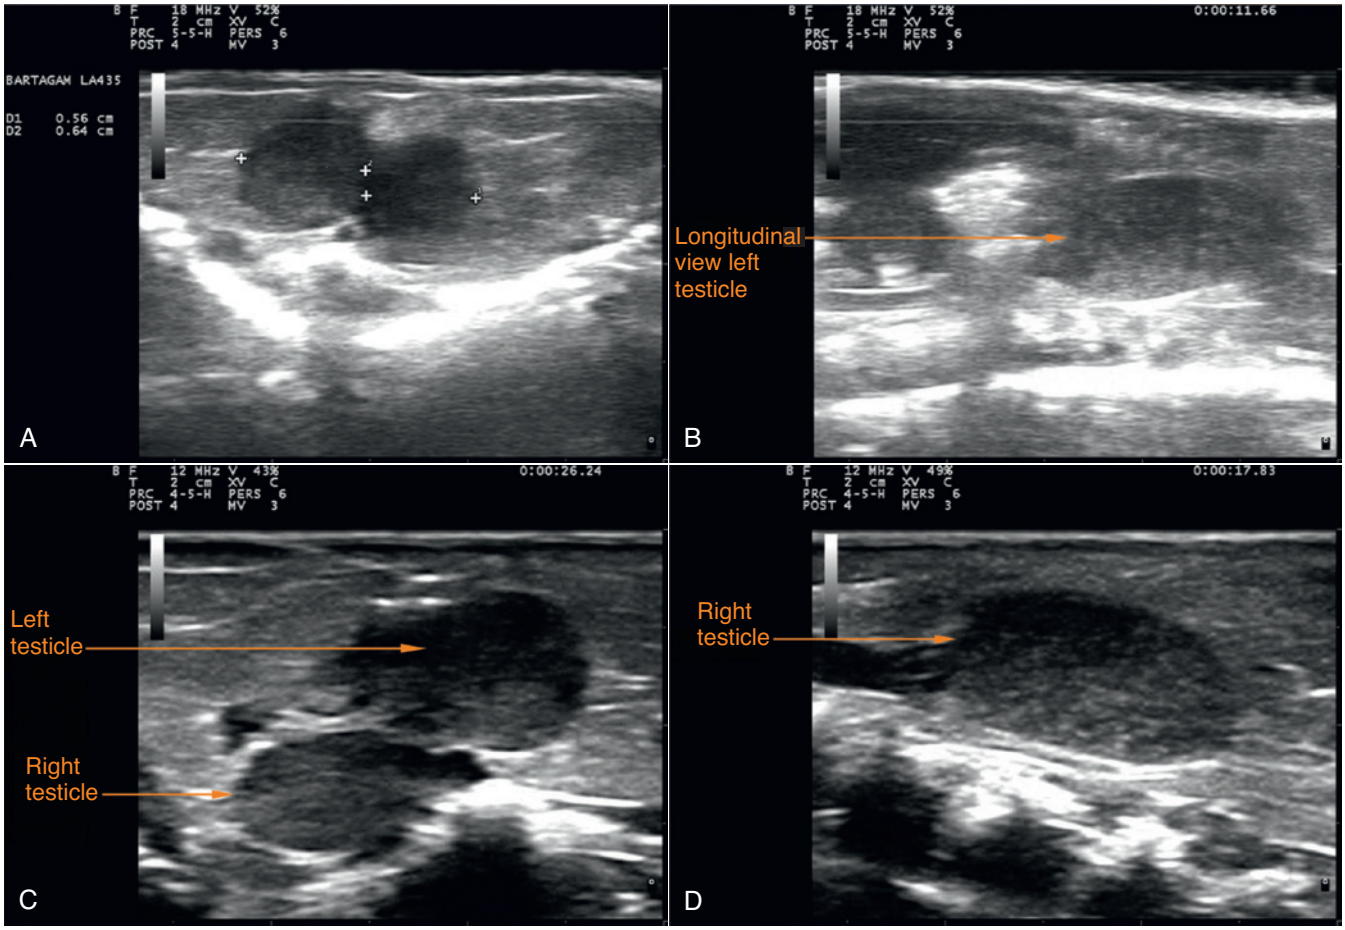

FIG 58.36 (A) Transverse plane image of the testes in a 9-month-old Rankins dragon (*Pogona henrylawsoni*). The right testis lies slightly cranial to the left, showing finely granular and homogenous echotexture. (B) Longitudinal ultrasound image of the left testis in the Rankins dragon from panel (A). (C) Transverse plane ultrasound image of the testes in an adult reproductively active bearded dragon (*Pogona vitticeps*). (D) Longitudinal view of the right testicle in the bearded dragon of panel (C).

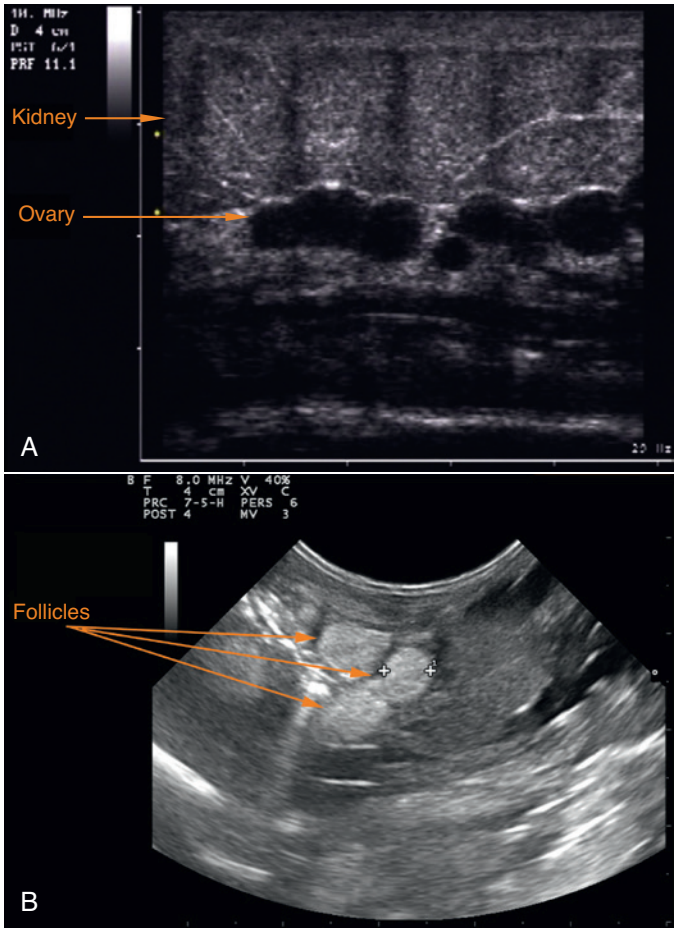

FIG 58.37 (A) Longitudinal slightly paramedian ultrasound image of the ovary in a green tree python (*Morelia viridis*). This is the beginning of the reproductive cycle, and different sizes of round, anechoic structures are aligned cranially to caudally. Laterally to the ovary, the right kidney is visualized. (B) Ultrasound image of the follicles in a red-eared slider (*Trachemys scripta elegans*). In tortoises, unlike snakes and lizards, the follicles already show a higher echogenicity at this early stage.

(Fig. 58.37A). In chelonians, they show higher echogenicity at this early stage (see Fig. 58.37B). The size varies from one to a few millimeters. Before ovulation they grow to large round structures, and their echogenicity increases. In snakes, many anechoic, round structures can be visualized before ovulation, depending on the size of the snake (up to 2 cm in diameter in large pythons). In the late preovulatory state, nearly the entire caudal coelom may be filled with round follicles (Fig. 58.38). After ovulation, the ova elongate, and a slightly hyperechoic wall is produced. Depending on the species, the egg wall will range from noncalcified to calcified (Fig. 58.39A and B). Depending on the degree of shell calcification, egg development can often be monitored. At the beginning of gravidity, the anechoic layer of albumin can be differentiated from the hyperechoic yolk (Fig. 58.40A and B). Occasionally, a small embryo can be visualized. In viviparous snakes and lizards, the development of the embryos can be monitored by the stage of development, activity, and heartbeat (Fig. 58.41A and B).

Pathologic changes can be monitored in all stages of the reproductive cycle. It is important to distinguish preovulatory follicles (e.g., follicular stasis) from postovulatory eggs (e.g., dystocia). Normally, preovulatory follicles are uniform, round, and either anechoic or hypoechoic. As the

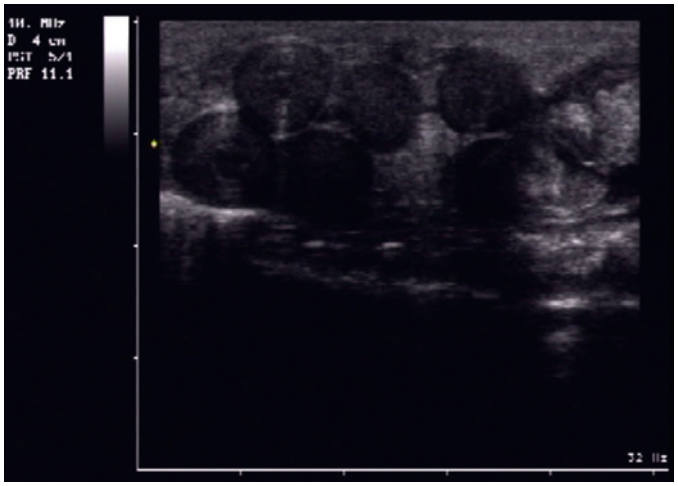

FIG 58.38 Ultrasound image of the ovary before ovulation in a bearded dragon (*Pogona vitticeps*). Round structures are starting to change from anechoic to more echogenic content. In this case, the bearded dragon developed preovulatory follicle stasis due to mismanagement.

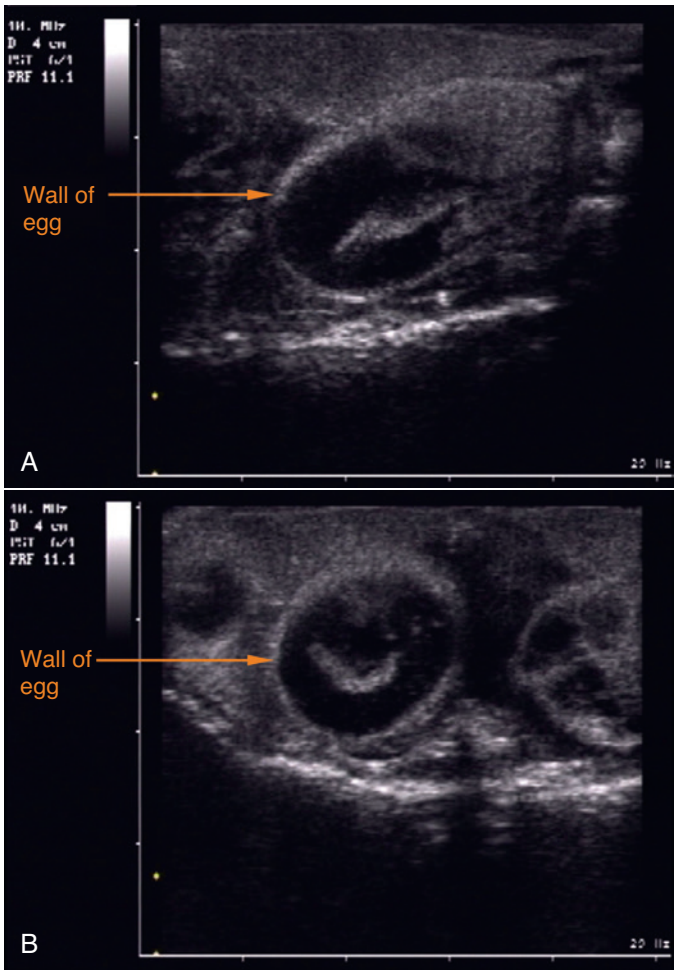

FIG 58.39 (A) Ultrasound image (sagittal plane) of a postovulatory egg with higher wall echogenicity in a bearded dragon (*Pogona vitticeps*). (B) Ultrasound image of the same egg in panel (A), in a transverse plane.

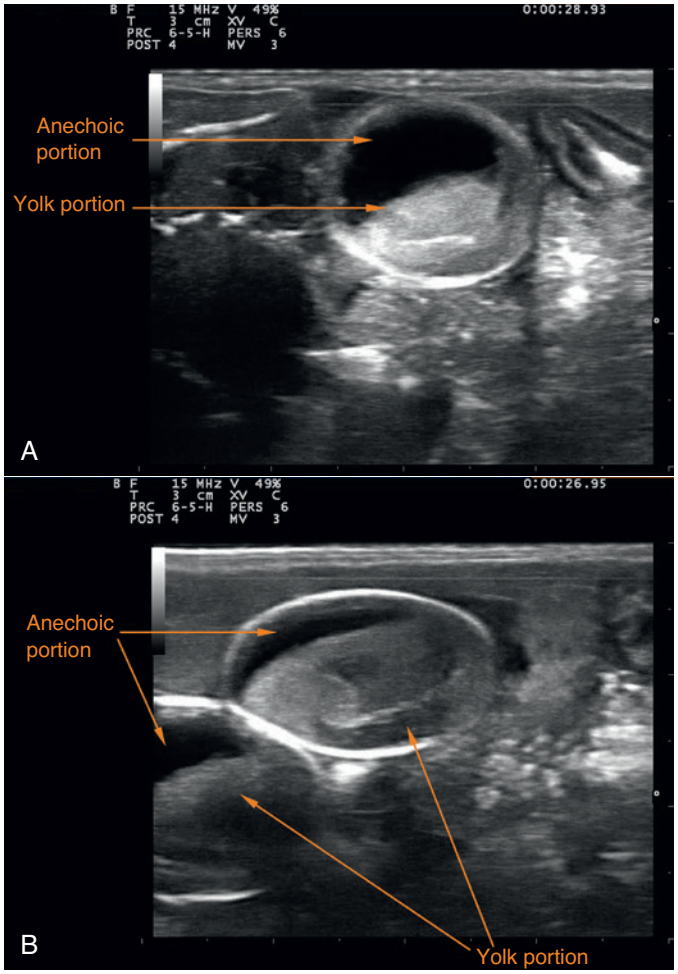

FIG 58.40 (A) Ultrasound image of eggs in a bearded dragon (*Pogona vitticeps*) in a transverse plane with differentiation of the yolk portion (more echogenic) from the albumin, visualized as the anechoic part of the egg. (B) Ultrasound image of one of the eggs from (A) in a bearded dragon in a sagittal plane with differentiation of the yolk portion and anechoic part of the egg.

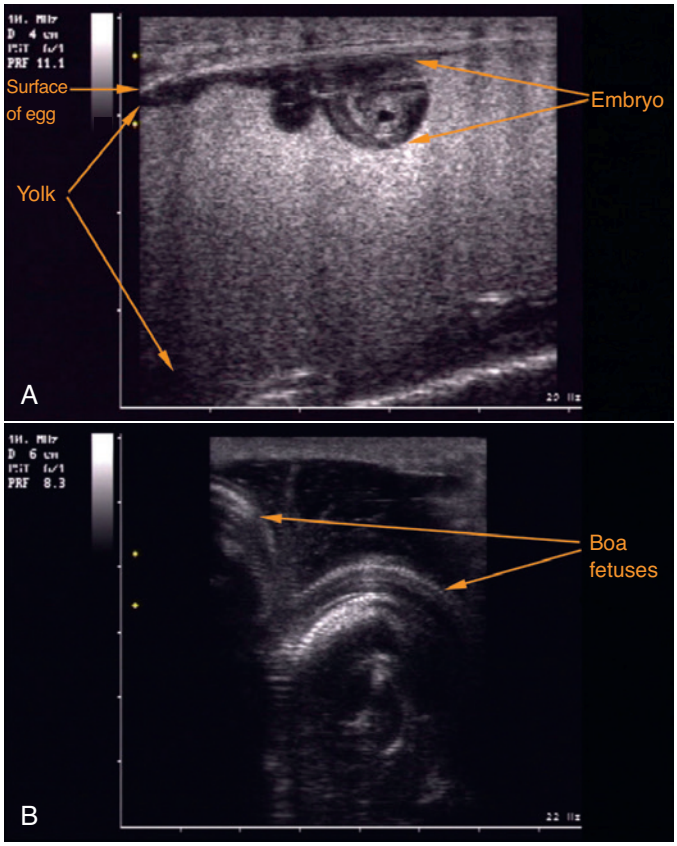

FIG 58.41 (A) Ultrasound image of an egg filled with highly echogenic yolk and a small embryo developing in a ball python (*Python regius*). (B) Ultrasound image just before birth in a viviparous boa constrictor; it is also possible to see the movements of the fetuses and the beating hearts at this stage.

follicles mature within the ovary, more echogenic layers appear. In addition, the echogenicity changes to a heterogeneous pattern, the surfaces of the follicles are no longer smooth and well demarcated, and anechoic fluid can be seen surrounding the follicles. Echogenic free-floating debris within this anechoic fluid often indicates inflammation (Fig. 58.42A and B).

After ovulation, the ova change to a more elliptical, echogenic structure. The wall of the egg is normally smooth, and irregularity of the surface can suggest delayed transit and likely dystocia. A heterogeneous pattern to egg contents combined with free fluid in either the distal oviduct (shell gland or uterus) or coelomic cavity generally indicates a poorer prognosis for successful laying. Pyometra may be associated with the complications of dystocia and may be evidenced with ultrasound (Fig. 58.43A and B).

Ultrasonography may also be useful in monitoring pathologic changes in the gonads.[22–24] Coelomic neoplasia of gonadal origin is often difficult to confirm because of the variable appearance of the gonads. Consequently, this may be a diagnosis of exclusion after successful identification of other normal coelomic structures (Fig. 58.44A and B).

URINARY BLADDER

The urinary bladder, when present, lies in the caudal portion of the coelomic cavity and has a thin, smooth, hyperechoic wall. The contents are generally anechoic with hyperechoic particles or larger aggregates of uric acid (Fig. 58.45).[25] Urate aggregates show a typical snowflakelike pattern, especially when the patient is moved. Calculi can be distinguished by their more solid structure and the distal shadowing of the ultrasound beam. Pathologic changes can be seen in tortoises with eggs within the bladder. They appear as large, round, multilayered structures within the urinary bladder. In these cases, the outer surface of the egg displays an irregular wall, with internal echogenic material. The urinary bladder wall may also be thickened because of mechanical irritation (Fig. 58.46A and B).

KIDNEYS

The kidneys show a higher echogenicity than the liver and fat bodies, with a clear granular echotexture and a distinctly marginated surface. In snakes, they are elongated and lobes can be visualized; however, no hyperechoic septae can be seen, unlike in the fat bodies, and this helps to differentiate between these structures (see Fig. 58.28). In some lizards, like the green iguana or bearded dragon, the kidneys lie largely within the pelvis and are not easily seen (Fig. 58.47). In other groups, such as the varanids, the kidneys are midcoelomic and readily scanned.

VetBooks.ir

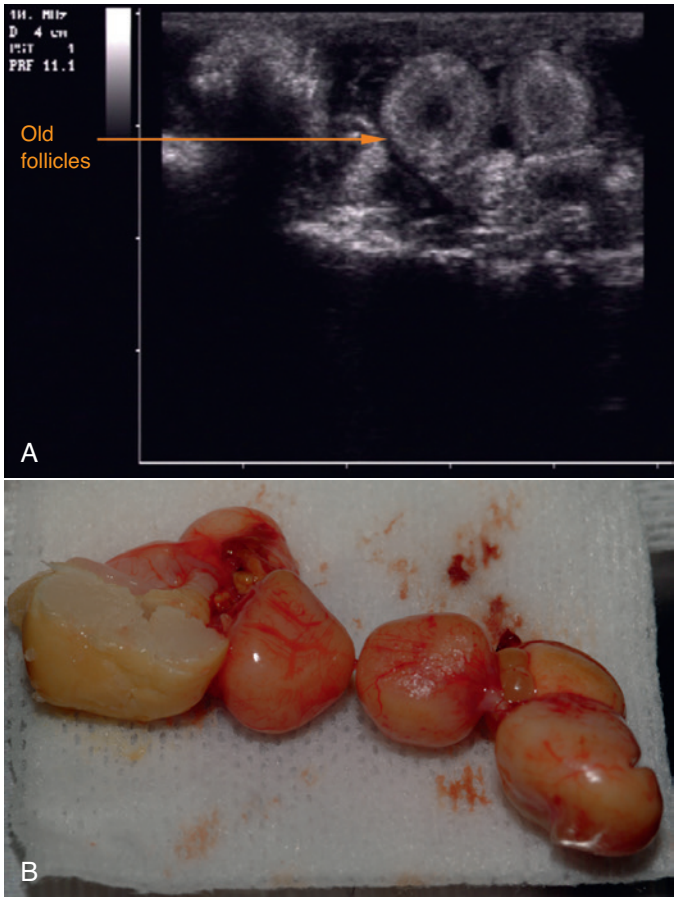

FIG 58.42 (A) Ultrasound image of older preovulatory follicles before surgery in a bearded dragon (*Pogona vitticeps*). The echogenicity increases and becomes slightly heterogeneous with aging of the follicles. (B) Preovulatory follicle stasis was identified surgically and removed in the bearded dragon from panel (A). The content of the follicles often solidify with progression of stasis.

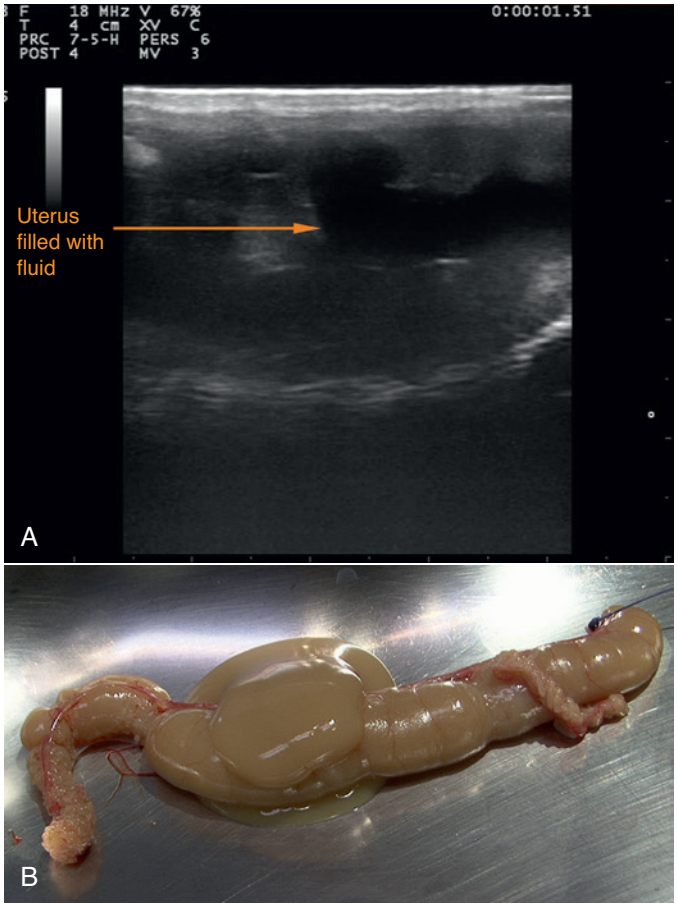

FIG 58.43 (A) Ultrasound image of the coelom of a veiled chameleon (*Chamaeleo calyptratus*). The curved tubular structure with anechoic content visualized on the left side of the caudal coelom represents an accumulation of purulent material in the fluid-filled salpinx. (B) Salpinx from the veiled chameleon in panel (A) filled with purulent exudate after surgery.

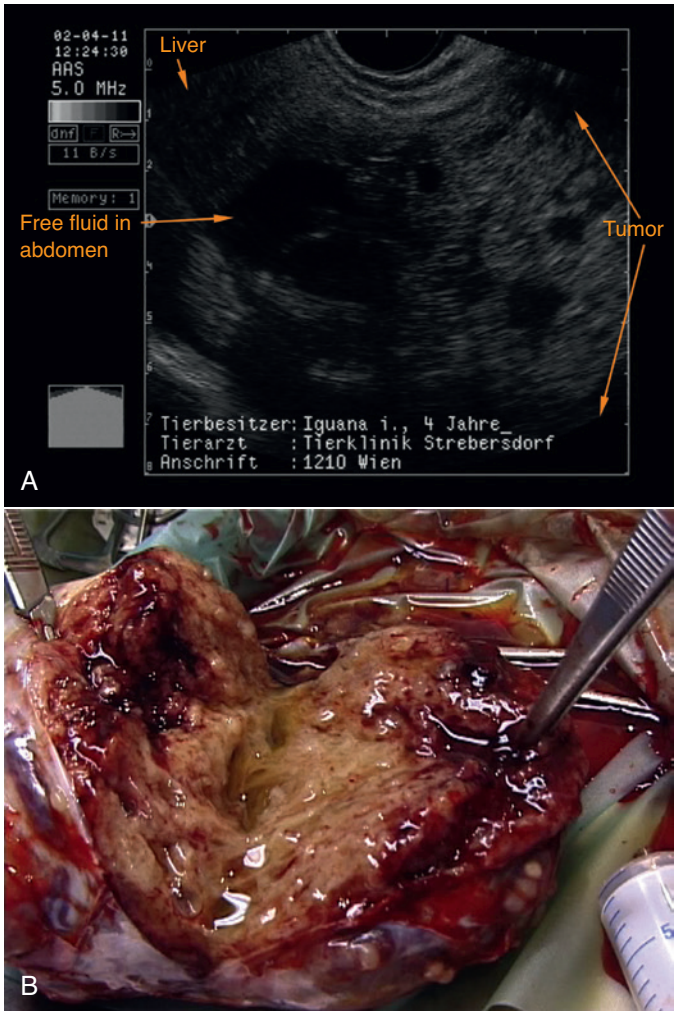

FIG 58.44 (A) Ultrasound image of a heterogeneous mass with anechoic patches distributed multifocally throughout the mass. A large amount of anechoic free fluid was found in the coelomic cavity of this green iguana (*Iguana iguana*). (B) After aspiration of 750 mL free fluid the surgical neoplasm was removed. Histopathology confirmed a cystic ovarian adenocarcinoma.

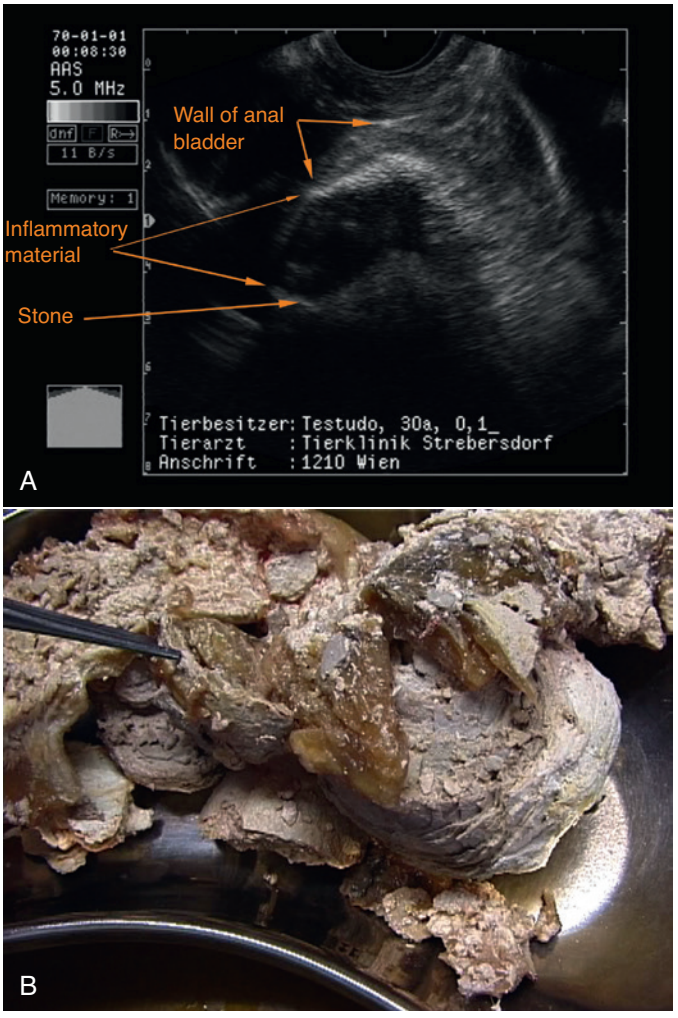

FIG 58.46 (A) Ultrasound image of the urinary bladder in a 30-year-old Greek tortoise (*Testudo hermanni*). The hyperechoic tissue of the urinary bladder is thickened, and a calculus is visible as a line with distal extinction of the ultrasound beam. Between the two structures is a thick layer of inflammatory reaction and fibrin. (B) The calculus with gel-like material on the surface. The cause of the calculus was determined to be the long-term presence of an egg in the lumen of the urinary bladder.

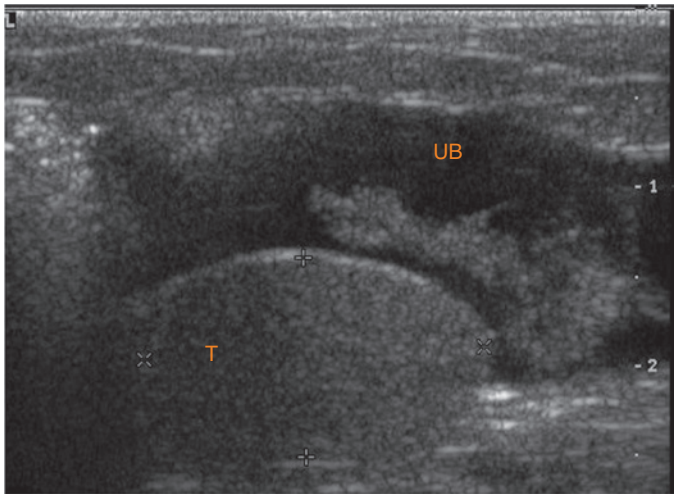

FIG 58.45 Sagittal plane ultrasound image in a healthy green iguana (*Iguana iguana*) showing an aggregate of echogenic urates suspended within the urinary bladder (UB). A testis can also be seen (T). The urinary bladder is thin walled and conforms to the surrounding organs.

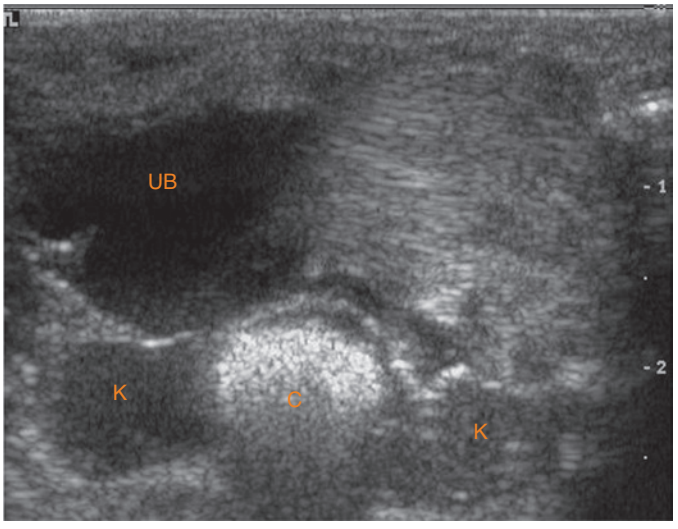

FIG 58.47 Transverse plane ultrasound image in a healthy green iguana (*Iguana iguana*). The cranial poles of the kidneys (K), which lie within the pelvic cavity in this species, can occasionally be seen by angling the transducer caudally at the pelvic inlet, as in this image. C, Colon; UB, urinary bladder.

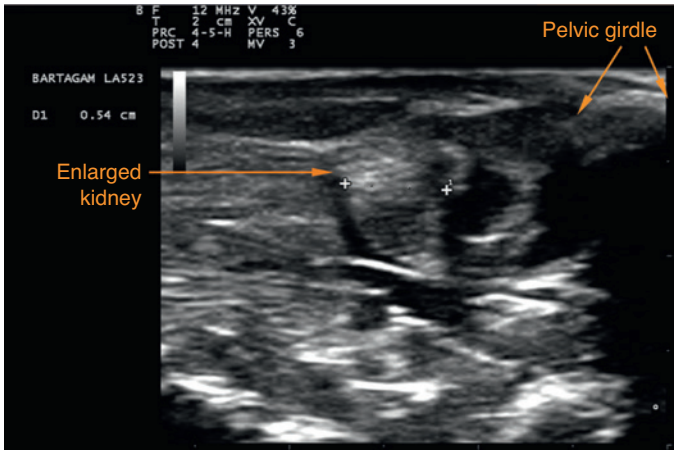

FIG 58.48 Ultrasound image of an enlarged kidney (+) in a bearded dragon (*Pogona vitticeps*) protruding cranially from the pelvic cavity.

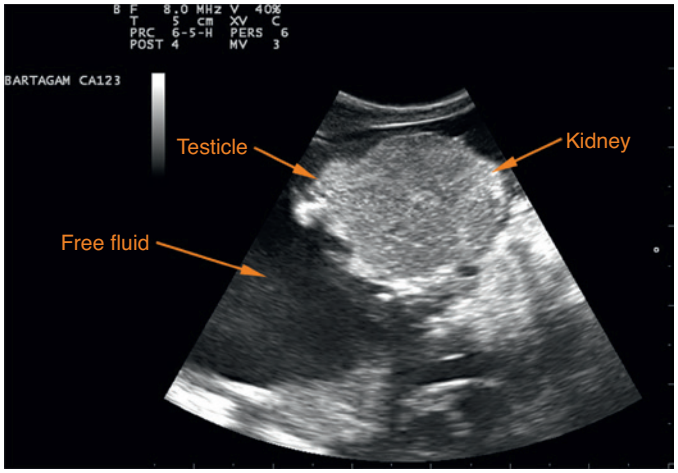

FIG 58.49 Ultrasound image of an enlarged kidney in a Greek tortoise (*Testudo hermanni*) with large hyperechoic granules in the tissue, as a result of renal failure. A large amount of free fluid was found in the coelomic cavity (same tortoise as Fig. 58.14).

In patients with intrapelvic kidneys, when renomegaly is present, the cranial renal poles can be visualized cranial to the rim of the pelvis[25] (Fig. 58.48). In the iguana, an acoustic window just caudal to the pelvis may provide the best visualization of the kidneys.

Often small-to-large hyperechoic granules due to the presence of urate tophi can be detected and monitored in enlarged kidneys (Fig. 58.49). Anechoic spherical structures, occasionally multifocal throughout the organ, indicate cystic changes (Fig. 58.50). Mineralization, with the characteristic appearance of distal attenuation of the ultrasound beam, can be seen; tumors may also be detected (Fig. 58.51).

THE EYE

Because of the small size of the normal reptilian globe, high-frequency transducers with a small footprint should be used to obtain a good image of the structures of the eye and the surrounding tissues. Probes with frequencies from 40 to 60 MHz will give even more detailed images. In ophthalmology, this technique is referred to as *ultrasound biomicroscopy*.[26] The coupling gel and the probe can be placed either directly on the cornea, the spectacle, or the eyelids (as in chameleons). Both eyes should always be investigated in sagittal, dorsal, and transverse planes for a thorough evaluation and bilateral comparison.

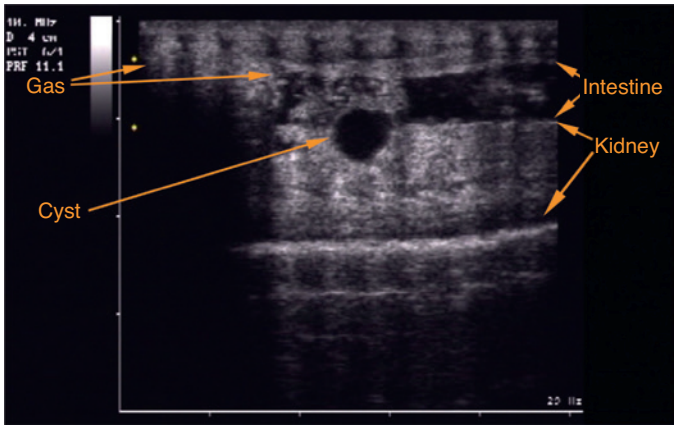

FIG 58.50 Ultrasound image of the kidney of a kingsnake (*Lampropeltis* sp.) with anechoic spherical structures in the tissue. A cystic abnormality of the renal tubules is seen on the surface of the kidney (same animal as Fig. 58.25). The intestine is filled cranially (on the left of the picture) with gas and caudally with fluid ingesta.

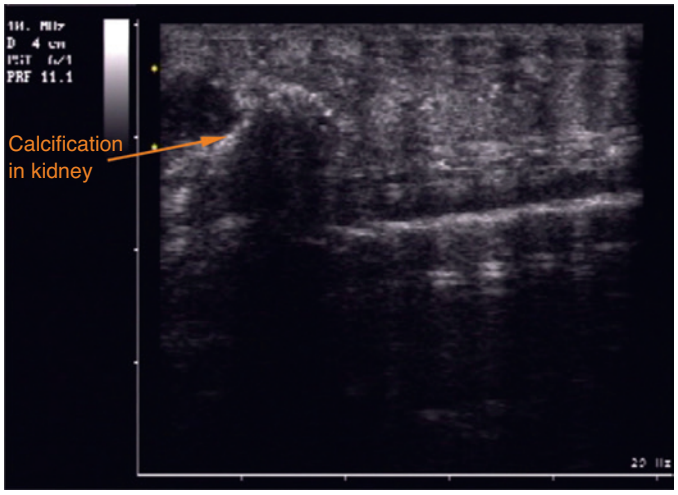

FIG 58.51 Ultrasound image of the kidney of the kingsnake (*Lampropeltis* sp.) from Fig. 58.25 and 58.50. The whole organ shows a slightly heterogeneous pattern. Focally there is a highly echogenic structure with distal attenuation of the ultrasound beam. On histopathologic examination, the changes in the kidneys were consistent with cystic adenocarcinoma with focal calcifications.

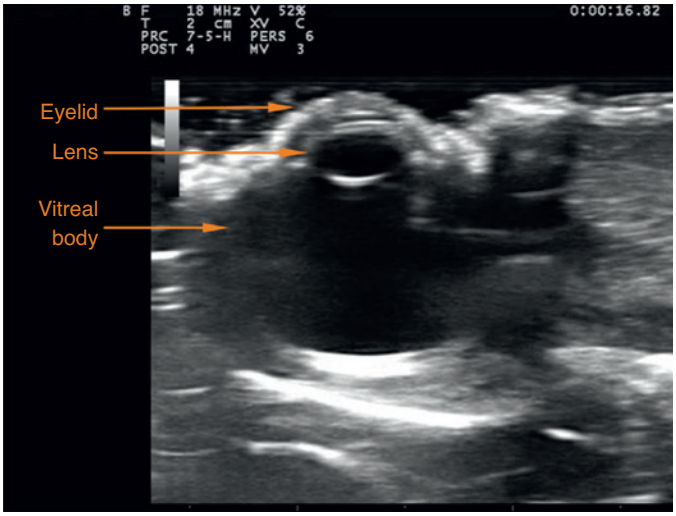
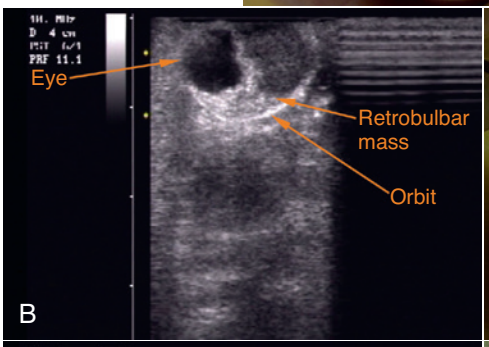
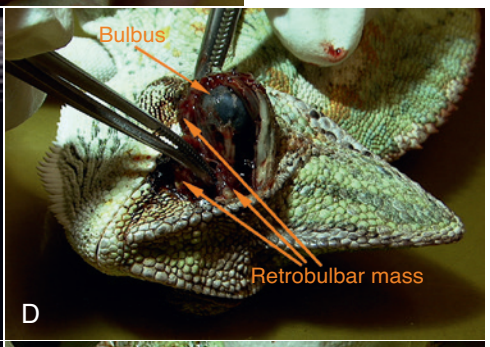
The image of the normal cornea and the attached spectacle in snakes is a small, parallel, hyperechoic two-lined structure. Posterior to the cornea, the anechoic anterior chamber is visible. The lens is an oval, anechoic structure with thin hyperechoic margins. The iris is slightly heterogeneous of medium echogenicity, and, especially in small reptiles, not easily distinguished from the ciliary body. The vitreal body should be anechoic, and the fundus of the globe should be uniformly concave. The conus papillaris is visualized as a higher echogenic structure reaching from the posterior pole of the wall into the vitreal body. Its size ranges from small to large, almost reaching the posterior lens capsule wall (Fig. 58.52). Changes associated with dysecdysis in snakes, intraocular hemorrhage, abscesses, and tumors of the structures of the eye and the orbit can be visualized (Fig. 58.53A–E).

VetBooks.ir







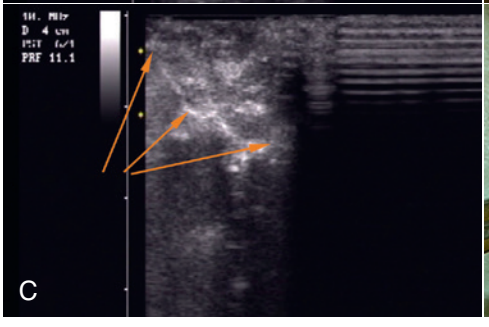


FIG 58.52 Ultrasound image with an 18 MHz transducer of a healthy eye in a veiled chameleon (*Chamaeleo calyptratus*). The most superficial echogenic structure is the eyelid; the lens appears as an oval, anechoic structure with thin hyperechoic margins; the vitreal body is anechoic; and there is a round border to the fundus.

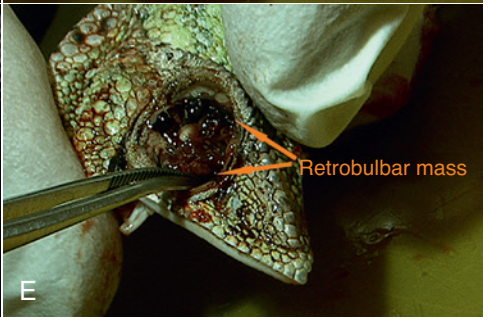

FIG 58.53 (A) Ultrasound with a 10MHz transducer was utilized to identify a large heterogenous hyperechoic mass posterior to the globe in this veiled chameleon (*Chameleo calyptratus*). (B) Ultrasound image of the heterogeneous hyperechoic retrobulbar mass from the same veiled chameleon. Histopathology confirmed soft tissue sarcoma. (C) Retrobulbar tumor in the same chameleon. (D) Postmortem view from the head of the same chameleon after opening the eyelid cranially and lifting up the bulbus. The retrobulbar mass had already spread underneath the eyelid. (E) Postmortem view from the head of the same chameleon after removal of the bulbus to get a view of the orbit, which is completely filled with the retrobulbar mass.

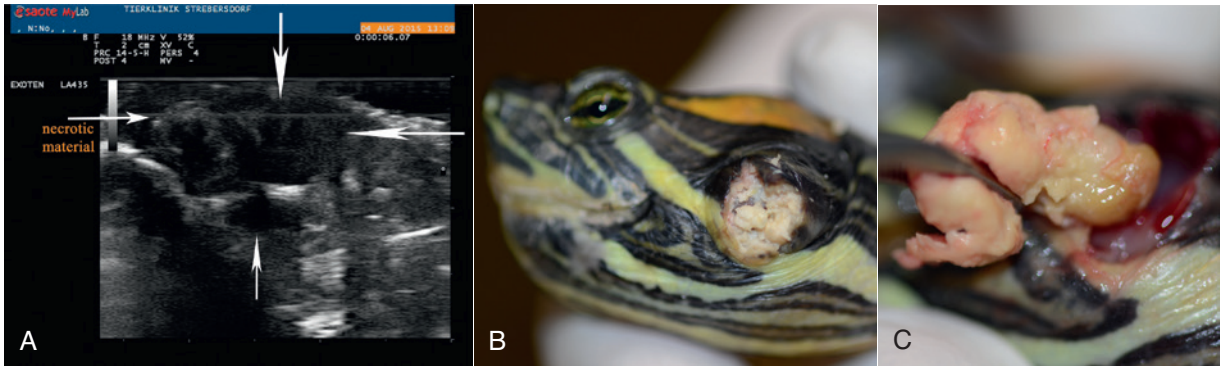

FIG 58.54 (A) Ultrasound image of the inner ear filled with purulent and necrotic material in a red-eared slider (*Trachemys scripta elegans*) associated with suspected hypovitaminosis A. (B) Gross view of necrotic material seen in the region of the ear of the same red-eared slider. (C) Necrotic material removed from below the tympanic scale in the same red-eared slider.

ABSCESSES

Internal abscesses can be challenging to image and diagnose.[27,28] Normally they have an inhomogenic pattern with a well-distinguished capsule. Size and shape of the necrotic area, as well as demarcations between healthy tissue, should be evaluated (Fig. 58.54A–C).

Computed Tomography

Ajay Sharma and Jeanette Wyneken

Reptile medicine and surgery is becoming multidisciplinary in keeping up with the expectations of pet owners, zoological collection managers, and conservationists. Diagnostic imaging is essential for providing clinically useful data in a noninvasive manner. Until recently, diagnostic imaging was limited to radiography and ultrasonography. Radiography, although providing excellent spatial resolution, is often limited by the two-dimensonality and superimposition of soft tissue and osseous structures. Additionally relatively poor soft-tissue contrast resolution limits assessment of coelomic organs. Ultrasonography, although a good noninvasive, real-time imaging modality, requires a high level of operator knowledge and proficiency and is limited for evaluation of gas-filled structures such as the gastrointestinal tract and lungs. In the past decade, there has been a tremendous increase in the use of advanced cross-sectional imaging in veterinary medicine. Computed tomography (CT) and magnetic resonance imaging (MRI) are now indispensible diagnostic imaging modalities in many academic and referral institutions.

The appropriate acquisition of CT images is equally, if not more, important than the clinician's interpretive ability. Standard CT imaging requires good restraint to avoid patient movement and selection of appropriate acquisition parameters, including slice thickness, pitch, anatomical region to be imaged, processing algorithm (soft tissue, bone, lung, etc.), contrast medium type, dose, rate of infusion, and timing of imaging relative to contrast administration. The precise acquisition parameters vary between CT machines and depend on manufacturer, age of the machine, and number of detector elements (e.g., 2-, 8-, 16-, or 64-slice CT). Computed tomography units that provide isotropic resolution are preferred for diagnostic quality 3D and multiplanar reconstructions. Multiplanar reconstructions (MPR) are the display of transverse images in sagittal and dorsal planes with the ability to triangulate a lesion on all three views (Figs. 59.1 and 59.2).

New multidetector CT (MDCT) machines provide good isotropic resolution and rapid multiplanar reconstructions and postprocessing in different windows/algorithms, such as soft tissue, bone, or lung. Other terms used to denote the window width/level include soft, sharp, and ultrasharp algorithms.

Assessment of a CT study includes quality control and diagnostic value. Quality control verifies that the entire anatomical region of interest is included, and appropriate slice thickness and processing algorithms have been selected. These are typically evaluated in real-time or immediately postacquistion using the transverse images. Evaluation of diagnostic quality includes presence or absence of motion and adequate contrast enhancement of normal tissues and cardiovascular structures. Intravascular access may be difficult in some patients, and the lack of contrast enhancement may be due to loss of vascular access and extravasation of contrast media, bradycardia, hypotension, and/or dyssynchrony between time of injection and start of the CT scan. Some CT machines have an inherent delay when using automatic injectors for contrast administration, resulting in mistiming of the start of the CT scan relative to contrast injection.

Once the CT images are acquired and are deemed to be of diagnostic quality, the next step is interpretation. Due to the large volume of data and relative infancy of CT in reptiles, image interpretation requires a quiet viewing area with appropriate ambient lighting and a high-resolution computer monitor and a good knowledge of relevant normal anatomy. Diagnostic evaluation should be performed on the transverse images, with use of MPR to help triangulate difficult or small lesions. 3D reconstructions are useful for publications and gross assessment/demonstration of organs or vasculature; however, during the reconstruction process, resolution is reduced due to the software process of smoothing various "edges" to create the pretty picture. This smoothing or interpolation process results in the loss of fine anatomical details. If 3D reconstructions are used for diagnostic purposes, it is imperative that these lesions be verified on the transverse images and further corroborated using MPR if available.

The use of proper nomenclature and anatomic terminology in interpretive reporting is essential to avoid ambiguity and confusion. Anatomical descriptors should follow Nomina Anatomica Veterinaire as closely as possible. Correct directional anatomical terminology includes cranial/rostral, caudal, dorsal, and ventral when referring to the head and body. Terms that are specific for limbs are proximal and distal and should not be used when describing lesions of the head/body/coelom. Because CT machines are designed for humans, correlative terms are: superior = cranial; inferior = caudal; anterior = ventral; and posterior = dorsal.

In humans (bipeds) it is appropriate to use terms proximal and distal when discussing the body; however, in quadripeds, the terms cranial and caudal are preferred.

In addition to knowledge of the physics, hardware, and software capabilities of CT, the application of CT in the diagnostic imaging of clinical patients requires a thorough understanding of normal imaging anatomy. Several excellent references are available that describe both CT acquisition and normal anatomy of several reptilian species.[1–10] With rare species, normal anatomic form may be undescribed. Although dissection of fresh dead animals for reference can provide a wealth of information, including important landmarks, species-specific organ structure, and the arrangement of organ systems, access to these specimens may be limited and may not be ethically appropriate.[6–13]

CT uses a rapidly rotating x-ray tube to acquire multiple projections in a 360-degree manner around the subject. The use of x-ray radiation results in images that represent the attenuation characteristics of structures. Dense tissues, such as bone, attenuate the incident x-rays

VetBooks.ir

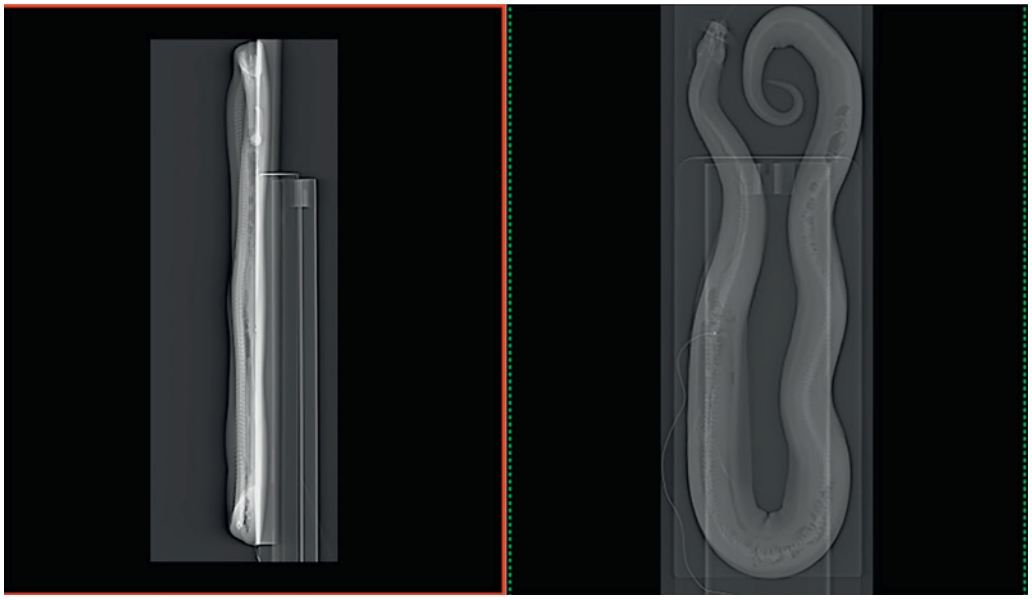

FIG 59.1 Computed tomography examinations are planned based on a short exposure or x-ray scout image using the CT machine. On the CT machine/computer monitor, the software provides reference lines that allow the imager to select regions of interest based on external topographical anatomy. These are often acquired in two planes. This image shows localizer/scout images of a snake in sagittal and dorsal planes. The localizer provides a guide for choosing the field of view using external anatomical landmarks when planning the CT scan. Because most commercially available CT machines have software specifically for human or large mammalian patients, one must carefully explain to the technician what planes of view are needed for reptilian patients. (Courtesy of Ajay Sharma.)

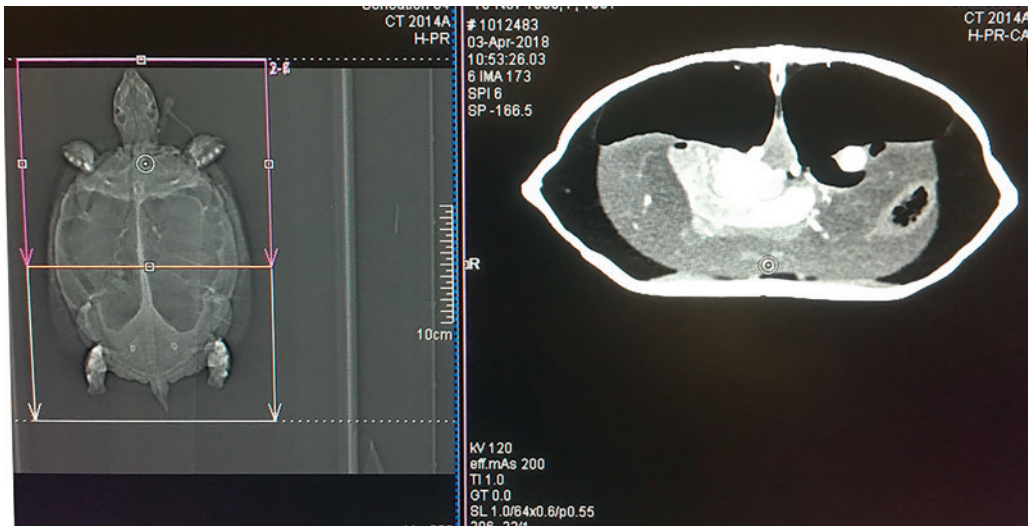

FIG 59.2 Screen capture showing the field of view (pink lines) and yellow grid line on a dorsal scout image and the corresponding transverse CT image at the level of the grid line in a chelonian patient. (Courtesy of Ajay Sharma.)

to a greater extent, resulting in a brighter image. Houndsfield units (HU) are the mathematical/numerical representation of structural densities on CT images. Structures/lesions are described in terms of their attenuation characteristics/HU values. For example, normal lungs are described as hypoattenuating or hypodense whereas bone is described as hyperattenuating/hyperdense. Typical HU values range from −500 for air to +1000 for bone, with a central value of 0 for water. Soft tissue structures range in density/HU values from 30 to 80. If there is contrast enhancement of a particular organ or structure, the HU value is often twice or three times the precontrast values (see Figs. 59.1 through 59.4). Modern multidetector CT (MDCT) machines provide complete imaging of large patients relatively quickly (seconds to minutes). Current MDCT uses helical or continuous image acquisition during movement (translation) of the patient/table through the gantry. This provides extremely rapid acquisition with minimal loss of spatial resolution using modern software and advanced reconstruction algorithms.[1] Older CT machines often used axial image acquisition. This is accomplished by acquiring one slice of data followed by automatic patient/table translation, before acquiring the next data slice. Axial imaging increases imaging time (and therefore also sedation and anesthesia) with no diagnostic advantage. Postprocessing reconstructions to obtain fine details of bone or soft tissue structures is available as needed (Fig. 59.5). The ability to acquire complete diagnostic imaging data quickly is useful in critical patients or in patients in whom general anesthesia is difficult or contraindicated.

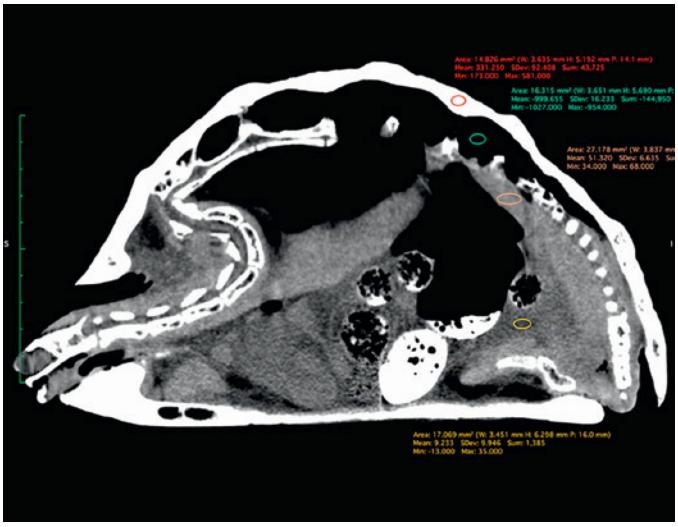

FIG 59.3 Sagittal image of a tortoise showing the different HU of various structures: Bone (*red oval*) mean HU = 331, Gas/air (*green oval*) mean HU = –999, soft tissue (*orange oval*) mean HU = 51, and coelomic fluid (*yellow oval*) mean HU = 3. (Courtesy of Ajay Sharma.)

Imaging data is reconstructed in two or three dimensions using standalone or proprietary software associated with the CT machine. Examples of standalone DICOM viewers include OsiriX (Pixmeo SARL, Geneva, Switzerland) or Horos (The Horos Project) and are available for Mac operating systems or Windows-based software such as RadiAnt (Medixant, Poznan, Poland). CT provides excellent anatomic detail and good spatial resolution; its resolution of osseous and pulmonary structures is exceptional, and soft tissue resolution is good. Because the images are collected serially along the axis specified by the clinician, CT scans can provide 2D section images, or the images are reconstructed as three-dimensional studies (see Figs. 59.5, 59.6, and 59.7). The same CT data can be reviewed in serial sections (Fig. 59.8) or reconstructed in a variety of ways to allow for the retention of three-dimensional landmarks (see Figs. 59.5 through 59.16).

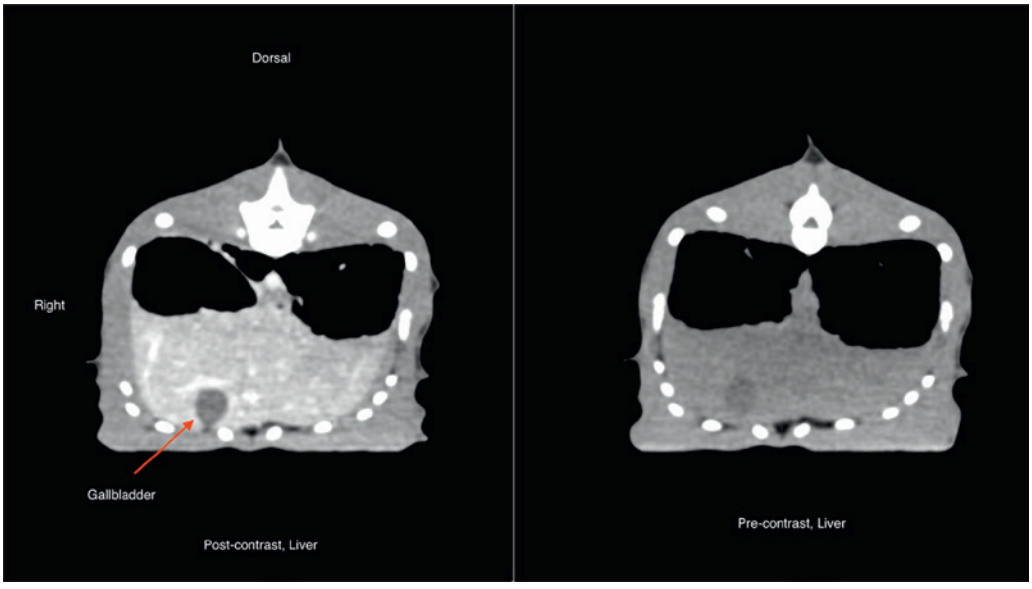

FIG 59.4 Transverse image of the cranial abdomen of an iguana (*Iguana iguana*) showing the strong contrast enhancement of the liver, the hepatic veins, and the fluid attenuating gallbladder. Noncontrast enhanced liver HU = 55; postcontrast enhanced liver HU = 150. (Courtesy of Ajay Sharma.)

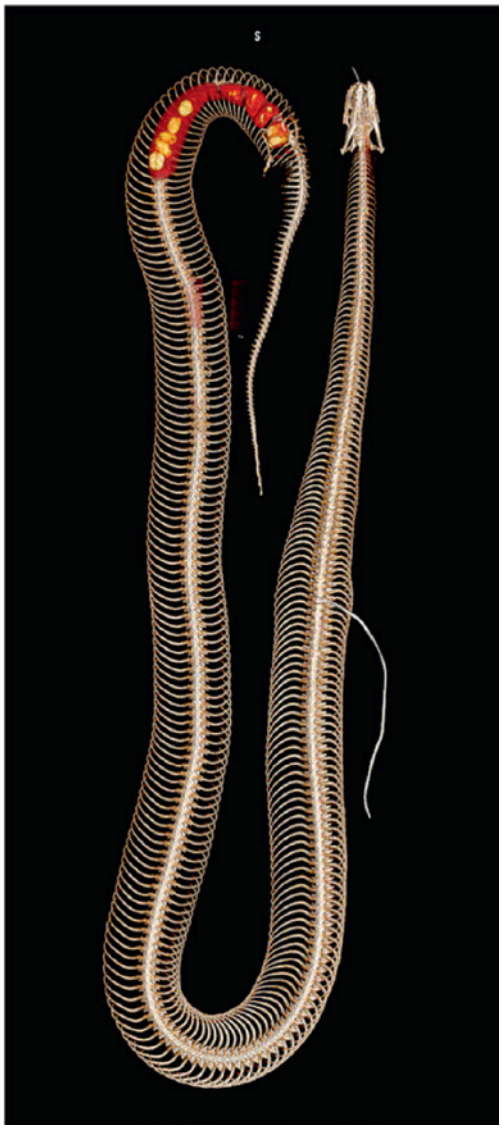

FIG 59.5 Precontrast 3D reconstruction of a Burmese python (*Python bivittatus*). The white-red material in the caudal aspect is feces. The white linear wire in the cranial third of the snake is a Doppler wire with the sensor placed on the heart. (Courtesy of Ajay Sharma.)

FIG 59.6 Postcontrast 3D reconstruction of the same patient as in Fig. 59.5 showing contrast enhancement of the heart, aorta, liver, renal arteries, and kidneys in a Burmese python (*Python bivittatus*). (Courtesy of Ajay Sharma.)

Computed tomography is essential for evaluating the lungs and airways and highly recommended for imaging the skeletal system, gastrointestinal tract, and reproductive organs in a variety of reptilian species (see Figs. 59.6 through 59.9 and 59.11 through 59.20). The technology is invaluable for assessment of the relative positions and sizes of organs and their functions, particularly for dynamic organ systems. Computed tomography is extremely beneficial in the management of patients with extensive osseous abnormalities such as osteomyelitis or trauma (see Figs. 59.18 and 59.20). CT is also used to assess the coelomic cavity, abnormalities of the urinary tract, and extracoelomic soft tissues (see Figs. 59.19, 59.21, 59.24, and 59.25). Virtual endoscopy is possible with appropriate software (Fig. 59.26).[13–20]

The use of positive contrast media and 3D reconstructions provides enhanced soft-tissue detail and good resolution of cardiovascular structures (see Figs. 59.3 through 59.6, 59.22, and 59.23). Positive contrast media include water-soluble iodinated compounds for intravascular injection and barium sulfate liquid for the gastrointestinal tract.

Over the past decade, the development of integrated videography, cineradiography, and CT imaging has enabled functional studies of a variety of vertebrate XROMM (x-ray reconstruction of moving morphology). Most address locomotion or feeding by manually and computationally merging motion data from in vivo x-ray video with skeletal data from CT scans into precise and accurate animations of bones moving in 3D space.[21–26] This contemporary rotoscoping provides contextual information to interpret skeletal function. Although generally used in functional anatomical studies of larger vertebrates, the approach has clinical utility in orthopedics and podiatry.[27,28]

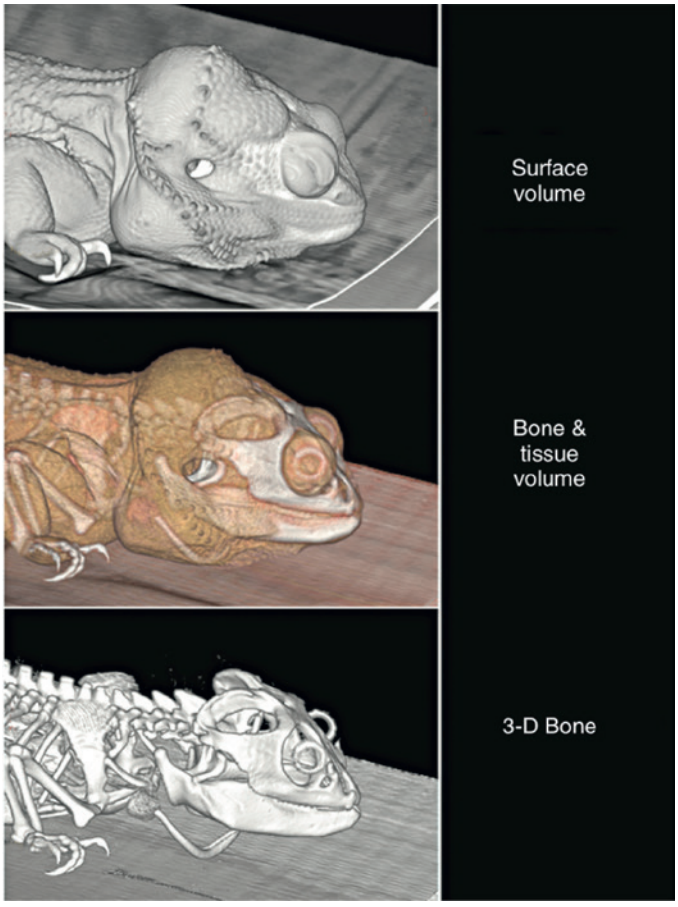

FIG 59.7 These lateral views of a bearded dragon's head and torso show the versatility of CT data. They may be reconstructed in three dimensions to emphasize different structure densities and to allow understanding of external landmarks and the internal structures (skeleton in this case). The same data set from a single CT scan shows the results of three reprocessing modes. Different threshold settings allow the same data set to be reconstructed as a surface image, showing the whole volume of the animal (surface volume), a translucent tissue image of the whole volume with the skeleton detected (bone + tissue volume), and a three-dimensional image of the skeleton alone. Bony sutures are not seen in this image because their small size was below the level of sampling resolution. Cartilage cannot be seen when reprocessing for bone but is included with other reconstruction settings that include the denser soft tissues. *Pogona vitticeps* snout-vent length was 22.5 cm. (Courtesy of Jeanette Wyneken.)

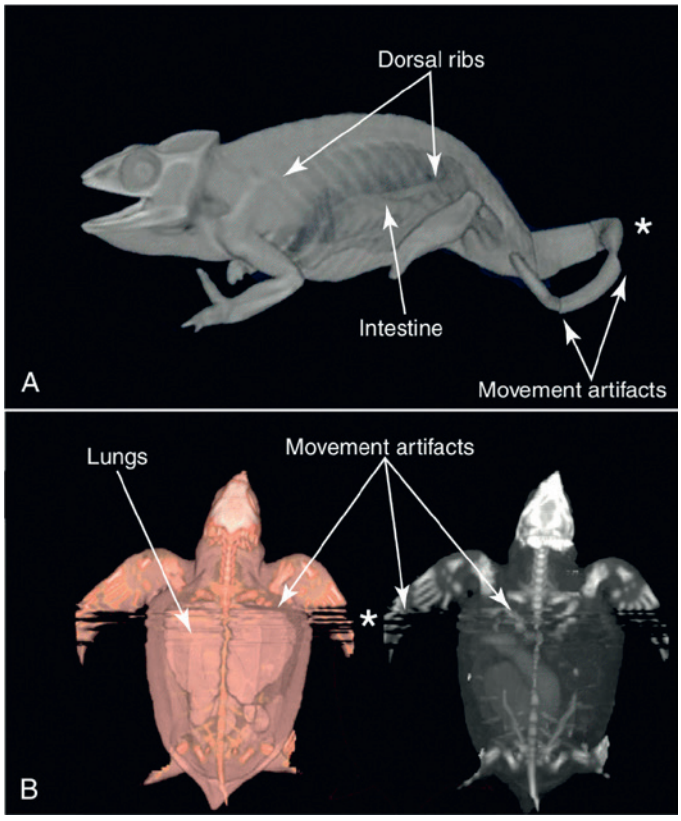

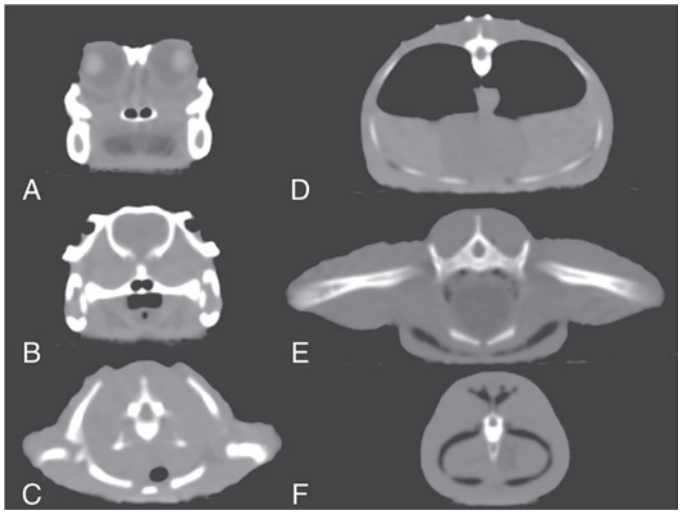

FIG 59.9 Chameleons have thin bones and large saclike lungs. The ribs are jointed at the articulations of the dorsal ribs, spine, and ventral ribs (Gastralia) from the belly. Chameleon ribs extend along the length of the trunk. These CT scans show the large areas of low-density lungs and the large numbers of ribs. *Furcifur pardalis* snout-vent length is 12.6 cm; in (A), the data were reconstructed from 0.6-mm serial images and reprocessed so that both skeletal and airway data could be seen. Postprocessing of the CT image data with false color (B) shows the lung field and skeleton of a posthatchling leatherback turtle. There is a movement artifact through the cranial lungs and distal flippers when the animal took a breath. *Dermochelys coriacea* straight carapace length is 5.7 cm. (Courtesy of Jeanette Wyneken.)

FIG 59.8 Two-dimensional transverse images along the body of an alligator. At the level of the eyes (A), the jaws form the boniest parts of the skull. Teeth can be seen extending from the lower jaw upward. The bony palate ventral to the choanae resides between spaces that are the palatal vacuities. The vitreous and the tongue are dark. The scleral ossicles appear light. (B) Posterior to the orbits, the palate is complete and the internal choanae can be seen joining the glottis. Dorsally is the oval braincase with posterior temporal bars extending ventrally and laterally. At the level of the shoulders (C), the vertebrae are mostly surrounded by the scapulae and procoracoids. The single element ventral to the trachea is the interclavical. (D) Posterior to the forelimbs, the body wall is supported by dorsal ribs and ventral ribs. The sternum is not detected. The dark heart can be seen ventral to the paired lungs. Two osteoderms are visible dorsal to the trunk vertebra. (E) The hind limbs are supported by robust ilia articulating with sacral vertebrae. The anterior aspect of the paired pubic bones can be seen ventrally. (F) The tail vertebra and ventral Y-shaped chevron bone are surrounded by muscle (gray) and tendon (black). *Alligator mississippiensis* snout-vent length is 22 cm. (Courtesy of Jeanette Wyneken.)

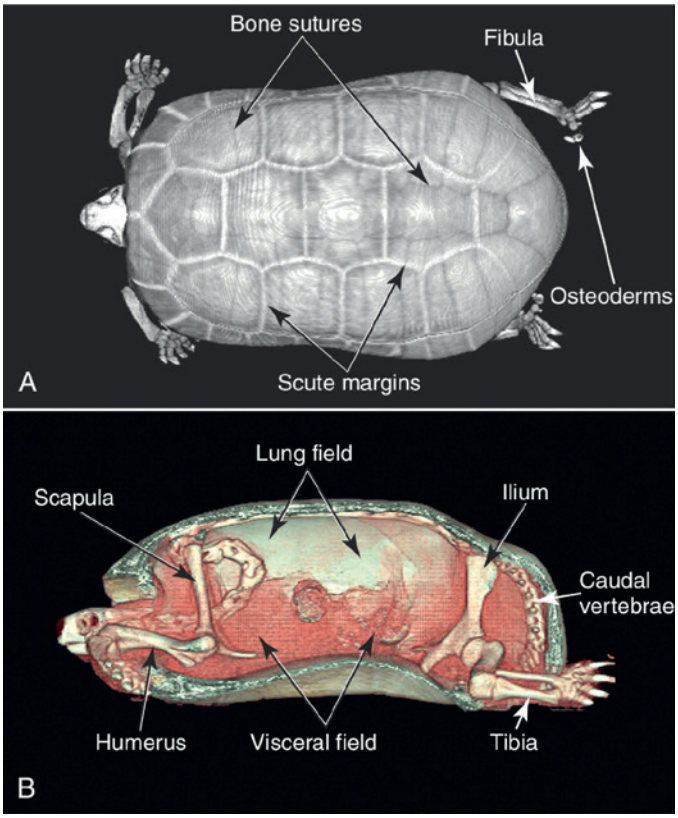

FIG 59.10 CT data can be reconstructed to show three-dimensional skeletal anatomy. Postprocessing software allows for the reconstructed images as whole skeletons that then can be cut virtually to show internal anatomy. Tortoise (Testudinidae genus and species unidentified) straight-line carapace length unknown, adult. (Courtesy of Jeanette Wyneken.)

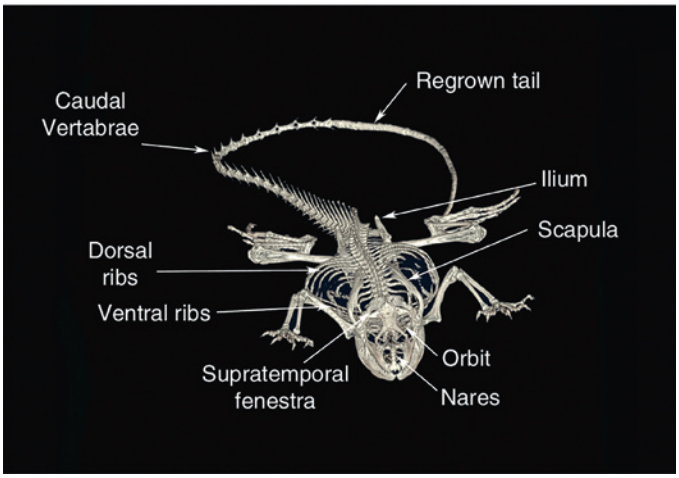

FIG 59.12 This three-dimensional reconstruction of an adult iguana skeleton shows normal anatomy, including the multiple fenestrae in the skull, arrangement of the vertebral spinous processes, and the dorsal limb girdle elements and a few common artifacts found in CT images. First, rib elements appear to be missing laterally. The thinnest rib ends and cartilaginous parts between the dorsal and ventral ribs are not detected in this kind of reconstruction. The thin nasal bones just behind the nares also appear to be missing. Their data fall outside of the threshold used by the software to make this kind of reconstruction. The striping, most apparent on the skeleton, is from reconstruction of sequential two-dimensional images. *Iguana iguana* snout-vent length = 41.8 cm. (Courtesy of Jeanette Wyneken.)

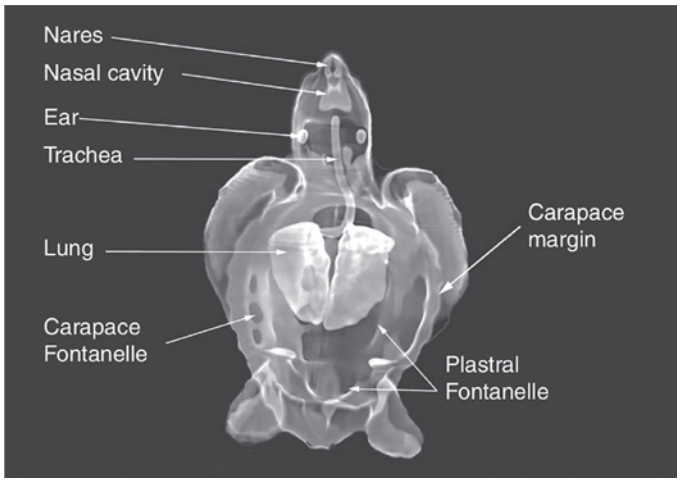

FIG 59.11 This CT scan of a small juvenile sea turtle was reconstructed applying threshold values to the data to make the bones and airways translucent and the surfaces and margins appear as outlines. The partial secondary palate of sea turtles allows the nares to be seen clearly and separately from the trachea, which opens at the base of the tongue. The lungs attach to the carapace and along the vertebral column. Unossified fontanelles are in the margin carapace and make up the center of the plastron. The otic chamber (labeled *ear*) is air filled. Other areas of trapped air appear in the neck and inguinal pockets. *Caretta caretta* straight-line carapace length is 6.3 cm. (Courtesy of Jeanette Wyneken.)

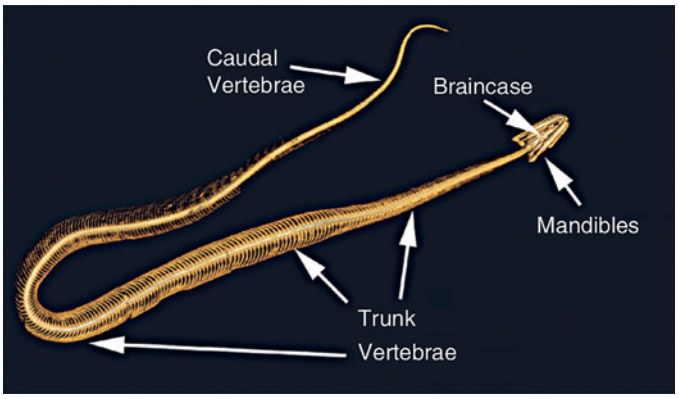

FIG 59.13 Ventral view of a ball python skeleton. This 3D reconstruction shows normal anatomy. The separate mandibles are easily seen. Snakes lack a secondary palate, so the roof of the mouth is also the floor of the braincase. Cervical vertebrae are limited to the anterior two and cannot be distinguished in this CT reconstruction. Trunk vertebrae have ribs and extend most of the length of the snake. Snakes lack ventral ribs. Caudal vertebrae lack ribs. The slight shift in registration of the reconstructed sections in the midbody are associated with one breath taken by the snake during scanning. *Python regius*, adult. Snout-vent length unknown. (Courtesy of Jeanette Wyneken.)

VetBooks.ir

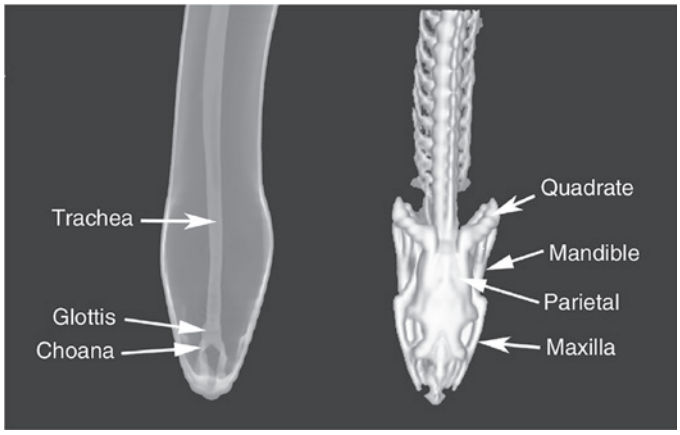

FIG 59.14 This close-up CT scan of the head structure shows the relationship of the airways in a corn snake to its skull and neck. Although snakes lack a secondary palate, the airways through the choanae and to the glottis are confluent. The reconstruction of the same CT scan as the snake's skull shows the bones that make the skull highly kinetic. Joints between the parietals, quadrate, and mandibles contribute to the snake's large gape. Highly mobile maxillae assist in prey capture and manipulation for swallowing. No rigid joint is found between the two mandibles or the maxillae. *Pantherophis guttata,* adult. Snout-vent length is unknown. (Courtesy of Jeanette Wyneken.)

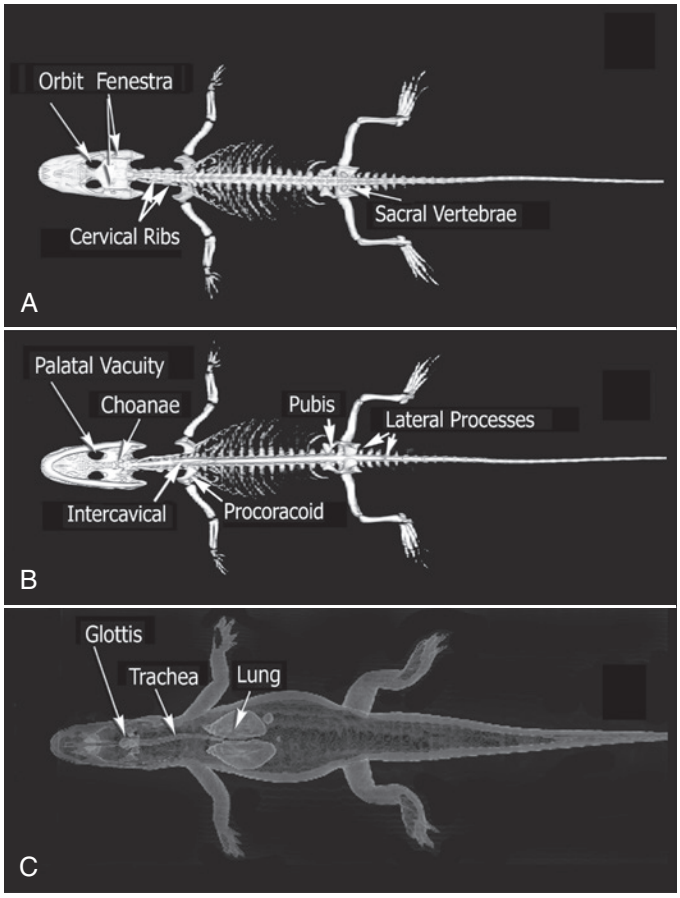

FIG 59.15 The skeleton of a small juvenile alligator from a CT scan. The scan shows normal anatomy of a small juvenile reconstructed for bones and airways. The diapsid skull architecture, in dorsal view (A), includes paired superior and lateral fenestrae located posterior to the large orbits. The ventral view (B) shows the large secondary palate separating nasal and oral passages. Paired palatal fenestrae (palatal vacuities) occur ventral to the orbits. The internal choanae, posterior to these openings, appear unpaired along the midline because of the resolution of this scan. The glottis in this lung volume reconstruction (C) aligns with the internal choanae. Crocodilians have cervical ribs (B), dorsal ribs that attach to a sternum, and extensive ventral ribs; the latter are not detected in this construction. The pectoral girdle of crocodilians is simple, with paired scapulae dorsally (A) and procoracoids ventrally (B); primitively it retains an unpaired interclavical. The pelvis is attached to the axial skeleton by robust sacral vertebrae (A). The more proximal caudal vertebrae have prominent lateral processes; these are absent near the end of the tail (A and B). The alligator's lungs occupy a relatively small volume in the body (C). *Alligator mississippiensis* snout-vent length is 22 cm. (Courtesy of Jeanette Wyneken.)

VetBooks.ir

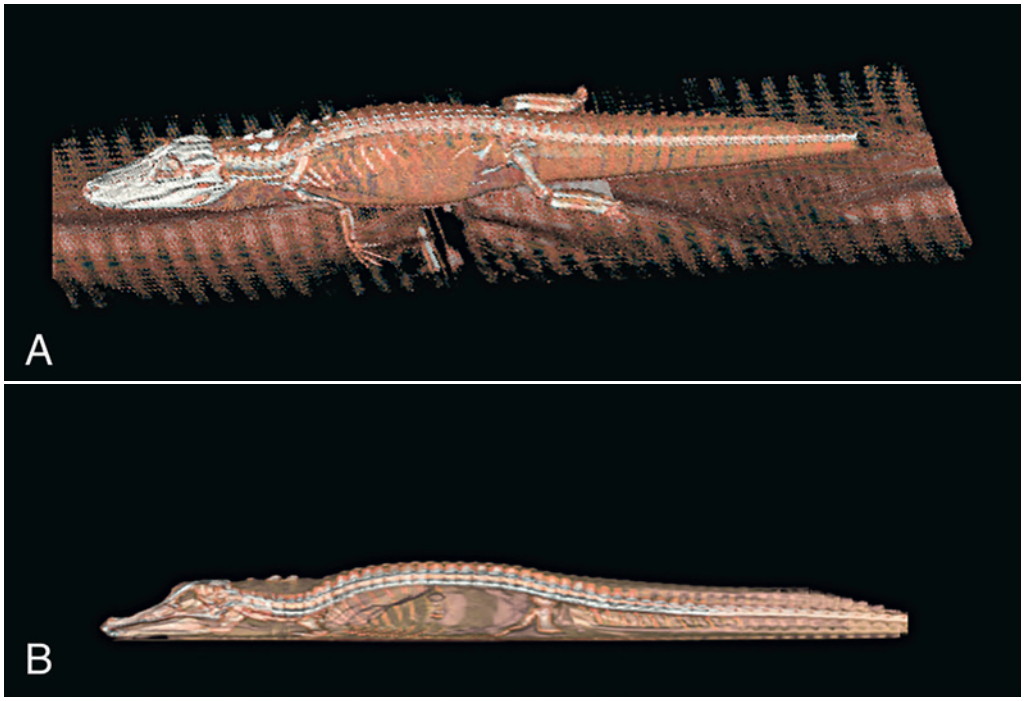

FIG 59.16 (A) The CT data of a small juvenile alligator are reconstructed in three dimensions. The bone and soft tissue together provide landmarks. (B) The reconstruction is cut virtually, showing the skull's internal architecture, spine, lungs, and pelvis. In both views, the terminal tail vertebrae were beyond the scanned field. *Alligator mississippiensis* snout-vent length is 22 cm. (Courtesy of Jeanette Wyneken.)

Magnetic Resonance Imaging

Shannon P. Holmes and Jeanette Wyneken

The progressive development of cross-sectional imaging techniques, such as magnetic resonance imaging (MRI) and computed tomography (CT) in veterinary medicine continues as the value of these modalities are realized and increasingly used in zoological species, including reptiles.[1] Historically, radiographic examinations have been the main diagnostic imaging tool and will remain a generally available first-line diagnostic. Summation of similar tissue opacities, the inherent low coelomic contrast of reptiles, and superimposition of structures represent the major limitations of radiography. MRI overcomes both limitations in an unparalleled manner. There is no other clinical imaging modality that provides the soft tissue contrast resolution with high spatial resolution like MRI. The value of detailed anatomical and tissue chemistry information are beneficial in clinical practice, as well as in a diversity of research areas.

The main strength of MRI is the soft tissue contrast provided. Depiction of tissue in shades of gray is fundamental to diagnostic images, yet MRI also provides information on normal and altered tissue chemistry (function).[2–4] The manner in which a tissue interacts with magnetism confers a specific shade of gray in its normal state, and thus deviations in the shade of gray indicate a chemical change in the tissue that is associated with a pathologic process. These shifts in shades of gray across time or compared with known normal values can herald specific pathologic processes.[5] Therefore MRI will delineate disease processes that may not alter anatomy sufficiently to be detectable with other modalities. It can be thought of as a sensitive and specific noninvasive diagnostic modality.[3] In clinical patients and research animals, the normal relative positions and sizes of living organs in vivo and their functions, as well as pathologic changes, can be evaluated in a manner that previously relied on radiographs, ultrasound, or dissection. In addition to superior contrast resolution relative to the other main cross-sectional modality CT, the other advantages of MRI include multiplanar acquisition and numerous pulse sequences that can delineate different tissue characteristics and disease processes with nonionizing radiation.[6]

MRI units that can be used to evaluate reptiles are increasing in availability, and owners have increased interest in pursuing advanced imaging.[1] This includes greater numbers of clinical high-field units that are better for evaluating many reptiles of small body size or body weight. There is also continued development of MR techniques that can be advantageous to advancing our understanding of anatomy and disease detection in even the most unusual species. Further advances within MRI have been developed and applied to reptile species. These advanced imaging modalities include functional MRI (fMRI), which uses changes in blood oxygenation to detect areas of activation (tissue activity), and MR microscopy for investigation of signal alterations in very small anatomic regions or cellular alterations.[7,8]

The following section provides descriptions of MRI with basics for understanding this modality. The examples provided will function as an introduction into applications in reptile MRI, while providing baseline reptile anatomy in several taxa.

PRINCIPLES OF MAGNETIC RESONANCE IMAGING

A comprehensive review of MRI physics and principles is beyond the scope of this chapter. The focus is to provide sufficient understanding of image degeneration and specific challenges encountered in reptile MRI studies.

MRI is unique among imaging modalities in that it does not involve the interaction of ionizing radiation or ultrasound waves with tissue. The signal that is produced to form MR images is caused by responses of hydrogen protons within the body to magnetism and radiofrequency pulses; specifically, the relaxation of protons back to an equilibrium state following excitation. Hydrogen protons exhibit magnetism due to their nucleus being composed of an odd number of neutrons and protons.[2,3,9] These hydrogen protons vary in number and in the chemical environments of the tissue they reside within (i.e., fat with long chains of hydrogen protons versus more bound protons within muscle fibers); these factors bestow distinct biochemical and biophysical properties to tissues that are represented in the MR image. Following excitation by the MRI unit, energy is released from the excited protons and used to produce MR images. Specifically, the protons relax back to an equilibrium state and the relaxation rate releases an energy equivalent that is converted into a grayscale signal intensity and used to generate the image. The process of excitation and relaxation must be repeated numerous times to generate the image, which is one reason MRI scans take longer than CT.[1,10] The pulse sequence, which defines the timing of radiofrequency pulse delivery to cause proton excitation and reception of signal to compose images, determines the kind of images that will be obtained, and imaging protocols consist of numerous different pulse sequences.[1–3] Different types of pulse sequences are used to depict different biochemical properties of tissues, as well as some that are used for specific pathologic change detection (i.e., hemorrhage detection).

The subject must be placed within the strong magnetic field of the MRI unit, and pulses of radiofrequency (RF) energy are delivered to excite the protons in the body.[9,10] It should be noted that in contrast to the ionizing radiation of radiographs or CT, no harmful effects have been associated with the high magnetic fields used in the MRI, nor in association with the radiofrequency energy deposition.

MR images are serial, two-dimensional representations of the sectioned three-dimensional anatomy, which are more commonly referred to as slices. Slices refer to the orientation of image acquisition, and

VetBooks.ir

slices can be oriented in any direction within the X-Y-Z Cartesian planes. The image, or slice of tissue representation, is composed of pixels similar to a television or computer screen. The higher the number, the better the spatial resolution.[2,3] The pixels in an MR image are grayscale representations of small boxlike sampled volumes of tissue, called voxels.[3,4] The amount of signal available to create the image is determined by the number of protons in the cubic sample or voxel of tissue, which is computationally translated into a grayscale number, and the displayed image is a composite of pixels. If the sampling boxes through the anatomy are made too small, there may not be sufficient signal to produce diagnostic images.[3,11] This can be a significant issue in smaller patients, such as geckos, where high spatial resolution is also desired to evaluate the proportionally smaller anatomy. A major advantage of the MRI is that the amount of signal per voxel increases substantially with increasing field strength. MRI units are described by the magnet strengths, with clinical units having field strengths of 0.3 Tesla (T), 1.5 T, 3.0 T, or less commonly 7.0 T.[2,11] Imaging smaller animals at 3.0 or 7.0 T is easier than at 1.5 T, but the 1.5 T units are the most commonly available strength of veterinary clinical MRI units.[3] There can be successful imaging of smaller reptiles with 1.5 T units or less. Successful reports of MRI using low field strengths (i.e., <1.0 T) have been reported and diagnostic for the delineation of a mass in a tortoise.[12] However, these weaker magnets make diagnostic imaging of smaller patients a challenge. Thus, field strength needs to be a consideration in planning MR in reptiles of various sizes.

The MRI unit produces the strong magnetic field and can come in a bore (closed) or open conformation.[2] The bore units are characterized by a long tubular area within the MRI that completely encircles the patient (Fig. 60.1). These have more uniform magnetic fields at their isocenter, where the imaging of the patient occurs, than do open units. The clinical images presented here were all collected with a closed MRI system. The MRI unit is the source of the applied energy (RF energy) that is used to excite the protons. For some units and for very large patients, the MR unit itself can also collect the signal, but this generally produces poorer quality images than when using a receiver coil. The most standard methods of MRI employ the use of a receiver coil to collect the signal.[3,9,10] The coils can be rigid and encircle the patient or they can be flat or flexible to conform to a surface of the patient. The former is ideal, as the signal throughout the anatomy is uniform, whereas the surface or flexible coils are only able to collect signal over a certain depth. It is critical to use an appropriately sized coil for the patient or the part of the patient to be imaged.[1,3] Signal loss occurs if there is distance between the patient and the coil. Another factor to consider with coil selection is the number of available channels; the more channels the better the signal reception. In veterinary medicine, the most commonly used coil for smaller patients is the knee coil.[3] These encircle the patient and are rigid. The reference to human anatomy allows one to estimate the size of the patient that can be imaged in these coils. In the authors' experience, the bore or closed MRI units with a rigid coil are most commonly used in reptile imaging (see Fig. 60.1B–D).[1] Focal areas of anatomy or smaller patients can often be imaged with a surface or flex coil. We have used these more in our 7.0 T MR unit. The aim with all coils is to position the receiver as close to the patient as possible to optimize the received signal.

Generally, in veterinary medicine, general anesthesia is necessary for most MRI examinations. It is critical that there is no patient movement, because movement degrades image quality.[3] Another factor that undoubtedly influences the need for anesthesia is the length of MR studies. An examination in reptile patients typically includes at least six pulse sequences that are between 4 to 8 minutes long. MR imaging these species can differ from dogs and cats, because some species will move little when handled or in certain environments. With restraint of the limbs via wrapping the body and/or with light pressure applied with cotton balls over closed eyes and wrapping around the head (see Fig. 54.1), we have been able to image iguanas without anesthesia for a 45-minute examination. The cold environment of the MRI unit likely contributes to low movement. More active patients will require anesthesia. Anesthesia is often elected for ease, because movement during a pulse sequence will render the images nondiagnostic and necessitate repeating the entire pulse sequence.[2,3] Securing the patient within the coil through use of MR-compatible positioners and medical tape is helpful. A final patient consideration is metal. Ideally, no metal can be on or in the animal. Metals with magnetic susceptibility are of greatest concern (e.g., most forms of stainless steel), because they produce large artifacts that distort or obscure the anatomy of interest.[2,3,13] In veterinary medicine, the most commonly encountered artifact is associated with microchips, and removal of the chip may be necessary in smaller patients because it is positioned close to the anatomy of interest. To avoid radiofrequency burns, it is important that the patient not contact the magnet or be wrapped in microfiber materials, as some technical fabrics contain metal fibers. Focal tissue heating and/or patient discomfort have been reported in human patients but have not been reported in veterinary medicine.

An MRI protocol consists of multiple pulse sequences designed to detect various physiochemical features of tissue and detect pathologic change. Patient data, MRI information, and annotations are included, not only to enhance the reader's appreciation of MRI utility in clinical reptile scanning but also to provide an introduction to its versatility. The most important of these is likely a T2-weighted (T2w) fast spin echo (FSE) sequence, which is present in all MR protocols of various body parts.[3,6,14] The value of the T2w-FSE is attributed to its sensitivity to changes in intracellular and extracellular fluid, which are components of virtually all pathologic disease processes. The grayscale in MRI is described as signal intensity, and anatomy would be described as hyper- or hypointense for a given pulse sequence. T2w images provide high contrast between different tissue types (Fig. 60.2A–B); for example, fluids and fat are hyperintense (or less formally bright or white), muscle is hypointense (or dark gray), and intraabdominal parenchymal organs are various shades of intermediate signal intensity (or shades of gray that are less than muscle).[2,3,11] Some tissues will be hypointense (or black) on imaging series. This is true for dense bone, such as cortical bone, because the protons within this tissue are so tightly bound they cannot resonate and emit signal intensity. Bone marrow is different because of the fat and hematopoietic constituents within the trabeculae, and it appears bright or hyperintense. Lungs are also hypointense on all MR images, because they essentially lack detectable protons. However, MRI is uncommonly used for interrogation of the lungs because CT is superior for this body system.

Another pulse sequence used frequently is T1-weighted (T1w) SE or FSE sequences. These sequences produce lower contrast images; their strength is in the depiction of anatomy and following contrast administration.[2,3] In T1w images, fat remains hyperintense, fluids are hypointense, and soft tissues and muscle are similar intermediate signal intensity (see Fig. 60.2C). Gadolinium-based contrast agents shorten T1 proton relaxation, and organs that undergo enhancement (e.g., heart, liver, kidney) will have varying degrees of increased signal intensity compared with the precontrast T1w images (see Fig. 60.2D). In the authors' experience, the standard dose for gadolinium-based contrast agents of 0.1 mmol/kg (Magnevist, gadopentetate dimeglumine [Bayer HealthCare Pharmaceuticals Inc.] or Prohance, gadoteridol [Bracco Diagnotics Inc.]) produces detectable contrast enhancement to detail the circulation and enhance the parenchyma in several species of turtles, pythons, and agamid lizards with no detectable adverse effects. This dose is similar to that which produces good results in dogs and cats.[3] In small patients, gadolinium generally increases the emitted signal, and therefore it can

VetBooks.ir

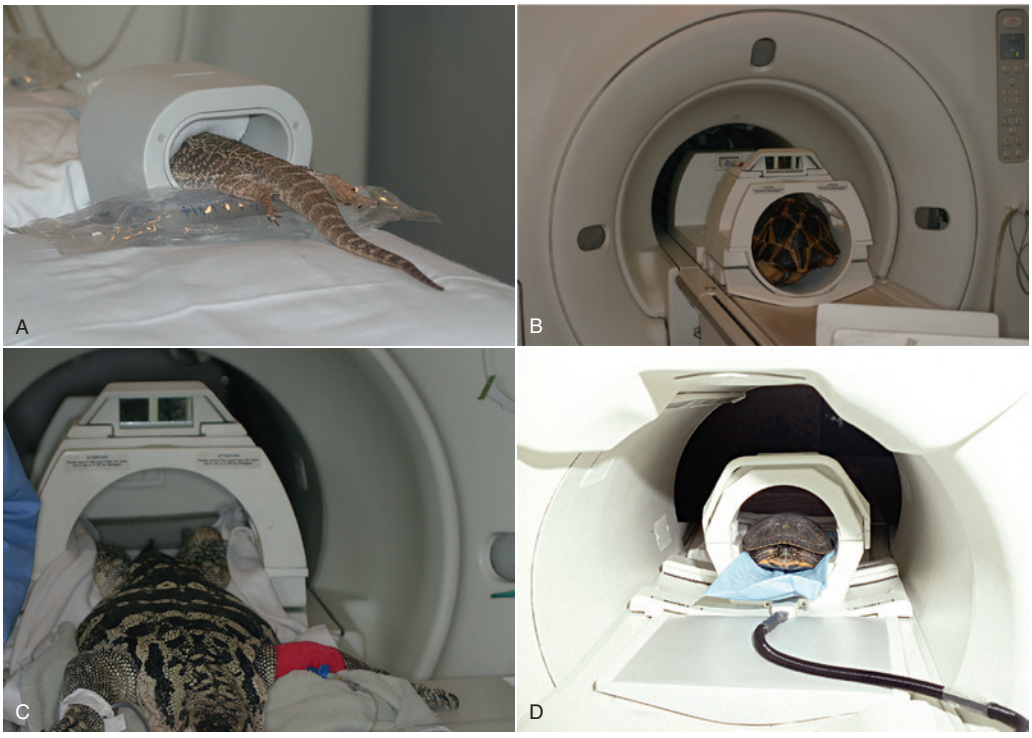

FIG 60.1 Closed MRI unit with two different receiver coils. The receiver coils are positioned at the bore opening of the MRI unit, and they will be advanced into the tube to the isocenter. The receiver coil optimizes the received signal when sized appropriately for the patient. If the receiver coil is too large for the patient, the released signal from the patient has to travel farther to be detected and will degrade. The phenomenon is similar to radio signal detection and improves with proximity to the radio station antenna. (A) A bearded dragon (*Pogona vitticeps*) is positioned in a wrist coil that wraps around the cranial coelom. As a result, only this portion of anatomy can be examined with this configuration. Positioning of the patient within the center of the coil is also important; a saline bag is elevating the caudal coelom and a towel is wrapped around the cranial coelom. The positioner within the coil aids in patient restraint. (B) A radiated tortoise (*Astrochelys radiata*) is positioned within a head and neck coil. In this instance the carapace is in contact with the coil. To avoid tissue heating, normally a layer is placed between the patient and the coil, but heating should not occur due to the tough keratinous and bone carapace composition; soft tissues are more vulnerable. The turtle will be moved into the bore head first so that it is positioned at isocenter for imaging. (C) The head and neck coil is used to examine the pelvis of this large water monitor (*Varanus salvator*). The width of the pelvis necessitates use of this coil, but the long distance between the dorsum of the patient is suboptimal. The caudal body is dorsoventrally compressed, and the pelvis is narrowed in this patient; a surface coil, such as a spine coil, could have been used. (D) A slider turtle (*Trachemys scripta*) is positioned in a receiver coil designed for human knees, and the receiver has been moved into the bore of the MRI. This shows how far in the magnet the isocenter is located (A, B, and C, Courtesy of Stephen J. Divers; D, courtesy of Jeanette Wyneken, Florida Atlantic University.)

be beneficial to repeat or acquire T2w sequences after contrast administration. This is not a standard practice in MR imaging because of concern for distortion by gadolinium contrast agent of representative tissue signal intensities in the T2w images. Gadolinium is mostly considered a T1 contrast agent with minimal effect on T2 relaxation. However, all possible techniques to increase signal intensity may be needed to image smaller reptiles, particularly when using the lower strength high-field (1.5 T) MR units.

There are almost endless numbers of pulse sequences that an MRI user can choose from, and the mixture of different pulse sequences acquired in different planes is responsible for the longer scan times associated with MRI. For example, inversion recovery (IR) sequences are extremely useful for depicting specific tissue chemistry features.[6,15] This kind of sequence uses MR physics and the application of an additional RF pulse to suppress the signal from a specific tissue or fluid. In the neurocranium, fluid attenuation inversion recovery (FLAIR) sequences are useful in suppressing the signal intensity from CSF or other pure fluids. These IR pulse sequences can be acquired as a T2w or T1w FLAIR series. Periventricular parenchymal high signal intensity is more easily distinguished on T2w FLAIR images compared with T2w images.[3,16] T1w FLAIR images are necessary at higher MR field strengths (i.e., 3.0 T or more) to distinguish the areas of ventricular fluid, since T1 relaxation is affected by field strength.[17] Short tau inversion recovery (STIR) images are another form of inversion recovery sequence in which tissues composed of fat are suppressed (see Fig. 60.2E).[3,6,11]

Gradient-recalled echo (GRE) sequences are the second-most commonly used group of pulse sequences after FSE sequences. These have greater issues with artifacts, but like FSE, sequences can provide specific tissue information.[2] These can be run as T2w or T1w, but the most commonly used GRE sequence in veterinary medicine is T2*-weighted

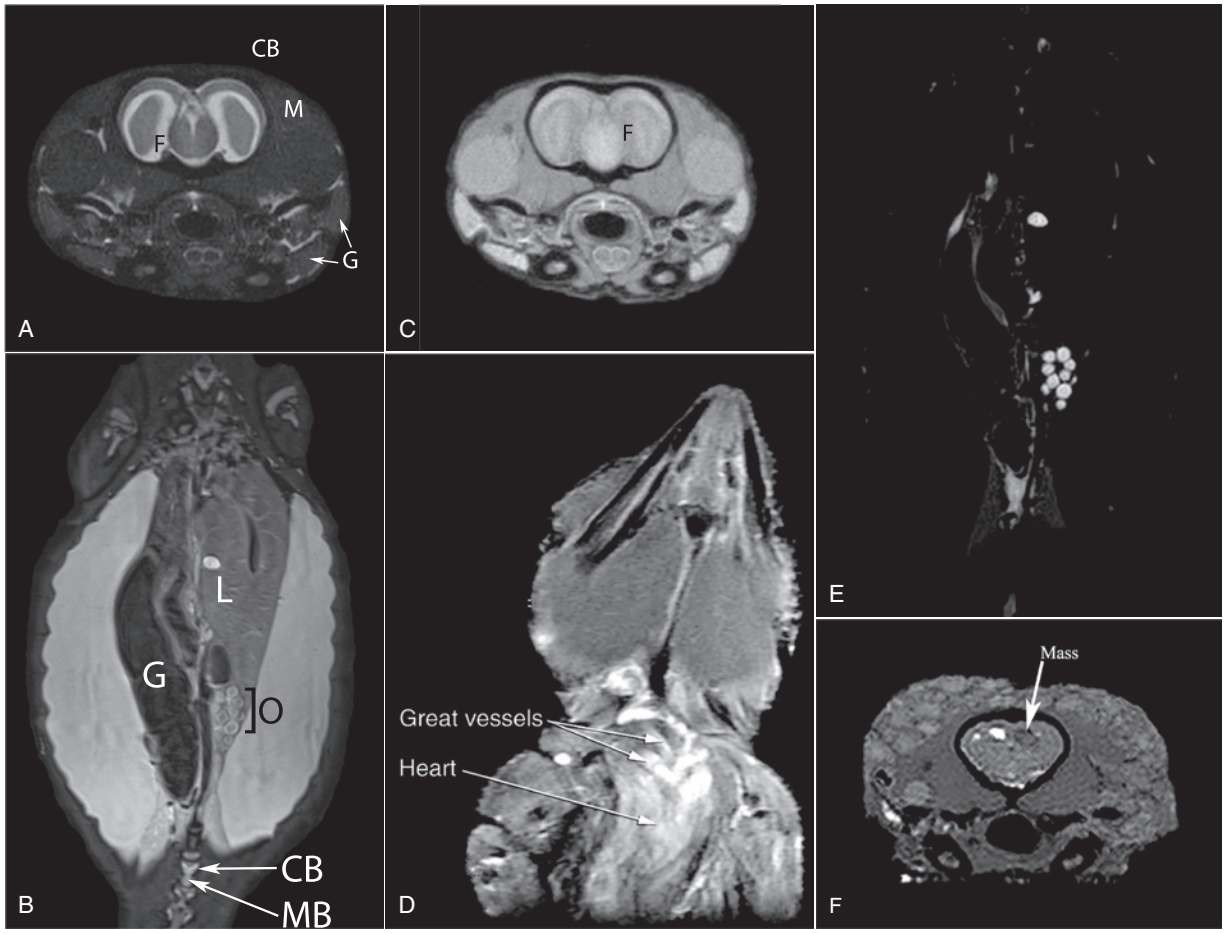

FIG 60.2 Examples of commonly used MR pulse sequences in reptile MRI. (A) T2w FSE transverse image centered on the brainstem of a ball python (*Python regius*). The CSF fluid (F) is markedly hyperintense, and fat would also be hyperintense if present. T2w are beneficial in the nervous system because of the enhanced distinction between the gray and white matter regions in the brain. Some hyperintense fluid is seen in the quadrate-articular joint. Cortical bone (CB) is most hypointense with muscle (M) being less hypointense. Glandular salivary tissue (G) is intermediate signal intensity. (B) T2w 3D FSE dorsal plane image of female lace monitor lizard (*Varanus varius*) centered in middorsal coelom. Bilateral large hyperintense fat pads (F) are identified and gas (G) in the colon is black because no protons are present. The liver (L) has uniform intermediate signal intensity with arborizing intraparenchymal foci that are both hyper- and hypointense, which is due to blood flow artifact. The gallbladder within the liver is hyperintense. The relative hyperintensity of medullary (MB) to cortical bone (CB) is seen in the included thoracic limbs (top of image) and vertebrae (bottom of image). The immature ova (O) have alternating signal intensity consistent with the parenchymal achitecture. (C) Precontrast administration T1w 2D GRE at the same level of the ball python brain in (A). The CSF fluid (F) is relatively hypointense to brain tissue. Note there is minimal to no distinction between the gray and white matter regions. (D) Dorsal plane postcontrast administration T1 images of a bearded dragon (*Pogona vitticeps*). The presence of gadolinium contrast in the circulatory system causes these structures to have increased signal intensity relative to precontrast. The hyperintensity in the heart is less than the greater vessels, which is most likely due to flow artifacts superimposed on the contrast-enhanced blood. (E) STIR dorsal plane image of the female lace monitor lizard matched to the coelomic image in (B). The fat pads are severely hypointense, which is due to complete suppression of all signal from fatty tissues. Interestingly, the liver is also markedly suppressed; this is not commonly seen in dogs or cats but would be expected in female reptiles with increased fat content within the liver in preparation for folliculogenesis, or secondary to hepatic lipidosis, which is common in many captive reptiles. The follicles and gallbladder are more conspicuous on the black background. This increased conspicuity of fluid areas is the primary benefit of this sequence. (F) T2*w transverse image of a ball python brain with an intraventricular mass that has a heterogeneous rim of hypointensity that was not present on any other imaging series performed. This rim of hypointensity was therefore most likely a rim of hemorrhage. Mineral can also be low signal intensity on this sequence but is similarly low signal intensity on other sequences. GRE sequences are more susceptible to artifact, and T2*w amplifies this susceptibility, making very small accumulations of hemorrhage visible. It is noted that this patient also has numerous intermediate signal intensity cysts encircling its head, which are abnormal and discussed in greater detail in Fig. 60.14. (D, Courtesy of Jeanette Wyneken, Florida Atlantic University.)

(T2*w). With T2* weighting, the sequence can be specifically used for hemorrhage detection and is capable of detecting microhemorrhagic foci (see Fig. 60.2F).[3,6,18] GRE sequences can be acquired as 2D or 3D acquisitions; the latter seems to be more frequently used in reptile imaging, especially on low field MRI units to optimize spatial resolution.[1,4] Although improvements in spatial resolution are one of the benefits of this sequence, the increased artifacts associated with this sequence compared with FSE sequences make it less useful and therefore is not commonly used in our reptile examinations. With MRI, angiography is possible both before and following contrast administration with the application of specific GRE sequences. 3D time-of-flight sequences are the easiest to use, because they do not require knowledge of the flow velocities, nor is the injection of contrast needed.[3]

Table 60.1 provides examples of pulse sequence protocols used to scan specific regions of the body. Each is designed to evaluate the tissue for both anatomical and biochemical appearance. The information gained from the different pulse sequences has been established in human, canine, and feline imaging and then extrapolated to reptils. The pulse sequence protocol for the neurocranium is a good example of how the appearance of a single tissue is depicted with different signal intensities or shades of gray on different pulse sequences (see Fig. 60.2).

Some newer pulse sequences have been developed and are particularly beneficial for imaging smaller patients, because they can acquire submillimeter slices. These are similar to 3D GRE sequences, but these possess contrast similar to FSE sequences.[19,20] Traditional MR slices for FSE sequences used in veterinary medicine usually need to be 2 to 3 mm thick.[15] One of the new sequences is essentially a 3D FSE sequence, with the name varying between MR companies (called CUBE in GE units, SPACE in Siemens units, VISTA in Philips units, and MVOX in Toshiba units).[20] These can be acquired as isotropic voxels, meaning the box sampling tissue in the anatomy is equal in all dimensions. The benefit of this form of acquisition is they can be reconstructed after the scan into different plans (Fig. 60.3), which is more similar to CT acquisitions. 3D sequences historically have been GRE or angiographic sequences, which offer less desirable tissue contrast than FSE. Therefore these newer 3D FSE sequences maintain the superior soft tissue contrast of 2D FSE sequences and can obtain thinner slices (i.e., submillimeter) within a clinically feasible time.[21] Therefore, ideal contrast resolution is maintained and spatial resolution is optimized over 2D FSE sequences.

TABLE 60.1 Examples of Pulse Sequence Protocols Used by the Authors to Evaluate Two Commonly Imaged Body Systems

Neurologic System	Coelom†
T2w sagittal and transverse	T2 sagittal and transverse
T2w FLAIR*	STIR dorsal
T2*w transverse	T1 dorsal and transverse
T1w transverse	Postcontrast T1w dorsal, transverse & sagittal
Postcontrast T1w transverse, ± sagittal & dorsal	
3D FSE or GRE, especially for small animals	

These are protocols used in reptile scanning but are similar to those outlined in human standard operating MRI protocols from the American College of Radiology (ACR). Some pulse sequences are more commonly used in different areas because of the biochemical information that is provided. For example, T2-weighted images are used in all MR imaging protocols, and this is attributed to their optimal soft tissue contrast and "fluid sensitivity" because abnormal fluid accumulations accompany most pathologic processes.
*T2w FLAIR images can be challenging in smaller patients since this sequence has low signal-to-noise inherently; it may need to be omitted in small patients scanned with a 1.5 T or less MRI unit.
†Negating effects of respiration (through respiratory gating) is rarely needed in reptiles.

MRI APPLICATIONS IN REPTILES

Based on current literature, there are more numerous MRI examinations of reptiles for anatomic studies and research than for clinical diagnostic purposes. This pattern follows the development of MR in human, canine, feline, and equine medicine. The number of clinical cases examined with MRI has increased in recent years with the increased accessibility to MRI units and likely as clinicians have realized the clinical benefit of this modality. Glodek et al. went further and indicated that MRI was the preferred imaging modality in exotic animals.[1]

Cross-sectional imaging modalities have transformed our knowledge of in vivo anatomy. With the superior soft tissue contrast resolution offered by MRI, detailed anatomy can be delineated. Obviously, the superimposition of anatomy associated with radiography is removed with cross-sectional imaging. Both MRI and CT imaging provide excellent spatial positioning of organs. The benefit of the soft tissue contrast resolution of MRI is that the anatomy is defined by specific signal intensity characteristics, and the parenchymal architecture within organs is identifiable without the need to administer gadolinium contrast intravenously. CT can depict the positioning of anatomy but is more dependent on the intravenous administration of iodinated contrast to depict finer anatomical details, such as parenchymal architecture. Basic reptile MRI anatomy examples are provided (Figs. 60.4–60.13) to illustrate both the spatial and contrast resolution features encountered at different MR unit strengths.

The MR anatomic appearance has been reported for crocodile musculature, testudine middle ear, snake venom system, and head and body of loggerhead sea turtles.[22–26] However, the varied research applications demonstrate the sensitivity and specificity of this modality, which is most likely associated with its soft tissue contrast resolution. MRI is considered the gold standard for noninvasive examination of the neurological system. Using MRI, researchers were able to detect differences between male and female dragon lizard (*Ctenophorus* spp.) primary nuclei (medial peroptic nucleus, MPON) and the ventromedial hypothalamic nucleus, VMN), as well as evolving changes in brain volume.[27] Nonneurologic and neurologic reptile soft tissue structural details have been delineated using MRI, including the structural features that facilitate lizard tail autotomy, fiber-type distribution in the lizard tongue, and crocodile brain volume changes.[28–30] We have used MRI to test changes in the liver of the green iguana (*Iguana iguana*) following carbon tetrachloride administration (Schnellbacher et al, unpublished data). These studies demonstrate the ability to acquire both morphologic and quantitative data from reptiles using MRI, with the latter often being critical for research credibility. All MR images can provide quantitative data if the signal intensity is assessed relative to established normal values. Additional morphologic and quantitative sequences that can be used include diffusion-weighted imaging (DWI) for strokes, diffusion tensor imaging (DTI) for assessment of fractional anisotropy in white matter tracts, and T2 or T1 relaxation time mapping to provide visual representation of tissue alterations.

The use of MRI in clinical applications is similar to human and veterinary patients. For neurologic system evaluation, Brady et al. used MRI to determine whether structural brain disease was responsible for seizures in a crocodile.[31] With smaller brain sizes, higher field MR units are ideal. The spatial resolution, as well as the contrast resolution, can

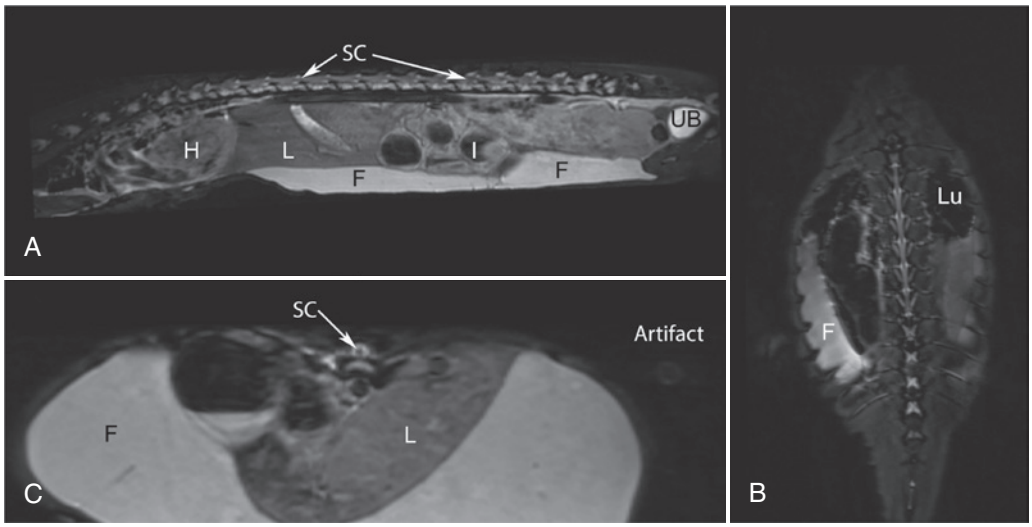

FIG 60.3 Standard MR imaging planes from a 3D FSE T2w sequence, consisting of sagittal (A), dorsal (B), and transverse (C) planes of a green iguana (*Iguana iguana,* snout to vent 30 cm). Unlike CT, which only acquires transverse plane images, MRI can acquire images in any plane. Historically, this meant that each plane had to be acquired separately. 3D FSE sequences acquire isotropic voxels in one plane, in this instance, in the dorsal plane (B), and then the voxels can be reconstructed into any plane. In this sequence, the voxel dimensions were 0.3 mm^3, which means the spatial resolution is 0.3 mm^2. This also means the slice thickness is 0.33 mm; contrast this to routine 2D FSE slice thicknesses of 1 mm at 7.0 T and 3.0 mm at 1.5 T. For reference, this lizard measured 43 cm in length by 7 cm in diameter. The spinal cord (SC) is distinguishable with this resolution. For reference, the coelomic anatomy (H, heart; Lu, lung; L, liver; F, fat; I, intestine; UB, urinary bladder) can also be well evaluated with this sequence.

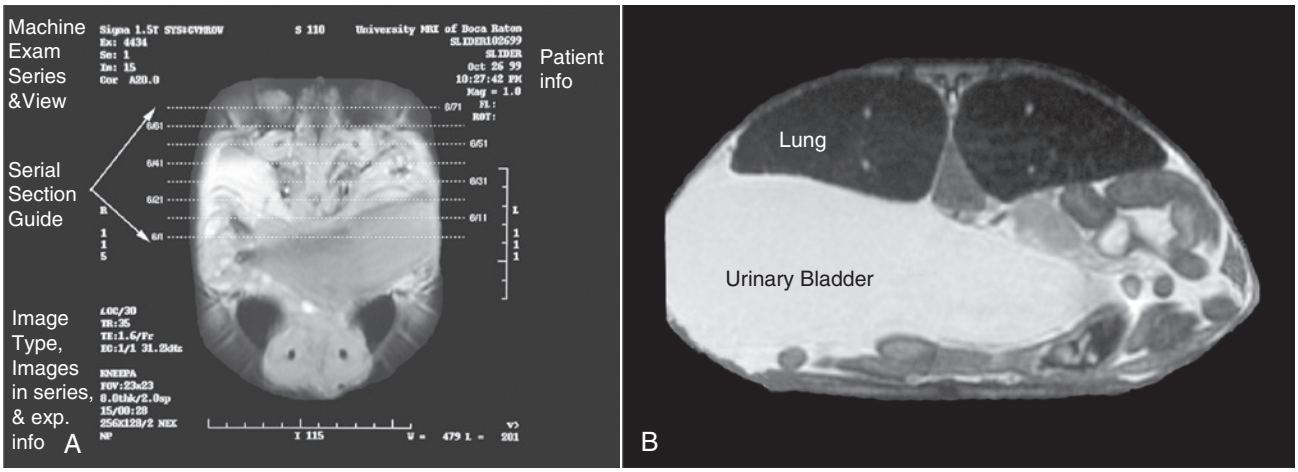

FIG 60.4 (A) Low-resolution "localizer" image is used to plan slices or the image planes. In this case, transverse T2w images are planned throughout the body of a slider turtle midbody. The turtle was oriented with the plastron down; left and right are not reversed in the image. (B) This image section represents localizer line labeled 6/1; the large fluid-filled urinary bladder (hyperintense) extends anteriorly and occupies most of the left half of the image. Bone is barely visible as a thin dark (hypointense) outline. Dorsally, the hypointense spaces are lung tissue with the paired pulmonary artery and vein seen as hyperintense dots. To the right are intestines with intermediate signal intensity; fat, intracoelomic fluid, and mesenteric blood are the most hyperintense areas. The darker gray caudal tip of the liver is ventral. The left side of the turtle was outside of the scanned area. This image was magnified slightly in processing the data. *Trachemys scripta,* adult.

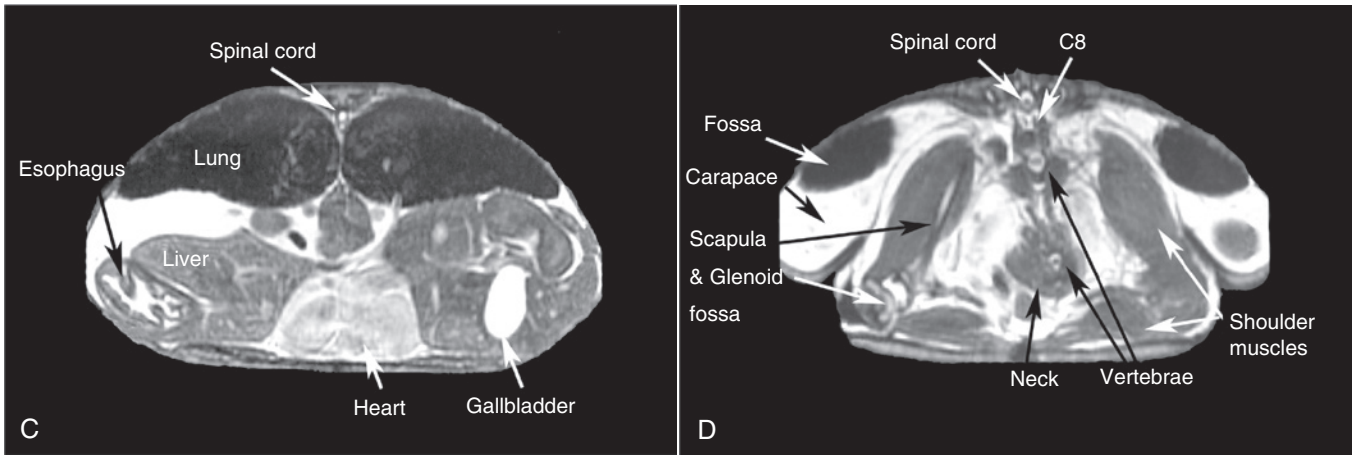

FIG 60.4, cont'd (C) This image is 20 slices more cranial (localizer line 6/21). At this level, the esophagus can be seen to the left. The liver has two large lobes that fill much of the ventral half of the body and one small lobe dorsal to the heart. The heart would be described as being hyperintense to the liver and is found midventrally. The hypointense lungs are dorsal and abut the vertebrae and carpacial bone. The spinal cord can be seen as a hyperintense (white) dot between the medial and dorsal parts of the lungs. (D) This image is another 30 slices more cranial (localizer line 6/51). Note the artifactual thickened appearance of the carapace; this is a partial volume artifact and is because the carapace passes through the slices oblique (i.e., along its curvature). The hypointense (black) spaces dorsolaterally are air-filled fossae where the forelimbs may retract. Medullary bone is hyperintense because of marrow fat. Muscle is among the most hypointense tissues but is less hypointense than cortical bone. Both sets of shoulder muscles and the left scapula are in this plane. In the middle of the body is the retracted neck at the level where the vertebrae form an s-curve. As a result, parts of vertebrae C8, C7 or C6, and C3 are seen from dorsal to ventral. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

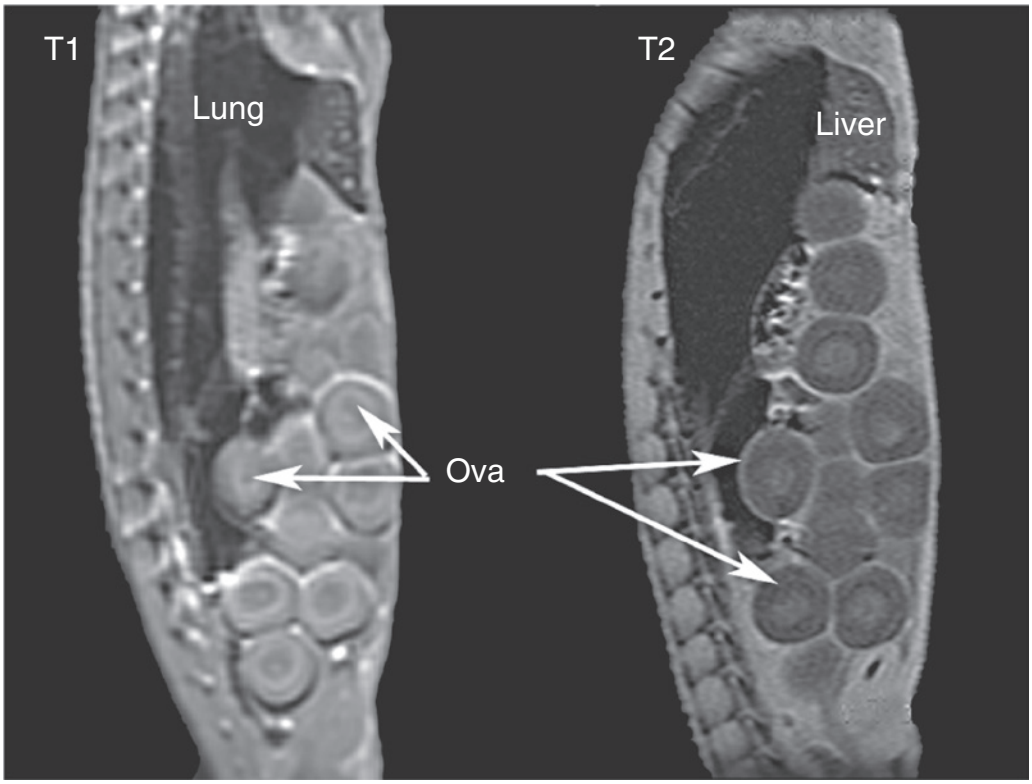

FIG 60.5 Two sagittal images of a female green iguana (*Iguana iguana*) torso taken at roughly the same position. Cranial is toward the top of the image. In the T1 image, fat is hyperintense, air is black, fluid (blood, edema, cerebrospinal fluid [CSF], or yolk) is hypointense, and cortical bone is the most hypointense tissue and will be on all images. Parts of the spinal nerves can be seen as the white dots running along the spine on the left side of the image. In T2 images, fluids are hyperintense; fats are also hyperintense not as hyperintense as fluid. The posterior trunk vertebrae and muscles are easy to identify. This T2 section caught little blood flow (seen immediately to the left of the more anterior ova). The more liquid centers of the yolked ova are clear in both images. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

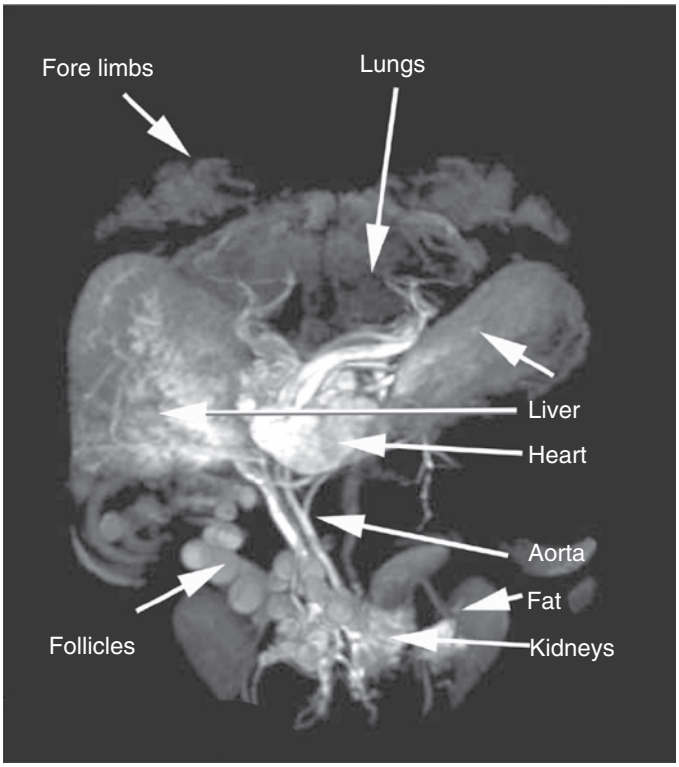

FIG 60.6 Soft tissue anatomy of a slider turtle (*Trachemys scripta*) in dorsal plane is outlined in this T2*-weighted MR image with the vasculature highlighted by the intravenous gadolinium contrast agent (acquired as part of a fMRI examination). The heart plus the highly vascular liver, pulmonary arteries and veins, and kidneys are clearly outlined. Forelimbs are outlined less densely. The two aortic arches join in the midbody as the single dorsal aorta. The larger vessel paralleling the dorsal aorta is the post caval vein. Follicles and fat pads are shown caudally. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

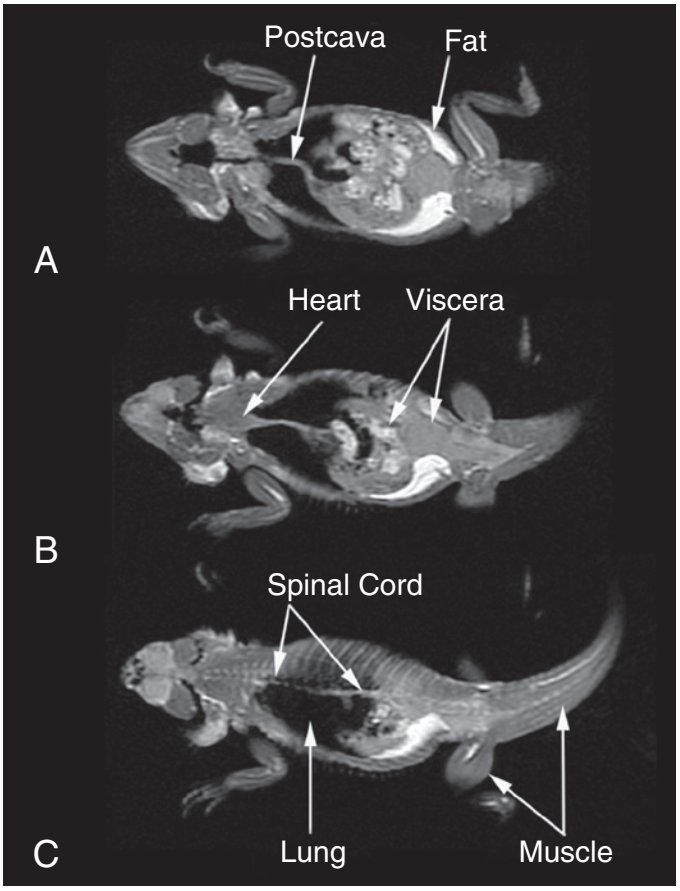

FIG 60.7 These three images are of an adult male bearded dragon (*Pogona vitticeps,* snout-to-vent length 17.6 cm) viewed serially from ventral to dorsal in dorsal plane T1w images, so fat and medullary bone are hyperintense. Fluid and nonfatty tissues appear gray. Air appears black. The most ventral section (A) passes dorsal to the tongue and through the trachea, lungs, postcava, liver, viscera, and through the proximal tail. Long bones and muscles of the limbs can be seen. More dorsally, (B) the lungs, heart, aorta, liver, viscera, and fat pads are clear. In the most dorsal view, (C) the air-filled nasal passages, the eyes, left lung, parts of the spinal cord (light), abdominal fat pads, and tail muscles and tendons can be discriminated. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

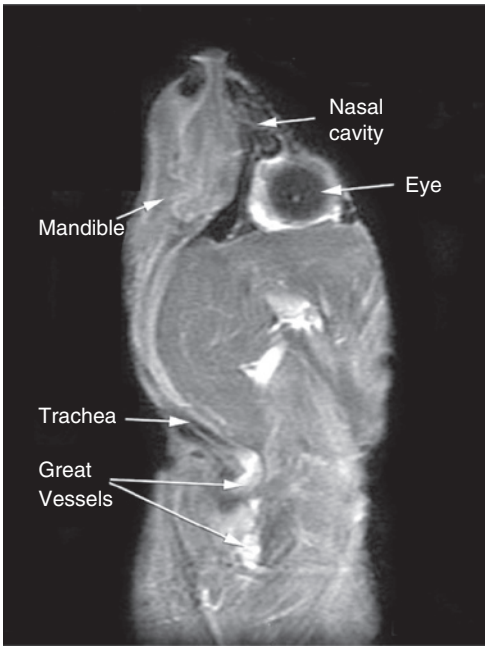

FIG 60.8 This two-dimensional parasagittal image of a bearded dragon (*Pogona vitticeps,* snout-vent length 22.5 cm) shows muscle, the medial edge of the mandible and the nasal cavity. The temporomandibular joint and part of the adjacent circulation (external jugular vein) appear hyperintense (white). This is a T1w image made after gadolinium contrast administration. Parts of the great vessels are caught in this plane of section, as is a small section of the trachea. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

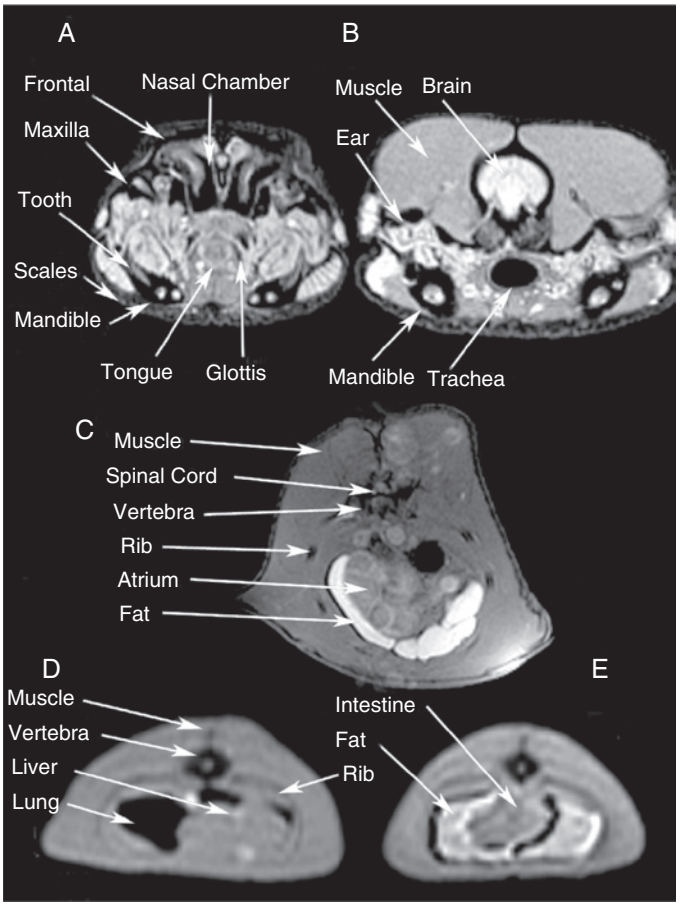

FIG 60.9 Transverse MRI of an adult male Burmese python (*Python bivittatus,* total length 2.9 m) made at multiple levels. MRI of whole snakes is difficult because of the tubular geometry of the animals. Often the snake must be examined in a series of sequential parts to avoid losing image quality (A–C). Snake images taken without the aid of a small imaging coil or in an open MRI may be of limited value, because they tend to have low signal to noise artifacts (D and E), resulting in a grainy appearance. For an MRI machine to have sufficient range to scan a whole snake, or even part of a large snake, the distance between the snake and receiver needs to be minimized. The entire length could only be examined if the snake fit the length of the longest coil in an MRI unit, which is the spine coil. These T1-weighted transverse images show nasal passages and mouth (A), more slices of the head show the brain is hypointense (white), and muscles are moderately hyperintense as various shades of gray (B). Sections through the trunk show the vertebrae and ribs as dark foci seen in part by the plane of view; the spinal cord is hyperintense. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

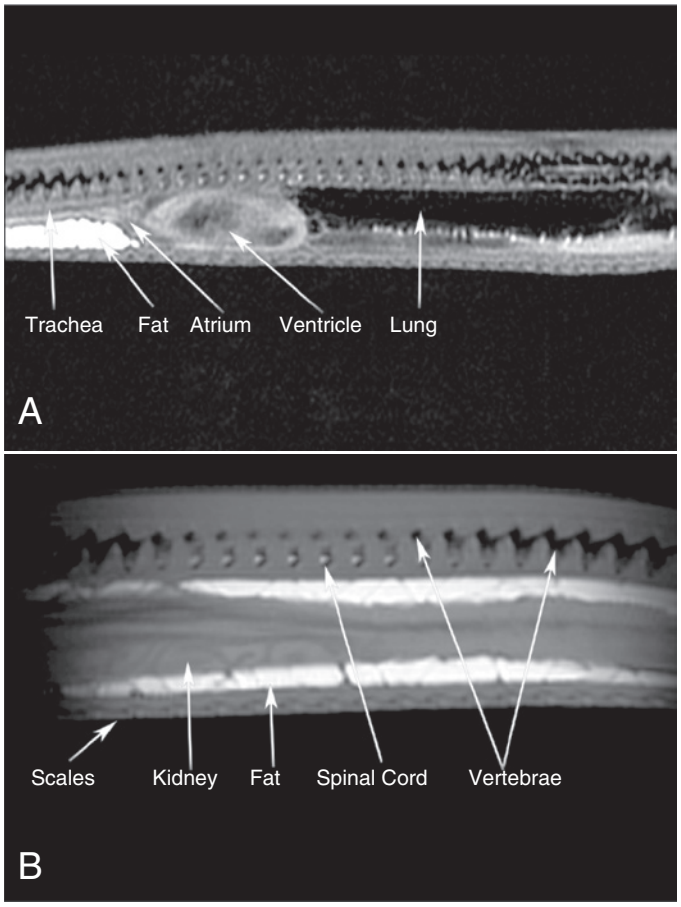

FIG 60.10 Sagittal or parasagittal T1w MR images of an adult male Burmese python (*Python bivittatus*, total length 2.9 m) demonstrating major structures of the cranial (A) and caudal trunk (B). The head is to the left in both images. A large hyperintense fat pad is located cranial to the heart. The heart (moderately hypointense) and lungs (hypointense) have less detail than the (moderately hypointense) lobular kidney tissues. Because the heart beats throughout image acquisition, some movement artifacts are seen in the cranial body. The thyroid and parathyroid glands could not be distinguished from the fat; this may be due to the pulse sequence or image resolution. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

be optimized for extremely small anatomy (Fig. 60.14), such as 1.5-kg ball python with a neurocranium diameter measuring less than 3 cm. The spine can also be examined. Spinal cord compressive lesions can be visualized well with MRI and used in determining feasibility of intervention.[32] We have used MRI to localize and diagnose spinal cord compression in a snake (Fig. 60.15), skink (Fig. 60.16) and monitor lizard (Fig. 60.17). The effect of field strength can be appreciated in this series of figures. The snake was 3 cm in diameter with the vertebral column width of 5 mm and a spinal cord width of 1.7 mm; therefore the 7.0 T MRI unit was needed to obtain high-resolution images in a clinically acceptable time. In contrast, the blue-tongued skink (6 cm in diameter with vertebral column width of 8 mm) was imaged with a 1.5 T MRI unit. If a patient this small is to be successfully imaged on a 1.5 T unit, it is necessary to scan for a longer period of time per pulse sequence to get sufficient signal, and the number of sequences may have to be reduced to those that are most diagnostically useful (i.e., T2w) to avoid prolonged anesthesia. The skink case demonstrates maintenance of the sensitivity of MRI because of superior soft tissue contrast resolution, but the specificity in characterizing the lesion is diminished with poorer image spatial resolution. The monitor lizard, with a neck thickness of 4 cm in diameter and spinal cord 3 mm in diameter, was also scanned on a 1.5 T MRI unit. This examination demonstrates the benefit of using 3D FSE and GRE sequences in patients with small anatomy. For reference, convention sagittal plane 2D FSE sequence obtained a single slice through the spinal cord, whereas the sagittal plane 3D FSE sequence produced 10 slices through the spinal cord at the level of the lesion, and these could be reconstructed into transverse and dorsal plane images after the examination was complete.

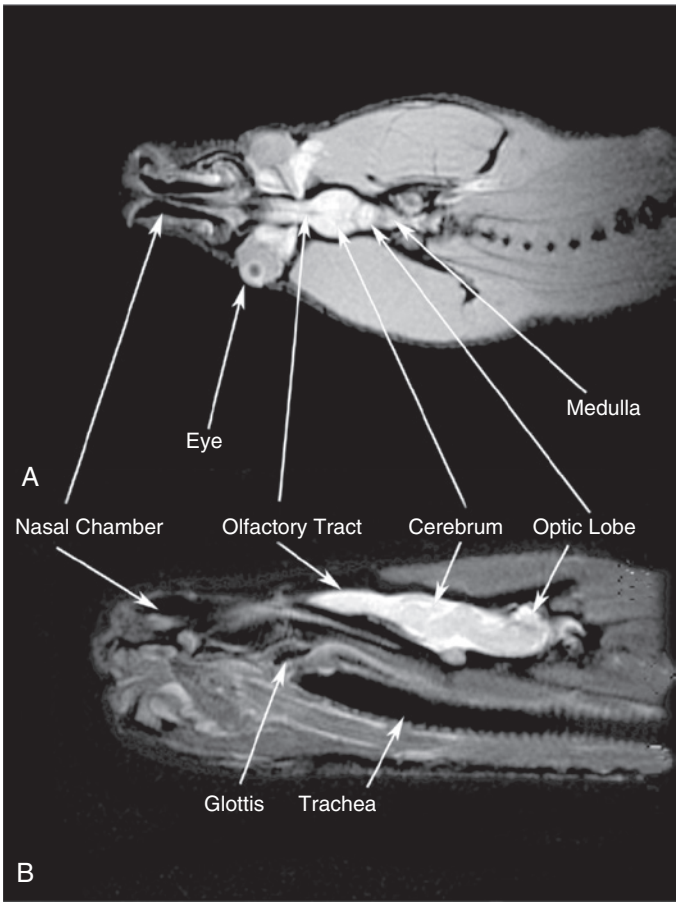

FIG 60.11 Dorsal and sagittal plane T2w MR images of the adult male Burmese python head (*Python bivittatus*, total length 2.9 m). This pair of images shows the major brain anatomy and some of the landmarks associated with the mouth and airway. The two images show the musculature surrounding the brain and calvarial vault (A) and the close proximity of the brain to the primary palate structure (B). (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

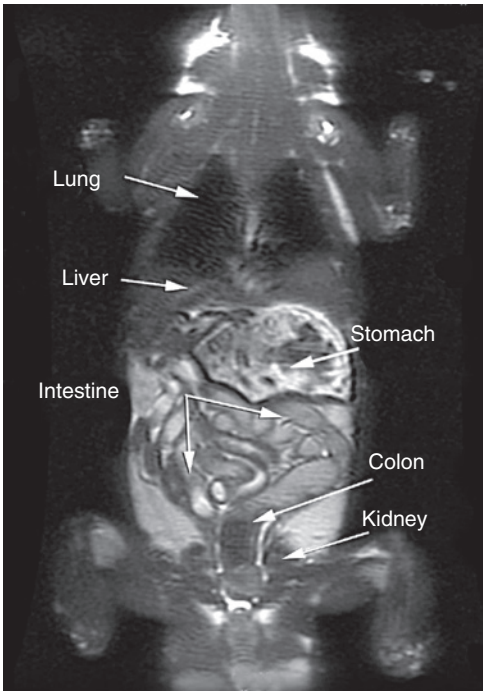

FIG 60.12 This T2w GRE magnetic resonance image (MRI) of a juvenile alligator (*Alligator mississippiensis*, snout-vent length 29 cm) torso is a two-dimensional image. The plane of view is a dorsal section of the ventral one-third of the animal. The gastrointestinal tract and its contents are clearly visible as moderately hypotense shades of gray. Fluids in the coelomic cavity and throat are hypertense. Fat is dark gray, and air in the lungs is hypotense (black). Portions of the kidneys are visible adjacent to the colon. (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

Therefore the lateralization of a lesion can be better defined, and additional planes can be made without extending anesthesia.

Reptiles can more greatly benefit from MRI and its superior soft tissue contrast resolution relative to many other species. Body MRI is more common in humans than in dogs and cats, yet, the number of case reports on body MRI of reptiles show its great value. For example, MRI has been used to diagnose coelomic masses (seminoma in a Greek tortoise, *Testudo graeca*), hepatocellular carcinoma in a green iguana, *Iguana iguana*) and cloacal stricture in a green sea turtle (*Chelonia mydas*).[12,33,34] In the Greek tortoise with a seminoma, the reported benefit of the MRI was localizing the mass within the coelom, discriminating and evaluating adjacent coelomic organs, and using the signal intensity characteristics of the mass to diagnose seminoma as the primary or more specific differential diagnosis. Knotek et al. were able to extrapolate the MR appearance of hepatocellular carcinomas in other species to reach a more specific noninvasive diagnosis in the iguana.[35] In our experience, neurological and coelomic MRI examinations are the most common clinical application in reptiles. This is due to its sensitivity in disease detection of the nervous system similar to that seen in other species and for the ability to provide a better distinction between normal coelomic anatomy (based on signal intensity characteristics) and alterations in coelomic organ signal intensities, which can represent different disease processes. Some examples showing coelomic MRI applications in clinical practice are provided (Figs. 60.17 and 60.18). The benefit of higher field strength with smaller patients is also demonstrated (Fig. 60.19).

Radiographic imaging of the reptile coelom is often challenging due to poor serosal detail. MRI negates this concern in clinical practice. Therefore the major advantage realized to date with MRI in reptiles is the ability to depict anatomical and pathologic processes with great specificity. It does generally require anesthesia and is the most expensive of all diagnostic imaging modalities. These disadvantages can be outweighed by the effective digital antemortem-like examination provided by MRI. Increased usage of MRI in reptile diagnostics is expected, with an increasing accessibility to MR units that are capable of imaging a wide range of reptile sizes and as reptile owners and clinicians gain better knowledge about MRI.

An important final note is that most diagnostic MR imaging studies will benefit from the involvement of a radiologist as well as an MRI technologist. Diagnostic scans are often challenging to obtain, especially in smaller reptiles where acquiring sufficient signal is needed to create diagnostic images. The anatomic variation, in addition to signal intensity variations in tissue, is a further challenge in reptile MR image interpretation that can be partially mitigated by a radiologist with expertise in this area. Lack of MR experience can lead to misinterpretation or the possibility of missing lesions because reference material on the normal

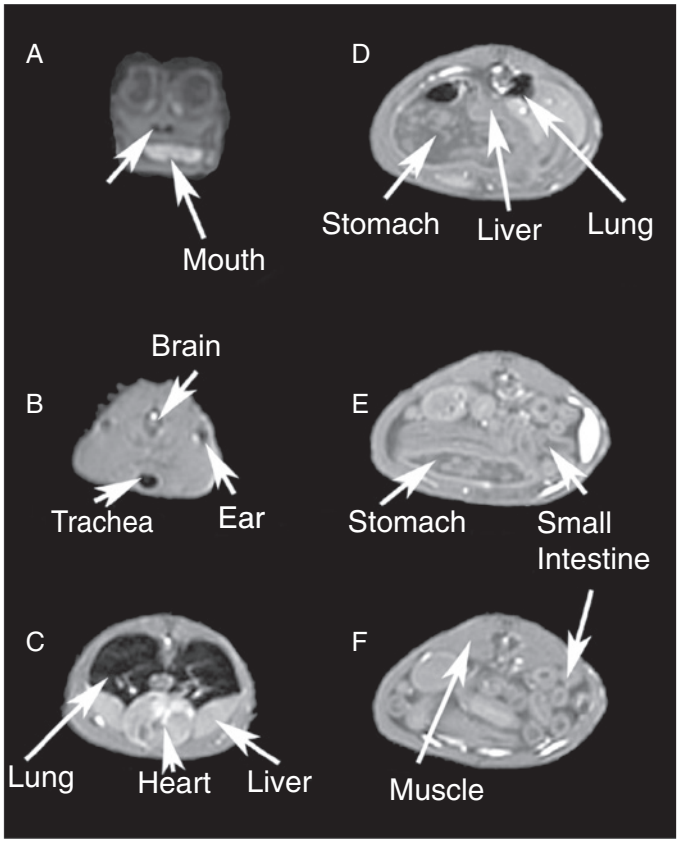

FIG 60.13 These MRI axial sections of a small alligator (*Alligator mississippiensis*, snout-vent length 22 cm) provide a survey of different parts of the animal from the head to the lower abdomen. They were collected using a 1.5 T unit to both deliver and receive signal. This approach provides information but limits the resolution. The eyes appear as light gray ovals with moderately hypointense (dark) gray centers (the vitreous); air in the nares, trachea, and ear cavities is hypointense (black); and the brain is hyperintense with gray surrounding bone (A and B). At the level of the heart (C), great vessels and the pulmonary circulation appear bright; the lungs are hypointense; muscles and liver appear moderately hypointense; and the spinal cord and cerebrospinal fluid (CSF) appear hyperintense. At the midbody, the lung sections are small. The stomach and liver are large, and major vessels including the abdominal veins and aortae can be seen (D). More posteriorly, the remainder of the gastrointestinal tract can be seen, and moderately hypointense (gray) epaxial muscles occupy much of the dorsal body (E and F). (Courtesy of Jeanette Wyneken, Florida Atlantic University.)

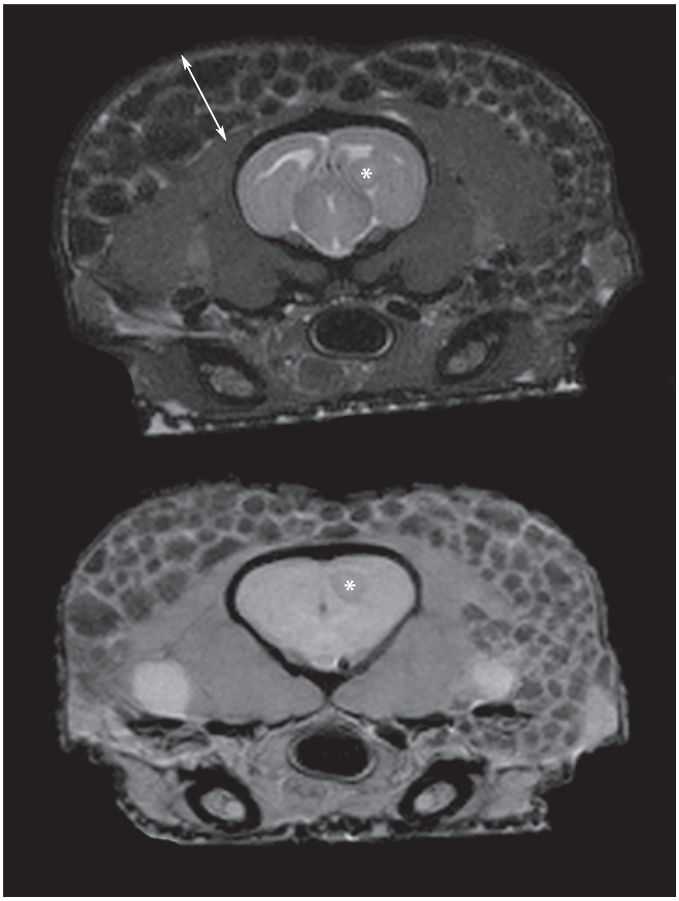

FIG 60.14 Transverse T2-weighted (*top*) and T1-weighted images acquired on a 7.0 T MRI unit of a 13-year-old ball python (*Python regius*, snout-to-vent length 95 cm) presenting with inappetence and facial swelling associated with the right cranium and left maxilla. Extensive distinctly marginated low signal intensity nodules (between arrowheads) are present just deep to the cutaneous layer and superficial to the temporal musculature. No evidence of infiltration into these structures was detected except extension into the deeper anatomical regions, such as into the area of the left maxilla. Because these nodules were hypointense in all imaging series, they were interpreted as consistent of dense tissue that exhibited minimal resonance. This included fibrous, keratinized, or less likely, mineralized foci. Biopsy confirmed extensive keratinized cysts. An intraventricular mass (*) was also identified in the left lateral ventricle. It was considered an incidental finding because there were no associated neurological abnormalities or deficits. For reference the images were acquired with field of view, 5.0 cm; slice thickness, 1 mm; pixel resolution, 0.2 mm^2. (Courtesy of Shannon P. Holmes.)

VetBooks.ir

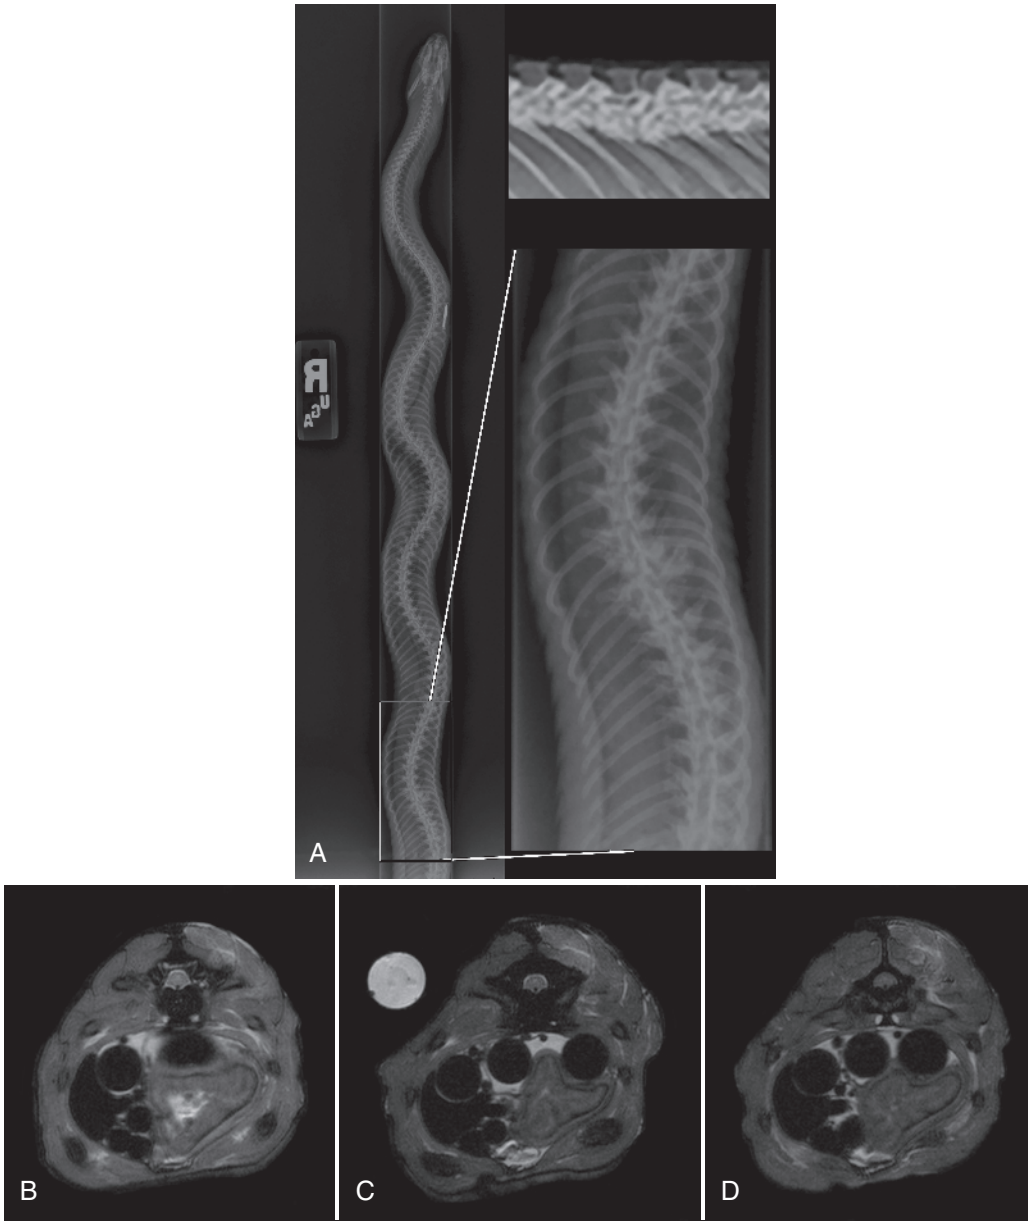

FIG 60.15 Dorsoventral and horizontal beam lateral radiographs (A) and 7.0 T T2-weighted MR images (B–D) of a 4-year-old female Florida king snake (*Lampropeltis getula floridana*, 96 cm total length) presented for evaluation of multiple areas of dull and wrinkled scales, and chronic dysedysis, inappetence, and severe weight loss. The spinous processes were abnormal on physical examination and multiple neurological deficits were exhibited, including flipping dorsally and delayed righting. Multifocal areas of exuberant osseous proliferation were present in association with the vertebral bodies, as well as areas of smooth periosteal proliferation on multiple ribs. Radiography was crucial for planning the areas to examine by MRI, because it is not possible to scan the entire length of the patient (maximum length dictated by the surface coil was 7 cm). The transverse images were acquired in the area seen in the lateral radiography where there was collapse of the interspinous space and mild focal lordosis. In the transverse images centered at this level, (D) there is moderate narrowing of the vertebral canal and mild to moderate dorsoventral spinal cord compression. Muscular asymmetry is also present with the left being swollen and having multifocal areas of hyperintense striations indicative of myositis. The normal appearance of the vertebral canal is seen distant to this lesion (A). There were also areas of canal narrowing that did not have associated spinal cord compression (B). For reference the images were acquired with field of view, 3.5 cm; slice thickness, 1 mm; pixel resolution, 0.1 mm^2. Notice the increase noise caused by decreasing field of view.

VetBooks.ir

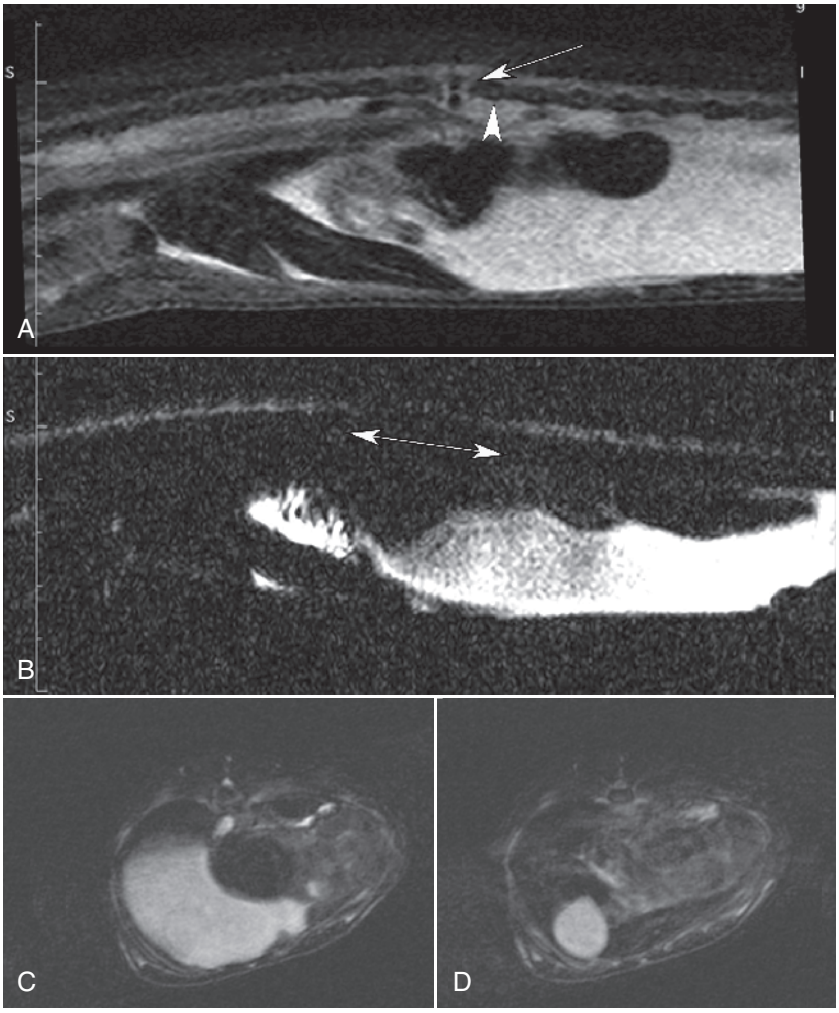

FIG 60.16 Multiplanar MR images of a blue-tongue skink (*Tiliqua scincoides intermedia*) acquired on 1.5 T MRI unit for evaluation of the spinal mass. (A) STIR sagittal, (B) sagittal MR myelogram, (C and D) 3D T2-weighted transverse of a normal vertebra (C), and at the level of the lesion (D). STIR sequences are often used to detect masses and are known for increasing lesion conspicuity. The vertebral mass is seen as an ovoid hyperintense lesion with central hypointensity. Extension in the canal is seen in the STIR images, but the myelogram shows the length of spinal cord change centered around the mass, causing attenuation of the signal from leptomeningial CSF (B). It is extremely difficult to see the spinal lesion in the transverse plane images due to poor resolution. For reference the images were acquired as follows: STIR sagittal series field of view: 14 cm; slice thickness, 1 mm; pixel resolution, 0.5 mm^2; and T2 3d transverse series field of view: 12 cm; slice thickness, 3 mm; pixel resolution, 0.65 mm^2. These images have increased image noise in spite of measures taken to increase the signal, such as increased field of view and slice thickness. The effect of field strength is most likely responsible. Good acquisitions on a 1.5 T are possible in these small patients but require longer scan times to get sufficient signal.

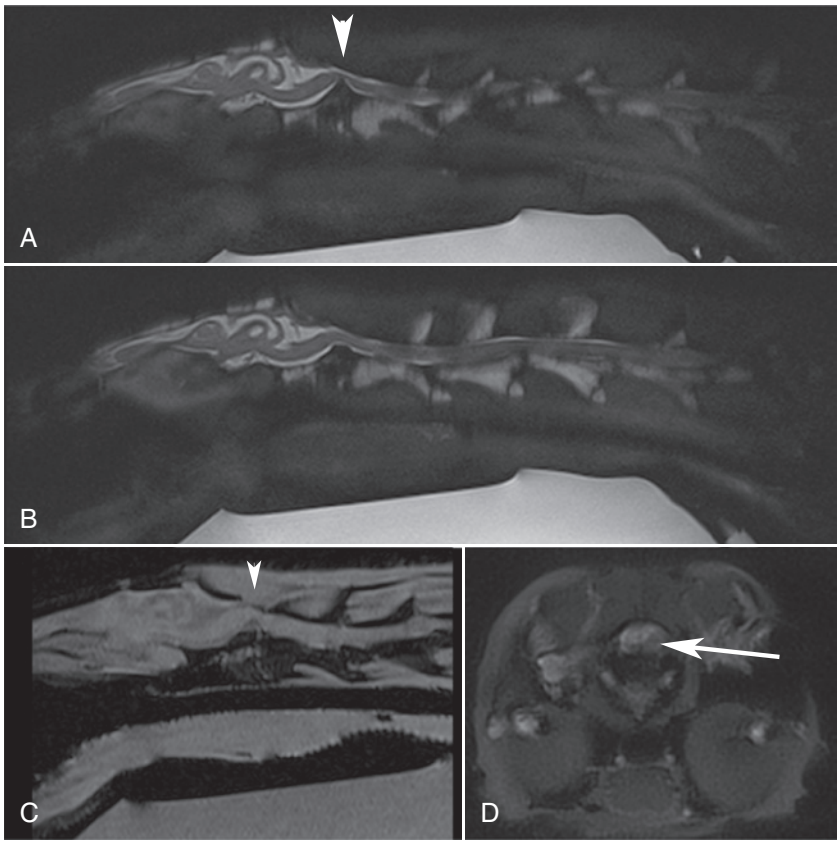

FIG 60.17 Multiplanar MR images of a lace lizard (*Varanus varius*) acquired on a 1.5 T MRI unit evaluated for prehension issue, stargazing, weight loss, and decreased appetite, as well as marked lethargy noted on physical examination. (A and B) 3D T2-weighted sagittal, (C) 3D T1-weighted sagittal, and (D) T2-weighted transverse images. Asymmetrical spinal cord compression is seen at the level of the C1-2 disc. The left half of the spinal cord (arrowhead in A and arrow in D) is compressed in association with disc herniation and/or degenerative proliferation associated with the endplate of the vertebrae. The right portion of the cord (B) is dorsally displaced by the disc and only mildly compressed. The value of 3D fast-spin echo series is demonstrated in small patients such as this; the slice thickness of 0.5 mm better resolves the tiny spinal cord in multiple slices (contrast to STIR sagittal in Fig. 60.16A). T1-weighted images (C) are excellent for evaluation of the osseous anatomy; the compressive material is less hypointense than the vertebrae, indicating greater fibrous content and/or heterogeneous mineralization. For reference and comparison to Fig. 60.17 (arrowheads in A and C), the 2D T2 transverse series field of view, 10 cm; slice thickness, 2.0 mm; pixel resolution, 0.4 mm^2, with an acquisition time of 6.5 minutes.

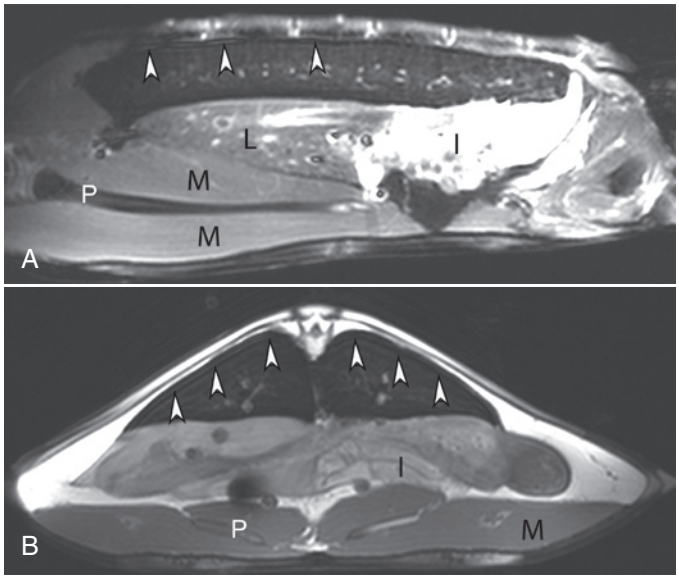

FIG 60.18 STIR sagittal (A) and T2-weighted transverse (B) images acquired on a 1.5 T MRI unit of a 6- to 8-year-old green sea turtle (*Chelonia mydas*) evaluated for persistent buoyancy issues. A thin rim of coelomic gas (*arrowheads*) is seen dorsal to the lungs and conforming to the carapace. The area is uniform and more hypointense than the lung parenchyma. The appearance of the lung parenchyma is a combination of the aerated regions with interstitium and vasculature. An artifact called chemical shift actually aids in visualization through the appearance of a surrounding hypointense rim. The liver (L), muscle (M) surrounding the procoracoid (P), and fluid-filled intestines (I) are distinguished based on appearance of parenchymal architecture and more unique on MRI because different types of soft tissues have different signal intensity. This differs from CT imaging where effacing soft tissues are less distinguishable. The compaction of these structures together is also seen in the transverse image (B), which visually demonstrates the cause of poor serosal detail noted in this area on radiographs.

VetBooks.ir

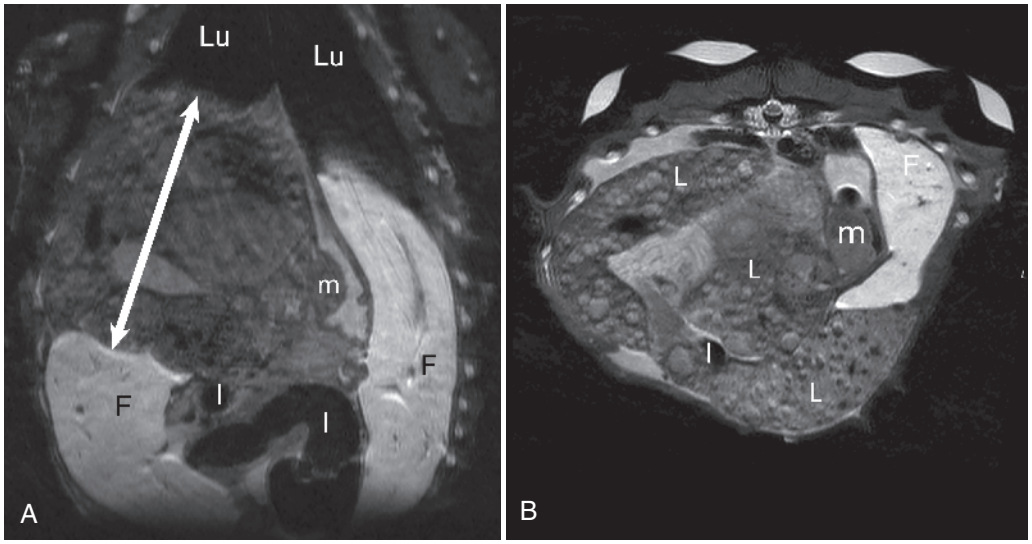

FIG 60.19 T2-weighted dorsal (A) and transverse (B) images of a bearded dragon (*Pogona vitticeps*) acquired on a 7.0 T MRI unit. The 3-year-old lizard presented with a 2-month history of anorexia, weight loss, and severe hyperglycemia. Radiographs were initially performed (see Fig. 54.14), and a soft tissue mass effect was present in the area of the liver. MRI was performed to better distinguish organ involvement and extent of disease in the coelom. Extensive nodular infiltrate was seen throughout the liver (L). The liver mass was extensive (double-headed arrow) and infiltrated into the area of the pancreas such that the pancreatic tissue was indistinguishable. A discrete mural mass (m) was also present in the medial wall of the stomach and is encircled by hyperintense fluid within the lumen (seen to right and dorsal of mass in A and B respectively). The fat pad (F) and intestine (I) are markedly caudally displaced in association with the mass effect. No soft tissue nodules were seen in the lungs (Lu), though small nodules were detected on gross evaluation of the lungs. Histopathologic diagnosis was a metastatic neuroendocrine carcinoma.

appearance is infrequently available in each species. With the availability of teleradiology services, the ability to involve a radiologist is easily accessible and recommended in both the planning of the MRI examination and in the interpretation.

ACKNOWLEDGMENTS

The authors thank Fred Steinberg, MD, Medical Director, University MRI, Boca Raton, for providing access to his high-resolution fMRI equipment and software. Gina Boykin, Andrew Kaufman, and Steve Rubel collected the images at UMRI Boca Raton. Dale Wilke (OMI of Jupiter) collected most of the turtle images presented here. Khan Hekmatyar, PhD, University of Georgia & 7.0 T MRI manager Bio-Imaging Research Center (BIRC), provided expertise and patiently operated the 7.0 T MR for our clinical reptile cases Animal Scan provided images of reptiles from their clinical MRI database. With special thinks to Stephen Divers, University of Georgia, who promotes the use of MRI for reptiles and provided cases to a veterinary radiologist with a special interest in MRI. The authors are grateful to these talented individuals for fine assistance and willingness to work with reptiles.

Scintigraphy

Mauricio Solano

Scintigraphy is a well-established imaging technique in which a pharmaceutical is tagged with a radioactive tracer, usually a gamma emitter, to obtain an image of an organ. To image the kidneys,[1] diethylenetriamine pentaacetic acid (DTPA) tagged with a gamma ray emitter known as technetium pertechnetate (^{99m}Tc) is used. Macro-aggregated albumin (MAA) is tagged with ^{99m}Tc to image the lungs,[2] and in skeletal scintigraphy, hydroxymethylene-diphosphonate (HDP) is tagged with ^{99m}Tc to obtain an image of the bones.[3] The gamma rays emitted by these radiopharmaceuticals are detected by a large scintillation crystal within the gamma camera. The crystal converts the gamma rays into light photons, which in turn are converted into a cascade of electrons. The stream of electrons is then used to form the image.[4]

SKELETAL SCINTIGRAPHY

A skeletal scintigram consists of three distinct phases designed to detect a radiopharmaceutical in the vasculature, soft tissues, and the bone matrix.[5] Skeletal scintigraphy is a commonly performed imaging technique for the diagnosis of bone diseases in veterinary medicine. While its primary use has been in equine orthopedics[6–8] and, to a lesser extent, in dogs[9–11]and cats,[12–14] little has been reported in reptiles. This chapter focuses on skeletal scintigraphy in Kemp's ridley sea turtles (*Lepidochelys kempii*). However, the information contained in this chapter can be applied to other reptile species. In turtles, skeletal scintigraphy has been used to stage osteomyelitis in an Aldalabra tortoise (*Aldabrachelys gigantea*),[15] Russian tortoise (*Agrionemys horsfieldii*; Hernandez-Divers et al, Proc ARAV, 2002, pp 103–104), and as an adjunct to radiography in cases of cold-stunned Kemp's ridley sea turtles.[16]

SCINTIGRAPHIC TECHNIQUES

Chemical restraint is usually required for all phases of the examination. However, it may not be necessary with cooperative animals. At the author's institution, propofol (Butler Healthcare Co., Irvine, CA) at 5 mg/kg IV, or a combination of medetomidine (Domitor, Pfizer, Exton, PA) 30 µg/kg IV and ketamine (Ketaset, Fort Dodge, Fort Dodge, IA) 3 mg/kg IV, are the standard protocols.

Images shown in this chapter were acquired using a 55 photomultiplier tube, rectangular large field-of-view planar gamma camera system (IS2 Medical Systems Inc. Ottawa, Canada) mounted on a mechanical gantry interfaced with a dedicated computer system (Segami Corporation, Columbia, MD) for image postprocessing. The patient is placed in ventral recumbency (Fig. 61.1) with the camera positioned underneath; 111 to 370 MBq of ^{99m}Tc-HDP is injected intravenously into the left or right dorsal cervical sinus (external jugular vein). The vascular phase is started at the time of injection in dynamic mode with 1-second-long frames, up to a total of 125 frames. The soft tissue phase can be performed in dynamic acquisition or static modes. For the dynamic mode, 60 seconds per frame for 8 frames are acquired, while in static acquisition mode images between 500,000 to 800,000 counts per image can be taken. For the bone phase of the scans, static images of 500,000 counts each are acquired 3 hours after radiopharmaceutical injection. After imaging, turtles are considered radioactive and remain in quarantine for a period of 24 hours until radioactive levels measure less than 2mR per hour at contact, typically after urination.

CASE 1

A 2.34 kg, juvenile, cold-stunned Kemp's ridley sea turtle (*Lepidochelys kempii*) was rescued off the coast of Massachusetts in late autumn. During the rehabilitation process, the turtle developed a fungal (*Penicillium* sp) infection with associated superficial perivascular lymphocytic-plasmacytic inflammation in the area of the left shoulder and neck with lameness and swelling of the elbows. Radiographs were taken at several intervals after the onset of clinical signs (Fig. 61.2). Due to the persistent lucencies noted between serial radiographs, skeletal scintigrams were performed at 7 and 9 months after the onset of clinical signs (see Fig. 61.2).

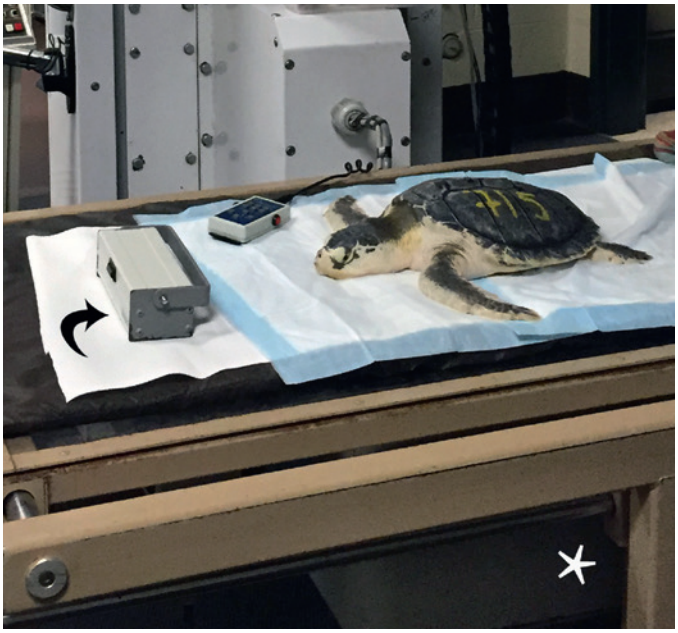

FIG 61.1 Image acquisition. The camera (*) is positioned below and as close as possible to the patient. Only a thin fiberglass tabletop and mat separates the camera from the patient. The radiopharmaceutical is placed in a syringe and is maintained inside a lead container (curved arrow) until delivered by intravenous injection. (Courtesy of Mauricio Solano.)

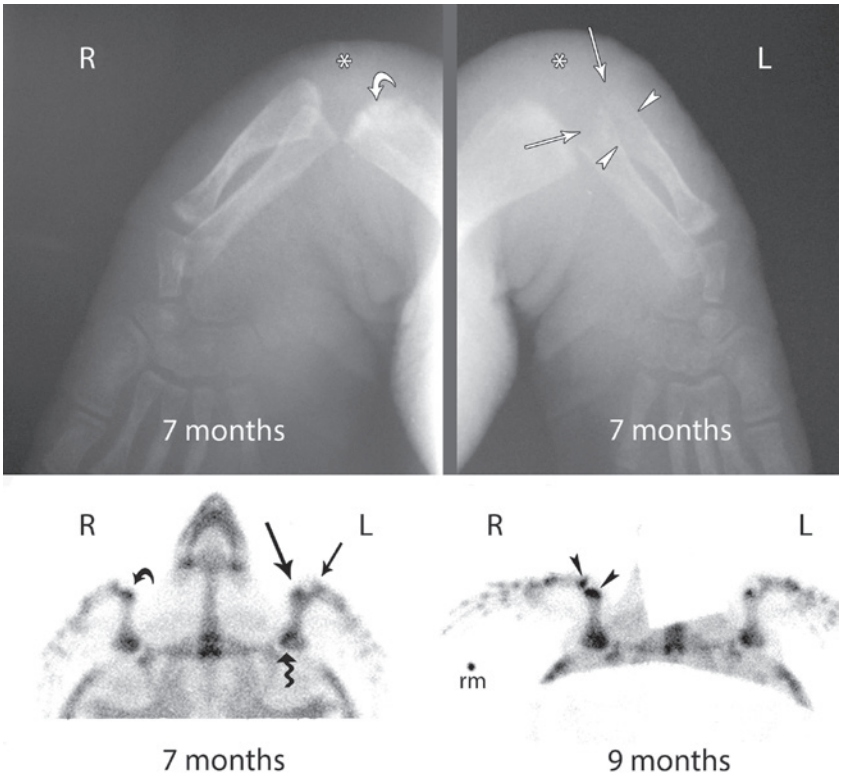

FIG 61.2 Dorsoventral radiographs and bone phase scintigrams performed 7 and 9 months into the rehabilitation process of a Kemp's ridley sea turtle (*Lepidochelys kempii*). The radioactive marker (rm) indicates the right flipper. There is bilateral soft-tissue swelling surrounding the elbow joints (*). Severe lysis of the proximal left radius and ulna (white arrows) is noted. The radial head and articular surface of the ulna are no longer present. Thinning of the proximal radial and ulnar cortices proximally (white arrowheads) and bilateral sclerosis of the distal end of the humeri is present. Sclerosis is more severe in the right humerus (curved white arrow). At 7 months, there is an ill-defined mild increase in radiopharmaceutical uptake associated with the proximal left radius and ulna (small black arrow) and moderate uptake in the distal left humerus (large black arrow). The right elbow uptake (curved black arrow) was initially deemed questionable as it did not appear to be as intense as the normal uptake of other long bones (wavy arrow). However, at 9 months, a more intense radiopharmaceutical uptake in the right humerus and radius was noted (black arrowheads), indicating that the right elbow lesion was already established at 7 months. Unchanged radiopharmaceutical uptake in the proximal left radius and ulna, and a persistent more localized uptake in the distal left humerus, were also noted at 9 months. (Courtesy of Mauricio Solano.)

Nuclear imaging studies taken at 7 months indicated the right-sided elbow lesion was at its early stages of development. At 9 months, the left elbow lesions were at the late stage of healing, somewhat quiescent, while the right-sided lesions were actively undergoing bone remodeling. The dynamic nature of the bone reaction was noticeable with the scintigrams but not with serial radiographs. While radiographically the left elbow lesion appeared more severe, it was the right elbow that showed a higher rate of bone changes and hence was more severe than the left elbow.

CASE 2

A captive 6-year-old Kemp's ridley sea turtle developed a slowly progressive soft tissue swelling along the right caudal aspect of the neck and bilateral decrease range of motion in the forelimbs. A CT exam confirmed the presence of large cranial coelomic masses in addition to loss of bone mass (Fig. 61.3). Ultrasonography through the left and right cervicobrachial areas revealed large fluid-filled space occupying lesions. *Mycobacterium chelonae* was confirmed following ultrasound-guided sampling. To further assess the affected bones a skeletal scintigram was also acquired (Fig. 61.4).

While initially not intended to be useful to assess the effects of these soft tissue masses on surrounding structures, the soft tissue phase of the scintigram revealed these large masses were extensive and were causing a left-sided displacement of the heart. The lesions were void of radiopharmaceutical uptake (photopenic), which indicated lack of blood supply consistent with the presence of necrotic tissue. There was no abnormal radiopharmaceutical uptake in the right humerus or the bones of the pectoral girdle, indicating the remaining bone was no longer actively responding to the large soft-tissue inflammatory reaction. This suggested the lesion was more chronic than originally expected. On the other hand, active bone remodeling was detected in the bones of the left shoulder joint.

The main advantage of skeletal scintigraphy over radiographs is the ability to detect bone lesions before they are apparent in radiographs.[10] The appearance of the scintigram is largely dependent on a patent vascular supply and the increased osteoclastic and osteoblastic activity of the bone.[3,17] In the management of cold stunned sea turtles, radiographic changes may lag behind the insult by several weeks, and once radiographic changes develop, they may persist for months in spite of resolution of the clinical signs.[16] Skeletal scintigraphy can be used in combination with radiographs to determine if animals can be released

VetBooks.ir

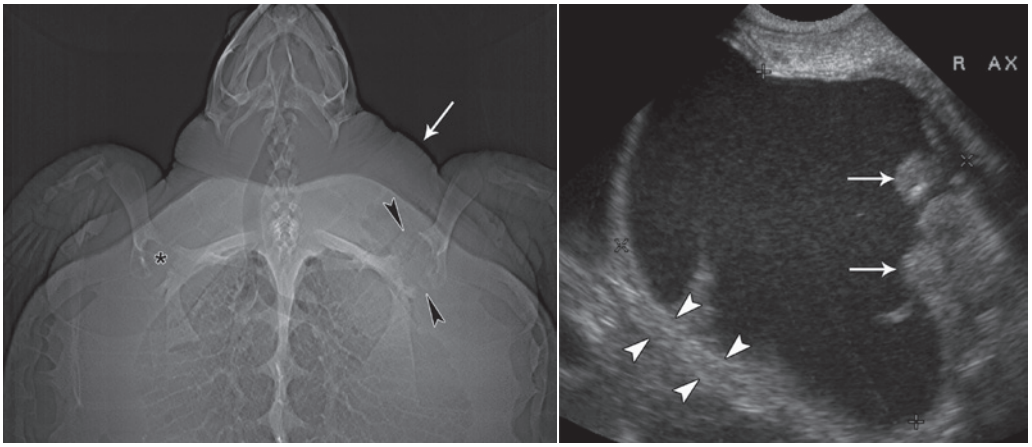

FIG 61.3 Dorsal CT scout projection and parasagittal ultrasound image of case 2 Kemp's ridley sea turtle (*Lepidochelys kempii*). Severe loss of bone mass is noted in the left and right shoulders. The right shoulder joint space (arrowheads) is obviously widened. The humeral head is no longer present, and the articular surfaces of the coracoid and scapula are irregular. A less-severe degree of loss of bone mass is also noted in the left shoulder (*). Soft-tissue swelling of the right cervicobrachial area is present (arrow). The ultrasound image depicts a large, fluid-filled mass in the right cervicobrachial area. The mass exhibits a thick wall (arrowheads), which in some areas is irregular and heterogeneous in echogenicity (*arrows*). The lesion is filled with homogenously echogenic contents. (Courtesy of Mauricio Solano.)

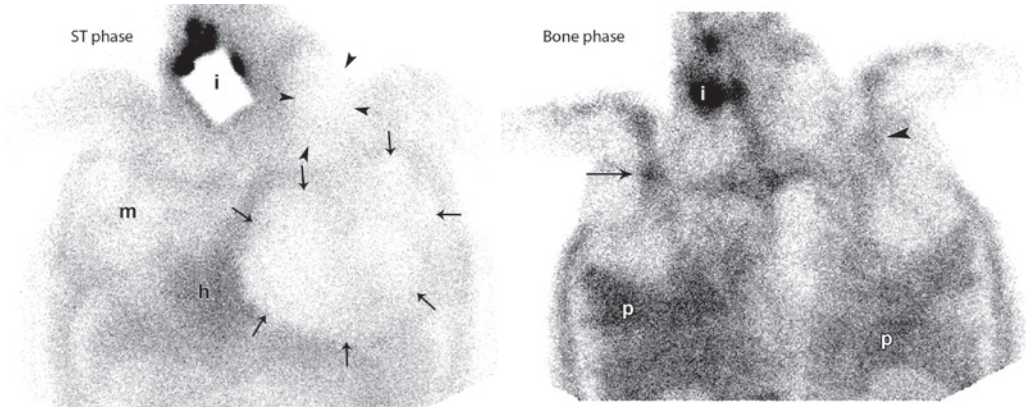

FIG 61.4 Soft tissue (left) and bone phase (right) scintigrams of case 2, Kemp's ridley sea turtle (*Lepidochelys kempii*). The rectangular photopenic area (i) represents a small lead shield that partially covers radiopharmaceutical activity at the injection site. In the left image, three large photopenic lesions are detected. The larger mass (arrows) displaces the heart (h) to the left of the midline. The smaller lesion (arrowheads) is the fluid-filled mass depicted in Fig. 61.3. The third mass (m) associated with the left shoulder is poorly defined but remains photopenic. In the bone phase of the scan (right image), the injection site (i) is no longer covered by the lead shield and indicates some perivascular leakage. A mild degree of poorly defined abnormal uptake is noted in the left shoulder (arrow). No abnormal uptake is present in the right shoulder area (arrowhead). The larger areas of diffuse bilateral moderate uptake caudally (p) represent the pattern of the plastron medial to the marginal scutes. (Courtesy of Mauricio Solano.)

in spite of the presence of radiographic lytic lesions. Other applications of skeletal scintigraphy in reptiles include cases of trauma to assess healing and viability of bone fragments. However, skeletal scintigraphy should not be used to assess fine anatomic detail, as the images are inherently of low resolution. Nuclear medicine offers an insight into the pathophysiology of bone that cannot be obtained by radiography or CT.

RENAL SCINTIGRAPHY

In an experimental study involving green iguanas (*Iguana iguana*),[18] the intravenous administration of ^{99m}TC-DTPA was followed by scan acquisition over a 20-hour period. However, scintigraphy was considered nondiagnostic for renal function because of serum protein binding and poor renal uptake of the isotope. Renal uptake and soft tissue clearance of ^{99m}TC-DTPA was 11.31 ± 3.06% at 20 hours. Nevertheless, renal uptake did produce distinct visualization of both kidneys. The percentage of radiopharmaceutical uptake in the kidneys has also been studied using different routes of administration in 16 iguanas. The route of administration did not change the dose accumulated in the kidneys.[19]

Diagnostic and Surgical Endoscopy Equipment

Stephen J. Divers

Despite the advances in flexible endoscopy equipment, rigid endoscopy still maintains a central role in reptile diagnostics largely because of its ability to gain access to areas of interest in most, including the smallest, reptiles. However, given variation in reptile size, species-specific anatomy, and a variety of procedures (including endosurgery and endoscope-assisted surgery) that may be performed, a selection of different endoscopes and instruments is recommended. This can be specifically tailored to suit individual practice needs (Table 62.1).[1,2] All rigid endoscopy equipment used by the author was supplied by Karl Storz Veterinary Endoscopy America, Inc. (Goleta, CA), and purchased by, not donated to, the Veterinary Teaching Hospital. Other manufacturers exist that can likely supply similar equipment.

TABLE 62.1 Diagnostic and Endosurgical Endoscopy Equipment

Equipment Description	Primary Indications
Visualization and Documentation	
Endovideo camera and monitor	Required for all endoscopy procedures
Xenon light source and light guide cable	
Digital capture device (e.g., AIDA-DVD)	
Rigid Telescopes and Endoscopes	
1 mm x 20 cm semirigid miniscope, 0°	Stomatoscopy, otoscopy, rhinoscopy, tracheoscopy in animals up to 500 g
1.9 mm x 18.5 cm telescope, 30° oblique, with integrated 3.3 mm operating sheath	Stomatoscopy, otoscopy, rhinoscopy, tracheoscopy, gastroscopy, colonoscopy, cloacoscopy, and coelioscopy in animals up to 2–3 kg
2.7 mm x 18 cm telescope, 30° oblique, with 4.8 mm operating sheath	Stomatoscopy, otoscopy, rhinoscopy, tracheoscopy, gastroscopy, colonoscopy, cloacoscopy, and coelioscopy in animals between 100 g and 20 kg
3 mm x 14 cm telescope, 0°	Coelioscopy of animals over 20 kg
5 mm x 29 cm telescope, 0°, with 6 mm x 6.5 cm Ternamian EndoTip cannula	Coelioscopy of animals, especially chelonians, over 20 kg
5 mm x 29 cm telescope, 30° oblique, with 6 mm x 6.5 cm Ternamian EndoTip cannula	Stomatoscopy and otoscopy in animals between under 50 kg
5 mm x 8.5 cm otoendoscope, 0°, with integrated operating sheath	
Flexible Instruments for Use With Rigid Telescopes and Operating Sheaths	
1 mm biopsy forceps	For use with 1.9 mm telescope and integrated sheath
1 mm grasping forceps	
1.7 mm biopsy forceps	For use with 2.7 mm telescope and 4.8 mm operating sheath
1.7 mm single-action scissors	
1.7 mm remote injection needle	
1.7 mm grasping/retrieval forceps	
1.7 mm wire basket retrieval	
1.7 mm needle end radiosurgery electrode	
1.7 mm polypectomy snare

TABLE 62.1 Diagnostic and Endosurgical Endoscopy Equipment—cont'd

Equipment Description	Primary Indications
Insufflation	
Dedicated CO_2 insufflator, capable of insufflation pressures as low as 3 mm Hg and flow rates as low as 0.1 L/min; CO_2 compressed gas with regulator; silicone supply tubing to endoscopy equipment	Used for insufflation during reptile coelioscopy
Sterile saline suspended above endoscopy table with intravenous drip line to a port on the operating sheath	Used for sterile saline infusion for cystoscopy, cloacoscopy, coelioscopy
Flexible Endoscopes	
Fiberscope, 2.5 mm x 100 cm working length, 1.2 mm instrument channel, 2-way tip deflection	Respiratory and gastrointestinal evaluations
Video bronchoscope, 5.9 mm x 61 cm working length, 2.2 mm instrument channel, 4-way tip deflection, suction, and irrigation	Respiratory and gastrointestinal evaluations
Video gastroscope, 9 mm x 140 cm working length, 2.2 mm working channel, 4-way tip deflection, suction, insufflation, and irrigation	Gastrointestinal evaluations in large reptiles
Instruments for Use With Flexible Endoscopes	
Grasping forceps, 1 mm x 120 cm Biopsy forceps, 1 mm x 120 cm	For 2.5 mm fiberscope
Biopsy forceps, round cupped jaws, diameter 1.7 mm, working length 120 cm Grasping forceps, alligator jaws, 1.7 mm x 120 cm	For 5.9 mm video bronchoscope
Biopsy forceps, round cupped jaws, diameter 1.8 mm, working length 180 cm Grasping forceps, alligator jaws, 1.8 mm x 180 cm	For 9.0 mm video gastroscope
Endosurgical Instrument Handles	
2 plastic handles without rachets 1 plastic handle with Mahnes-style rachet 1 plastic handle with hemostat-style rachet	These ClickLine handles are interchangeable and can be used with most instruments from 2 mm to 5 mm
Cannulae, Trocars, and Endosurgical Instruments	
3.9 mm graphite and plastic cannula and trocar, with silicone leaflet valve and luer-lock insufflation port	Accommodates 2.7 mm telescope and 3.5 mm protection sheath
2.5 mm x 4 cm, graphite and plastic threaded cannula and trocar, with silicone leaflet valve, and luer-lock insufflation port (for 2 mm instruments, typically two required) 2 mm Reddick-Olsen dissecting forceps 2 mm Metzenbaum scissors 2 mm Babcock forceps	For endosurgery in animals 0.1–5 kg Instruments are all 20 cm in length
3.5 mm graphite and plastic threaded cannula and trocar, with silicone leaflet valve, and luer-lock insufflation port (for 3 mm instruments and 3 mm telescope, typically 2 required) 3 mm fenestrated grasping forceps 3 mm Reddick-Olsen dissecting and grasping forceps 3 mm short curved Kelly dissecting and grasping forceps 3 mm atraumatic dissecting and grasping forceps 3 mm Babcock forceps 3 mm Blakesley dissecting and biopsy forceps 3 mm scissors with serrated curved double action jaws 3 mm micro-hook scissors, single-action jaws 3 mm Mahnes bipolar coagulation forceps 3 mm irrigation and suction cannula 3 mm palpation probe with cm markings 3 mm distendable palpation probe 3 mm ultramicro needle holder 3 mm knot tier for extracorporeal suturing	For endosurgery in animals 0.5–10 kg Instruments are all 20 cm in length

VetBooks.ir

TABLE 62.1 Diagnostic and Endosurgical Endoscopy Equipment—cont'd

Equipment Description	Primary Indications
6 mm x 5.5 mm Ternamian EndoTip cannula, with silicone leaflet valve and insufflation stopcock (for 5 mm instruments, typically two required)	For endosurgery in animals 10–100 kg Instruments can be 36 cm or 43 cm in length
5 mm biopsy forceps	
5 mm Blakesley dissecting forceps	
5 mm curved Kelly dissecting & grasping forceps	
5 mm Babcock grasping forceps	
5 mm curved Metzenbaum scissors	
5 mm suction and irrigation cannula	
5 mm needle holders	
5 mm hook scissors	
5 mm bipolar forceps	
Hemostasis Equipment	
Ellman 3.8 or 4.0 MHz dual radiofrequency unit with foot pedal	Enables many endoscopic instruments to be used as monopolar devices and facilitates bipolar coagulation using bipolar forceps. A wide variety of 2 mm, 3 mm, and 5 mm instruments available
Monopolar lead to connect to plastic instrument handles	
Bipolar lead to connect to 3 mm Mahnes bipolar coagulation forceps	
LigaSure Force-Triad energy platform with foot pedal	Only available in 5 mm or 10 mm instrument sizes, but a useful instrument that combines sealing and cutting. The instruments are disposable human items but most veterinarians clean and reuse
5 mm x 37 cm LigaSure laparoscopic instrument

DIAGNOSTIC ENDOSCOPY EQUIPMENT

Telescopes and Sheaths

The 2.7-mm telescope system, first championed by Michael Taylor for avian species, still remains the workhorse in exotic animal practice because of its versatility and ability to be expanded as individual practice caseload dictates.[3–5] The 2.7-mm Hopkins telescope can be used with a 3.5-mm protection sheath or with a 4.8-mm operating sheath that possesses ports for gas or fluid infusion and an operating channel for the introduction of 1.7-mm (5Fr) instruments (Fig. 62.1). A smaller 1.9-mm telescope with an integrated sheath (3.2-mm) that can accommodate introduction of 1 mm (3Fr) instruments and a 1.0-mm semi-rigid (fiberoptic) miniature straight endoscope are particularly useful for smaller species (Fig. 62.2), while 4-mm, 5-mm, and even 10-mm telescopes can be used with large-to-giant reptiles.

Flexible Endoscopes

There are two main classifications of flexible endoscope; the fiberscope (which transmits the image via a bundle of fiberoptic fibers) and the video-endoscope (which transmits the image electronically from a charge-coupled device [CCD] stationed at the distal tip). Fiberscopes are less expensive and are available in smaller diameters but suffer from pixelation and poorer image quality compared to video-endoscopes (Fig. 62.3). Video-endoscopes have tended to be larger in diameter

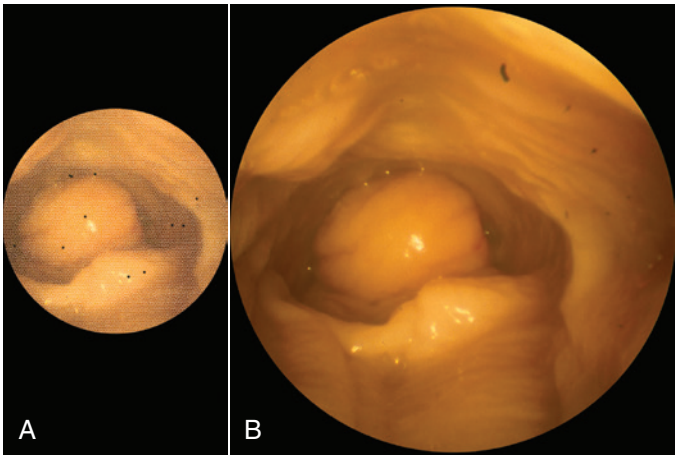

FIG 62.3 Relative comparison in endoscopic views of a snake's stomach using a 2.5-mm fiberscope (A) and 5.9-mm videobronchoscope (B). Note the smaller image, increased pixelation, and black dots (broken fibers) associated with the fiberscope. (Courtesy of Stephen J. Divers.)

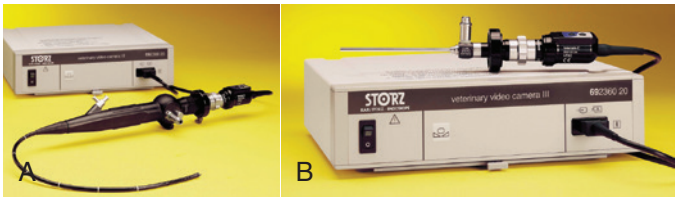

FIG 62.4 Both flexible (A) and rigid (B) endoscopes can now be connected to the same camera system and light source, thereby reducing and refining equipment requirements. (Courtesy of KARL STORZ GmbH & Co. KG.)

because of the need to accommodate the terminal CCD chip, and their initial purchase costs have been considerably higher. Furthermore, until relatively recently, flexible and rigid endoscopy light sources and cameras were generally incompatible, which necessitated separate rigid and flexible tower systems. This undoubtedly forced practitioners to make a choice for one or the other. Fortunately, the advent of modern cameras and light sources now enables practitioners to invest in just one endoscopy tower that can be used with both rigid and flexible endoscopes (Fig. 62.4). Consequently, the ability to offer both flexible and rigid services has substantially increased in practice.

Flexible endoscopes vary from 14 mm to less than 1 mm in diameter, and those greater than 2 mm often offer tip deflection and possess a working channel (for instruments). Larger flexible scopes greater than about 6 to 8 mm often have four-way tip deflection, working channels as well as air insufflation and suction (Fig. 62.5). Current commercial video-endoscopes are limited to around 2.5 mm with a 1.2-mm instrument channel (although technology now exists to produce a <1-mm video camera). Therefore smaller fiberscopes (0.5 to 2.5 mm and considerably cheaper) still have a role in small reptile flexible endoscopy, although they often have just one- or two-way tip deflection and smaller working channels (Fig. 62.6).

Light Sources

The telescope is connected via a fiber-optic light guide cable to a light source (Fig. 62.7). While halogen light sources are far cheaper and effective for small animals <2 kg, xenon light sources provide better quality light and an intensity that can illuminate the body cavities of larger animals. The LED light source of the mobile Karl Storz Telepak Vet X has an

FIG 62.5 A 9 mm x 140 cm video-gastroscope with 2.2-mm working channel attached to a xenon light source and endovideo camera. (*Inset*) Handling technique that permits the endoscopists to control four-way tip deflection using their thumb, while their first finger operates the 2 buttons that control air insufflation, suction, and fluid irrigation. FIG 62.8 (A) Rigid endoscopy tower with xenon light source (1), endovideo camera base unit (2), DVD digital capture device (3), and monitor display (4). (B) Operating room layout demonstrating the preferred ergonomics and positioning for a right-handed surgeon performing chelonian coelioscopy. Note how the surgeon is facing the monitor with endoscopy instruments within easy reach on the right side. (A, Courtesy of Stephen J. Divers; B, courtesy of Educational Resources, University of Georgia.)

extended life expectancy of up to 30,000 hours, and these mobile units have been used to perform coelioscopy in giant tortoises up to 100 kg.

Cameras

An endovideo camera connected to the eyepiece of the telescope, although once considered a luxury addition, is an integral part of the endoscopy system and greatly facilitates the surgeon's performance (see Fig. 62.4; Fig. 62.8A). Cameras, available in both European PAL and American NTSC formats, can vary dramatically in cost from budget single-chip cameras to three-chip digital high-definition models. The traditional video system provided a resolution of 720 × 480, and therefore inevitably led to some cropping of the image for display on a traditional 4:3 aspect monitor. The advent of HD (high-definition) systems has increased the video size to 1920 × 1080 pixels. In addition, the new 16:9 aspect ratio provides a 33% wider field of view while progressive (as opposed to interlaced) scan produces improved resolution, color clarity, and refresh rates. Additional camera advances including 4k high-resolution, 3D, light filters, fluorescence imaging, and chromoendoscopy are already available, and, although typically outside of the veterinary hospital budget, secondhand equipment may make these items a practical option for some hospitals. The fact remains that any camera will greatly improve performance compared to using the eyepiece and will also facilitate photodocumentation. Operating room setup is important, and the monitor should be positioned directly in front of the endoscopist, with instruments within easy reach (see Fig. 62.8B).

Photodocumentation

The ability to record stills and videos of procedures is becoming increasingly important for maintaining accurate medical records, as well as

FIG 62.9 (A) Documentation devices such as this AIDA™ with SMART-SCREEN® can record still images and videos, including DICOM-compatible formats, and upload them to a previously defined network location or export them to a USB stick, CD, or DVD (B) Close-up of the interactive display. (Courtesy of KARL STORZ GmbH & Co. KG.)

for generating pictures for brochures, presentations, or scientific publications. Most camera systems generate s-video or digital outputs that can be connected to myriad nonprofessional, commercial recording devices (e.g., laptops, DVD recorders) that can ultimately save material in various formats to digital media. Professional-grade devices, although more expensive, provide dedicated functions that are important in medicine (Fig. 62.9). For example, most professional endoscopy recording devices will support still images (tiff, bmp, jpeg) and video (SD and HD) with audio voice-over (WAV). Modern systems can also provide network and web-based storage and file sharing, including industry-standard DICOM (digital imaging and communications in medicine) support.

Mobile Units

The Tele Pack Vet X system (Karl Storz Veterinary Endoscopy) combines an LED light source, endovideo camera, 38 cm (15″) color liquid crystal display (LCD) with digital image and video capture onto SD memory cards or USB drives into a portable unit that is well suited for veterinarians working in the field (Fig. 62.10). This unit has also become popular in practice as it supports both rigid and flexible endoscopy systems. An even more mobile option is the Endogo HD camera and battery-powered light, which provides real pocket-mobility albeit with reductions in light intensity and quality (Fig. 62.11).

FIG 62.10 The Tele Pack Vet X LED is a mobile unit that can be readily transported and used in field situations. In this example, the endoscopist is performing coelioscopy in a Galapagos tortoise at the Charles Darwin Research Station, Santa Cruz Island, Galapagos Islands (Courtesy of Stephen J. Divers). (*Inset*) A close-up of the Tele Pack Vet X LED mobile endoscopic video system, which integrates every component necessary for endoscopic imaging: camera, LED light source, monitor, insufflation pump and image capture. This device is compatible with all types of endoscopes, including video endoscopes, rigid endoscopes, fiberscopes, and exoscopes. (Courtesy of KARL STORZ GmbH & Co. KG.)

FIG 62.11 The EndoGo is a compact, battery-powered endoscopy camera and LED light system that offers true pocket-sized mobility. In this example, the endoscopist is performing an upper gastrointestinal examination in a neonate green sea turtle *(Chelonia mydas)* at the Grand Cayman Turtle Farm, British West Indies. (*Inset*) Close-up of the EndoGo camera and E-Zenon LED light source attached to a 2.7-mm telescope. (Courtesy of Stephen J. Divers.)

CO_2 Insufflation and Saline Infusion

Some form of insufflation is required for most coelioscopic procedures. CO_2 gas delivered by a dedicated endoflator is preferred (Fig. 62.12), but air delivered by syringe or a small aquarium air pump has been used with limited success. The risks associated with the use of air, specifically air emboli, cannot be ignored but appear rare. Dedicated endoflators precisely maintain the set insufflation pressure within the coelom by matching gas inflow with any leakage.

In some situations, the use of sterile saline can be especially helpful for creating mild distension. Saline infusion is particularly useful when dealing with a hollow viscus (e.g., upper gastrointestinal tract, bladder, cloaca, etc.), or when performing coelioscopy in small reptiles (e.g., juvenile chelonian gender identification). Saline infusion may also be preferred for coelioscopy of certain aquatic reptiles where there are potential ill-effects of residual insufflation gas on postoperative buoyancy (Fig. 62.13).

FIG 62.12 Electronic endoflator designed to precisely control the delivery of CO_2 for insufflation. In this example, the patient pressure has been set to 4 mmHg, with a CO_2 flow rate set to 0.4 L/min and a total gas consumption of 1.3 L. (Courtesy of Stephen J. Divers.)

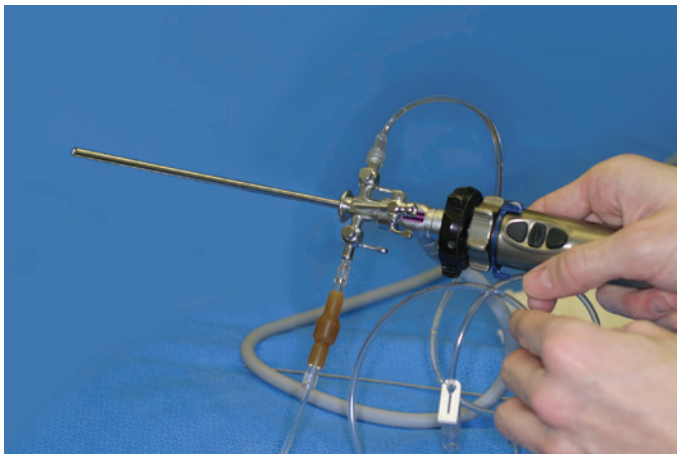

FIG 62.13 A simple saline infusion system requires a bag of sterile saline to be suspended above the animal (not shown) and an ingress fluid delivery line attached to one of the ports on the 4.8 mm operating sheath. A second intravenous line is used as an egress and empties into a bucket under the table. By adjusting the sheath ports, the endoscopist can control the rate of fluid entering and leaving an area. Such a system works well for neonate turtle coelioscopy, cloacoscopy, and gastrointestinal evaluations. It is important that the temperature of the saline is appropriate to the patient to avoid inducing hypothermia. (Courtesy of Stephen J. Divers.)

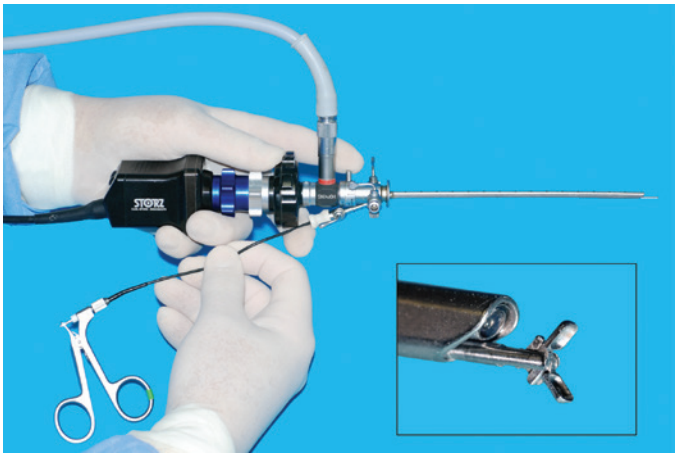

FIG 62.14 A 2.7-mm telescope within a 4.8-mm operating sheath, with TriCam 3-chip endovideo camera and light guide cable attached. Biopsy forceps (1.7 mm) passed through the working channel emerging in front of the terminal lens *(inset)*. (Copyright 2017 UGARF, photography Christopher B. Herron.)

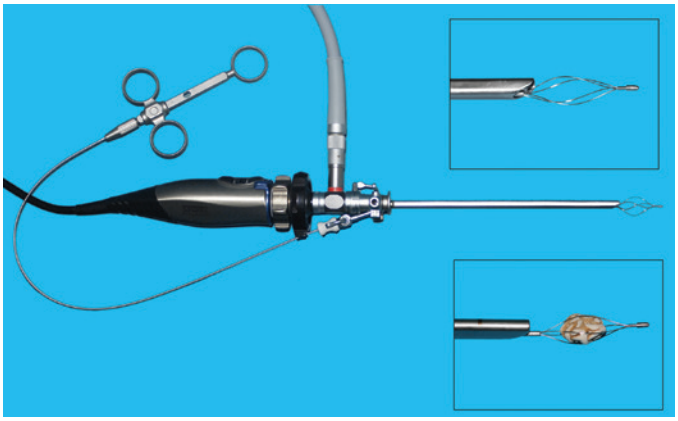

FIG 62.15 A 2.7-mm telescope within a 4.8-mm operating sheath, with Image-1 endovideo camera and light guide cable attached. Wire-basket retrieval device (1.7 mm) passed through the working channel with close-up views of the device opened and closed around a stone *(insets)*. (Copyright 2017 UGARF, photography Christopher B. Herron.)

Flexible Instrumentation

The basic and most frequently used instruments include biopsy forceps, retrieval forceps, scissors, and needle (see Fig. 62.1C). The 1.0 and 1.7 mm (3 and 5 Fr) grasping forceps are useful for manipulating tissues, debridement, and retrieving foreign objects or parasites. The fine aspiration/injection needle can be used for the aspiration of fluid from cystic structures where biopsy may be contraindicated due to postsampling leakage. The needle can also be used for irrigation and endoscopic drug administration. The 1.0- and 1.7-mm flexible biopsy forceps are used to harvest tissue samples for histopathology and microbiology in patients as small as 30 g. The small sample size usually permits the collection of several biopsies for multiple laboratory tests and serial biopsies to monitor disease progression over time to assess response to treatment. To take a tissue sample, the biopsy forceps are inserted down the operating channel and into the field of view (Fig. 62.14). It is much easier to advance and manipulate the sheath-telescope-instrument as a single device than to try and keep the sheath-telescope still and independently move the biopsy forceps back and forth. With the biopsy forceps held open, the sheath-telescope-instrument is advanced to the tissue of interest and when tissue enters the biopsy cup, the handle is released. These instruments are delicate and the biopsy handle is typically only required to open the biopsy jaws. The handle's spring mechanism is usually sufficient to take a soft-tissue biopsy without much additional manual pressure, if the instrument is sharp. Clamping down with force on the handle will damage the forceps and increase biopsy crush artifact. Some organs may be protected by a more fibrous membrane. The fixed blade of the scissors is inserted at a shallow angle through the membrane, and the sheath-telescope-scissors are advanced as a single unit, cutting the membrane as they proceed. The scissors can then be replaced by the biopsy forceps to take a sample through the capsular incision. Other instruments that can be invaluable in specific situations include a wire basket retrieval device (for removal of fibrous foreign bodies or stones; Fig. 62.15), polypectomy snare (for removal of small growths and polyps; Fig. 62.16) and radiosurgical needle electrode (for pinpoint ablation or coagulation).

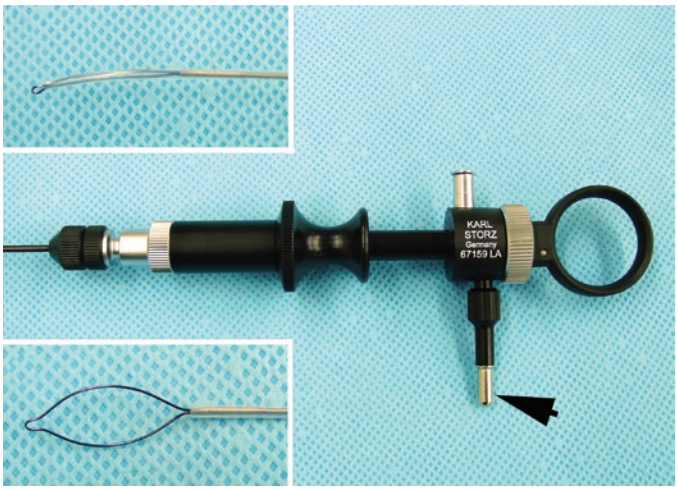

FIG 62.16 Polypectomy snare (1.7 mm) with radiosurgical connection (*arrow*), and close-ups of the retracted and extended snare *(insets)*. (Courtesy of Stephen J. Divers.)

ENDOSURGICAL EQUIPMENT

To operate inside the reptilian coelom, in addition to the telescope it is necessary to introduce additional, yet independent, instruments.[6] These instruments, and the cannulae through which they pass, are grouped into various size classes that are often color coded. For example, 2-mm instruments are used in conjunction with 2.5-mm cannulae, 3-mm instruments with 3.5-mm cannulae, and 5-mm instruments with 6-mm cannulae (Fig. 62.17). In addition, the 2.7-mm telescope housed within a 3.5-mm protection sheath will pass through a 3.9-mm cannula. Alternatively, a 3-mm telescope can be used through a 3.5-mm cannula. A listing of available equipment is provided in Table 62.1.[6]

Cannulae and Trocars

Cannulae are used to provide additional access ports (Fig. 62.18). They are of surgical steel or graphite/plastic construction and have internal leaflet valves and optional insufflation stopcocks for CO_2 delivery. These valves are designed to prevent loss of gas during insufflation. Insufflation stopcocks are optional, but at least one is required for the attachment of the insufflation line. The metal cannulae are more robust and heavier

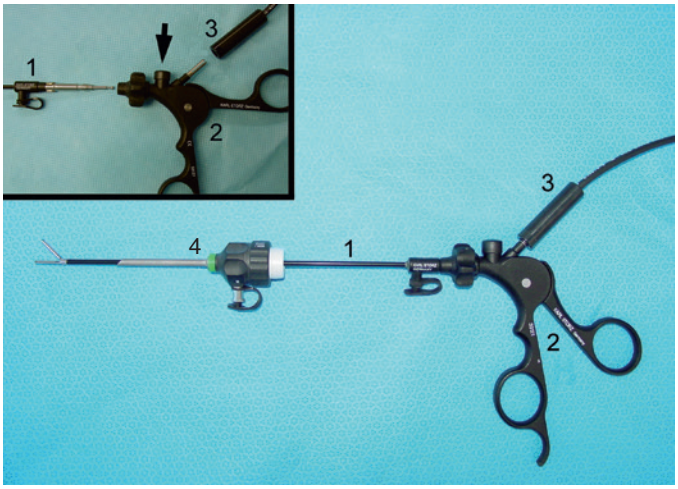

FIG 62.17 Miniature 3-mm laparoscopy equipment. A 3-mm instrument (1) attached to a standard ClickLine handle (2). The instrument, attached to a radiosurgery unit via a connector on the handle (3), has been inserted through a 3.5 mm graphite/plastic cannula (4). (*Inset*) Instrument (1) and handle (2) can be quickly exchanged by pressing on the release button (arrow). The radiosurgical connection is also shown (3). (Courtesy of Stephen J. Divers.)

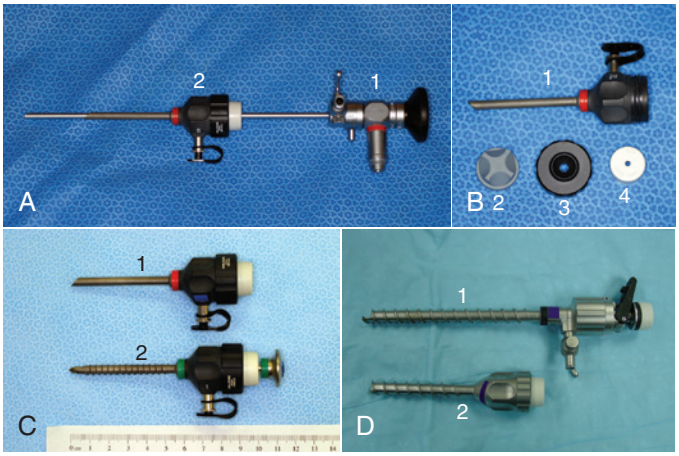

FIG 62.18 Cannulae and trocars. (A) A 2.7-mm telescope within a 3.5-mm protection sheath (1) inserted through a 3.9-mm x 10-cm graphite/plastic cannula with insufflation side-port (2). (B) A 3.9-mm x 10-cm graphite/plastic cannula disassembled to illustrate the graphite cannula (1), leaflet valve (2), screw cap (3), and instrument seal (4). (C) A 3.9-mm x 10-cm graphite/plastic cannula with insufflation side-port (1), and a 3.5-mm x 10-cm threaded cannula with insufflation side-port and trocar inserted (2). The 3.9 mm cannula can accommodate the 2.7-mm telescope housed in a 3.5-mm protection sheath while the 3.5-mm cannula can accommodate 3-mm instruments and telescopes, and, thanks to the threaded design, resists dislodgement in small exotic species. (D) Threaded (Ternamian endotip) cannulae: 6-mm x 15-cm with insufflation side-port and multifunctional valve (1), and a 6-mm x 10.5-cm cannula with silicone leaflet valve. These metal cannulae are heavier and best restricted to animals >10 kg. (Courtesy of Stephen J. Divers.)

and therefore are reserved for larger animals over 10 kg (i.e., 6-mm cannulae for 5-mm instruments). The plastic-graphite models are extremely light and ideally suited to most smaller reptiles (i.e., 2.5-mm and 3.5-mm cannulae for 2-mm and 3-mm instruments, respectively). Most cannulae are used in conjunction with trocars. A trocar is a solid,

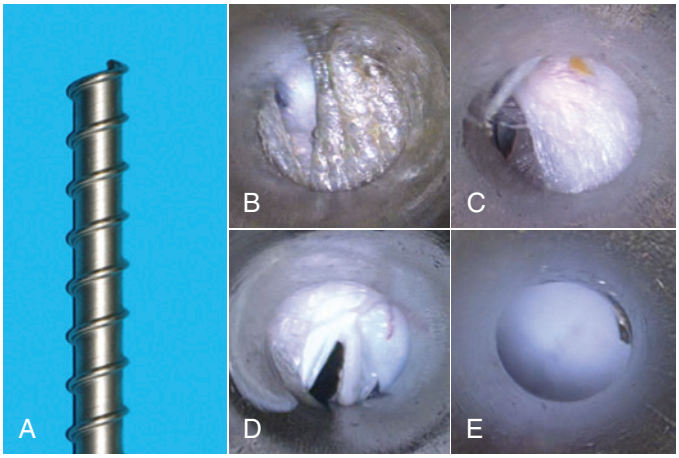

FIG 62.19 (A) Terminal end of a 6-mm threaded cannula. Screwed entry of the threaded cannula through an initial skin incision (B), subcutaneous tissue (C), and finally the coelomic membrane (D) before entering the coelomic cavity (E). (Courtesy of Stephen J. Divers.)

often sharp and pointed metal rod that is inserted into the cannula to assist with placement. Most are sharp to facilitate perforation of the body wall when axial and penetrative force is applied.

The threaded cannula (e.g., EndoTip) is a recent improvement that has an external screw-thread to enable gradual advancement by rotation (Fig. 62.19).[7] These threaded cannulae are available in 3.5-mm, 3.9-mm, and 6-mm sizes and do not require a trocar or much in the way of axial penetrative force for insertion. A telescope positioned inside the cannula provides a magnified view during entry into the coelom. As the cannula is advanced, the fascia and then the muscle fibers spread radially and are transposed onto the cannula's outer thread. The thin coelomic membrane is transilluminated so that viscera, vessels, and/or adhesions are visualized before entry into the coelom. The risks of iatrogenic visceral damage are therefore greatly reduced. In addition, the threads also provide greater security, and such cannulae are less prone to being dislodged.

Instruments and Handles

At least one, generally two, and rarely three instruments are inserted through cannulae and into the endoscopic field of view. Instruments must be triangulated to bring the instrument tips together (convergence) and enable surgery within the reptilian coelom. There is a huge assortment of 5-mm instruments available, initially developed for humans but equally applicable for animals over 10 to 20 kg. However, it was not until the development of human pediatric laparoscopy that smaller 2- and 3-mm instruments became available and multiple-entry endosurgery became feasible in smaller reptiles.[8]

Currently, 2-mm instruments are limited to Babcock forceps, Reddick-Olsen forceps, and scissors. A greater selection of 3-mm instruments is available, including a variety of dissection forceps, grasping forceps, scissors, biopsy forceps, and palpation and irrigation probes (Fig. 62.20). All these instruments have a standard attachment that enables them to be used interchangeably with a selection of ClickLine handles (Fig. 62.21). Handles are of plastic or metal construction and can possess a radiosurgical connection that enables scissors or forceps to be used as monopolar devices. An optional hemostat, Mahnes, or disengageable-style rachet mechanism is available to maintain firm hold of tissue, even if endoscopists release their grip on the handle.

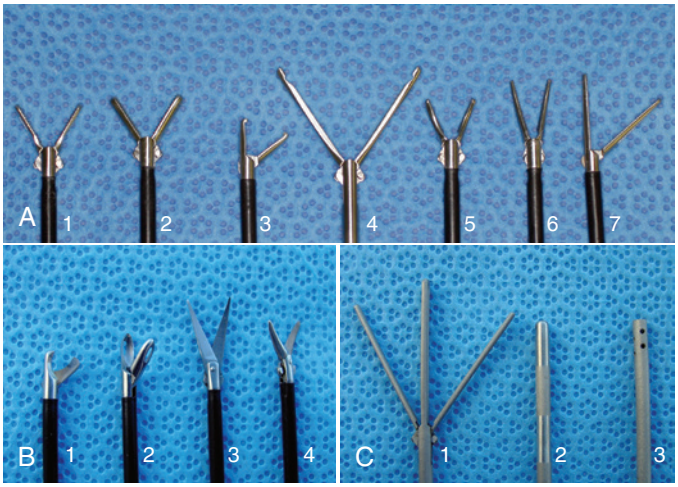

FIG 62.20 A selection of 3 mm instruments. (A) Forceps: fenestrated atraumatic grasping forceps (1), Reddick-Olsen dissecting forceps (2), small Babcock forceps (3), large Babcock forceps (4), short curved Kelly dissecting and grasping forceps (5), long curved Kelly dissecting and grasping forceps (6), and atraumatic dissecting and grasping forceps with single-action jaws (7). (B) Scissors and biopsy instruments: micro-hook scissors with single action jaws (1); Blakesley dissecting and biopsy forceps (2); long scissors with sharp, curved double-action jaws (3); and short scissors with serrated, curved double-action jaws (4). (C) Probes: distendable palpation probe (1), palpation probe with cm markings (2), and irrigation and suction cannula (3). (Courtesy of Stephen J. Divers.)

(C) Plastic handle with Mahnes-style rachet (arrow). (D) Metal handle without rachet or radiosurgery connection. (E) Metal handle with disengageable rachet but no radiosurgical connection. (F) Metal Y-handle with spring action. (Courtesy of Stephen J. Divers.)

Surgical Devices and Hemostasis

To effectively and safely perform endosurgery, accurate hemostasis becomes increasingly critical as the mere act of clamping a bleeding vessel or dabbing with gauze may be impossible. Surgical devices including radiosurgery and laser have become available and facilitated the ability

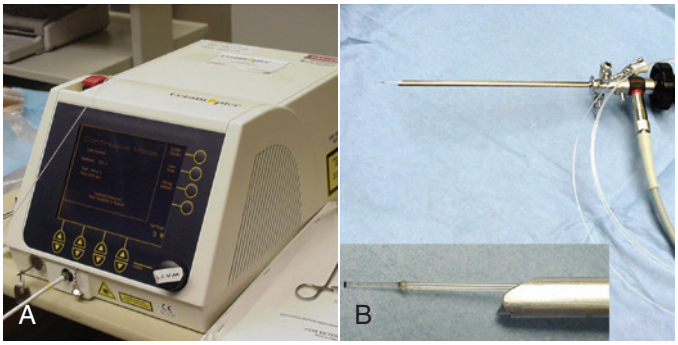

FIG 62.22 (A) A 980-µm diode laser unit. (B) A 600-µm diode laser fiber inserted down the instrument channel of the 4.8-mm operating sheath and emanating from the terminal end of the sheath in front of the terminal telescope lens *(inset)*. (Courtesy of Stephen J. Divers.)

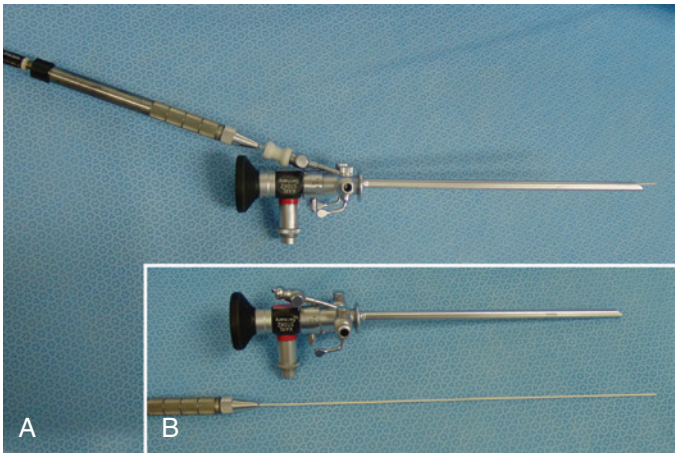

FIG 62.23 (A) Elongated ceramic CO_2 laser tip inserted down the instrument channel of the 4.8-mm operating sheath. (B) The same ceramic tip alongside the sheath. (Courtesy of Stephen J. Divers.)

to incise and debride internally while controlling hemorrhage. Diode lasers (e.g., AccuVet Lumenis Inc, Norwood, MA) are by design able to pass through flexible fiber-optic probes that can be inserted through instrument channels or cannulae (Fig. 62.22).[9,10] A variety of diode laser probes are available; however, 400- to 600-µm conical or flat tips at 2 to 10 watts are generally most useful (SurgiMedics Inc, The Woodlands, TX). Until recently CO_2 lasers (AccuVet Lumenis, Inc) could not be used via endoscopic instrument channels because of the inflexible nature of the ceramic delivery probes. The development of a long semirigid probe (AccuVet Lumenis, Inc), however, has enabled the use of the CO_2 laser via the 1.7-mm instrument channel of the 4.8-mm operating sheath, but, although functional, it is rather cumbersome (Fig. 62.23). Probably the most versatile, especially when using ≤3 mm instrumentation systems, is radiosurgery because a wide variety of tools is available for use with foot-pedal-activated units (e.g., 3.8 and 4.0 MHz Surgitron, Ellman International Inc, Oceanside, NY; Autocon III 400, Karl Storz Veterinary Endoscopy America, Inc.) (Fig. 62.24)[11]; the most useful of which include various needle electrodes, bipolar forceps, and retractable polypectomy snares. The degree of radiosurgical power required during endosurgery varies with operating conditions and the instrument being used, but due to the microsurgical nature of most endosurgical procedures, lower settings are generally required compared to open surgery. Considerable growth in endoscopic radiosurgery has

FIG 62.26 A LigaSure Atlas hand-piece. This 10-mm instrument has a working length of 20 cm and is capable of sealing and transecting vessels up to 7 mm in size. The smallest-diameter endoscopic instrument currently available is 5 mm, restricting this device to the largest of reptiles. (Copyright 2017 UGARF, photography Christopher B. Herron.)

led to the availability of many monopolar and bipolar devices. One particularly favored device amongst human and veterinary endosurgeons is the Ligasure Force-Triad (Covidien, 5920 Longbow Drive, Boulder, CO) (Fig. 62.25). This system detects the thickness (by measuring electrical impedance) of tissue to be coagulated and automatically defines the amount of energy required and the delivering time. An acoustic signal informs the surgeon when vessel obliteration is complete and transection is possible. Unfortunately, endoscopic handpieces below 5 mm are not available, limiting its usefulness to 5-mm systems and the largest of reptiles (Fig. 62.26).

Another useful item from human and domestic animal laparoscopy is the endoscopic vascular clip applicator (Fig. 62.27). These devices contain a cartridge of clips that can be rapidly used without having to remove from the patient and reload. Again, the smallest available size is 5 mm, which restricts their use to large reptiles.

Endoscopy Tables and Support Arms

Tilting tables are utilized to modify patient positioning and create advantageous organ displacement during surgery. Most of the table-mounted configurations used in veterinary medicine are designed for

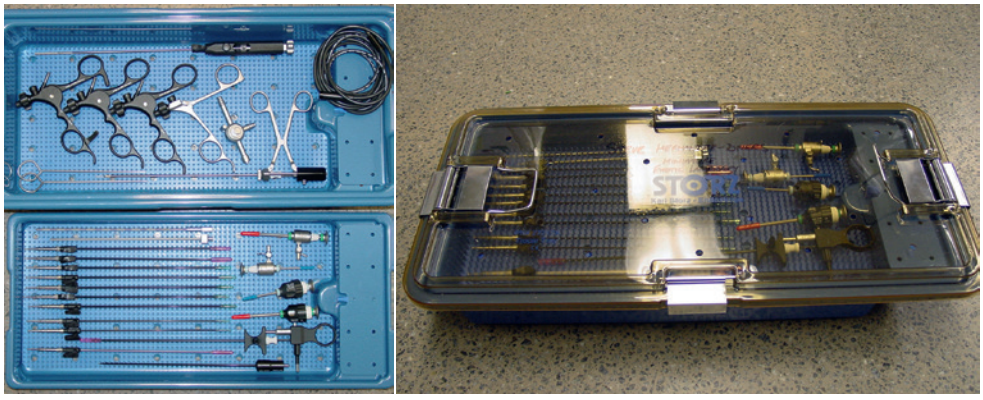

FIG 62.30 Plastic storage cases help protect equipment during storage and sterilization. (Courtesy of Stephen J. Divers.)

mammals and are less compatible with most reptiles. In addition, joystick-controlled tilting surgery tables (Fig. 62.28) are helpful but expensive and likely to be limited to teaching hospitals and other major referral institutions. Most practitioners can probably achieve similar positioning, albeit with less intraoperative versatility, by using towels, sand bags, vacuum pads, tape, and various other positioning aids.

It is often necessary to have an assistant hold the camera to permit the primary surgeon freedom to utilize two separate instruments during endosurgery. Alternatively, mechanical holding arms (e.g. VITOM, Karl Storz Veterinary Endoscopy America Inc) can be used to secure and hold the telescope when operating as a single surgeon (Fig. 62.29).

EQUIPMENT CLEANING, STERILIZATION, AND STORAGE

Specific and detailed cleaning instructions provided by manufacturers should always be followed. In general, endoscopes are first wiped and flushed to remove gross debris and tissue fluids before being soaked in a neutral pH enzymatic detergent. Ultrasonic cleaners are useful for many endoscopy items but should not be used with any optical equipment. High-level disinfection or sterilization can be achieved using ethylene oxide gas sterilization or cold sterilization using a 2%, 14-day, low-surfactant glutaraldehyde solution (Cidex or MetriCide). Cold-sterilized equipment must obviously be thoroughly rinsed with sterile water before use. While most modern telescopes are autoclavable, some optical devices, including older endoscopes and camera heads, may be irreversibly damaged by high-pressure, high-temperature steam. Equipment should be stored in a safe and secure manner, and a variety of metal and plastic containers have been designed to purposefully house items and withstand sterilization (Fig. 62.30). It can be a disadvantage to store equipment sterilized, as this may dissuade the novice endoscopist from reaching for the endoscope to practice.

ACKNOWLEDGMENTS

Although the author uses Karl Storz Veterinary Endoscopy equipment, it should be noted that other companies can likely provide similar items. All hospital equipment used by the author was purchased, not donated, from Karl Storz, and the author receives no payment from any endoscopy company.

Endoscopy Practice Management (Fee Structures and Marketing)

Stephen J. Divers

VetBooks.ir

While the clinical virtues of diagnostic and surgical endoscopy in herpetologic practice are obvious, appropriate management including a fiscally responsible fee structure appears to be more challenging. The costs of a basic rigid endoscopy system for a herpetologic practice can range between $10,000 and $30,000 (average around $25,000) and is not an insignificant capital investment; therefore a suitable fee structure is required to help recoup costs associated with purchase (or lease), use, repair, replacement, technician time, and practice facilities. A survey of veterinarians indicated reliance on the 2.7 mm telescope system (Table 63.1).[1] From discussions with various colleagues, it became obvious that there was widespread variation in endoscopy practice management. In addition, concerns regarding fee structures were frequently raised by attendees at endoscopy courses.

EQUIPMENT CHARGES, ANCILLARY FEES, AND PROCEDURAL FEES

There will obviously be considerable variation in charging mechanisms between practices and different countries. However, whatever charging system is employed it is important to identify the costs involved with providing the service:

1) Use of an endoscopy or operating room
2) Setup, cleaning, and storage of equipment
3) Operating supplies (e.g., surgical pack, drape, gloves, caps, mask)
4) Equipment wear and replacement
5) Anesthesia supplies and equipment use
6) Laboratory submissions (e.g., histopathology, microbiology)
7) Technician or nurse time

When it comes to actually charging for endoscopy procedures, there are a variety of options that veterinarians have used. Some use a tiered fee structure based on complexity and likely duration (e.g., level 1–6, see Table 63.2), while others may prefer an individual fee for every specific procedure (e.g., coelioscopy, tracheoscopy, gastroscopy, etc.). The advantage of a tiered fee structure is that it provides flexibility to increase or decrease fees depending upon difficulty and duration, is simple and easily utilized by staff and doctors, and avoids numerous fee codes and individual descriptors in computer systems. A major advantage of using detailed descriptors is that electronic medical record searches can be more targeted; however, this is at the expense of inputting considerably more data into a computerized accounting system.

Table 63.3 lists a number of exotic animal endoscopy procedures and the mean fees charged by veterinarians who responded to an internet survey in 2014. It must be appreciated that, just like any fee structure, there was considerable variation between low and high levels (approximately 50%–150% of stated means) that was probably related to geographic location and the associated costs of living. An audit of the

TABLE 63.1 Endoscopy Equipment Ownership by Surveyed Exotic Animal Veterinarians

Endoscopy Equipment Items	Ownership %
Separate xenon light source	60%
Separate halogen light source	34%
Separate standard-definition camera and monitor	66%
Separate high-definition camera and monitor	34%
All-in-one integrated light source, camera, and monitor system (e.g., TelePak)	23%
CO_2 insufflator	40%
Tilting endoscopy table	25%

practice's exotic animal case load can be especially useful to identify likely endoscopy revenue streams (Table 63.4).

MARKETING

Whenever a practice develops a new service area, appropriate marketing is essential. The ability to capture images and video for documentation makes it relatively simple to showcase the procedure to the client or referring veterinarian. It is important that the name and telephone number of the practice accompanies any image or video, as clients will frequently show their friends and family. Past materials can also be used in the examination room to demonstrate a proposed diagnostic plan to a new client (Fig. 63.1). These images should also be incorporated into letters sent to other veterinarians regarding cases that they referred for endoscopy, or for referral brochures. Some practices have also discovered the benefits of holding an open house, where the public can take a behind-the-scenes tour and see demonstrations, including the use of endoscopy equipment (Fig. 63.2).

When marketing endoscopy to clients, verbal delivery is critical. Take the following as an example.

Mrs. Smith, your ball python appears to have respiratory disease, most likely bacterial. We could anesthetize for a radiograph and even perform endoscopy, or we could start treatment today with broad-spectrum antibiotics.

Compare the above delivery with the following and consider (a) which would be more convincing for the client and (b) more medically appropriate.

Mrs. Smith, your ball python appears to have respiratory disease, but there are several possible causes and different treatments. We need to stabilize before briefly anesthetizing for radiographs, and then consider endoscopy and biopsy to determine the best approach to treatment. Precise diagnosis will maximize treatment success.

The second delivery is more convincing and avoids the inappropriate use of antimicrobials. However, it does depend on the veterinarian having confidence in his or her endoscopic abilities. Therefore it is as important to invest in the appropriate training as it is in the appropriate equipment. Fortunately, there are a variety of training opportunities within the United States and Europe, and short 4- to 8-hour workshops are frequently available at veterinary conferences (e.g., ARAV, AAV,

TABLE 63.2 Tiered Endoscopy Fee Structure Used at the University of Georgia by All Services Including Zoologic Medicine

Endoscopy Fee Level	Cost (June 2018)	Examples of Exotic Animal Procedures
1	$96.87	Basic stomatoscopy, tracheoscopy, otoscopy
2	$215.96	Complicated stomatoscopy, tracheoscopy, otoscopy Basic rhinoscopy, gastroscopy, cloacoscopy
3	$314.96	Complicated gastroscopy, cloacoscopy Basic coelioscopy with biopsy
4	$414.45	More complicated coelioscopy, bilateral entries, basic endosurgery (e.g., granuloma removal)
5	$513.68	More complicated endosurgery, multiple ports, surgical assistant
6	$60.74	Reptile gender identification fee per animal belonging to the same owner (in addition to a $500 setup fee)

These fees only represent the procedure. Anesthesia, equipment, and laboratory tests are additional.

TABLE 63.3 Mean Fees Charged for Specific Herpetologic Endoscopy Procedures Performed by 35 Experienced Clinicians (2014 Values Adjusted for Inflation to 2018)

Reptile tracheoscopy	$159
Reptile tracheoscopy with biopsy or debridement	$287
Reptile esophagoscopy/gastroscopy	$205
Reptile esophagoscopy/gastroscopy with biopsy or debridement or foreign body removal	$326
Reptile coelioscopy	$262
Reptile coelioscopy with biopsy or debridement	$335
Reptile coelioscopy and gonadectomy	$456
Reptile juvenile gender identification by coelioscopy	$148
Reptile juvenile gender identification by cloacoscopy	$99
Reptile cloacoscopy for disease investigation	$181
Reptile cloacoscopy with biopsy or debridement	$240
Reptile pulmonoscopy (transcutaneous lung examination)	$265
Amphibian tracheoscopy	$142
Amphibian orograstroscopy	$58
Amphibian coelioscopy	$64
Amphibian cloacoscopy	$49

Data from Divers SJ: Endoscopy practice management, fee structures, and marketing, *Vet Clin North Am Exot Anim Pract* 2015: 18:579–585.

TABLE 63.4 Example of a Case Audit Used to Determine Approximate Monthly Revenue (Using the Mean Fees From Table 63.3)

Case	Procedure	Anesthesia	Procedural Charge	Lab Fees	Monthly Revenue
Cloacal prolapse	Cloacoscopy	$188	$181	$175	$544
Snake with respiratory disease	Transcutaneous pulmonoscopy	$188	$265	$295	$748
Anorectic lizard	Coelioscopy	$188	$262	$175	$625
Total monthly revenue					$1917

Note: This calculation is based upon only three reptile cases in a month and does not take into account any other exotic species, dog, or cat cases; most practices would probably do more. Just one of these streams would cover the $300 to $400 monthly equipment lease.

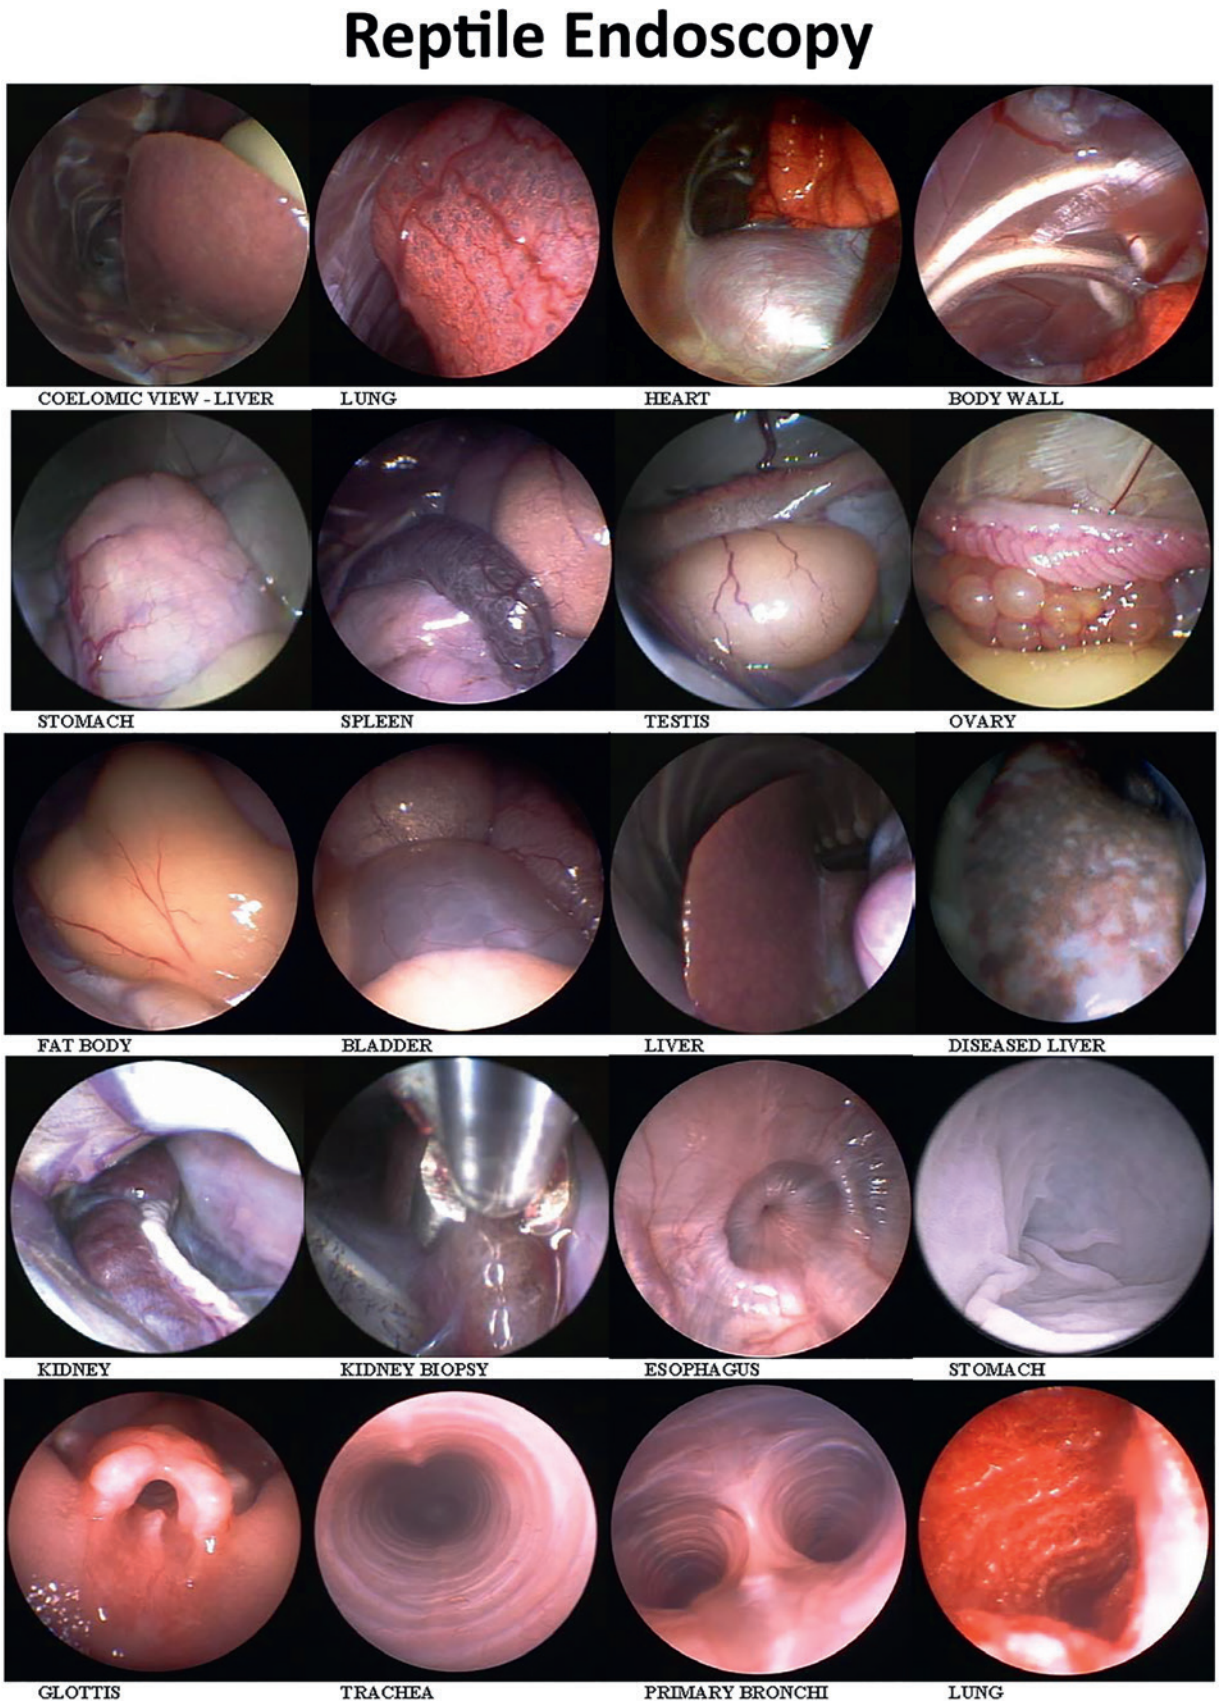

FIG 63.1 A laminated chart of reptile endoscopy images can be useful for client education and marketing purposes. (Courtesy of Stephen J. Divers.)

VetBooks.ir

FIG 63.2 Endoscopy station at the annual open house day at the University of Georgia's Veterinary Teaching Hospital. Under veterinary staff supervision, children get to play various endoscopy games using old (autoclaved) disposable instruments. Such events can showcase practice facilities and staff, and improve client awareness and appreciation. (Courtesy of Stephen J. Divers.)

AEMV, AAZV, ICARE). More extensive 2- to 3-day courses on reptile/avian or small mammal endoscopy are regularly provided at the University of Georgia (http://www.vet.uga.edu/ce).

CONCLUSION

With a capital investment of around $15,000 to $25,000 (or $300 to $400 monthly lease) and basic training, a practice can offer endoscopy services to their herpetological clientele to create new and exciting revenue streams.

Diagnostic Endoscopy

Stephen J. Divers

A definitive diagnosis is important to maximize treatment success, but reptile cases are frequently mismanaged simply because of a failure to identify a specific problem and provide appropriate therapy. Definitive diagnosis relies on the demonstration of a host pathologic response (by histopathology, less reliably cytology, or with paired rising antibody titers) and the causative agent (by microbiology, parasitology, or toxicology). There are few reliable serologic tests available for reptiles, and those that are available require a minimum of 6 to 9 weeks to demonstrate the necessary twofold increase in titers. It is therefore clear that tissue samples offer the most expedient means to a diagnosis, and endoscopy offers a visually accurate, minimally invasive, antemortem method to collect such material. Previously plagued by vague medical histories, nonpathognomonic physical examinations, indistinct diagnostic images, and non-conclusive clinical pathology results, many clinicians have discovered that diagnostic endoscopy offers an unparalleled ability to facilitate antemortem diagnosis and maximize treatment success.

The class Reptilia consists of over 10,000 species, but preference has been given to those species and procedures that are most commonly performed in clinical and zoological practice. Prior to the 1990s there were only sporadic reports of reptile endoscopy. The majority of earlier reports described the use of endoscopy to examine or retrieve foreign objects from the gastrointestinal tract, along with case descriptions of coelioscopy, bronchoscopy, and urogenital endoscopy.[1–11] More recently, there has been further development and reviews of single- and multiple-entry techniques that have expanded endoscopic applications in the Reptilia.[12–16] In particular, validation of endoscopy procedures in lizards (e.g., liver and renal biopsy in iguanas), chelonians (e.g., renal biopsy in various species, neonate sex identification), and snakes (e.g., pulmonoscopy in ball pythons, *Python regius*) have helped confirm safety and diagnostic value.[7–11,17] Given the often small and delicate nature of small reptile species, the continued development of minimally invasive endoscopy appears assured in these taxa.

Since Taylor's original chapter on reptile endoscopy was published in the second edition of this book, the 2.7-mm telescope system has continued to gain popularity as an invaluable diagnostic tool in reptile practice.[18] Endoscopy has continued to grow and evolve with multiple journal publications, conference proceedings, and continuing education events dedicated to reptiles. Probably the greatest hindrance to undertaking endoscopic evaluations is lack of equipment and confidence, and here attendance at training courses can be beneficial. However, once confidence and skill are attained, endoscopy becomes a primary diagnostic modality that should be undertaken early in the course of disease investigation—not as a last resort.

PREOPERATIVE EVALUATIONS AND ANESTHESIA

Patient Selection, Evaluation, and Contraindications

Most reptiles are presented in a state of advanced, often chronic disease, and therefore medical stabilization is important prior to anesthesia and surgery. The most common endoscopic procedures performed by the author include coelioscopy, gastroscopy, cloacoscopy, tracheobronchoscopy, and pulmonoscopy. However, most of the procedures described (or necessary modifications thereof) can be undertaken in most reptiles assuming equipment can be matched to patient size. In addition to anesthetic complications, small patient size often presents the greatest challenge. Obesity is less of an issue in chelonians and lizards, because they store fat in discrete fat bodies rather than diffusely around organs like mammals do. Obesity in snakes can still be a significant hindrance during coelioscopy, however, due to their more widespread coelomic fat reserves.

The benefits of endoscopy are numerous but mostly center on the fact that traditional approaches are more invasive, require longer anesthetic periods, and can carry significantly greater procedural risks (e.g., coeliotomy vs coelioscopy). With the ability to internally examine the patient and collect tissue samples, the array of antemortem diagnoses has increased considerably, with accurate diagnosis resulting in more appropriate targeted therapy and improved clinical success.

Knowledge of species-specific anatomy, physiology, husbandry, and nutritional requirements are vital to properly evaluate the reptile patient. Inexperienced clinicians are directed to various chapters throughout this text and should prepare in advance.[19,20] Complete physical examination, including accurate body weight, is essential but may require sedation or anesthesia for aggressive, venomous or uncooperative reptiles. Serial clinicopathologic data can be helpful to quantify dehydration and indicate infection/inflammation and organ damage or dysfunction. However, most published reference ranges are too broad to be of value unless patient data is severely abnormal. Complete blood counts and biochemistry panels are recommended. Even in animals <100 g, hematocrit and total solids can still be obtained.

Patient Preparation and Anesthesia

In most cases, the sick reptile presents with anorexia of days to months duration, and fasting is usually not a concern. However, when dealing with animals that are still feeding, fasting should be in accordance with body size and feeding strategy. For example, a 20-kg python would typically be fasted for 2 to 3 weeks, whereas a 50-g gecko would require only 1 to 2 days. Likewise, fasting a carnivorous turtle for 1 to 3 days would reduce the volume of food in the stomach, whereas

fasting an herbivorous tortoise for the same period would have little effect given the majority of digesta is located within the large intestine. As a general guide, a single feeding cycle should be avoided prior to anesthesia and surgery. In general, fluid therapy is the mainstay of stabilization, and rehydration using crystalloid fluids (with an osmolarity of 260–290 mOsm/L) at 25–45 mL/kg/day is recommended.[21] Fluids may be given intravenously or intraosseously for critical cases, or intracoelomically, subcutaneously or orally. It is advisable to avoid oral fluids within 24 hours of gastroscopy, and intracoelomic fluids within 72 hours of coelioscopy.

Certain examinations (e.g., stomatoscopy, cloacoscopy) may be possible in the conscious or sedated patient using appropriate restraint (including a mouth gag for oral approaches), but complete immobilization is preferred to avoid risking damage to equipment, patient, or staff. General anesthesia is recommended for all endoscopy procedures (including oral and cloacal examinations) and is required for any invasive procedures (including coelioscopy).[9,22] Conscious coelioscopic examinations may be acceptable in research animals or wildlife under an appropriate experimental license, but in clinical practice, analgesia and anesthesia are mandatory. Although some authors have reported using only local anesthesia for chelonian coelioscopy, this provides inadequate analgesia for more involved coelioscopic procedures.[23] In a recent comparison of local versus general anesthesia for chelonian coelioscopy, struggling was significantly reduced for procedures conducted under general anesthesia compared to local lidocaine alone.[9] For a detailed description of sedation, anesthesia, and analgesia, see Chapters 48 to 52. Careful consideration should be given to intubation and adequate ventilation, especially when insufflating the coelom during coelioscopy. Opiate and nonsteroidal antiinflammatory drugs are used routinely to relieve or minimize any pain or discomfort associated with these endoscopic procedures.

OPERATING ROOM PREPARATION, ERGONOMICS AND EQUIPMENT HANDLING

Some consideration should be given to room setup and positioning, which will greatly facilitate procedural success. Procedural technique (incl whether the surgeon is left or right handed) and species anatomy are key factors in animal positioning and are dealt with under each individual procedure. The endoscopy tower and especially the video monitor should be positioned directly in front of the endoscopist (Fig. 64.1). Trying to observe a monitor to one side, or even worse over a shoulder, creates confusion, frustration, and discomfort. For right-handed surgeons, the instrument table should be placed on the right (and vice versa for those who are left handed).

The fact that most reptiles weigh <2 kg necessitates careful control of the telescope, with the eye-piece and camera supported using the superior hand and the distal shaft of the telescope held by thumb and forefinger of the inferior hand (Fig. 64.2A). Handling the telescope in this fashion provides fine control without tremor; however, for a single surgeon to be able to use instruments a modified hold is required. In order to insert and manipulate instruments through the operating sheath, it is necessary to change from a two-handed to a one-handed technique. The usual thumb and forefinger support of the telescope shaft is now adjusted so that the inferior hand takes the entire weight of the sheath-telescope-camera system. The thumb is slid up the shaft of the sheath, and the fingers are curled over the top to encircle the sheath. Now that the sheath is grasped in a fist-like grip with the sheath further supported by the thumb to prevent rotation, the superior hand can be removed to manipulate an instrument down the operating channel (see Fig. 64.2B). This can only be performed using a correctly sheathed telescope; damage will otherwise occur to the telescope.

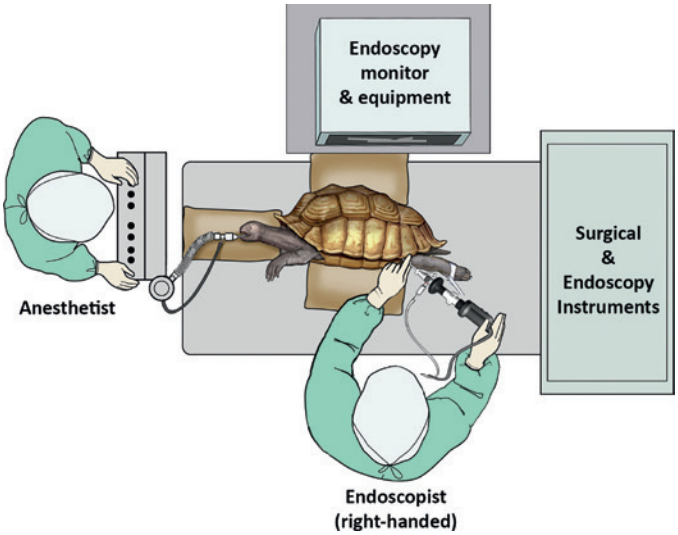

FIG 64.1 Operating room layout for a right-handed surgeon performing a left prefemoral approach for coelioscopy in a tortoise. (Courtesy of Educational Resources, University of Georgia.)

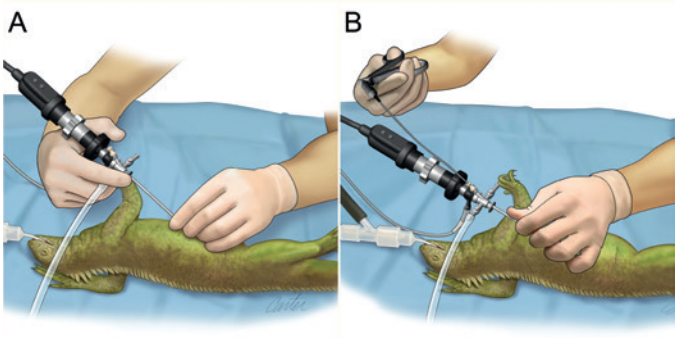

FIG 64.2 Correct handling of the 2.7-mm telescope housed within the 4.8 mm operating sheath. (A) The two-handed technique for general evaluation involves supporting the sheathed telescope and camera with the superior hand while the thumb and forefinger of the inferior hand provide fine motor control and prevents tremor. (B) The one-handed technique facilitates instrument use by a single surgeon and involves the inferior hand taking the weight of the sheathed telescope and camera by gripping the entire shaft, with the thumb slid up the sheath to prevent rotation. The inferior hand is now free to manipulate an instrument into the operating channel. (Courtesy of Educational Resources, University of Georgia.)

DIAGNOSTIC ENDOSCOPY PROCEDURES

Tracheoscopy and Pulmonoscopy

Depending upon the size of the reptile, a suitably sized rigid or flexible endoscope can be used to examine the glottis and at least part of the anterior trachea of most lizards, chelonians, and snakes (Fig. 64.3).[12] It is always preferable to use a protection sheath with the finer telescopes, but the increased diameter may be prohibitive. Rigid scopes of sufficient length can usually be directed into the lungs of lizards by careful manipulation of the lizard's head, neck, and body. It is often beneficial to provide a large breath immediately prior to inserting the endoscope. For large snakes and chelonians, fine diameter flexible endoscopes or videoscopes will permit a deeper examination into the lungs (Fig. 64.4).[18,24]

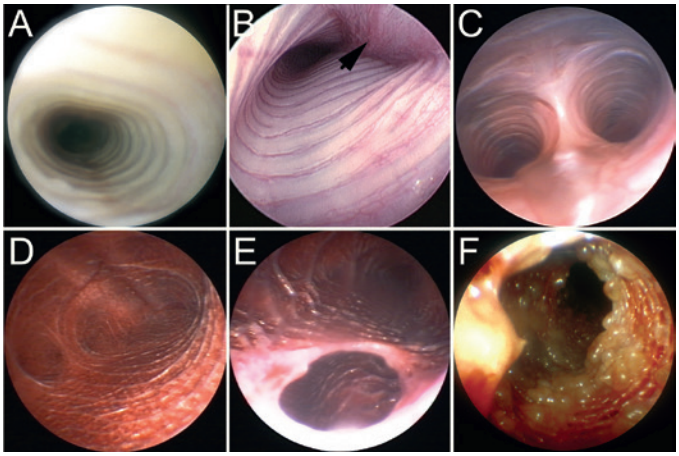

FIG 64.3 Tracheobronchoscopy. (A) Greek tortoise (*Testudo graeca*) trachea with complete tracheal rings. (B) Ball python (*Python regius*) trachea with obvious dorsal ligament (arrow). (C) Tracheal bifurcation and primary bronchi in a green iguana (*Iguana iguana*). (D) Simple saclike lung in a green iguana. (E) Compartmentalized lung in a panther chameleon (*Furcifer pardalis*). (F) Granulomatous pneumonia due to *Mycobacterium* spp in a ball python. (Courtesy of Stephen J. Divers.)

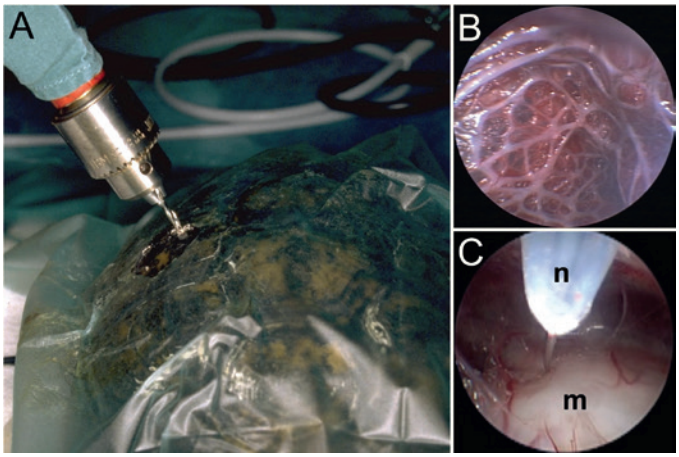

FIG 64.5 Chelonian transcarapacial pulmonoscopy. (A) Drilling a 4-mm temporary osteotomy through the carapace of a Greek tortoise (*Testudo graeca*) to access the lung. (B) Normal view of the chelonian lung through the temporary osteotomy. (C) Large mass (m) within the lung of a juvenile loggerhead sea turtle (*Caretta caretta*) via a temporary carapacial osteotomy. Aspiration is first attempted using an endoscopic needle (n) and, if not fluid-filled, biopsies are taken. In this case the lesion was an encapsulated fungal granuloma. (Courtesy of Stephen J. Divers.)

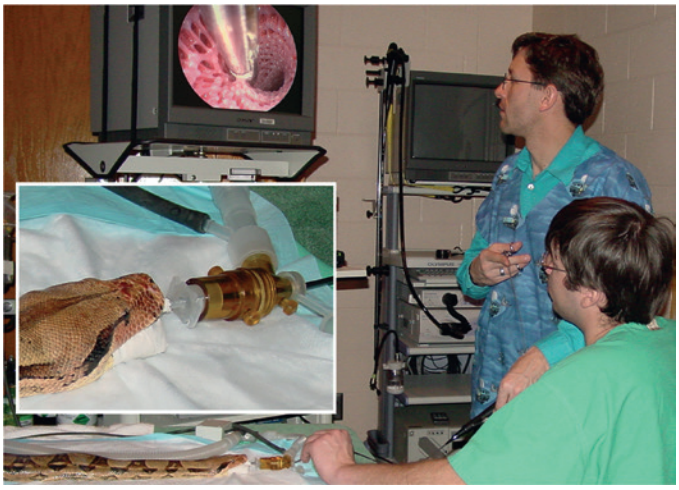

FIG 64.4 Tracheobronchoscopy in a boa constrictor (*Boa constrictor*) using a 2.5-mm fiberscope. Note the endotracheal adaptor (*inset*) that facilitates introduction of the fiberscope while maintaining anesthesia. (Courtesy of Stephen J. Divers.)

The anesthetized reptile is positioned in dorsal or sternal recumbency, with head and neck extended. A mouth gag is recommended to guard against a lightly anesthetized reptile from biting down on the endoscope. The endoscope should be inserted through the glottis and gently advanced under direct visual control to avoid damaging the mucosa. Complete tracheal occlusion for several minutes is well tolerated, and there is no need to provide an alternative airway. The incomplete (Squamata) and complete (Chelonia, Crocodilia) tracheal rings and mucosa can be clearly seen. Parasites, abscesses, granulomas, trauma, and mucosal defects, as well as chondromas and other neoplasms, can be readily appreciated.

A tracheal approach to the chelonian lung is particularly difficult because of the narrow trachea and meandering primary bronchi. It is possible in the largest species (e.g., giant tortoises, sea turtles) using fine flexible endoscopes, but not in smaller specimens, and therefore two alternative approaches to the chelonian lung have been developed: carapacial and prefemoral.[12] The carapacial approach requires a 4- to 5-mm temporary osteotomy over the suspected pulmonary lesion, pinpointed by diagnostic imaging (Fig. 64.5A). The pleuropulmonary membrane is punctured using a trocar or straight hemostats while the animal is held at maximal inspiration. Leakage of anesthetic gases confirms entry into the lung, and additional anesthetic gas scavenging should be positioned close to the surgical site, or ventilation should be temporarily suspended during the procedure. The sheathed telescope can then be inserted into the lung for examination, remembering that, due to the rigid nature of the shell, telescope movements will be restricted (see Fig. 64.5B and C). Following endoscopy, the osteotomy can be closed using epoxy or acrylic, but it may be advantageous to secure a capped, intravenous catheter within the hole to permit intrapulmonary therapy. Following successful treatment, the catheter is removed and the hole sealed. The shell typically heals within 12 weeks.

The second, prefemoral approach to the chelonian lung is particularly suitable for those species that have a relatively large prefemoral fossa, which facilitates surgical entry into the coelom and identification of the caudolateral aspect of the postpulmonary membrane (septum horizontale) and caudolateral lung. A small (2–4 cm) craniocaudal incision is made in the craniodorsal aspect of the prefemoral fossa (Fig. 64.6A). The coelomic membrane is perforated and opened using hemostats. By frequently and maximally ventilating the lungs, the caudolateral lung can be readily identified. Two stay sutures are placed through the caudoventral border of the lung to facilitate elevation to the level of the skin incision. A stab incision through a thin, avascular portion of the exposed lung provides access for the telescope. Due to the soft tissue nature of this approach, greater endoscope maneuverability is possible and the pulmonary examination can proceed from caudal to cranial, and in some species it is possible to visualize the opening of the primary bronchus (see Fig. 64.6B and C). Upon withdrawal, the lung must be closed using fine suture material to avoid postoperative pneumocoelom, and this is most easily achieved by using the preplaced stay sutures. Coeliotomy closure is otherwise routine.

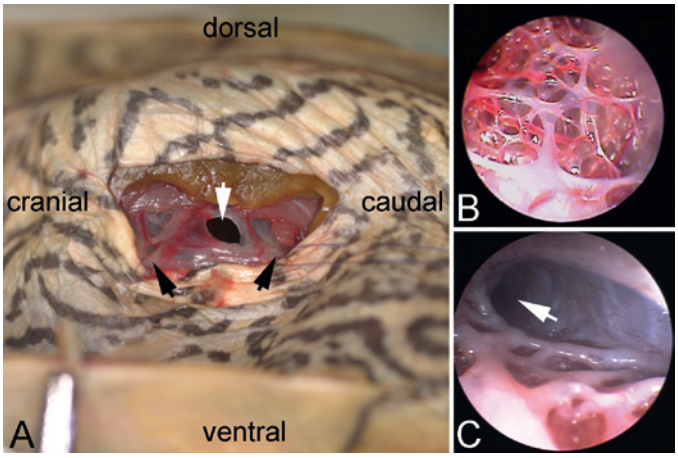

FIG 64.6 Chelonian transcutaneous pulmonoscopy. (A) Surgical view of the prefemoral fossa of a map turtle (*Graptemys* sp) following a mini-coeliotomy incision. Two fine stay sutures (black arrows) have been placed to elevate the lung to the skin incision, and a small stab incision has been made through an avascular window of the lung (white arrow). (B) Endoscopic view from within the lung of a map turtle demonstrating the characteristic edicular nature of the tissue. (C) Endoscopic view from within the lung of a Greek tortoise (*Testudo graeca*), demonstrating the opening to the left primary bronchus (arrow). (Courtesy of Stephen J. Divers.)

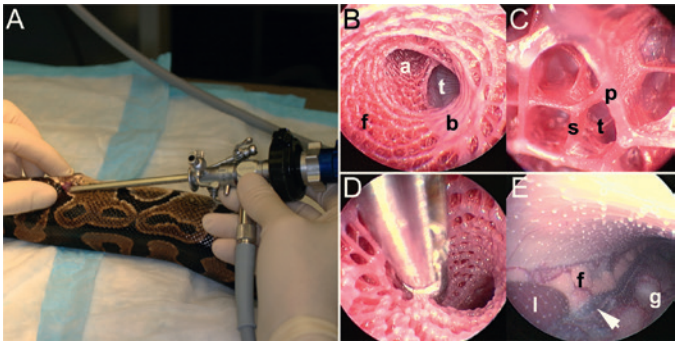

FIG 64.7 Ball python (*Python regius*) transcutaneous pulmonoscopy. (A) The sheathed 2.7-mm telescope inserted through the lateral body wall and introduced into the cranial lung of a research python that has not been draped to permit visualization of the snake's position and surgical entry site. (B) View of the cranial lung demonstrating the distal trachea (t), intrapulmonary bronchus (b), anterior lung lobe (a), and the faveolar lung tissue (f). (C) Close-up view of the faveolar region demonstrating the primary (p), secondary (s), and tertiary (t) septae of the anterior vascular lung. (D) Lung biopsy using the 1.7-mm biopsy forceps. (E) View of the thin, transparent, caudal air sac through which the caudal edge of the liver (l), fat body (f), gastrointestinal tract (g), and caudal vena cava (arrow) can be seen. (Courtesy of Stephen J. Divers.)

A transcutaneous approach to the lung of snakes has also been described.[11,25] This involves a minicoeliotomy approach approximately 35% to 45% from snout-to-vent, on the right side in boids and colubrids (or either left or right side for boas and pythons because they have two lungs). Following a 1-cm skin incision, and blunt dissection through an intercostal space, the lung is identified as it is ventilated, grasped, secured, and punctured using a scalpel blade before insertion of the telescope. Depending on the size of the snake, this approach can facilitate evaluation of the distal trachea, primary and intrapulmonary bronchus, cranial faveolar lung, transitional zone, and the caudal air sac (Fig. 64.7). In giant boids, a flexible endoscope can be inserted and advanced cranially and caudally to examine most of the unilateral pulmonary system. Lung and skin are closed routinely as separate layers. This technique has been thoroughly evaluated in ball pythons (*Python regius*), where the surgical approach and visualization of the distal portion of the trachea; primary bronchus; intrapulmonary bronchus; cranial lung lobe; and faveolar, semisaccular, and saccular lung regions were excellent.[11] This study also evaluated faveolar biopsy specimens collected using 1.7 mm biopsy forceps and concluded that the diagnostic quality of specimens that were shaken from biopsy forceps into physiological saline solution before fixation in 2% glutaraldehyde or neutral-buffered 10% formalin was good to excellent. Reevaluation of the same snakes a year later confirmed complete healing of the previous entry and biopsy sites with no apparent deleterious effects.

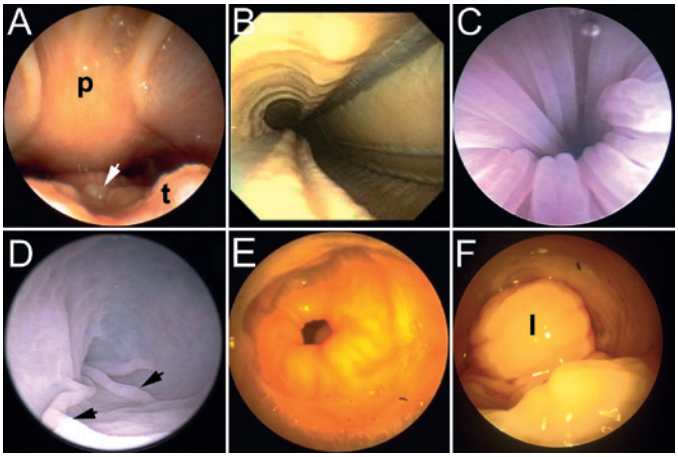

FIG 64.8 Stomatoscopy, esophagoscopy, and gastroscopy. (A) Oral cavity of a radiated tortoise (*Astrochelys radiata*) demonstrating the choana and hard palate (p), fleshy tongue (t), and larynx (arrow). (B) Air-distended esophagus of a Burmese python (*Python bivittatus*). (C) Saline-infusion view of the green iguana (*Iguana iguana*) distal esophagus. (D) Stomach of a savannah monitor (*Varanus exanthematicus*) with normal rugal folds (arrows). (E) Gastric hypertrophy in a corn snake (*Pantherophis guttata*) with cryptosporidiosis. (F) Leiomyoma (l) obstructing the pyloric outflow in another corn snake that presented with chronic regurgitation. (Courtesy of Stephen J. Divers.)

Stomatoscopy and Gastroscopy

Sternal or dorsal recumbency with head and neck extended is preferred for stomatoscopy and gastroscopy. It is often helpful to have the reptile close to the table edge or positioned on a raised surface. The rigid telescope-sheath system can be used to examine the buccal cavity, esophagus, and stomach of small lizards, crocodilians, and chelonians (Fig. 64.8). Flexible endoscopes are required to gain access to the stomach for most snakes and larger reptiles of other orders (Fig. 64.9). Air insufflation can be used to dilate the tract, which provides good exposure for detecting gross lesions and foreign bodies. Warm saline irrigation provides superior clarity, especially when examining for mucosal detail, although tracheal intubation is essential to avoid aspiration. Whether air or saline is used, it is important to gently dilate the tract as the endoscope is advanced to avoid damage and laceration to the wall. Foreign bodies can be readily retrieved, and biopsy collection should be undertaken with care to avoid perforation of the intestinal tract, which is more likely in the thin-walled esophagus than the stomach.

FIG 64.9 Flexible gastroscopy in a color-mutant burmese python (*Python bivittatus*). *(Inset)* Endoscopic view of an esophageal lymphoid aggregate ("esophageal tonsil"). (Courtesy of Stephen J. Divers.)

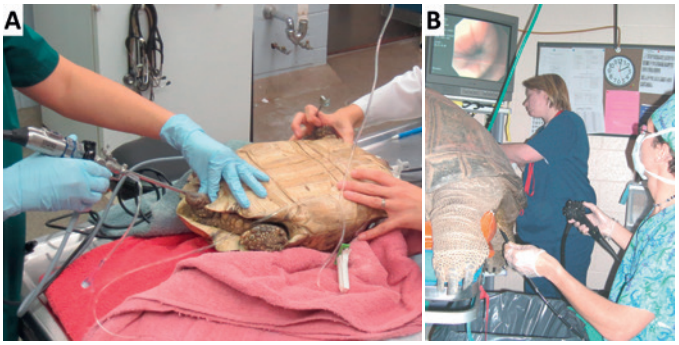

FIG 64.10 Chelonian cloacoscopy. (A) Cloacoscopy using a 2.7-mm telescope and saline infusion in an African spurred tortoise (*Centrochelys sulcata*). (B) Cloacoscopy using a 9.0-mm video gastroscope in an Aldabra tortoise (*Aldabrachelys gigantea*). (Courtesy of Stephen J. Divers.)

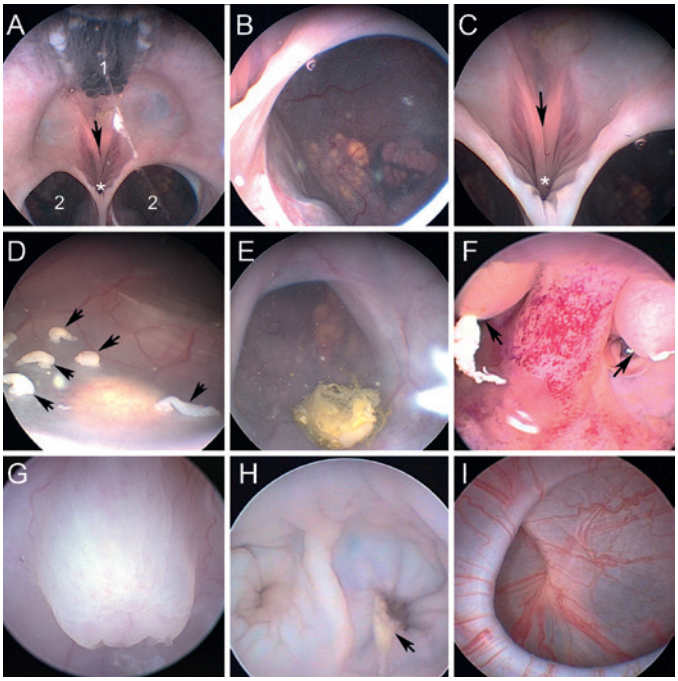

FIG 64.11 Cloacoscopy. (A) Endoscopic view of the cloaca of a female yellow-bellied slider (*Trachemys scripta*) demonstrating the clitoris lying on the ventral wall (1), bilateral accessory bladders (2), openings to the colon (*), and the urodeum (arrow), where the genital openings and urethra are located (dorsal recumbency using saline infusion). (B) Close-up of one of the accessory bladders. (C) Close-up of the openings to the urodeum and urethra (arrow), and the colon (*). (D) Cystoscopy in a female yellow-bellied slider demonstrating several trematode parasites (arrows) attached to the bladder wall. (E) Colonoscopy of a yellow-bellied slider with a small fecal mass visible. (F) View within the urodeum of a green iguana (*Iguana iguana*) with uric acid emerging from the urogenital papillae (arrows). (G) The single urogenital papilla within the urodeum of the ball python (*Python regius*). (H) View within the urodeum of a hognose snake (*Heterodon nasicus*) demonstrating the oviductal openings. Note the discharge emanating from one of the oviducts (arrow) that was associated with retained egg material. (I) Colonoscopy of a ball python (*Python regius*) demonstrating the normal spiral folds. Cloacoscopy

Although snakes can also be positioned in sternal or dorsal recumbency, chelonians and lizards are generally easier in dorsal (Fig. 64.10). Endoscopy using warm saline irrigation promotes unparalleled examination of the proctodeum, urodeum, and coprodeum. Detailed appraisal of the distal colon, cloacal mucosa, urogenital papillae, oviductal openings in females, and (when present) the urethral opening and bladder (Fig. 64.11) are possible. With practice, the endoscope can be directed through the urethra into the thin-walled bladder in chelonians and some lizards. It is also possible to enter the distal oviducts of reproductively active females. Cloacoscopy has been used to remove shell and egg material from the distal oviducts and bladder, guide exteriorization of partially prolapsed tissue and resection, and facilitate bladder catheterization. Mucosal biopsies should be taken with care, especially from the colon and bladder due to their thin nature and the risks of perforation. More recently, a technique for neonate gender identification that centered on observing the gonads through the bladder wall via a cloacoscopic approach has been described in Hermann's tortoises (*Testudo hermanni*).[26] This technique has the advantage of avoiding entry into the coelomic cavity but, because examination is through a membrane, may not be as sensitive as direct coelioscopic visualization. In addition, research at UGA involving sliders (*Trachemys*) indicated that perforation of the urethra and bladder were common and the technique could not be recommended (Proenca, unpublished data). There may be species-specific safety limitations for this cystoscopic technique.

Coelioscopy

As reptiles lack a true abdomen, the term coelioscopy is preferred over laparoscopy. For a detailed discussion of generic laparoscopy methodologies the reader is referred to the dedicated literature, as only reptile specifics will be highlighted here.[27–30] Laparoscopy has been shown to offer significant advantages over traditional surgical options, both in human and veterinary medicine. In particular, laparoscopy is, with practice, faster, less traumatic, and causes less postoperative pain, with a more rapid return to normal function.[31–42] Until the advent of 2- and 3-mm human pediatric equipment, coelioscopy was limited to a single-entry system using the sheathed telescope; however, multiple-entry techniques are now possible and practical for animals over 500 g (see Chapter 65).[43]

Precise positioning for coelioscopy depends upon the reptile's body shape and confirmation, the structure(s) of interest, and the preferences

of the endoscopist.[13] The entry site is aseptically prepared and draped, and adhesive clear plastic drapes permit better visualization of the patient. Insufflation is essential for lizards and snakes and, although the shell prevents coelomic collapse, can still be helpful in many chelonians. Typically CO_2 insufflation pressures of 3 to 5 mm Hg are used, which are lower than those recommended for mammals (8–12 mm Hg). In some situations, saline infusion may be preferred over gas. In the author's experience this is especially true when dealing with neonates, juveniles, and other very small reptiles, or aquatic species, where residual gas may have a negative effect on postoperative buoyancy.

Lizards. Dorsoventrad compressed lizards (e.g., bearded dragons) are more easily positioned in dorsal recumbency, while laterally compressed lizards (e.g., old world chameleons) in lateral. Round-bodied lizards (e.g., green iguanas) can be easily placed in either lateral or dorsal recumbency, but lateral is generally preferred and allows easier access to both ventral and dorsal structures. Given the relatively small size of most lizards, a single paramedian or paralumbar entry point will usually permit examination of most, if not all, organ systems.

While anatomic differences exist between families, the green iguana serves as a useful model for saurian coelioscopy.[7,44] In the iguana, there is no significant difference in visualization of lung, liver, pancreas, small intestine, large intestine, ovary, oviduct, testis, epididymis, vas deferens, bladder, fat body, or kidney from either left or right approaches. However, a left lateral approach to the heart, stomach, and spleen, and a right lateral approach to the gallbladder, are preferred.[7] Right-handed surgeons will find that a left paralumbar approach is easier, while left-handed surgeons will prefer a right paralumbar approach. Unless physical examination, diagnostic imaging, clinicopathology or anatomy suggests an asymmetric location the endoscopist's preference can prevail. For a left lateral approach, which is often favored by right-handed surgeons, the iguana is positioned in right lateral recumbency, with the left pelvic limb taped caudad against the tail base. The entry area is bordered craniad by the ribs, dorsad by the spine, and caudad by the pelvic limb (Fig. 64.12). However, in larger lizards an intercostal approach is also practical. Aseptically, a small skin incision is made in the center of the defined area. The skin and underlying muscle is grasped and elevated away from the coelomic viscera and the sheath (with obturator), aimed parallel to the table and toward the head, are gently forced through the coelomic musculature and into the coelomic cavity. It is wise to temporarily cease artificial ventilation until the telescope has been introduced into the coelom, thereby reducing the possibility of damage to an inflated lung or viscus. The obturator is replaced by the telescope and the insufflation line attached to one of the sheath ports. By making a small skin incision and breach in the muscle, the sheath will be tight fitting, and insufflation gas leakage will be minimized if there is any gas leakage, a mattress suture can be placed through the skin and around the sheath. Once a pneumocoelom has been created, it may be necessary to gently touch the tip of the telescope against a coelomic membrane to clean the terminal lens of condensation or tissue fluid. If there is fat or blood on the lens it is often necessary to remove the telescope from the sheath, clean with gauze moistened with sterile saline, and replace. It is unwise to continue with poor visualization.

Upon entry via a left paralumbar approach in the iguanid lizard, the first organ to note is the large brown liver lying in the midventral coelom (Fig. 64.13A). Advancing the telescope craniad will reveal the heart at the cranioventral extent of the coelom, close to the cranial coelomic inlet (see Fig. 64.13B). There are no diaphragmatic, postpulmonary, or longitudinal membranes in iguanas. However, these membranes do exist to a greater or lesser extent in tegus, monitors, and certain other saurians (see Fig. 64.13C). Minor perforation of these membranes by the telescope will not cause any harm, but care is required

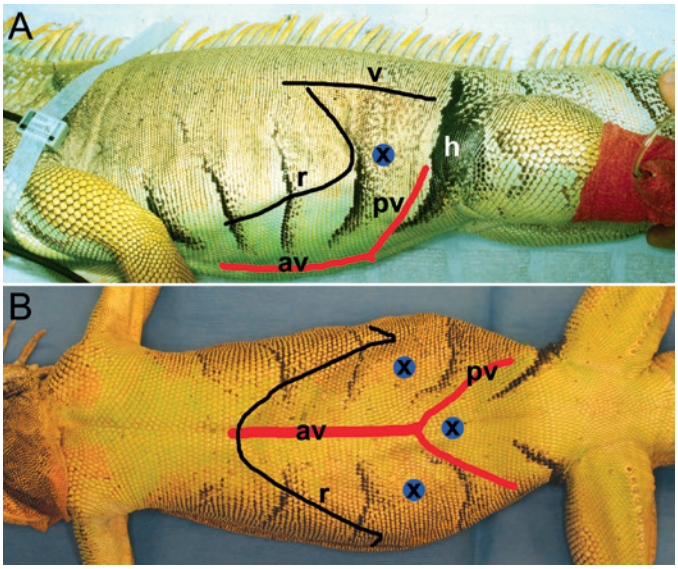

FIG 64.12 Common telescope entry sites for coelioscopy in lizards. (A) For a lateral entry into the coelom, the entry point (x) is bordered craniad by the last rib (r), dorsad by the lateral processes of the lumbar vertebrae (v), caudad by the musculature of the hind limb (h), and ventrad by the ventral abdominal (av) and pelvic veins (pv). (B) For a ventral approach to the coelom, insertion points (x) may be in the midline, behind the anastomoses of the lateral pelvic veins (pv), or lateral to the ventral abdominal vein (av), caudal to the last rib (r), and cranial to the pelvic veins (pv). (Courtesy of Stephen J. Divers.)

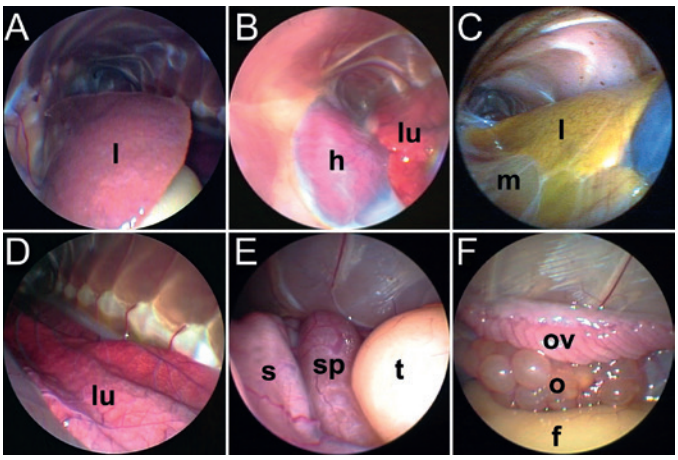

FIG 64.13 Lizard coelioscopy. (A) Left liver lobe (l) in a green iguana (*Iguana iguana*) (left lateral approach). (B) Heart (h) and lung (lu) in a green iguana—note the absence of a postpulmonary membrane (left lateral approach). (C) Left liver lobe (l) behind the post-hepatic membrane (m) in a monitor lizard (*Varanus* sp.) (left lateral approach). (D) Lung (lu) in a green iguana; note the absence of a postpulmonary membrane in this species (left lateral approach). (E) Stomach (s), spleen (sp), and testis (t) in a green iguana (left lateral approach). (F) Oviduct (ov), ovary (o), and fat body (f) in a green iguana (left lateral approach). (Courtesy of Stephen J. Divers.)

to avoid perforating the underlying viscera. Dorsal to the heart and extending to midcoelom are the paired lungs (see Fig. 64.13D). Lung ventilation will be substantially reduced during CO_2 insufflation, and careful communication with the anesthetist is required to balance ventilation and coelomic pressures. Caudal to the lungs, in the midcoelom, is the stomach with the spleen, an elongated dark red organ in iguanas,

VetBooks.ir

situated close behind (see Fig. 64.13E). Careful examination medial to the stomach and spleen will reveal the splenic limb of the pancreas. The gonads are located just caudal to the spleen, on either side of dorsal midline. Rigid endoscopy can be utilized to determine the gender of reptiles, even at a very early age. This is extremely useful in monomorphic species or when involved in an endangered species breeding program that requires gender identification of neonates or juveniles.[9] Endoscopy also provides feedback on reproductive activity and disease. The testis is usually ovoid and smooth, and size may vary dramatically with season (see Fig. 64.13E). The immature or inactive ovary appears as a cluster of small, fluid-filled follicles (see Fig. 64.13F). As the ovary matures some of the follicles will enlarge and appear yellow to orange in color as they fill with yolk. Some species of lizards have thin post-hepatic or postpulmonary membranes that may be pigmented and obscure the gonads. The membrane can be breached to allow better visualization by grasping and tearing with retrieval forceps or incising using scissors. Care must be taken not to damage the follicles because leakage results in coelomitis.

Dorsal to the gonads are the adrenal glands, which lie adjacent to the renal veins (see Fig. 64.14A). The vas deferens of males and oviducts of females are also visible and can be followed caudad to the pelvic inlet. The kidneys of most lizards are situated in the caudodorsal coelom; however, those of the iguana are intrapelvic but can still be visualized (see Fig. 64.14B). Moving ventrad from the pelvic inlet the bladder (if present) and fat body can be seen (see Fig. 64.14C). A left paralumbar approach will reveal the small intestine and terminal colon; however, a right paralumbar approach will provide access to the gallbladder and caecum (see Fig. 64.14D). The majority of the pancreas is easier to locate via a right approach, residing caudal to the liver and gallbladder and closely associated with the duodenum (see Fig. 64.14E). On the right side, the heart is partially obscured by the ascending vena cava (see Fig. 64.14F).

This approach to saurian coelioscopy has been validated, at least in the green iguana, and found to be both safe and effective.[7] In addition, endoscopic biopsies of liver and kidney have also been demonstrated to be safe and capable of producing samples of diagnostic quality.[8,10]

Snakes. Snakes are less commonly subjected to coelomic endoscopy because (1) they have more extensive coelomic fat, (2) it is impossible to examine all the major organs via a single entry point, and (3) insufflation is generally more difficult; however, targeted coeliotomy can be readily performed along the entire length of the coelom. If a targeted endoscopic approach to a single coelomic region is required, lateral entry between the ribs in larger snakes, and ventrolateral entry just medial to the ribs in smaller snakes, are practical options (Fig. 64.15A).[13] A recently developed technique for liver biopsy entails access via the pulmonoscopy approach to the serpentine air sac. From within the air sac it is possible to visualize and biopsy the liver (see Fig. 64.15B–D).

Chelonians. With the chelonian supported in lateral recumbency, the most useful coelioscopic approach is via the left or right prefemoral fossa (Fig. 64.16).[13] Right-handed surgeons will generally find it easier to enter the left prefemoral fossa, and left-handed surgeons the right. Again, unless unilateral pathology or organ asymmetry exists, the surgeon's preference can prevail. A large bladder can hinder coelioscopy, and chelonians should be encouraged to urinate prior to surgery. This can be achieved by bathing the animal or by gentle digital stimulation of the cloaca prior to anesthetic induction.

The pelvic limb is retracted and taped caudad to expose the prefemoral fossa. In chelonians with a well-developed plastron hinge (e.g., box turtles), it is wise to place a wedge between the caudal plastron and carapace to maintain exposure. Following aseptic preparation, a small (2–4 mm) craniocaudal skin incision is made in the center of the prefemoral fossa. The subcutaneous fat and connective tissues are bluntly

dissected using hemostats down to the coelomic aponeurosis (formed by the broad tendinous portions of the transverse and oblique abdominal muscles), being careful to remain cranial to the sartorius muscle and ventral to the iliacus muscle that lies between the femur and ventral surface of the ilium. The coelomic aponeurosis is penetrated by advancing hemostats (or the sheath with obturator) toward the head (i.e., parallel, not perpendicular, to the table). Some force is required to breach the coleomic membrane and gain access to the coelomic cavity. An objective evaluation of coelioscopy in freshwater turtles (*Trachemys scripta* spp) has been published.[45] This study evaluated the ability of the 2.7 mm telescope to visualize the coelomic viscera of red-eared and yellow-bellied sliders and collected diagnostic biopsies from liver and kidney. Ease of entry and organ visualization were satisfactory to excellent for all observed structures, except the spleen, which could only be located from the right side.[17]

The dark red-brown to tan liver is the most obvious organ to use for orientation (Fig. 64.17A). The heart is cranioventral to the liver and partially obscured by a prominent pericardium (see Fig. 64.17B). The stomach is most prominent on the left (see Fig. 64.17C) and, while potentially seen from either lateral, the pancreas and closely associated duodenum are easier to see from a right approach (see Fig. 64.17D). The gallbladder is obvious and associated with the caudal edge of the right liver lobe (see Fig. 64.17E), but the spleen is often hard to locate under the right liver lobe, close to the duodenum and pancreas (see Fig. 64.17F). The ventral aspects of the lungs are located dorsad and are most obvious in those species that lack a prominent postpulmonary membrane (Fig. 64.18A). The colon, gonads, oviducts (in females), bladder, and kidneys can be viewed from either side. The bladder is situated in the most dependent area, while the ovaries and oviducts of reproductively active females can occupy much of the coelom (see Fig. 64.18B and C). The male testes (cream, yellow, or brown in color) are situated in the caudodorsal coelom and are closely associated with the vasa deferentia, epididymides, adrenal glands, and retrocoelomic kidneys (see Fig. 64.18D). Recently, coelioscopy using saline-infusion has been shown to be accurate for identifying gender in hatchling and neonate chelonians. A study in Chinese box turtles (*Cuora flavomarginata*) concluded that gonads could be visualized and sex easily identified in animals as small as 10 g (see Fig. 64.18E and F).[9] More than 300 individual juveniles of various chelonian species have been subjected to early gender identification by coelioscopy (Fig. 64.19) (Divers S, unpublished data). Thus far, this technique has been found to be accurate and safe and has become established as a significant clinical service to breeders as well as curators of head-start conservation programs.

The kidneys are retrocoelomic, residing behind an often transparent coelomic membrane (Fig. 64.20A). When presented with a pigmented coelomic membrane, the close association with the testis (or immature ovary) can help indicate their location (see Fig. 64.20B). However, in adult females where the ovary and suspensory ligament have enlarged and fallen away from the pigmented coelomic membrane, it can be challenging to locate the kidneys unless they are grossly abnormal (see Fig. 64.20C).[17] An extracoelomic approach to the chelonian kidney is also possible in those species with a more flattened carapace and negates the need to enter the coelomic cavity. The sheathed endoscope is gently advanced from the same prefemoral skin incision in a caudodorsal

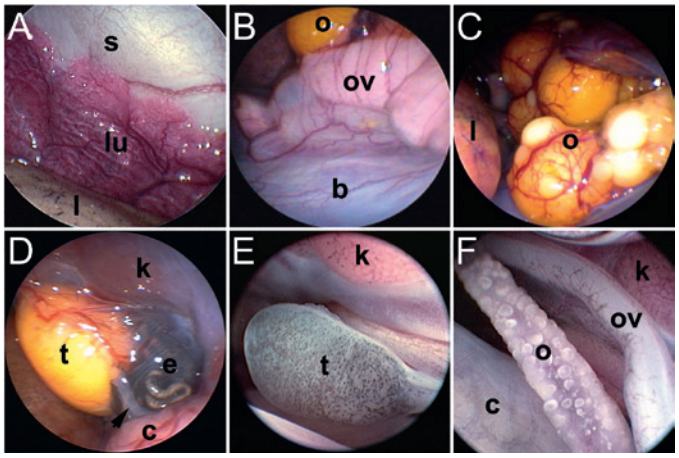

FIG 64.18 Chelonian coelioscopy. (A) View of the serosal surface of the dorsal shell (s), left lung (lu), and liver (l) in a red-eared slider (*Trachemys scripta elegans*) (left prefemoral approach). (B) Urinary bladder (b), oviduct (ov), and ovary (o) in an African spurred tortoise (*Centrochelys sulcata*) (left prefemoral approach). (C) Mature ovary (*o*) extending to the caudal edge of the left liver lobe (l) in a Hermann's tortoise (*Testudo hermanni*) (left prefemoral approach). (D) Testis (t), epididymis (e), and vas deferens (arrow) in the caudodorsal coelom of a red-eared slider. Note the closely associated retrocoelomic kidney (k) and the distal colon (c) (left prefemoral approach). (E) Immature testis (t) closely associated with the kidney (k) in a hatchling Chinese box turtle (*Cuora flavomarginata*) (left prefemoral approach with saline infusion). (F) Immature ovary (o) and oviduct (ov) closely associated with the kidney (k) and distal colon (c) in a hatchling Chinese box turtle (left prefemoral approach with saline infusion). direction between the coelomic aponeurosis and the broad iliacus muscle. A combination of gentle lateral movements of the telescope tip and intermittent insufflation are used to further separate the coelomic aponeurosis from the adjacent musculature to reveal the kidneys (see Fig. 64.20D).

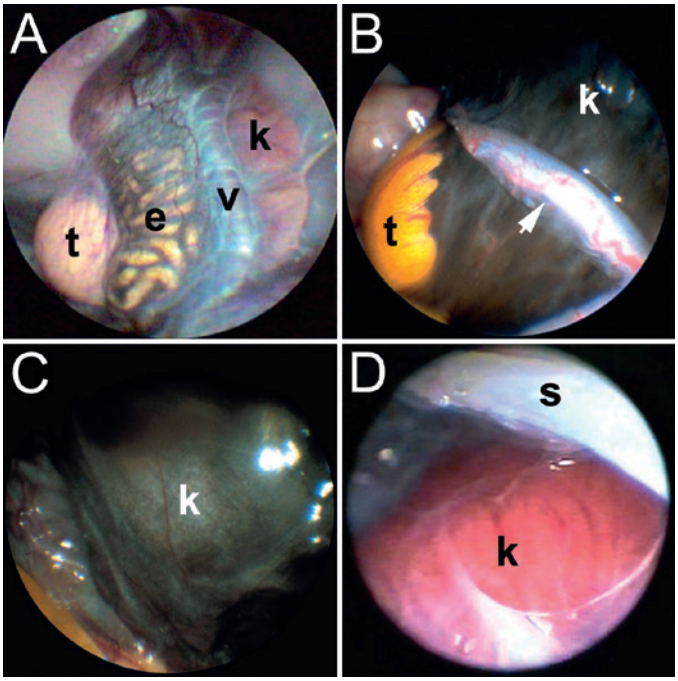

FIG 64.20 Chelonian renal examination. (A) View of the retrocoelomic kidney (k), renal vasculature (v), and closely associated testis (t) and epididymis (e) in a male red-eared slider (*Trachemys scripta elegans*). Note that renal visualization is possible thanks to the transparent nature of the coelomic membrane (left prefemoral approach). (B) View of the same caudodorsal region in an adult male Greek tortoise (*Testudo graeca*). The retrocoelomic kidney (k) is obscured by the pigmented coelomic membrane; however, its position can be determined by the obvious testis (t) and vas deferens (arrow) (left prefemoral approach). (C) View of the same caudodorsal region in an adult female Greek tortoise with the retrocoelomic kidney (k) obscured by a pigmented membrane. With no closely associated gonad to indicate the kidney's location, the endoscopist must rely on accurate anatomical knowledge alone (left prefemoral approach). (D) Direct, extracoelomic view of the kidney (k) and internal surface of the caudodorsal carapace (s) in a loggerhead sea turtle (left prefemoral approach). (Courtesy of Stephen J. Divers.)

Natural Orifice Transluminal Endoscopic Surgery (NOTES)

Natural orifice transluminal endoscopic surgery (NOTES) is an experimental surgical technique whereby "scarless" abdominal operations can be performed with an endoscope passed through a natural orifice (e.g., mouth, urethra, anus) then through an internal incision in the stomach, vagina, bladder, or colon, thus avoiding any external incisions or scars.[46] An increasing number of clinical procedures have been published in the human literature, and NOTES is considered the next frontier of human endoscopic surgery.[47] To date, the only reptile NOTES that the author is aware of involves the evaluation of gonads through the transparent bladder wall of juvenile tortoises (*Testudo marginata*).[26] This technique has the advantage of being less invasive (as the coelom is not entered), but it does not provide the same degree of visual acuity as direct examination and has been found to be unsafe in juvenile sliders (Proenca, unpublished data). Therefore in species where the immature gonads appear very similar or the bladder wall is less transparent, accuracy may be decreased (Fig. 64.21).

Pathology and Endoscopic Biopsy

A variety of pathologies may be appreciated endoscopically, often with surprisingly few clinicopathologic or discernible radiographic or

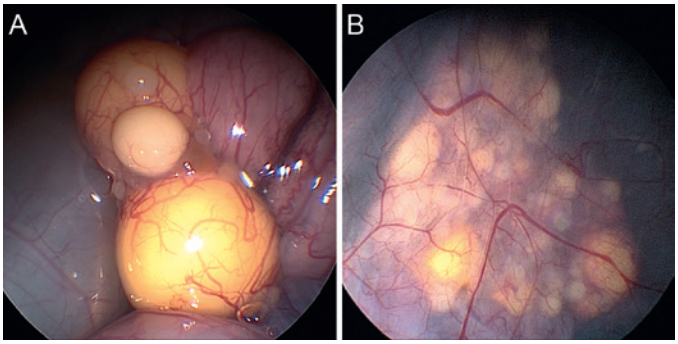

FIG 64.21 Endoscopic gender identification in the same adult female yellow-bellied slider (*Trachemys scripta scripta*). A comparison between direct examination by coelioscopy using CO_2 insufflation (A) and indirect examination using sterile saline and a translumenal technique across the accessory bladder wall (B, natural orifice translumenal endoscopic surgery). Note the reduced clarity of the ovary using the transluminal technique, which may be clinically significant when dealing with immature and less developed gonads. (Courtesy of Stephen J. Divers.)

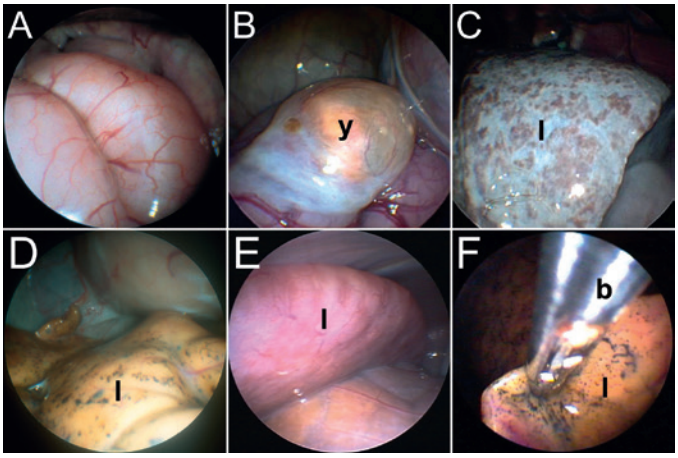

FIG 64.22 Endoscopic pathology and liver biopsy. (A) Grossly distended small intestine in a Russian tortoise (*Agrionemys horsfieldii*). This herbivorous tortoise was fed dairy products, which resulted in fermentative enteritis (left prefemoral approach). (B) Retained, inspissated yolk sac (y) in a juvenile radiated tortoise (*Astrochelys radiata*) that presented for intermittent anorexia and poor growth. Clinicopathology and diagnostic imaging were unremarkable but endoscope-assisted removal proved curative (left prefemoral approach). (C) Chronic hepatic fibrosis in a green iguana (*Iguana iguana*) that presented for anorexia and occasional regurgitation. Diagnostic imaging and clinicopathology were unremarkable. Endoscopic biopsy confirmed the diagnosis of severe hepatic fibrosis with cholestasis (left lateral coelioscopy). (D) Pale liver (l) in an Aldabra tortoise (*Aldabrachelys gigantea)* that presented with intermittent anorexia. All liver parameters were unremarkable, but severe hepatic lipidosis was diagnosed following liver biopsy (left prefemoral approach). (E) Diffuse hepatomegaly (l) in a green iguana that presented with lethargy and anorexia. Diagnostic imaging and liver biochemistry were unremarkable; however, moderate leukocytosis, predominantly heterophilia and azurophilia, was evident. Endoscopic liver biopsy confirmed the diagnosis as bacterial hepatitis due to *Klebsiella*, and appropriate treatment proved curative (left lateral coelioscopy). (F) Biopsy from the edge of the chelonian liver (l) using 1.7-mm biopsy forceps (b) (left prefemoral approach). (Courtesy of Stephen J. Divers.)

ultrasonographic changes (Fig. 64.22A–E). Tissue samples can be easily harvested from most organs and, in general, any abnormal soft tissue structure. Liver disease may be focal or diffuse, and although the caudal edge is easiest to sample, biopsies can also be taken from the surface by first incising the serosal covering (see Fig. 64.22F). A variety of renal diseases have also been described (Fig. 64.23A and B).[17,48] In lizards and snakes the lobulated kidney is easy to approach and biopsy directly (see Fig. 64.23C). However, in chelonians its flattened retrocoelomic position first requires incision of the coelomic membrane via a coelioscopic approach (see Fig. 64.23D–F). Endoscopic liver and kidney biopsies have been objectively assessed in freshwater turtles and green iguanas.[10,45,49] These studies have confirmed the ability of the 2.7-mm telescope to visualize and harvest samples from liver and kidney using the 1.7-mm biopsy forceps. No significant iatrogenic trauma was reported, and biopsy specimens were consistent with tissues collected at necropsy and were considered acceptable for histologic interpretation. Furthermore, the ability to diagnose renal diseases using endoscopic biopsy has also been demonstrated for a variety of chelonian species.[17]

Various studies have concluded that endoscopic biopsies are more diagnostic than ultrasound-guided aspirates or biopsies.[31,38,50] Endoscopic biopsies are delicate and measure approximately 1 mm^3 when collected using 1.7-mm forceps. Handling and other histologic artifacts are reduced by gently dislodging the tissue from the biopsy cups into a small volume of sterile saline, before then decanting into a biopsy cassette or bag, and submitting in 10% neutral buffered formalin (Fig. 64.24A).[11] Picking the biopsy out of the instrument using a needle will cause severe damage, and even moistened cotton-tipped applicators have been shown to cause tissue alteration (see Fig. 64.24B and C). Biopsies for microbiology are best submitted in sterile saline for immediate processing. Alternatively, if mailing to a laboratory, they should be submitted in appropriate transport media. For the submission of samples for toxicology or parasitology, it is wise to consult with the laboratory prior to sample collection.

POSTOPERATIVE CARE, COMPLICATIONS, AND OUTCOMES

Reptiles should be continuously maintained within their species-specific preferred optimum temperature zone and closely supervised until fully recovered from anesthesia. Opiates and meloxicam are often relied on for postoperative analgesia. Continued fluid therapy is more important than an immediate return to feeding. Typically, reptiles return to normal function and behaviors more quickly after endoscopic procedures compared with traditional surgeries. Sutures are removed at 6 to 8 weeks.

The major complications encountered are typically associated with anesthesia and advanced states of disease. The importance of a thorough preoperative evaluation and stabilization cannot be ignored but early endoscopic evaluation to reach a definitive diagnosis cannot be overemphasized. Minor hemorrhage following tissue biopsy is common but clinically insignificant. Return to normal behaviors and weight gain are often the most useful indicators of overall improvement. Serial clinicopathology can also be useful if abnormalities were detected preoperatively. Serial endoscopic evaluations can be used to monitor patients, especially because some diseases (e.g., hepatic lipidosis, glomerulonephrosis) may have a protracted course. Most endoscopy issues are related to poor or inappropriate equipment and/or operator error until competency has been achieved. To facilitate endoscopy caseload without compromising patient welfare, it is recommended that the surgeon obtains training and retains the option to convert to a traditional surgical approach if required.

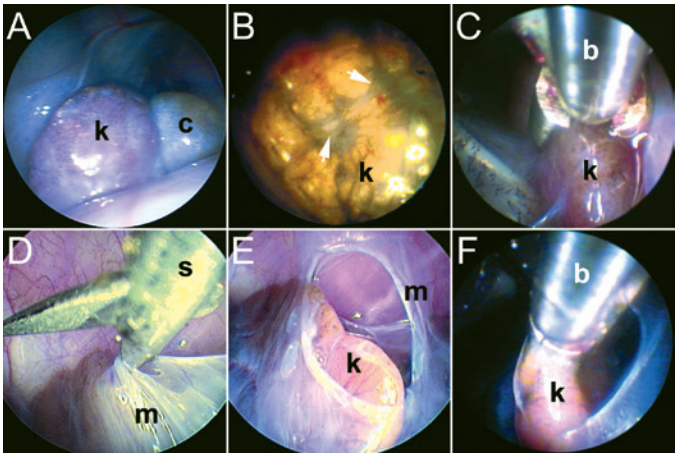

FIG 64.23 Endoscopic pathology and kidney biopsy. (A) Enlarged kidney (k) with associated renal cyst (*c*) in a green iguana (*Iguana iguana*) that presented with anorexia and cachexia. Radiography and ultrasonography confirmed renomegaly, while plasma biochemistry revealed reversed calcium:phosphorus ratio and elevated uric acid. Endoscopic biopsy confirmed the diagnosis of glomerulonephrosis with renal gout and mineralization (left lateral coelioscopy). (B) Abnormal kidney (k) with fibrous bands (arrows) in a female Greek tortoise (*Testudo graeca*) that presented with anorexia, lethargy, and polyuria. Diagnostic imaging and clinicopathology were unremarkable; however, renal biopsy confirmed the diagnosis as severe tubulonephrosis (left prefemoral approach). (C) Biopsy of an iguanid kidney (k) using 1.7-mm biopsy forceps (*b*) (right lateral coelioscopy). (D) Incising the caudodorsal coelomic membrane (m) of a yellow-bellied slider (*Trachemys scripta scripta*) using 1.7-mm endoscopy scissors (*s*) to gain access to the retrocoelomic kidney (left prefemoral approach). (E) View of the incised coelomic membrane (m) revealing the kidney (k) (left prefemoral approach). (F) Biopsy forceps (b) being passed through the incision to collect a biopsy from the kidney (k) (left prefemoral approach). (Courtesy of Stephen J. Divers.)

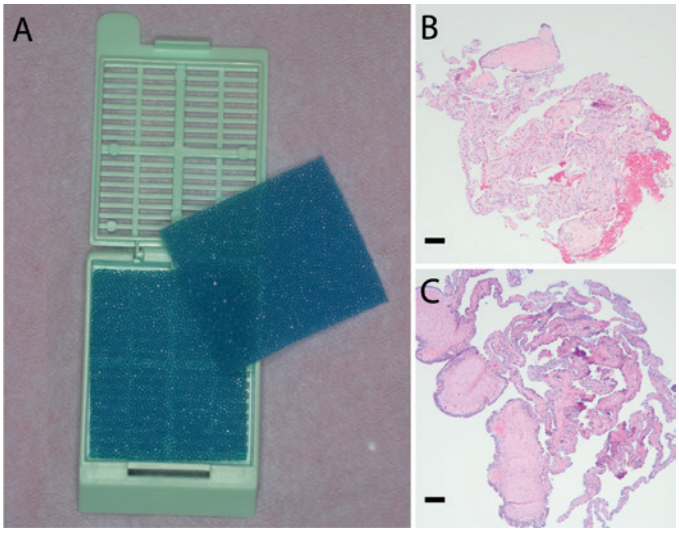

FIG 64.24 (A) Endoscopic biopsies are best sandwiched between foam and secured within a histology cassette. (B) Crush artifact in a snake lung biopsy caused by a cotton-tipped applicator used to transfer the tissue from forceps to histology cassette (H&E, bar = 300 µm). (C) Another snake lung biopsy exhibiting reduced artifact because it was shaken from the forceps into sterile saline before being decanted into the histology cassette (H&E, bar = 300 µm). ACKNOWLEDGMENTS

The author would like to thank Karl Storz Veterinary Endoscopy and, in particular, Dr. Chris Chamness, Mike Bateman, and Dan McMahon for supporting endoscopy research, development, and training at the University of Georgia. In addition, I am indebted to Drs. Scott Stahl, Charles Innis, Sam Rivera, and Jörg Mayer, as well as the large number of residents, for their collegiality and support in various endoscopic ventures. I am also fortunate to work with highly motivated and dedicated technicians, including Ashley Schuller, Nia Chau, Danielle Stewart, and Robert Miller, who collectively ensure that equipment is clean, functional, and protected from overzealous veterinarians.

Endoscope-Assisted and Endoscopic Surgery

Stephen J. Divers

In human medicine, endosurgery has been credited with numerous advantages over traditional open procedures, including reductions in pain, operating time, hospital stay, and convalescence periods.[1,2] Although such advantages may be less easily quantified or documented in zoological medicine, over the past decade there have been considerable advances in minimally invasive endosurgery of exotic species, including reptiles.[3–8] Considering that most reptiles weigh less than a few kilograms, the development of minimally invasive endosurgery would seem a logical evolution in their surgical care, particularly given the hindrances of the chelonian shell.[7–9]

The transition from a technique that is purely diagnostic (see Chapter 64) to one that is more complex and allows surgical manipulation requires additional equipment (see Chapter 62), and even more taxing, a more refined surgical skill set. It is no exaggeration that the technical difficulty associated with multiple-port endosurgery is a magnitude greater than that required for single-entry diagnostic endoscopy. This chapter is an extension of the previous chapter and should not be read in isolation. Only supplemental techniques are covered here, and a firm grounding in diagnostic endoscopy is assumed.

Endosurgical Principles and Techniques

As already indicated, endosurgery requires placement of the telescope and triangulation of additional instruments (Fig. 65.1). Advanced endosurgical skills can only be built upon a firm foundation in single-entry diagnostic endoscopy. Minor errors or inadequacies that can be tolerated in single-entry procedures are likely to become magnified, resulting in serious problems during endosurgery. Well-executed and atraumatic placement of the telescope is essential and can only come from practice. Poor technique will result in tissue damage, increased tissue fluid including blood on the terminal lens, and decreased visibility. The need to practice instrument triangulation and develop fine motor skills with limited tactile feedback in a three-dimensional environment may exceed the endoscopy caseload, at least initially. Therefore the reptile endoscopic surgeon must find additional means to practice and maintain skills. One method is to maintain equipment in a clean, yet nonsterile, state. This will not dissuade the veterinarian from using equipment to practice on a cadaver, as opening a sterile pack would. In addition, inexpensive artificial trainers can be readily made from supplies found at local hobby and home-improvement stores. A clear plastic Tupperware container can serve as the basis for such a trainer. First, a large square hole is cut from the lid and replaced with rubber matting. Several 4 mm holes can be made in the rubber top and in the front of the container to provide a selection of instrument access ports (Fig. 65.2). A variety of "endoscopy games" can be devised to be completed inside the box. These can include dissection of a drawn shape on tissue paper, picking up felt discs off one pin and transferring to a second pin, or even endoscopic suturing (Fig. 65.3).

Surgeon ergonomics also become increasingly important when fine motor control now becomes more complicated by the need to triangulate and establish a perception of depth using a two-dimensional monitor. The monitor should, whenever possible, be directly in front of the surgeon, who should be comfortably standing on a padded mat or sitting (Fig. 65.4). Finally, the usual degree of tactile feedback experienced when handling tissues with standard instruments is greatly reduced when working with endoscopic instruments at distances of 20 cm or more from the tissues (Fig. 65.5).

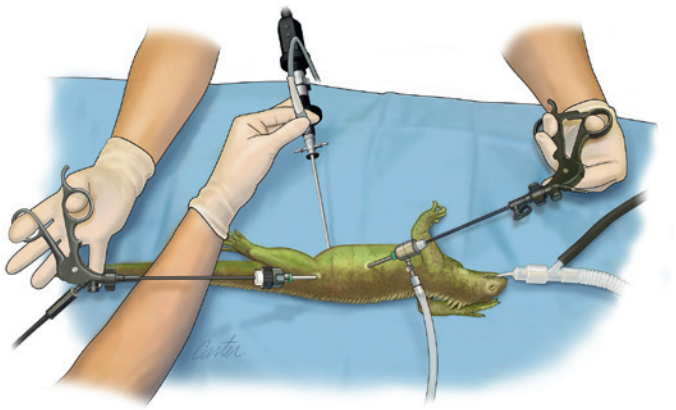

FIG 65.1 Illustration demonstrating instrument triangulation during left orchiectomy in an iguanid lizard. (Courtesy of Educational Resources, University of Georgia.)

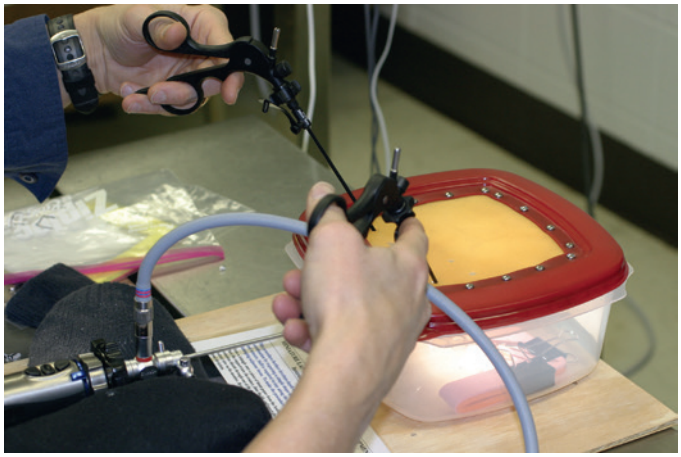

FIG 65.2 An endoscopy trainer fashioned from a modified plastic Tupperware container. Holes at the front permit the introduction of the telescope, which is supported using sand bags. The top has been largely replaced by a sheet of rubber containing several holes for the introduction of instruments. (Courtesy of Stephen J. Divers.)

VetBooks.ir

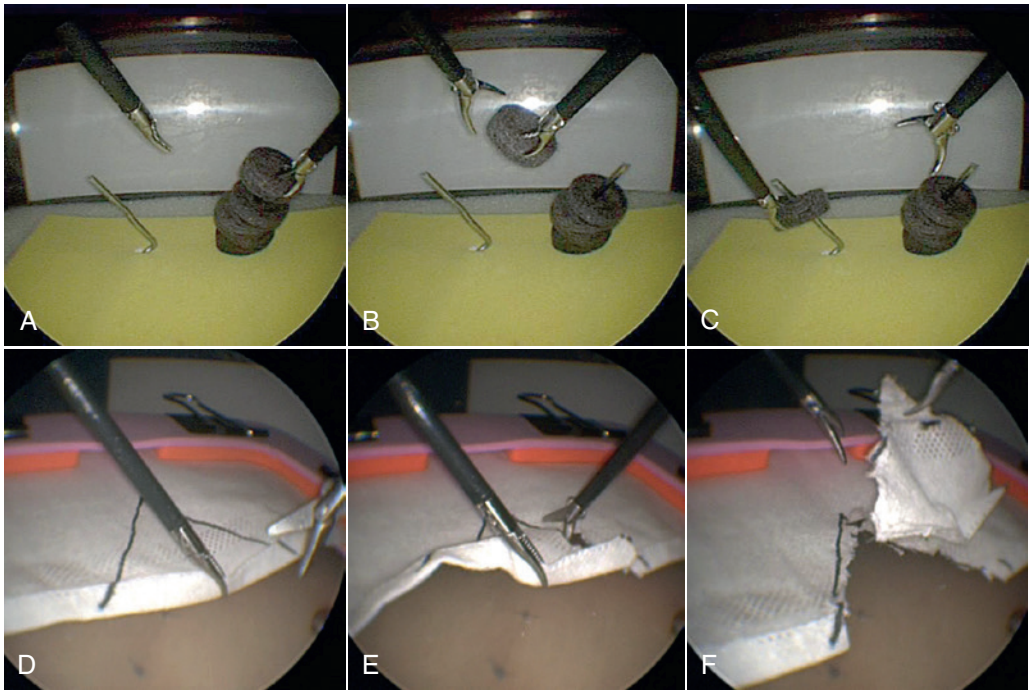

FIG 65.3 Endoscopy training exercises. (A–C) This basic exercise involves picking up a felt ring from one pin using forceps, exchanging the ring to a second pair of forceps, and then placing the ring on a second pin. This game helps with depth perception, instrument triangulation, and instrument to instrument transfer. It can be made more difficult by changing the orientation and direction of the pins. (D–F) This more difficult exercise involves using forceps and scissors to dissect a shape from a piece of tissue paper. This game helps with depth perception, instrument triangulation, and instrument dexterity. It can be made more difficult by increasing the complexity of the shape and by swapping the scissors and forceps. (Courtesy of Stephen J. Divers.)

FIG 65.4 Proper positioning and orientation of the surgeon(s) to the patient and monitor becomes increasingly critical with endosurgery. In this example, the two surgeons are perpendicular to the monitor while they perform endosurgery in a small chelonian. (Courtesy of Stephen J. Divers.)

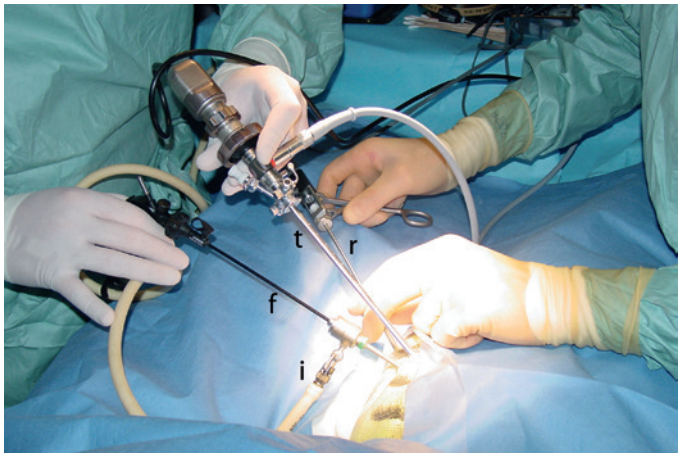

FIG 65.5 Tactile feedback and sensation is reduced during endosurgery because tissues are manipulated at a greater distance than with traditional surgery. This photograph also demonstrates the concept of triangulation with the two instruments on either side of the camera but converging toward the common endoscopic field of view. (Courtesy of Stephen J. Divers.)

ENDOSCOPE-ASSISTED PROCEDURES

An endoscope-assisted procedure is a hybrid that combines elements of endoscopy with traditional surgery. In its simplest form, an endoscope-assisted procedure uses endoscopy to identify and grasp an internal structure, which is then exteriorized through a miniature coeliotomy incision for completion of the procedure outside the body cavity. The advantages of endoscope-assisted procedures are that they decrease the size of the coeliotomy incision and exposure of internal viscera to the environment. An assortment of endoscope-assisted coelomic procedures, including enterotomy, enterectomy, cystotomy, salpingotomy, and salpingohysterectomy, are now possible. These techniques rely on the ability to exteriorize the tissue of interest out through a small, targeted coeliotomy incision. If the tissue cannot be exteriorized then

the procedure cannot be completed externally, and a true endosurgical technique is required.

Endoscope-assisted procedures have been most commonly used in chelonians, where a soft tissue prefemoral approach has now superseded the need for transplastron coeliotomy in many situations. Of particular practical relevance is endoscope-assisted, prefemoral oophorectomy (or ovariectomy) of mature female chelonians that negates the need for a transplastron coeliotomy.[10] By virtue of the extensive mesovarian found in mature females, an endoscope-assisted procedure is practical in animals weighing a few hundred grams to 100 kg or more (Fig. 65.6).[10,11] With the chelonian in dorsal recumbency, a unilateral surgical approach to the coelom is made via one prefemoral fossa. The telescope is inserted into the coelom and used to locate the ipsilateral ovary. Then, using the telescope to guide atraumatic forceps (or even long hemostats in small chelonians), the interfollicular tissue is grasped and gently elevated to the skin incision. Once the first follicle is exteriorized, the telescope is no longer required, as the ovary is carefully manipulated out of the coelom. Once the entire ovary is exteriorized, oophorectomy proceeds using traditional techniques. The same procedure is repeated for the contralateral ovary, but it is usually not necessary nor recommended to remove the oviducts unless diseased. In most species, both ovaries can be removed from the same incision; however, in some terrestrial tortoises with particularly restrictive prefemoral fossae or voluminous large intestinal tracts or bladders, it may be necessary to perform a bilateral procedure. The prefemoral approach is closed routinely. This technique has several advantages over traditional transplastron approaches, namely, less invasive with faster healing.

Similar endoscope-assisted procedures have also been accomplished for the removal of retained eggs, bladder calculi, and gastrointestinal foreign bodies. The general technique and endoscopy skills are very

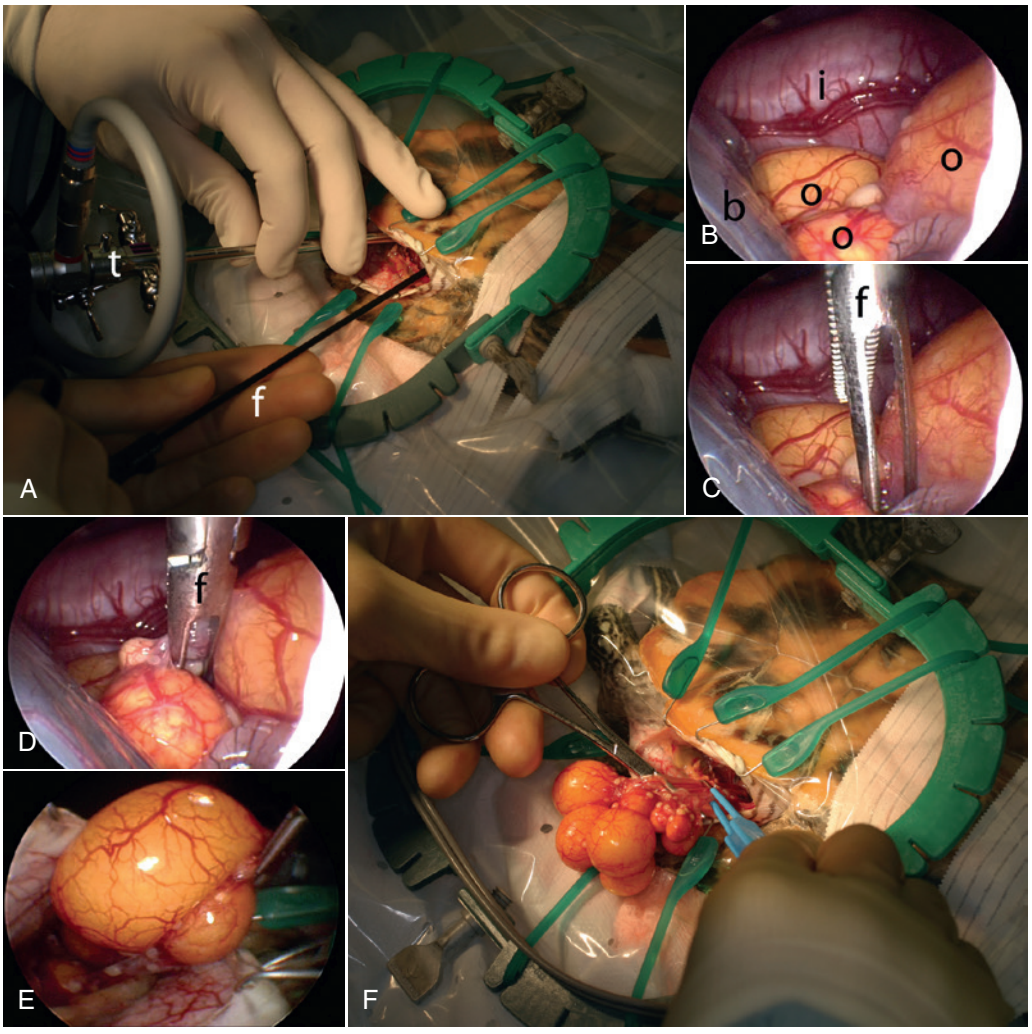

FIG 65.6 (A) Endoscope-assisted oophorectomy in an adult red-eared slider (*Trachemys scripta elegans*). (A) Following a prefemoral approach to the coelom, the ipsilateral ovary is located and retracted to the incision using the telescope (t) and 3 mm atraumatic forceps (f). (B) Endoscopic view of the caudal coelom demonstrating the ovary and three large ova (o), closely associated with the bladder (b) and gastrointestinal tract (i). (C) Endoscopic view of 3 mm atraumatic forceps (f) being used to grasp the interfollicular tissue. (D) Endoscopic view of the ovary being gently retracted toward the prefemoral incision. (E) External view (taken using the telescope) demonstrating the first two follicles of the ovary exteriorized through the prefemoral incision. (F) Continued manipulation to exteriorize the whole ovary precedes surgical oophorectomy using radiosurgery. In many species, the contralateral ovary can also be removed through the same prefemoral incision. (Courtesy of Stephen J. Divers.)

VetBooks.ir

similar. First, diagnostic imaging is used to determine which side is favored for the approach. Then following a prefemoral coeliotomy, the telescope is used to identify the structure of interest and guide atraumatic tissue forceps. While any tissue that is due to be resected and removed can be grasped using Kelly or Babcock forceps (or similar), any tissue that is to ultimately be replaced should ideally be handled using atraumatic or fenestrated forceps. This is especially important when handling the bladder, gastrointestinal, or reproductive tracts.

ENDOSURGERY

To date, endosurgery has been more commonly performed in chelonians, although endosurgical orchiectomy of iguanids has also been described.[7] Although established endosurgical dogma dictates that telescopes are often placed through the umbilicus or linea alba and instrument ports are placed far enough apart to facilitate triangulation, reptile anatomy often necessitates a modified approach.

Endosurgical procedures usually commence with the placement of the telescope cannula, and two main techniques are commonly used. Either the telescope cannula is surgically placed via a mini-coeliotomy incision, after which the CO_2 line is attached and the coelom insufflated, or a Veress needle can be used. Placing the telescope cannula surgically, as preferred by the author, ensures intracoelomic placement, reduces the risks of iatrogenic trauma, but does require a mattress suture around the cannula to close the incision and prevent gas leakage.

Chelonians

Due to the constraints of the chelonian shell, it is seldom possible to place the telescope and ports where established protocols would suggest. There are two major approaches, depending upon the size of the animal. For larger chelonians, the telescope and instruments may all be inserted through one prefemoral fossa (Fig. 65.7), while in smaller animals the telescope and instruments may be placed through one or both fossae (Fig. 65.8). There are advantages and disadvantages to both approaches. Placing all instrumentation through a single fossa enables the surgeon to control both instruments even in large animals, but instrument triangulation and coordinated use can be more difficult due to the acute angles involved (often ≤20 degrees) because instruments run more parallel. Nevertheless, compared to a bilateral fossa technique, a unilateral approach is less invasive, with only a single surgical approach required, and in addition enables the animal to be positioned in lateral recumbency, which may aid organ visualization. A single surgeon can utilize both prefemoral fossa in smaller animals, but here the angle of triangulation is often obtuse (90–180 degrees), again making coordinated instrument manipulation more challenging. If the target structure is cranial to the bladder and the chelonian is less than 20 kg, it is often preferable for one instrument and telescope to be inserted through one prefemoral fossa, while the second instrument is inserted through the contralateral fossa. For such procedures, the animal is in dorsal recumbency and enjoys the advantage that instruments can be more easily triangulated within the cranial to mid coelom. However, in larger chelonians it can be difficult to impossible for a single surgeon to operate through both prefemoral fossa simultaneously, and in such cases a second surgeon is required to operate through one fossa. The endosurgical approach to caudal structures (e.g., bladder, kidney, adrenal, gonad) is more problematic as it is often difficult to access the same structure simultaneously from both fossae. Therefore where a caudal structure is the focus of the procedure, insertion of telescope and instruments through a single prefemoral fossa is often preferable. In such cases, the chelonian is generally positioned in dorsal or lateral recumbency, which provides greater accessibility as the intestines and bladder fall away into the more dependent areas of the coelom. This approach is easier in those animals with a large prefemoral fossa, but even so the close placement and parallel nature of instrumentation can make triangulation more difficult. In addition, it is often easier (especially in smaller animals) to make a single large prefemoral incision for the insertion of all instruments, rather than place three cannulae adjacent to one another (see Fig. 65.7). Insufflation is seldom essential due to the noncollapsible nature of the chelonian shell, and therefore endoscopic devices can still be used through an incision without the need for cannulae.

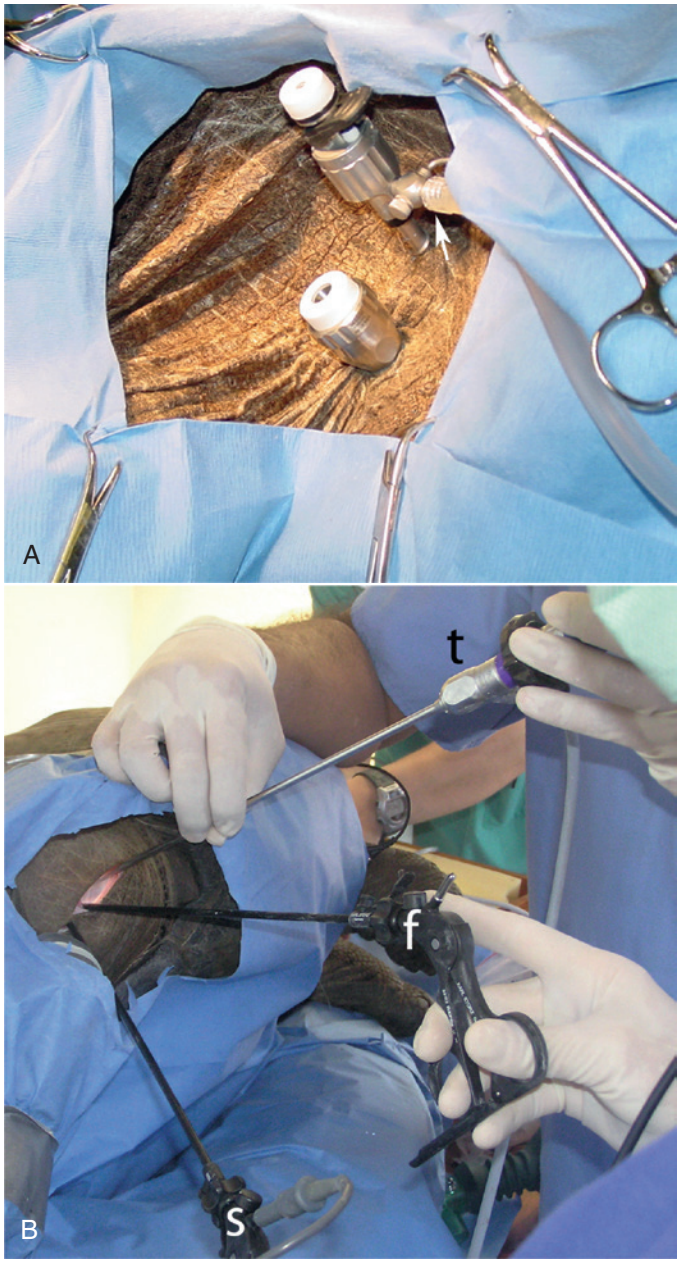

FIG 65.7 (A) Placement of two 6-mm Ternamian endotip cannulae, one with an insufflation port and CO_2 line attached (arrow) through the prefemoral fossa of an Aldabra tortoise (*Aldabrachelys gigantea*). (B) Surgical view of a juvenile Galapagos tortoise (*Chelonoidis nigra*) undergoing endoscopic oophorectomy. The telescope (t), held by an assistant, with grasping forceps (f) and radiosurgical scissors (s) operated by the primary surgeon, have all been introduced via a single prefemoral incision, rather than using separate cannulae. (Courtesy of Stephen J. Divers.)

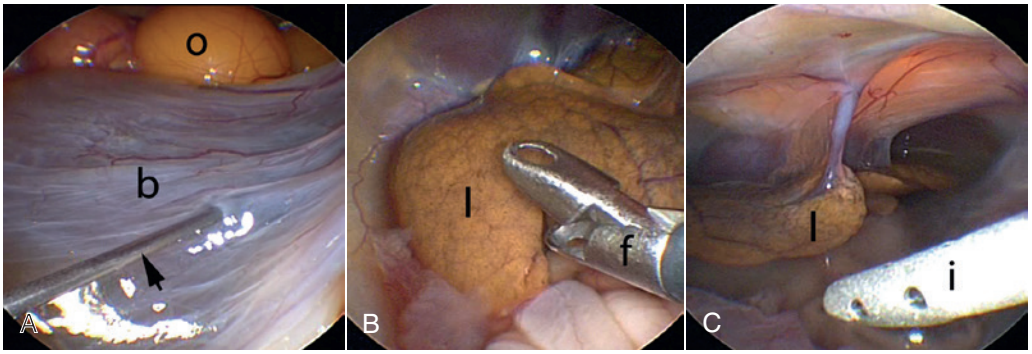

FIG 65.8 (A) Endoscopic view of the caudal coelom demonstrating the bladder (b) and right ovary (o) as seen through a left prefemoral approach in a box turtle (*Terrapene carolina*). In this example, an aspiration needle has been placed through the same left fossa and is being used to perform cystocentesis and collapse a full bladder. (B and C) Endoscopic views of the cranial coelom and liver (l) of another box turtle with ascites, as seen through the left prefemoral fossa. Biopsy forceps (f) and irrigation/suction cannula (i) have been introduced through the right fossa, which provides greater instrument triangulation. (Courtesy of Stephen J. Divers.)

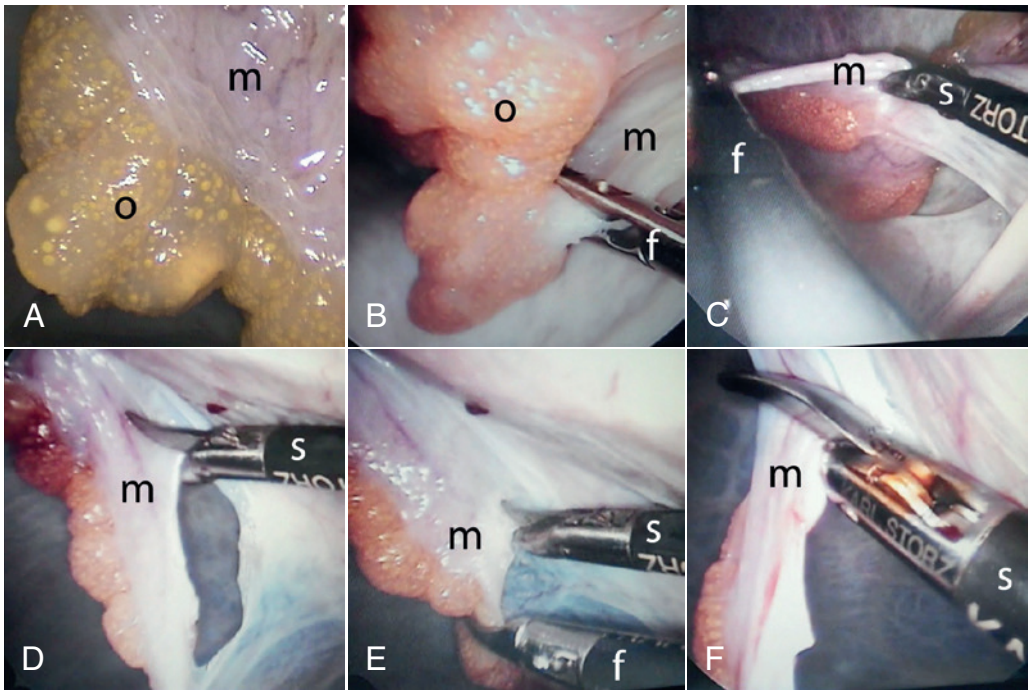

FIG 65.9 Endoscopic left oophorectomy in a juvenile Galapagos tortoise (*Chelonoidis nigra*) with all instrumentation inserted through the left prefemoral fossa as shown in Fig. 65.7B. (A) Normal, immature, left ovary (o) suspended from the caudodorsal body wall by a short mesovarium ligament (m). (B) Grasping forceps (f) are introduced and used to grasp the mesovarium (m) but not the friable ovary (o). (C) The mesovarium (m) is stretched by moving the forceps (f) cranially, while radiosurgical scissors (s) are used to incise through the suspensory ligament. (D–F) Dissection through the mesovarium (m) continues using forceps (f) and scissors (s) until the ovary is dissected free and can be removed through the prefemoral incision. The incision is closed before the procedure is repeated via the right prefemoral fossa to remove the contralateral ovary. (Courtesy of Stephen J. Divers.)

Oophorectomy of Immature Females

Intracorporeal oophorectomy has been described in immature, Galapagos tortoises (*Chelonoidis nigra*) using 5 mm instrumentation.[11] However, there is no reason why this same technique could not be applied to smaller chelonians with suitably sized (3 mm) instrumentation. In addition, this technique provides a model for other possible endosurgical procedures. The paired, immature ovaries reside within the caudodorsal coelom, and in close association with the retrocoelomic kidney. The bladder often obscures the contralateral ovary, and so a bilateral endosurgical approach is often necessary. With the animal in lateral recumbency, a prefemoral approach to the coelom is made in order to accommodate the telescope and two instruments via a single incision (see Fig. 65.7B). Cannulae generally are not helpful because the instruments are so closely aligned and insufflation is not required. The telescope is positioned and held by a surgical assistant or mechanical arm in order to maintain the view of the ovary. The immature ovary is elevated away from the serosal surface of the kidney and caudodorsal shell using Babcock or Kelly forceps, and monopolar scissors are used to dissect the ovary free from its mesovarian attachments (Fig. 65.9). The prefemoral incision is closed routinely, and the procedure is repeated on the opposite side.

Orchiectomy

Researchers originally developed a similar approach for safe and effective orchiectomy, using the red-eared slider (*Trachemys scripta elegans*) as a model.[12] The animal is again positioned in lateral recumbency and, following prefemoral coeliotomy, a surgical assistant identifies and maintains a clear view of the testis (Fig. 65.10). The endosurgeon then uses Babcock or Kelly forceps to grasp and elevate the testis away from the kidney and epididymis to expose the mesorchium and associated vessels. Both monopolar radiosurgery and vascular clips have been used to ensure hemostasis before scissors are used to dissect the testis free (Fig. 65.11). At least in *Trachemys* it is possible to remove both testes via a unilateral prefemoral approach.

Further procedural development was required to permit orchiectomy in larger tortoises where the mesorchial attachments are typically more substantive and require extensive dissection to free the testis. Using the desert tortoise (*Gopherus agassizii*) as a model, a single-surgeon technique was developed that employed a mechanical support arm for the telescope, freeing the surgeon to utilize a combination of endoscopic vascular clips and radiosurgical dissection to dissect each testis free (Figs. 65.12 and 65.13).[13]

Lizards

It is particularly important to remember that the standardized placement of cannulae through the linea alba cannot be applied to most lizards due to the presence of the midline abdominal vein; however, placement of a midline cannula, caudal to the umbilicus, is certainly practical and often preferred, particularly in iguanids (Figs. 65.14 and 65.15).

Orchiectomy

With the iguana in right lateral recumbency, the telescope and protection sheath are inserted, just lateral to the ventral midline, close to the anastomosis of the left and right pelvic veins as they form the ventral abdominal vein. The first cannula is placed cranial to the telescope, just caudal to the last rib, while the second cannula is placed caudal to the anastomosis of the pelvic veins in the ventral midline (see Figs. 65.14C and 65.15). Grasping forceps are inserted through one cannula and used to elevate the testis, while scissors (attached to monopolar radiosurgery) are inserted through the other cannula and used to coagulate and cut through the mesorchium and associated vessels (Fig. 65.16). In larger iguanas, bipolar forceps are used to coagulate blood vessels prior to scissor dissection. The testis is extracted through the forceps cannula hole, which can be enlarged using hemostats if necessary. The cannula holes are closed with a single suture or tissue adhesive. The iguana is rotated into left lateral recumbency, and using the same telescope entry site, the procedure is repeated for the second testis.

ENDOSCOPY TRAINING

The ability to perform diagnostic endoscopy and endosurgery is not innate, and training is certainly required. Fortunately, various continuing

education courses offer training in the United States, Europe, and less commonly elsewhere. The Association of Reptilian and Amphibian Veterinarians (https://www.arav.org) regularly offers a 4-hour introduction to reptile endoscopy at the annual conference. In addition, the University of Georgia offers a 2- to 3-day course in reptile, avian, and small mammal diagnostic endoscopy and endosurgery every December (http://www.vet.uga.edu/CE/).

ACKNOWLEDGMENTS

The author would like to thank Karl Storz Veterinary Endoscopy, especially Mike Bateman and Chris Chamness, for supporting endoscopy research, development, and training at the University of Georgia. In addition, I am indebted to Drs. Scott Stahl, Charles Innis, Sam Rivera, Randon Feinsod, Joe Flanagan, and Joerg Mayer, as well as numerous students, interns, and residents for their collegiality and enthusiasm in pursuing various endoscopic ventures at the University of Georgia.

Urology

Stephen J. Divers and Charles J. Innis

Continued strides in captive husbandry and nutrition have resulted in many reptiles surviving to adult and geriatric ages. Nevertheless, renal disease remains a major cause of morbidity and mortality, particularly among older reptiles, and continues to be of significant concern to veterinarians and owners alike.[1–3] Protein excess, dehydration, overheating, and secondary nutritional hyperparathyroidism are considered common predisposing factors for the development to chronic renal disease, while acute renal failure, infectious or toxic in nature, tends be less common and sporadic.[1–4]

GROSS ANATOMY

The reptilian urinary tract consists of paired kidneys, ureters, urodeum, and the bladder or cloacocolon (Fig. 66.1). In those species with a bladder, urine enters the bladder via the urodeum of the cloaca and urethra, not directly from the ureters. In those species without a bladder, urine storage may occur within distal, dilated ureters, or within the cloacocolonic region (Table 66.1). Unlike mammals, reptiles do not have separate external orifices for the discharge of urinary and digestive wastes. The cloaca is divided into three regions: (1) the coprodeum is most anterior and receives waste products from the large intestine; (2) the middle section, or urodeum, receives the ureters, urethra, and genital ducts and in some species the genital ducts and ureters enter the urodeum separately, however in other species they fuse before entering the urodeum (Fig. 66.2); and (3) the last, posterior section, proctodeum, receives waste and urogenital products, which are discharged through the vent.

Order Squamata: Suborder Sauria

The saurian kidneys may be located within, or cranial to, the pelvis (Fig. 66.3). The kidneys are paired, symmetrical, elongated, slightly lobulated, and often flattened, dorsoventrally in most species and laterally in chameleons.[5] In some species, the caudal aspects of the kidneys are fused (e.g., iguanas), while in others (e.g., water monitors) they remain separate. The kidneys of mature males can undergo hypertrophy of the distal convoluted tubules (sexual segment) to produce secretions for seminal fluid.

A fully developed bladder, connected to the urodeum by a urethra, is present in many saurians; however, in others the bladder may be small, rudimentary, or absent (Table 66.1, Fig. 66.4). A rudimentary bladder exists in some agamas, Australian dragons, banded geckos, zebra-tailed lizards, collared lizards, spiny lizards, tree lizards, and night lizards. Apart from a single report of a bladder in western whiptail lizard (*Cnemidophorus tigris*), members of the Teiidae do not possess a bladder, nor do snake lizards or horned lizards. Most monitors appear to lack a bladder, although there is some controversy with ultrasonography demonstrating a bladder in water monitors (*Varanus marmoratus*) but not in savannah monitors (*Varanus exanthematicus*).[6–8]

Like all reptiles, the saurian kidney is supplied by both arterial and portal venous supplies (Fig. 66.5).[9,10] Arterial blood is supplied by a variable number of renal arteries that branch off the aorta. These arteries form an interlobular arterial supply that deliveries blood to the afferent arterioles of the glomeruli. The efferent arterioles from the glomeruli then supply the peritubular capillary network. The portal venous supply is formed by the returning blood from the tail (via the caudal vein)

TABLE 66.1 Presence of Urinary Bladders in Different Reptiles

Taxa With Well-Developed Urinary Bladders	Taxa With Rudimentary Urinary Bladders	Taxa Without Urinary Bladders
Chelonia	**Lizards**	**Snakes**
Rhynchocephalia	Agamidae	**Crocodilians**
Lizards	Gekkonidae	**Lizards**
Anguidae	Coleonyx	Teiidae (except *Cnemidophorus tigris*)
Chamaeleonidae	Iguanidae	Varanidae* (except *V. marmoratus*)
Gekkonidae	Callisaurus	Pygopodidae
Gekko	Cophosaurus	Iguanidae

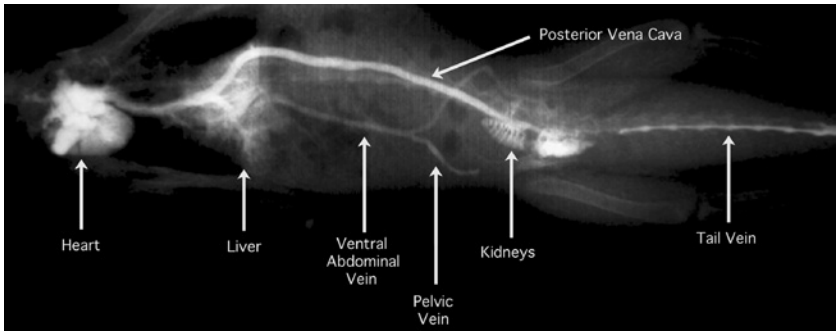

FIG 66.6 Contrast angiography showing the major vascular anatomy of the green iguana (*Iguana iguana*). Renografin-60 (Diatrizoate Megulime and Sodium, Squibb, NY), a high osmolar contrast medium (292 mg I/mL), was injected at a dose of 2 mL/kg body weight into the caudal tail vein. The radiograph was exposed immediately after the injection was administered. (Courtesy of L. Pace.)

and hind legs (via the iliac veins). This venous blood enters the left or right afferent renal portal veins that supply their respective kidneys. In the kidneys, this portal blood enters a series of capillaries that perfuse the renal tubule cells but not the glomeruli. Venous blood from the renal tubules drains into the interlobular efferent veins and then into the renal veins before fusing to form the postcaval vein, which conveys blood back to the heart (Fig. 66.6). Pelvic veins connect to the iliac veins before their attachment with the afferent renal portal veins and can divert blood around the kidneys into the single ventral abdominal vein. From here, the blood flows to the liver.

Suborder Serpentes

Boid kidneys are paired, flattened, and elongated organs that contain 25 to 30 lobules (Fig. 66.7A), except for dwarf and rough boas (Tropidophiidae), whose kidneys are not lobulated.[5,11] The right kidney lies cranial to the left, and studies have reported renal position as a proportion or percentage of the distance between the snout and the cloaca (76%–84% in boids, 84%–96% in colubrids, 80%–92% in elapids, and 84%–96% in viperids).[11,12] The kidneys occupy approximately 10% to 15% of the snake's body length and can hypertrophy and become paler due to sexual segment development in mature males (see Fig. 66.7B). A ureter connects each kidney to the urodeum (see Fig. 66.2B). There is no urinary bladder, but urine may be stored in the distal colon or in dilated distal ureters.[5]

Arterial blood supply is similar to that of the Sauria (Fig. 66.8). The venous blood flow is also similar except for the absence of iliac veins. Blood can bypass the kidneys through the mesenteric vein, which receives connections directly from the afferent renal portal veins. The mesenteric venous blood is carried to the liver. The abdominal vein is present and is connected to the afferent renal portal veins in some species (e.g., African rock python, *Python sebae*), while in others it originates in the fat bodies.[9]

Order Rhynchocephalia

The kidneys of the Tuatara (*Sphenodon punctatus*) are similar to those of lizards. They are paired, single-lobed, and crescentic in outline, located

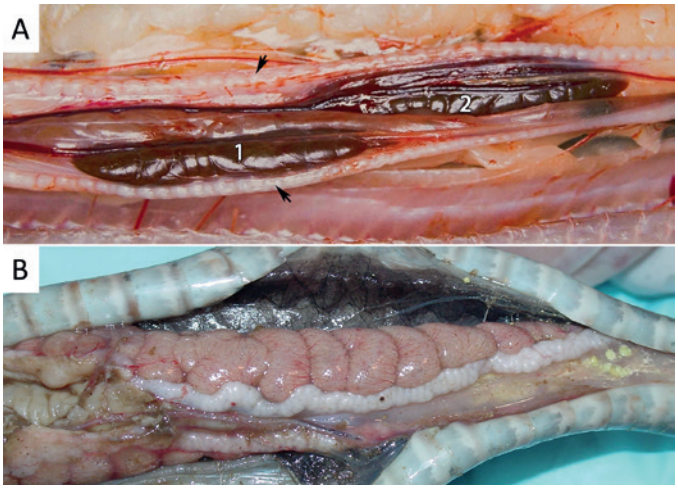

FIG 66.7 (A) Right (1) and left (2) snake kidneys with closely associated vasa deferentia (*arrows*). (B) Pronounced swelling and pallor of the left kidney due to sexual segment proliferation in a reproductively active male snake. (Courtesy of Stephen J. Divers.)

dorsally within the pelvic canal. The 2 kidneys meet posteriorly, but they do not fuse.[5] The blood supply is also similar to lizards; however, no direct connection exists between the iliac veins and the abdominal vein. A connection to the abdominal vein has been postulated to exist within the body of the kidneys.[13] A bladder is present.

Order Testudines

Chelonian kidneys are paired, retrocoelomic, and lie in the caudodorsal coelom just ventral to the caudal carapace (Fig. 66.9A). In marine turtles, the kidneys are cranial to the pelvic girdle. The kidneys are flattened, lobulated, and symmetrical (see Fig. 66.9B). Ureters leave the kidneys and enter the urodeum, close to the opening of the urethra, which connects the bladder to the urodeum (see Fig. 66.9C).[5] The bladder is a single large or bilobed structure, and smaller bilateral accessory bladders usually exist on either side of the urodeum. Arterial and venous blood supply is similar to that of the lizards; however, two abdominal veins are found that are linked by a transverse anastomosis (Fig. 66.10).[9]

Order Crocodilia

Crocodilians have paired lobulated kidneys that lie against the dorsal body wall adjacent to the spinal column. The left kidney may be larger than the right kidney. Ureters enter the cloaca at the urodeum. No urinary bladder exists.[5] Arterial and venous supply is similar to the

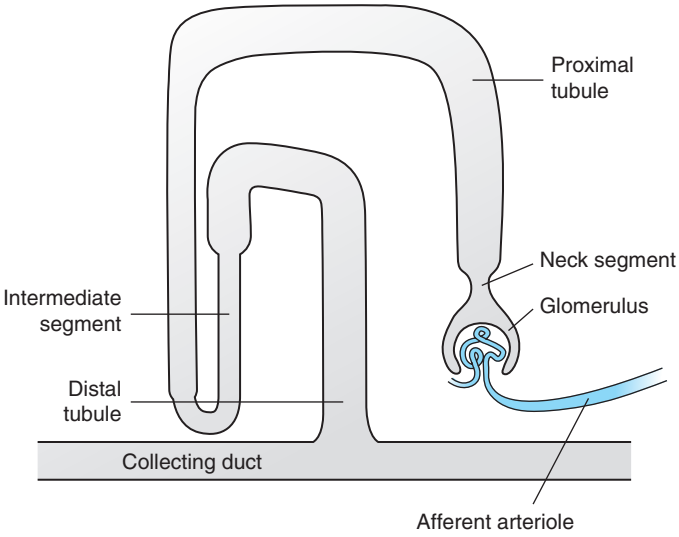

FIG 66.13 The reptilian nephron. The glomerulus is followed by the neck segment, the proximal tubule, the intermediate segment, and the distal tubule.

lizards. However, two abdominal veins each connect to an iliac vein, and as for snakes, a mesenteric vein originates from the afferent renal portal veins (Fig. 66.11).

MICROSCOPIC ANATOMY

Reptilian kidneys have no pelvis or pyramids and are not divided into medulla and cortex (Fig. 66.12). They contain a few thousand nephrons, compared with the typical million or so of mammalian kidneys.[5] Where measured, reptilian nephrons are 2 to 8 mm long, compared with bird nephrons that are approximately 18 mm and human nephrons that are 30 to 38 mm.[14] Each nephron is oriented at right angles to the long axis of the kidney and enters the collecting duct at right angles. The renal corpuscles lie in a circular pattern near the midportion of each lobule.[15]

Structurally, reptilian glomeruli are less developed, with a lower number of capillaries per gram body weight compared with birds.[14] The glomerulus is followed by the neck segment, proximal tubule, intermediate segment, and distal tubule (Fig. 66.13). There is no loop of Henle (ansa nephroni). All of the segments, except the distal tubule, consist of ciliated cuboidal cells. The cells of the distal tubule lack cilia. The distal tubule is followed by the sex segment in male squamates. The cells are flat and filled with mucus during the nonbreeding season; however, during reproductive activity, these cells increase in height two to four times and are filled with large refractile granules that stain brightly eosinophilic with hematoxylin and eosin.[16] They contain acid phosphatase, phospholipids, glycoprotein, mucoprotein, and amino acids. The function of the sex segment secretions has not been definitively determined; however, a number of theories have been proposed, including

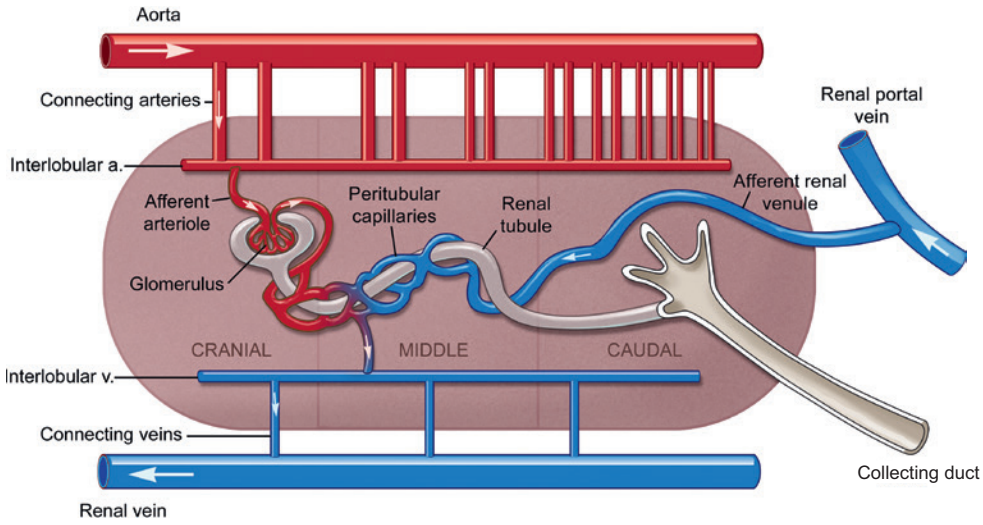

FIG 66.14 Schematic illustration of the nephron and associated vasculature in a green iguana (*Iguana iguana*) kidney. (Courtesy of Educational Resources, University of Georgia.)

(1) creation of a copulatory plug to prevent rivals from mating successfully, (2) blockage of the tubules during copulation to functionally separate semen and urine, or (3) as an activator or source of sustenance for sperm survival.[16]

After the sex segment, the nephron terminates with the collecting duct. These cells are similar to those contained within the sex segment, except mucus is only present at the tip of the cell. The collecting ducts are oriented at right angles to the long axis of the kidney. They originate on the dorsolateral surface of each lobule, wrap around the lateral margin of the lobule, and pass ventrally into the ureter, which lies on the ventromedial surface of the kidney.

Blood supply to the nephron consists of an afferent arteriole that forms the glomerular capillary tuft, which is surrounded by Bowman's capsule. Blood exits in the efferent arteriole, which supplies blood to the tubule cells. Venous blood, via the renal portal system, mixes with the arteriolar blood at the start of the proximal tubule (Fig. 66.14).

PHYSIOLOGY

The metabolism of protein and amino acids results in the production of nitrogen, which must be excreted as ammonia, urea, or uric acid (Table 66.2). The production and excretion of ammonia is the simplest method for this task. However, ammonia is toxic to the central nervous system and requires large amounts of water for its excretion. Hence, its production in reptiles is limited to aquatic species of turtles and crocodilians.[14,17] Urea is less soluble than ammonia but 40,000 times more soluble than uric acid. It must also be excreted with water and is most common in aquatic species; however, significant amounts can be found in some terrestrial chelonians. Reptile kidneys lack a loop of Henle (ansa nephroni) and so cannot produce urine hypertonic to that of plasma. Consequently, other means of water conservation are employed, including a greater reliance on uric acid production and decreases in glomerular filtration rate (GFR).

Reptiles have reduced GFRs to the order of 5 to 25 mL/kg/hr compared with those of birds and mammals (100–200 mL/kg/hr).[3,14] GFR has been reported for several species using clearance methods (Table 66.3). The differing physiological challenges of marine, freshwater, and terrestrial environments, combined with methodologic differences, may explain the differences reported from different species.

During dehydration (experimentally studied with the intravenous infusion of hyperosmotic saline solution), GFR tends to decrease, and water-loading (experimentally studied with the intravenous injection of sterile water) increases GFR; however, considerable variation exists between different species from different habitats. As an example, GFR of the Puerto Rican gecko is 3.33 ± 0.37 mL/kg/h with dehydration and 24.3 ± 1.67 mL/kg/h with water loading.[14] In some species that possess an alternate method for salt excretion (e.g., nasal salt glands of the sand monitor, *Varanus gouldii*), dramatic elevations of plasma osmolarity may not cause the expected decrease in GFR because mechanisms for postrenal reabsorption of water from the cloaca, colon, or bladder are usually well developed.[14]

Few studies have evaluated the effects of temperature on GFR in reptiles, but in two saurian species (*Tiliqua rugosus* and *Sauromalus obesus*), significant increases in GFR have been associated with increasing temperature from 5°C to 25°C, mediated by increases in mean arterial pressure.[14] However, these same studies also indicate that within the preferred optimal temperature zone, mean systemic arterial pressure and urine flow appear to be virtually independent of temperature.

The concept that overall GFR is mediated by changes in the number of filtering glomeruli rather than subtle variations in individual nephron filtration rates appears justified, because the maximum rate for renal tubular transport of para-amino-hippurate (PAH) has been shown to vary directly with GFR.[14] If changes in GFR resulted from changes in the amount filtered by each glomerulus with all glomeruli continuing to function, the renal tubular transport for PAH would not be expected to change because the mass of tissue transporting PAH would not have changed. In addition, microscopic studies in various reptile species, including the eastern blue-tongue skink (*Tiliqua scincoides*), have indicated that the ratio of open-to-closed proximal tubular lumina correlates with GFR. A tubule collapses when the glomerulus ceases filtering, supporting the concept that changes in GFR result from changes in the number of functioning nephrons.[14] The cessation of blood flow through the glomerulus would place a nephron at risk from ischemic necrosis. To prevent this from happening, reptiles evolved a renal portal blood supply that continues to perfuse the tubules despite low GFR. As discussed previously, blood from the caudal regions of the body can be diverted through the kidneys or bypass the kidneys. Presumably more blood is shunted through the renal portal system during times

of water deprivation. A valve responsible for regulating the direction of blood flow has been tentatively described in red-eared sliders (*Trachemys scripta elegans*).[18]

Arginine vasotocin (AVT), released from the posterior pituitary, causes a significant reduction in GFR by vasoconstriction of the afferent glomerular arteriole, which appears to be independent of systemic arterial pressure. More recent studies have suggested that AVT may also stimulate dilution of urinary fluid in the thin-intermediate segment and facilitate water reabsorption along an osmotic gradient as the urine passes through the final segments of the nephron.[19] Antidiuretic effects and reductions in GFR have been attributed to high doses of oxytocin, while prolactin increases GFR. However, at least in some species, these effects appear to be mediated by reductions in systemic arterial blood pressure.[14]

Tubular function includes the regulation of water, sodium, potassium, hydrogen ions, calcium, phosphorus, and nitrogenous compounds. Uric acid is freely filtered by the glomeruli and actively secreted into the proximal tubule against a concentration gradient. Instead of dissolving in solution, like urea, uric acid complexes with protein and either sodium, potassium, or ammonium cations to form a colloidal suspension.[14,17] This suspension contains spheres that are composed of about 65% uric acid and range in diameter from 0.5 to 15 µm. The kidney secretes mucoid substances that contain glycoprotein or mucopolysaccharides that aid in sphere formation and prevent clogging of collecting ducts with urates.[14,17]

Only 30% to 50% of the filtered water is absorbed in the proximal tubules, compared with 60% to 80% in mammals. The rest is absorbed in the distal tubules, colon, cloaca, and where present, bladder. The acidification of urine through hydrogen ion secretion or bicarbonate absorption, combined with water reabsorption in the cloaca or bladder, enhances the formation of urate precipitates from the colloidal material present in the aqueous phase of urine.[17] Failure to adequately excrete urate leads to hyperuricemia, gout, and death. Electrolytes, including sodium and potassium, are freely filtered by the glomerulus. Most of

the ultrafiltrate sodium (and water) is reabsorbed from the nephron, collecting duct, colon, cloaca, or bladder. Studies in hydrated geckos (*Hemidactylus* sp.) and iguanids (*Phrynosoma* sp. and *Tropidurus* sp.) have indicated that only 15% to 46% of sodium filtered by the glomeruli is actually excreted in urine.[14] Isosmotic sodium reabsorption occurs in the proximal tubule. However, because the osmolarity of ureteral urine is generally lower than plasma, fluid reabsorbed from the distal tubule varies from isosmotic to hyperosmotic. In many species, the colon, cloaca, and bladder are more important sites for the regulation of sodium excretion and water reabsorption than the kidneys. Control of sodium and potassium regulation has been poorly studied in reptiles, but AVT, aldosterone, and temperature have been shown to exert significant effects.[14] The theoretic ineffectiveness of furosemide (as a loop diuretic) in the reptile kidney, lacking a loop of Henle, has not been confirmed experimentally. Indeed, studies in chelonians and lizards have shown that furosemide exerts significant diuretic effects by increasing sodium, chloride, potassium, and water losses from the kidney (probably at the site of the intermediate segment), colon, cloaca, and bladder.[20–22]

While the injection of renal-tubularly excreted drugs (e.g., carbenicillin) into the caudal body of a reptile may result in a statistically significant effect on some pharmacokinetic parameters, the effect on plasma drug concentrations and hence clinical efficacy are likely inconsequential.[23] However, the possibility of high-dose first-pass effects of renally toxic drugs (e.g., aminoglycosides) may still suggest avoidance of the caudal body, despite a lack of obvious pharmacokinetic effects.

As well as functioning as an excretory organ, the reptilian kidney is also responsible for vitamin C synthesis and the conversion of 25-hydroxycholecalciferol to the active forms, 1,25-dihydroxycholecalciferol or 24,25-dihydroxycholecalciferol.[24,25]

In summary, because reptiles represent the first group of vertebrates to adapt to a wholly terrestrial lifestyle, their kidneys have evolved to maximize water conservation. This is accomplished with comparatively few nephrons, reliance on uric acid production (in squamates), and a low GFR with tubular blood flow maintained by a renal portal supply.

CLINICAL INVESTIGATION

Diagnosis of urinary tract disease in reptiles is made on the basis of history, physical examination, hematology, biochemistry, urinalysis, diagnostic imaging, and ultimately histopathology, microbiology, and evaluation of renal function.

History and Physical Examination

Reptiles affected by urinary tract disease may present with acute onset of depression, anorexia, and sometimes cessation of urine and urate output. Such cases often involve individuals that are poorly managed and often in unhygienic conditions. Recent exposure to nephrotoxins, including aminoglycoside antibiotics and high doses of vitamin D_3, may be inferred from a detailed case history and previous medical or owner records. Total water deprivation, severe dehydration, or hemorrhage could also lead to poor renal perfusion and acute renal failure.

Reptiles with chronic urinary tract disease have often suffered from long-term mismanagement. High-protein diets rich in purines and in particular the use of canned dog or cat foods can lead to azotemia and hyperuricemia, with increased demands for effective nitrogenous waste excretion. Likewise, persistently inadequate humidity or inappropriate water provision (e.g., for some species, water bowl instead of misting) can result in chronic dehydration. The regular use of oral vitamin D_3 as a substitute for broad-spectrum (including UVB) lighting can cause soft tissue mineralization, including nephrocalcinosis. Reptiles that recover from secondary nutritional hyperparathyroidism as juveniles may have sustained chronic renal damage from the cytotoxic effects of excess parathyroid hormone.[26] Affected animals tend to have a more protracted history, including deteriorating body condition, capricious appetite, and reduced activity that may extend over weeks or months, and as a result, most cases present dehydrated and emaciated. Only rarely do owners report polydipsia or polyuria.

A thorough physical examination is always indicated and should include an accurate measurement of weight and body condition assessment. Reptiles with severe renal compromise present in a depressed and weakened state (Fig. 66.15). Those with acute renal failure often exhibit better body condition than those with chronic renal compromise. Dehydration may be inferred from reductions in skin elasticity, salivary, and ocular secretions. Pharyngeal edema is not uncommon and lizards may present with bilateral exophthalmia and/or increased scleral vascularity. Digital palpation of the kidneys percutaneously, or in larger animals, per cloaca, is possible in some species, and the size, shape, and contours of the kidneys may be appreciable. Pronounced renomegaly may cause constipation and cloacal prolapse.

Clinical Biochemistry

Azotemia, hyperuricemia, or uremia seldom ensue before the majority of renal function has been lost and renal failure is evident. In clinical practice, creatinine is considered a poor indicator of renal disease in reptiles because of low production and variable excretion.[17] Creatinine

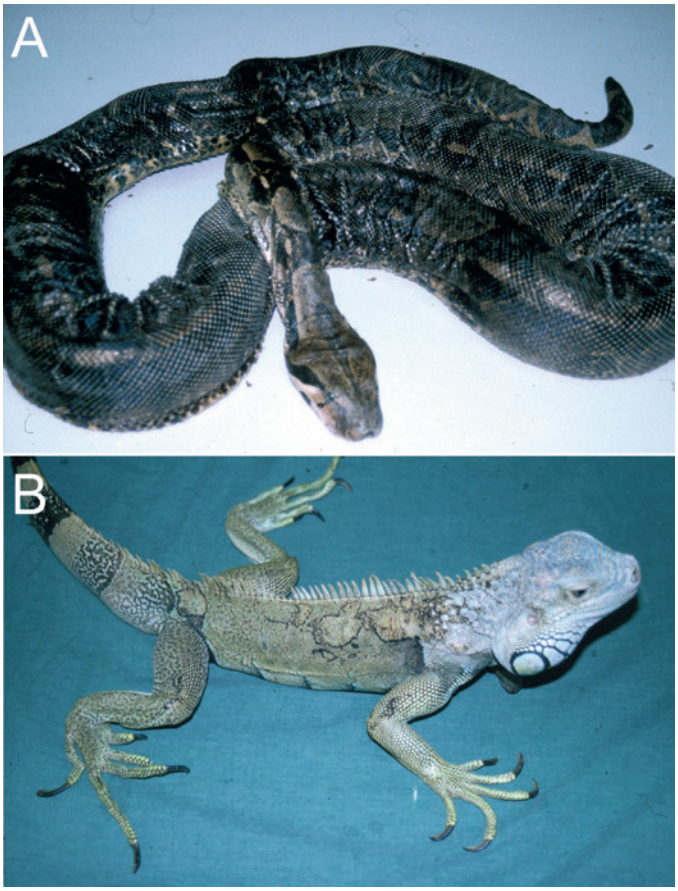

FIG 66.15 Physical presentation of reptiles with chronic renal disease. (A) Boa constrictor (*Boa constrictor*) with severe nephrosis and renal gout. (B) Green iguana (*Iguana iguana*) with tubulonephrosis and glomerulonephrosis attributed to high-protein diet, low humidity, and inappropriate water provision. (Courtesy of Stephen J. Divers.)

VetBooks.ir

and creatine values have been described in a limited number of healthy iguanas and individuals with renal disease (Boyer, 1996, Proc ARAV, pp113). Creatinine production and excretion appear to be too variable for useful clinical value, and creatine, like uric acid, only rises during renal failure in iguanids. For most squamates, uric acid is the principle nitrogenous metabolite to measure. However, urea and ammonia quantification may be important in many chelonians and crocodilians (see Table 66.2). To complicate matters further, the relative proportions of ammonia, urea, and uric acid may vary with hydration status, postprandial effects, and hepatobiliary disease.[17] Serial measurements of relevant nitrogenous metabolites probably offer the greatest clinical value. Reliance on uric acid alone to assess nitrogenous excretion in many reptiles is flawed, with urea and ammonia often deserving consideration in some species. While urea and uric acid assays are typically available from commercial laboratories and using in-practice equipment, ammonia presents more of a challenge because it must be collected into cold heparinized syringes, kept on ice, and analyzed within an hour.[27]

In some species, notably the green iguana, calcium/phosphorus ratios may become inverted in many, but not all, cases of renal failure. Other electrolytes, including sodium, potassium, and magnesium, may also be informative; however, significant regulation of sodium and potassium is possible at extrarenal sites in some species (e.g., nasal salt glands). Hyponatremia and hyperkalemia may be expected from dysfunction of the distal tubules, cloaca, colon, bladder, or extrarenal salt glands. Other plasma biochemical parameters, including aspartate aminotransferase (AST), creatinine phosphokinase (CPK), and lactate dehydrogenase (LDH), may be elevated during renal disease, but their wide tissue distribution makes them non-specific markers of renal damage.[28] Tubular disease may be expected to result in increased urinary loss of the brush border enzyme, gamma glutamyl transferase (GGT); however, further studies are necessary to confirm this theory. Severe glomerular disease may increase urinary loss of albumin and lead to hypoalbuminemia (protein-losing nephropathy); however, albumin determinations by anything other than electrophoresis are likely inaccurate.[29] Fibrinogen may also be useful for identifying inflammation, and, although an observed range has been documented for the red-eared slider (*Trachemys scripta elegans*), elevation due to inflammation could not be demonstrated.[30] Chronic disease may lead to renal secondary hyperparathyroidism as a result of either inadequate renal hydroxylation of calcidiol to 1,25-dihydroxycholecalciferol, or from phosphate retention resulting in hypocalcemia and increased parathyroid hormone secretion. While accurate measurement of reptile-specific parathyroid hormone is difficult, a measurement of 1,25-dihydroxycholecalciferol is available commercially (Heartland Assays, Iowa State University Research Park, Ames, IA). Normal reference ranges for 1,25-dihydroxycholecalciferol are unavailable, and therefore comparison with conspecifics kept under the same management would be necessary.

Gender, season, nutrition, and management can significantly affect many biochemical values, even within the same species, and therefore published ranges must be interpreted with caution. Furthermore, most published ranges do not meet the criteria of the American Society of Veterinary Clinical Pathologists for true reference interval designation.[31] Given these variations, biochemical values derived from a healthy reptile during regular health examinations may prove to be the most useful comparison for that individual patient during times of illness. In addition, serial sampling offers the best approach for ongoing evaluation.

Hematology

Pathologic elevations of packed cell volume are usually related to dehydration. The clinician must also be aware that chronic renal disease may lead to a nonregenerative anemia that may mask hemoconcentration. Unless immunosuppression is present, acute infection or inflammation usually results in heterophilia and/or azurophilia. In cases of chronic renal disease, a decreased, normal, or mildly increased total white blood cell count, often with monocytosis, is more common. Reptiles constantly exposed to temperatures below the preferred optimum temperature zone may become immunocompromised and fail to show an appropriate leukocyte response, even in the face of overwhelming infection. Although hematologic ranges have been published for many species, few comply with the criteria for reference range generation and should be used with caution.[31]

Urinalysis

The reptilian kidney cannot concentrate urine, and so urine-specific gravity is of limited use in the assessment of renal function. Furthermore, renal urine passes through the urodeum of the cloaca before entering the bladder, and therefore bladder urine is often not sterile. The clinical picture is further complicated by electrolyte and water changes that can occur across the bladder (or cloacocolonic) membrane.[18] Nevertheless, despite these biochemical drawbacks, urine samples are useful for cytologic assessments of inflammation and infection, and for the identification of renal casts.

Urine Collection. The urinary, genital, and intestinal tracts empty into a common cloaca, and therefore any samples voided from the vent may represent material derived from, or contaminated by, any of these systems. Voided urine and urates, although useful for cytology, must be critically evaluated whenever a culture is obtained. Urine microbiology results must be particularly scrutinized if the sample was collected from the floor of the enclosure or the examination table. Fresh urine and urate samples can be collected as a free catch. Many reptiles spontaneously void urine and urates (often with fecal material) when handled. More stoic individuals may be encouraged to urinate with gentle digital stimulation of the cloaca.

Cystocentesis prevents the gross contamination associated with free catch or collection from the floor or table. However, given the thin, fragile nature of the bladder, the potential for postsampling leakage and coelomitis must be appreciated. Given the passage of urine through the cloaca and the electrolyte and water changes that can occur in the bladder, urine collected by cystocentesis may not be representative of renal urine with respect to electrolyte composition and osmolarity. Such samples are often unsterile, although a heavy pure growth should alert the clinician to a potentially significant infection. The saurian bladder can be approached laterally or ventrally just anterior to the pelvis, aiming the needle anteromedially (Fig. 66.16A). The caudal extent of the liver on the right side of the chelonian coelom makes a left prefemoral approach preferable (see Fig. 66.16B). Rotation of chelonians may allow the bladder to fall dependently toward the prefemoral fossa and increase the chance of success. A 22-g to 25-g needle is appropriate, but the smaller needle sizes may become clogged. Ultrasound-guided cystocentesis may reduce the chances of iatrogenic trauma to other structures, including the intestines.

In general, catheterization of the bladder is challenging, although dilation of the cloaca with a nasal or vaginal speculum may be helpful, while cloacoscopy (often requiring saline infusion) will allow visualization of the urethral opening ventral to the opening of the large intestine (see Figs. 66.4B and 66.9C). Following endoscope-guided placement, the urethral catheter can be secured in place to permit estimation of urine output and repeated acquisition of samples (Fig. 66.17).

Urine Evaluation. Standard urinalysis technique can be used to evaluate reptilian urine. Ideally, urinalysis should be performed immediately after obtaining a sample because changes in pH and bacterial populations,

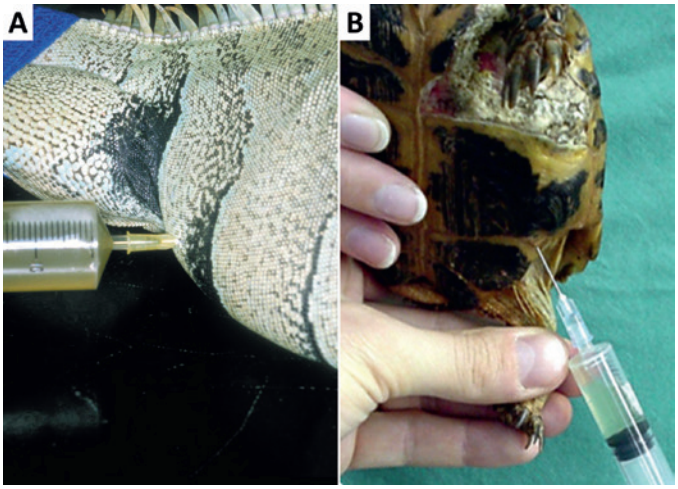

FIG 66.16 (A) Cystocentesis in a green iguana (*Iguana iguana*). (B) Cystocentesis in a Greek tortoise (*Testudo graeca*). Following aseptic preparation, the smallest gauge needle should be used and ultrasound guidance is recommended. (Courtesy of Stephen J. Divers.)

Divers.)

lysis of cells, and precipitation of crystals could occur as the urine ages. As in mammalian medicine, a complete urinalysis should include gross observation, biochemical testing, specific gravity measurement, and microscopic sediment evaluation. A gross evaluation of the urine is the appropriate first step. Much can be learned regarding the patient's well-being with evaluation of the appearance of the urine sample. Starvation and hepatic disease promote the production of biliverdin, which may turn urine a lime green color (Fig. 66.18).

Standard urine chemistry dipsticks appear to be useful, albeit not validated. Although not all dipstick assays are of value, several appear to provide important information. Unless otherwise specified, detection of abnormalities with urinalysis should prompt the clinician to consider any and all causes of the abnormal values as seen in other species. For example, severe proteinuria may be seen with protein-losing nephropathy, and hematuria may be seen with cystic calculi.

Urine pH. Initial studies in chelonians indicate that urine pH may have significant diagnostic value. Unpublished data suggest that the urine pH of several herbivorous tortoise species is normally alkaline (Innis, Proc ARAV, 1997, pp 109–112; Kolle, Proc ARAV, 2000, pp 111–113), while that of omnivorous box turtles (*Terrapene*) is slightly acidic (Gibbons et al, Proc ARAV, 2000, pp 161–168). However, published data indicate mean urine pH of 5.6 to 7.3 in desert tortoises (*Gopherus agassizii*), 6.7 in red-eared sliders, and 5.9 to 6.2 in hawksbill turtles (*Eretmochelys imbricata*).[32-34] Published reports of the urine pH of lizards and snakes are lacking. Acidic urine has been observed in herbivorous tortoises under conditions of drought, with high-protein diets, near the end of hibernation, or during prolonged periods of anorexia from illness.[32] Although the pathogenesis of acidic urine production in these tortoises is unclear, protein catabolism and ketogenesis may contribute. In most cases, tortoise urine pH has been shown to return to the alkaline range within several weeks of active foraging after hibernation or recovery from illness. As such, monitoring the urine pH of herbivorous reptiles may be a simple means of monitoring recovery from illness and return to positive energy balance. Acidic urine and dehydration may be predisposing factors for precipitation of urate crystals and uroliths. If so, attempts to alkalinize the urine through dietary change and medical therapy may be of use in preventing recurrence of such stones after surgical removal. Although not yet proven, alkaline urine in a carnivorous reptile could indicate the presence of urinary tract infection from a urease-positive bacteria. This situation has been well-documented in human and domestic animal urology.[35]

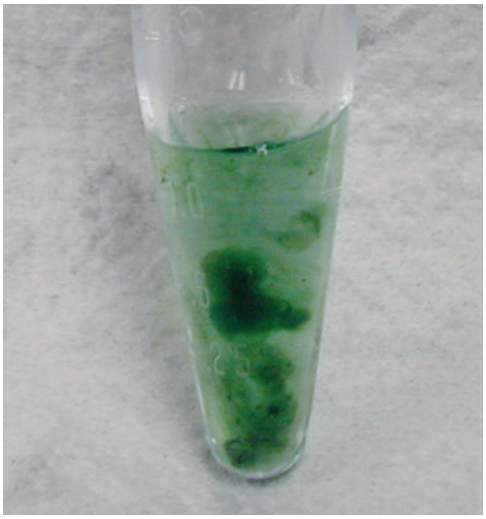

FIG 66.18 Urine from a cachectic reptile demonstrating green biliverdin pigment. (Courtesy of Charles J. Innis, New England Aquarium.)

Protein. Urine dipstick protein assays primarily respond to the presence of albumin. False-positive protein readings may occur with hematuria and pyuria or in the presence of reproductive secretions.[35] Unpublished observations of tortoise and box turtle urine indicate that zero to trace protein levels are detected in active healthy specimens. Protein levels of 30 mg/dL or higher have been noted during hibernation or during illness.

Glucose. Glucosuria is not normally present in significant amounts in those reptiles that have been studied. Glucosuria was noted by Koelle (Proc ARAV, 2000, pp 111–113) in 12 of 25 tortoises with renal disease and by Gibbons (Proc ARAV, 2000, pp 161–168) in several box turtles, including one that was hyperglycemic (plasma glucose 372 mg/dL). Better documentation of glucosuria and correlation with plasma glucose and organ pathology are needed to ascertain the significance of glucosuria.

VetBooks.ir

Potential causes of glucosuria include diabetes mellitus, liver disease, stress/excitement, and renal tubular diseases.[35]

Occult blood. Free hemoglobin, myoglobin, or intact erythrocytes may produce a positive reaction for "blood." A positive dipstick reaction should be verified with urine sediment microscopy. Hematuria may also be associated with cystocentesis and excessive force during bladder expression. Free hemoglobin may be caused by transfusion reactions, hemolytic anemia, disseminated intravascular coagulation, and heat stroke. Myoglobinuria may occur secondary to severe rhabdomyolysis associated with crushing injuries.

Ketones. The role of ketones in reptile physiology is largely unstudied, but there is evidence of increased plasma and urine β-hydroxybutyrate in desert tortoises in response to drought but not hibernation, indicating that this may be a clinically important ketone in reptiles.[32] Unfortunately, most urine dipsticks utilize a nitroprusside reagent and respond to acetoacetic acid and, to a lesser extent, acetone, but not to β-hydroxybutyrate.[35] Further studies on the pathophysiology of reptile ketogenesis and the relative amounts of various ketones produced are needed. Trace ketonuria has been detected with dipstick in the urine of tortoises emerging from brumation (hibernation) but resolved within several weeks of resumed activity and feeding. Abnormal urine color may result in false-positive ketone reaction on dipsticks.[35]

Leukocyte esterase reaction. The leukocyte test on urine dipsticks reacts to the presence of esterases produced by granulocytes, and although accurate in humans has poor sensitivity in dogs and poor specificity in cats.[35] Its utility in reptile urinalysis has not been evaluated.

Nitrite. The nitrite assay reacts to the presence of nitrite produced by nitrate-reducing bacteria. Although useful in humans it has not been validated in other species, including reptiles. The significance of positive reactions in reptiles is unclear as urine is not typically sterile.

Urobilinogen and bilirubin. The role of urobilinogen in reptiles is unclear, and it has not been reported to be present in their urine. Only snakes appear capable of producing bilirubin in significant quantities, but the renal threshold for urinary bilirubin is unknown.[36] Most reptiles produce very little bilirubin, and so the bilirubin assay is largely useless. A biliverdin assay has been developed but is currently not commercially offered.[37]

Urine-specific gravity. Although validated for human urine, dipstick-specific gravity correlates poorly with refractometric results in various domestic animals.[35] Therefore for an accurate determination of specific gravity in reptile urine, a refractometer should be used; however, the value of specific gravity for evaluation of renal function is questionable as reptiles cannot concentrate urine above that of plasma. Urine-specific gravity may provide an indirect method of evaluating plasma specific gravity.

Urine sediment evaluation. Microscopic evaluation of the urine sediment is an important part of reptile urinalysis and should be performed on fresh samples as casts and cellular elements degenerate rapidly. Urine should be spun in a centrifuge at 1000 to 1500 rpm for 5 minutes and examined both unstained and stained using Sternheimer-Malbin stain, although Romanowsky and Gram stains may also prove useful.[35]

Erythrocytes, leukocytes, epithelial cells, microorganisms, spermatozoa, crystals, and casts may be identified (Fig. 66.19). In clinically healthy tortoises, urine may reveal small numbers of leukocytes and epithelial cells but is generally acellular. Erythrocytes are not routinely seen unless catheterization or cystocentesis has been performed. Some reptile bladder epithelial cells are ciliated, and finding such cells in the urine sediment in small numbers is not surprising.[38] The numbers of leukocytes, erythrocytes, or epithelial cells are reported per high power field, and large numbers should prompt further investigation.

Because urine passes through the urodeum of the cloaca to enter the bladder, some degree of bacterial contamination is often present in bladder urine. With experience, however, the microscopist may become comfortable with subjectively assessing the relative numbers and morphology of the urine flora. A mixed population of moderate numbers of rods and cocci may be normal, but a huge number of monomorphic bacteria or yeasts should be concerning, especially if combined with a prominent inflammatory response (see Fig. 66.19A). In such cases, urine culture may be useful; however, qualitative and quantitative data on reptile urine flora are currently lacking, and clinical judgment should be used when interpreting microbiological results. Pure, heavy cultures are generally more clinically significant than mixed, scant growth. As renal biopsy becomes more common, data correlating renal tissue culture and histopathology with urine culture results should better define the value of urine culture in diagnosing bacterial nephropathies.

Occasionally, protozoan or metazoan parasites may be detected (see Fig. 66.19B). The flagellated protozoan and renal parasite *Hexamita* has been reported from chelonian urine samples.[39] Myxozoan parasites (*Myxidium*, *Myxobolus*) have been reported to cause dilated renal tubules and interstitial nephritis in a variety of aquatic turtles.[39] In snakes and crocodilians where urine is stored in dilated, distal ureters and/or in the colon, urine evaluation may serve as a useful substitute for fecal testing in an anorectic animal that is not producing feces.

The presence of casts and crystals in reptile urine may be significant, but more data are needed before definite recommendations can be made. Urinalysis in mammals is useful for the demonstration of

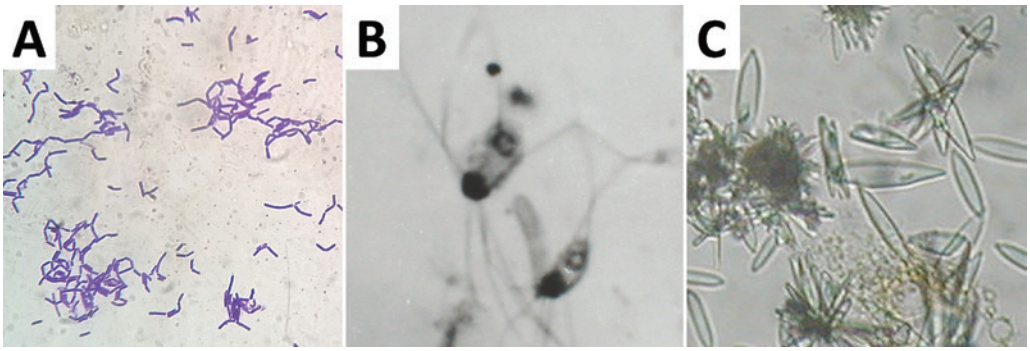

FIG 66.19 Urine sediment evaluation. (A) Gram-positive rods in urine from a radiated tortoise (*Astrochelys radiata*) collected by cystocentesis (Gram stain, x1000 original magnification). (B) *Hexamita parva* in urine from a leopard tortoise (*Stigmochelys pardalis*) (direct wet-preparation, x1000 original magnification). (C) Urate crystals in the urine from a green iguana (*Iguana iguana*) (direct wet-preparation).

ammonium biurate crystalluria and uric acid; however, given the variable expectation for such nitrogenous products in many reptiles, their diagnostic usefulness is probably limited as an adjunct to hepatic disease diagnosis. Although crystals and casts may be seen, one should be cautious in assuming that these have the same significance as their mammalian counterparts on the basis of appearance alone. For example, biochemical assays to determine the chemical composition of various crystals and histochemical staining to determine the nature of cast components have not been performed on reptile urine. In many reptilian urine sediment samples, small spherical urate crystals may be seen (see Fig. 66.19C).[14,17] Other crystals that have been identified on the basis of morphology include calcium oxalate, cholesterol, cystine, hippuric acid, leucine, sodium urate, tyrosine, bilirubin, and triple phosphate.[14]

Radiography

Normal reptile kidneys are not always readily appreciable on plain radiographs, especially in chelonians; however, dorsoventral and lateral (horizontal beam) views are generally the most useful (see Chapters 54 through 57). Radiographs can reveal renomegaly, radiopaque uroliths, macroscopic soft tissue mineralization, and chronic (mineralized) gout (Fig. 66.20). Renomegaly can cause extramural obstruction of the colon with resultant constipation and/or prolapse. This constipation or prolapse is often radiographically more obvious than the renomegaly. Intravenous urography can be used to highlight the kidneys, identify masses (abscesses, neoplasia, calculi), and show renal or ureteral damage or obstruction. Bolus intravenous injection of 800 to 1000 mg/kg of aqueous iodine contrast media (e.g., iohexol) is followed by serial dorsoventral and lateral radiographs at 0, 2, 5, 15, 30, and 60 minutes, with the reptile maintained within the species-specific-preferred optimum temperature zone.[2,40]

Ultrasonography

Ultrasonography permits an appreciation of normal tissue and mineralization, cysts, and other gross pathologic changes (see Chapter 58). Ultrasonography also aids kidney visualization for transcutaneous biopsy, although the risks of iatrogenic damage to renal vasculature and ureters must be considered. In the iguana, the bony pelvis is a barrier to ultrasound waves, and therefore the transducer must be angled caudad from a prepelvic location in the ventral midline just cranial to the hind limbs or craniad from a cloacal position at the ventral tail base. Sonographic evaluation of the kidney is often more rewarding than radiography alone, especially in snakes and chelonians (Fig. 66.21). Transcloacal imaging should be considered in giant reptiles.

Scintigraphy

Technetium has been shown to be useful to evaluate renal function in healthy green iguanas. Experimental scintigraphy studies involving 10 normal iguanas documented normal renal uptake of technetium-99m dimercaptosuccinic acid (99mTc-DMSA), and iguanas with reduced functional renal mass were postulated to exhibit a decrease in technetium uptake.[41] However, the expense of such equipment combined with radiation regulations makes this an impractical method for most private practices.

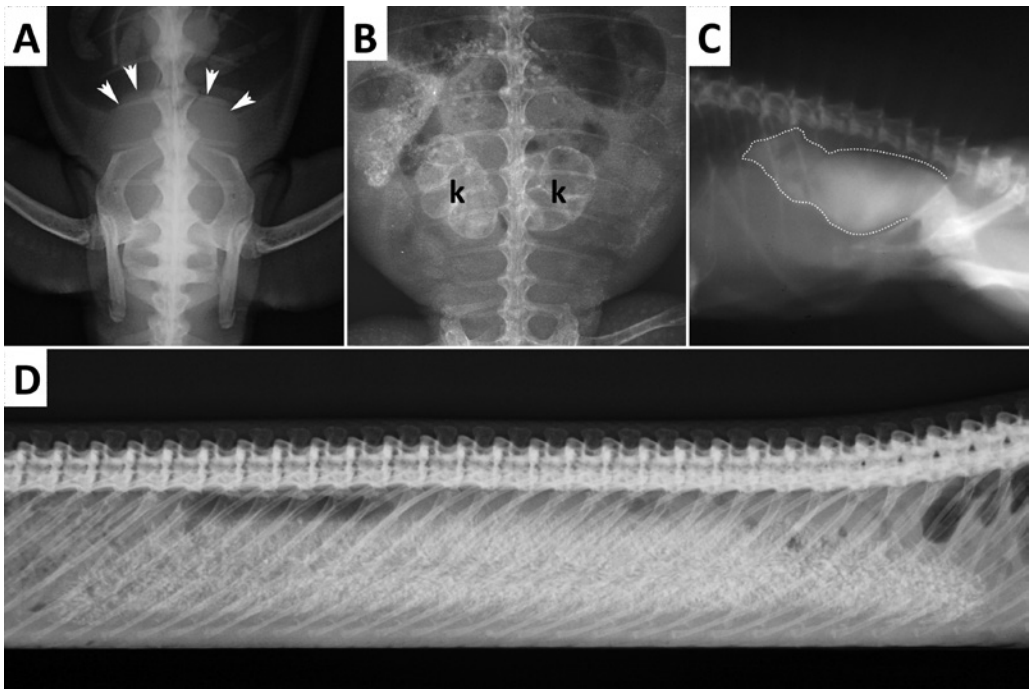

FIG 66.20 (A) Dorsoventral radiograph of the caudal coelom of a green iguana (*Iguana iguana*) demonstrating protrusion of the renal silhouettes (arrows) cranial to the pelvic rim, suggestive of renal enlargement. Note the multiple, hyperechoic pinpoint areas throughout the renal parenchyma in all views. Renal biopsy subsequently confirmed heterophilic nephritis with tubular and glomerular degeneration, tubular mineralization, and interstitial fibrosis. (Courtesy of Stephen J. Divers.)

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

Advanced cross-sectional imaging can be useful for the evaluation of renal size, shape, and space occupying lesions. CT is typically faster, less expensive and often offers greater resolution; however, MRI can also provide information on parenchymal changes and renal blood flow. The acquisition of pre- and postcontrast images can be particularly useful when evaluating a renal mass and planning surgical removal or radiation therapy. CT can also be used to triangulate biopsy needles. See Chapters 59 and 60 for more details.

Endoscopy

Endoscopic techniques for the evaluation of the chelonian and saurian coelom have been well described (see Chapters 63 and 64).[3,42,43] The use of fine-diameter rigid endoscopes has permitted the direct visualization of a color-magnified image of visceral organs, including the kidneys, through a small surgical entrance into the coelomic cavity (Fig. 66.22).[1,3,43] Equipment should be matched to patient size; the 2.7-mm telescope with 4.8-mm operating sheath is appropriate for most reptiles <10 kg. Insufflation, preferably with carbon dioxide, is essential for lizards and snakes and preferred for chelonians. General anesthesia, lateral positioning, aseptic preparation, and paralumbar (in lizards) or prefemoral (in chelonians) entry permits examination of the coelomic cavity. In most lizards the kidneys are viewed cranial to the pelvis but are intrapelvic in iguanids. In chelonians they are intimately associated with the caudodorsal carapace, behind the coelomic membrane, which if opaque can make visualization difficult. In those turtles with a more flattened carapace, it is possible to approach the kidneys retrocoelomically without entering the coelom.[1] Adequate examination of both kidneys from a single entry point is possible, although visualization of the contralateral organ is more difficult. The endoscope entry site requires a single suture for closure. Endoscopy offers an unrivaled appreciation of renal size, surface contours, color, and lesions, which should be documented as focal, multifocal, or diffuse. Endoscope-guided fine needle aspiration for cytology or endoscopic biopsy are practical options for obtaining diagnostic samples.[1,3,43]

Needle Aspiration and Cytology

Palpably enlarged squamate kidneys may be aspirated transcutaneously with or without ultrasound guidance. Aspiration of normal-sized or smaller squamate kidneys may be more challenging, and aspiration cannot be recommended in chelonians without imaging guidance. Needle aspirates produce relatively small amounts of diagnostic material in comparison to biopsy samples. In addition, the lack of tissue architecture often complicates pathologic evaluation and interpretation. Nonetheless, needle aspirates often provide enough material for culture and may produce sufficient material for cytology.

Renal Biopsy

The relatively poor diagnostic value of urinalysis, the late detection of renal disease by blood biochemistry, and the poor regenerative capabilities of the diseased kidney exemplify the importance of renal biopsy early in the diagnostic process. Furthermore, renal biopsy is preferred over cytologic evaluations because cellular architecture is maintained and pathologic interpretations are often more reliable.

Ultrasound-Guided Biopsy. Ultrasound-guided needle biopsies may be possible in many squamates, but anesthesia is mandatory,

and imaging is required for appropriate targeting in chelonians, and lizards with intrapelvic kidneys. Even so, there are still significant risks associated with iatrogenic trauma to the ureters, bladder, large intestine, reproductive tract, and major blood vessels. Depending on the quality of the equipment and skill of the ultrasonographer, multifocal or focal lesions may be appreciated or missed. Needle biopsy techniques have not been evaluated for reptile kidneys, but hepatic needle biopsy in anesthetized snakes and iguanids have resulted in gastrointestinal perforation (6%) or hemorrhagic death (12%).[45,46] The risks associated with renal biopsy would appear even greater, and therefore extreme caution is required.

Endoscopic Biopsy. The endoscope permits evaluation of renal size, color, and shape via a single, small surgical entry in anesthetized snakes, lizards, and chelonians. Studies have evaluated endoscopic renal biopsy techniques in freshwater turtles and iguanid lizards and concluded that they are rapid, safe, and effective for acquiring diagnostic samples without any reported mortality or morbidity.[1,3,43] Endoscopic scissors and biopsy forceps, under direct visual control, permit the incision of the coelomic membrane or thickened renal capsule and the collection of quality samples with less risk to surrounding structures (Fig. 66.23). The excellent optics of the telescope also permit an assessment of focal and multifocal disease and the selection of appropriate biopsies that may otherwise be difficult to ascertain without a color, magnified image. Endoscopic samples can be submitted for histology, microbiology, parasitology, or toxicology.

Surgical Biopsy. Coeliotomy provides access to the kidneys for harvesting surgical biopsies. The advantage of open surgical access is the ability to collect larger samples, as well as an improved opportunity to more completely evaluate and sample other visceral structures. Surgical access to the chelonian and intrapelvic iguanid kidneys can be particularly challenging using traditional surgical approaches, and in all cases increased surgical exposure and duration of anesthesia must be considered. Surgical biopsies can be collected using a standard wedge technique in snakes, while small biopsy forceps or needle biopsy devices can also be used (Fig. 66.24A and B). Hemorrhage must be controlled, and radiosurgery, hemostatic materials (e.g., GelFoam), and digital pressure are effective.

A relatively simple technique to biopsy the intrapelvic kidneys of iguanids requires a cranial tail cut-down procedure under local or, more commonly, short-term general anesthesia. A small longitudinal incision is made in the lateral midline just below the lateral processes of the coccygeal vertebrae at the tail base. The incision extends for 1 to 3 cm caudad, starting just behind the hind limb. Blunt dissection between the dorsal and ventral coccygeal muscles permits exposure of the caudolateral aspect of the kidney that can then be sampled (see Fig. 66.24C). This technique is particularly valuable when the kidneys are not enlarged, surgical approach to the intrapelvic kidneys is difficult, and endoscopy is not available. It is limited to unilateral biopsy unless bilateral cut-down procedures are undertaken. Furthermore, because only a small area of the caudal kidney can be visualized and sampled, this technique is best reserved for diffuse or focal diseases of the caudal kidney.

Functional Renal Evaluation

Elevations of nitrogenous metabolites in plasma are poor indicators of renal function, because they can be affected by hydration status,

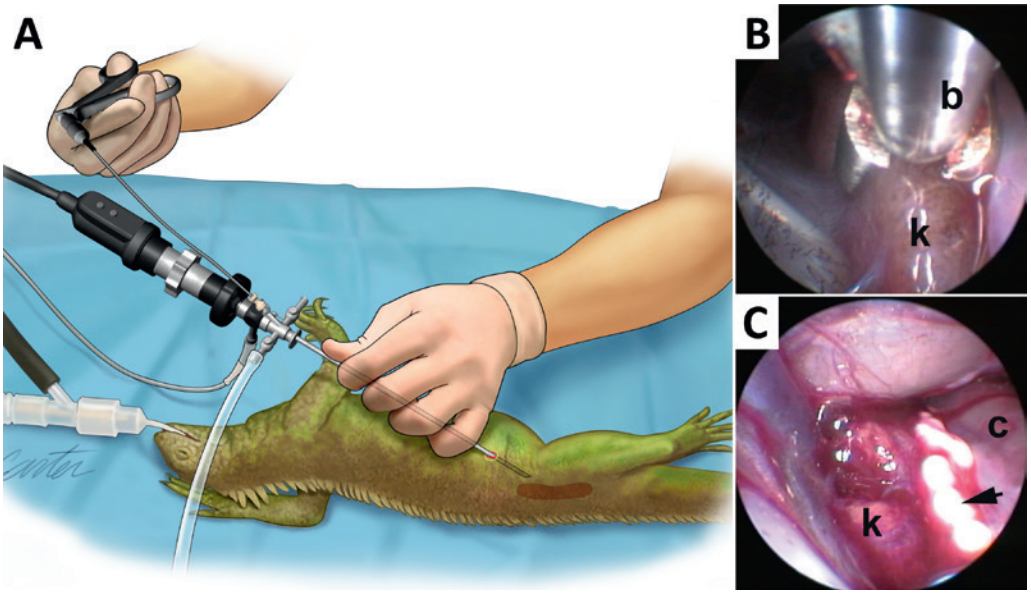

FIG 66.23 (A) Endoscopic biopsy in an iguanid lizard using a 2.7-mm telescope, 4.8-mm operating sheath, and 1.7-mm biopsy forceps. (B) Endoscopic view of the biopsy forceps (b) being advanced onto the kidney (k). (C) Postbiopsy view of the kidney (k) demonstrating minor hemorrhage. and pathologic changes tend to only occur once the majority of renal function has been lost. In human and domestic animal medicine, measurement of renal function has been established as an important tool in the diagnosis and surveillance of kidney disease. Advanced imaging modalities, including scintigraphy, and magnetic resonance imaging to measure renal blood flow or renal clearance of radioactive nuclides or contrast agents have been used in human and veterinary medicine. Other techniques relying on the plasma clearance of an exogenous compound (e.g., phenolsulfonphthalein, inulin, creatinine) have also been used in veterinary medicine but require bladder catheterization for urine collection. Postrenal modification of urine occurs in the bladder, while many reptiles lack a bladder, and therefore catheterization of the ureters would likely be required.

Glomerular function assessment is essential in the diagnostic approach to animals with suspected renal disease because GFR is directly related to functional renal mass.[35] Iohexol clearance has proven to be useful for determining GFR in mammals and is the only renal function test that has been evaluated in reptiles.[3,47–52] Iohexol is a nonionic radiographic iodine contrast medium of low osmolarity that is excreted solely by glomerular filtration with negligible extrarenal elimination in mammals. The plasma clearance of iohexol can be determined with analysis of plasma iohexol concentration over time after a single intravenous injection (Fig. 66.25). The rate of clearance of iohexol from plasma can be used to estimate GFR by dividing the iohexol dose by the area under the curve (AUC). In addition, this methodology has the advantages of (i) requiring just three small blood collections over 24 hours, (ii) not requiring urine collection, and (iii) being practical for reptiles as small as 300 g.

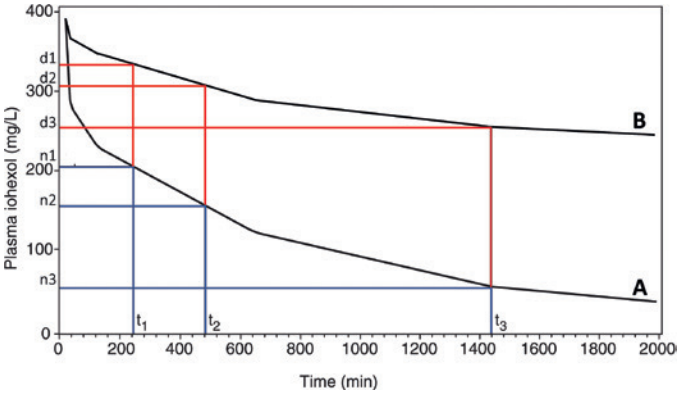

FIG 66.25 Iohexol excretion curves for a healthy iguana (A) and one with significant reductions in glomerular filtration rate (GFR) but no other changes on blood biochemistry (B). Timed blood samples are collected at 4 (t1), 8 (t2), and 24 (t3) hours post iohexol administration. Plasma levels of iohexol for the normal (n1–n3) and unhealthy lizards (d1–3) were then used to calculate GFR values of 16.5 mL/kg/hr and 8.2 mL/kg/hr, respectively. (Courtesy of Stephen J. Divers.)

TABLE 66.4 Protocol of Glomerular Filtration Rate (GFR) Determination in Reptiles

1. In the United States, contact the Diagnostic Center for Population and Animal Health (DCPAH, Michigan State University, East Lansing, MI 48824, 517-353-1683, https://www.animalhealth.msu.edu/) to check for any changes to the blood collection and/or submission requirements for iohexol assay and GFR calculation. Additional laboratories that offer iohexol assays are often available and include the following; however, they should be contacted to ensure appropriate sample volumes are collected:
   The Royal Veterinary College, University of London (http://www.rvc.ac.uk/pathology-and-diagnostic-laboratories/therapeutic-drug-monitoring)
   IDEXX Reference Laboratories (test code 3384), available in the United States, Europe, Australia, Africa, and Asia (https://www.idexx.com/small-animal-health/products-and-services/reference-laboratories.html)
2. Ensure the reptile is hydrated and fasted for 24 hours.
3. Obtain an accurate body weight to the nearest gram and inject 75.0 mg/kg iohexol intravenously at time 0.
   IV administration is critical and catheterization should be considered to reduce the risks of perivascular injection that will invalidate the results.
4. Collect 0.5 mL blood sample into heparin at 4 hours and record the exact time of blood collection. Spin down the blood, separate, and freeze the plasma. At least 0.2 mL of plasma is required.
5. Repeat blood collection, plasma separation, and freezing at 8 hours and 24 hours postiohexol administration. Again, record the exact times of blood collection. Given that a total of 1.5 mL of blood is required (at least for DCPAH), this protocol is limited to reptiles weighing approximately 300 g or more.
6. Send frozen plasma samples on ice overnight to the laboratory.

Calculation of GFR by iohexol clearance has been validated in green iguanas and sea turtles.[3,47] In healthy green iguanas, GFR was reportedly 16.56 ± 3.90 mL/kg/h, with a 95% confidence interval of 14.78 to 18.34 mL/kg/h. Iguanas with renal disease exhibited significant reductions in GFR even in the absence of other clinical or biochemical signs. Similarly, Kemp's ridley sea turtles with histologically confirmed renal disease showed GFR reductions that correlated to the severity of renal disease.[47] Notably, for turtles, renal function testing allowed for prognostic determination such that treatment could be continued or the patient could be euthanized, as appropriate. Iohexol clearance testing confirmed that naturally cold-stunned Kemp's ridley turtles were affected by 75% decreased renal function even after several days of hospitalization, while convalescent GFR were normal.[52] A suggested protocol for GFR determination has been published and summarized in Table 66.4, while published reptile GFR values are included in Table 66.3.[3] Unlike most other clearance techniques, iohexol excretion does not require bladder or ureteral catheterization, and unlike scintigraphy, it does not require expensive equipment or radioisotopes to perform. Given that iohexol assays are commercially available, functional renal evaluation in reptiles can be easily undertaken in private practice.

GENERAL APPROACH TO TREATMENT

Medical management of urinary tract diseases of reptiles largely relies on extrapolation of principles used in mammalian species. The reader is referred to various chapters throughout this book that are likely to be ancillary to the therapeutic management of renal disease cases. Success is more likely if a definitive diagnosis has been obtained and targeted, specific therapy can be provided.

Fluid therapy is used routinely and should be tailored to correct any electrolyte imbalances, with serial biochemistry and weight used to evaluate hydration and progress. Other treatments that may be considered include antimicrobials, diuretics, intestinal phosphate binders, allopurinol, colchicine, enalapril, calcitriol, or other agents used for management of renal conditions in other species. Aside from some antimicrobials and allopurinol, there are no pharmacokinetic/pharmacodynamic data for use of these drugs in reptiles.[53] Although the use of certain diuretics (e.g., furosemide) could be questioned in species that lack a loop of Henle, there is evidence in freshwater turtles that furosemide and ethacrynic acid are effective in increasing urine volume and urine electrolyte excretion by tubular effects.[22] Furosemide (2 and 5 mg/kg) produced no changes in blood pressure, hematocrit, plasma electrolytes, GFR, or plasma renin activity; however, sodium excretion increased 20-fold, whereas chloride and potassium excretion increased 12-fold. Dehydration by administration of furosemide and withholding fluid therapy has been reported as a successful treatment for brevetoxicosis in sea turtles.[54]

Oral allopurinol (xanthine oxidase inhibitor) at 25 mg/kg once daily has been shown to decrease uric acid levels by 45% in green iguanas.[53] Probenecid and sulfinpyrazone act by inhibiting uric acid reabsorption from the proximal tubule; however, given that very little, if any, reabsorption occurs in reptiles, the efficacy of these medications is questionable. Hypocalcemia should be treated with oral calcium supplementation with food (which also competes with phosphate absorption). Injectable calcium therapy should be avoided because most cases exhibit concurrent hyperphosphatemia, and the sudden elevation of calcium with high phosphorus can elevate the solubility index and precipitate soft-tissue mineralization. If calcium therapy for tetany is required, then it should be given slowly, preferably IV or IO, to effect with concomitant diuresis and phosphate binders. Oral phosphate binders (e.g., oral aluminum hydroxide) should be given between meals or they may interfere with dietary calcium absorption.[55] Human chronic renal failure can be treated with low, carefully titrated doses of cholecalciferol (vitamin D_3) to reduce the nephrotoxic effects of increased intracellular calcium within renal cells.[56] In reptiles, such accurate and titrated dosing is unlikely to be practical, and therefore it is safer to provide access to broad-spectrum lighting, preferably unfiltered sunlight. Antimicrobials should be used

only when infection has been demonstrated, with drug selection based on culture and sensitivity or, better still, MIC testing. The indiscriminate and widespread misuse of antimicrobials is unfortunately all too common.

In humans and domesticated animals, emphasis is placed on nutritional management. Protein restriction and the selective provision of pyrimidines (thymine and cytosine) over purines (guanine and adenosine) may help to reduce uric acid production. In addition, potassium supplementation may also be beneficial. Until concrete dietary recommendations for chronic renally impaired reptiles are forthcoming, the data in Table 66.5 may help clinicians make informed decisions regarding dietary choices. Further detailed information on human food compositions can be easily obtained from the USDA National Nutrient Database (https://ndb.nal.usda.gov/).

SPECIFIC UROLOGIC DISEASES

Gout

Gout is a metabolic disease characterized by overproduction or underexcretion of uric acid, resulting in hyperuricemia and deposition of positively birefringent monosodium urate (MSU) crystals in tissues.[57]

Clinical Significance. Although gout is frequently seen in humans and primates, it is not a common problem in general veterinary medicine. As a result, veterinarians who specialize in avian and reptilian patients must rely on the human medical literature for information regarding diagnosis and treatment.[58–60] Gout, in any of its forms (visceral, articular, and periarticular), is a common affliction in reptilian patients. Few studies cite the incidence of gout in reptiles, but unpublished data of 280 European tortoise necropsies indicated 64.3% had evidence of renal disease and 16% showed gout Kolle and Hoffman, 2002, Proc ARAV, pp 33–35).

Known Etiological Cause(s). In vertebrates, uric acid is derived from both exogenous and endogenous nucleic acids that are degraded in the liver to yield free purine and pyrimidine bases.[17] If these free bases are not reused by the body, they are further degraded and ultimately excreted. The pyrimidines are catabolized to the end products CO_2 and NH_3 that enter the ornithine cycle (Fig. 66.26). In some vertebrates, including primates, the dalmatian dog, birds, squamates, and some chelonians, purine degradation can produce significant quantities of uric acid.[17] Degradation of the major purines, adenine and guanine, starts initially with a conversion to hypoxanthine and then to xanthine for adenine and directly to xanthine for guanine. Both of these pathways require the flavoprotein, xanthine oxidase, to form uric acid (see Fig. 66.26). While carnivores are well adapted to high-protein diets and may even experience normal postprandial hyperuricemia, herbivorous reptiles may be overwhelmed by excessive animal protein, which results in pathologic hyperuricemia.[53]

In reptiles, uric acid is cleared from the blood by glomerular filtration but mainly by secretion from the proximal renal tubules. Urates are poorly water soluble and precipitate at low concentrations. While uric acid secretion is independent of glomerular filtration, in cases of dehydration where glomerular filtration and tubular flow are decreased, secretion of uric acid eventually ceases, and the renal tubule becomes blocked with uric acid. The reptilian nephron actively secretes three times more urates when normally hydrated.[14]

In blood, uric acid is present predominantly as MSU. Both free uric acid and urate salts are relatively insoluble in water. When the concentration of either or both of these forms becomes elevated in the blood (hyperuricemia) or in other body fluids (e.g., synovial fluid), MSU crystallizes, forming insoluble precipitates that are deposited in various tissues. Crystallization in synovial fluid results in acute, painful inflammation of the joint, a condition called gouty arthritis. Crystals can also

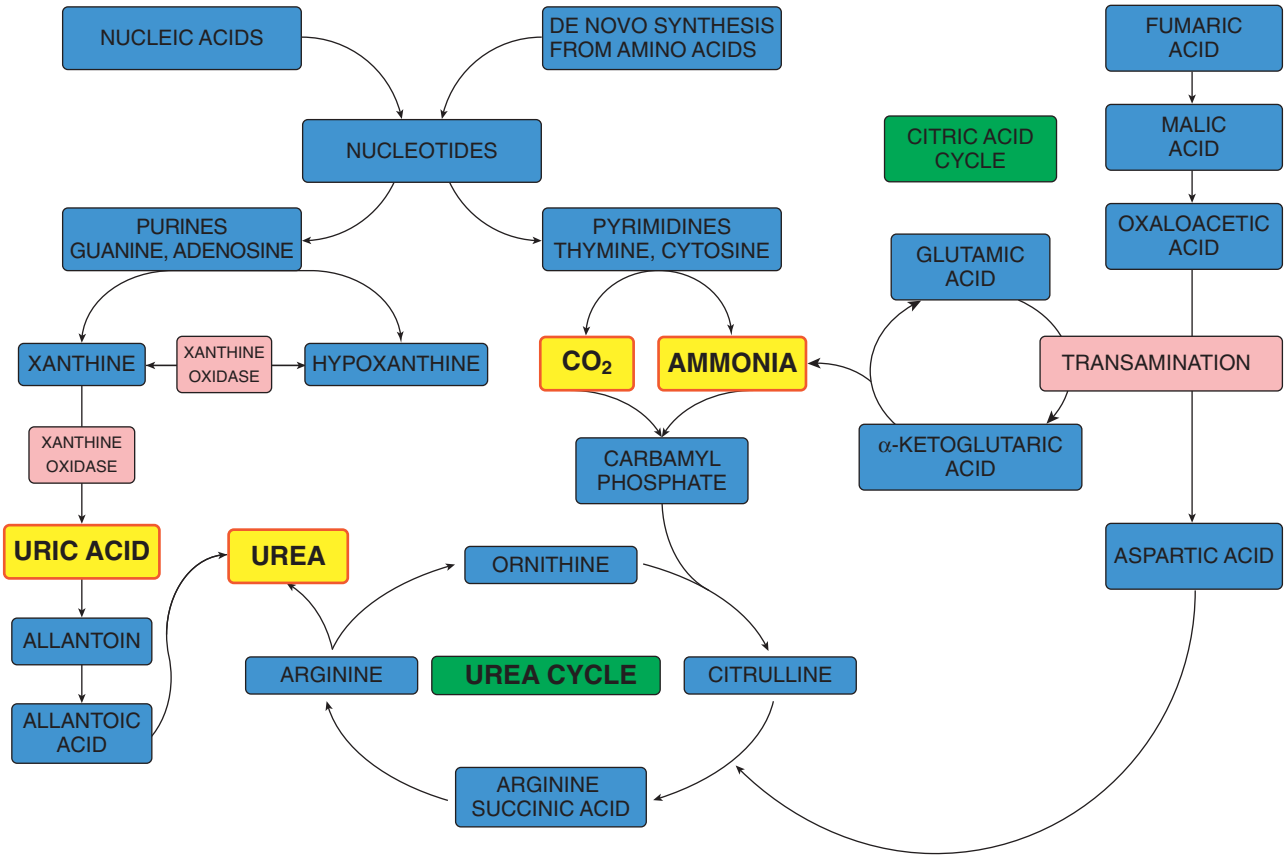

FIG 66.26 Hepatic nucleotide, amino acid, and nitrogenous metabolism in reptiles.

deposit around the joints (periarticular gout) and in other subcutaneous and internal tissues (visceral gout). The MSU crystals form small, macroscopic white nodules called tophi.

Most cases of gout involve the final stage of chronic renal failure and/or dehydration; however, hypovitaminosis A has also been suggested as a predisposing factor in crocodile hatchlings by reduced uric acid secretion due to squamous metaplasia of tubular cells.[61] True gout is caused by the presence of MSU, while pseudogout occurs as a result of any other precipitate (e.g., calcium hydroxyapatite, calcium pyrophosphate dihydrate), which can also cause an acute articular or periarticular inflammatory response.[62]

In primary gout, hyperuricemia results from overproduction of uric acid. Secondary gout occurs when hyperuricemia results from an acquired chronic disease or a drug that interferes with the normal balance between the production and excretion of uric acid. Diuretics are the drugs most commonly implicated in causing gout in humans. Furosemide decreases the renal tubular excretion of uric acid and is contraindicated in dehydration, hyperuricemia, or cases of suspected gout. Misuse of potentially nephrotoxic antibiotics (e.g., aminoglycosides and sulfonamides) can cause tubular nephrosis and predispose the patient to hyperuricemia, especially if dehydrated.

Clinical Presentation. In reptilian patients, common sites for MSU tophi deposition include the pericardial sac, kidneys, liver, spleen, lungs, subcutaneous, and other soft tissues (Fig. 66.27A–C). Clinical signs are typically related to the structures affected and may include anorexia, lameness, joint swelling, and organ dysfunction.

Diagnostic Confirmation. Presumptive diagnosis of gout is made based on history and clinical examination. Laboratory sampling may or may not demonstrate plasma hyperuricemia, depending on the state of health at the time of sampling. Radiographs may reveal lytic lesions in, around, or near the joints. Soft tissue tophi are generally radiolucent and may go unnoticed; but more chronic lesions often become complexed with calcium and may be radiographically visible (see Fig. 66.20D). Ultrasonography may demonstrate MSU deposits as hyperechoic lesions without posterior acoustic shadowing, which enables their differentiation from calcifications (see Fig. 66.21). While standard CT may show crystal aggregates, it does not enable specific identification of MSU crystals; however, dual-energy CT can distinguish MSU crystals from deposits containing calcium.[63] Endoscopic evaluation of the coelomic viscera enables a minimally invasive means of identifying lesions (see Fig. 66.27B and C).

A definitive diagnosis of gout is made by demonstrating MSU crystals in affected joints or tissues. Cytologic examination by phase contrast microscopy of joint aspirates is useful to identify MSU crystals. Visceral gout can be diagnosed by histopathologic examination of soft-tissue biopsies collected by traditional or endoscopic techniques (see Fig. 66.27D). When using polarized light, the tissues must be fixed in absolute ethanol, because MSU crystals tend to degrade and wash out during formalin (aqueous solution) fixation.[64] However, even though MSU may be lost from formalin-fixed tissues, histologic diagnosis is usually still straightforward. If there are no obvious lesions to biopsy then renal function assessments using iohexol clearance should be considered, as GFR measurements are still directly related to functional renal mass.

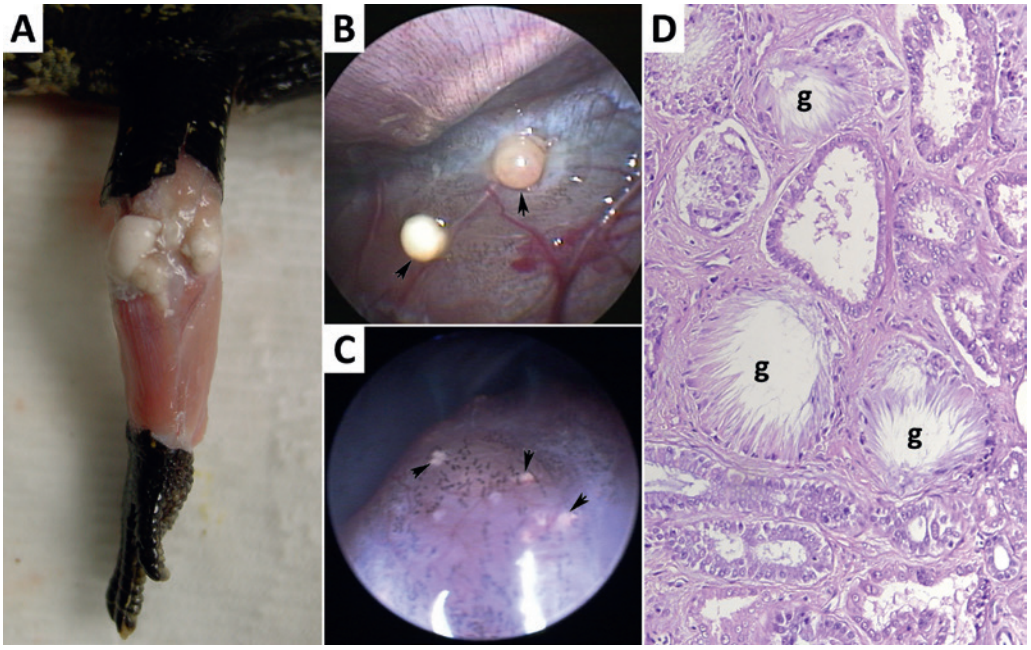

FIG 66.27 (A) Gouty arthritis of the left stifle of a blue-tongued skink (*Tiliqua gigas*). (B) Gout tophi (arrows) associated with the coelomic wall in a green iguana (*Iguana iguana*). (C) Small gout tophi (arrows) visible on the surface of a veiled chameleon's (*Chamaeleo calyptratus*) kidney. (D) Renal biopsy histology from the same chameleon, demonstrating the characteristic appearance of tophi (g). Note that the urate material has been largely washed away from this formalin-fixed sample, but the appearance is still considered pathognomonic (H&E, original magnification ×400). (Courtesy of Stephen J. Divers.)

Prognosis and Prevention. The overall prognosis for patients with severe gout is grave. Advanced cases can be maintained for a short period with suppportive care. In humans, acute gouty attacks are painful, and one should assume that antiinflammatories and analgesics are required for reptiles. Localized disease may be managed surgically.

Appropriate nutrition, particularly the provision of appropriate protein, both in terms of amount and type (animal vs plant) is important. In addition, appropriate provision of water (both dietary and free) to prevent dehydration, and species-specific thermal environments to maintain renal metabolism, are essential.

Specific Treatment. Treatment of gout is threefold: (1) lower blood uric acid levels with antihyperuricemic drugs such as allopurinol, (2) promote urate excretion by diuresis, and (3) manage localized inflammatory tophi through surgical removal (or amputation), and/or antiinflammatory drugs such as colchicine and, if necessary, corticosteroids. Allopurinol at 25 mg/kg PO daily has been shown to decrease plasma uric acid levels in hyperuricemic iguanas by 45%, and there are case reports to confirm its clinical value.[53,65,66] While human drugs such as probenecid act by blocking urate reabsorption from the proximal tubule, there is no evidence of net urate reabsorption along any part of the reptile nephron, and therefore efficacy is more doubtful.[17] The need for analgesics should not be overlooked, and opiates are preferred over nonsteroidal antiinflammatory drugs (NSAIDs) if renal function is questionable.

Newer drugs may have potential for use in herpetologic medicine, but minimal clinical use has been reported to date. Newer xanthine oxidase inhibitors such as oxipurinol and febuxostat are first-line treatments for human patients with renal calculi, renal insufficiency, and hyperuricemia. In humans, they appear safe and well-tolerated with few side effects.[67] Recombinant urate oxidase is used for the treatment of tumor lysis hyperuricemia in human cancer patients, while pegylated urate oxidase shows promise in patients with hyperuricemia and gout.[68] If the patient has severe gouty arthritis, surgically entering the affected joint and physically removing the MSU crystals is possible. However, by the time the crystals have formed, severe joint damage is usually present, and permanent arthopathy ensues. In these cases, treatment may be attempted with long-term allopurinol therapy or amputation.

Glomerulosclerosis, Nephrosclerosis, Glomerulonephrosis, and Tubulonephrosis

Clinical Significance. Degenerative nephroses represent the most common renal diseases encountered and are usually characterized by variable degeneration or necrosis of the glomeruli (glomerulonephrosis) or tubules (tubulonephrosis) (Fig. 66.28). When the majority of renal function has been lost, gout and aberrant calcium metabolism may result in MSU crystals within soft tissues, including the kidney. Calcification of the great vessels and myocardium can lead to congestion of peripheral blood vessels (especially obvious on the sclera of the eye), poor circulation, and ischemic necrosis of the tail or digits. Fracture of mineralized vessels can lead to severe internal hemorrhage. Gastrointestinal effects may include vomiting and passing poorly digested food.

Known Etiological Cause(s). High-protein diets are considered a predisposing cause of hyperuricemia, gout, and nephrosis in herbivorous reptiles. Blockage of the renal tubules with secreted urate in the proximal tubule is another process that impairs renal function and has been associated with chronic dehydration in snakes. The maintenance of high-humidity rainforest species in dry, overheated, captive conditions may result in chronic dehydration and nephropathy.

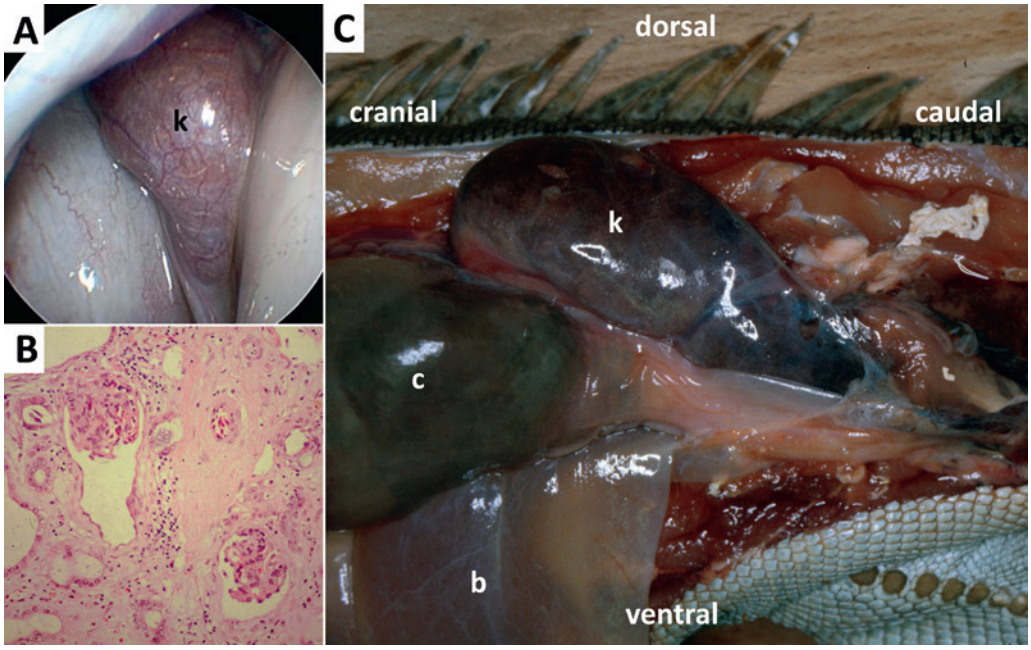

FIG 66.28 Glomerulonephrosis and tubulonephrosis in iguanid lizards. (A) Endoscopic view of an enlarged kidney. (B) Histology section of an endoscopic kidney biopsy revealing glomerulonephrosis, tubulonephrosis, and fibrosis (H&E, original magnification x400). (C) Saggital necropsy view of the pelvic region with the left pelvic limb and pelvis removed revealing a grossly enlarged kidney (k), bladder (b), and constipation of the colon (c) due to extramural pressure. (Courtesy of Stephen J. Divers.)

Clinical Presentation and Diagnostic Confirmation. Typically, reptiles present late in the course of disease when the majority of renal function has been lost, and clinical signs typically include anorexia, weight loss, and poor body condition (see Fig. 66.15). Unlike chronic renal disease in mammals, affected reptiles often present with enlarged, not small, fibrotic kidneys (see Fig. 66.20). Renal biopsy is required for a definitive diagnosis (see Figs. 66.23 and 66.24), but functional evaluation by iohexol clearance is also useful for prognosis.

Prognosis, Prevention, and Treatment. Prognosis depends on the degree of renal function remaining and the extent of the pathologic changes, but is generally guarded to poor. Prevention usually centers on good husbandry, including suitable thermal environment, appropriate humidity/temperature, and removal of animal protein from herbivorous diets. Treatment is supportive and often includes efforts to increase water intake (i.e., soaking plant foods and feeding wet, injecting vertebrate prey with water), decrease purine loads, decrease nitrogenous waste levels, and increase potassium intake.

Interstitial Nephritis, Glomerulonephritis, Tubulonephritis, and Pyelonephritis

Clinical Significance. Inflammatory conditions of the kidneys appear to be less commonly encountered but have been associated with bacterial, viral, fungal, and parasitic infections in reptiles.[4] In addition, drug-induced nephritis has been reported in humans and may be possible in reptiles. Severe, acute infections can cause acute renal failure; thus it is important to diagnose these conditions accurately because prompt and appropriate therapy may result in reclamation of temporarily lost renal function and complete recovery.

Known Etiological Cause(s). Various bacteria, including *Citrobacter, Escherichia, Moraxella, Salmonella, Serratia, Aeromonas, Listeria, Leptospira, Streptococcus, Mycobacteria,* and *Chlamydia* have been isolated from reptile kidneys, either as primary agents of nephritis or secondary to generalized sepsis (Fig. 66.29A). Renal geotrichosis, phaeohyphomycosis, cryptococcosis, coccidioidomycosis, and candidiasis have also been identified in select individuals with renal pathology. *Entamoeba invadens, Hexamita parva, Myxidium, Klossiella,* and *Caryospora* are documented protozoan causes of nephritis and renal necrosis, while *Spirorchis* nematodes have been reported from aquatic chelonians, and filarial nematodes from lizards (see Fig. 66.29B). Herpesviruses, adenoviruses, arenaviruses, and iridoviruses have been associated with inflammatory or necrotic renal lesions.[4]

Clinical Presentation and Diagnostic Confirmation. Many of these conditions may result in chronic debilitation, chronic renal disease, and renal insufficiency, whereas acute conditions can result in acute renal compromise and even renal failure. Such acute cases usually present in good body condition, and aggressive case investigation is warranted because appropriate treatment can regain lost renal function and recovery. Pronounced inflammation and/or infection may induce leukocytosis. Ultimately, renal biopsy is required for definitive diagnosis, although urinalysis, especially sediment evaluation, can provide valuable clinical insight in cases of parasitic, bacterial, or fungal nephritis. In cases of bacterial or fungal nephritis, culture and sensitivity or, better still, MIC testing, is always indicated.

Prognosis and Prevention. Prognosis is dependent on the degree of renal damage and the success of treatment. Following treatment, iohexol clearance can be repeated to monitor renal function for long-term prognosis. Some conditions are associated with obligate pathogens, and strict attention to quarantine and preventative health programs should be effective for prevention. Many bacterial infections, however, are opportunistic and involve commensal flora. In these cases, some degree of immunosuppression is often considered a predisposing factor and may include inappropriate environment, poor nutrition, inappropriate multianimal grouping, and unsanitary conditions.

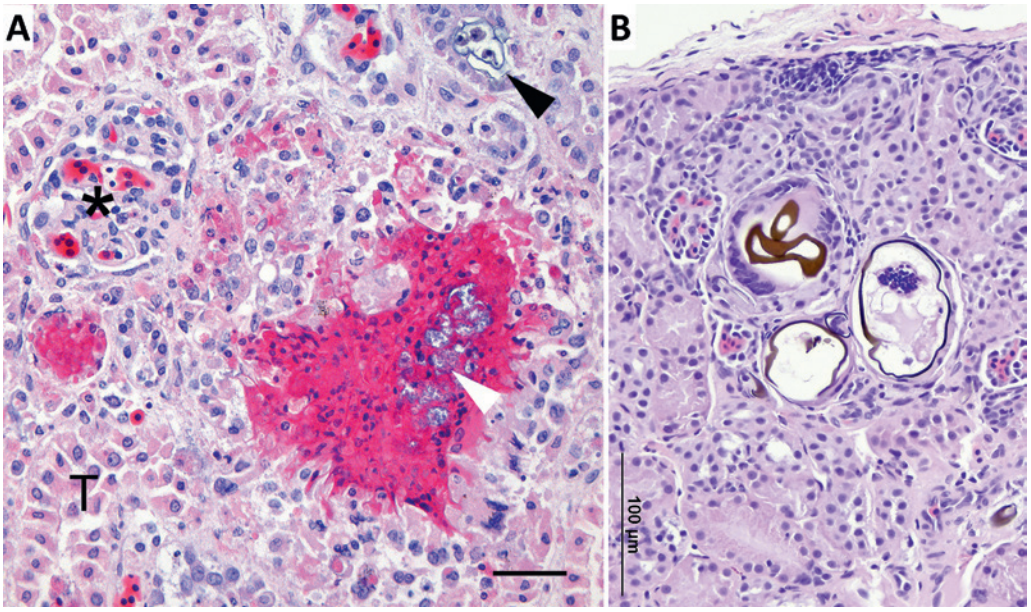

FIG 66.29 (A) Kemp's ridley turtle (*Lepidochelys kempii*), bacterial nephritis. Heterophils and macrophages infiltrate tubules (T) and the renal interstitium, forming heterophilic granulomas containing bacteria (white arrowhead). Also shown are a tubule containing mineralized material (black arrowhead) and a glomerus (asterisk) bordering the inflammation (H&E, bar = 50 µm). (B) Histologic section demonstrating a *Spirorchis* nematode within the kidney of a *Trachemys* slider (H&E, bar = 100 µm). (A, Courtesy of Brian Stacy, National Oceanic and Atmospheric Administration Fisheries; B, courtesy of Stephen J. Divers.)

Treatment. In addition to general supportive measures, a definitive diagnosis will dictate specific antibacterial, antifungal, antiparasitic, or antiviral therapies. The appropriate use of culture and sensitivity or MIC data to direct treatment cannot be overemphasized. In humans with severe renal insufficiency, there are specific drug dose reductions/modifications that have been formulated when using drugs that are renally excreted. Although no such determinations have been made for reptiles, it would be wise to monitor for potential drug accumulation and toxicity if using renally excreted drugs. Serial monitoring of drug levels probably provides the most accurate means of therapeutic management.

Toxic Nephropathy

Toxic nephropathies have been associated with aminoglycosides and exogenous vitamin D_3 supplementation. While any aminoglycoside can cause nephrotoxicity, gentamicin has been well-documented in snakes.[69,70] Heavy metals, including lead, tend to bioaccumulate in liver and kidney tissues and might be expected to compromise function.[71] Exogenous vitamin D_3 supplementation may be used by some to avoid the expense of providing broad-spectrum lighting; however, this can result in soft tissue mineralization, including the kidneys (see Fig. 66.20B). Radiographic demonstration of metallic gastric foreign bodies with elevated blood levels are diagnostic for heavy metals. Vitamin D_3 (25-hydroxcholecalciferol) assays are available commercially. Other toxicities are difficult to confirm because assays and testing are toxin-specific. Preserving frozen tissues following necropsy can be helpful if, following histological evaluation, further toxicological investigations are warranted. Diuresis, physical removal, and chelation therapy for heavy metals, and preventing further exposure, are the mainstays of treatment.

Renal oxalosis has been documented in both health and unhealthy green turtles (*Chelonia mydas*) and desert tortoises (*Gopherus agassizii*).[72,73] While it is often stated that captive herbivorous reptiles should not be fed plants that contain substantial amounts of oxalate (e.g., spinach), it is highly likely that herbivores have evolved tolerance for modest oxalate ingestion. It is notable that no cases of oxalate urolithiasis have yet been documented in reptiles. However, the diagnosis of subclinical oxalosis in two herbivorous chelonian species suggests that additional investigation of oxalate tolerance is indicated.

Urolithiasis

Urolithiasis (cystic calculi, ureteroliths, cloacal uroliths) has been reported in chelonians and lizards.[74–77] Urolith location may be anywhere along the urinary tract, including the kidneys, ureters and cloaca; however, cystic calculi are most common.[78] Most uroliths are composed of urate salts, however, calcium-phosphate, -carbonate, -oxalate, and mixed compositions have been reported.[74-77] Postrenal obstruction, either by ureteroliths or uroliths lodged within the urodeum, can result in renal failure.[76]

Clinical Significance and Known Etiological Cause(s). It has been proposed that chronic dehydration, high-protein diets, and overheating may factor in the etiology of urolithiasis.[74] Urine modification occurs across the bladder epithelium with water reabsorption along a concentration gradient resulting in further urine concentration (but not exceeding that of plasma).[33,79] Therefore chelonians will often not urinate until they have the ability to drink and replenish their bladders. Consequently, chronic dehydration, overheating, and lack of drinking water are likely to increase water absorption from the bladder, leading to supersaturation of urates, which, along with prolonged urine retention, may predispose to urolith formation. Small cystic calculi probably do not cause significant problems other than minor irritation. Larger stones, because of their size and weight, can act as space-occupying lesions and result in severe cystitis, pressure necrosis of the bladder wall and internal viscera, and coelomitis.

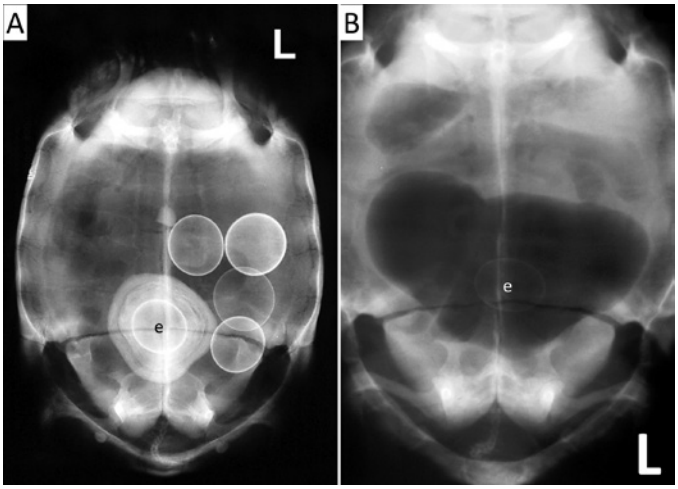

FIG 66.31 (A) *Testudo* tortoise with several retained eggs; however, one egg (*e*) is within the bladder and, as a nidus, has led to the development of a cystic calculus. (B) Pneumocystography to demonstrate the presence of a poorly mineralized egg (*e*) within the bladder of a *Testudo* tortoise. (Courtesy of Stephen J. Divers.)

Clinical Presentation and Diagnostic Confirmation. Many cystic calculi probably have protracted subclinical courses; however, anorexia, constipation, tenesmus, dystocia, dysuria, poor growth, cloacal prolapse, lethargy, hind limb paresis, and lack of fecal/urine production may become apparent. Palpation of the prefemoral fossae of chelonians, caudal coelom of lizards, or per cloaca may reveal a hard structure. Gentle rocking of the patient from side to side often allows for digital ballottement of large calculi. There may be a predisposition, in chelonians, for cystic calculi to be located in the left lobe of the urinary bladder.[74] Hematology, plasma biochemistry, and urinalysis do not appear to be routinely beneficial in the diagnosis of urolithiasis in reptiles; however, obstructive uroliths may cause biochemical changes indicative of postrenal obstruction, and severe cystitis may result in leukocytosis and hematuria.

Urinary calculi are most easily confirmed by radiographic demonstration of radio-opaque, rounded laminar structures in the caudal coelom, intrapelvic, or cloacal regions (Fig. 66.30). While urate calculi are sometimes radiolucent in mammals, reptilian stones are often composed of potassium or calcium urate salts and are radiodense. Variable mineral complexes result in variable radiographic appearances and, rarely, calcium apatite or calcium phosphate stones have been reported.[74,76,80] Ultrasonography, CT, MRI, or cystoscopy can also be useful in select cases. Urolith evaluation can include chemical analysis, infrared spectroscopy, optical crystallography, radiographic microanalysis, and scanning electron microscopy, with radiographic microanalysis and scanning electron microscopy providing nondestructive, rapid analysis, for both the exterior and interior of stones.[81]

Preferred Medical or Surgical Treatment(s). There are no medical dissolution recommendations for reptile uroliths, and surgical removal is recommended. Cystic calculi can be removed during coeliotomy and cystotomy, with recurrent cases managed with cystectomy (see Chapters 97 through 101 and 104).[82] Care must be taken to avoid contamination of the coelom as bladder contents are seldom sterile, and in addition to perioperative antibiotics, thorough irrigation of the coelom should be performed after bladder surgery. Cystic and cloacal calculi can be endoscopically removed through the vent.[78] There are few reports of endoscopic laser lithotripsy in reptiles, which describe variable success; however, extracorporeal shockwave lithotripsy does not appear to have been tried but may be worthy of consideration given reported success in humans.[83,84]

Prognosis and Prevention. The prolonged subclinical stage of cystic calculi has prompted many clinicians not to treat this condition. However, a retrospective study has indicated urolithiasis as a cause of death in 50% of chelonians necropsied with urolithiasis.[74] The prognosis following surgical removal is good, although recurrence is possible. Reducing dietary protein of herbivores, ensuring appropriate thermal and humidity gradients, and adequate provision of water are probably important for prevention.

Ectopic Eggs in the Urinary Bladder

Retrograde displacement of shelled eggs into the urinary bladder has been documented in chelonians (Fig. 66.31).[85,86] In some cases there is a previous history of oxytocin therapy to induce laying. Like cystic calculi, ectopic eggs can traumatize the bladder mucosa and act as a nidus for infection and urolith formation. Egg removal from the chelonian bladder can be pursued via traditional plastronotomy or prefemoral coeliotomy but has also been successfully performed cystoscopically.[85,86] Saline-infusion cystoscopy is used to identify and isolate the egg, and a variety of techniques have been used to fragment and remove egg material. Thorough lavage of the bladder ensures complete removal of egg fragments and contents. Endoscopic snares and baskets may be useful for retrieving eggs during cystoscopic visualization.

Neoplasia

A variety of urinary neoplasias have been reported from snakes, lizards, and chelonians, but not, as yet, crocodilians. Renal adenomas, adenocarcinomas, neofibroblastoma, fibroma, myxofibroma; cloacal carcinoma, transitional cell carcinoma, sarcoma, and ureteral transitional cell carcinoma have been reported (Fig. 66.32).[87] Few clinical signs have been reported and have typically been nonspecific; however, firm swellings associated with the caudal coelom (75%–95% snout-to-vent) of snakes, or the caudodorsal coelom or tail base dorsal to the cloaca of lizards, should be treated with suspicion.

Miscellaneous Diseases

Renal cysts, fibrosis, renal edema, renal amyloidosis, and cholesterol deposition have been reported.[4,88,89] Patent urachus and yolk coelomitis was diagnosed in a neonate prehensile-tailed skink (*Corucia zebrata*). Clinical signs included coelomic swelling, weakness, and dehydration. Diagnosis was confirmed by contrast radiography per cloaca, and surgical ligation was successful.[90]

CONCLUSION

Urinary tract disease remains an important veterinary consideration; however, much remains to be learned about reptile urologic pathophysiology. In many cases, initiating causes are often inferred from poor management or extrapolated from histopathologic interpretations made late in the course of the disease or too often, at necropsy. The link between parathyroid hormone and renal disease in humans has been well documented, and given the high prevalence of clinical (and subclinical) nutritional secondary hyperparathyroidism in many captive-reared reptiles, this certainly warrants further investigation. Along with hyperparathyroidism, chronic dehydration, overheating, and protein excess appear to be common predisposing factors, especially in herbivores.

In cases of chronic renal disease, clinical signs and biochemical changes are unlikely to become apparent until late in the disease. Iohexol clearance appears to be a safe and practical method for estimation of GFR in practice. Endoscopic evaluation provides a safe and effective means for visualization and biopsy of kidneys. Appropriate therapeutic and surgical decisions (including euthanasia) can only be made after an accurate diagnosis.

ACKNOWLEDGMENTS

The authors would like to acknowledge the profound influence of those that have contributed to our clinical knowledge of reptile urology, notably Doug Mader and Peter Holz, whose efforts in producing the previous chapter and edition have remained foundational for the current chapter.

Hepatology

Stephen J. Divers

The reptilian liver is similar in structure and function to that of other vertebrates. It is the largest single visceral organ and may be elongated in snakes and some lizards, or transverse in testudines and other lizards. Liver disease is not uncommon in reptiles, and yet a review of spontaneous hepatopathies indicates that the vast majority of cases have been diagnosed postmortem.[1–11] This implies deficiency in the current clinical approach to hepatobiliary disease diagnosis. Therefore the aim of this chapter is to familiarize the clinician with hepatic anatomy and physiology and provide clear guidance on antemortem diagnosis of hepatobiliary diseases in reptiles.

ANATOMY

The embryonic liver originates from the endodermal gut with the hepatic diverticulum branching as it advances, giving rise to the bile ducts and gallbladder.[12] The formed organ is typically (except in snakes) bilobed, dark brown to almost black in some species, and comprises about 4% to 5% of body weight in most squamates. In temperate species, the liver tends to weigh more in the fall before hibernation when glycogen and intrahepatic fat stores are maximal; however, great interspecies variation exists. The liver of snakes typically lies alongside the right lung or is retroperitoneal along the dorsal body wall, 30% to 58% snout-to-vent depending on taxa, with the heart cranial and the stomach caudal (Fig. 67.1A).[13] The saurian liver is often divided into left and right lobes, although some species may possess a large middle or even accessory lobes. The liver of lizards is usually triangular in shape and traverses the cranial to mid coelom (see Fig. 67.1B).

The chelonian liver is large and traverses the cranial coelom. The smaller, left lobe is connected to the concave side of the stomach by the gastrohepatic ligament, and the right lobe is attached to the duodenum by the hepatoduodenal ligament (Fig. 67.2). The coronary ligament connects the chelonians liver to the transverse septum, while the pericardial sac rests in the depression between the left and right lobes. A very short mesentery, equivalent to the falciform ligament of other vertebrates, attaches the liver to the parietal peritoneum. This mesentery contains the ventral abdominal veins that carry blood from the caudal coelom and viscera to the portal vein. In crocodilians, the liver occupies a large portion of the cranial to mid coelomic cavity, more so on the right. During inspiration, the liver is pulled caudad, allowing the lungs to expand, and although not homologous to the mammalian diaphragm, there are certainly some functional similarities.

The blood supply to the liver includes the portal vein and hepatic artery (Fig. 67.3). The portal vein is variably formed by the anastomosis of the anterior abdominal, gastric, lienogastric, and intestinal veins.[12] Additional venous supplies may come from the dorsal gastroesophageal and parietohepatic veins.

Although the parenchyma is one continuous mass of cells, it is not functionally homogenous. However, the reptilian liver is less clearly divided into lobules compared to its mammalian counterpart, and metabolic zonation, common in mammals, is difficult to appreciate in reptiles. Portal tracts may consist of a bile duct and a portal vein branch surrounded by a small amount of connective tissue; however, the distribution of portal tracts is not uniform (Fig. 67.4). Histologic cross-sections suggest that the hepatocytes are arranged in a tubular or trabecular fashion, but most of these cords are arranged in sheets or plates. The reptilian hepatocyte shares many similarities with its mammalian counterpart, and there are three additional main cell types that form the hepatic sinusoids, namely, the endothelial cells, macrophages (including Kupffer cells), and stellate or Ito cells. The sinusoids are lined by a thin layer of endothelial cells, and filamentous material between these cells and the hepatocytes may play an insufflating role in ectotherms, maintaining metabolism despite variations in body temperature. The Kupffer cell is an intraluminal macrophage attached to the endothelium, charged with clearing the portal blood of intestinally derived endotoxins. A second macrophage is perisinusoidal and is variably pigmented. Clusters of these macrophages or melanomacrophages are numerous in a parasinusoidal position in amphibians and reptiles and are believed to be responsible for the removal of free radicles. The stellate cell, Ito cell, or lipocyte has been well-studied in various reptiles. They lie between the endothelium and sinusoidal surface of the hepatocyte and are numerous in crocodilians but less so in testudines. The cytoplasm of the resting form contains round, fat droplets, which, being rich in vitamin A ester, are the main site of vitamin A storage.

The bile canaliculi form a meshwork throughout the parenchyma. Most reptiles have a gallbladder embedded within the caudal margin of the right lobe; however, in snakes it is distinct and caudal to the liver. The gallbladder of colubrid snakes splits into many branches, forming a biliary plexus that joins the cystic duct. The common bile duct passes to the right of a small spherical gallbladder and through the pancreas to the ampulla of Vater, where it is joined by the pancreatic duct before entering the small intestine. In some lizards, the common bile duct does not go through the pancreas but enters the ampulla directly. In chelonians, peristaltic contractions have been noted in the gallbladder and common duct, beginning at the fundus and proceeding down to the duodenum. These contractions are stimulated by the presence of fat in the duodenum.

PHYSIOLOGY

Hepatic metabolism changes as the reptile develops from egg to hatchling to adult. In addition there are annual cycles in those animals that hibernate. The rate of hepatic metabolism in adult reptiles is similar

to that of the kidney and only slightly less than that of the heart. Liver function is sensitive to changes in temperature and decreases sharply in a linear fashion when core body temperature falls. One of the most important functions of the liver is to supply glucose. The normal precursor of glucose in the hepatocyte under aerobic conditions is glycogen. Glycogenolysis is a multistep enzymatic process similar to that documented in mammals. The liver can produce glucose from pyruvate, lactate, fats, and some amino acids by gluconeogenesis. Blood glucose levels typically vary between 25 and 150 mg/dL (1.38–8.26 mmol/L). Reptiles do not incur cerebral cortical damage at the very low blood glucose levels measured during hibernation and after prolonged dives. Some reptiles maintain blood glucose during prolonged fasting as well as glycogen stores (mainly derived by gluconeogenesis) from protein sources. Consequently, metabolic reserves are depleted and insulin levels fall. Hepatic glycogen storage is maximal in the fall in those animals that hibernate and becomes quickly depleted during hibernation. When glycolysis switches from aerobic to anaerobic, hepatic and muscle tissues produce lactate, which under aerobic conditions is converted to pyruvate in the liver. The resulting lactic acidosis causes a drop in blood pH and heart rate, even if the animal is active (e.g., during a dive).

Unlike mammals, fat is not stored in subcutaneous sites, but instead reptiles tend to possess discrete intracoelomic fat bodies. The main purpose of this fat is to supply material for vitellogenesis during the reproductive cycle and as an energy supply during most of hibernation,

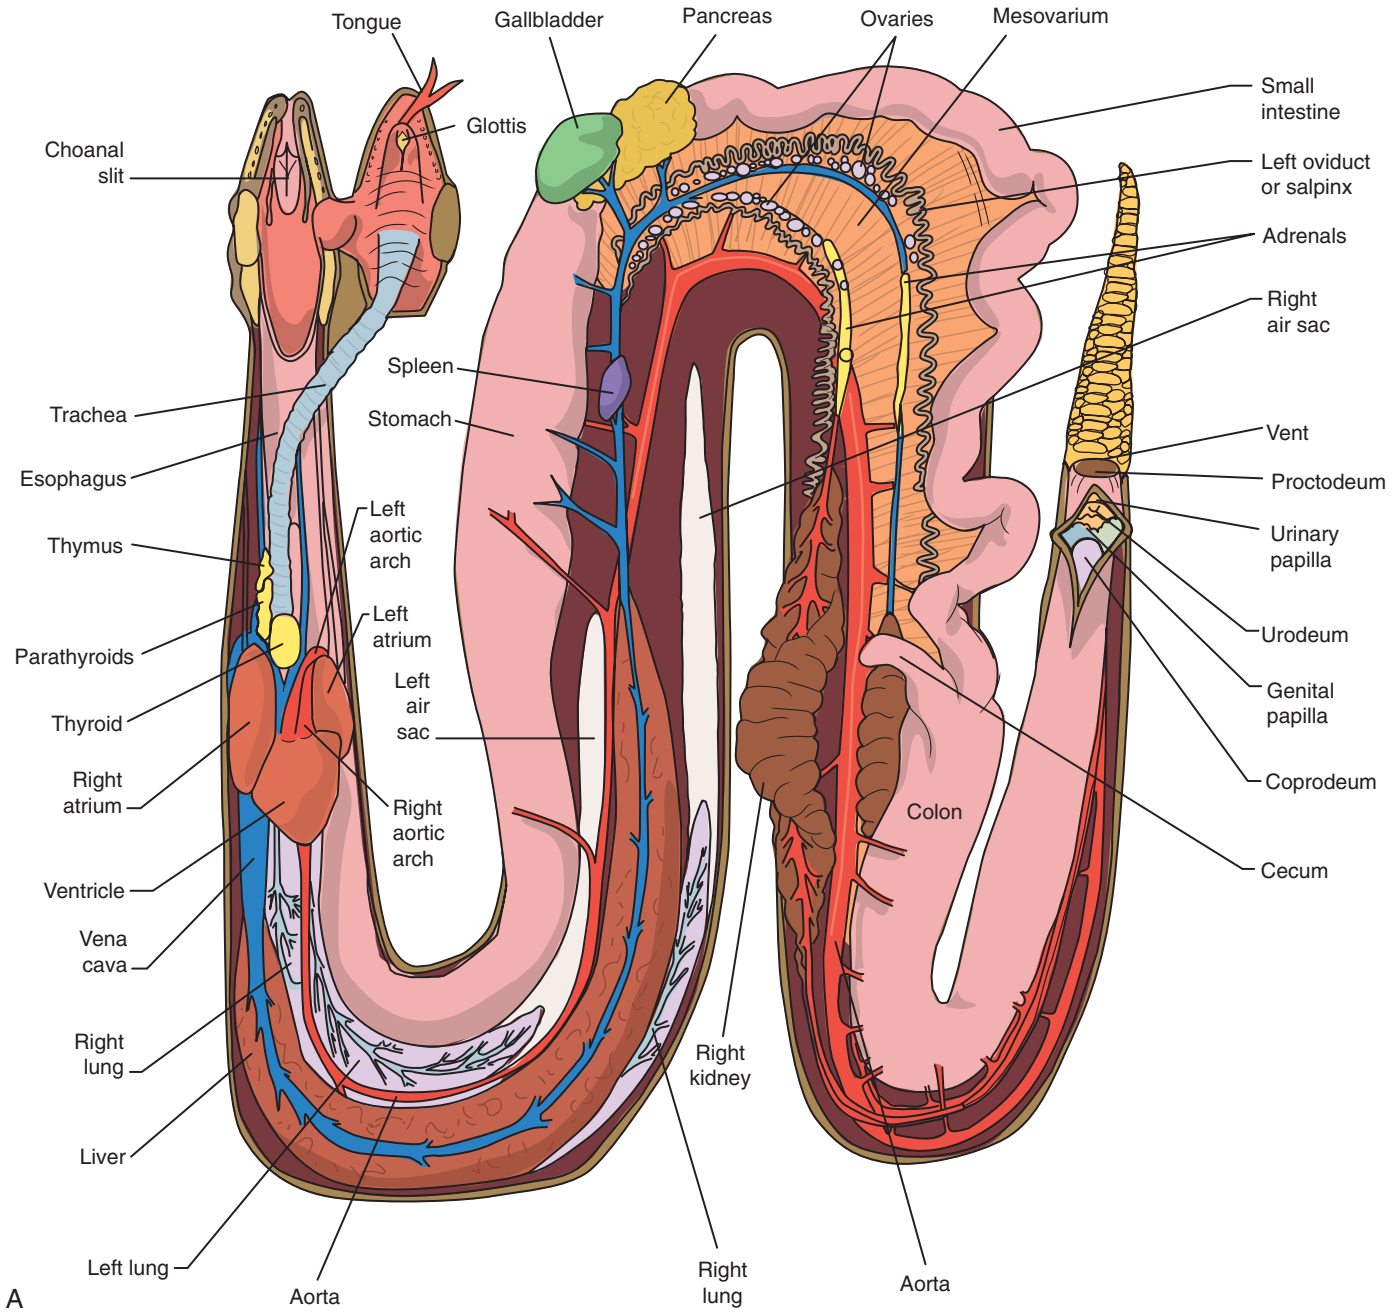

FIG 67.1 (A) Snake coelomic anatomy.

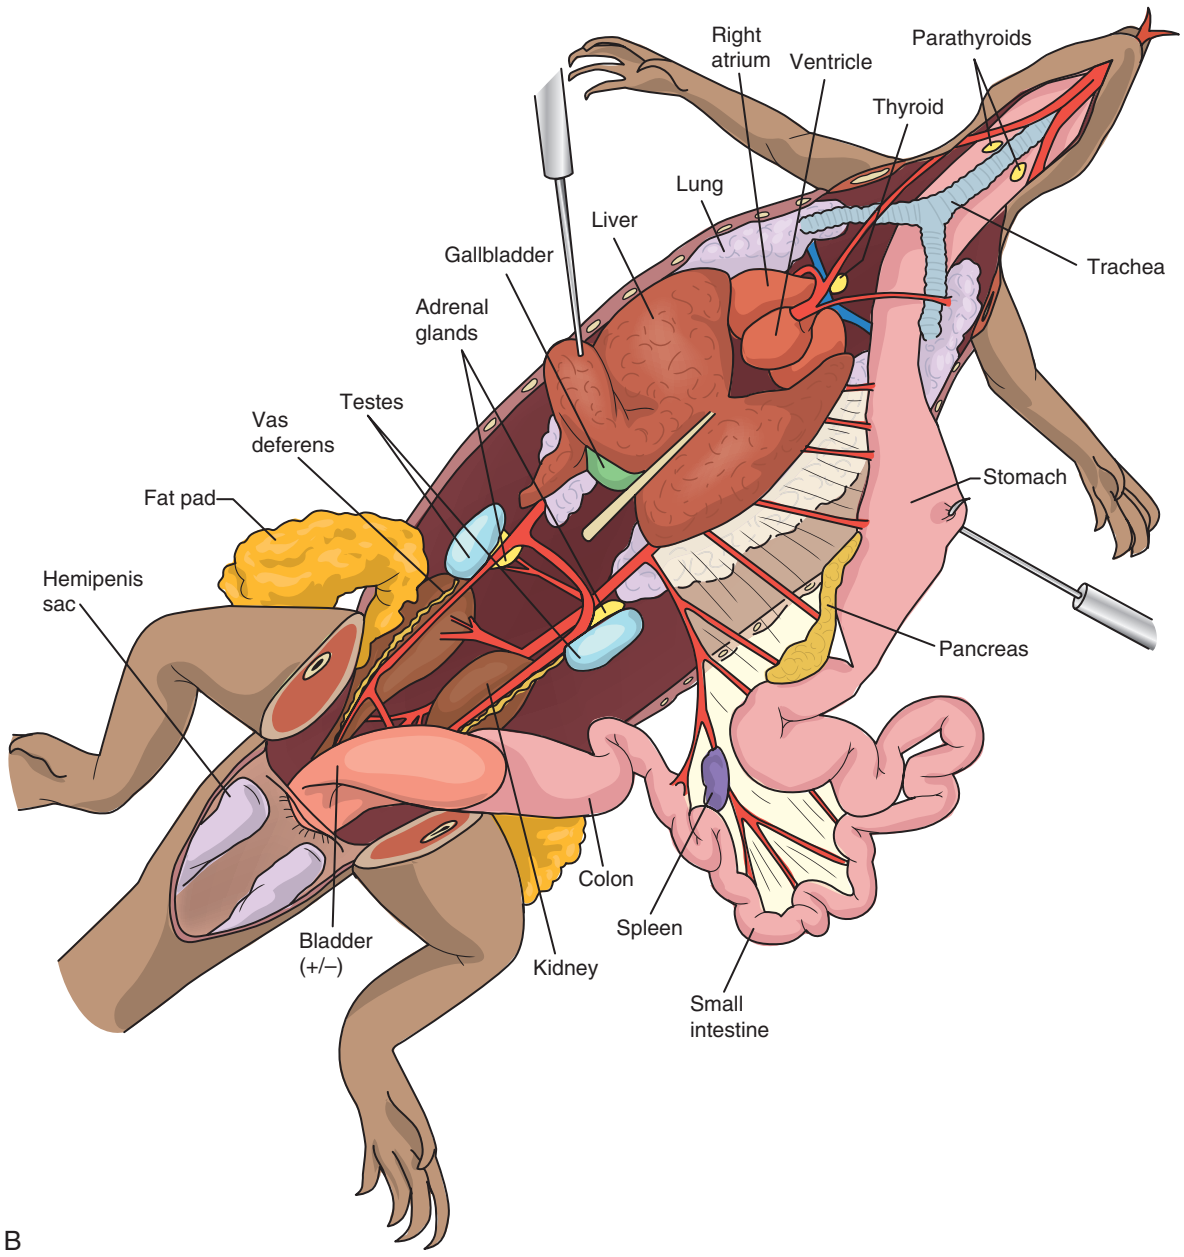

FIG 67.1, cont'd (B) Lizard coelomic anatomy.

periods of prolonged fasting, and in hatchlings following the absorption and translocation of yolk lipids. The fat content of the liver is highest just before hibernation and lowest at emergence. Typically, the livers of females tend to contain more fat than those of males; however, this additional fat should naturally become depleted after reproduction. Captive, temperate reptiles that are not permitted to hibernate, and females that are not permitted to reproduce, may go through annual cycles of increased fat deposition, resulting in obesity and hepatic lipidosis. Fat is transported to the liver as unesterified fatty acids and becomes esterified and lipoprotein-bound before entering the circulation. The liver also exports phospholipids and cholesterol.

Bile acids, derived from cholesterol, are only formed in hepatocytes and are important in lipid digestion and absorption. Bile acids of reptiles have been extensively studied from an evolutionary perspective with the most primitive bile acid, 3α-hydroxyl bile acids, found in all reptiles studied (Table 67.1). This is convenient as bile acid assays used in veterinary medicine measure this 3α-hydroxyl metabolite.

Reptiles can develop hyperbilirubinemia with jaundice/icterus due to impairment of bile flow, either intrahepatic or posthepatic. Most reptiles lack the biliverdin reductase and are reportedly unable to reduce biliverdin to bilirubin. However, snake plasma contains bilirubin and not biliverdin, although biliverdin may still be the predominant pigment in serpentine bile. The enzyme responsible for conjugation of bilirubin with glucuronic acid is less prominent, and the hepatic uptake of unconjugated bilirubin is much slower in snakes than in mammals. The plasma of indigo snakes (*Drymarchon* sp) contains 10 times more unconjugated bilirubin in the absence of hemolysis than that of other species of snakes. In addition, the bile of these snakes contains more than 95% biliverdin.

The liver is central to protein metabolism as it processes alimentary amino acids and peptides for the reptile's own distinctive proteins. The majority of the synthesis occurs in the endoplasmic reticulum of hepatocytes. During hibernation of temperate species, protein metabolism may actually increase with formation of more amino acids and amides.

The liver is the only source of albumin, which is required for the carriage of many endogenous (e.g., calcium) and exogenous substances, and for maintaining the colloid osmotic pressure of plasma. The liver produces clotting proteins (including fibrinogen; prothrombin; and factors V, VII, VIII, IX, and XI) and is also responsible for the synthesis and degradation of carrier proteins. These include transferrin; ferritin; various hormone-transporting proteins for secretions of the thyroid, adrenal cortex, and pituitary, and more. During acute liver injury, carrier proteins may rise in plasma and behave like acute phase reactants. Fibrinogen and enzymes of hepatocellular origin may also participate in the response to acute hepatic injury. This is the basis for the widely used measurements of alanine transaminase (ALT), aspartate transaminase (AST), and sorbitol dehydrogenase (SDH) activities for assessing hepatocellular damage. Enzymes related to bile secretion include alkaline phosphatase (ALP), gamma glutamyl transferase (GGT), 5′ nucleotidase, and leucine aminopeptidases. The range of normal or observed activities of these and other hepatocellular enzymes has been documented in only a few reptilian species (see Chapters 34 and 35), although very few, if any, conform to the requirements for the establishment of reference ranges published by the American Society of Veterinary Clinical Pathologists.[14]

The liver also processes proteins prior to recycling or removal from the body. The amino groups may be used in transamination or converted to urea by the ornithine–citrulline-arginine cycle (Fig. 67.5). Urea is formed in hepatocellular mitochondria, and although the kidneys excrete most, some enters the intestinal tract, either in bile or by diffusion. Urea production in reptiles tends to be low and variable, having a more significant function in chelonians and crocodilians, especially aquatic species. Nucleic acids, especially those of purine origin, are degraded to uric acid by the liver and then secreted by the proximal renal tubules. This uricotelic process is present in some terrestrial chelonians but is most pronounced in the lizards and snakes. The most toxic nitrogenous waste product, ammonia, is produced by pyrimidine degradation and

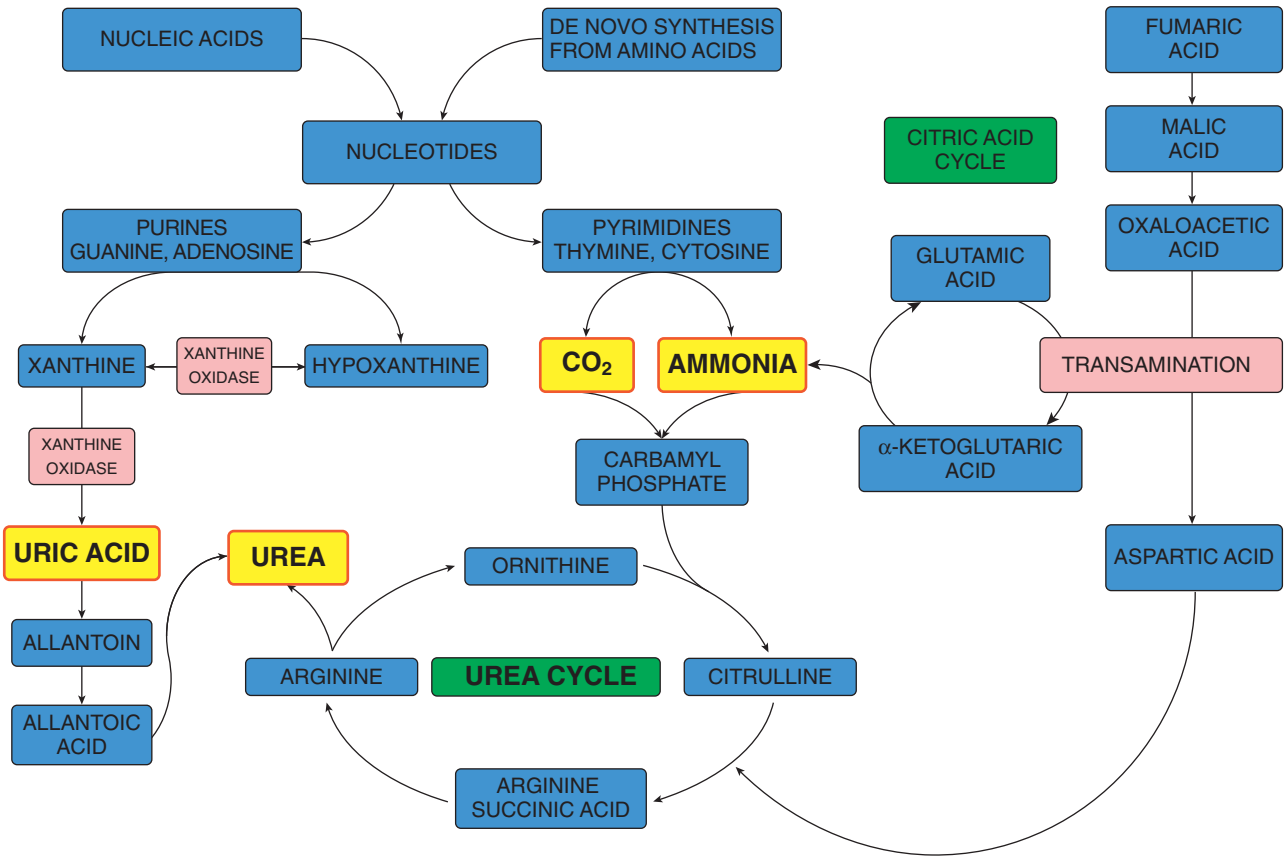

FIG 67.5 Hepatic nucleotide, amino acid, and nitrogenous metabolism in reptiles.

deamination of glutamate within hepatocytes. However, ammonia is combined with carbon dioxide to form carbamyl phosphate, which drives the urea cycle. The variability of ammonia, urea, and uric acid excretion is variable between species and affected by ecology (desert vs rainforest vs aquatic) and even the season (Table 67.2).[15] It would be a mistake for clinicians to rely solely on uric acid (often the only nitrogen parameter in commercial biochemistry reptile profiles) and to ignore the significant contributions of ammonia and urea in non-squamates.

The liver removes and degrades many hormones from the circulation, a process that may involve oxidation, reduction, and conjugation. The hepatic metabolism of progesterone has been examined in Shingleback lizards (*Tiliqua rugosa*) and was found to be similar to that of mammals. Estrogen receptors have been identified within the liver of painted turtles (*Chrysemys picta*), with levels varying during the year but highest in the spring (preovulatory), with a smaller peak in the fall (vitellogenesis). Seasonal variations in the hepatic metabolism of adrenal hormones have been studied in some agamids (*Calotes* sp), with levels greatest in the spring and lowest in the fall. Epinephrine increases, and thyroidectomy decreases, hormonal metabolism by the liver. Vitellogenins, stimulated by estrogen, are the yolk protein precursors that are formed exclusively in the liver and transported to the ovaries by the general circulation.

CLINICAL INVESTIGATION

History and Physical Examination

The approach to hepatic disease investigation in reptiles is similar to that in mammals. Recently, the World Small Animal Veterinary Association (WSAVA) published guidelines for the diagnosis of known hepatic diseases in dogs and cats.[16] Although these guidelines relate specifically to dogs and cats, they serve as a useful guide for the appropriate investigation of hepatobiliary disease in reptiles. They also serve as a useful reminder that just because a specific disease process has not been identified in reptiles, it does not mean that it cannot occur. As clinicians involved in the evolution of herpetologic medicine, we must continually strive to watch for the first case of a portal systemic shunt or hepatocutaneous syndrome.

Detailed information on performing a physical examination is covered elsewhere (see Chapter 42). Clinical signs, physical examination findings, and clinicopathologic abnormalities associated with hepatobiliary disease often reflect disruptions in normal structure and function. The liver possesses a large functional reserve, and therefore the appearance of potentially hepatic-associated signs such as icterus and ascites typically represents exhaustion of these reserves that occur late in the course of disease. Therefore any reptile exhibiting such signs should be investigated as a matter of urgency. Nonspecific signs including intermittent anorexia, vomiting, and lethargy can occur with diseases associated with the liver or a variety of other organ systems. Therefore diagnostic investigation is also required to differentiate from hepatic and nonhepatic diseases.

Historical events such as the ingestion of known hepatotoxic substances (e.g., aflatoxins, pyrrolizidine alkaloids) or treatment with potentially hepatotoxic drugs (e.g., NSAIDs, glucocorticoids) may suggest the presence of hepatobiliary disease. An obese reptile that becomes anorectic may be predisposed to hepatic lipidosis, while chronic hepatic disease often predisposes to gastrointestinal ulceration, hematemesis, coelomic pain, and melena.

[a]Calculated as % sum of the ammonia, urea, and uric acid when total nitrogen data were not available. Molecular weights of 18, 60.1, and 168.1 and percentages N of 83%, 46.7%, and 33.3% were used, respectively, in calculations.
From Campbell JW: Excretary nitrogen metabolism in reptiles and birds. In Walsh PJ, Wright P, eds. *Nitrogen Metabolism and Excretion*. London: CRC Press; 1995;147–178.

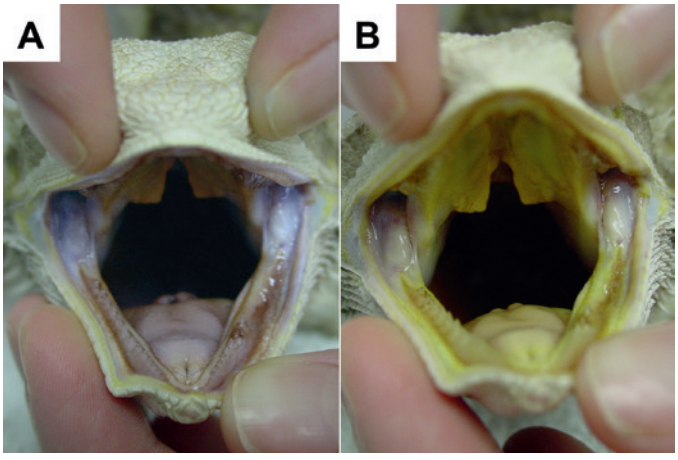

FIG 67.6 (A) Normal and (B) icteric appearance of the oral cavity in two bearded dragons (*Pogona vitticeps*). (Courtesy of Stephen J. Divers.)

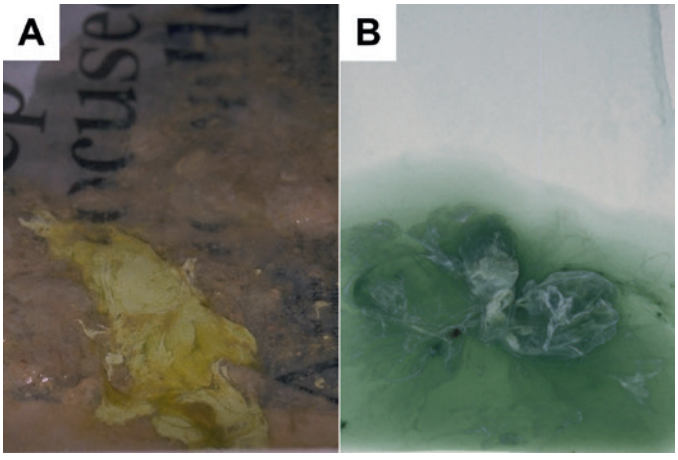

FIG 67.7 Voided urine from (A) a boa constrictor (*Boa constrictor*) and (B) a Greek tortoise (*Testudo graeca*). Note the yellow to green pigmentation of the urine/urates. (Courtesy of Stephen J. Divers.)

The presence of icterus is the most significant and specific sign associated with hepatobiliary disease. In those squamates that produce bilirubin, a yellow discoloration to the mucus membranes may be obvious, while in other species, a more green pigment, especially in urine/urates, is often appreciated (Figs. 67.6 and 67.7). However, in many cases, mucous membrane pigmentation often complicates evaluation. Commonly reported in mammals, polyuria/polydipsia is seldom appreciated in reptiles; however, coelomic enlargement due to ascites or hepatomegaly, anorexia, poor body condition, neurologic depression, and lethargy might also be indicators of an underlying hepatic disorder.

Data from Schnellbacher R et al, unpublished data.

Clinical Enzymology

Although evaluations of hepatobiliary enzymes (e.g., ALT, AST, ALP, GGT, and SDH) are routine in human and domesticated animal medicine, it would be wrong to assume that they are as reliable in reptiles (Table 67.3). All of the commercial enzyme measurements are designed for mammals and are run at 37°C. Very few studies have attempted to objectively measure hepatocellular enzyme activities in healthy reptiles, and even fewer have attempted to demonstrate changes following an hepatic insult. Very few, if any, of the published studies have managed to satisfy the requirements of the American Society for Veterinary Clinical Pathologists (ASVCP) for reference range determination. Therefore clinicians should be cautious of including or excluding hepatobiliary disease on the basis of plasma biochemistry results. Taking the green iguana (*Iguana iguana*) as an example, moderate activities of LDH and AST were found in many tissues, making differentiation between hepatic and nonhepatic (especially muscle) sources impossible.[17] Whereas, ALT and ALP activities were also generally low but again found in a variety of tissues. Recent research at the University of Georgia demonstrated significant elevations in a number of parameters, compared to controls, following an acute hepatotoxic insult (Schnellbacher et al, Proc ARAV, 2014, pp 127–128). AST, SDH, and LDH activities increased more than 15-fold and ALT increased 4-fold, whereas ALP and GGT did not change significantly (see Table 67.3). Nonhepatic tissue trauma (especially involving muscle) can also cause increases in AST and LDH, and these parameters are considered less specific. Enzyme activities remained high for at least 48 hours after insult, but decreased by day 6 in most cases. Therefore elevation of AST, ALT, LDH, and SDH are consistent with the initial phase of acute liver injury, but there is little information on the plasma half-lives of reptile hepatic enzymes. Furthermore, although the degree of enzyme activity is considered proportional to the degree of hepatobiliary damage, they are not predictive of hepatic function and therefore do not indicate prognosis.[19]

Plasma Proteins

Albumin is exclusively produced by the liver, but because of functional capacity and protein half-life, hypoalbuminemia is typically only seen during chronic hepatic disease. Liver cirrhosis may result in hypoalbuminemia, sodium, and water retention, and lead to ascites. Hypoalbuminemia is not specific and can occur secondary to protein-losing nephropathies/enteropathies, exudative cutaneous lesions (e.g., severe burns), vasculitis, acute blood loss, or excessive blood collection. Inadequate nutrition and systemic inflammatory conditions can curtail albumin synthesis. Unfortunately, the measurement of albumin by the bromocresol green dye-binding method has been shown to be inaccurate in turtles when compared to the gold standard of protein electrophoresis.[20] Recent work at the University of Georgia has also demonstrated inaccuracies between albumin measurements by bromocresol green when compared to electrophoresis in the bearded dragon (*Pogona vitticeps*) (Comolli et al, Proc ICARE, 2017, pp 575–576). Based upon current knowledge, the measurement of albumin in chelonians and bearded dragons by bromocresol green is inaccurate. Until proven otherwise, the accuracy of albumin measurements in all reptiles by anything other than protein electrophoresis should be considered questionable.

The plasma globulin fraction is composed of immunoglobulins and nonimmunoglobulins, and hepatic impairment can result in decreases in α- and β-globulins. However, because many immunoglobulins are acute phase proteins and hepatic production is increased during systemic response to inflammatory disease, hepatitis may actually lead to hypergammaglobulinemia.[22] Some commercial laboratories are able to offer acute phase protein assays, including C-reactive protein, haptoglobin, and amyloid A, although their accuracy and relevance to reptile diseases have not been proven.

Coagulation abnormalities are common in mammals with severe hepatopathy, but appear to be rare in reptiles where the extrinsic and common pathways are thought to play major roles in coagulation. The extrinsic pathway can be assessed using prothrombin times (PT); however, the use of commercially available tests using mammalian thromboplastin results in prolonged coagulation times or lack of coagulation. Recent investigations into PT in green iguanas (*Iguana iguana*) and red-eared sliders (*Trachemys scripta elegans*) using reptile-derived thromboplastin have demonstrated clotting times in the range of 22 to 37 seconds, which are not dissimilar to those reported in endotherms (Sladakovic et al, Proc ICARE, 2017, p 570). The value of activated partial thromboplastin time (APTT) in reptiles is likely negligible due to the relative lack of intrinsic pathway clotting factors. Although not completely understood, the impacts of temperature and calcium need to be considered when assessing coagulation in reptiles.

Ammonia

The liver is responsible for detoxifying ammonia of intestinal bacterial origin through the urea cycle (see Fig. 67.5). Ammonia is an important, but not exclusive, cause of hepatic encephalopathy; however, it is currently the only measureable toxin. Hepatic failure or shunting of portal blood away from the liver can result in hyperammonemia, although in mammals test sensitivity is greater for shunting disorders. The greatest issue facing

testing is sample handling as blood must be collected into cold heparinized tubes and transported on ice for immediate laboratory evaluation. Currently, there is very little information on the use of ammonia in reptiles.

Uric Acid and Blood Urea Nitrogen

Decreased urea levels have been documented in mammals with severe hepatic fibrosis due to decreased hepatic production. It would also seem likely therefore that urea and uric acid levels, in ureotelic and uricotelic reptiles, would also be decreased due to decreased hepatic production. A recent study investigating hepatotoxin-induced hepatopathy in iguanas reported resting levels of urea and uric acid of 3.5 mg/dL and 4.1 mg/dL, respectively (Schnellbacher et al, Proc ARAV, 2014, pp 127–128). Peak levels of 11.5 mg/dL and 4.4 mg/dL were recorded at 96 hours postinsult. These elevations (rather than decreases) emphasize the many confounding variables that can influence urea and uric acid levels, which include hydration status, dietary protein content, recent feeding, gastrointestinal hemorrhage, glomerular filtration rate, drug therapy (e.g. allopurinol), and diuresis.

Bilirubin and Biliverdin

In those snakes that can reduce biliverdin to bilirubin, hepatobiliary disease would be expected to cause an elevation in unconjugated bilirubin. Although elevated bile pigments are more specific for hepatobiliary disease, they are generally less sensitive than hepatocellular enzymes. Hyperbilirubinemia and hyperbiliverdinemia can be prehepatic, hepatic, or posthepatic. Prehepatic causes include severe hemolysis and can be confirmed by demonstrating a decrease in packed cell volume. Hepatic causes can be due to impaired uptake, conjugation, or excretion, which cause severe intrahepatic cholestasis. Differentiation between hepatic and posthepatic causes is difficult but important as posthepatic conditions typically require surgical decompression of the gallbladder, and intrahepatic cases are treated medically. A recent experimental study in iguanas documented resting bilirubin levels of 0.2 ± 0.1 mg/dL, rising to 0.6 ± 0.1 mg/dL 96 hours following the administration of hepatotoxin (Schnellbacher et al, Proc ARAV, 2014, pp 127–128). However, for most nonserpentine reptiles measurement of biliverdin is required and, despite the existence of validated assays, few are commercially offered.[24]

Bile Acids

In normal animals during fasting, when the enterohepatic recirculation of bile acids is low, total serum or plasma bile acids are also low. In dogs and cats, bile acids are highly specific for hepatobiliary disease and are an ideal hepatic function test. However, with the exception of portosystemic shunts, the sensitivity of bile acids is insufficient to warrant use as a screening test, and the same may be true for reptiles.[19] In clinically healthy green iguanas and bearded dragons, mean fasting levels of 7.5 (range 2.6–30.3) µmol/L and 4.6 (range 0.8–33.7) µmol/L, respectively, have been documented (Cusack LM, Divers SJ, unpublished data).[25] Significant postprandial effects have also been demonstrated, and in iguanas, mean elevations to 33.3 ± 22.0 µmol/L have been recorded 3 hours postfeeding. In bearded dragons, mean elevations to 6.9 (range 1.4–37.6) µmol/L and 11.9 (4.3–31.0) µmol/L have been documented at 4 and 24 hours postfeeding. The duration of this postprandial effect has not been determined but suggests that reptiles should be fasted for several days prior to sampling, probably longer in large carnivorous species. A number of factors can affect total plasma bile acids, including degree of gallbladder emptying, rate of gastric emptying, intestinal transit rate, efficiency of ileal bile acid reabsorption, frequency of enterohepatic cycling, fat and amino acid content of the test meal, and amount of test meal consumed. Therefore a consistent approach to performing a bile acid stimulation test is important (Box 67.1).

BOX 67.1 Recommend Bile Acid Stimulation Procedure for Reptiles

Fast insectivorous and herbivorous lizards and chelonians for 3 days.
Fast carnivorous lizards, snakes, and small crocodilians for 7 days.
Fast large boids and crocodilians for 14 days.
Calculate daily maintenance calorific requirements and prepare full daily calorific provision using a commercial carnivore, omnivore, or herbivore critical care feeding diet.
At time 0, collect blood into heparin and then immediately assist feed by gavage tube.
(If ammonia testing is available, heparinized blood should also be submitted immediately for blood ammonia levels.)
Centrifuge and harvest plasma for resting 3α hydroxyl-bile acids.
At 4 hours, collect a postprandial sample.
(If ammonia testing is available, heparinized blood should also be submitted immediately for blood ammonia levels.)
Centrifuge and harvest plasma for resting 3α hydroxyl-bile acids.

Glucose

Hypoglycemia occurs in mammals with hepatic failure but is rare in cases of chronic disease. Given the already low resting glucose levels of most reptiles, and the effects of nutrition and handling stress, the detection of hypoglycemia may be difficult unless accurate baseline values for a specific patient have been repeatedly documented over time. Following hepatotoxin insult to iguanid livers, no significant changes in glucose levels were appreciated over a 6-day period (Schnellbacher et al, Proc ARAV, 2014, pp 127–128).

Cholesterol, Triglycerides, and Lipids

The liver converts fatty acids into triglycerides, which are either stored or released from the liver as very low-density lipoproteins (VLDL). Cholesterol may be synthesized within the liver or acquired through chylomicron remnants and low-density lipoproteins (LDL). Hepatic cholesterol can be esterified and secreted in lipoproteins or stored in the liver. Hypercholesterolemia can be associated with excessive production or decreased excretion (e.g., extrahepatic biliary obstruction). Normal female reptiles undergoing vitellogenesis often exhibit increases in cholesterol and triglycerides; however, sustained elevations or elevations in males are often seen in cases of hepatic lipidosis. There is a variable postprandial effect on triglyceride levels (less so for cholesterol) in bearded dragons, and fasting prior to sampling is recommended (Cusack LM, Divers SJ, unpublished data). In addition to cholesterol and triglycerides, some commercial laboratories offer lipoprotein profiles.

Urinalysis

Urinalysis in mammals is useful for the demonstration of ammonia biurate crystalluria and uric acid; however, given the variable expectation for such nitrogenous products in many reptiles, their diagnostic usefulness is probably limited as an adjunct to hepatic disease diagnosis. Bilirubinuria is considered abnormal in cats but not dogs. Only snakes appear capable of producing bilirubin in significant quantities, but the renal threshold for urinary bilirubin is unknown.

Hematology

Coagulopathies are rare, but bleeding could result in regenerative anemia. Nonregenerative anemia may be present in cases of chronic hepatobiliary disease, and normocytic, normochromic anemia would be expected

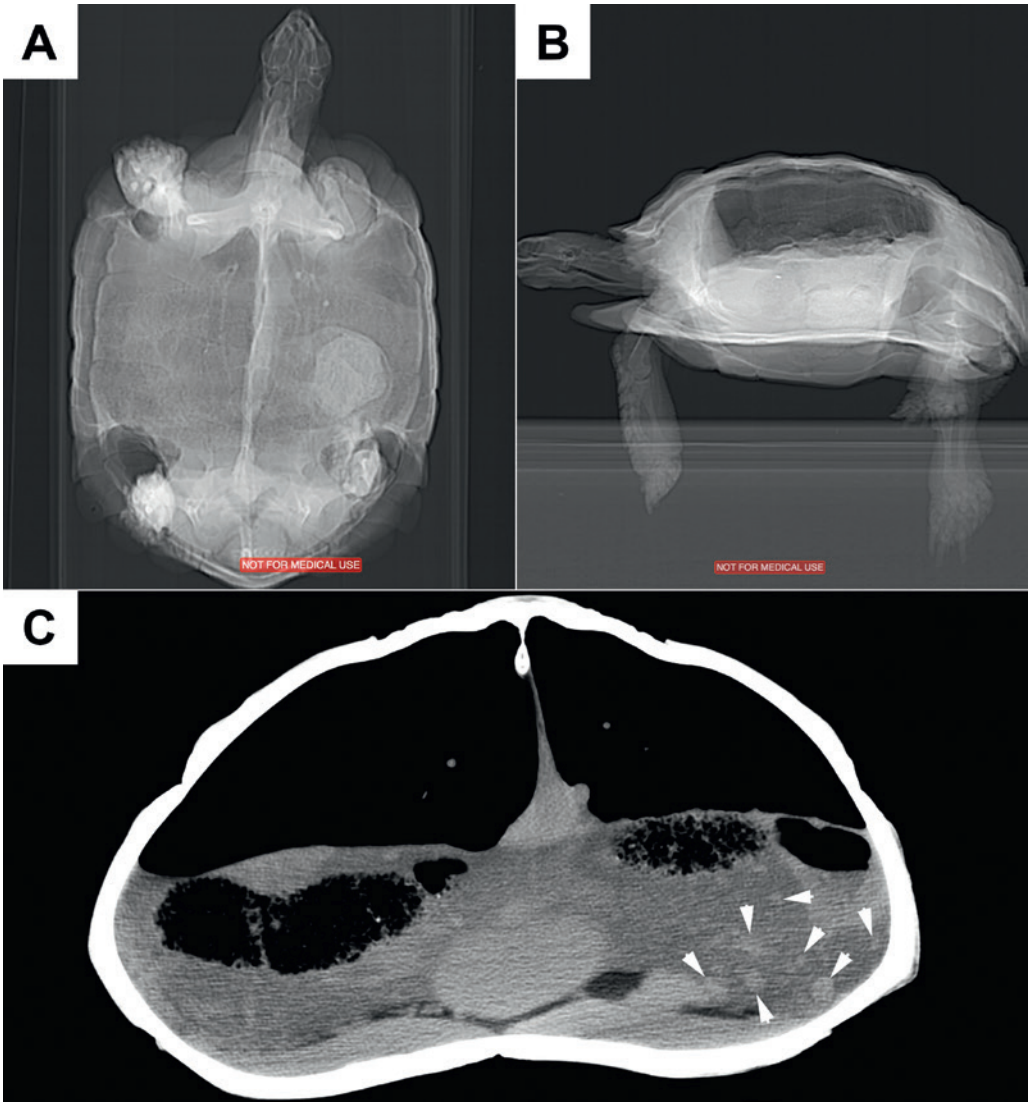

FIG 67.8 Radiographic and CT images from a male Texas tortoise (*Gopherus berlandieri*) that presented with an AST of 178 U/L. (A and B) Survey radiographs demonstrating a cystic urolith, but the hepatic region looks unremarkable. (C) CT image showing multiple nodules (arrows) throughout the left liver lobe. (Courtesy of Stephen J. Divers.)

because of inefficient utilization of systemic iron stores (anemia of chronic disease).

Radiography

The size, shape, and position of the liver can sometimes be determined from plain radiographs of the cranial coelom (see Chapters 54 through 57). Unfortunately, due to lack of diffuse, peri-organ, fat, serosal detail is typically poor in reptiles, and evaluation of liver margins is often not possible (Fig. 67.8A and B). In addition, although hepatomegaly can cause displacement of the stomach, there is little appreciation of changes in gastric axis in reptiles. Hepatomegaly commonly occurs due to infiltrative disease (e.g., neoplasia, lipidosis, amyloidosis) and inflammatory disease (e.g., bacterial hepatitis). Focal enlargement due to a neoplasm, cyst, granuloma, or abscess may be appreciated by displacement of adjacent tissues. Microhepatica, often associated with fibrosis and atrophy (including chronic cachexia), is seen as a decrease in the size of the liver silhouette. Normally the liver is homogenous in appearance. Mineralization can be diffuse (choledocholithiasis), or a focal discrete opacity associated with the right liver lobe in lizards and chelonians, or just caudal to the liver in snakes. Gas opacities may be associated with abscesses or as a grave sign associated with severe necrotizing gastroenteritis.

Computed Tomography (CT)

The size and structure of the liver can be assessed using CT, in much the same way as in mammals (see Chapter 59) (see Fig. 67.8C).[27,28] Pre- and postcontrast images in both soft tissue and bone algorithms should be collected. Computed tomography can be used to detect alterations in the X-ray attenuation of hepatic parenchyma. In healthy juvenile sea turtles (*Chelonia mydas*) a mean attenuation value of 60.09 ± 5.3 Hounsfield units (HU) has been reported, and in general values between 50 to 70 HU are considered normal for chelonians.[29,30] However, in male captive red-footed tortoises (*Chelonoidis carbonaria*) hepatic values were much lower at 11.2 ± 3.0 HU and were attributed to multiple cases of hepatic lipidosis in the group, although this was not confirmed histologically.[31]

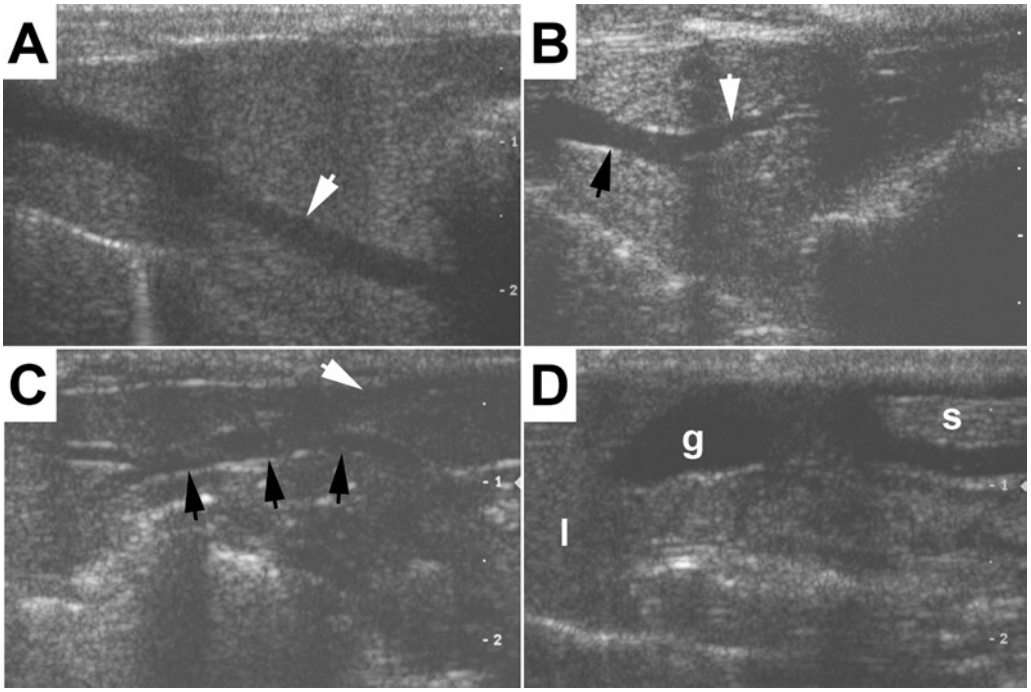

FIG 67.9 Ultrasonographic anatomy of the iguanid liver. (A) Saggital view of the right liver lobe with the intrahepatic portion of the vena cava visible (arrow). Note the homogenous hepatic echotexture. Cranial is to the left. (B) Oblique plane showing entry of a hepatic vein (white arrow) into the caudal vena cava (black arrow). Note the echogenic walls of the hepatic vein. Acoustic shadows from ribs are also present. Right cranial is to the left. (C) Saggital view of the portal vein at the porta hepatis. The portal vein (black arrows) can be seen accepting the ventral abdominal vein (white arrow) and then entering the liver. Cranial is to the left. (D) Saggital plane image of the gallbladder (g), which lies adjacent to the caudoventral surface of the liver (l), slightly to the right of midline. The aboral aspect of the pyloric portion of the stomach (s) is seen caudal to the gallbladder. Cranial is to the left. (Courtesy of Stephen J. Divers.)

Ultrasonography

Ultrasonography is useful for the evaluation of coelomic viscera, including the liver (see Chapter 58). However, despite the relatively few descriptions of ultrasonographic anatomy, it is generally considered useful for the differentiation between focal and diffuse disease, as well as assessment of displacement/compression, parenchymal changes, gallbladder disease, and vascular abnormalities.[32]

In the green iguana, hepatic parenchyma is of uniform echotexture with medium echogenicity, similar to that of the spleen, testes, and fat bodies (Fig. 67.9).[33] Hepatic lobation is generally indistinct. The gallbladder is easily identified adjacent to and partially embedded in the caudoventral border of the liver, right of midline. Gallbladder contents are normally anechoic, but small amounts of dependent material of mineral echogenicity can sometimes be identified. The subadult iguanid gallbladder is an elongated oval in the sagittal plane with mean ± SD long-axis dimensions of 1.67 ± 0.40 cm (1.00 to 2.72 cm), and mean short-axis dimensions in the sagittal plane of 0.67 ± 0.16 cm (range, 0.34 to 1.00 cm). However, significant linear correlations between body weight and gallbladder dimensions appear to be lacking. Preliminary investigations into contrast-enhanced hepatic ultrasonography have indicated that peak enhancement of 19.9% ± 7.5% (11.7%–34.6%) is achieved after 134.0 ± 125.1 seconds (59.6–364.5). However, as the distribution of contrast medium in iguanas differs from that of mammals, specific reference ranges of hepatic perfusion for diagnostic evaluation of the reptilian liver are still needed.[34]

Ultrasonographic liver anatomy has also been briefly described for the desert tortoise (*Gopherus agassizii*) via left and right mediastinal or cervicobrachial acoustic windows.[35] No descriptions of hepatic parenchymal structure or measurements were given, although visualization of the gallbladder was limited by the amount of gastrointestinal gas present. The liver of the boa constrictor (*Boa constrictor*) has been described as uniformly heterechoic, fusiform, and primarily located on the right side of the coelom, with the vena cava ventral and hepatic vein dorsal.[36] The gallbladder, anechoic with hyperechoic wall, is located just caudal to the caudal margin of the liver, in close association with the pancreas, spleen, and fat body.

Magnetic Resonance Imaging (MRI)

The hepatobiliary system can be evaluated using MRI, with most current descriptions involving chelonians (see Chapter 60).[37,38] Image quality is largely dependent upon the size of the animal, strength of the magnet, and scanner software. In general, units capable of generating magnetic fields of 3+ tesla provide better quality images for most reptiles. The liver is more signal intensive in T_1-weighted images compared to those that are T_2-weighted (Fig. 67.10). In addition to hepatic size, parenchymal homogeneity can be assessed, and its fat content compared to that of fat bodies. The internal parenchymal structure is interrupted by vessels, which, along with the biliary system, are better evaluated using T_2-weighted images.

Endoscopy

Endoscopic techniques for the evaluation of the chelonian and saurian coelom have been well described (see Chapter 64).[39-41] Endoscopic evaluation of the liver provides magnified, color visualization of the

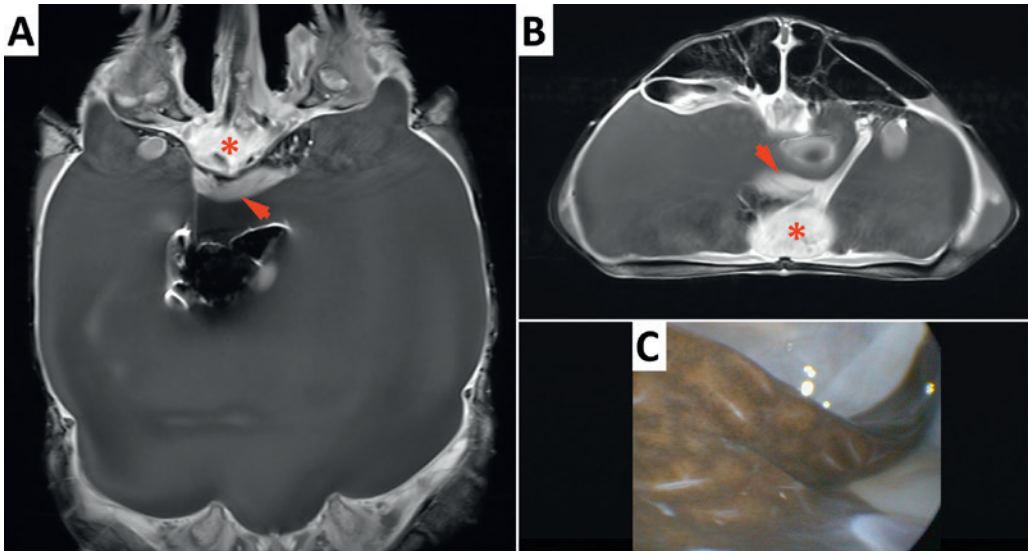

FIG 67.10 MRI of a desert tortoise (*Gopherus agassizii*) with microhepatica. (A and B) T1 postcontrast coronal (dorsal) and transverse images at the level of the heart (*) demonstrating microhepatica (arrow) and a coelom largely filled with fluid. (C) Endoscopic image of microhepatica. Histopathology demonstrated marked atrophy, hemosiderosis, and an absence of glycogen and lipid stores. (Courtesy of Stephen J. Divers.)

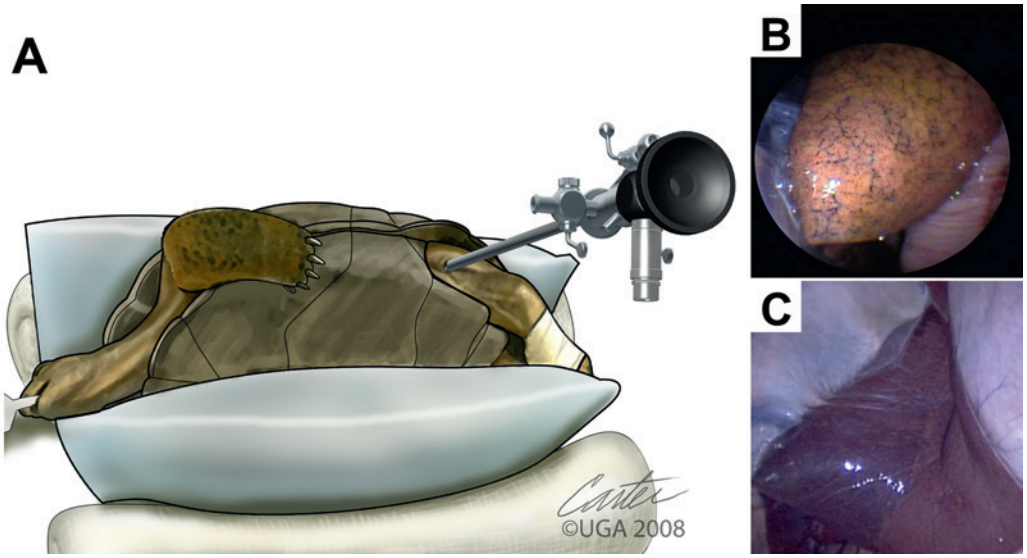

FIG 67.11 (A) Endoscopic examination of a chelonian from a left prefemoral approach. (B) Endoscopic view of the liver of an adult female slider (*Trachemys scripta*). Note the pale parenchyma and prominent sinusoidal pattern outlined by the melanomacrophages. This increased intrahepatic fat is physiologically normal in females preparing for folliculogenesis. (C) Endoscopic view of the liver in juvenile male Aldabra tortoise (*Aldabrachelys gigantea*). The parenchyma is not as pale due to reduced intrahepatic fat content, which is characteristic of healthy males. Intrahepatic fat would be expected to increase in males of temperate species during fall, in preparation for hibernation. Cranial is to the left. (Courtesy of Stephen J. Divers.)

hepatic surface and gallbladder, although deeper lesions can often be appreciated, especially if large. In addition, significant lesions can often be identified endoscopically, despite the lack of obvious clinicopathologic, radiographic, ultrasonographic, or cross-sectional imaging abnormalities. In laterally recumbent chelonians and lizards, a lateral prefemoral or paralumbar approach provides visualization of the ventral and dorsal surfaces of the ipsilateral liver lobe (Figs. 67.11 and 67.12). In dorsal recumbency, a prefemoral/paramedian approach provides access to the ventral surface of the entire liver. In green iguanas and red-eared sliders, entry of a 2.7-mm telescope within a 4.8 mm operating sheath and visualization of the liver from both left and right paralumbar approaches was easily performed without complications; however, the gallbladder could only be reliably seen from a right approach (see Fig. 67.12).[40,41] In snakes, a targeted coelioscopic approach is often required because, in most cases, no single entry can permit examination along the length of the entire liver. However, examination from within the air sac does permit evaluation over a much greater hepatic length.

Fine Needle Aspirate Cytology

Fine needle aspiration from the liver is possible under ultrasound or CT guidance. However, due to the loss of tissue architecture, such cytologic aspirates are generally inferior to endoscopic or surgical biopsy.[42,43] A recent study investigated hepatotoxin-induced disease in green iguanas, and invariably, ultrasound-guided fine needle aspirates were of poor diagnostic value (Fig. 67.13) (Schnellbacher et al, Proc ARAV, 2014, pp 127–128). Fine needle aspirates may be more useful in disease processes that are highly cellular (e.g., neoplasia) and for microbiologic evaluation, as well as when longer periods of general anesthesia carry unacceptable risks.

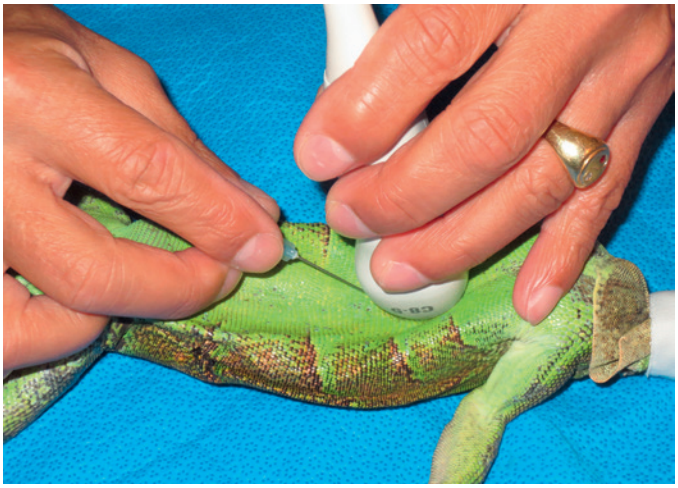

FIG 67.13 Ultrasound-guided fine needle aspiration of an iguanid liver using a 22-g hypodermic needle. Cytologic quality of hepatic aspirates were consistently poor and nondiagnostic. (Courtesy of Stephen J. Divers.)

Biopsy

Clinicopathological changes may be attributable to hepatobiliary disease; however, they do not reliably differentiate between different disease processes and do not provide an accurate prognosis. In order to reach a definitive diagnosis it is essential to demonstrate both (1) an accurate host pathological response and (2) the etiologic or causative agent. While paired rising titers are definitive, there are few commercial assays available for reptiles, and those that are available typically require samples 6 to 9 weeks apart. Given the poorer diagnostic value of cytology compared to histopathology, tissue biopsy is generally preferred. Tissue biopsies can be used for histopathologic, microbiologic, parasitologic, and toxicologic evaluations and can typically provide a definitive diagnosis within days of collection. Indications for hepatic biopsy include elevations of hepatic enzymes (especially AST and SDH), bile acids, biliverdin/bilirubin, unexplained coelomic effusion/ascites, and hepatomegaly.[44] The most common complication concerning hepatic biopsy (especially following needle biopsy) is hemorrhage, and therefore consideration should be given to platelet count, PT, PTT, and buccal mucosal bleeding time. Biopsy samples may be collected using cutting biopsy needles (e.g., Tru-Cut), endoscopically, or by standard wedge or excisional surgical techniques.

Handling of biopsies must be undertaken with atraumatic instruments to minimize damage. Small endoscopic and needle biopsies should be gently shaken free into sterile saline, and not removed using cotton-tipped applicators, or worse still, a hypodermic needle. Small samples are placed into labeled histology filters before being submitted in 10% neutral buffered formalin for histopathology. For transmission electron microscopy (TEM), glutaraldehyde is often preferred, while ethanol or methanol may be preferred for urate tophi or parasite evaluations. Tissue samples for microbiology often need to be sent in appropriate transport media depending upon whether fungal, bacterial, or viral investigations are most important. Additional biopsies can be frozen at –20°C while histopathology results are pending. Then, if histopathologically indicated, such frozen tissue can be submitted for specific microbiological (often virologic) investigations.

Ultrasound-guided, percutaneous hepatic biopsies have been reported from 1 to 25 kg boid snakes using an 18-g × 20-cm biopsy needle.[45] All collected biopsies were considered diagnostic, and all snakes survived; however, multiple biopsy attempts were required for some snakes and

iatrogenic gastric perforation was documented in at least one animal.[45] Although general anesthesia is seldom employed for such biopsies in humans and dogs, it is still recommended for reptiles to ensure adequate restraint. Automated needles are preferred and operated by the ultrasonographer to ensure that vessels and other organs are not in the path of the needle. Holding an anesthetized reptile at maximum inspiration tends to improve localization and visualization of the liver. The biopsy site should be evaluated for postsample hemorrhage. Comparison between needle biopsies and wedge biopsy (gold standard) in dogs and cats has indicated an overall agreement on only 48%, and similar results would might be expected for reptiles.[46]

Endoscopic liver biopsies have been experimentally evaluated in green iguanas and freshwater chelonians (Fig. 67.14).[39,41] Biopsies were collected using 1.7-mm biopsy forceps, and each contained a mean of 1.9 and 3.1 portal tracts in iguanas and sliders, respectively. Although peripheral crush artifact was common, it was minimal, and all samples were considered diagnostic. No adverse effects of endoscopic hepatic biopsy were reported. Multiple samples can be readily collected and should be routinely submitted for histopathology, bacterial (aerobic/anerobic), and fungal cultures. Additional parasitic or toxicologic analyses can also be considered on an individual case basis. This technique enables gross evaluation of most, if not all, of the liver, extrahepatic biliary system, and surrounding structures. The ability to collect multiple samples from various hepatic locations decreases the risks of sampling artifact in cases of regional diversity within the liver. The standard oval/round cup biopsy forceps also produce less hemorrhage than biopsy needles, but if hemorrhage is encountered direct pressure can be applied by the closed biopsy forceps or a blunt probe, or radiosurgical coagulation can be used. Direct visualization of the hepatic parenchyma enables the clinician to correlate clinical data with liver appearance and histopathology to adjudicate the most accurate diagnosis.

Coeliotomy provides access to the liver for harvesting surgical biopsies. The advantages of open surgical access include the ability to collect larger liver samples, as well as an improved opportunity to completely evaluate and sample other visceral structures (e.g. intestines). Nevertheless, increased invasion and duration of anesthesia must be considered. Surgical biopsies can be collected using a standard wedge technique.[44] Hemorrhage can be controlled using hemostatic material (e.g., GelFoam) and digital pressure. Advantages and disadvantages are similar to those of endoscopy.

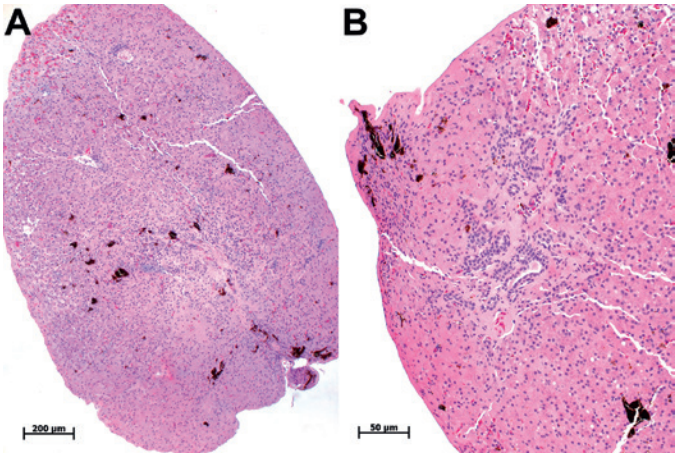

FIG 67.14 Iguanid liver biopsy collected using 1.7-mm (5Fr) biopsy forceps. (A) The specimen has minimal crush artifact confined to the periphery of the section. H&E, bar = 200 µm. (B) Mild hyperplasia of the biliary ductules is apparent. H&E, bar = 50 µm. (Courtesy of Stephen J. Divers.)

GENERAL APPROACH TO TREATMENT

Provision of species-specific thermal requirements must be provided initially. The route of drug therapy will be directed by the animal's condition at the time of presentation. Mild to moderate cases of hepatic lipidosis are usually anorectic on presentation but in good condition, and in these cases oral fluids are often adequate. Reptiles with more severe/acute hepatobiliary disease will often require intracoelomic, intravenous, or intraosseous fluid and drug administration. In cases of severe liver pathology it may be wise to avoid solutions containing lactate. Other medications may be employed at the clinician's discretion, but care should be taken not to invalidate future diagnostic investigations. For example, blood samples should be collected prior to fluid therapy, while antibiotic medication should be delayed until after liver biopsy and culture.

There are many different therapeutic approaches to treating liver disease. In general, for a treatment to be recommended there must be a well-established connection between pathophysiology and medicinal effects. For example, to appropriately treat a green iguana with clostridial hepatitis, the clinician would first and foremost need to make the definitive diagnosis by hepatic biopsy for histopathology and bacterial cultures (or PCR). Only then could the case be treated with an antimicrobial drug with demonstrated efficacy (either through disc sensitivity, minimum inhibitory concentration, or inherent biologic efficacy) against the organism and for which pharmacokinetic drug data for that species was known. In this case, such data is available to advocate the use of metronidazole for the treatment of clostrial hepatitis in the iguana.[47,48] The second, and indeed preferable, way a therapy can be scientifically proven to be effective is through randomized, double-blinded, and placebo-controlled clinical trials. Currently, as far as this author is aware, no such studies have been published for the treatment of any reptile disease. Table 67.4 provides an overview of medications that have been subjectively advocated for the treatment of liver disease in reptiles.

Ascites is typically a late decompensatory sign in the course of chronic liver disease due to portal hypertension and/or hypoalbuminemia. Diuretics should be used with caution in cases of concurrent hepatic encephalopathy, because alkalosis and hypokalemia both exacerbate the production of more toxic forms of ammonia. Indeed, ammonia levels may be low because the toxic form enters cells, becomes ionized, and subsequently sequestered. This cellular ammonia trap is best avoided by using potassium-sparing diuretics such as spironolactone.[49] Free coelomic fluid can account for more than the entire circulating volume, and the renin-angiotensin-aldosterone system is likely activated during this time, resulting in sodium and water retention and potassium loss. Cautious coelomocentesis is the best approach to avoid complications of hepatic encephalopathy. While in animals that are anorectic, fluid therapy and potassium supplementation are required. Sodium restriction should be considered if portal hypertension (e.g., secondary to hepatic fibrosis) is likely.

Intestinal protein digestion produces ammonia and aromatic amino acids that must enter the general circulation to cause encephalopathy. In dogs, the functional reserve of the liver is sufficient, such that concurrent portosystemic collateral circulation is required for clinical signs. However, cats with hepatic lipidosis can also develop encephalopathy due to metabolic derangements. It is unknown whether portosystemic collateral circulation or hepatic lipidosis can result in encephalopathy in reptiles; however, it may be a key factor in the signs of depression that are frequently observed in cases of severe hepatobiliary disease, including hepatic lipidosis. While reduction in dietary protein may be helpful, catabolism is even more problematic and must be avoided. Lactulose and soluble fiber may help reduce ammonia uptake from the large intestine and should be administered at a dose sufficient to cause

VetBooks.ir

TABLE 67.4 Drugs of Potential Value for the Treatment of Liver Disease

Drug Class/Name	Indications	Precautions/Comments
Prednisolone Prednisone	Autoimmune hepatitis	Immunosuppressive, contraindicated in cases of infectious disease
Azathioprine	Autoimmune hepatitis, where steroid-induced side effects are unacceptable	Can cause bone marrow suppression More expensive Potentially toxic in humans
Ursodeoxycholic acid	Natural, nontoxic, bile acid that, in humans, prevents mitochondrial damage and cellular apoptosis, increases bile flow, reduction in immune response, increases production of glutathione (GSH) and metallothionein to reduce oxidative damage	Only really proven in chronic severe cholestatic diseases and cholangitis Contraindicated in cases of extrahepatic bile duct obstruction
Antioxidants		
Vitamins C and E	Natural antioxidants	No proven efficacy, but little risk
L-Carnitine	Normally synthesized endogenously from methionine, lysine, and SAMe, but can be derived from diet. Essential cofactor for fatty acid oxidation, may prevent hepatocellular accumulation of free fatty acids and help remove toxic acetyl groups from mitochondria	Surmised that in hepatic lipidosis a relative deficiency of hepatocellular carnitine exists Use medical grade as solubility may limit oral availability
S-adenosyl-L-methionine (SAMe)	Natural hepatic metabolite and precursor to cysteine and GSH. Important in defense against free oxygen radicals. Basically replaces methionine (precursor to SAMe) to restore GSH in deficient hepatocytes	Some evidence of positive effects in domesticated animals with liver toxicity
Silymarin/silibinin (milk thistle extract)	Strong free-radical scavenger, with proven effects against oxidative liver intoxication, for a variable time	Most useful against oxidative stress and intoxication
Colchicine	Antifibrotic via stimulation of collagenase activity	Rarely vomiting, diarrhea, and neurological side effects reported. Clinical trials in humans failed to demonstrate any effect
Anticopper Medications		
D-penicillamine Trientine	Copper toxicity maybe more of a clinical concern in aquatic reptiles and amphibians. Chelators that bind copper and increase renal excretion	Give with food to reduce inappetance, nausea, vomiting. Treat for 3–6 months then reassess
Zinc	Induces metallothionein in enterocytes, which sequests copper and is eliminated by senescent cells in feces	Give 1–4 hours before food. Avoid concurrent use with chelators

stool softening but not diarrhea. Neomycin has also been advocated in humans and appears to be synergistic with lactulose to alter intestinal flora. Gastrointestinal bleeding can acutely elevate ammonia levels and encephalopathy, necessitating the use of protectants and antiulcer medications. Glucocorticoids are contraindicated because they stimulate lipolysis and fatty acid accumulation in the liver and induce catabolism and the risk of hyperglycemia. Anabolic steroids have been advocated in an attempt to increase hepatic metabolism.

SPECIFIC HEPATIC DISEASES

Hepatic disease can be classified as acute or chronic, inflammatory (hepatitis) or degenerative (hepatosis), and a variety of hepatobiliary diseases have been reported in the literature. Most reports involving free-ranging or large collections focus on infectious etiologies, especially viral diseases, while individual companion reptiles are more likely to suffer from degenerative hepatopathies, especially hepatic lipidosis, or abscesses/granulomas. A full investigation is essential to differentiate accurately between acute and chronic liver disease, and it is important that pretreatment blood samples are collected prior to initiating fluid therapy and other treatment measures. Antimicrobial therapy should not be started until material has been obtained for microbiology.

Hepatic Lipidosis

Clinical Significance. Hepatic lipidosis is a well-recognized condition that is frequently diagnosed post mortem in numerous species. Unfortunately, there is a paucity of information concerning the pathogenesis of hepatic lipidosis in reptiles, and until relatively recently, the collection of biopsies for definitive antemortem diagnosis presented a challenge to clinicians. Although many of the difficulties of sample acquisition have now been overcome, the practitioner is still faced with the problems of microscopic (histopathologic and electron microscopic) interpretation. A logical case investigation is described with particular emphasis on histologic interpretation through the grading of microscopic lesions.

Hepatic lipidosis is probably one of the most frequently stated and misunderstood diagnoses made, both ante- and postmortem. For example, increased hepatic fat in an adult male Greek spur-thighed tortoise (*Testudo graeca*) in October might not be pathologic, as many temperate reptiles will normally increase intrahepatic fat levels prior to hibernation. In addition, many female reptiles will naturally increase intrahepatic fat in preparation for vitellogenesis. Therefore the problem is more complex and extensive than perhaps has been previously appreciated from our knowledge of domesticated mammals. In addition to diet and body condition, consideration must also be given to age, gender, reproductive status, and ecology.

Known Etiological Cause(s). Hepatic lipidosis is a metabolic derangement and not a single clinical disease. There are a host of factors that can predispose to increased hepatic fat. Classically, the high-fat diet (e.g., obese laboratory rats, waxworms, etc) have been implicated in obesity, an increase in the size of coelomic fat bodies, and an increase

in hepatic fat. Equally, reduced activity and energy expenditures are common in captive reptiles that are maintained in small enclosures with little opportunity to roam, exercise, or forage. Another predisposing factor is the apparent prevalence in nonbreeding adult to aged females. Many female reptiles undergo seasonal cycles of lipogenesis in preparation for vitellogenesis. Those females that do not have the opportunity to reproduce and lose this fat through egg production appear more prone to obesity in captivity. Males and females of temperate regions are also known to increase hepatic and fat body stores in preparation for periods of reduced environmental temperatures, reduced food intake, and hibernation. When not given the opportunity to go through these natural fasting periods, temperate and subtropical species, with these annual cycles of increased fat deposition, are likely to become obese. Finally, acute hepatosis is rare but can occur secondary to toxic insult, and ivermectin-induced hepatic lipidosis is a documented example.[50]

Clinical Presentation. Hepatic lipidosis is usually chronic, and therefore observant owners and keepers who maintain accurate records may report a gradual reduction in appetite, activity, fecundity and fertility, weight gain (or later weight loss), hibernation problems including posthibernation anorexia, and changes in fecal character and color (Fig. 67.15). However, it may only be during episodes of increased physiological demand (e.g., hibernation, breeding, concurrent disease) that the underlying hepatic dysfunction becomes clinically apparent. Unfortunately, many caretakers miss these early signs of disease. As a result, veterinary attention is usually only sought once the animal has deteriorated to a life-threatening condition. When lipidosis is advanced, most affected reptiles are in poor condition, lethargic and weak. The body weight (mass) is usually below normal but can be elevated due to large fat bodies or ascites. Diarrhea is uncommon, as most affected animals will have been anorectic for a prolonged period of time.

Diagnostic Confirmation. Presumptive concerns regarding hepatic lipidosis can arise when plasma biochemical changes, including elevations in triglyerides, cholesterol, and lipoproteins, are appreciated.[51] There is usually minimal to no elevation in hepatocellular enzymes because cellular damage is usually minimal; however, reduced hepatic function can result in elevations of bile acids and hypoalbuminemia. Cholestasis is not usually a feature, and elevations of biliverdin would not be expected. Hemoconcentration can result in elevations of packed cell volume, but there is generally little to no inflammatory response in the leukogram. Radiographic evidence of hepatomegaly may be discernible in lizards and snakes but is challenging in chelonians. Ultrasonography and CT are more useful, especially when the hepatic parenchyma is compared to fat bodies. Reptiles with hepatic lipidosis typically exhibit hyperechoic livers and reduced radiographic attenuation (<20 HU).[31]

It is important to identify the primary cause of liver disease, which may remain undiscovered when the diagnosis of lipidosis is based on fine needle aspirates of the liver rather than biopsy. At present, there appears to be nothing to surpass the diagnostic value of hepatic biopsy for both microscopic and, where infectious agents may be present, microbiologic culture. Endoscopic hepatic biopsy is straightforward and well proven (Fig. 67.16).[39,41] In addition to facilitating a definitive diagnosis, serial biopsies offer the best means of monitoring disease progression and response to treatment and are invaluable for providing an accurate prognosis.

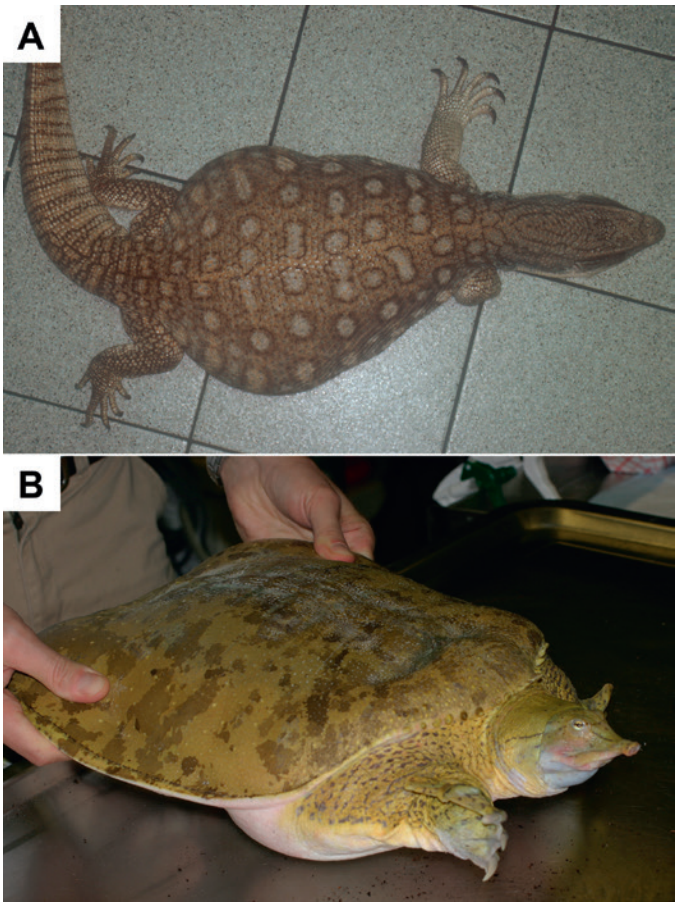

FIG 67.15 Grossly obese monitor lizard (*Varanus exanthematicus*) (A) and spiny softshell turtle (*Apalone spinifera*) (B). (Courtesy of Stephen J. Divers.)

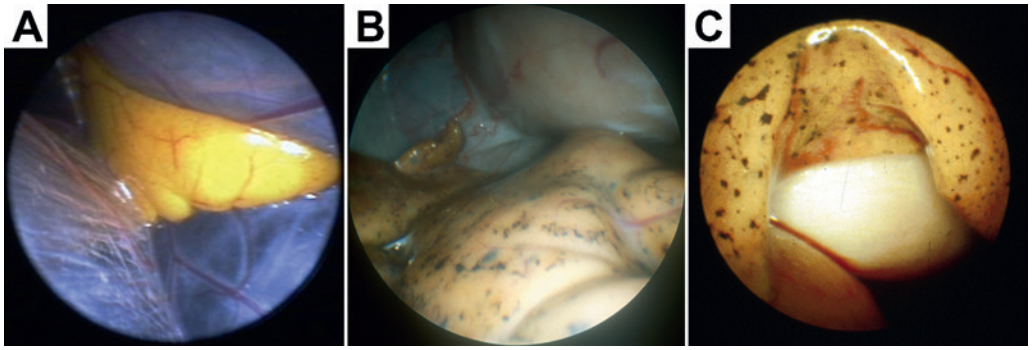

FIG 67.16 Endoscopic views of hepatic lipidosis in (A) a bearded dragon (*Pogona vitticeps*), (B) a Greek tortoise (*Testudo graeca*), and (C) a leopard tortoise (*Stigmochelys pardalis*). (Courtesy of Stephen J. Divers.)

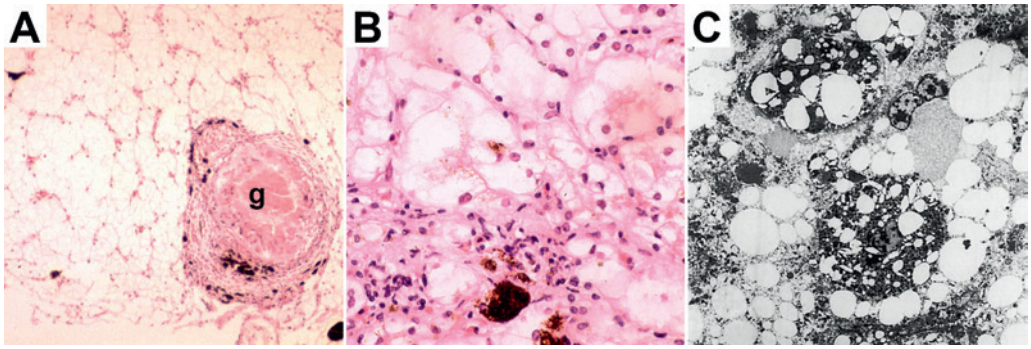

FIG 67.17 (A) Histologic section of the liver of a Greek tortoise (*Testudo graeca*) shows marked vacuolation of hepatocytes. A bacterial granuloma (*g*) is also evident. H&E, x20. (B) Higher magnification of the same liver demonstrating nuclear margination and pyknosis. H&E, x200. (C) Transmission electron micrograph (TEM) of the liver of a Round Island gecko (*Phelsuma guentheri*) shows a mixture of microvesicles and macrovesicles. Some lipid has been phagocytosed by granulocytes. ×3000. (A and B, Courtesy of Stephen J. Divers; C, courtesy of John E. Cooper.)

When performing a necropsy on a hepatic lipidosis suspect, care must be taken to ensure that all other body organs are meticulously examined. In particular, note should be taken of (1) other fat deposits, including the size and weight of fat bodies and presence or absence of adipose tissue under the skin and around the heart, and (2) changes in other organs, such as the pancreas, that may have been predisposed to fatty change.

In hepatic lipidosis, the liver color may be pale tan to almost white (see Fig. 67.16). The color may also be affected by the natural color of fat in the species, and that, in turn, can be influenced by diet. A "fatty liver" is usually swollen, with rounded, nonangular edges, and may weigh more than normal—organ weights can be helpful in this respect. Markedly fatty livers will have a soft fatty "feel" when held for cutting and are friable—easily torn. Both the surfaces of the scalpel and the touch preparation, even before staining with specific stain (ORO, Sudan), may show greasy fat droplets.

There can be both normal and pathologic deposition of fat within the liver. Schaffner,[12] writing specifically about the reptilian liver, states categorically that "small fat droplets normally may be found in cytoplasm." He goes on to emphasize that the amount of fat can vary depending on such factors as gender and season. Thus the presence of fat in the liver of reptiles is not, per se, indicative of lipidosis. A more accurate description would be "fatty change" but not necessarily "lipidosis."

The detection of fat in a reptile's liver is not usually difficult. In a standard paraffin-embedded section, the lipid will appear as "holes"—vacuoles or vesicles—and usually these can be assumed to be fat (Fig. 67.17A and B). However, some caution is needed since vacuoles can, on occasion, contain water, glycogen, or other nonlipid material. Sometimes light microscopy will per se permit a distinction to be made, but often other tests are needed, such as special stains or even TEM. Once it has been ascertained by histology that fat is present, a number of subsidiary questions need to be asked before a diagnosis (tentative or definite) of hepatic lipidosis can be made. These include an appreciation of the precise location, position, and size of the fat vacuoles. Evidence of hepatocellular dysfunction or degeneration, and inflammatory changes, must also be noted. It should be mentioned in passing that other techniques could also be used to investigate fatty change in the liver of reptiles. TEM is hardly suitable for routine diagnosis but has an important role to play when working with valuable or endangered species—for instance, where lipidosis is a feature of a disease "outbreak," perhaps linked with other metabolic changes, such as xanthomatosis. In such cases TEM can provide essential information on pathogenesis, including the presence or absence of changes in intracellular organelles or the presence of pathogens (see Fig. 67.17C).[52] TEM is also one of the keys to more research on fat metabolism in reptiles.[53]

Even when the presence of what appears to be "excess" fat has been established, a diagnosis of hepatic lipidosis cannot usually be confirmed without taking into account the following.

1. The clinical history and the clinician's assessment of the case (including other laboratory results).
2. The patient's details and circumstances (e.g., species, age, sex, reproductive status, hibernation status, estivation, diet).

Specific Treatment(s). In advanced, severe cases correction of dehydration with nonlactate, nonglucose-containing fluids is advisable. Vitamin K administration can be considered, especially if coagulopathy has been confirmed. In many instances, hepatic lipidosis is a chronic disease that may take months, if not years, to reverse. Therefore a means of providing long-term fluid and nutritional support (e.g., esophagostomy tube) is typically required.

The importance of nutritional support cannot be overemphasized and, given the available literature in human and veterinary medicine, appears to offer the best therapeutic approach to hepatic lipidosis. When providing nutritional support it is important to consider (1) the patient's energy and nutritional requirements and (2) the patient's natural dietary preference (e.g., herbivorous, omnivorous, carnivorous), as well as (3) attempt to use natural foods for long-term support and only rely on artificial, critical care substitutes during initial stabilization. Total calorific requirements and total daily food requirements (see Chapter 122) should be calculated. However, these calculations are mere estimates, and actual requirements could vary by ±50%. Care is also required to avoid refeeding syndrome and gastric overload in reptiles that have been anorectic for prolonged periods. In general, it is safer to start feeding at 10% of calculated daily requirements using a dilute formula and increase slowly with the aim of achieving 100% of daily requirements by 10 to 30 days. Efforts should be made to correct hypokalemia and hypophosphatemia during initial stabilization. Subsequent adjustments should be based upon monitoring weight, defecation, and plasma biochemistry. The esophagostomy tube is also useful for oral drug delivery.

Supplementation with L-carnitine (a derivative of lysine and required for the transportation of acyl-CoA across the inner mitochondrial membrane of hepatocytes) may improve hepatic metabolism of fat. A daily dose of 100 mg/kg L-carnitine mixed with the tube-feeding formula appears to be safe in reptiles. Supplementation with water-soluble vitamins may also be beneficial and appears to be safe. Antioxidantas, such as SAMe (which replaces the previous recommendation of

VetBooks.ir

methionine) and vitamin E, may also be beneficial, and because no reptile-specific doses have been produced, allometric calculation from mammalian doses is probably appropriate.

Prognosis. If the condition is diagnosed early prior to the onset of obvious clinical signs (e.g., during annual health evaluations or routine sterilization surgery), then the prognosis is good, and resolution, although taking months or even years, is often possible with appropriate improvements in husbandry and nutrition. However, once clinical signs develop and hepatic dysfunction is advanced, then the prognosis becomes more guarded and often requires prolonged nutritional support, medication, and nursing for months until the animal regains appetite. Such cases can often take years to resolve excessive hepatic fat, fat body size, and body condition.

Prevention. Although there are no clear guidelines established for the treatment of hepatic lipidosis in reptiles, addressing the following factors can often help reduce or prevent occurrence.

1. Provide a suitably large enclosure to facilitate exercise and foraging. This is often the most difficult change to make given the culture of maintaining reptiles in small enclosures.
2. Avoid excessive feeding, both in terms of frequency and calorific quality of food items. For example, snakes are often fed on a predetermined weekly schedule whether they show hunger (foraging/hunting) behaviors or not. It may be preferable to feed well-adjusted reptiles when they actually show hunger and increased foraging behaviors. Another example would be feeding arid land tortoises (e.g., *Testudo graeca*, *Centrochelys sulcata*) high-quality grocery fruits and vegetables, when lower energy items, including hay, are preferable.
3. Facilitate the natural loss of fat, both hepatic and fat body, by permitting temperate species to fast and hibernate and intact females the ability to reproduce.
4. Caretakers should be encouraged to keep health logs (including monthly weight and body lengths [straight carapace or snout-to-vent]) for their reptiles and seek annual or biennial health evaluations (including physical examinations and routine blood testing).

Hepatitis

Clinical Significance. Hepatitis (an inflammatory change) is not uncommon in reptiles and often associated with infectious agents. The condition can be acute (often viral) or chronic (often parasitic, bacterial, or fungal). If several animals are affected simultaneously, a common etiology is most likely.

Known Etiological Cause(s). Herpesvirus (*Boa, Testudo*), adenovirus (*Boa, Pogona*), orthoreovirus (*Boa*), hepatitis B virus (*Mauremys*), and West Nile Virus (*Alligator*) are viral infections that have either, naturally or experimentally, been shown to cause liver disease in reptiles.[2,5,6,8,10,54–56] Most of these viral diseases have been reported to cause acute hepatitis or hepatocellular necrosis. Bacterial and mycotic hepatopathies tend to be more chronic and cause granulomatous hepatitis. *Providencia rettgeri* (*Varanus*), *Salmonella typhimurium* (*Testudo*), *Mycobacterium* spp (*Caiman, Phrynops, Trionyx, Gonyosoma, Pituophis*), *Chlamydia* (*Bitis*), *Coccidioides* (*Pituophis*), *Penicillium* (*Geochelone, Chamaeleo*), and unidentified anerobic Bacillus (*Natrix*) have been reported; however, the actual list of potential bacterial and fungal pathogens is probably far longer.[1,4,9,57–62] In some cases, the involvement of the liver is likely secondary and a reflection of systemic infection and generalized sepsis. Acute bacterial hepatitis is less common, but chlamydial hepatitis has been reported in hatchling crocodiles (*Crocodylus*), and the author has seen diffuse hepatic swelling due to acute bacterial infections (Fig. 67.18A).[8] Parasitic hepatitis has also been reported; histiocytic hepatitis due to microsporidia in bearded dragons, necrotizing hepatitis due to *Entamoeba* in snakes and tortoises, and granulomatous hepatitis due to *Hepatozoon* meronts in water snakes.[7,63,64] Metazoan larval migrations have also been reported through the reptilian liver.[65] Hepatitis can be aseptic and associated with surface/serosal inflammation in response to yolk proteins and coelomitis (see Fig. 67.18B).

Clinical Presentation. Reptiles with acute liver disease usually present in good body condition, and may exhibit depression, anorexia, regurgitation, or acute mortality. Severely affected animals will usually be

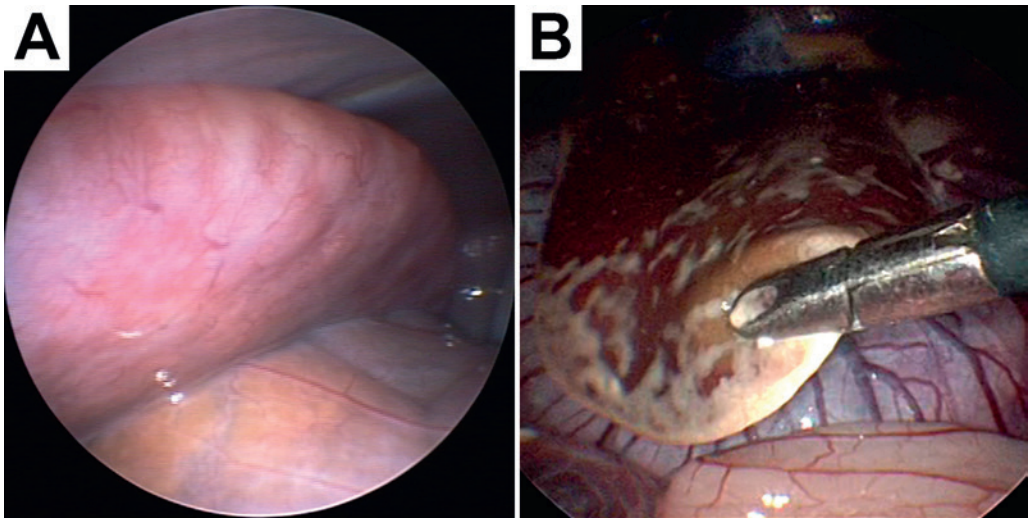

FIG 67.18 (A) Diffuse hepatic swelling with loss of the sharp caudal border associated with acute bacterial hepatitis in a green iguana (*Iguana iguana*). (B) Multifocal areas of pale, proteinaceous material and hepatitis that were inflammatory reactions to yolk coelomitis in a female box turtle (*Terrapene carolina*). This pathology was not appreciable on radiographs, CT, or ultrasonography. Note the use of 3-mm biopsy forceps to obtain a biopsy. (Courtesy of Stephen J. Divers.)

depressed, lethargic, and weak, while mucous membranes may be pale, hyperemic, or icteric. As already stated, the early signs of chronic disease may be missed; this, in conjunction with the rapid onset of severe clinical signs, may confuse and convince the clinician that this is an acute hepatitis rather than the end-stage presentation of a chronic condition.

Diagnostic Confirmation. This author could not find any documented cases of naturally occurring hepatitis that included appropriate antemortem diagnostic testing with histopathologic confirmation. This is obviously an area of clinical medicine that can be improved with the adoption of endoscopic or surgical biopsy (see Fig. 67.18). Nevertheless, plasma increases in AST, ALT, LDH, and SDH may be seen in cases of hepatitis; however, AST and LDH are also found in muscle, and potential nonhepatic sources must be appreciated. Elevation in bile acids or ammonia would not be expected unless there was major functional impairment. Hematology may reveal a leukocytosis characterized by heterophilia, azurophilia, or monocytosis, depending upon the acute or chronic nature of the condition. Eosinophilia might be seen in cases of parasitic hepatitis. Ultimately, liver biopsy is required for a definitive diagnosis, accurate prognosis, and to direct specific therapy.

Specific Treatment(s). Early definitive diagnosis is a prerequisite for, and typically dictates, selecting appropriate drug therapies. Consequently, any drug that can affect histopathology, microbiology, parasitology, and toxicology should not be started until after samples have been collected. Initial antimicrobial drug selection can be based on Gram-stained impression smears, clinical knowledge and experience, likely causative organisms, and host-drug preferences. The routine use of advanced broad-spectrum drugs, including fluoroquinolones, implies a low level of clinical expertise. First-line drugs include tetracyclines, macrolides trimethoprim-sulfa and amoxycillin-clauvulanate with subsequent modification-based culture and sensitivity or MIC testing. Successful treatment relies on the selection of an effective drug and effective delivery of an appropriate dose to maintain tissue levels well above MIC for a period of time. Consequently, MIC testing is preferred because it not only provides more reliable sensitivity data but can also be used to determine the actual dose required (assuming volume of distribution, Vd) (Box 67.2). Even so, actual drug levels can often deviate from pharmacokinetic research, and it is still wise to measure antimicrobial blood levels and adjust dose and frequency, as and where necessary.

Prognosis. The paucity of reported cases makes establishment of an accurate prognosis impossible. However, early diagnosis of acute bacterial or mycotic hepatitis probably has a better chance of successful treatment compared to chronic cases with innumerous, encapsulated granulomas that are more resistant to antimicrobial penetration.

Prevention. Appropriate husbandry, nutrition, preventive health programs (including quarantine), and regular veterinary evaluations can help reduce the incidence of disease or ensure that it is detected early. Appropriate diagnosis and treatment of dermatological, gastrointestinal, and pulmonary infections can help to reduce systemic spread to other visceral structures including the liver.

Toxic Hepatopathy

Clinical Significance. The only clinical reports of toxic hepatopathies relate to ivermectin usage in chelonians, where there was an association with (but not proven to cause) hepatic lipidosis.[50] Meloxicam at 5 mg/kg daily for 12 days failed to induce hepatic changes in green iguanas.[66] Experimental studies using carbon tetrachloride induced hepatocellular necrosis in green iguanas (Fig. 67.19) (Schnellbacher et al, Proc ARAV, 2014. pp 127–128). Many bacterial toxins, compounds, and environmental pollutants might be expected to affect reptiles in similar ways to other vertebrates.

BOX 67.2 Determination of Required Antimicrobial Drug Dose Using Minimum Inhibitory Concentration (MIC) and Volume of Distribution (Vd)

Hepatic biopsy reveals Salmonella hepatitis in a slider *(Trachemys scripta)*

	Disc Sensitivity	MIC (µg/mL)	Vd (L/kg)	Calculated Dose* (mg/kg)
Carbenicillin	Intermediate	16	0.24	31 mg/kg required[a]
Enrofloxacin	Sensitive	1	2.48	20 mg/kg required[b]
Metronidazole	Resistant	128	0.74	758 mg/kg required[c]

*Calculated drug doses from MIC calculated as follows: MIC (µg/mL = mg/L) × Vd (L/kg) × treatment factor (often 4–10, using 8 in this example). If drug is given orally, then the bioavailability needs to be considered (e.g., if oral availability is 82%, calculated drug dose should be increased by 100/82).

[a]The calculated dose (31 mg/kg) is well below the pharmacokinetically evaluated, published dose (200 mg/kg).[82] Therefore use of the published dose would easily achieve high tissue levels and greater likelihood of treatment success, despite the *intermediate* disc sensitivity.

[b]The calculated dose (20 mg/kg) is greater than the pharmacokinetically evaluated, published dose (10 mg/kg).[83] Therefore use of the published dose would fail to achieve adequate tissue levels and result in treatment failure, despite the *sensitive* disc sensitivity. The high calculated dose may achieve adequate tissue levels at the expense of causing drug toxicity.

[c]The calculated dose (758 mg/kg) is far greater than the pharmacokinetically evaluated, published dose (20 mg/kg).[84] Therefore use of the published dose would fail to achieve adequate tissue levels and result in treatment failure, and is consistent with the *resistant* disc sensitivity. It would likely be impossible to achieve such high tissue levels, and attempts to do so would cause drug toxicity.

Known Etiological Cause(s). Chronic exposure of arsenic-, cadmium-, selenium-, strontium-, and vanadium-contaminated fish (coal-ash contaminated site) results in hepatic accumulation and hepatic fibrosis in watersnakes (*Nerodia*).[67] Organic pesticide residues (including methoxychlor, aldrin, dichlorodiphenyltrichloroethane [DDT], endosulfan I, endosulfan II, and lindane) have been reported within the hepatic tissues of viperids, colubrids, and heloderms.[68]

Clinical Presentation. In the experimental carbon tetrachloride study, lethargy, reduced food intake, and weight loss were noted in some iguanas. Chelonians with ivermectin toxicity typically display profound neurologic depression, which is thought to be associated with the GABA agonist effects within the CNS, rather than hepatic encephalopathy.

Diagnostic Confirmation. Most toxins cause hepatocellular leakage and necrosis, and therefore elevation in hepatocellular enzymes, and possible functional impairment and elevation of bile acids may be expected. Hepatic biopsy is required to demonstrate histologic changes, although the precise etiologic agent cannot be demonstrated without employing toxicologic analyses for likely agents (see Fig. 67.19C). Such toxicologic sampling typically requires the harvesting of larger biopsies

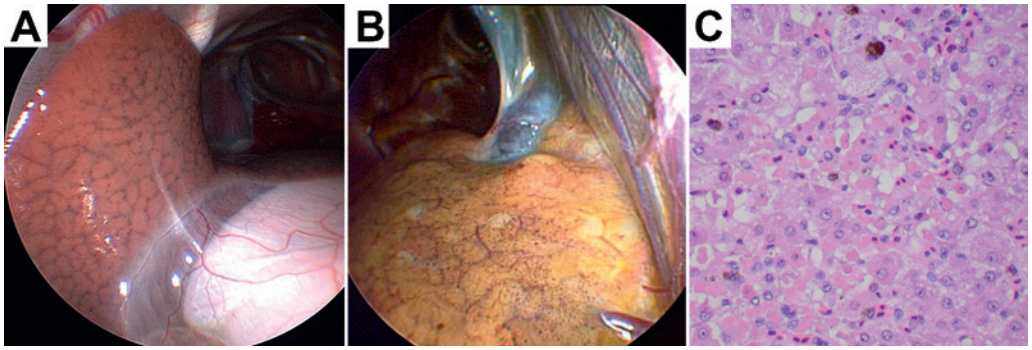

FIG 67.19 Carbon tetrachloride hepatic toxicity in green iguanas (*Iguana iguana*). (A) Endoscopic view of the normal liver. (B) Endoscopic view of the liver 6 days after toxic insult. (C) Liver biopsy histopathology demonstrating hepatocellular necrosis. (Courtesy of Stephen J. Divers.)

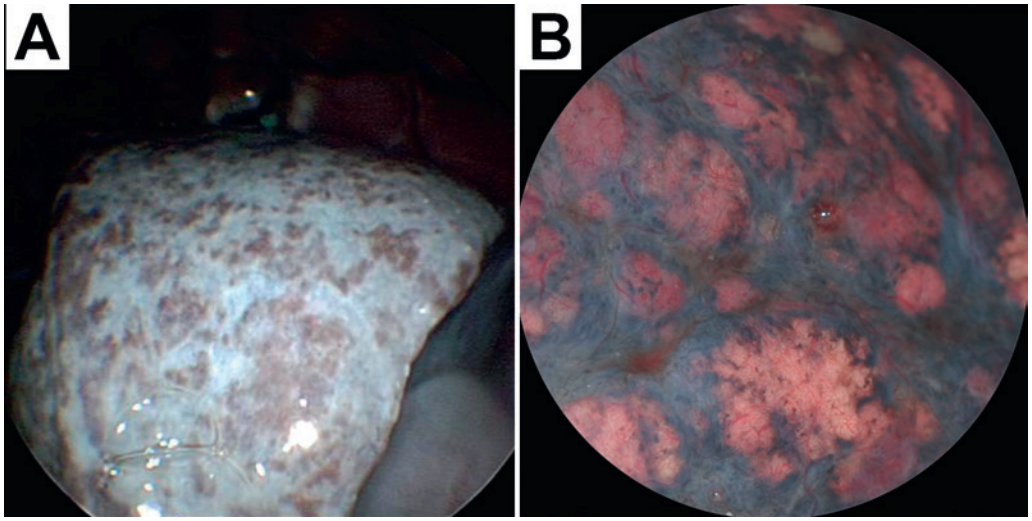

FIG 67.20 (A) Endoscopic view of the liver of a green iguana (*Iguana iguana*) demonstrating bands of pale fibrosis. The liver was enlarged but functionally deficient due to extensive fibrosis. (B) Close-up endoscopic view of the hepatic parenchyma of a Texas tortoise (*Gopherus berlandieri*) demonstrating fibrous bands and nodular hyperplasia. (Courtesy of Stephen J. Divers.)

and some idea of which class(es) of toxins may be involved. Survival from acute insults or chronic, intermittent exposure may result in fibrosis and nodular hyperplasia (Fig. 67.20).

Specific Treatment(s). Treatment is generally supportive; however, if there is a known antidote to a specific toxin then its administration may be beneficial.

Prognosis. Prognosis is unknown but probably guarded to poor once clinical signs are established. Serial sampling and improvement in clinicopathological results would give cause for continuing therapy.

Prevention. Preventing access to environmental pollutants/chemicals and avoiding inappropriate or unnecessary drug use will be beneficial.

Cholangitis, Cholecystitis, and Cholecystolithiasis

Clinical Significance. Inflammatory conditions involving the biliary system have been reported from terrestrial chelonians, large iguanid lizards, and snakes.[69] In most cases, the lesions are coincidental findings at necropsy, but chronic disease can lead to gross distension of the gallbladder, wall thickening, and fibrosis. Choleliths and cholecystoliths are uncommon but have been reported in association with trematode infestation of the liver and gallbladder.

Known Etiological Cause(s). Several metazoan (trematodes) and protozoan parasites (e.g., *Hexamita, Eimeria, Trichomonas*) have been associated with the bile ducts and gallbladder, probably due to migration from the gastrointestinal tract.[69]

Clinical Presentation. Intra- and posthepatic biliary obstruction can cause icterus.

Diagnostic Confirmation. Elevation of bilirubin (snakes) or biliverdin is likely following intrahepatic or posthepatic biliary obstruction. Leukocytosis, characterized by heterophilia, azurophilia, and/or monocytosis might be expected given the granulomatous inflammation that often accompanies cholecystitis. Ultrasonographic evaluation of the biliary system may help identify thickened biliary walls and cholecystoliths. Routine fecal evaluations for protozoan and metazoan parasites should be performed.

Specific Treatment(s). Cholecystectomy remains the treatment of choice in humans. A variety of treatments have been advocated in humans

VetBooks.ir

and laboratory animal studies, including ursodiol, ursodeoxycholic acid, hyodeoxycholic acid, ezetimibe, aspirin, and dietary cholesterol restriction.[70–72] Most of these therapies were geared toward preventing gallstone development rather than dissolution of existing stones. Extracorporeal shock wave lithotripsy has been used successfully in some human patients; however, reptile cholecystoliths tend to be soft and friable rather than lithic and therefore may be less affected by such therapy.[73] Parasitic infections should be treated accordingly.

Prognosis. The prognosis is unknown as most cases appear to be identified postmortem.

Prevention. Unknown in reptiles, but in humans and domesticated animals lean body condition, exercise, and regular meals have been advocated for prevention.

Hepatic Neoplasia

Clinical Significance. Neoplasia is not uncommon, and indeed recent surveys have indicated that hepatic neoplasia (hepatic adenoma and adenocarcinoma) is particularly prominent in squamates.[11,74–80] However, there have been very few antemortem diagnoses and no documented cases describing successful management.

Known Etiological Cause(s). There are no known carcinogens, although genetic/taxa predispositions have been suggested.[81]

Clinical Presentation. In snakes with a solitary hepatic mass, a firm midbody swelling may be appreciated 28% to 60% snout-to-vent, depending on species. A large liver or associated soft tissue mass effect may be palpable in lizards but is difficult to impossible to appreciate in chelonians due to their shell. More discrete nodular disease is more difficult to evaluate without advanced imaging, endoscopy, or surgical exposure (Fig. 67.21).

Diagnostic Confirmation. Elevation of hepatocellular enzymes and bile acids may be appreciated.[11] Ultimately, biopsy is required for a precise diagnosis, and even then staging is recommended but has not been previously reported for hepatic neoplasia in reptiles (see Chapter 78).

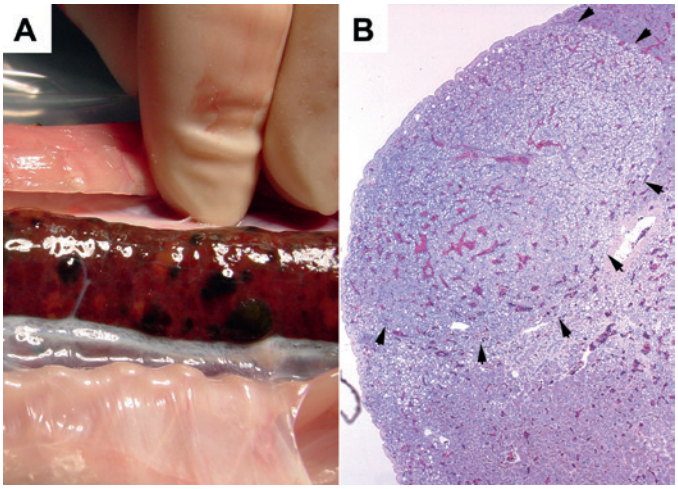

FIG 67.21 California king snake (*Lampropeltis getula californiae*) with hepatic melanomas. (A) Gross appearance of the liver intraoperatively. (B) Histologic photomicrograph of a melanoma nodule. H&E, ×20. (Courtesy of Stephen J. Divers.)

Specific Treatment(s). Oncologic treatments can include surgery, chemotherapy, and radiation, with the specific recommendation dependent upon a histological diagnosis and staging. In general, oncological therapy is often aimed at prolonging quality of life rather than cure.

Prognosis. Prognosis is dependent upon histopathology and determination of malignancy. A solitary, benign hepatoma may be resectable and carry a good prognosis. The prognosis for carcinomas and other malignancies is probably poor.

Prevention. No specific preventative measures have been identified.

Cardiology

Lionel Schilliger and Simon Girling

Until recently, primary cardiovascular conditions were rarely considered to affect ectotherms. This assumption is now challenged by the increased availability of diagnostic tools that have improved our knowledge of reptile cardiovascular anatomy, physiology, and pathology. Diagnostic techniques such as auscultation, electrocardiography, radiography, and, in particular, ultrasonography are now readily available in general practice. Despite a good basic understanding of reptilian cardiac anatomy and physiology, cardiology remains a poorly developed subspecialty in herpetological medicine compared to some other disciplines. The etiology, diagnosis, and treatment of cardiac conditions in reptiles are often poorly understood. However, translating our present knowledge of physiology and pathology into clinical practice will allow us to advance the discipline.

Cardiac physiology and anatomy differs markedly between mammals and reptiles and also between reptile taxa.[1–4] As in mammals, the reptilian heart is part of the circulatory system. The circulatory system consists of both a cardiovascular system that distributes blood pumped by the heart and a lymphatic system that distributes lymph throughout the body via a well-developed set of coelomic, muscular, cutaneous, and vertebral lymphatic vessels.[2,5–7]

The circulatory system is connected to all organ systems and plays a crucial role in homeostasis. In association with the respiratory system, it provides transport of gases between sites of external and internal respiration. Additionally, the circulatory system distributes products of digestion for metabolic use or energy storage, waste products to the kidneys, and electrolytes and hormones to target tissues. The circulatory system also plays a key role in the distribution of heat and immune system components throughout the body and adapts to variations of blood pressure.[8,9]

Reptiles in general have a smaller ratio of heart size to body mass than birds or mammals.[1,10] The presence of a single undivided ventricle in the heart of noncrocodilian reptiles originally thought to represent a simplistic or primitive precursor to the mammalian heart is now understood to be a complex, compartmented, and specialized chamber that confers physiological benefits to these animals, which have a low basal metabolic rate and a high tolerance for anaerobic respiration.[8,11]

CARDIAC ANATOMY AND PHYSIOLOGY

The reptilian heart is very similar to the early embryological heart of mammals and birds before ventricular septation.[2,12] It is grossly composed of two atria and one ventricle in noncrocodilians.

The basic embryonic pattern common to reptiles, birds, and mammals includes six aortic arches, of which arches III, IV, and VI persist in reptiles.[2,4,9] During embryonic development, the right aortic arch, left aortic arch, and the pulmonary trunk (the latter incorporating the base of the paired sixth arch) are formed from the ventral aorta. The right and left systemic arches (the right one being the most prominent of the two) merge caudally to form the common dorsal aorta.[2,4] Thus, these three efferent arterial trunks produce one pulmonary circuit and two systemic circuits, each of which arises independently from the heart.

Most publications of reptilian cardiac anatomy describe a small range of species that show variable designs in anatomy and physiology.[13–19] Little is known about the cardiac anatomy and physiology of the other 10,000 species of reptiles, and generalizations should be avoided whenever possible.

Cardiac Size, Shape, and Position

Heart mass compared to total body mass ranges between 0.2% and 0.3% in reptiles, similar to that found in amphibians (0.16%–0.32%).[1,12] This ratio is variable according to the degree of physical activity. For example, in "athletic" tree snakes, which also experience higher pressures due to gravitational and behavioral effects, the heart mass can reach 0.45% of the body weight, compared to 0.16% in slow-moving species such as the Brisbane short-necked turtle (*Emydura macquari*) or the European slow-worm (*Anguis fragilis*).[1]

Despite minor variations, the external anatomy of the reptilian heart tends not to vary significantly between species, but the position of blood vessels (efferent arteries and afferent veins) (Fig. 68.1) and inner structures can vary among groups and be more species specific.[4] The shape of the heart is broad and globoid in chelonians, elongated in ophidians, and ovoid in lizards and crocodilians.[1,10]

The location of the heart varies between taxa reflecting their phylogenetic position and ecological niche (Fig. 68.2).[20] In most species, the heart is roughly positioned along the axial midline and relatively cranially within the coelom. In snakes, the heart is found along the midline axis, but its longitudinal position varies with species. In marine and freshwater snakes, it is positioned nearer to the middle of the body. In non-tree-dwelling snakes it is found at about 25% snout-to-vent length (svl) and even more cranially in arboreal species (up to 15% svl).[1,4,9,21] These differences can be understood by considering the different physical forces to which the heart is subjected in different environmental conditions. A cranially positioned heart reduces the hydrostatic pressure above the heart and stabilizes variations in cephalic blood pressure.[1,4,9] Some studies have shown that those species of snakes that spend time raising their heads (arboreal and other climbing snakes) possess relatively shorter vasculature between the heart and head than do terrestrial species. The reverse is true in aquatic species, where the effect of gravity in water is minimal.[22]

Because of the absence of a diaphragm, the ophidian heart is mobile within the coelomic cavity. This probably facilitates the movement of large whole prey inside the esophagus.[1] In the coelom, the heart is found adjacent to the caudal tracheal rings, caudal to the thyroid, cranial to the bronchial bifurcation, close to the cranial pole of the lung(s), and just cranial to the liver.[1,4,23,24] Externally, the position of the heart

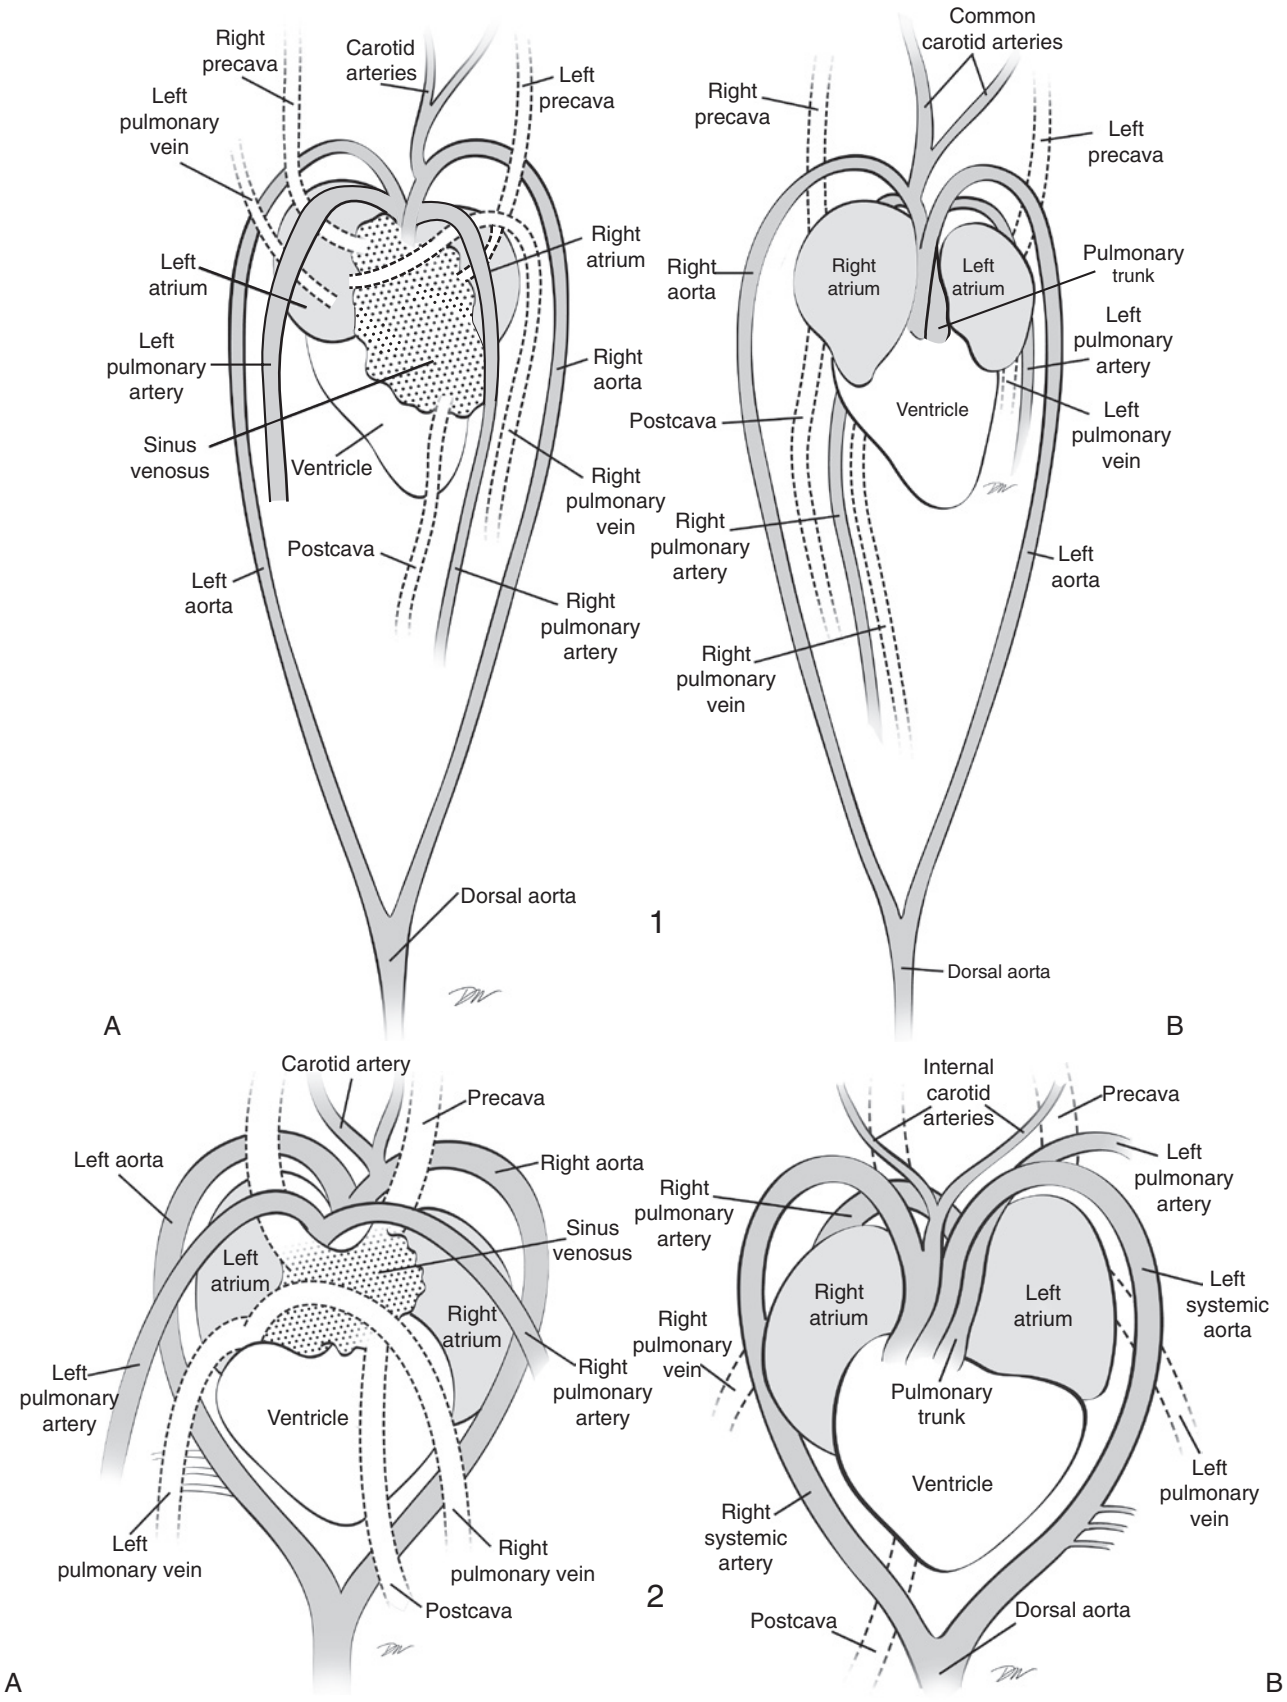

FIG 68.1 (1) Snake heart. (2) Lizard heart. (A) Dorsal view. (B) Ventral view.

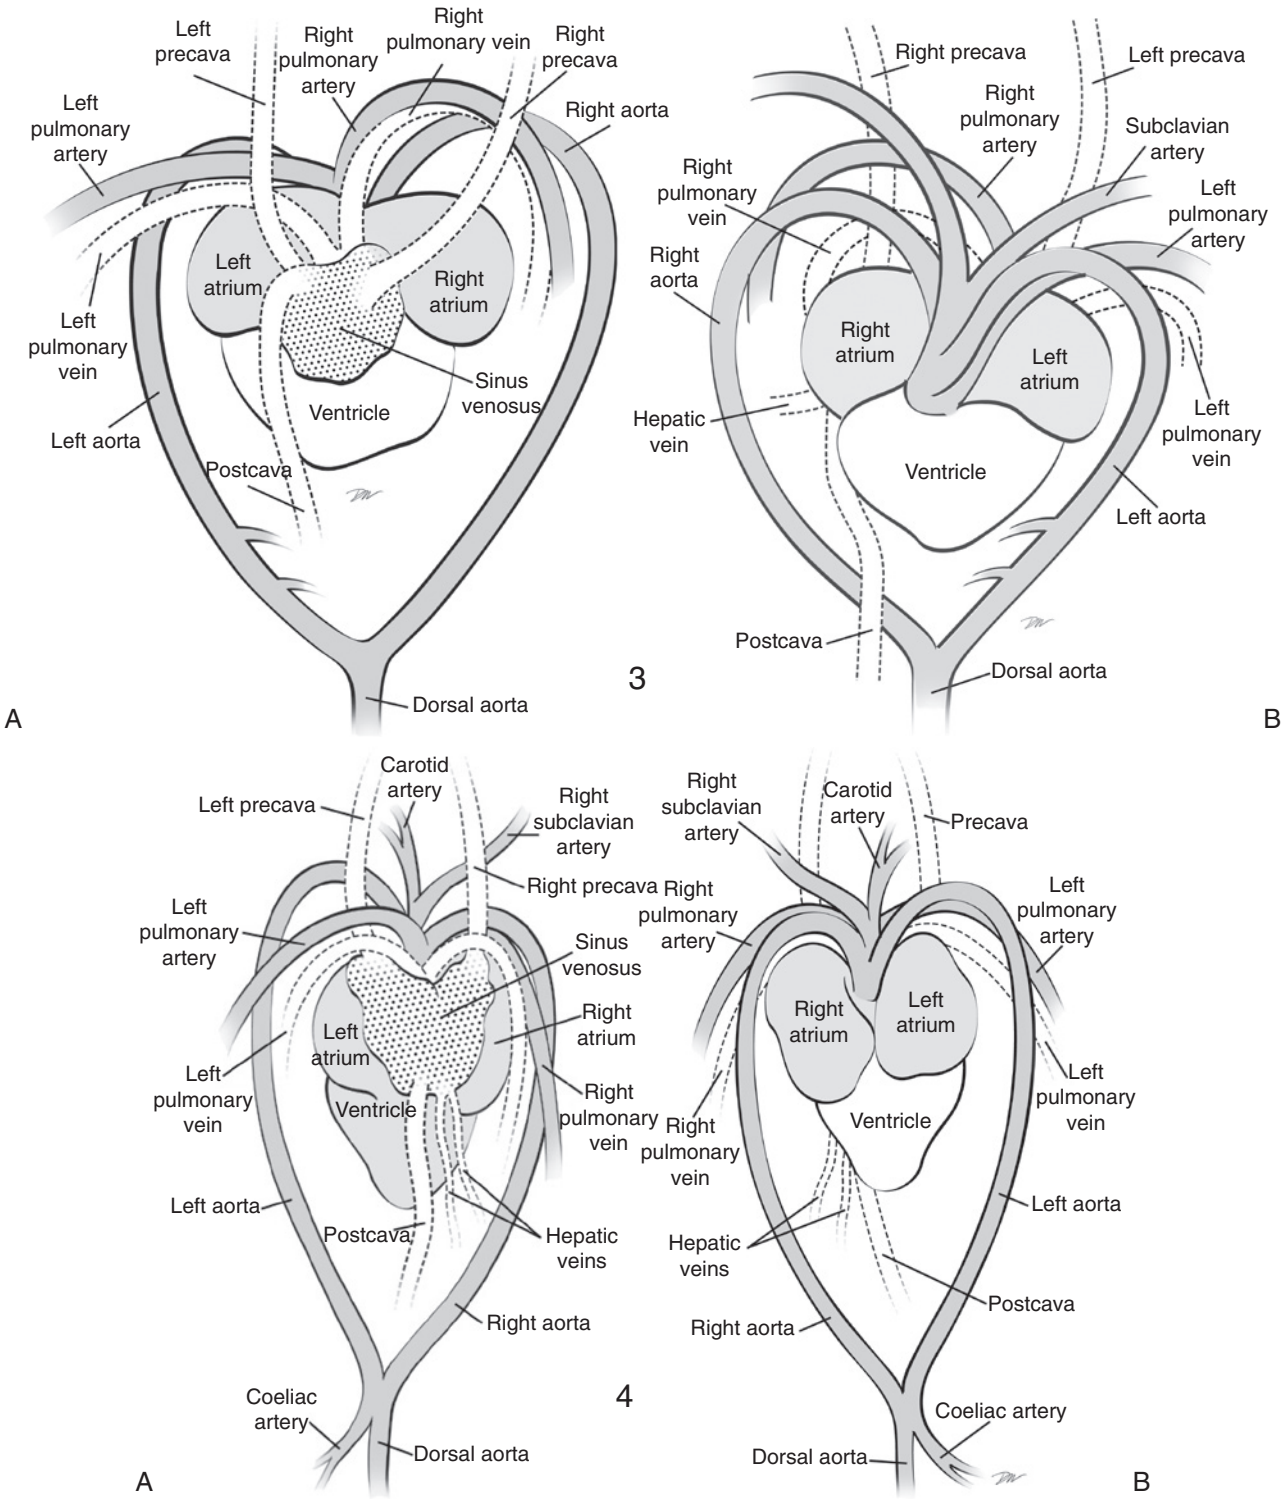

FIG 68.1, cont'd (3) Turtle heart. (4) Crocodilian heart. (A) Dorsal view. (B) Ventral view. (Reprinted from Murray MJ, Wyneken J. Cardiopulmonary anatomy and physiology. In Mader D, ed. *Reptile Medicine and Surgery*. 2nd ed. St. Louis: Elsevier; 2006:124–134, with permission from Elsevier.)

is indicated by percutaneous visualization of the ventral precordial tap when stretching the animal and placing it in dorsal recumbency. This is particularly obvious in the anesthetized and relaxed reptile.[23]

In chelonians, the heart is located in the ventral midline at the level of the intersection of the humeral, pectoral, and abdominal scutes of the plastron.[4,25] In some species it is positioned more caudally, above the junction of the humeral-pectoral and pectoral-abdominal scute lines.[25] This may, however, be an unreliable landmark, as the positions of the pectoral and humeral scutes differ widely among species.[4] In the coelom, the heart is bordered dorsally by the septum horizontale and the cranial lungs, laterally by the liver lobes, and ventrally by the coelomic membrane and plastron.[23] In soft-shelled turtles (*Trionychidae*), which

possess a very streamlined carapace and hence vertically compressed coelomic cavity, the heart is displaced to the right.[4,26] This is due to a long protractile neck, which when retracted into the carapace causes a displacement of the heart and liver to the right and of the stomach to the left.[1]

In most lizards, the heart is encased within the pectoral girdle of the gular region. In tegus (*Teiidae*), Gila monsters (*Helodermatidae*), and monitor lizards (*Varanidae*), the heart is located more caudally in the coelomic cavity.[1,4,9,23]

In crocodilians, the heart lies midline approximately midway between the pelvic and pectoral girdles.[1,4,15,27] The apex lies deep between the right and left medial aspect of the hepatic lobes, adjacent to the liver isthmus. The base of the heart extends slightly cranial to the cranial border of the liver and lies within the mediastinum, ventral to the primary bronchi and esophagus.[28]

Pericardium

As in mammals, the heart lies in a visceral space known as the pericardial cavity and is covered by the pericardium (Fig. 68.3). The innermost layer of the pericardium is the epicardium, and immediately adjacent to this is the myocardium. The heart apex is attached to the pericardium by a ligament termed the *gubernaculum cordis*, except in snakes and varanids where the ventricle remains free within the pericardial space.[1,2] The pericardial sac lies within the caudoventral part of the thoracic cavity in crocodilians.[1,4,15,28]

Heart Anatomy

Reptilian hearts can be loosely classified into two basic patterns: the noncrocodilian heart (in squamates and chelonians) and the crocodilian heart (in crocodiles, alligators, gavials, and caimans) (Figs. 68.4 and 68.5).[1,4,9,29]

Noncrocodilians. The noncrocodilian heart has historically been described as a three-chambered organ composed of two atria and one single ventricle (Fig. 68.6). The ventricle is morphologically considered as a single chamber due to the lack of a complete interventricular septum. It is only partially partitioned by muscular ridges (see later) that incompletely subdivide it with various degrees of structural and functional compartmentalization depending on adaptations to specific ecological and physiological parameters. This contrasts with the four-chambered crocodilian heart, where the presence of a complete interventricular septum anatomically and functionally separates the ventricle into two chambers.

The ophidian heart is substantially asymmetric with a larger right atrium extending caudally and covering a larger area of the right side of the ventricle than the left atria covers the left side of the ventricle. Three arterial trunks—the left aortic arch, the right aortic arch, and the pulmonary trunk—are visible on external examination (Fig. 68.7A). They run from the ventricle and emerge between the two atria, rotate toward the right, and form a 180-degree angle. The right (but not the left) aorta branches off several major arteries (including the right and left carotid arteries) and fuses caudally with the left aorta to form the common abdominal aorta (dorsal aorta) (see Fig. 68.7B).[1,2,4,9,23,25,27,30] The pulmonary artery later divides into left and right pulmonary arteries to supply the left and (where present) right lungs respectively. In species that only have one predominant right lung (e.g., most ophidians) the left pulmonary artery is absent or vestigial.[1,2]

The sinus venosus is situated on the dorsal aspect of the heart and is attached to the dorsal wall of the ventricle by the dorsal ligament (see Fig. 68.7C). It is composed of spontaneous contractile tissue and contains the pacemaker. It receives deoxygenated blood from the two cranial vena cavae and the caudal vena cava and drains into the right atrium through a sinoatrial orifice guarded by a pair of small flap valves, termed the sinoatrial valves. In some species, the hepatic vein or jugular vein also drain directly into the sinus venosus. In most squamate species, the sinus venosus possesses a partial septum.[1,2,4] As the sinus venosus can be considered as an additional chamber, the noncrocodilian heart may also be regarded as an atypical four-chambered heart.[1,2,8,9,26]

The left atrium is generally smaller than the right atrium and receives blood from the two pulmonary veins. In some species, paired valves are found in the pulmonary veins as they enter the atria.[23] The atria communicate with the ventricle via the atrioventricular funnels separated from the ventricle by monocuspid atrioventricular valves. This AV valve-complex is made of connective tissue and is bell-shaped with the concave side facing the ventricle.[23] Fibrous strands similar to chordae tendinae join the atrioventricular valves to the ventricular musculature in some species.[1,2,4]

In noncrocodilian reptiles, the ventricle is subdivided into three subchambers: the cavum pulmonale, the cavum venosum, and the cavum arteriosum (see Fig. 68.6).[1,2,4,23] The internal structure of the ventricle is complex. Two-dimensional anatomical illustrations may give an incomplete understanding of its structure, especially considering the anatomical and topographical diversity among species. Essentially, the cavum venosum and arteriosum are mostly dorsal (often collectively referred to as the *cavum dorsale*) and to the cavum pulmonale is ventral (sometimes named *cavum ventrale*).[1] The left and right aortic arches arise from the cavum venosum at two orifices with bicuspid valves (rather than tricuspid valves as in mammals). The pulmonary trunk is a continuation of the cavum pulmonale, and its base also contains small semilunar valves.[1] In some species of turtles and squamates, a foramen connects the left and right aortas. The functional significance of this is unknown, as both aortas originate from the cavum venosum.[16]

Noncrocodilian reptiles have two ventricular septa. One is the muscular ridge (also called the *horizontal septum*), which runs from the apex to the base of the heart and is incomplete toward the base. It separates the cavum pulmonale from the cavum venosum/cavum

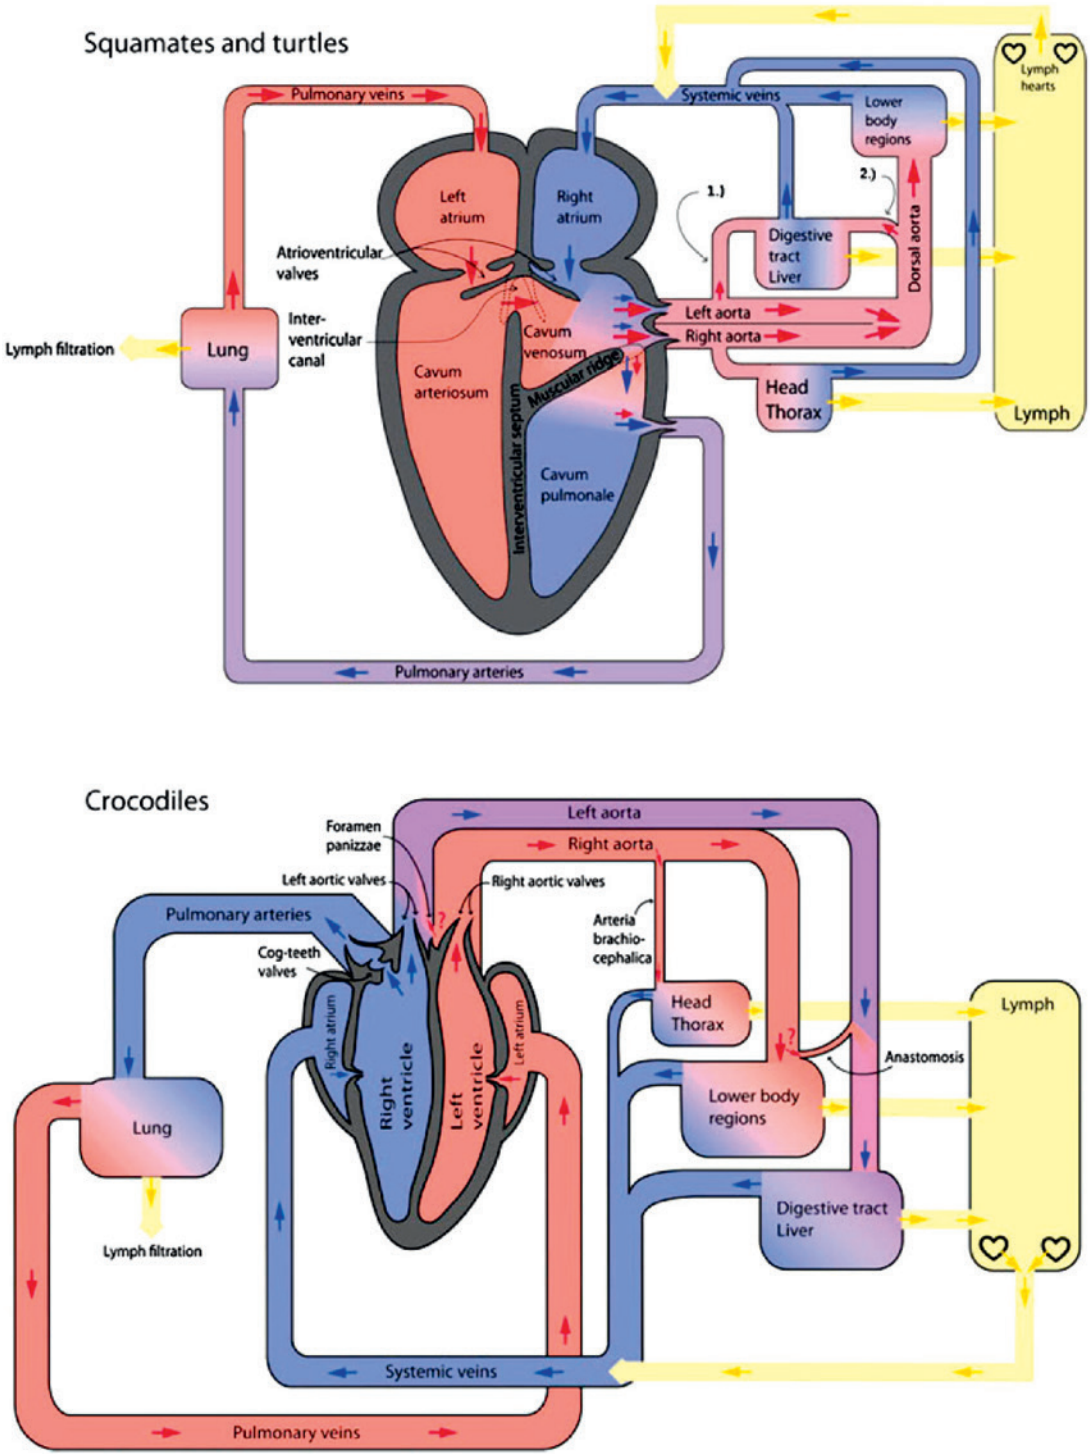

FIG 68.5 Schematic illustration of the circulatory and lymphatic systems in squamates/turtles and crocodiles. arteriosum predominantly during the ventricular systole. This muscular ridge is relatively inconsistent in structure and position across species. It is poorly developed in chelonians, except marine turtles and giant tortoises.[1] It is more developed in varanids and pythons compared to other squamates and many species of chelonians.[1,14,16] In evolutionary terms, the interventricular septum present in archosaurs (crocodilians and birds) seems to have evolved from this muscular ridge.[1,10,27]

An incomplete muscular septum (also called the *vertical septum* or *interventricular septum*) divides the cavum dorsale into the cavum arteriosum to the left and the cavum venosum to the right and often

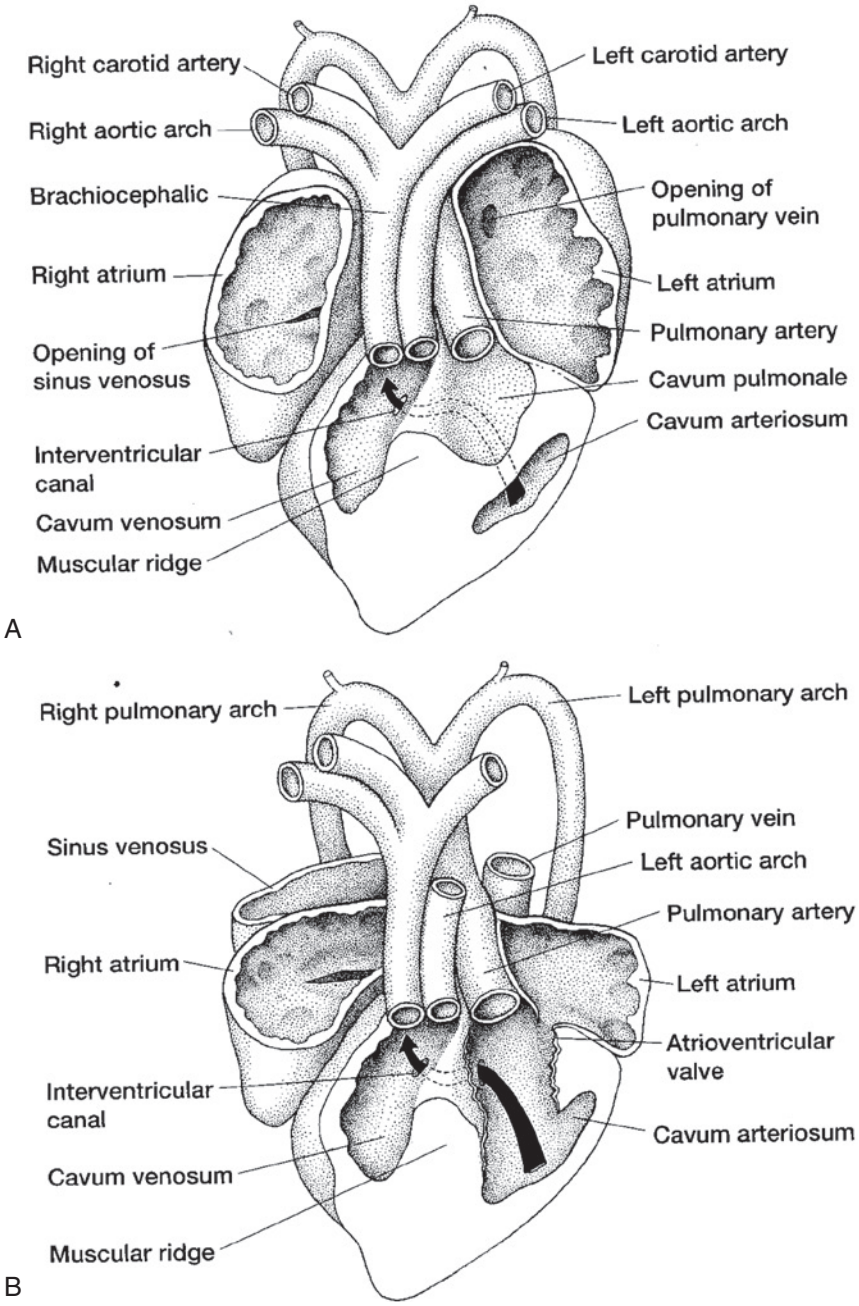

FIG 68.6 Lizard heart, ventral view. (A) Part of the ventral wall of the heart has been removed to show its three interconnected compartments (cavum venosum separated by a muscular ridge from the cavum pulmonale and deeper cavum arteriosum. joins the muscular ridge at its base. It contributes to the separation of pulmonary venous blood from systemic flow during ventricular diastole.[1]

Another septum, the bulbus lamelle, lies opposite the muscular ridge, curving over and around it. It is situated immediately to the right of the vertical septum.[18]

A large interventricular canal, located below the atrioventricular valves, is the only connection between the cavum arteriosum and the cavum venosum (see Fig. 68.6). The atrioventricular valves are positioned in such a way that, when pressed toward the midline (i.e., opened), they partially or completely obstruct the interventricular canal. This system allows a certain functional separation of the systemic and pulmonary circulation, with the cavum pulmonale (cavum ventrale) being the functional homologue to the mammalian, crocodilian, and avian right ventricle, and the combined cavum venosum and arteriosum (cavum dorsale) being the functional homologue to the mammalian, crocodilian, and avian left ventricle.[1,2,4]

The cavum venosum is a relatively small cavity that receives both oxygenated and deoxygenated blood at various times during the cardiac

cycle. This is particularly marked in varanids and pythons.[1,16,19,31] Thus, two kinds of cardiac morphologies can be roughly defined in noncrocodilian reptiles:

1. The typical noncrocodilian heart has a ventricle that is a continuous single chamber, operating as a single pump during the entire cardiac cycle. This is seen in most chelonians, such as freshwater turtles and tortoises, and in squamates, including aquatic snakes, grass snakes, rattlesnakes, and most lizard species. In this type of heart, the muscular ridge is relatively small and not well developed.[1,2,4,9,10,32] The right aortic and the intraventricular pressures are equal (Fig. 68.8).[1,19]
2. The varanid and python heart possess a large, well-developed muscular ridge, which almost forms a complete ventricular septum that can be visualized as an asymmetric thick wall. This is also found in at least one species of marine turtle, the leatherback turtle.[1] Moreover, in these reptiles, the cavum arteriosum is enlarged and the cavum venosum is reduced. In this heart model, the cavum pulmonale becomes functionally separated from the cavum venosum and from the cavum arteriosum during systole. Thus, this kind of ventricle functions as a double pump, with higher pressures in the cavum venosum and the systemic arches than in the cavum pulmonale and pulmonary arteries (Fig. 68.9).[19] This complete separation of the pulmonary and systemic circulations has been clearly shown in varanids (*Varanus exanthematicus* and *Varanus niloticus*), in the Burmese python (*Python bivittatus*), and in the ball python (*Python regius*).[10,16,19,31,33,34]

Crocodilians. The four-chambered crocodilian heart has a complete interventricular septum that anatomically and functionally separates the ventricle into two chambers. It resembles that of mammals and divides pulmonary and systemic flow (Fig. 68.10).[1,4,9,27] The gubernaculums cordis is a ligament that extends from the right ventricle (not from the apex as in Testudines and Sauria) and anchors the heart to the pericardium. The sinus venosus is much reduced and possesses a partial septum internally. It resembles an elongated pyramid, with the base lying cranially and the apex caudally. The right and left atria are of similar size. Both aortic arches remain. The left ventricle ejects blood

into the right aorta while the right ventricle ejects blood into the left aorta and the pulmonary artery. As they exit the ventricle, all three vessels are of similar diameter. As they run cranially, the aortae and the pulmonary artery are bound together by a connective tissue sheath. The base of each efferent artery has a bicuspid valve, the medial cusp being longer than the lateral one. A narrow channel, called the foramen of Panizza, creates a connection between the left and the right aortic arches, shortly after their exit from the ventricules.[1,2,4] The bicuspid atrioventricular valves, which guard the connection between the atria and ventricles, are composed of a left septal and a right marginal cusp. The left atrioventricular valves are membranous and the marginal cusp of the right atrioventricular valve is a thick, liplike structure. As in

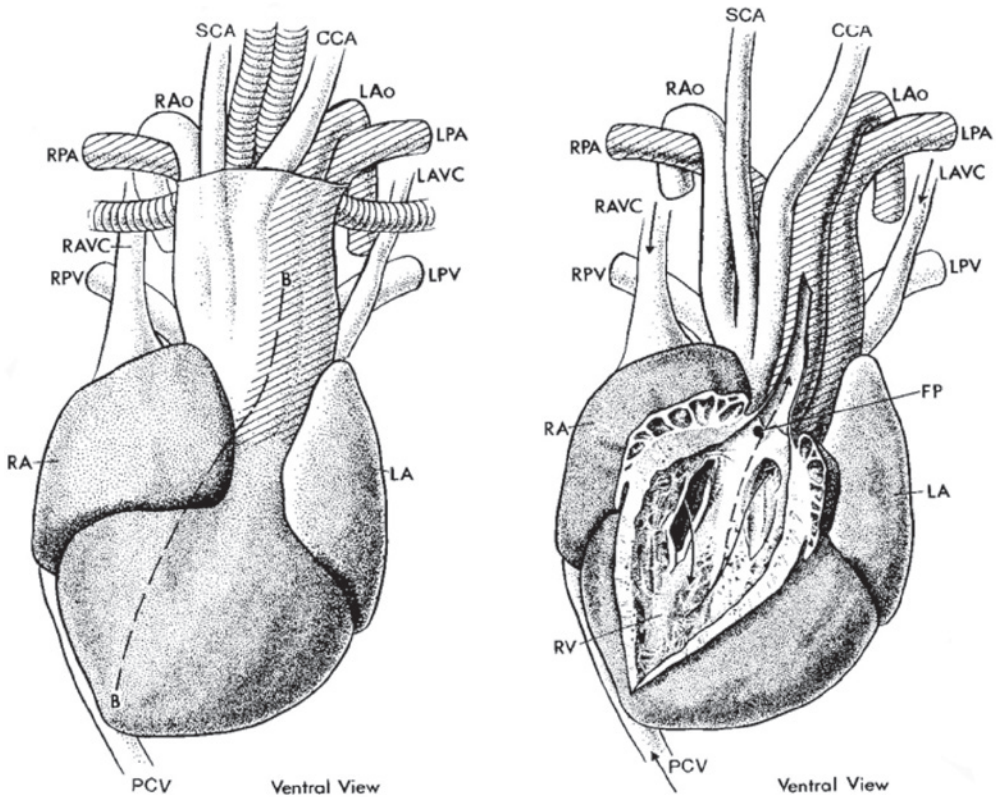

FIG 68.10 Schematic diagram of the crocodilian heart (*Crocodylus porosus*). The right side of the figure shows the heart opened ventrally along the line B. The solid arrows show the direction of flow during normal air breathing from right atrium to right ventricle to pulmonary arch. The dashed arrow, from right ventricle to left systemic arch, indicates the direction of blood flow when the pulmonary bypass shunt operates (e.g., during diving). mammals, the pulmonary veins are devoid of valves. The right and left aortic arches anastomose at two locations, first at the foramen of Panizza and second at the level of the midcoelomic cavity by the dorsal connecting artery.[1,2,4] Opening of the foramen of Panizza is actively controlled and is discussed below.

Cardiac Physiology

Pacemaker and Heart Rate. Unlike mammals, reptiles do not have a specialized cardiac conduction system such as pacemaker nodes and Purkinje fibers.[1,35] Instead, the contractions are initiated by cardiac muscle. The contractions originate in fibers within the sinus venosus of the right atrium, which spread in sequential coordination, first to the left and then toward the apex caudally.[36] The ventricle is depolarized starting at its base and then proceeding to the left. Repolarization starts from the base and spreads symmetrically to the right and left toward the apex. It is believed that specific areas of cardiomyocytes slow conduction between different heart compartments, creating marked delays in electrical conduction. Such delays are clearly visible on the ECG of all researched reptile species with a characteristic rapid systolic phase and far slower diastolic one. Thus, the spongy myocardium of the ventricle functions as a medium for both conduction and contraction.[35]

The heart receives innervations from both parasympathetic and sympathetic fibers. The parasympathetic fibers run in the vagus nerve and provide cholinergic (inhibitory) control. The less-developed sympathetic fibers cause positive chronotropism and inotropism via adrenergic innervation.[1,4]

The heart rate (HR) is generally slower in reptiles than in mammals or birds. HR is dependent on numerous factors.[4] Myocardial efficiency is optimum when the reptile is within its preferred optimal temperature zone and at its preferred body temperature. Tachycardia occurs when the animal is exposed to higher temperatures, and, together with peripheral vasodilatation, increases heat loss from cutaneous vascularization. Conversely, lower temperatures stimulate bradycardia, and, together with peripheral vasoconstriction, reduce heat loss. This mechanism, which often anticipates internal temperature variations, is regulated by cutaneous thermoreceptors. HR is proportional to metabolic level and inversely proportional to body size. Reptiles that experience hypovolemia (e.g., as a result of surgery or trauma) may become tachycardic to maintain cardiac output and tissue oxygenation. Bradycardia is observed during apnea as pulmonary resistance increases and blood flow to the lungs decreases, effectively creating a right-to-left cardiac shunt.[37] Other effects on HR include digestion, gravidity, sensory stimulations (such

as handling, postural, and gravitational stress), méthylatropine, and certain anesthetics and sedatives (e.g., α-2 agonists).[1,4,38]

Blood Flow During Normal Breathing

Noncrocodilians. In noncrocodilian reptiles (Fig. 68.11A.a and B), the ventricle is not physically divided, but pulmonary and systemic blood flow are separated and regulated by functional plasticity. Oxygenated and deoxygenated blood flowing from the aortic arches are partially mixed, the amount of mixing being determined by the degree of development of the muscular ridge and interventricular septum.

During early ventricular diastole, both atrioventricular valves open simultaneously and block the interventricular canal between the cavum arteriosum and the cavum venosum. The cavum venosum and pulmonale receive deoxygenated blood from the right atrium, and the

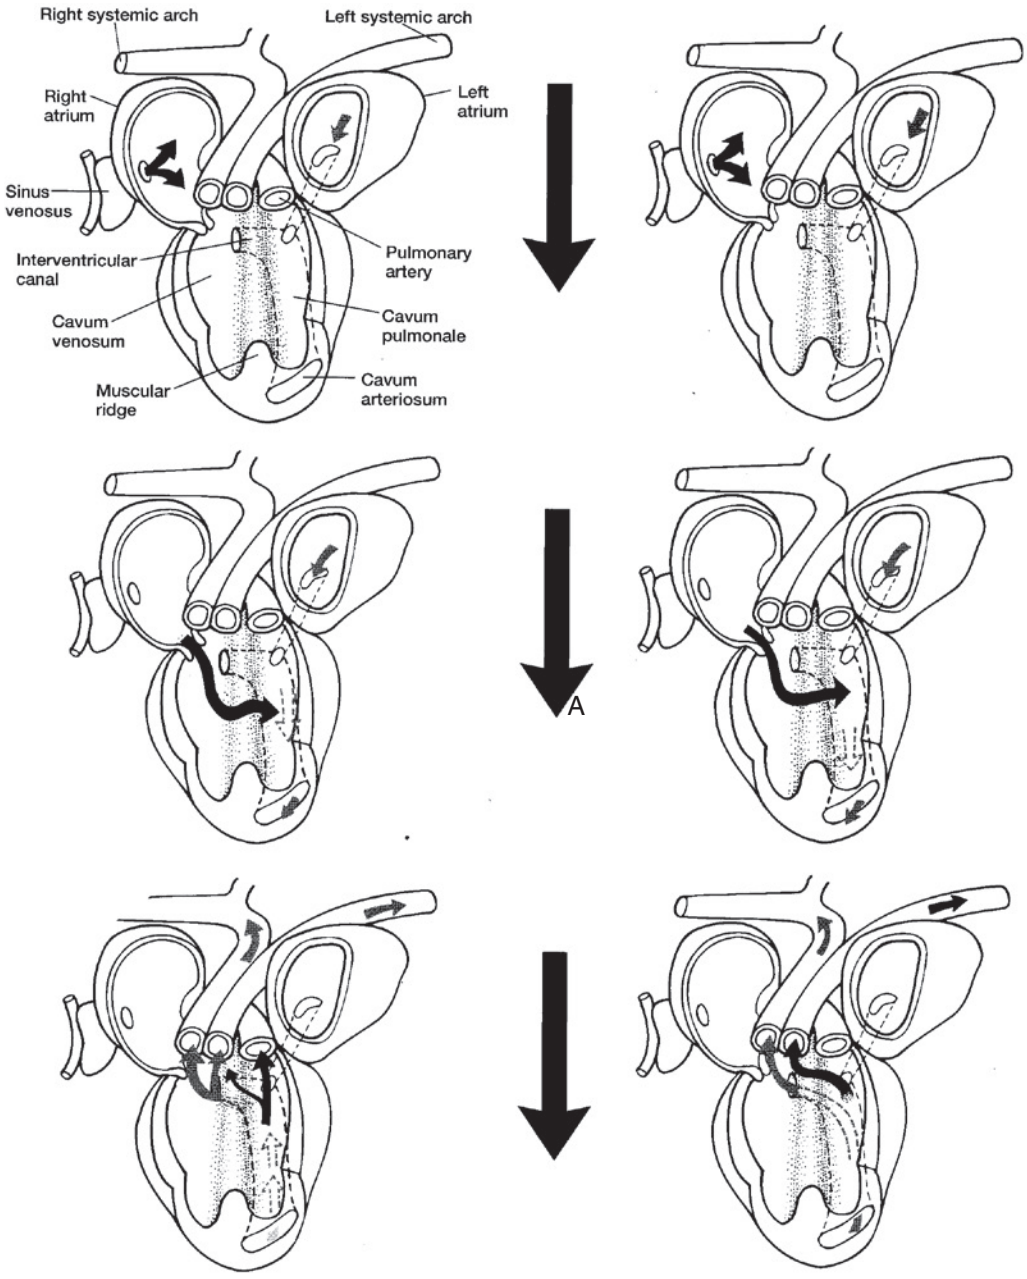

FIG 68.11 Blood flow through the noncrocodilian (squamate and chelonian) heart. (A) (a) When squamates breathe air on land, venous blood from the right atrium enters the cavum venosum of the ventricle and crosses a muscular ridge to fill the cavum pulmonale momentarily. Upon ventricular contraction, most of this blood exits via the pulmonary artery. Simultaneously, blood from the left atrium enters the cavum arteriosum. Contraction of the ventricle moves this blood through the interventricular canal, and then the blood departs via the left and right systemic arches. (b) When squamates and turtles dive, resistance to pulmonary blood flow encourages blood that would normally exit to the lungs to move instead across the muscular ridge and depart primarily via the left aortic arch.

Continued

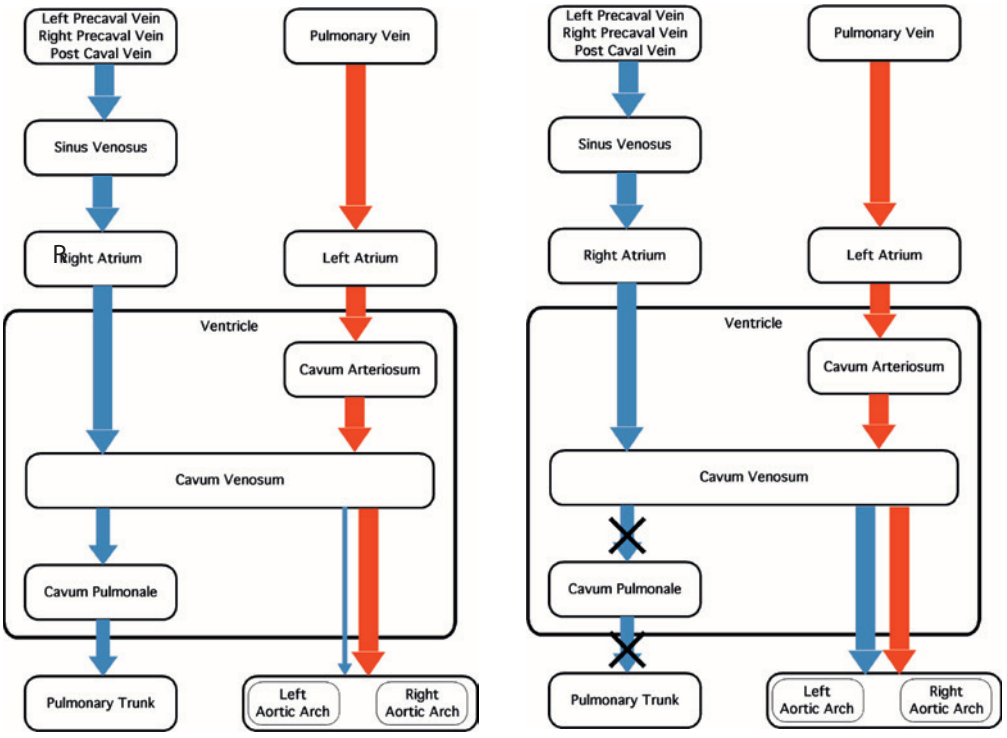

FIG 68.11, cont'd (B) Schematic drawing of blood flows during normal breathing. (C) Schematic drawing of blood flows during apnea. (Reprinted from Kardong KV. The circulatory system. In Kardong KV, ed. *Vertebrates. Comparative Anatomy, Function, Evolution,* ed 6. New York: McGraw-Hill; 2012:451–498, with permission from McGraw-Hill; B and C, courtesy of Lionel Schilliger.)

cavum arteriosum receives oxygenated blood from the left atrium. During the late ventricular diastole, blood flow from the atria ceases, and deoxygenated blood from the cavum venosum flows into the cavum pulmonale. During ventricular systole, the atrioventricular valves close the atrioventricular funnels. This opens the interventricular canal and allows blood flow from the cavum arteriosum into the cavum venosum. During late systole, the muscular ridge moves cranially and separates the cavum venosum and the cavum pulmonale. Oxygenated blood is then pumped out of the cavum venosum into the left and right aortic arches, and deoxygenated blood is pumped out from the cavum pulmonale toward the pulmonary arterial trunk (see Fig. 68.11A.a and B).[1,2,4,16,29] Because the diastolic blood pressure is lower in the pulmonary arches than in the systemic ones, blood flows first in the pulmonary arteries and then in the systemic arteries. Ventricular systole tends to be long and diastole is short. As already mentioned, the muscular ridge nearly completely separates the two sides of the ventricle in varanids and pythons. This produces a more pronounced separation of blood flow and allows for higher systemic pressures. In many chelonians, the cavum venosum is much larger, and so more blood mixing occurs between the left and right sides of the ventricle.[1,25,27] Unlike mammals, the reptilian atria make an active contribution to ventricular filling. On a cellular level, the atrial and ventricular walls are composed of an inner, thick, spongy and outer, compact myocardium. The spongy cardiomyocytes receive nutrition by diffusion from luminal blood via intramural flow, and a coronary circulation supplies the compact myocardium of the ventricles.[17]

Crocodilians. When crocodilians have free access to air, the heart functions in a similar way to mammals with separate systemic and pulmonary circulations (Fig. 68.12a). Because the blood pressure in the pulmonary vasculature is much lower than in the systemic vasculature, the pressure generated in the right ventricle is much lower than in the left ventricle. The blood pressures in the left and right aorta are equalized via the foramen of Panizza (which opens during ventricular diastole) and the dorsal connecting artery. Consequently, the bicuspid valve at the orifice of the left aorta (which exits the right ventricle) remains closed, as the right ventricular pressure does not exceed left aortic pressure. Hence, all the blood in the right ventricle is pumped into the pulmonary circulation. In addition, the blood in the left ventricle goes primarily into the right aorta, as one of the valves guarding the right aorta folds back to completely cover the foramen of Panizza during systole.[1,4,5,24,27,30]

Cardiac Shunting. Given their unique anatomy, reptiles have the ability to regulate blood shunting in the ventricle based on their metabolic needs.[39,40] While cardiovascular shunting is detrimental in birds and mammals and is only seen in congenital abnormalities, it serves important physiological functions in reptiles.[8]

The extent of shunting is determined by differences in pulmonary and systemic vascular resistance, which is partially regulated by parasympathetic and sympathetic tones. During periods of high parasympathetic tone (e.g., during rest, fasting, diving, apnea, hibernation), vasoconstriction causes an increase in pressure in the pulmonary artery and a decreased blood pressure in the pulmonary veins. These results in high pulmonary outflow resistance, and a right-to-left (R-L) shunt may occur, decreasing pulmonary perfusion. The R-L shunt ensures blood perfusion to vital organs during anoxia (see Fig. 68.11A.b and C).[1,2,39,40]

Inversely, increased sympathetic tone as a result of physiological or environmental events causing an increase in metabolism (such as increases in temperature, exercise, or digestion) causes a left-to-right shunt. This facilitates pulmonary perfusion and increases blood oxygenation and

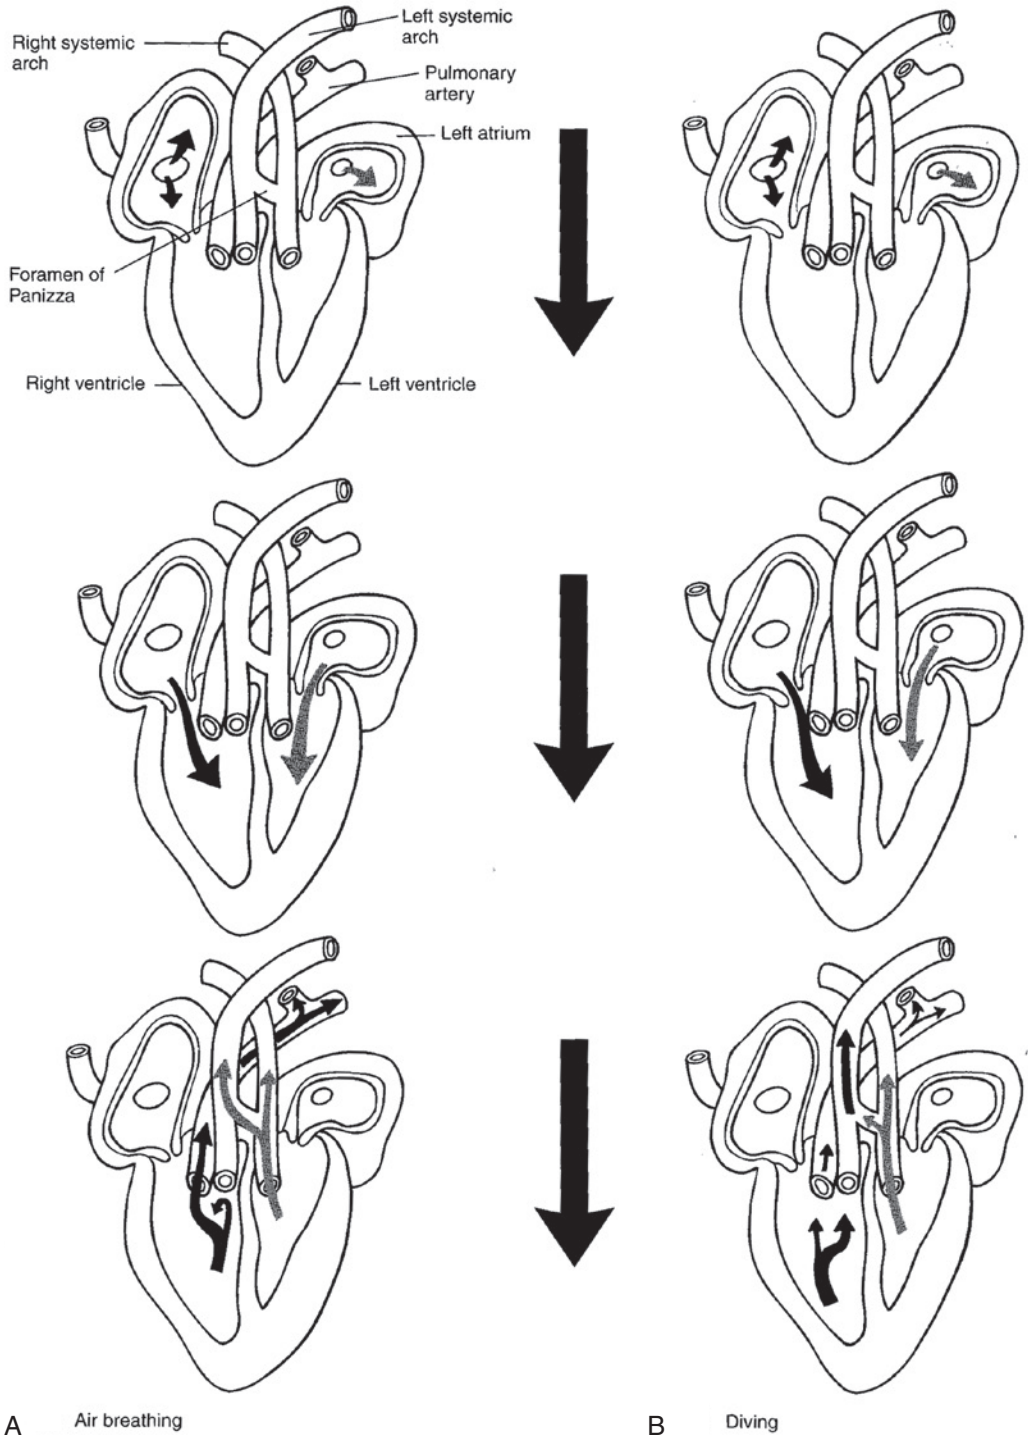

FIG 68.12 Blood flow through the crocodile heart. (A) Systemic and pulmonary blood flow when the crocodilian breathes air. (B) Internal changes that result in decreased pulmonary flow when the crocodilian dives. (Reprinted from Kardong KV. The circulatory system. In Kardong KV, ed. *Vertebrates. Comparative Anatomy, Function, Evolution,* ed 6. New York: McGraw-Hill; 2012:451–498, with permission from McGraw-Hill.)

gaseous exchange. In most reptiles breathing is intermittent with long, nonventilatory phases of apnea. The ability to shunt blood in both directions may therefore be optimal to limit ventilation/perfusion mismatch.[1,2,39,40]

This kind of cardiac shunting mechanism is observed in chelonians and also in most squamates, where the heart acts as a single-chamber pressure pump. This is termed "pressure difference shunting," whereby the balance between R-L or L-R shunts depends essentially on the ventilatory state of the animal (i.e., the pulmonary and systemic vascular resistances). "Washout shunting" may also be responsible for cardiac shunting in reptiles. The main difference between these two shunting mechanisms depends on the ability of the muscular ridge to separate the cavum pulmonale from the cavum venosum and cavum arteriosum during systole. "Pressure difference shunting" only occurs in crocodiles,

whereas in turtles, both "pressure difference shunting" and "washout shunting" occurs.[1,40]

The "washout" mechanism is probably the primary physiological determinant of intracardiac shunting in species with a partially developed "double pressure" pump (varanids and pythons). In varanids and pythons, the separation between the cavum pulmonale and the two other cava prevents any resistance in outflow pressure to influence intracardiac shunting during ventricular systole (as is the case in other squamates). "Washout shunting" occurs when the residual volume of blood remaining in the cavum venosum is mixed within the pulmonary or systemic circuit during the cardiac cycle. During right atrial systole, even though most of the systemic venous blood passes into the cavum pulmonale, a residual amount of deoxygenated blood remains in the cavum venosum. During ventricular systole, the cavum arteriosum injects blood into the cavum venosum and into the systemic arches. This results in the mixing of the two atrial supplies and thus creates an R-L shunt. At the end of ventricular systole, oxygenated pulmonary venous blood may remain in the cavum venosum (i.e., end-systolic volume of the cavum venosum is not zero). During the next diastole, deoxygenated systemic venous blood pumped out from the right atrium through the cavum venosum and the cavum pulmonale will mix with this oxygenated pulmonary venous blood, resulting in a L-R intracardiac shunt. This end-systolic oxygenated blood is washed from the cavum venosum into the cavum pulmonale during the following diastole. Thus, the degree of R-L shunt depends on the volume of deoxygenated blood in the cavum venosum at end diastole in addition to the volume of blood ejected from the cavum arteriosum during systole. The degree of L-R shunt depends on the volume of oxygenated blood in the cavum venosum at the end of systole in addition to the volume of systemic venous blood.[1,40] Thus, "washout shunting" is dependent on preload, contractility of the heart, and afterload. This has been demonstrated in the ball python, in which shunting occurs in the cavum venosum, when the atrioventricular valves open but the muscular ridge is not yet closed. During fasting and resting, up to twice as much blood flows into the systemic circulation than into the pulmonary one (R-L shunt), whereas during digestion, more blood is pumped through the pulmonary circulation (L-R shunt) because of increased oxygen demand.[16]

The direction and degree of cardiac shunting in squamates and chelonians may also be influenced by internal and/or external factors, including temperature, disease/healing, digestion, vascular sphincters, hibernation, and, in aquatic species, the dive reflex. Various investigative approaches have been followed in order to better understand the potential physiological benefits.[4,25,29,39,40] It is also reasonable to assume that anesthetic drugs, pulmonary ventilation, and the composition of inhaled air may have an effect on cardiac shunting during anesthesia. This is likely to vary between species and may impact the duration of anesthetic recovery and anesthetic gas excretion.

In crocodilians, despite a complete ventricular separation, cardiovascular shunting can still occur via the foramen of Panizza, which joins the two aortae originating from separate ventricles.[1,4,40] During apnea (see Fig. 68.12b), increased pressure in lung tissue together with coglike valves at the base of the pulmonary artery causes an increase in pulmonary resistance. This results in the pressure of the right ventricle overcoming that of the pressure in the left systemic aorta, and blood from the right ventricle enters the left aorta and pulmonary artery. During apnea, most of the blood follows the course of the left aorta. However, some blood passes into the right aorta via the foramen of Panizza and, at the confluence of the left and right aortic arches, results in some mixing of oxygenated and deoxygenated blood in the systemic circulation.[1,4,40]

Other cardiac physiological parameters, such as heart rate, stroke volume, and blood pressure, greatly depend on environmental and behavioral parameters (e.g., temperature, oxygen demand, and activity). Different cardiovascular variables are important in reptilian thermoregulation, such as heart rate and cutaneous vasodilation.[4,9] For instance, green iguanas (*Iguana iguana*) exposed to heat experience tachycardia, and about 20% of blood flow is shunted from right-to-left to increase thermal diffusion across the body. The presence of two aortae is beneficial in reptiles: shunting toward the left aorta contributes to thermal diffusion while the right aorta (having more branches, including the carotid arteries) still supplies the brain and major organs with well-oxygenated blood.[5]

Aside from cardiac shunting, another important physiological benefit is postprandial cardiac hypertrophy of intermittent feeders. In large, postprandial boids, blood flow to the intestines and portal system can increase by up to 30% and 300%, respectively.[29,41,42] This is supported by an increase in ventricular mass to support the postprandial increase in metabolism and blood flow. Heart mass can increase by 40% within 48 to 72 hours of a fasted Burmese python (*Python bivittatus*) ingesting a large meal. Such an increase in cardiac mass seems to be promoted by the presence of certain plasma fatty acids.[42]

DIAGNOSTIC TOOLS IN REPTILE CARDIOLOGY

Physical Examination

Ambient temperature can influence cardiopulmonary parameters in reptiles, so it must be considered during examination.[4] When cardiac pathology is suspected, the clinician should initially evaluate for concurrent disease to determine if any cardiac issue is primary or secondary.

In general, clinical signs of cardiovascular diseases in reptiles are similar to those in mammals, but certain differences exist due to differing cardiovascular physiology and anatomy. They include swelling around the cardiac region (cardiomegaly) (Fig. 68.13), cyanosis, peripheral edema (e.g., gular) (Fig. 68.14A), pulmonary edema, ascites (see Fig.

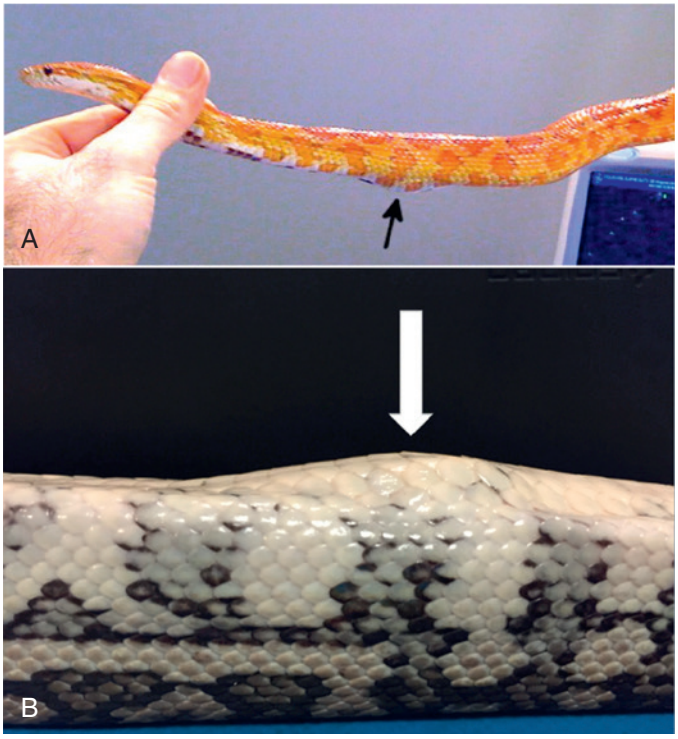

FIG 68.13 Cardiomegaly. (A) Corn snake (*Pantherophis guttatus*), black arrow, and (B) McDowell's carpet python (*Morelia spilota mcdowelli*), white arrow. (Courtesy of Valérie Chetboul.)

68.14B), and exercise intolerance.[4,11] Decreased cardiac output can cause exercise intolerance, syncope, tachycardia, cyanosis, decreased peripheral perfusion, and arrhythmias. Brain anoxia, secondary to heart failure and atherosclerosis, may cause neurological signs, such as ataxia and head tilt.[43]

Because reptiles lack a true diaphragm, coughing is not a feature of congestive heart failure (CHF) as observed in mammals.[11,23] The pathophysiology of CHF is likely to be similar across vertebrate taxa because of shared neuroendocrine regulation of cardiovascular circulation and hemodynamic constraints. However, some differences exist between mammals and reptiles, mainly regarding physiological regulation of the cardiovascular system and the relative importance of neural versus humoral influences. For instance, in mammals, blood volume is regulated principally by the renal and gastrointestinal systems, whereas some reptiles (especially lizards) possess additional osmoregulatory organs such as salt glands. Additionally reptile respiratory physiology and their ability for cardiac shunting differs greatly from mammals and influences the pathophysiology of heart failure, notably edema formation.[8]

Clinical signs of CHF result from chronic, excessive compensatory mechanisms to maintain cardiac output and blood pressure. Increased preload leads to pulmonary edema and coelomic effusion, and increased afterload further impairs cardiac output and cardiac remodeling. The ability to shunt blood (of major physiological importance) and having a single cardiac ventricle (and consequently a different mechanism of blood ejection) are two major differences between mammals and reptiles that will be greatly affected by cardiac pathology and will have implications for blood oxygenation and ventilation/perfusion mismatch.[8]

Auscultation

Heart sounds in reptiles are muffled and may be difficult to auscultate with a standard stethoscope. A pressure-sensitive acoustic stethoscope (e.g., Ultrascope-Parker Medical Associates LLC, aka Ultrascope Inc., Charlotte, NC) allows for the diagnosis of heart murmurs but is only suitable in large snakes and lizards where the heart lies in the midcoelomic region and not within a bony pectoral girdle (e.g., monitor lizards). A continuous Doppler ultrasonic probe (8 MHz) can be used for cardiac "auscultation" in all reptiles. The probe is placed with an acoustic coupling gel coating on the epidermal surface at the level of the heart or large efferent arteries (Fig. 68.15). Doppler only indicates blood flow and not valve closure but allows determination of heart rate and rhythm.[4,11]

Heart rate (HR) varies but can be roughly estimated using an allometric formula; $HR(bpm) = 33.4xW_{(kg)}^{-0.25}$ in general, and $HR(bpm) = 20.6xW_{(kg)}^{-0.229}$ more specifically for snakes.[44] This formula should be used in conjunction with known HR parameters (if available), as it tends to overestimate heart rates in some species such as bearded dragons (*Pogona vitticeps*).[45] The reptile should be within its preferred optimum temperature zone for assessment of HR.

Blood Pressure Measurement and Pulse Oximetry

Measuring arterial pressure with a typical cuff and Doppler probe is not reliable. The thick and highly keratinized skin in the limb and tail regions constitutes a major obstacle to the penetration of acoustic waves from the Doppler probe. Oscillometric techniques using a cuff and Doppler probe in boid snakes and green iguanas were determined to be unreliable.[46,47] Direct blood pressure measurements are accurate and consistent but require surgical exposure of a large artery and are impractical for clinical practice.[38] Pulse oximetry machines use mammalian hemoglobin algorithms and are less helpful in reptiles, owing to the different structure of the hemoglobin molecule. It may be possible to assess changing trends in SpO_2 using a pulse oximeter that may provide limited information on response to treatment.[38]

Clinical Pathology

Creatine kinase (CK) and lactate dehydrogenase (LDH) may increase with conditions affecting cardiac muscle, such as myocarditis or infarct. However, increased plasma CK can also result from skeletal muscle damage from traumatic injuries, loss of body condition, and intramuscular injections (in particular, caustic drugs such as enrofloxacin).[4,11] Several LDH isoenzymes have been described but, unlike mammals, none have thus far been utilized for reptile clinical cardiology. Dyslipidemias such as hypercholesterolemia have been associated with atherosclerosis in a bearded dragon.[43] Hypocalcemia, commonly seen with nutritional disorders, can affect striated cardiac muscle and be visualized as electrocardiographic abnormalities.[11] Cardiac troponins have been used to detect myocardial damage in humans and domestic animals. There are two main troponins measured—troponin I and troponin T—and both are cardiac regulatory proteins that control the calcium-mediated interaction between actin and myosin. Elevation in cardiac troponin levels are the standard mammalian test to diagnose myocardial infarction. Point-of-care analyzers currently available in the veterinary field predominantly test for cardiac troponin I.[48] Currently, cardiac

troponins have not been assessed in reptiles, but one of the authors (Girling) has found their measurement useful to assess progressive trends/worsening of clinical cases of cardiac dysfunction/failure. Leukocytosis, lymphocytosis, and heterophilia may be present and indicate underlying infections (such as vegetative or septic endocarditis) or hematopoietic neoplasia with secondary cardiac effects.[49]

Electrocardiography

Electrocardiography (ECG) is valuable, particularly in reptile species where the heart is difficult to observe using conventional radiography and echocardiography.[4,11] Widened QRS complexes and lengthened Q-T intervals were found in a green iguana (*Iguana iguana*) with aortic stenosis and atrioventricular dilatation. Tall and wide QRS complexes were reported in a carpet python with atrioventricular valve insufficiency, and increased P-R intervals associated with decreased Q-T intervals were seen in a boa constrictor (*Boa constrictor*) with atrioventricular valve insufficiency.[50]

The main challenges associated with the use of ECG in reptiles are the low electric amplitudes (usually <1.0 mV) that do not always provide readings of diagnostic quality. Moreover, standard parameters are not established for many species, thus interval and segment values may not always be of much use (Tables 68.1 and 68.2). Where reference ranges do exist they may not be reproducible because lead placement and temperature have not been clearly described. Even slight alterations in lead placement may alter an ECG. Performing routine ECGs on healthy reptile patients (with electrode positions and ambient temperature precisely identified) can help build up baseline values for future comparison.[4,11,36,51,52]

Reptile ECG interpretation is very similar to that of mammals, with similar P, QRS, and T complexes. An SV wave is represented by the depolarization of the sinus venosus (and the caudal vena cava) and is measured just before the P wave (Fig. 68.16). The SV wave is followed by sinusal contraction, the P wave is followed by atrial contraction, and the R wave is followed by ventricular contraction. The T wave indicates ventricular repolarization (Fig. 68.16).[4,11,36,51–53] Common findings in the normal reptilian ECG include P wave pleomorphism, very reduced Q and S deflections, and prolonged Q-T intervals as compared to similar-sized mammals.[4,11,36,51–53] Being of low amplitude (typically 0.1 mV or less), the SV wave may be obscured by background interference associated with skeletal muscle activity. When the SV wave is detected, it occurs after the T wave and before the P wave. In some cases the SV wave is difficult to separate from the preceding T wave.[55]

Correct electrode placement is essential to avoid erroneous ECG readings. The electrodes can be attached to the reptile by using self-adhering skin electrodes, stainless steel hypodermic needles, stainless steel suture material, or alligator clips (although care should be taken with the latter, as skin damage can occur). Placement of the electrodes varies according to species, but usually the traditional four-limb lead placement prevails. In snakes, the cranial limb leads should be placed two heart lengths cranial and the caudal limb leads two heart lengths caudal to the heart (Fig. 68.17). The negative lead can also be placed on the right side, one heart length cranial to the heart, and the positive lead can be placed on the left side, roughly 60% to 75% the distance from the head. The neutral or ground lead should be placed on the right side, across from the positive lead. In lizard species where the heart is within the pectoral girdle (e.g., Iguanidae, Agamidae, Chamaeleonidae, Scincidae), the two cranial limb electrodes should be placed on the cervical region instead of the forelimbs (yellow lead on the left, red lead on the right), and the caudal electrodes should be placed on the lateral body wall, cranial to the pelvis (green lead on the left, black lead on the right) (Fig. 68.18). In those species in which the heart is caudal to the pectoral girdle (Crocodilia, Teiidae, Varanidae), cranial

electrodes should be placed on the forelimbs or cranial coelom and caudal electrodes on the hindlimbs or torso. The four-limb placement is not appropriate in chelonians because of the low surface voltage, and the two cranial electrodes should be placed in the cervical region, lateral to the neck and medial to the forelimbs. The caudal leads can be placed on the cranial skin fold of the stifles or caudally to the pelvic limbs.[4,11]

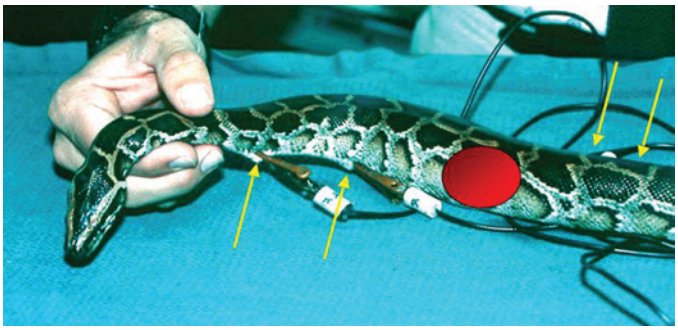

FIG 68.17 Lead placement in a snake can be a challenge because of the lack of limbs. Placing the two forelimb leads cranial to the heart (shown as a red circle) and the rear limb leads caudal to the heart yields a tracing similar to a standard lead II in dogs and cats. (Courtesy of Douglas R. Mader.)

The mean electrical axis (MEA) is difficult if not impossible to determine in reptiles due to low potentials and is of limited value due to inconsistent placement of electrodes.[11]

Diagnostic Imaging

Radiography. Although radiography is central to reptile disease diagnosis, it remains challenging to produce images of high diagnostic value, especially when assessing the cardiac silhouette. Radiographs can rarely be used alone to evaluate the reptilian heart, mainly due to reduced tissue contrast and anatomical location. In chelonians and crocodilians, for example, the heart cannot be visualized, as it is superimposed with other visceral soft tissues and masked by osteoderms.[11,56] In lizards, particularly agamids and iguanids, the heart is obscured by the bony pectoral girdle (Fig. 68.19). Some of these difficulties may be overcome by using different settings; however, the use of computed tomography (CT) and digital radiography allow post-acquisition enhancement (level and window parameters) that can greatly improve image quality. Despite these limitations, radiographs can be used to evaluate the size of the cardiac silhouette in monitor lizards (Fig. 68.20) and snakes (Fig. 68.21).

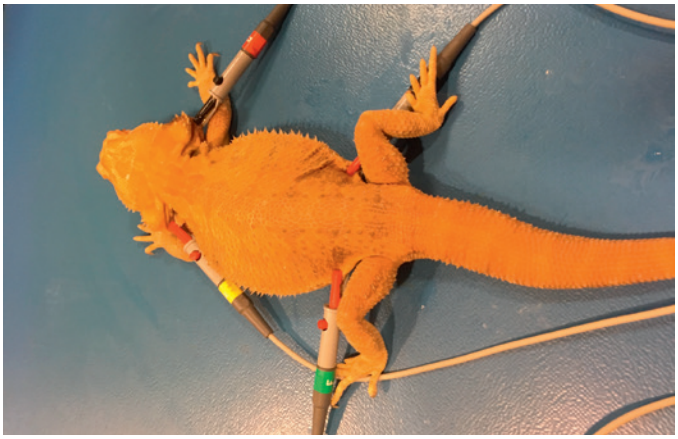

FIG 68.18 ECG in a bearded dragon *(Pogona vitticeps)*. The two cranial electrodes should be placed in the cervical region instead of on the forelimbs and the two caudal ones on the lateral body wall, cranial to the pelvis. (Courtesy of Lionel Schilliger.)

The paucity of normal reference parameters is another limitation to cardiac radiography. This can be overcome by archiving radiographs performed for other indications or during routine health evaluations in order to acquire a database of standard parameters.[57] Normal physiological variations in heart size should be taken into account when assessing cardiac enlargement (see anatomy and physiology section). As with any routine radiographic examination, two orthogonal projections should be taken: a dorsoventral view and a horizontal beam lateral view. In chelonians, a craniocaudal view can be useful but is most valuable for visualizing lung fields.[11,52,53,55] Mineralization of the great vessels may be observed as a result of hypervitaminosis D_3 or other metabolic disturbances.[9]

Computed Tomography and Magnetic Resonance Imaging. CT typically offers greater resolution than MRI and is particularly valuable for visualizing lung tissue (e.g., for pneumopathy, lung traumas induced by road accidents) and bone tissue (trauma, osteomyelitis, metabolic bone disease). Due to its ability to differentiate, MRI is generally preferred

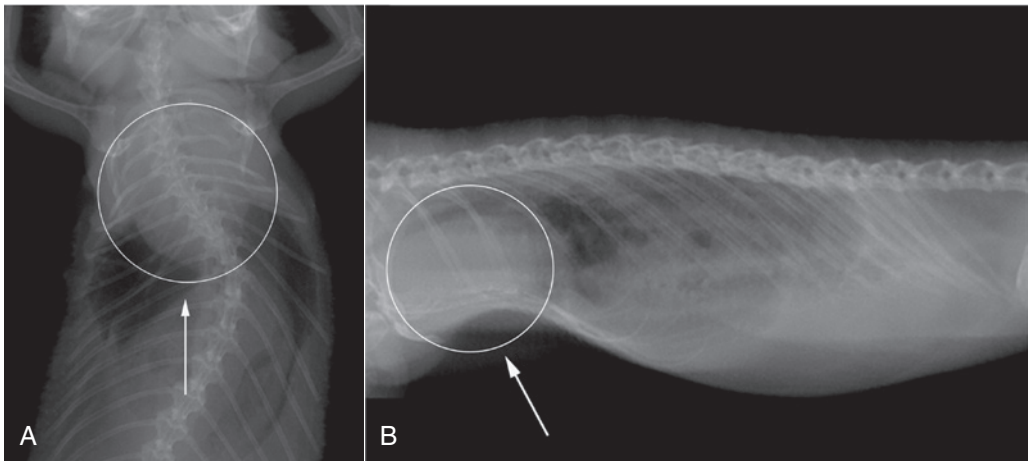

FIG 68.19 In lizards that have their heart located close to the pectoral girdle, the cardiac silhouette (white circles) is lost behind the surrounding bones and soft tissue on the dosroventral (A) and lateral (B) views. (Courtesy of Lionel Schilliger, with permission from the *Journal of Veterinary Diagnostic Investigation*.)

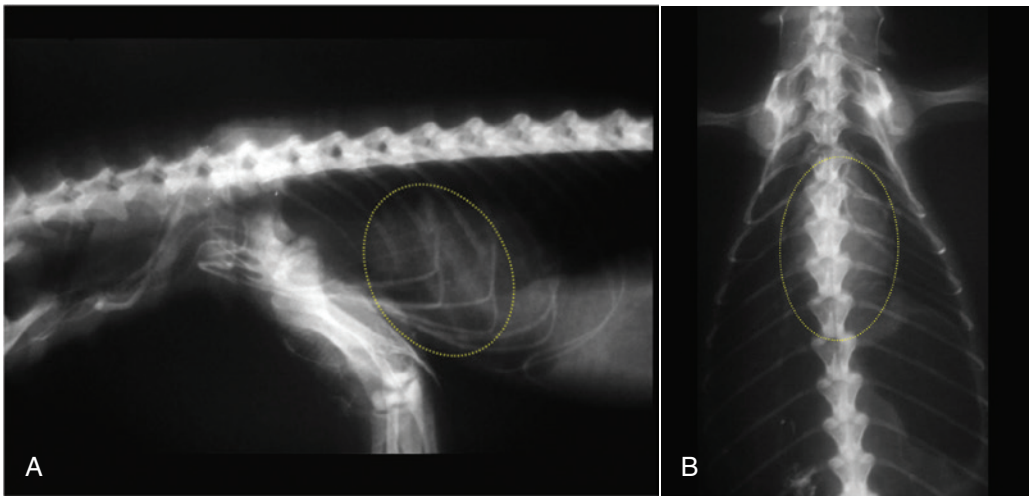

FIG 68.20 In lizards with a more caudally placed heart (e.g., varanids), both the lateral (A) and dorsoventral (B) views are useful, with the former giving the best cardiac image. (Courtesy of Douglas R. Mader.)

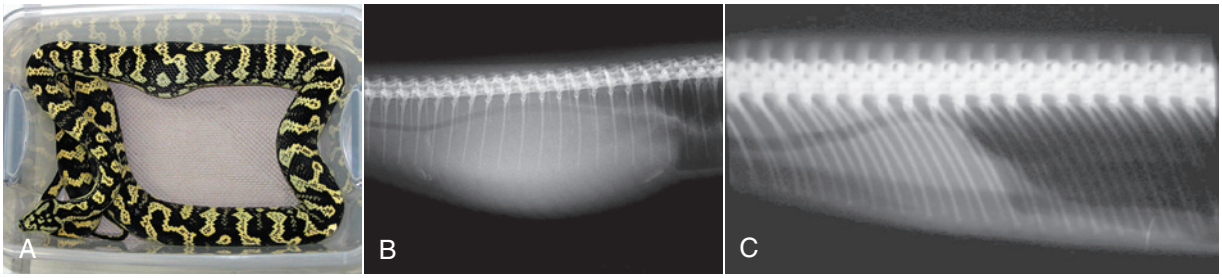

FIG 68.21 (A) This carpet python (*Morelia spilota variegata*) was seen for cranial coelomic swelling. (B) Radiograph of the patient shows an enlarged cardiac sillouette. (C) Radiograph of a normal python for comparison (A and B, Courtesy of Stephen Barten; C, courtesy of Douglas R. Mader.)

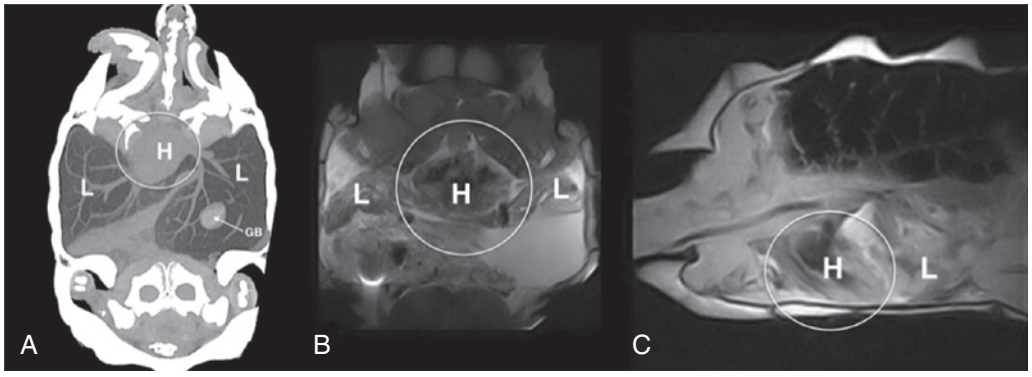

FIG 68.22 (A) CT scan in a radiated tortoise *(Astrochelys radiata)* showing the cardiac silhouette (H) between the two liver lobes (L). (B and C) MRI (T2 = spin-spin or transverse relaxation time) in a spur-thighed tortoise *(Testudo graeca)* with better contrasts. H, Heart; L, liver; GB, gallbladder. (A, Courtesy of M. Huynh; B and C, courtesy of L. Cauzinille.)

for soft tissue evaluations (Fig. 68.22). MRI is indicated for the examination of soft tissues, especially the central nervous system, liver, the reproductive system, and the kidneys. Apart from obvious cardiomyopathy, neither CT nor MRI (unless using very high magnetic field strengths) is of use for visualizing moving cardiac structures. Depending upon the equipment available and the speed of image acquisition, sedation or general anesthesia are typically required to ensure patient immobility and may be contraindicated in cases of heart failure.[56]

Echocardiography

Ultrasonography with Doppler is often the most practical diagnostic tool for antemortem evaluation of reptilian heart diseases and allows visualization of blood flow within the heart.[56,58–65] Patterns of normal blood flow in ball pythons (*Python regius*) and cardiac anatomy in Hermann's tortoises (*Testudo hermanni*) and Russian tortoises (*Agrionemys horsfieldi*) have been documented through the use of a combination of B-mode, color-Doppler, and contrast-echocardiography.[16,66,67]

A great range of ultrasound equipment is currently available, and many of these units are suitable for reptiles. The size and depth of the structures of interest dictate the transducer probes needed to perform echocardiography. Reptiles less than 250 g will require a 15 to 20 MHz or greater transducer; reptiles between 250 g to 2 kg can be scanned using a 10 to 15 MHz transducer; a 5 to 8 MHz transducer is used for reptiles between 2 to 20 kg; and a 3 to 5 MHz probe may be warranted for large crocodilians, lizards, or chelonians over 20 kg. A linear array is often used in snakes and lizards, while a biconvex sector scanner is recommended for chelonians because of their small acoustic windows. A thick layer of acoustic coupling gel should be applied at least 10 minutes prior to the examination to allow it to penetrate between the scales and obliterate any air pockets.[56,59,61,65,68,69]

Ultrasonography is challenging in most lizards and chelonians where boney obstructions (e.g., pectoral girdle, plastron) restrict the penetration of ultrasound waves. In lizards where the heart is located in the cranial coelom within the pectoral girdle (e.g., iguanids, chamaleonids, lacertids, agamids), the acoustic window is craniocaudal and the probe must be positioned in front of (or behind) and above the bony pectoral girdle (Fig. 68.23A and B). This window is relatively narrow and restricts visualization of the entire heart. To counter this issue, the probe can be placed in the left or right axillary region in sternal or lateral recumbency (see Fig. 68.23C and D).[70] In the *Varanidae* and *Teiidae*, the heart can be easily accessed via a ventral midline approach caudal to the sternum (see Fig. 68.23E and F).[56,65]

In chelonians, the transducer is placed in the cervicobrachial area (Fig. 68.24A and B).[71] The heart lies immediately dorsal to the plastron and is caudal to the thyroid. The left and right atria are of similar size with thin walls. The ventricle is thick walled, and the two atrioventricular valves echogenic with their movement clearly discernible. In soft-shelled turtles (e.g., *Trionyx*, *Apalone*, *Cyclanorbis*) and pancake tortoises (*Malachochersus*), the heart is located more to the right side so the probe can either be placed in the right axillocervical fossa or pressed directly on the plastron, which is cartilaginous and so will permit, albeit it reduced, ultrasound wave penetration (see Fig. 68.24C and D). Echocardiography can also be performed on neonate or juvenile chelonians and crocodilians when ventral scutes have yet to become mineralized.

A standardized, two-dimensional echocardiography approach, based on established procedures used in mammals, has been advocated from work in boid snakes and bearded dragons (*Pogona vitticeps*).[58,60,70] Chelonian echocardiography techniques, including intravenous contrast, have been described in freshwater and terrestrial species (*Trachemys scripta elegans*, *Testudo hermanni*, and *Agrionemys horsfieldi*).[67,72]

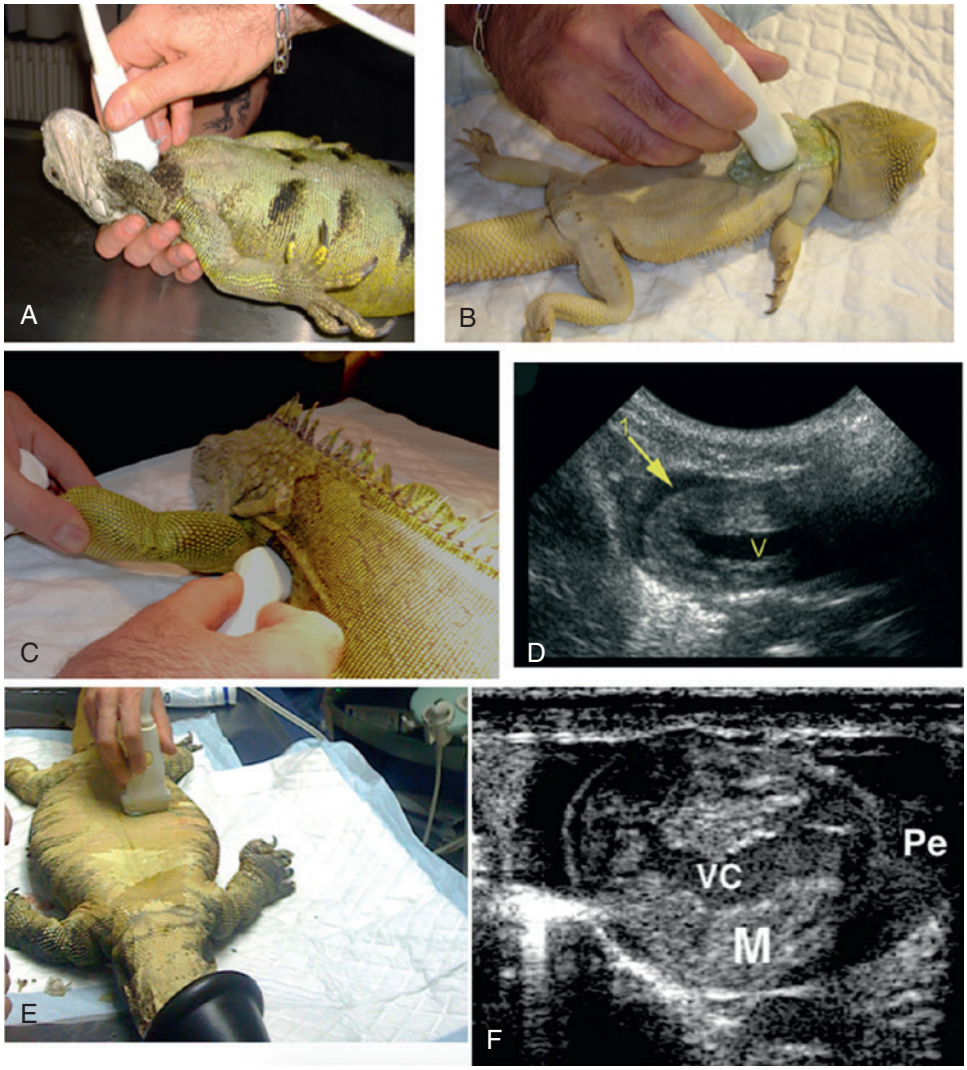

FIG 68.23 Acoustic windows that enable visualization of the heart in saurians. M, Myocardium; Pe, pericardial fluid; VC, ventricular cavity. (Courtesy of Lionel Schilliger, D with permission from the *Journal of Veterinary Diagnostic Investigation*.)

In snakes, three approaches are used in succession to define the ultrasound windows (Fig. 68.25).[60]

1. Ventral examination with the probe ventral to the heart to view (i) the organ from the caudal ventricular apex to the cranial atria, (ii) the sinus venosus, (iii) the atrioventricular junctions, and (iv) the three arterial trunks.
2. and 3. Right and left intercostal approaches obtained by lateral positioning of the probe to obtain lateral visualization of (i) the three arterial trunks, (ii) both atria, and (iii) the single ventricle.

By placing the probe ventral to the heart, the operator can scan or "sweep" the organ from the apex to the arterial trunks along its short axis (short-axis views). Thus, two transventricular views can be obtained by ventral approach:[58,60]

1. The apical or transapical short-axis view shows a transverse view of the apical myocardium and the pericardium from behind, in the form of an echogenic line (Fig. 68.26.1a).
2. The transventricular, subarterial, short-axis view shows a transverse view of the three cava surrounded by the peripheral myocardium (the ventral cavum pulmonale, the right dorsal cavum venosum, and the left dorsal cavum arteriosum) (see Fig. 68.26.1b). The interventricular (vertical) septum, located in the ventricular cavity between the cavum arteriosum and the cavum venosum, can be partially visualized, as can the muscular ridge (horizontal septum) marking the separation between the cavum venosum and the cavum pulmonale.

By moving the probe cranially, a transarterial short-axis view is obtained, giving a transverse view of the three large arterial trunks: the two aortic arches of equal diameter and the pulmonary trunk of larger diameter (producing a "Mickey-Mouse-head" figure) (see Fig. 68.26.2).

The probe is then kept in a ventral position but moved slightly to the right. The resultant right transatrial short-axis view shows the opening of the sinus venosus into the right atrium and enables assessment of both sinoatrial valves (see Fig. 68.26.3).[58,60]

Long-axis views are obtained by turning the probe 90 degrees in relation to the previous projections. Starting from the transventricular or subarterial view, the rotation of the probe provides two long-axis views of the heart. These are the atrioventricular sections, and they show both atrial cavities

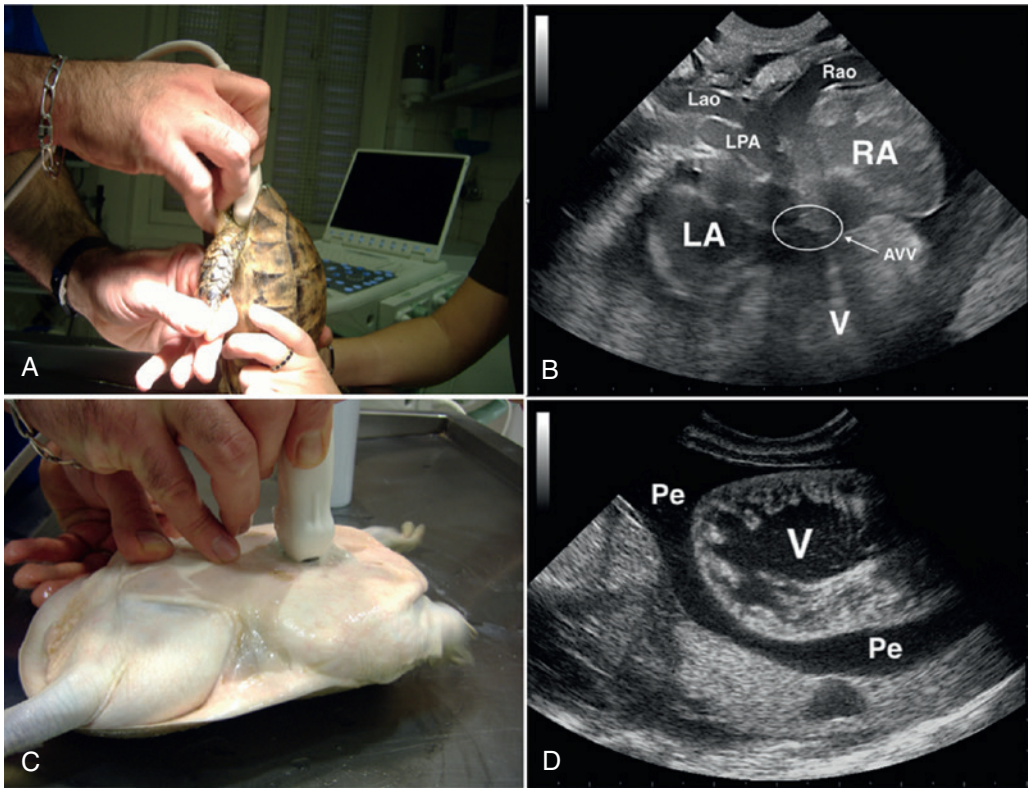

FIG 68.24 Acoustic windows that enable visualization of the heart in chelonians. (A) Cervicobrachial window in a spur-thighed tortoise (*Testudo graeca*). (B) Echocardiographic image from an African spurred tortoise *(Centrochelys sulcata)*. (C) Ventral approach through the plastron in a Chinese soft-shell turtle (*Pelodiscus sinensis*). FIG 68.25 The three acoustic windows for echocardiography of ophidians: ventral, right, and left intercostal approaches. (From Schilliger L, Tessier D, Pouchelon JL, et al. Proposed standardization of the two-dimensional echocardiographic examination in snakes, *J Herp Med Surg.* 2006;6[3]:76–87, with permission from the *Journal of Herpetological Medicine and Surgery*.)

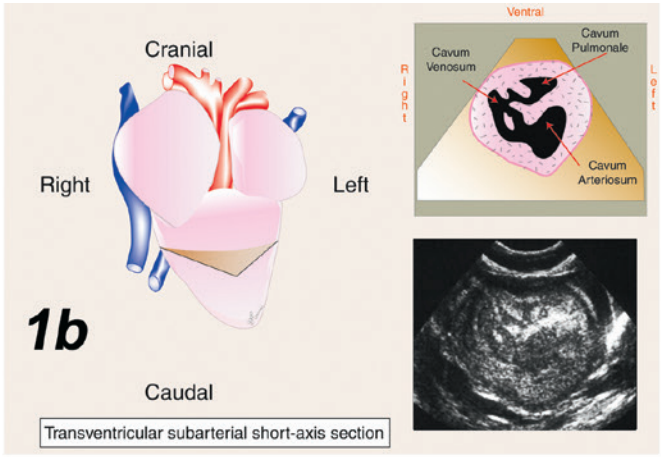
opening into the single ventricle. The left atrioventricular junction can be observed by orientating the ultrasound plane ventrodorsally from the right to the left (see Fig. 68.26.4a). The right atrioventricular junction can be observed by orientating the ultrasound plane ventrodorsally from the left to the right (see Fig. 68.26.4b). The atrioventricular valves, also known as septal monocuspid valves, can be visualized.[58,60]

Similarly, starting from the short-axis transarterial view, the probe is rotated by 90 degrees to obtain a long-axis transarterial section. This reveals the right aortic arch and the pulmonary trunk with parallel paths (see Fig. 68.26.5). The path of the pulmonary artery can be located by moving the probe caudally. The path of this artery comes closer to the probe ventrally and then opens out on the right with the cavum pulmonale. Finally, starting from the right transatrial short-axis view, the probe is rotated again by 90 degrees and moved caudally to give the long-axis transcaval section. This shows the caudal vena cava from the level of the sinus venosus running parallel to the pulmonary vein (see Fig. 68.26.6).[58,60]



In the case of small snakes, the examination is completed with two intercostal approaches. The transarterial long-axis section is obtained by the right intercostal approach, and the probe is placed laterally on the right so that the cross-section is parallel to the animal's body and the left atrium is removed from the proximal field occupied by the large arterial trunks. This provides clear visualization of the left atrium. Conversely, the left symmetrical intercostal section provides a good approach for observing the right atrium.[58,60]

In bearded dragons, echocardiography can be performed through windows in the left and right axillae (Fig. 68.27), with the animal in lateral recumbency.[70] The window in the left axilla allows for a subjective and objective assessment of cardiac structure and function. The right axillary window allows for evaluation of pulmonary artery flow. Both views provide data for the presence of pericardial effusion or valvular insufficiency. With optimized imaging planes, cardiac chambers and fractional area change, along with fractional shortening in the longitudinal and transverse planes, can be calculated (Table 68.3). Body weight and cardiac chamber dimensions of males were significantly larger than for females. Ventricular fractional area change was the most consistent functional assessment (Table 68.4). The majority of animals were found to have no evidence of valvular insufficiency, while approximately half had evidence of pericardial fluid. Pulmonary artery flow was assessed in all patients.

In red-eared sliders *(Trachemys scripta elegans)*, the best imaging was obtained through the right cervical window (Fig. 68.28), which facilitated base-apex inflow and outflow views, as well as measurements of ventricular size, ventricular wall thickness, and ventricular outflow tracts. Fractional shortening was calculated. Pulsed-wave Doppler interrogation enabled the diastolic biphasic atrioventricular flow and the systolic ventricular outflow patterns to be recorded. The following Doppler-derived functional parameters were calculated: early diastolic (E) and late diastolic (A) wave peak velocities, E/A ratio, ventricular outflow systolic peak and mean velocities and gradients, velocity-time integral, acceleration and deceleration times, and ejection time (Table 68.5).[72]

Endoscopy. Endoscopy is limited in its ability to aid in the evaluation of cardiac disease. It can be used to evaluate the surface of the heart (and the myocardium if the pericardium is transparent). In general, only changes of the pericardium can be appreciated: for example, gout deposition, neoplasia, or pericardial effusion.

CARDIAC DISEASES

A variety of pathological lesions have been reported involving the reptilian cardiovascular system, including cardiomyopathy,[73,74] septic endocarditis,[64,74,75] valvular insufficiency,[50,63] myocarditis,[62,76–80] pericardial effusion,[43,81] infarcts,[82] atherosclerosis,[43] aneurysms,[82] gout,[83,84] arterial calcification,[11,85] thrombus,[74] parasitic infestation,[86–90] congenital heart defects,[57,82,91] and even tumors.[43,92–95] In many cases, the definitive diagnosis was made postmortem. Inadequate husbandry, resulting in chronic stress, immune suppression, and malnutrition, is the most likely common predisposing factor for the development of cardiovascular conditions in captive reptiles.[96] Cardiac diseases can be classified as noninfectious, infectious, or parasitic.

Noninfectious Cardiac Disease

Congenital Defects. Congenital cardiac diseases are considered rare in reptiles. A secundum atrial septal defect located on the craniodorsal portion of the interatrial septum was reported in a Komodo dragon (*Varanus komodoensis*).[57] Various congenital conditions have been reported in several species of snakes: ventricular mural hypoplasia with plasmacytic pericarditis (Burmese python); aortic valvular stenosis with secondary cardiomyopathy (Children's python, *Liasis childreni*); and enlarged/abnormally shaped cardiac chambers, bifid ventricles, and reduced muscular ridge causing inadequate ventricular pressure separation with pronounced hemodynamic consequences (ball pythons, *Python regius*).[91]

Aortic and subaortic stenosis have been reported in other species: histopathological examination of the heart of a green iguana (*Iguana iguana*) with aortic stenosis associated with dilatation of the right atrium and the ventricle revealed atrophy of myocardial fibers and a thickening of the intima of both aortic arches with consequent narrowing of the lumen. No diagnosis was established, but chronic congenital lesion was suggested as a differential diagnosis. Bilateral subaortic stenosis was also described in an alligator (*Alligator mississippiensis*).[97]

Cardiomyopathies. Cardiomyopathies have been described in various species of snakes. A black king snake (*Lampropeltis niger*) that presented with marked cardiomegaly, dilatation of the ventricle, and congestive heart failure (CHF) was diagnosed with dilated cardiomyopathy upon necropsy.[96] CHF was also reported in a Deckert's rat snake (*Pantherophis obsoleta deckertii*) with degeneration and necrosis of myocardial fibers and mineralization of blood vessels with focal aggregates of lymphocytes within the lamina.[77] CHF was diagnosed in a mole king snake (*Lampropeltis calligaster rhombomaculata*) with myocardial collagen proliferation and osteoidlike material. The etiology of this disorder was unclear;

however, microscopic examination of this snake's kidneys and liver revealed severe heterophilic inflammation.[73,98] Cardiomyopathy of undetermined origin was also reported in two pythons: a Children's python (*Liasis childreni*) and a juvenile Burmese python (*Python bivittatus*) (Frye FL, personal communication).

Restrictive cardiomyopathy with alteration of the myocardial compliance and CHF was diagnosed for the first time in a 2-year-old captive lethargic Carpet python (*Morelia spilota variegata*), based on echocardiography, Doppler, and histopathology. The disease was characterized by left atrial dilation, displacement of the interatrial septum, subsequent right atrial collapsus, and sinus venosus dilation with thrombosis in the sinus venosus (Fig. 68.29).[99]

Myocardial degeneration can occur as a result of metabolic disorders and can be observed grossly. For example, gout (of metabolic,

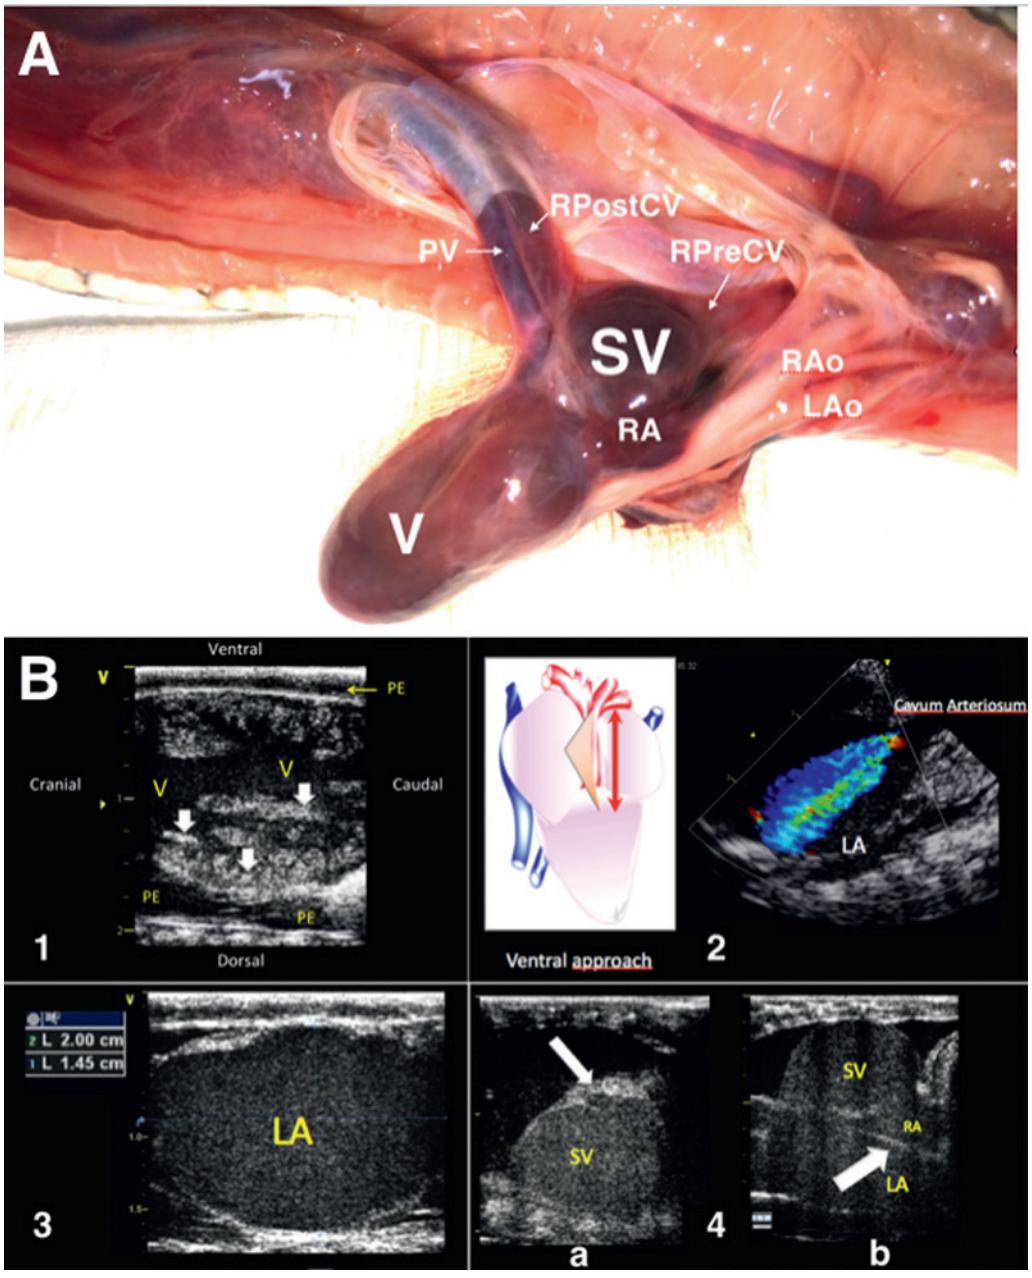

FIG 68.29 (A) Necropsy: restrictive cardiomyopathy associated with SV dilation and thrombosis within the SV in a McDowell's carpet python (*Morelia spilota macdowelli*). (B): (1) Long-axis transventricular section obtained by ventral approach. Note the abnormal heterogeneous myocardium characterized by the presence of diffuse hyperechoic lesions mainly within the left myocardium (arrows). (2) Color Doppler flow examination. Long-axis left transatrioventricular section obtained by ventral approach showing a severe left atrioventricular insufficiency characterized by an aliased signal encoded in blue. (3) Left intercostal approach. Marked dilatation of the LA responsible for localized swelling of the coelomic cavity. (4) (Right intercostal approach) (a) thrombus within the dilated SV (white arrow). (b) Severely dilated SV and displaced interatrial septum toward the RA (white arrow) during the systolic time with secondary right atrial compression. LA, Left atrium; LAo, left aortic arch; PE, pericardial effusion; PV, pulmonary vein; RA, right atrium; RAo, right aortic arch; RPostCV, right postvacal vein; RPreCV, right precaval vein; SV, sinus venosus; V, ventricle or ventricular cavity. (Courtesy of Lionel Schilliger and Valérie Chetboul.)

nutritional, or iatrogenic origin) can cause deposition of urate crystals in multiple tissues, including the myocardium.[81,82,97] With vitamin E and selenium deficiencies, the myocardium undergoes degeneration with loss of myocytes replaced by fibrous stroma and gross whitish/grey discoloration.[3,4,11,98]

The myocardium and the major arteries may also be subject to mineralization (calcification) when a diet contains excessive levels of calcium and vitamin D_3.[11,98] Aortic rupture associated with mineralization of the aorta attributed to nutritional secondary hyperparathyroidism is reported in lizards.[3]

Noninfectious Valvulopathies (Valvular Endocardiosis). There is no current evidence for primary degenerative endocardiosis occurring in reptiles. However, occasionally reported cardiac conditions of undetermined etiology suggest that this might be a possibility. For example, right atrioventricular insufficiency resulting in bilateral heart failure was observed in a young carpet python.[50] The lack of septation in squamates may cause sufficient elevation in diastolic pressure to cause bilateral heart failure. Valvular regurgitation can be confirmed with echocardiography (see Fig. 68.29B.2).[63,99]

Pericardial Diseases. Visceral gout can lead to thickening of the pericardium with urate deposition, which is easily recognizable by endoscopy or during postmortem examination.[84] Traumatic hemopericardium with the formation of hematomas can occur as a result of cardiac blood sampling in snakes.[100,101] It has also been reported in a green iguana (*Iguana iguana*) in conjunction with a myocardial abscess.

Pericardial effusion can be inferred from radiography but can only be confirmed by ultrasonography. It can also be an unexpected finding during necropsy (Fig. 68.30).

Pericardial effusion has also been reported in tortoises. A Californian desert tortoise (*Xerobates agassizi*) with cervical fractures and osteomyelitis also had pericardial effusion, but no attempt was made to investigate the implication and underlying cause.[102] Echocardiography, radiography, and necropsy of an 80-year-old male spur-thighed tortoise (*Testudo graeca*) with posthibernation anorexia and lethargy revealed pericardial effusion, atrial dilatation, six liver lesions containing choleliths, pneumonia, and/or pulmonary edema.[81] These findings were confirmed by postmortem after nonresponse to treatment. Pericardial effusion has also been reported in a 2-year-old male bearded dragon suffering from atherosclerosis in the major arteries of the base of the heart.[43] Pericardial effusion can also be secondary to neoplasia, as was the case in a female reticulated python (*Malayopython reticulatus*) diagnosed with endocardial fibrosarcoma at the base of the aorta.[103] A small amount of fluid within the pericardial sac may be normal, and therefore volume measurement is advised during postmortem examinations.[70]

Neoplasia. Primary neoplasia of the cardiovascular system is uncommon in reptiles. Cardiac tumors in snakes are frequently visible as a distinct mass located approximately 15% to 25% svl, depending on species. Reported cases include a cardiac rhabdomyosarcoma in a boa constrictor and a black king snake (*Lampropeltis getula nigrita*), a cardiac hemangioma of the left atrium in a corn snake (*Pantherophis guttatus*), a cardiac hemangiosarcoma in a copperhead (*Agkistrodon contortrix*) and a Madagascar giant hognose snake (*Leioheterodon madagascariensis*), a fibrosarcoma in a Gaboon viper (*Bitis gabonica*), and an endocardial fibrosarcoma in a reticulated python.[81,92,96,103–106]

Metastasis to the heart has also been reported; metastatic chondrosarcoma (Schmidt, RE, and Reavill, DR, personal communication) and oviductal adenocarcinoma have been reported in a corn snake with metastasis to the heart.[107] Similarly, a disseminated mast cell tumor in an eastern king snake (*Lampropeltis getulus getulus*), multicentric lymphoblastic lymphoma in a loggerhead sea turtle (*Caretta caretta*), and lymphoblastic malignant lymphoma in a boa constrictor affected the heart as well as other organs.[47,94] Disseminated coelomic papillomas affecting various organs, including the heart, were found in 39% of 255 stranded green turtles (*Chelonia mydas*) with fibropapillomatosis.[108]

Infectious Cardiac Disease

Bacterial (Endocarditis, Myocarditis, and Pericarditis). In captive reptiles, infections of the cardiovascular system are often secondary to systemic infections. Where it cannot be attributed to a specific bacteria, endocarditis is most commonly associated with aerobic gram negative infections.[62,63,64,74] *Salmonella* spp., for example, has been isolated in various species of snakes: ultrasonography and angiography revealed a blood flow obstruction in the right atrium of a Burmese python; postmortem isolation confirmed *Salmonella arizonae* in addition to *Corynebacterium* spp.[74] *S. arizonae* was also isolated in a coelomic culture in a Dumeril's boa (*Acrantophis dumerili*).[62] This was concomitant with a granulomatous myocarditis associated with a fibrinous and necrotic pericarditis, as well as hepatitis, pneumonia, and thyroiditis with bacterial infiltration (Fig. 68.31). *Salmonella enterica* was also diagnosed in a

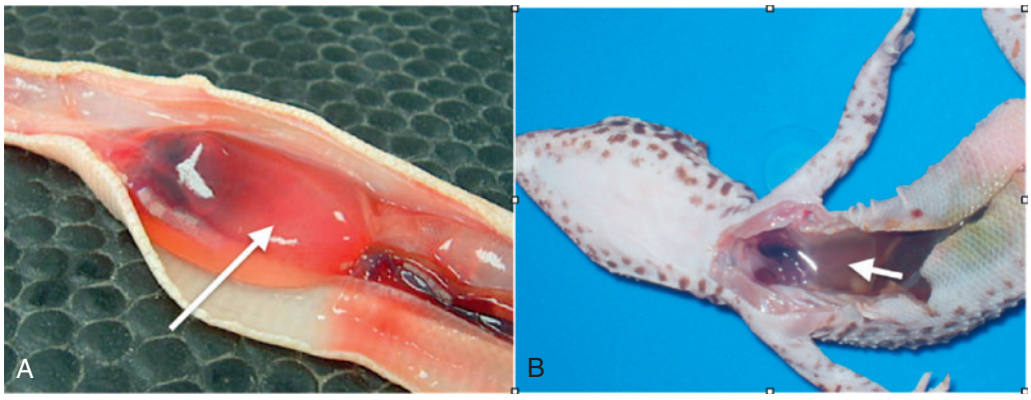

FIG 68.30 Pericardial effusions (white arrows) in (A) an albino boa (*Boa constrictor*) and (B) a leopard gecko (*Eublepharis macularius*). (Courtesy of S. Girling.)

Burmese python with valvular endocarditis and dilated pulmonary trunk and sepsis.[64] Pericarditis can also be associated with fibrinonecrotic lesions (Fig. 68.32).

Concomitant bacterial pneumonia and valvular insufficiencies suggesting bacterial endocarditis can be observed (but without a demonstrated cause-effect relationship); sinoatrial (Fig. 68.33.1) and atrioventricular (see Fig. 68.33.2) insufficiencies were diagnosed on echocardiographic examination in a Burmese python suffering from concurrent pneumonia caused by *Pseudomonas aeruginosa*. Histopathological examination of the valve was not performed as the snake survived.[63] An Argentine boa (*Boa constrictor occidentalis*) presenting with cardiomegaly, pneumonia, and inclusion body disease showed a large vegetative lesion on the right atrioventricular valve with valvular insufficiency, a mildly dilated right atrium, and pulmonary hypertension on echocardiographic examination. Cultures of a tracheal wash sample resulted in growth of *Ochrobactrum intermedium* and *Pseudomonas putida*. Postmortem examination confirmed the presence of pneumonia and bacterial endocarditis with dystrophic mineralization of the right atrioventricular valve, with different bacteria (gram-positive) than those cultured from the tracheal wash.[75]

Flavobacterium meningosepticum and *Vibrio damsel* have been isolated from the myocardium of a Barber's map turtle (*Graptemys barbouri*) and a vegetative thrombus attached to the left atrioventricular valve and interventricular wall of a stranded leatherback turtle (*Dermochelys coriacea*).[80] *Mycobacterium* spp. was reported in granulomatous myocarditis in a frilled lizard (*Chlamydosaurus kingii*).[11] *Chlamydophila* (*Chlamydia*) spp. has also been associated with cardiovascular disease. Reported cases include granulomatous pericarditis and myocarditis in a puff adder (*Bitis arietans*),[108] necrotizing myocarditis in green sea turtles,[74] and histiocytic granulomas (determined by transmission electron microscopy) in the heart and organs of an emerald tree boa (*Corallus caninus*).[74,78,108] *Mycoplasma alligatoris* is responsible for pericarditis (and for pneumonia and arthritis) in American alligators (*Alligator mississipiensis*).[109]

A diagnosis can be obtained with ultrasound, hemoculture, postmortem tissue culture, and/or histopathological examination (valves, myocardium, pericardium). In cases where bacterial infection is confirmed, antimicrobial treatment can be attempted.

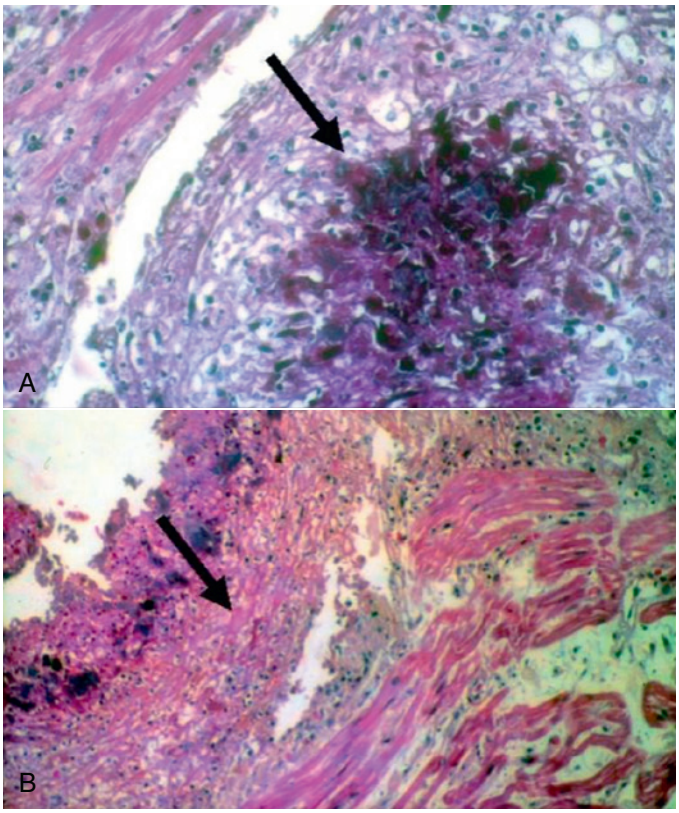

FIG 68.31 (A) Myocardial granuloma (H&E, x40) and (B) pericarditis (H&E, x 20) due to *Salmonella enterica arizonae* in a Madagascarian Dumeril's boa (*Acrantophis dumerili*). (From Schilliger L, Vanderstylen D, Pietrain J. Granulomatous myocarditis and coelomic effusion due to *Salmonella enterica arizonae* in a Madagascarian Dumeril's boa [*Acrantophis dumerili*, Jan. 1860]. *J Vet Cardiol.* 2003; 5:43–45, with permission from Elsevier.)

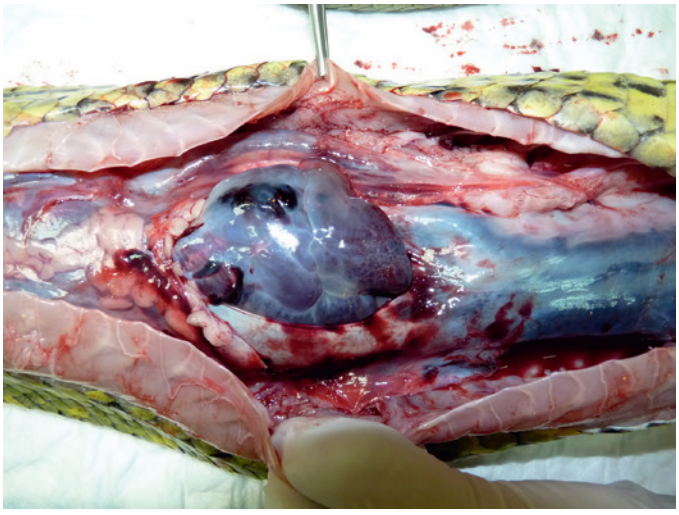

FIG 68.32 Diffuse fibrinonecrotic bacterial pericarditis in a green anaconda (*Eunectes murinus*). (Courtesy of Lionel Schilliger.)

Viral (Myocarditis, Degeneration, Necrosis). Inclusion body disease (IBD), thought to be caused by an arenavirus, affects snakes and causes large eosinophilic intracytoplasmic inclusion bodies in many different organs, including the heart.[110] Acute deaths of a Savannah monitor with myocarditis and Rosy boas (*Lichanura trivirgata*) with hepatitis and endocarditis were attributed to an adenovirus.[111,112] Flaviruses have been reported to cause myocardial degeneration and necrosis in farmed American alligators.[79,113]

Parasitic. Encapsulated cestodes have been reported within the heart of lizards, with one study finding a prevalence of 5% in 220 wild whiptail lizards (*Cnemidophorus* spp.).[90] Filarial nematodes within the cardiovascular system can cause edema, thrombosis, and necrosis.[3,114] *Macdonaldius oschei* has been observed in fresh blood smears and myocardial histology in various species of reptiles.[98] Trematodes have been reported in the heart chambers and major vessels of chelonians (attached to, or found freely floating within, the lumen) in wild and wild-caught chelonians.[87] Green sea turtles can be infested with spirorchid flukes that cause arteritis, endocarditis, thrombosis, and aneurysms.[88] Similarly, spirorchid eggs and adult *Learedius learei* were observed inside the heart of black sea turtles (*Chelonia mydas agassizii*).[86] Spirorchid eggs were observed in multiple organs and associated with granulomatous lesions in the myocardium of *Trachemys scripta elegans* and *Chrysemys picta*.[89] Besnoitiosis and sarcosporidiosis have also been observed in histological sections of ophidian hearts.[98] All these parasitic diseases were diagnosed postmortem. The use of targeted anthelminthic drugs may be a treatment option when antemortem parasite identification is performed (fecal examination, blood smear cytology).

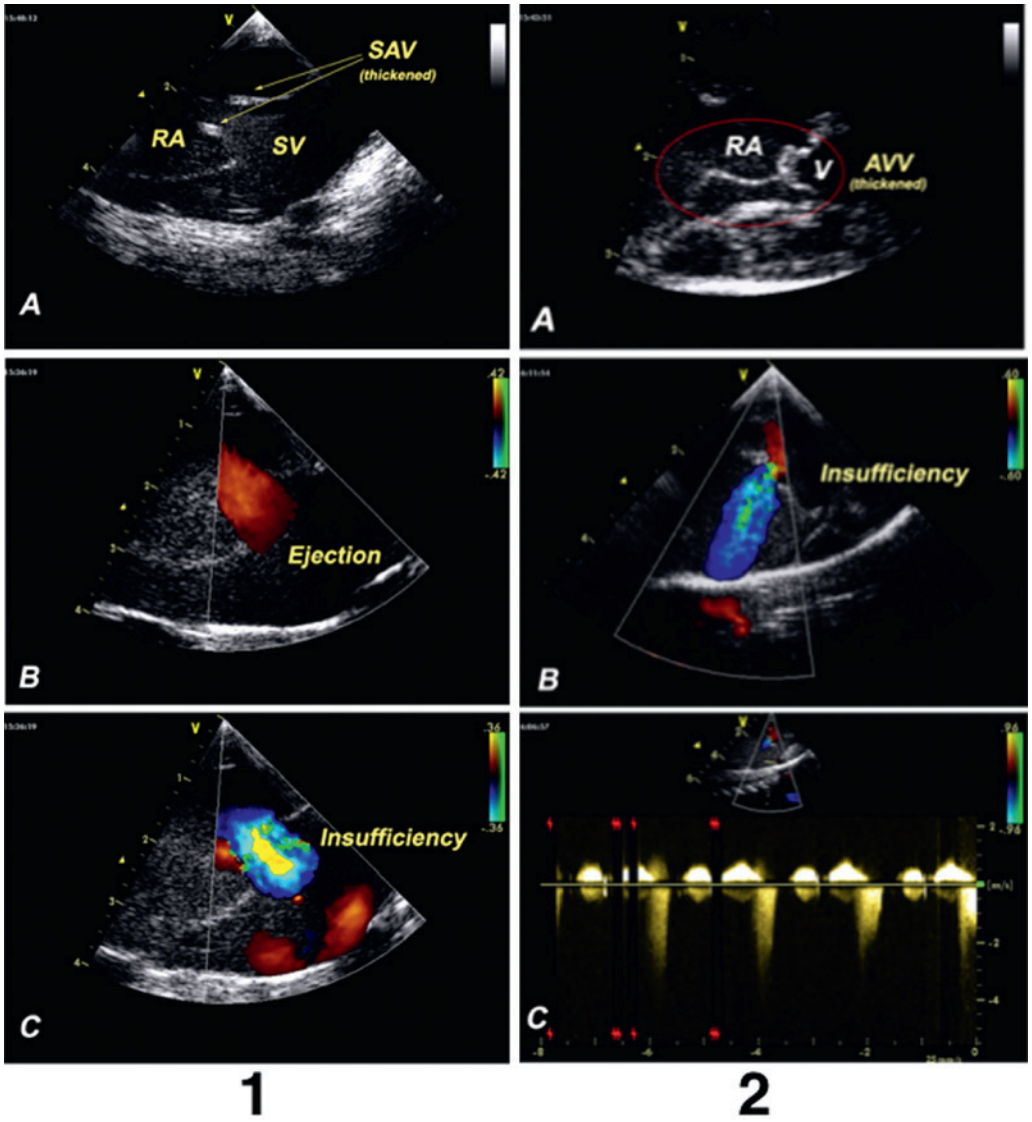

FIG 68.33 (1): (A) Two-dimensional echocardiography (right transatrial short-axis view) showing the abnormal sinoatrial valves (*SAV*) during atrial diastole in a Burmese python *(Python bivittatus)* with bacterial pneumonia. (B and C) Color Doppler examination of the sinoatrial valve showing a normal ejection flow colored in red (B) and an abnormal regurgitation with aliasing (C) during atrial systole. (2): (A) Two-dimensional echocardiography (right atrioventricular long-axis view) showing the abnormal right atrioventricular valvular leaflet (AVV). (B) Color Doppler examination of the atrioventricular valve showing a marked aliased regurgitation in the right atrium during ventricular systole. (C) Continuous-wave Doppler mode examination confirming a high-velocity regurgitant jet (peak velocity of 4 m/s, arrows). RA, Right atrium; SV, sinus venosus; V, ventricle. (From Schilliger L, Tréhiou-Sechi E, Petit AMP, et al. Double valvular insufficiency in a Burmese python suffering from concomitant bacterial pneumonia. *J Zoo Wildl Med.* 2010;41:742–744, with permission from the *Journal of Zoo and Wildlife Medicine*.)

TREATMENT/MANAGEMENT OF CARDIAC DISEASE

Little information exists regarding cardiovascular treatment, and the pharmacological actions of cardiac drugs in reptiles. Future advances in herpetological medicine will likely improve knowledge in the diagnosis and treatment of cardiovascular diseases.

As a rule, pharmacological agents exert their effect on the heart (effect on contractibility and rate), blood vessels (causing constriction or dilatation), and/or blood volume (increase or decrease in volume). Different drugs are often used in combination in mammals, but extrapolation from canine and feline cardiac management may be inappropriate due to reptile differences in size, metabolism, anatomy, and physiology. However, basic principles remain applicable. Non-drug-related management of cardiac disease in reptiles may also include reducing metabolic rates by maintaining the reptile at the lower end of its preferred optimum temperature zone, reducing stress by minimizing handling and separating from cage mates, and using caution not to overfeed, as this has resulted in the death of snakes with cardiomyopathy.[77,82]

The cornerstone of managing congestive heart failure rests on reducing the volume of extracellular fluid and reducing preload. This is achieved through the use of diuretics and vasodilators in mammals, but reptiles

VetBooks.ir

suffering from cardiac disease are often diagnosed postmortem and thus are rarely subject to therapeutic trials. Oxygen supplementation should be instituted for dyspneic animals, especially if pulmonary edema is present, but in reptiles this may alter blood shunting, and the response to therapy is often difficult to assess.

Inotropes

Inotropes are pharmacological agents that alter the force of muscular contractions. Positive inotropes enhance cardiac contractility. Pimobendan is commonly used in small animal cardiology and has been shown to increase both survival time and quality of life in canine dilated cardiomyopathy.[115] Digoxin is a positive inotrope, negative chronotrope, and positive lusitrope. It increases the cytosolic calcium concentration by inhibiting Na/K ATPase pumps, resulting in increased contractility.[116] It is mainly indicated for atrial fibrillation. Beta-blockers (e.g., atenolol, propranolol) and calcium channel blockers (e.g., diltiazem) are negative inotropes. They are mainly indicated in the treatment of hypertrophic cardiomyopathy in cats and supraventricular arrhythmias. Side effects include bradycardia and hypotension.[117] Beta-blockers can be used for treatment of supraventricular tachycardia and atrial fibrillation, but these are uncommon in reptile patients, and their effectiveness is unknown in reptile patients.

Atenolol administration significantly reduced resting HR and the range of the baroreceptor reflex in 15 conscious healthy juvenile green iguanas (*Iguana iguna*) but did not alter their upper or lower mean arterial blood pressure thresholds, indicating that atenolol did not affect baroreceptor reflex function per se.[38] As expected, the upper HR plateau (i.e., tachycardia) was substantially lower after administration of atenolol, whereas the lower plateau (i.e., bradycardia) was unaffected by the β-adrenoceptor antagonist.

In the same study, methylatropine administration resulted in an increase in the iguanas' resting HR but did not significantly affect the mean arterial blood pressure recorded at the midpoint of the heart rate range. After injection of methylatropine, the mean sensitivity of the baroreceptor reflex was substantially diminished, and consequently, the range of the baroreceptor reflex was substantially reduced.[38]

Angiotensin-Converting Enzyme (ACE) Inhibitors

In mammals, ACE inhibitors block the formation of angiotensin II, which promotes venous and arterial vasodilation, and block aldosterone production and reduce preload and afterload through venous and arterial vasodilation. Enalapril and benazepril are the most commonly used ACE inhibitors in dogs and cats because of their longer half-life, but it is unknown if this is also the case in reptiles. Enalapril inhibited angiotensin I conversion in alligators, and at 0.5 to 0.7 mg/kg once every 24 hours (combined with spironolactone and furosemide) briefly managed CHF in a spiny-tailed monitor (*Varanus acanthurus*) (Clayton, LA, Hadfield, CA, Gore SR, et al., personal communication).[118]

Diuretics

Diuretics increase water excretion and so reduce fluid overload and decrease edema and effusions. In mammals the principle diuretic is furosemide, a loop diuretic that acts by inhibiting sodium, potassium, and chloride cotransporters in the ascending limb of the loop of Henle of the kidney. Reptiles have a metanephric kidney that lacks a loop of Henle; however, furosemide has shown a diuretic effect in chelonians and ophidians.[119–122] Two main mechanisms of action have been suggested in reptiles: the first is that in those species that possess a urinary bladder, sodium:potassium pumps in the wall of the bladder can be influenced by furosemide.[123] A second hypothesis is that furosemide may act upon the sodium:potassium pumps present in the terminal colon and cloaca, as many reptiles reflux urine from the cloaca into the distal colon to absorb water in conjunction with NaCl.[124]

A spur-thighed tortoise with atrial dilatation and pericardial effusion was administered furosemide at a dose of 5.2 mg/kg on two occasions, 3 weeks apart, which resolved peripheral edema.[81] A carpet python diagnosed with atrioventricular insufficiency and secondary pulmonary edema and pericardial effusion failed to respond to furosemide at 5 mg/kg.[50] Furosemide should be used with caution in reptile patients with renal disease, and biochemical parameters including potassium, phosphorus, and the major nitrogenous waste product (ammonia, urea, or uric acid) should be monitored.

Information on other diuretics in reptiles is lacking. Hydrochlorothiazide has been used as a diuretic in lizards with renal disease (Divers SJ, personal communication). Methylated xanthines (aminophylline and theophylline) have successfully induced diuresis. Their diuretic effect may be partly due to their stimulatory effect on cardiac function, increased renal blood flow, and increased glomerular filtration rate. The major diuretic effect of these compounds is apparently due to increased rates of excretion of sodium and chloride ions by renal tubules.[23]

Spironolactone is an aldosterone antagonist and a weak diuretic in mammals.[125] It is a potassium-sparing diuretic that can either be used alone or in conjunction with furosemide to offset the loss of potassium. Nothing is known about its potential use in reptiles.

Dermatology—Skin

T. Franciscus Scheelings and Tom Hellebuyck

The immense variation observed in modern vertebrates can be attributed to two pivotal moments in the history of Earth's biodiversity. Firstly, and probably most profoundly, the advent of the amniotic egg severed the reliance that animals had on water for reproduction and paved the way for unprecedented terrestrial evolutionary radiation. However, this momentous biological accomplishment was insufficient on its own to support terrestrial vertebrate life, and the early terrene conquerors had to devise an array of strategies in order to resist the challenges that their potential new environment presented. The second crucial stratagem for terrestrial exploitation came in the form of the reptilian integument. Reptile skin had to evolve as a protective barrier to conserve body fluids from deeper tissues and prevent their exposure to the dehydrating external environment; it had to combat ultraviolet (UV) irradiation, protect against an invading army of novel pathogens, and withstand the daily mechanical trauma that accompanies a terrestrial existence. The dawn of the reptilian integument occurred during the late Devonian period and was necessitated by the warming and drying of Earth's climate. By the late Triassic period, reptiles were the most dominant vertebrates on Earth, and they have managed to survive in myriad forms today, on every continent except for Antarctica.

There are over 9000 species of extant reptiles, and as such, there has been enormous diversity in scalation as the class has undergone rapid change to fill various ecological niches. Not only does the integument of reptiles act as a protective barrier to environmental and biological threats, it has further been adapted to trap and conserve thermal energy and collect water, and has evolved important appendages for communication and defense. In addition, the skin of reptiles has played an integral part in the psyche of human history. In various cultural myths and legends, the periodic shedding and renewal of reptilian skin has been portrayed as both sinister and rejuvenating, and as such, reptiles have been depicted as either heroic or evil, with important ramifications for their conservation. Furthermore, the value of many captive-bred animals is inherently linked to their skin color and patterns.

Pathological conditions of the reptilian integument are common, particularly in captive animals. They may be primary in nature, secondary to systemic illness, or as a consequence of inadequate husbandry conditions. Therefore a sound understanding of the pathophysiology of reptile dermatological disease, as well as the husbandry requirements of captive animals, is critically important for veterinarians who treat reptiles.

ANATOMY

Fundamentally, the skin of reptiles is similar to that of other amniotes in that it consists of two layers: the outer epidermis and the underlying dermis. The epidermis is covered by either α- or β-keratin.[1] β-keratin is a durable, lightweight material that is critical for increasing the mechanical resistance of the reptilian epidermis.[2] The epidermis of reptiles is a stratified squamous epithelium comprised of multiple distinct layers. From superficial to deep these are (Fig. 69.1)[3] as follows:

- Outer epidermal generation
  - Oberhautchen: the outermost portion of the β-layer and characterized by serrations, surface ornaments, and pits
  - ß-keratin: inelastic, tough, stratified epithelial layer, composed primarily of β-keratin (the hinge area between scales is lacking this layer)
  - Meso stratum: transitional cells between the α- and β-layers
  - α-keratin: soft, flexible epithelial layer composed primarily of α-keratin
  - Lacunar stratum: innermost layer of outer portion of skin, tightly adhered to newly forming oberhautchen
- Inner epidermal generation
  - Presumptive β-keratin layer
  - Presumptive meso layer
  - Presumptive α-keratin layer
  - Stratum germinativum: deepest basal layer of progenitor columnar epithelium

The scales of reptiles represent a folding of the epidermis and, for the most part, cover the entirety of the reptile integument. The β-keratin

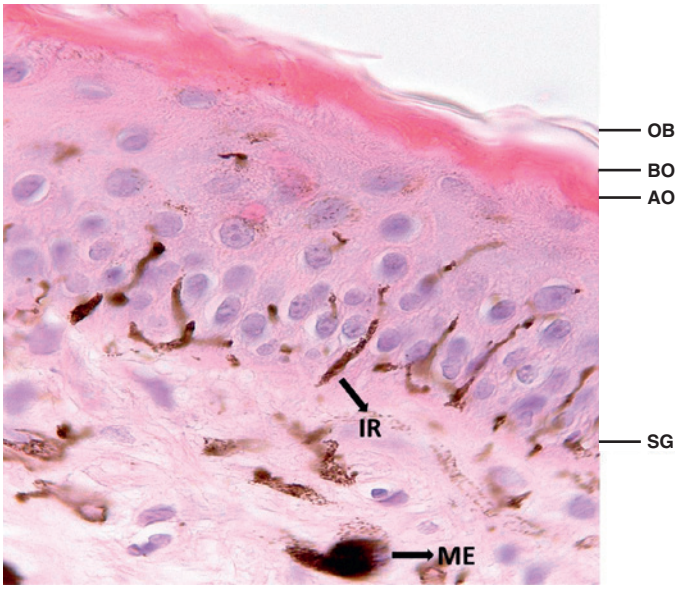

FIG 69.1 Higher magnification photomicrograph of the skin of a boa constrictor (*Boa constrictor*). The epidermis consists of oberhautchen, α-layer (AO), β-layer (BO), and stratum germinativum (SG). Two types of pigment cells are seen in the dermis: melanophores (ME) and iridophores (IR). (Courtesy of Tom Hellebuyck.)

forms the outer exoskeleton layer, which protects the underlying soft inner stratum of connective tissue containing α-keratin. This layer is usually thinner, and less rigid, and forms the ''joint'' or hinge at the base of the scale.[2] Such an arrangement provides greater flexibility than the completely rigid exoskeleton seen in insects.[2]

There are four extant orders of modern reptiles, Crocodilia (crocodiles and alligators), Chelonia (turtles and tortoises), Squamata (snakes and lizards), and Rhynchocephalia (tuataras),[1,4,5] with each group employing one of three scalation types (Fig. 69.2).[2,5,6] Morphologically, the scales of crocodilians show little variation and only minor overlapping.[5] Chelonians have a soft, folded skin in the limbs, tail, neck (most aquatic turtles), and a scaled/scute form of the shell.[7,8] In the limbs and tail of terrestrial turtles, hard scales containing β-keratin are also present, but β-keratin is decreased or absent in the hinge regions.[5] In most chelonians the shell is covered by β-keratin, except for soft-shelled chelonians in which α-keratin covers the carapace and plastron.[9] In squamates, the most frequently occurring scale type is the overlapping scale, which is found on the body. These scales are asymmetric and have distinct outer

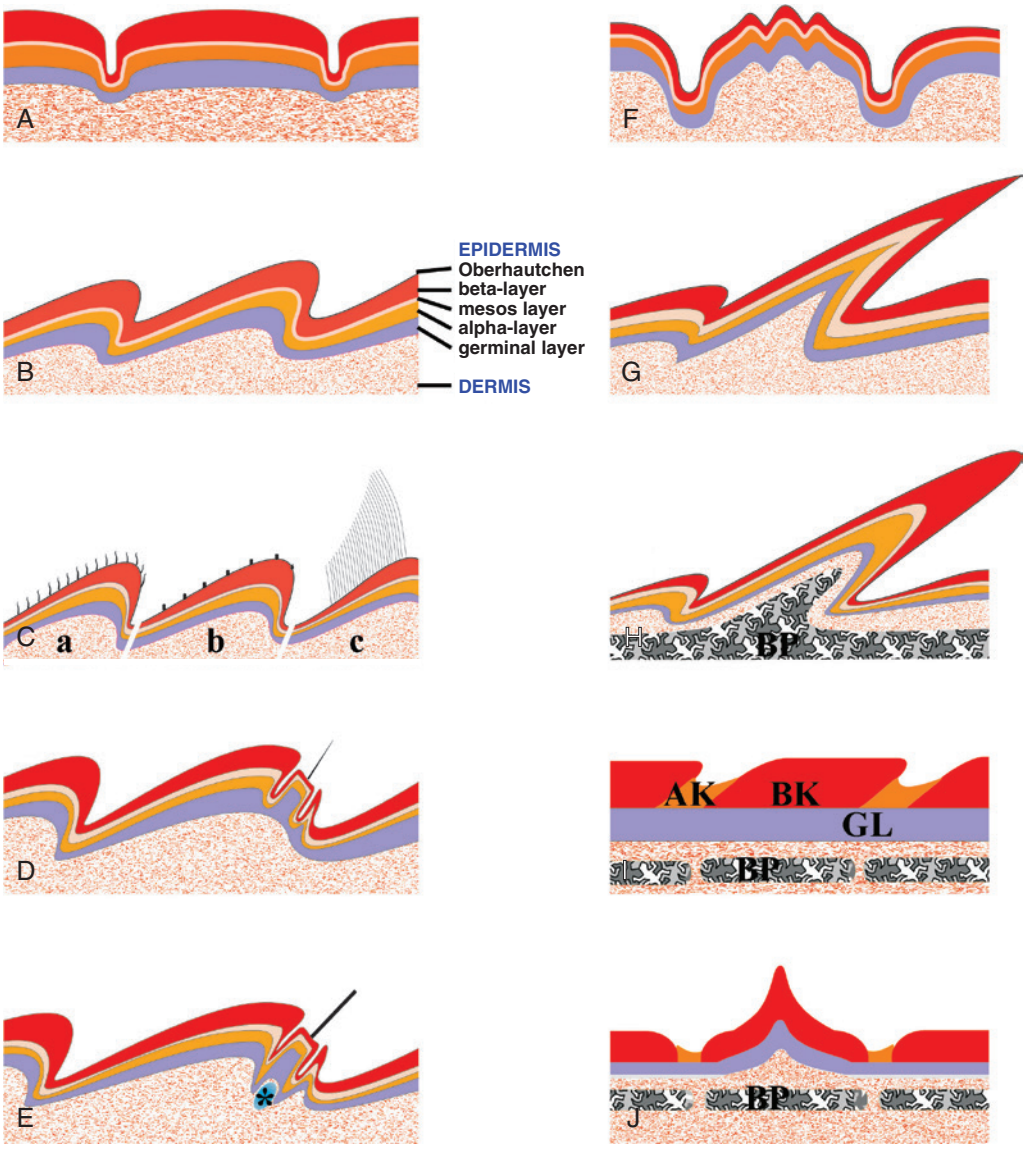

FIG 69.2 Schematic drawings showing different types of reptile scales. (A) Nonoverlapping tuberculate type scales. (B) Overlapping scales commonly seen in squamates. (C) Variations of microstructures from the oberhautchen layer, illustrating short spines in a and b and long setaes in c (such as those in the adhesive pad lamellae in geckos). (D) Pits on the scales of anole, gecko, and iguana (mainly epidermal sensory organs). (E) Tactile sensory organ on the hinge side of a scale in agama. Some follicle-like structures have clustered dermal cells associated to their base. (F) Scales with ridges are seen on the back of skink or the neck of anole. (G) Frills, or very elongated scales, are seen on the back of iguana. (H) The horn on the head of the chameleon contains a bony element core (osteoderm). (I) Scales on the limb of crocodilians show only minor overlapping. (J) Keeled scales with a central, elevated corneous ridge are seen on the dorsal body of crocodilians and some armored agamid lizards (e.g., Australian spiny desert lizard or moloch). Legends: a, fine "hair" on scales of anoles; b, microornamentation on scales of snakes; c, toe pad of anole or gecko; AK, α-keratin; BK, β-keratin; BP, bone element; *, dermal cells clustered at the base of sensory organs in Agama. VetBooks.ir

and inner surfaces and a hinge at the caudal end.[5] In contrast, the head scales of squamates are nonoverlapping and do not exhibit cranial-caudal polarity. These cranial scales are typically arranged in precise, exquisite patterns and usually form the basis for species identification in this order. In chelonians and crocodilians, α- and β-keratins in epidermal scales alternate horizontally while the keratins in the outer portion of squamate scales alternate vertically.[9]

The skin of reptiles contains relatively few glands, and is generally dry. Some species have musk glands adjacent to the cloaca, while in crocodilians they are medial to the dentary bone. Mental or chin glands are present in some chelonians, and specialized glands are associated with the angle of the jaw in chameleons.[9] The exact function of these glands is unknown, but they may play a role in scent marking or predator deterrence. In many lizards the males develop prominent femoral or precloacal pores associated with sexual maturity (Fig. 69.3). These glands are located along the ventral surface of the hind limbs or cranial to the vent, and their function is to secrete pheromones and a thick waxy substance that aids in adhering the male to the female. Another secretory gland that is used for defense against predation is the paired Rathke's gland of chelonians, located between the dorsal corners of the bridge/carapace junction, caudal to the foreleg and cranial to the hind leg. In some species this gland emits a foul-smelling liquid when the animal has been disturbed. Integumentary sense organs located in the postcranial and ventral scales have been described in a range of crocodilian species, and it has been hypothesized that they may serve as either mechanoreceptors or chemosensory organs.[10]

Boas, pythons, and vipers possess specialized pits that are utilized to sense infrared radiation to aid in the location of prey. In pythons and boas, they are located along the edges of the labial scales and cover almost the entire upper or lower lip (Fig. 69.4). In vipers they are found bilaterally, midway between the nostril and the eye, and are focused in a forward direction (Fig. 69.5).

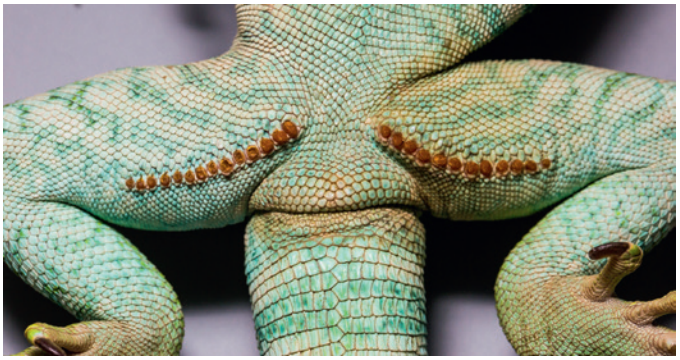

FIG 69.3 Femoral pores are associated with sexual maturity in males of many lizard species. (Courtesy of T.F. Scheelings.)

FIG 69.4 In pythons and boas, heat-sensing pits are located along the edges of the labial scales. (Courtesy of T.F. Scheelings.)

The parietal eye is a structure unique to lizards and is most well developed in the tuatara. It is located on the dorsal head and consists of a rudimentary lens and retina. Its function is to relay environmental cues to the pineal gland, thus controlling hormone production and influencing thermoregulation. In some species it is also important for spatial relation, helping animals return to their homerange.[11,12]

Deep to the epidermis, and separated by a basement membrane, lies the dermis, which is a highly vascular structure that contains sensory tissue, chromatophores and osteoderms in some species. It is the complex arrangement (both vertically and horizontally) of pigment cells within the dermis that gives each reptile its unique coloration. Four basic chromatophores have been identified in reptiles and include melanophores containing melanin, erythrophores and xanthophores containing pteridines and carotenoids, and iridophores containing reflecting platelets of guanine, adenine, hypoxanthine, and uric acid.[13,14]

Entrenched within the dermis of many reptiles are bony plates known as osteoderms (Fig. 69.6). Osteoderms are pleisomorphic for reptiles

FIG 69.5 In vipers, the heat-sensing pits are focused in a forward direction and are located between the eye and the nostril. (Courtesy of T.F. Scheelings.)

FIG 69.6 Osteoderms are mineralized dermal tissue and are commonly seen in many reptiles, like this heloderm lizard. They may be evident when radiographing animals. (Courtesy of Stephen J. Divers.)

VetBooks.ir

but demonstrate considerable lineage-specific variability in size, shape, and composition.[15] The most extreme example of osteoderm development is the carapace and plastron of chelonians. All osteoderms share embryonic origins with other dermal tissues and are predominately comprised of osseous material. Histologically, osteoderms are not uniform and contain variable amounts of mineralized and nonmineralized connective tissue and bone marrow.[15] Osteoderms are an evolutionary relic of the fully mineralized skins of ancient, now extinct, fish species.

PHYSIOLOGY

Undoubtedly the most identifiable physiological trait of reptilian skin is the periodic process of sloughing and renewal known as ecdysis (Fig. 69.7). In most chelonians and archosaurs (crocodiles and birds), desquamation is continuous, while in other species such as lepidosaurs (lizards, amphisbaenids, sphenodontids, and snakes) and some chelonians, the process is discontinuous, where shedding of epidermal areas of variable dimensions occurs.[16] In lepidosaurs, skin sloughing is cyclical, and, depending on the species, an animal may shed its entire skin at once (snakes and some lizards) or in small portions over a 1- to 2-week period. A cycle consists of a resting stage (consisting of three subdivisions) followed by five stages of renewal.[9,16,17] The resting phase follows a slough and is the normal state. During this time there is little cellular activity. The renewal phase is characterized by cellular divisions in the epidermis that results in the generation of a new skin. Once the old skin is ready to be replaced, the two layers are separated by enzyme-induced digestion of the bonds holding the old skin to the new, and at this time animals may appear dull or have a bluish hue.[9,16,17] In contrast to lepidosaurs, the large, flat, keratinous scutes of chelonians and crocodilians are shed fragmentally. Continued epidermal growth adds keratinous material over the inner surface of individual scutes, compensating for wear. When the outer layer of scutes becomes excessively worn, there is a switch from β to α–keratin production, resulting in the formation of a shedding layer. There is then a slow intracorneous detachment of the more external layers, with the surface of the scute being sloughed, followed by the formation of a new β-keratin layer.[2,18]

No matter the species, skin sloughing appears to be under hormonal control from the pituitary-thyroid axis and may be influenced by factors such as age, temperature, UV-B exposure, skin trauma, and frequency and amount of food consumption.[9,16,17,19]

Although most reptiles exhibit a changeless or slowly changeable color pattern (morphological color change), some species of reptiles possess the ability to rapidly change color in response to environmental stimuli such as background color, light intensity, or changing social context.[20] This color alteration is known as physiological color change and is achieved by repositioning of the pigment granules within the cytoplasm of chromatophores by microscopic intracellular microorganelles. This process is affected by the nervous and endocrine systems, and depending on the species they may use one or a combination of both systems.[20] For example, in the green anole (*Anolis carolinensis*), chromatic transformation is solely controlled by hormonal activity. In response to a dark background, visual cues sent to the brain result in a release of melanocyte-stimulating hormone (MSH) from the pituitary gland, leading to stimulation and dispersal of melanin granules within melanocytes and a resultant darkening of the skin. Conversely, when placed onto a light background, MSH is no longer released and the animal pales.[21] Additionally, stress hormones such as adrenalin and noradrenalin may also affect the color of green anoles.[21] In contrast, color change in the old world chameleon is under sympathetic nervous regulation and contrary to popular belief evolved primarily as a social signaling system with camouflage being a secondary concern.[22,23] In the horned lizard (*Phrynosoma* spp.), both nervous and hormonal agents appear to play a role in the regulation of chromatophores.[21]

Morphological color change, such as the ontogenetic color adjustment that occurs in the green tree python (*Morelia viridis*) and the emerald tree boa (*Corallus caninus*), usually reflects a shift in life-stage requirements and an adaptation to a new ecological niche. It results from altered pigment cell number and/or amount of pigment within cells.[24]

Another extraordinary skin adaptation of some species of desert-dwelling reptiles is the ability to harvest free-standing water or rain. For example, the thorny devil (*Moloch horridus*) inhabits much of arid Australia, where rainfall is sporadic and surface water is in low supply.

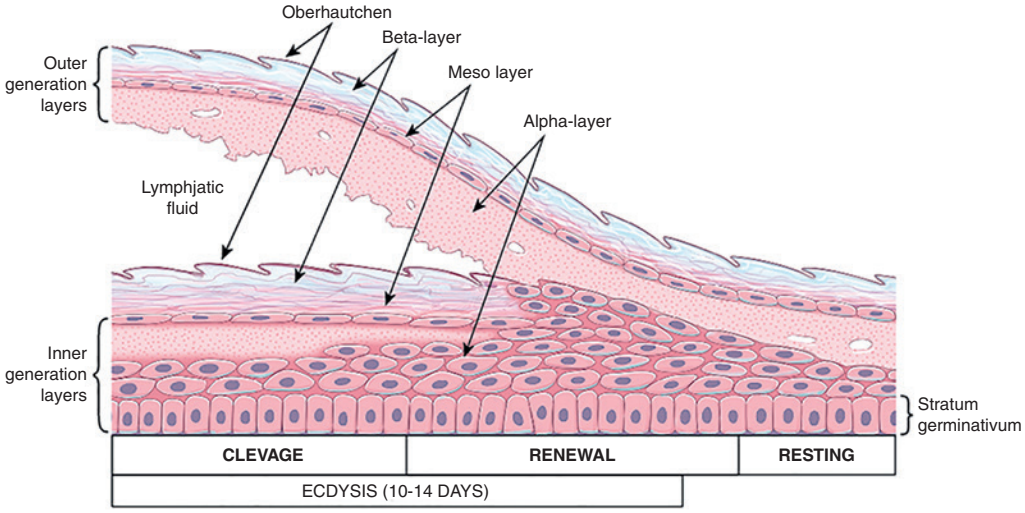

FIG 69.7 The normal shedding cycle of reptilian skin is characterized by two major phases: the resting phase and the renewal phase. The process of ecdysis (from midresting to the conclusion of the renewal phase) takes approximately 10 to 14 days in most species. The length of the resting phase is variable and is dependent on extrinsic factors such as environment and diet. The old skin is cleaved from the newly formed layer by the enzymatic activity of lymphatic fluid that floods the space between the two layers. It is this process that gives the skin of shedding reptiles a blue hue.

VetBooks.ir

Subsequently, the skin of thorny devils has developed hygroscopic properties that allows direct uptake of water from dew, wet foliage, standing water, and damp sand.[25–27] This process is achieved by the presence of minute interscalar capillary channels about 5 to 50 µm wide that support a pressure head of about 10 cm of water.[26,27] As water is drawn into these conduits, it is directed toward the labial scales where it is mixed with saliva and imbibed.[24–27] The existence of these interscalar capillary channels is not unique to the thorny devil, as they have also evolved independently in other species such as the sunwatcher toadhead agamid (*Phrynocephalus helioscopus*) and the Texas horned lizard (*Phrynosoma cornutum*). However, in these species the scalation does not have the same drawing power as in the thorny devil and cannot facilitate movement of ground water into the capillary channels. Instead, these animals rely on rainfall to capture water and exhibit distinctive behavioral postures during storms to maximize their dorsal body surface area and thus increase the volume of water that they are able to collect. This phenomenon is known as "rain harvesting" and is not seen in thorny devils.[26–28]

CLINICAL DISEASES

Infectious Dermatoses

Viral Diseases. Reptile virology is a dynamic and rapidly evolving discipline in herpetological medicine, with new viruses identified regularly. A number of viral diseases have been described in which a component of the disease process affects the integument (Fig. 69.8). A summary of these has been provided in Table 69.1. A diagnosis of viral infection usually requires the examination of biopsies with light and/or electron microscopy as well as molecular techniques. Clinicians should remember to include these on their list of differential diagnoses especially in cases unresponsive to conventional treatment. See Chapter 30 for more information.

Bacterial Diseases

Clinical significance. Various bacterial agents have been associated with dermatological diseases in reptiles. Demonstrating a causative relationship between the isolation of bacteria and the observed dermatological disorder, however, should be based on a multidirectional diagnostic approach to demonstrate a host pathological response (e.g., cytology or histopathology) in combination with the pathogen. Consideration should be given to possible underlying disease and environmental stressors, leading to immunosuppression and secondary bacterial dermatitis.[29–31] In addition to secondary invaders, a relatively small number of bacterial agents have been implicated as primary pathogens of reptiles.[31] Appropriate precautions may need to be instigated in view of the zoonotic potential of some of the organisms associated with dermatological disorders in reptiles. Nevertheless, the risk must be seen in the context of other dangers, including the fact that other apparently less pathogenic bacteria may cause disease in immunocompromised humans.

Known etiological cause(s) and clinical presentation. *Aeromonas*, *Pseudomonas*, *Flavobacterium*, *Staphylococcus*, *Salmonella*, *Morganella*, *Edwardsiella*, *Klebsiella*, *Micrococcus*, *Neisseria*, *Proteus*, *Serratia*, and *Enterobacter* spp. are commonly isolated from dermal lesions in reptiles.[29–32] Anaerobic bacteria, including *Bacteroides*, *Fusobacterium*, *Peptostreptococcus* and *Clostridium* spp., have been demonstrated to be part of the normal microbiota in reptiles and are frequently reported to cause dermal disease following bite lesions, scratches, or septicemia.[33]

Several bacterial agents belonging to the Actinobacteria have been reported to cause primary dermatological disease in a wide array of taxa.[31] Infection with *Dermatophilus congolensis* has resulted in cutaneous ulceration, hyperkeratosis, necrosis, and subcutaneous abscesses in lizards, snakes, and saltwater crocodiles.[34–37] *Austwickia chelonae*, formerly referred to as *D. chelonae*, has been cultured from skin lesions in chelonians.[38,39]

Devriesea agamarum has been designated as the causative agent of devrieseasis, a dermatological disease entity that is mainly characterized by chronic proliferative dermatitis and septicemia, especially in desert-dwelling (Fig. 69.9) and dry land lizard species.[40] While certain saurian taxa such as dab lizards (*Uromastyx* spp.) show high morbidity, mortality remains low. In other lizard species such as collared lizards(*Crotaphytus* spp.) and Agamid (*Agama* spp.) lizards, entire collections may be eradicated in a few weeks or months.[40,41] Persistence of devrieseasis in lizard collections has been attributed to the presence of asymptomatic carriers, especially bearded dragons, and long-term environmental survival of the bacterium under relatively moist environmental conditions and relatively low ambient temperatures.[41,42] In dab lizards as well as tropical lizard species, such as basilisks (*Basiliscus* spp.) and water dragons (*Physignathus* spp.), *D. agamarum* has been associated with the development of chronic subcutaneous abscesses and septicemia.[43,44]

TABLE 69.1 Reptile Viral Diseases That Often Have a Dermatological Manifestation

Virus	Species Affected	Clinical Signs
Poxviridae		
Chelonian poxvirus	Hermann's tortoise (*Testudo hermanni*)	Small, white-yellow papular lesions of the lower eyelids and the rostrum.
Crocodilian poxvirus (CRV)	Caimens, Nile crocodile (*Crocodylus niloticus*), saltwater crocodile (*Crocodylus porosus*), freshwater crocodile (*Crocodylus johnstoni*)	Typically present as brown wartlike lesions that may affect any part of the body. Some crocodilians may develop grey-white patches of skin. An atypical form has been identified in Nile crocodiles, with genetic analysis revealing it may be related to but not identical to CRV.
Tegu poxvirus	Tegu lizard *(Tupinambus teguixin*)	Multiple brown-colored papules distributed over the integument.
Iridoviridae		
Ranavirus	Predominately chelonians, but other species include green pythons (*Morelia viridis*) and occasionally lizards	Lethargy, nasal and ocular discharge, subcutaneous cervical oedema, gastrointestinal disease, granulomatous inflammation of the tail. High morbidity and mortality.
Invertebrate iridoviruses	Frilled lizard (*Chlamydosaurus kingii*), various other lizard species	Poxlike lesions of the skin, sudden death.
Herpesviridae		
"Grey Patch Disease" (ChHV-1)	Green sea turtles (*Chelonia mydas*)	Areas of patchy, gray discoloration of the skin in aquaculture-reared young turtles. Associated with chronic illness and death.
Fibropapillomatosis	Green, loggerhead (*Caretta caretta*), hawksbill (*Eretmochelys imbricata*), and olive ridley (*Lepidochelys olivacea*) sea turtles.	Papillary, arborizing neoplasms on the external surface of the body.
Herpesvirus of crocodiles (CrHV-1, 2 and 3)	Saltwater crocodile, freshwater crocodile	Lymphonodular skin proliferations.
Lacertid lizard papilloma	European green lizard (*Lacerta viridis*)	Papilloma lesions covering the skin with varied distribution associated with sex. No abdominal lesions observed.
Papillomaviridae		
Chelonian papilloma virus (Cc-PV-1, Cm-PV-1)	Bolivian side-neck turtle (*Platemys platycephala*), Russian tortoise (*Testudo horsfieldii*), loggerhead turtle, and green turtle	Circular papular skin lesions with occasional skin necrosis.
Lizard papilloma virus	European green lizard	Benign wartlike neoplasms on the surface of the skin.
Reoviridae		
Lizard reovirus	European green lizard	Papillomatous skin lesions and death.
Flaviviridae		
West Nile Virus	Crocodilians	Neuropathies and death. Lymphohistiocytic proliferative cutaneous lesions in American alligators (*Alligator mississippiensis*).

Adapted from Marschang RE: Viruses infecting reptiles. *Viruses*. 2011;3:2087–2126; Jacobson ER: Viruses and viral diseases of reptiles. In Jacobson ER, editor: *Infectious Diseases and Pathology of Reptiles*, Boca Raton, FL: CRC Press, 2007; and Hernandez-Divers SJ: Reptile viral diseases—summary table. In Mader DR, editor: *Reptile medicine and surgery,* 2nd edition. St. Louis: Saunders Elsevier, 2006.

Mycobacterium spp. are considered ubiquitous in the environment and may infect animals following a breach of integrity of the skin or through ingestion.[45,46] The pathogenicity of these acid-fast bacteria seems to vary significantly and may be associated with granulomatous inflammation of the skin but systemic disease may also develop.[45,46]

Skin lesions characterized by the presence of subcutaneous erythema, fluid-filled vesicles, and bullae typically (but not always) on the ventrum are often referred to as blister disease, necrotizing dermatitis, and "scale rot." The condition is most frequently seen in captive snakes, and occasionally in lizards, and is considered to be induced by inadequate environmental factors such as poor ventilation, excessively high humidity levels, and inadequate hygiene. If confined to the ventrum and there is associated ventral heat source (or dorsum with a radiant heat source), thermal damage may need to be excluded. Efficient treatment necessitates elimination of predisposing factors, topical antiseptics, and antimicrobial treatment.[17,29,32]

Diagnostic confirmation. Diagnosis is usually based on the detection of bacteria in scale samples, touch preparations, squash preparations, swabs, or biopsies.[29–32] Cutaneous granulomas comprised of multinucleated giant cells coupled with the presence of acid-alcohol fast bacteria typify mycobacterial infections**.** PCR can be used to confirm the diagnosis.[45] See the section on diagnostic testing at the end of this chapter for more information on diagnostic testing and the selection of relevant microbial isolates from skin samples.

Medical therapy. Besides systemic antimicrobial treatment, based upon culture and sensitivity testing, and debridement of hyperkeratotic skin lesions and abscesses, factors promoting persistency of the disease should also be eliminated.[29,31,43] Accordingly, identification and correction

of husbandry issues and treatment of concurrent diseases, the use of effective disinfection procedures for the captive environment and identification of asymptomatically infected animals are essential for establishing a holistic therapeutic approach for the treatment of microbiological causes of skin disease in reptiles.[31,32,42] Debridement of proliferative and necrotic lesions is invaluable because of the limited penetration of these poorly vascularized tissues, resulting in the establishment of inadequate drug concentrations at the target sites.[31,43,47]

Prognosis. Taking into account the overall multifactorial nature of bacterial skin disease in reptiles, the prognosis largely depends on correct identification and elimination of the etiological agent involved combined with the correction of factors that promote the onset of the disease.

Prevention. As most bacterial skin infections are secondary to substandard husbandry and underlying disease, providing an optimal captive environment is essential in the prevention of bacterial skin disease in reptiles.[31] The introduction of bacterial agents acting as primary agents causing high morbidity in captive collections may be prevented through clinical examination of newly acquired reptiles and correct sampling of skin lesions for microbial examination. The importance of adequate quarantine measures and the identification of asymptomatically infected carriers cannot be overemphasized.[45]

Mycotic Diseases

Clinical significance. As for bacterial infections, dermatomycosis in reptiles is often secondary to inadequate environmental conditions or underlying disease. Clinical signs may be similar in appearance to dermatitis, abscesses, and granulomas caused by bacteria.[30–32,48] Several dermatomycoses in reptiles on the other hand are caused by obligate pathogenic fungi of different orders and have been associated with high mortality and morbidity in captive and free-living reptiles.[49,50]

Known etiological cause(s) and clinical presentation. Various fungal species have been reported to cause dermatomycoses in reptiles, including *Aspergillus*, *Basidobolus*, *Chamaeleomyces*, *Geotrichum*, *Lecanicillium*, *Mucor*, *Saprolegnia*, *Penicillium*, *Fusarium*, *Purpureocillium (Paecilomyces*; Fig. 69.10), *Trichophyton*, *Trichosporon*, *Oospora*, and *Alternia*.[31,32,51] Infections with yeasts and yeastlike fungi such as candidiasis, cryptococcosis, and trichosporonosis are less commonly observed.[31] Many of these fungal agents use a breach of skin integrity as a portal of entry and initially attack superficial areas of skin but can quickly develop into a subcutaneous mycelial growth, eventually leading to deep and disseminated mycosis.[31,48]

Primary pathogenic fungi, formerly referred to as *Chrysosporium* anamorph of *Nannizziospsis vriessii* (CANV), have been reassigned to the family Onygenaceae based on phylogenetic studies. Currently, the CANV-complex comprises nine different species, clustered in three phylogenetic lineages. One lineage represents the genus *Nannizziopsis* including isolates from saurians and crocodiles; two other lineages represent the genus *Ophidiomyces* with *Ophidiomyces ophiodiicola*, the etiological agent of a cutaneous fungal disease syndrome known as snake fungal disease (SFD), occurring in free-ranging and captive snakes, and *Paranannizziopsis* spp. infecting squamates and tuataras.[48–50] In general, clinical infections are characterized by the development of localized, crusty, yellow to brown skin lesions, vesicles, and hyperkeratotic lesions evolving to necrosis of extensive areas of skin.[48,52–59] Although considered as obligate fungal pathogens, substandard environmental conditions seem to determine disease initiation and progression. *Nannizziopsis guarroi* infection is frequently associated with severe and sometimes fatal dermatomycosis in inland bearded dragons (Fig. 69.11) and green iguanas (Fig. 69.12).[52] The pericloacal and mandibular region seem to be predilection sites for the development of associated skin lesions.[52,57–59] SFD is an emerging disease characterized by superficial dermatitis and subcutaneous nodules with subsequent morbidity and mortality.[53–55]

FIG 69.12 Fungal granuloma at the tail of a green iguana (*Iguana iguana*). (Courtesy of Tom Hellebuyck.)

Diagnostic confirmation. Many of the considerations made toward the diagnosis and treatment of bacterial skin disorders equally apply for dermatomycosis. Diagnosis is usually based on the detection of

VetBooks.ir

fungi with a host inflammatory response in skin samples. Incubation of fungal cultures derived from reptile patients often require specific temperature conditions, and fungal growth may be relatively slow in comparison to mycotic agents that are isolated from dermatological lesions in domesticated mammals.[48] Obtained isolates may be a part of the skin microbiota in healthy reptiles.[31,32,56]

Except for fungal isolates with a known primary pathogenicity, repetitive and correct sampling of skin lesions, adequate culture, histopathological examination of skin and underlying tissue, the use of molecular methods to identify fungal isolates to the species level, and demonstration of a host pathological response are mandatory to assign a fungal isolate as the causative agent of an observed dermatological disorder.[31,32,48]

Medical therapy. Besides the systemic use of triazole antimycotic agents, such as ketoconazole, itraconazole, terbinafine, fluconazole, and voriconazole for the treatment of filamentous fungi infections, debridement of skin lesions and treatment with topical terbinafine or 0.125% chlorhexidine solution may facilitate the treatment of dermatomycosis.[31,57,60] If possible, susceptibility testing of fungal isolates should be performed as resistant clones have been demonstrated.[60] As dermal and deep mycosis often require long-term treatment, the effectiveness of antimycotic treatment and signs of toxicity should be carefully monitored, especially for itra- and ketoconazole.[31,58,60] Voriconazole is recommended as a safe and effective alternative, but the use of the latter agent should be investigated in species such as chameleons that seem to be poorly tolerant to the recommended dosages.[48] When confirmed fungal lesions are isolated to appendages, amputation may also be considered as a viable treatment option, as potential toxicity and antifungal treatment failure are not uncommon.

Efficacy of antimycotic treatment should be confirmed by regular sampling of skin lesions to confirm elimination of the causative agent.[31,60]

Abscesses

Known etiological cause(s) and clinical presentation. The lesions in reptiles that are usually termed abscesses generally appear as raised, hard, and demarcated cutaneous or subcutaneous nodular swellings (Fig. 69.13).[17,31,47] Although mostly gram-negative bacteria are involved, infection with gram-positive bacteria, anaerobic bacteria, or mixed infections may be encountered. Dermal abscesses may also originate from hematogenous spread of bacterial infection, especially when a multifocal distribution is observed.[17,31] Most reptilian abscesses are well encapsulated and show a lamellar appearance on cross-sectional cut. Histological examination of such lesions usually reveals a central core containing bacteria surrounded by inflammatory cells and fibrosis, presumptively to entrap bacteria and prevent systemic spread and resulting in the typical solid appearance. These lesions might be better termed fibriscesses.[61] Similar processes with a more cellular component are essentially granulomas. If *Salmonella* or *Mycobacterium* spp. are isolated from dermal abscesses or granulomas, the presence of concurrent infectious osteoarthritis, osteomyelitis, or soft tissue abscesses should be considered.[30,47,62] Neoplastic disorders, parasitic cysts, fungal granulomas, epidermal cysts, hematomas, and aneurysms might show a similar appearance and should be differentiated from bacterial abscesses.[30]

Cellulitis is a deep suppurative infection characterized by dissemination through the skin and can result in a whole network of infected sinuses and tracts within the dermis (Fig. 69.14). The presentation is similar to that of a large abscess, but as the caseous core is often missing the swelling is soft and fluid can often be aspirated.[17]

Pododermatitis and abscessation of the feet are regularly observed in large saurians such as monitors (*Varanus* sp.), iguanas (*Cyclura* spp., *Iguana iguana*) (Fig. 69.15), and chelonians following bacterial infection of skin lesions caused by inappropriate husbandry such as excessive

FIG 69.15 Pododermatitis and abscessation in a green iguana (*Iguana iguana*). (Courtesy of Tom Hellebuyck.)

humidity and exposure to an abrasive substrate.[63] In chronic stages, deeper tissues may be affected and osteomyelitis can develop.

Diagnostic confirmation. Definitive diagnosis of an abscess usually requires aspiration or collecting swabs from the inside wall of the fibrous capsule for cytology and culture/sensitivity testing. Anaerobic and fungal cultures should be performed as well as gram, Wright-Giemsa, periodic acid shift, and acid-fast staining of cytological preparations or histopathological sections.[17,32] If the involvement of bony structures with the development of osteomyelitis is suspected, the use of radiography is essential toward installing an appropriate treatment.

Medical and surgical therapy. Due to the presence of caseous pus and thick capsules in most abscesses, these lesions are poorly penetrated by antimicrobial agents.[43] Accordingly, abscesses and granulomas are best excised in toto. If complete excision is not possible, surgical exposure, followed by marsupialization and/or the removal of a large area of epidermis, is important. These techniques will allow continued debridement, aggressive flushing, topical antiseptic treatments, and prolonged topical antimicrobial therapy (when possible based on culture and sensitivity testing).[31,43] Systemic antimicrobials are seldom warranted for the treatment of a discrete abscess.

Parasitic Diseases

Clinical significance. External parasites frequently infest both captive and wild reptiles. Pathology associated with these infections can range from subclinical to severe debilitation depending on the species of parasite and the overall health of the affected reptile. Importantly, external parasites have been implicated as vectors for transmission of serious infectious diseases such as arenavirus.[64,65]

Known etiological cause(s). The most important external parasites in reptiles include ticks and mites. Aquatic reptiles may additionally have to contend with leech infections but these are rare. Ticks and mites are acari parasites, of which over 400 species have been described in reptiles.[65] Parasites within this taxon are characterized as having three pairs of legs as larva and four pairs of legs as nymphs and adults. The head, thorax, and abdomen are fused. Ticks and mites show variable host specificity with some being generalists, while others are highly species specific. Mites from the families Macronyssidae, Paramegistidae, Heterozerconidae, Trombiculidae, and Leeuwenhoekiidae have all been described in reptiles.[65] Of the Macronyssidae, only the genus *Ophionyssus* are ectoparasites of reptiles, and the snake mite, *Ophionyssus natricis*, is the most common species seen.[65] More than 100 soft- and hard-bodied ticks belonging to eight genera of the families Argasidae and Ixodidae have been collected from reptiles worldwide.[65]

The life cycle of acarid parasites of reptiles are varied, with some species spending their entire life on the host, whereas others may have intermittent periods as free-living stages.[65] For example, in the snake mite, *Ophionyssus natricis*, five life periods are recognized: the egg, larva, protonymph, deutonymph, and adult. Only the protonymph and adult are parasitic, feeding on the blood of the host, while the other stages are free-living in the environment.[66]

Clinical presentation. Clinical signs associated with external parasites are typically nonspecific. Mite or tick infestations may result in behavioral changes such as continued rubbing on cage furnishings or prolonged soaking in water bowls. Mite-infected animals often appear dull, or dirty, and may be covered in small, white, powderylike dots, which are mite feces. Dysecdysis or increased frequency of shedding may be observed in affected animals. In severe infestations animals may become lethargic, anorectic, septicemic, or anemic.

Diagnostic confirmation. Diagnosis is confirmed by observation of parasites on the animal. Mites have areas of predilection, including the periocular region, in the folds of skin under the chin, around the cloaca, in the thermosensory pits of snakes, and in the axillae and tympanic recesses of lizards.[67] Ticks often bury themselves under scales, with their presence being disclosed only by slight raising of the scale that they are embedded beneath. Once parasites have been located, they should be removed for microscopic examination. Although most clinicians will readily be able to distinguish between mites and ticks, further identification beyond this level can be difficult in-house and may require specialized training. For submission to a parasitologist, mites and ticks should be stored in an eppendorf container in 70% to 90% ethanol. Where possible, it is best to get as many different life stages and sexes to aid in identification.

Medical therapy. Successful therapy relies on a combination of treating the host, as well as environmental management to break the life cycle. A number of chemicals have been proposed for the treatment of acarid infections in reptiles;[68] however, some carry inherent toxicity risks and are not recommended. The most effective treatments are fipronil spray (Frontline Spray Treatment, Merial, Duluth, GA; active ingredient 0.29% fipronil) or a pyrethroid spray (Provent-a-Mite, Coulston Products Inc, Safety Harbor, FL; active ingredient 0.5% permethrin and the only ectoparasiticide licensed for reptiles in the United States). Although these compounds are relatively safe, care should be taken when using them, as inappropriate application may still result in toxicity to the reptile host. Some clinicians advocate the use of macrocyclic lactones (e.g., ivermectin, moxidectin) as either a spray or an injection, but it should never be used in chelonians and great care taken in crocodilians. In addition, the first author (FS) of this chapter has seen instances of toxicity with their use in some lizard species, in particular those belonging to the genus *Tiliqua*. If a topical treatment is used, it is recommended to wipe the drug off the animal prior to returning it to its enclosure. Reptilian ticks can easily be removed manually, and in most circumstances this is the best method for eliminating them. All topical treatments should also be accompanied by aggressive treatment of the environment to eradicate any free-living stages. Methods suitable for sanitation include applying an acaricide such as a pyrethrin, pyrethroid, carbaryl, or organophosphate to enclosure surfaces and cage furnishings. Other acceptable methods include immersion in boiling water or washing with a 3% bleach solution. No matter which compound is used, it is important that the enclosure is rinsed thoroughly afterward in order to remove any chemical residues and prevent inadvertent toxicity when reptiles are placed into it.

Prognosis. For the majority of cases, acarid infections in reptiles carry an excellent prognosis provided that the animal is not severely debilitated.

Prevention. Preventing infections from entering collections is best achieved with sound quarantine protocols. New animals should be isolated from the existing animals, preferably in a separate room or facility, for a minimum of 3 months. Where possible, it is also a good idea to have enclosures within the quarantine area further isolated by surrounding them with a moat to prevent acarids from dispersing.[45] All animals should be thoroughly examined prior to entering quarantine for the presence of external parasites. At this time, prophylactic treatment may also be administered. Unauthorized personnel should be excluded from entering the quarantine facility, and ideally anyone servicing isolated animals should change clothes before having any contact with the main collection. All enclosures and cage furnishings (water bowls, hides, etc.) used for quarantined animals should be sanitized between occupants, and most importantly before these are used in acarid-free enclosures.[45]

Noninfectious Dermatoses

Dysecdysis

Definition. Dysecdysis is the term given to abnormal or impaired shedding of the outer layer of skin.

VetBooks.ir

Clinical significance. Although one of the most commonly observed dermal problems in reptiles, this disorder should be considered as a nonspecific clinical finding.[31]

Known etiological cause(s). Dysecdysis may be associated with numerous infectious diseases that directly or indirectly affect the skin as well as inappropriate environmental conditions, nutritional deficiencies, dehydration, and traumatic injuries that interfere with the normal shedding process. Dehydration may starve the cleavage zone of the fluids necessary for normal segregation and new epidermal layers. Hypoproteinemia may interfere with the normal enzyme production necessary for the breakdown of the fission layer.[31,69]

Clinical presentation. Retention of sloughed skin may affect the entire integument or may be restricted to retained spectacles in snakes and constricting bands of old skin on the digits or the tail.[69] The latter may eventually result in avascular necrosis or dry gangrene and inevitable loss of distal extremities if left untreated. Dysecdysis should be differentiated from normal fragmented ecdysis as observed in many lizard species.[31]

Diagnostic confirmation. Besides taking into account the history and shedding habits of the affected patient, a thorough assessment of captive husbandry and identification of any underlying or concurrent diseases is often necessary to discern the origin of the observed shedding problems and to instigate appropriate therapeutic measures.

Medical therapy. The therapeutic approach for dysecdysis is often directed by the chronicity of the problem, the number of layers of retained skin, and the size and location of the affected skin site. Aggressively peeling back retained or shed skin as well as premature removal of older epidermal layers should be avoided, as this may result interfere with normal skin integrity and cause considerable loss of fluids and proteins.[69] See Chapter 71 on reptilian ophthalmology for a more detailed discussion on the diagnosis and treatment of the retained spectacle.

Increasing the environmental humidity by spraying the animal and its environment may be sufficient to accomplish the removal of relatively small pieces of retained skin. For snakes, retained skin sloughs are often readily removed with gentle 20-minute soaks in warm, shallow tap water.

Prevention. Applying optimal husbandry protocols based on a sound knowledge of the captive requirements of commonly kept species and eliminating any condition that may interfere with a normal shedding cycle are essential for prevention of this secondary skin disorder.

Prognosis. If the actual source of dysecdysis is left unidentified, captive reptiles are doomed to repeat the problem with each subsequent shed. Once the primary problem is diagnosed and treated, normal ecdysis should return within two or three cycles. If the problem is detected and dealt with early, most animals have an excellent chance of recovery.[69]

Burns

Clinical significance. Reptiles are frequently presented to veterinarians for treatment of thermal burns. These can range from mild to life threatening. It is not completely understood why reptiles are prone to burns but their behavior (not moving away or off of heat devices causing thermal damage) predisposes them to this type of injury.[70] Less common burn injuries include electrical and chemical burns. All serious burns should be considered medical emergencies, and treatment is essentially the same regardless of the initiating cause.

Known etiological cause(s). Burn injuries are typically caused by provision of inappropriate heat sources. Most burn injuries occur when animals are given direct access to heating elements, such as "hot rocks" or heat mats. These devices are unreliable and frequently overheat or have electrical faults. A second important source of potential injury comes from heat lamps placed too close to animals or inside enclosures without any screen guards. An uncommon source of burns are fan heaters and hot water, but nonetheless, they still pose a significant risk if used improperly.

Clinical presentation. Burns are classified based on the degree of tissue damage.[70] Superficial (first-degree) burns only involve the epidermis and are painful but heal quickly if treated appropriately. In some cases, small blisters may be seen. Superficial partial-thickness or deep partial-thickness (second-degree) burns are very painful, resulting in the patient adopting an abnormal posture to relieve pressure on the affected areas. There is complete destruction of the epidermis with marked swelling and blister formation. Full-thickness (third-degree) burns involve both the epidermis and dermis. These are usually painless due to loss of sensory nerve endings and are very slow to heal. The final category, fourth-degree burns, involve the skin and underlying tissue such as muscle and bone and may extend into the coelomic cavity in severe cases.

Diagnostic confirmation. Diagnosis and confirmation is based on a combination of clinical signs (Fig. 69.16) and investigation into husbandry practices.

Medical or surgical therapy. The diagnostic plan and management of reptile wounds should follow standard protocols described for domestic animals. It is important to realize that in many instances the full extent of the burn injury may not be apparent until a few days to a week after the initial trauma. Particularly in circumstances of acute presentation, the client must be made aware that the wound may first look worse before it improves. A complete blood count and plasma biochemistry are useful tools in assessing the physiological state of burnt reptiles. Burns that affect large surface areas are likely to result in significant fluid loss as well as electrolyte imbalances, and so provision of fluids is essential in these cases. Under most circumstances lactated ringer's solution is appropriate for fluid replacement in reptiles as osmolarities are similar to mammals. Intravenous or intraosseous fluid administration is by far the most effective way to correct fluid deficits, and it can be administered as boluses in small patients or via indwelling catheters in larger animals. It is also important to remember that burn injuries typically lose a significant amount of protein, so nutritional support is of paramount importance to prevent animals from becoming hypoproteinemic. In inappetent animals, this may require assisted feeding. For superficial burns, first aid should comprise of rinsing it under a cold tap or applying a cold compress to the affected area. In these cases, topical application of an antimicrobial ointment such as silver sulfadiazine is usually all that is required to prevent contamination of the wound.

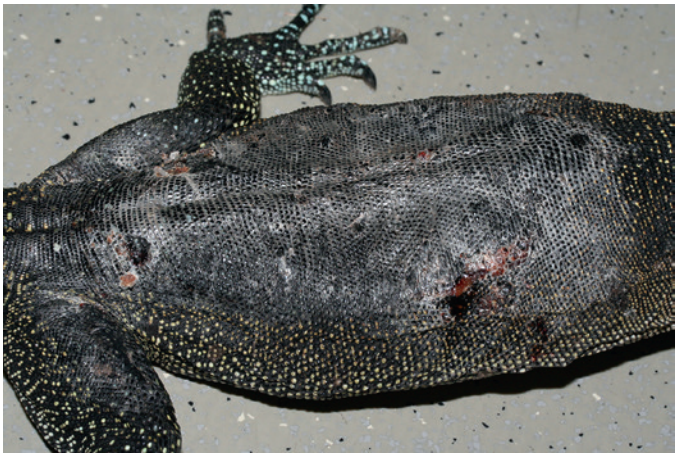

FIG 69.16 Second-degree burn in a peach-throated monitor (*Varanus jobiensis*) resulting from the inappropriate installation of heat sources. (Courtesy of Tom Hellebuyck.)

VetBooks.ir

For any burn that is more severe than superficial, more involved treatment is required and will be dependent on the extent of tissue damage. Such wounds may require surgical debridement or daily bandage changes. These wounds are prone to infection with possible septicemia, so systemic antibiotics may be warranted if extensive. Wounds should be covered with a protective layer that promotes healing and inhibits microbial growth. Suitable products include silver-impregnated gels or ointments or honey/sugar bandages. This initial layer then needs to be further protected using an absorbent bandage material, and finally, covered with a more robust layer to prevent rubbing. Initially, bandage changes should be performed daily, as wounds will leak significant amounts of fluid, but this can be extended out to every 3 or 4 days once the wound has stopped oozing. No matter the type of burn, analgesia should be provided to all animals. A combination of NSAIDs and opioids are recommended. For bandage changes, the clinician should routinely consider general or local anesthesia prior to cleaning wounds.

Prognosis. Superficial to deep partial-thickness burns have a good prognosis, full-thickness burns carry a guarded prognosis, while fourth-degree burns have a grave prognosis. When embarking on management of burn injuries, the client should be well-informed that treatment and healing times are often prolonged and require a significant commitment on their behalf.

Prevention. Reptiles should not be given direct access to heat sources. It is not recommended to use hot rocks or heat mats inside enclosures. Where possible, heat lamps should be placed outside enclosures or covered with a protective cage. Aquarium heaters can be placed inside a PVC pipe to prevent aquatic reptiles touching the heating elements.

Bites From Prey

Clinical significance. Live prey items offered to reptiles may inflict serious injuries if left unattended in enclosures (Fig. 69.17). Bites may occur from rodents or invertebrate prey. In extreme cases wounds may result in the death of the reptile.

Known etiological cause(s). Live prey items left in enclosures for extended periods of time may attack predators in self-defense, or they may inflict damage on the reptile as they are being captured. Invertebrates may start biting or feeding on reptiles if they are not consumed. Reptiles may become inappetent for a variety of reasons and a thorough investigation into general health and husbandry is recommended for any animal that consistently refuses food items.

Clinical presentation. Wounds may range from superficial abrasions to deep and contaminated bites with extensive soft-tissue damage. They may be singular, or as is often the case in invertebrate bites, they may be disseminated over the entire body. Infections may lead to septicemia and/or severe debilitation.[29]

Diagnostic confirmation. Confirmation occurs by discussing husbandry practices with the client.

Medical therapy. The general principles of decontamination, antibiosis, and analgesia apply to any wounds arising from bites by prey.

Prognosis. Prognosis is dependent on the extent of the injuries.

Prevention. Offering live rodents should be discouraged (and is illegal in many areas). Ultimately, feeding freshly killed or frozen/thawed rodents is more humane for the prey item and is also more cost-effective for the hobbyist. Invertebrates not eaten within 15 minutes of being placed into an enclosure should be removed and reoffered at another time.

Rostral Abrasions

Clinical significance. Captive reptiles are particularly liable to the development of rostral abrasions. In chronic cases and if left untreated, affected animals may be unable to feed or succumb to osteomyelitis and systemic infection.

Known etiological cause(s) and clinical presentation. Rostral abrasions are commonly caused by rubbing on glass or wire surfaces, especially in lizard species that show explosive bursts of flight behavior (e.g., *Physignathus* and *Basiliscus* spp.; Fig. 69.18) and nervous snake species. If left untreated, these lesions may develop into deep abscesses, and in severe cases necrosis or osteomyelitis of underlying bone may occur.

Diagnostic confirmation. Besides taking into account the species predisposition, the location and appearance of these lesions, confirmation is by assessment of the captive environment.

Medical therapy. Topical antiseptic or antimicrobial therapy and wound care should prevent the entry of pathogens. In those cases where deep infection occurs, surgical intervention and prolonged systemic antimicrobial therapy (based upon culture and sensitivity testing) is often required.[17,29,31]

Prognosis. Prognosis is dependent on the extent of the injuries, especially the involvement of bony structures and the establishment of environmental adjustments.

Prevention. These injuries can be prevented by providing animals with adequate housing and an environment in which they feel secure and unthreatened.

VetBooks.ir

Nutritional Dermatoses

Clinical significance. Nutritional dermatoses are frequently observed, especially in captive lizards and chelonians, due to the considerable interspecies differences in nutrient requirements. These may present as abnormal color changes, dysecdysis, abrasions, or keratinization disorders resulting in an abnormal appearance to skin texture. Delayed wound repair of the skin may indicate general malnutrition.[31,71–73]

Known etiological cause(s) and clinical presentation. Hypovitaminosis A in reptiles is primarily recognized as a disease of chelonians, although the prevalence of hypovitaminosis A may be underdiagnosed in saurians (Fig. 69.19). Palpebral edema, conjunctivitis, cheilitis, and aural abscesses in chelonians, especially in aquatic species, are common indicators of this nutritional disorder. Impaction of precloacal and femoral pores as well as the development of hemipenile plugs with secondary infection may be associated with hypovitaminosis A in lizards.[31,72–74] Tissues that have been pathologically altered as a consequence of hypovitaminosis A are prone to secondary bacterial and mycotic infection.[62]

Abnormal fragility of the skin with separation and skin tearing has been anecdotally reported in snakes and is associated with poorly organized collagen and vitamin C deficiency. However, there is little scientific evidence to support these diagnoses. Steatitis of the skin with necrosis and sloughing is observed in piscivorous reptiles fed diets high in polyunsaturated fats, especially when rancid.[17]

Diagnostic confirmation. Diagnosis of nutritional causes of dermatological problems are often presumptive and based on clinical history, assessment of the management, and response to therapy.[72,73,75]

Medical therapy. As for other fat-soluble vitamins, parenteral administration of vitamin A should be carefully dosed to avoid iatrogenic hypervitaminosis A, and dosing intervals based on clinical response to treatment should be respected. Doses of 2000 to 5000 IU/kg vitamin A are considered safe in those patients showing signs related to hypovitaminosis A.[62,63,75] Alternatively, nutritional improvement and oral supplementation are safer. Metaplastic abscesses should be surgically removed and local or systemic antimicrobials may be required.[31,72–75]

Prognosis. Nutritional dermatoses have a good prognosis if adequate treatment is initiated and dietary imbalances are corrected.

Prevention. β-carotene-rich food sources should be included in the diets of susceptible species as a part of the prevention and long-term treatment of vitamin A deficiency. In primarily insectivorous lizard species (geckos, chameleons), supplementation with preformed vitamin A may be necessary, as clinically they appear to have a decreased ability to utilize beta carotenoids as vitamin A precursors.

FIG 69.19 Vitamin A responsive cheilitis in a leopard gecko *(Eublepharis macularius)*. (Courtesy of Tom Hellebuyck.)

Cutaneous Neoplastic Disorders

Known etiological cause(s). Cutaneous neoplasms are regularly diagnosed in reptiles and include fibrosarcomas, liposarcomas, chromatophoromas, epitheliomas, mast cell tumors, and squamous cell carcinomas (SCC; Fig. 69.20).[31,76–80] In chelonians, the shell may be directly or indirectly involved. Papillomatosis and fibropapillomatosis associated with viral infection have been discussed previously.

Chromatophoromas are classified as melanophoromas or melanomas, iridophoromas, xanthophoromas, erythrophoromas or mixed depending on the type of pigment-producing cells involved.[79] Although once considered uncommon, melanophoromas (Fig. 69.21) and iridophoromas seem to show a relatively high incidence, especially in diurnal species. As for SCC, continuous exposure to high doses of artificial UV radiation has been proposed as a predisposing factor in the development of chromatophoromas.[78,79]

Clinical presentation. While most skin neoplasms present as cutaneous or subcutaneous demarcated proliferative or nodular processes, diffuse skin masses may be observed. Secondary microbial infections

FIG 69.20 Squamous cell carcinoma located at the dorsal skin in a blue-tongued skink (*Tiliqua gigas*). (Courtesy of Tom Hellebuyck.)

FIG 69.21 Cutaneous melanophoroma located at the dorsal side of the tail in a bearded dragon *(Pogona vitticeps)*. (Courtesy of Tom Hellebuyck.)

VetBooks.ir

may complicate the clinical picture, especially when the integrity of the epidermis has been breached. Although most of these types of skin neoplasms exhibit locally aggressive behavior, they show a relatively low tendency to metastasize.[31] Mast cell tumors, squamous cell carcinomas, and melanophormas may show a multicentric appearance.

Diagnostic confirmation. Cytological or histopathological examination is usually essential to distinguish a neoplasm from other lesions such as abscesses and granulomas. Immunohistochemistry is a valuable tool toward the differentiation of dermal neoplasms in human and traditional small animal medicine but is left largely unexplored in reptiles. Evaluation for metastases should be investigated in each patient with a confirmed diagnosis of cutaneous neoplasia.

Medical or surgical therapy. In addition to, or as an alternative to, surgical excision, cryotherapy, laser ablation, or radiation may be of value in some patients. Intralesional and systemic chemotherapy protocols have been described for the treatment of some neoplastic disorders in reptiles with variable effectiveness.

Prognosis. In general, the selection of appropriate therapies on the basis of the stage and biological behavior of the tumor in question determines the prognosis. Those cases where complete surgical excision is possible carry a fair prognosis. Nevertheless, long-term monitoring is often required, as many reptile skin neoplasms show a moderate to high recurrence rate. If complete resection is deemed impossible because vital structures are involved or the presence of metastases exist, the prognosis is worse.

DIAGNOSTIC TESTING

Evaluation of the reptilian integument necessitates a holistic approach with particular attention paid to both the animal and its environment. A general physical examination should be accompanied by detailed analysis of husbandry. Where possible, pieces of shed skin may provide valuable information so clients should be encouraged to bring these to the appointment if available. As many reptiles are small, magnification may aid in diagnosis. For detailed information on clinical examination of reptile patients, refer to earlier chapters.

The collection of skin samples plays an important role in diagnosis. Many of these tests can be performed in-house by clinicians. Tests that should be performed at the initial examination include swabs or impression smears of wounds, skin scrapes, and sticky-tape preparations. Samples can be stained with Romanowski stain (Diff-Quick or similar) and examined immediately. Laboratory diagnostics may then be necessary depending on these results, and consideration should be given to collect samples for microbiological culture, PCR, and skin biopsies for histological examination.

Skin biopsies can be collected under a combination of sedation/manual restraint and local anesthesia, or while the animal is under general anesthesia. The decision of which method to utilize depends on the competency of the handler and the behavior of the animal, as well as the scenario in which the procedure is being performed (i.e., in the hospital or in field conditions). Once the area to be biopsied has been identified, care must be taken not to surgically prepare the site as this may potentially eliminate etiological agents such as bacteria or fungi. However, sterile saline flushing and a sterile drape should be used to isolate the area, and the surgeon should prepare themselves as for other surgical procedures. In most instances, biopsy punches (Fig. 69.22) are an effective method for obtaining diagnostic samples in reptiles, but in rare cases (e.g., tough skin, larger biopsy required) a section of skin may need to be removed using a scalpel blade. Once the biopsy has been obtained, it should be placed gently into 10% neutral buffered formalin for histopathological examination. Larger areas of skin should be placed on card to prevent rolling before being placed in formalin. Where appropriate, an additional biopsy sample should also be collected into a sterile pot for microbiological culture. Care must be taken not to crush biopsy samples after they have been collected. If the clinician is having difficulty retrieving the sample from the biopsy tool, then flushing it with sterile saline from a 25 g needle into the formalin pot is usually the easiest way to extricate the tissue. The resultant wound can be closed with sutures or alternatively by covering it with a small dressing and allowing it to heal by secondary intention.

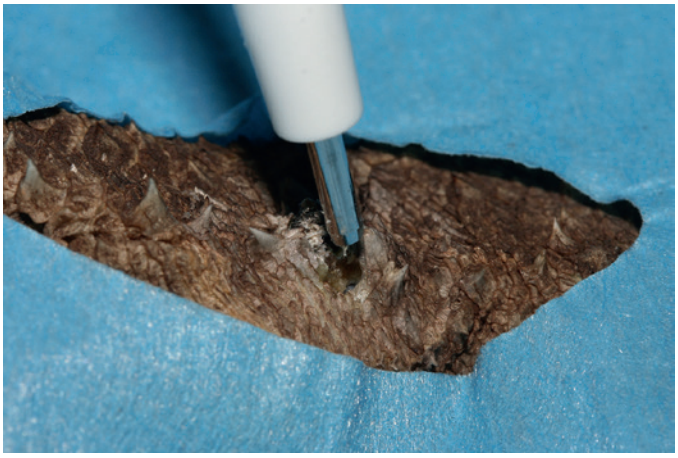

FIG 69.22 Collection of a full-thickness skin biopsy using a biopsy punch. (Courtesy of Tom Hellebuyck.)

FIG 69.23 Debridement of dried scabs associated with skin lesions allows sampling of the deeper infected tissue, which results in more accurate microbiological isolates from culture. (Courtesy of Tom Hellebuyck.)

Cultured bacteria and fungi from skin lesions, especially superficially, do not always represent the primary causative agents as contamination from the environment, together with secondary infection, can complicate the picture. Moreover, relatively little is known concerning the normal microbiota of reptile skin and adnexa.[31,32] The correct selection of dermal sampling sites and methods may facilitate the selection of clinically important bacterial and fungal isolates (Fig. 69.23).[29] In addition, the identification of microbiological agents should always be correlated with the results of other tests (e.g., hematology, cytology, and histopathology).

Dermatology—Shell

Jean Meyer and Paolo Selleri

Chelonian anatomy is unique as it contrasts with the anatomy of other tetrapods by encasing the shoulder girdle into the rib cage, providing an unprecedented way of protection. The exact evolutionary steps that lead to the formation of the shell are mostly speculative, as transitional forms of fossils are missing from the fossil record.

Four major index fossils are the basis for the tentative decryption of the evolution of the chelonian body plan: *Eunotosaurus* (260 million years [myr]), *Pappochelys* (240 myr), *Odontochelys* (220 myr), and *Proganochelys* (214 myr). The first three taxa share the common feature of craniocaudally broadened ribs and elongated trunk vertebrae, shortening the trunk to nine dorsal vertebrae.[1,2] The axial arrest of the dorsal ribs (see also Embryonic Development of the Shell) can be demonstrated in *Odontochelys*, going hand-in-hand with the incorporation of the clavicle and interclavicle into the plastron. The final encapsulation of the scapula within the shell, as well as the metaplastic ossification of the carapace and the presence of peripherals suggesting the formation of a carapacial ridge (see Rib Growth Mechanisms), are the most striking features of *Proganochelys.*[3] Broadened gastralia in *Pappochelys* might be at the origin of a fully developed plastron that is already present in *Odontochelys*. Fossils of *Odontochelys* and *Proganochelys* demonstrate that their shells were already covered by scutes.[2]

ANATOMY

The chelonian shell consists of the dorsal convex carapace and the ventral flatter plastron. The carapace and the plastron are usually rigidly joined laterally by the bridge formed by the conjunction of lateral extensions of the carapacial and the plastral bones (plastrocarapacial bridge).

Embryonic Development of the Shell

The mechanisms involved in the embryonic development of the chelonian shell are a source of numerous debates and are still not completely resolved. Chelonian anatomy is unique as it contrasts the anatomy of other tetrapods by encasing the shoulder girdle into the rib cage. Two main different hypothetical approaches to the development of this topographic peculiarity are proposed. The first emphasizes the role of the growth pattern of the ribs, which leads to roofing of the shoulder girdle and thus enclosing it into the rib cage,[4–7] whereas another approach is based on evolutionary morphologic changes in the shoulder girdle itself, being independent of specific alterations in rib growth.[8]

Rib Growth Mechanisms

To elucidate the former theory, new investigational strategies are warranted by a multimodel approach using immunohistochemistry and genetic analysis. These sophisticated methods permitted to demonstrate that the rib growth patterns differ between studied hard-shell (red-eared slider turtle, *Trachemys scripta elegans;* Reeve's pond turtle, *Chinemys reevesii*; loggerhead sea turtle, *Caretta caretta;* snapping turtle, *Chelydra serpentina*) and softshell (Chinese softshell turtle, *Pelodiscus sinensis*) chelonians. Both groups share two common features in embryonic development: First the formation of a carapacial ridge (CR) bilaterally along the flanks extending craniocaudally between the limb buds (Fig. 70.1) and second the flabellate primaxial growth of the ribs, which in contrast to other vertebrates do not grow ventrally to encompass the viscera but enter into the dermis and extend over the pectoral and pelvic girdle. The CR is a unique structure in vertebrates and seems to influence rib growth by two different strategies. In hard-shell turtles, rib precursor cells seem to be attracted by means of paracrin signaling pathways to the CR. This model shows some evidence that fibroblast growth factors (FGF) secreted by CR cells lead to migration of the rib precursor cells laterally through the muscle plates. The developing ribs extend centrifugally in a peripheral direction. Reaching the CR mesenchyme, their tips fold beneath the ridge and ultimately unite with the peripherals, taking shape in the CR at the periphery of the shell. In softshell turtles, by contrast, no FGF could be demonstrated immunohistochemically in the CR area. Furthermore, rib growth is characterized by "axial arrest" hypothetically promoted among other factors by the CR.[5] The ribs are subjected to ossification early in the development, impeding further longitudinal growth. In these turtles, the carapacial disc is likely to grow independently of the ribs, leading to an inward

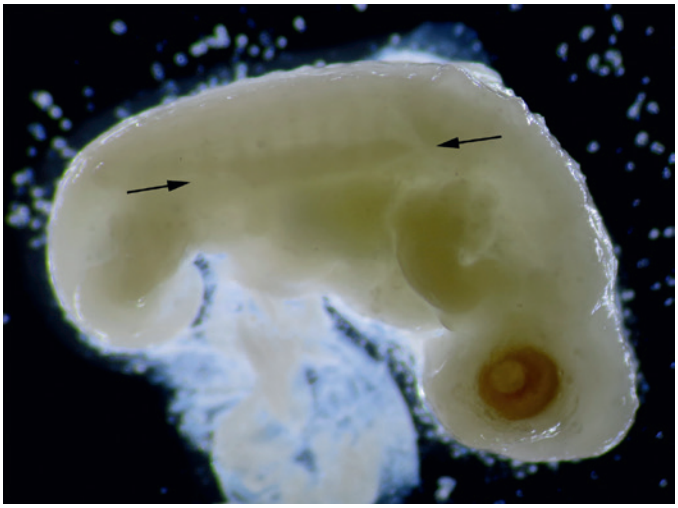

FIG 70.1 Carapacial ridge in a *T. hermanni* embryo, extending between the limb buds in craniocaudal direction (between the arrows). (Courtesy of Jean Meyer.)

folding of the lateral body wall thus enclosing the shoulder girdle in the carapace. A number of studies aimed at deciphering the genetic basis for the axial arrest of rib growth but demonstrated missing similarities in the expression of these genes between different turtle species.[9–12] However, again, differences between softshell turtles (*P. sinensis*) and hard-shell turtles (*T. scripta, E. orbicularis*) could be highlighted.

Formation of the Solid Carapace

Rib growth alone is insufficient to elaborate a solid carapace. Further ossification is necessary to fill in the gaps between the ribs and form the interdigiting plates. Putatively, two different mechanisms find their expression depending on whether the turtle develops a hard or a soft shell.[4] Hard-shell chelonians rely on exo- and endoskeletal ossification. Formation of the shell starts with small bony protrusions budding in cranial and caudal directions from the periosteum surrounding the ribs (Fig. 70.2). It is suspected that bone morphogenic proteins (BMPs) are secreted by the ribs and induce metaplastic ossification of the surrounding intramembranous dermal cells, thus leading to formation of the dermal plates embedding the ribs. The overwhelming part of this process takes place after hatching. In softshell chelonians the growth of costal bony plates is rudimentarily concentrated to the area close to the vertebrae and seems to be solely derived from extensions of the periosteum of the ribs.[5] The unique plywood-like arrangement of bony crystals in the cortex of the shell of *Trionychids*[13] might have its origin in a new bone formation modality in soft shells, which still needs to be elucidated.

Formation of the Plastron

In hard-shell chelonians the plastron is composed of nine bony plates, which develop by dermal ossification.[14] The ossification starts in nine separate ossification centers, which grow in the direction of the midline and form long spicules. As the hatchling grows, these spicules cross the midline and interdigit without immediately fusing. Recent investigations on the origin of the plastral bones in red-eared sliders (*Trachemys scripta*) using immunohistochemistry suggests that they are derived from late emigrating populations of trunk neural crest cells.[15]

Development of the Scutes

The scutes overlying the dermal bone originate from local epithelial thickenings called placodes. Placode arrangement follows a pattern of somatic segmentations and is highly conserved throughout the taxa. They appear early during embryonic development, first at the carapacial ridge, followed by the costals and vertebrals on the carapace, and the peripheral plastral placodes.[16] The scutes grow radially and contiguously in the epidermis until they contact the adjacently forming scutes.[17–19] Scute growth is potentially governed by the expression of a number of genes for growth factors, and morphogenic proteins. Inhibition of these proteins lead to loss of scute placodes. The loss of epidermal scutes in softshell turtles may be owed to the evolutionary loss of these placodes.[19] Where scutes meet, a small furrow is formed, impressing a sulcus into the underlying bones thus reinforcing the cohesion of the shell structures. Of clinical importance, the location of the scute seams does not show a one-to-one conformance to seams of their bony counterparts (Fig. 70.3A and B).

FIG 70.2 Carapacial bony structure of an 8-week-old *T. hermanni*, showing the ongoing ossification of the carapace in caudal and cranial direction starting from the ribs. (Courtesy of Jean Meyer.)

Dermal Bones

The shell is in general formed by 58 bony plates (49 carapacial and 9 plastral) of dermal origin and covered by epidermal keratin scutes (see Fig. 70.3A and B). A large number of species- or family-specific variations exist.[20] The shapes and the size of the bone plates determine the overall cross-section and size of the shell, whereas the numbers stay relatively constant. The bony dorsal midline of the carapace covering the spine is formed by an unpaired row of up to 12 smaller neural bones. The most cranial bone of this row is called the nuchal, and the most posterior is the pygal. Interposed between the pygal and the last neural lies the suprapygal. On either side of the neurals the costals form the dome of the carapace and verge laterally on the peripherals, composing the outer ventral rim of the carapace. An odd number of bony plates form the ventral plastron with the unpaired entoplastron lying ventral to the pectoral girdle. The entoplastron may be absent in mud turtles (*Kinosternidae*). Cranial to the entoplastron the paired epiplastron shapes the cranial edge of the plastron. Posteriorly to the foresaid plates follow the paired hyoplastron, hypoplastron, and xiphiplastron, divided by a central seam. All bony plates of the shell are deeply interlocked by bony sutures. The leatherback turtle *Dermochelys coriacea*, as well as *Trionychidae*, shows a large variety of reductions of the ossified shell (see Plastral Pecularities in this chapter).

Scutes

The dermal bony shell is in general covered by keratin scutes or shields of epidermal origin. In softshell turtles (*Trionychidae*), the Fly River turtle (*Carettochelys insculpta*), and the leatherback turtle (*Dermochelys coriacea*), the scutes are completely reduced. The epidermal layer of hard-shell turtles generally consists of 38 carapacial and 16 plastral scutes (see Fig. 70.3A and B). The size and shape of these scutes do not show a one-to-one conformance to their bony counterparts and bear a divergent designation. The dorsal unpaired midline scutes are called vertebrals, lined on either side by the pleurals that are bound in turn by the marginals. Cranially, a cervical scute may be present. The absence or presence of the cervical may be one of the few distinguishing marks between the Indian star tortoise (*Geochelone elegans*) (absent) and the South African geometric tortoise (*Psammobates geometricus*) (present). On the plastron all scutes are paired with the gular or the intergular, being the most cranial, followed by the humerals, pectorals, abdominals, femorals, and anals in caudal direction. An axillary and inguinal scute lines the cranial and caudal rim of the bony bridge. Inframarginals are present between the marginals and pectorals and abdominals in all families other than *Trionychidae* and *Testudinidae*. Alligator snapping turtles (*Macrochelys temminckii*) may feature a row of supramarginals between pleurals and marginals. The seams, also called epidermal hinge regions, where the keratin scutes are joining do not line the bony sutures but in contrary indent into the dermal structures, reinforcing the shell structure (see Fig. 70.3A and B). Individual variations in scalation

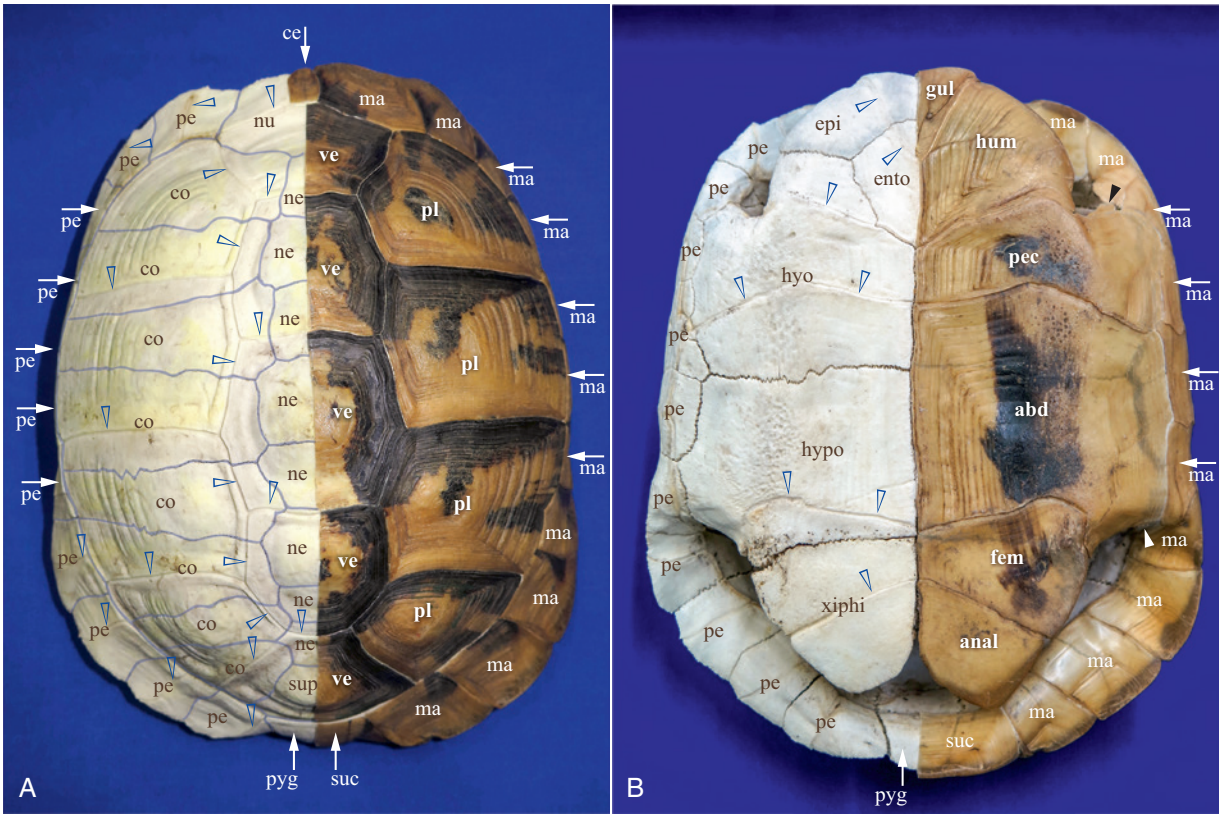

FIG 70.3 (A) Carapace of a *Testudo hermanni*, bones (left) and scutes (right). The bony sutures are highlighted with thin blue lines. are common and may on one hand be the result of impairments during ontogenetic development (see previous section, Embryonic Development of the Shell) and on the other hand represent morphologic variation. A number of publications deal with these variations in terms of localization and frequency in different genera.[21] Pigmentation and color patterns of the scutes may be characteristic for a certain species and even allow the gender differentiation in certain *Pseudemydid* species, where males gradually become melanistic with age.

Kinesis—Flexible Skeletal Hinges

Kinesis of the shell describes the development of a certain flexibility of the shell by means of skeletal hinges. These skeletal hinges allow either partial or total closure of the shell, thus enhancing its protective function, or facilitate oviposition if posterior plastral elements are involved. Plastral, carapacial, or pankinesis may be distinguished.

Plastral kinesis can be localized just cranially (e.g., *Pyxis arachnoides*), just caudally (e.g., *Homopus, Rhinoclemmys, Testudo* spp.), or at both ends by a transverse central hinge (e.g., *Terrapene, Cuora* spp.). The unique carapacial hinge in *Kinixys sp*. requires special anatomic adaptations like the replacement of peripheral bones by pliable soft tissue, a floating neural plate, and the transversal alignment of the lumbar bony sutures.[20] These specific anatomic features should not be mistaken for fractures.

A unique feature is the carapacial pankinesis of the Malayan softshell turtle *Dogania subplana*, which develops with maturity by breakdown of sutures[22] and should not be misinterpreted as progressive metabolic bone disease.

Fontanels

Fontanels are generally defined as membranous gaps between growing bony segments of the shell, thus allowing certain flexibility (Fig. 70.4). Fontanels may be extremely large in hatchlings of *Leucocephalon yuwonoi* and *Heosemys spinosa* or completely absent in the side-necked turtles of the family *Pelomedusidae*. During growth, the gaps decrease in size and become completely ossified. Pritchard describes the enormous variability of these fontanels.[20] In the south East Asian genus *Batagur,* males will retain lifelong large porthole-like structures in the ventrolateral aspect of the costal bone plates. These can be used for ultrasonographic, endoscopic, or surgical approaches.

Plastral Peculiarities

The plastron may be reduced to a cross-shaped entity (e.g., *Macrochelys*, *Chelydra*, *Sternotherus*, *Staurotypus*, *Claudius* spp.), enhancing the range of motion of extremities as well as of their large head and neck. Another form of plastral reduction is the arrangement of the plastral bones in the form of a ring, leaving a central soft-tissue window as in the pancake tortoise (*Malacochersus tornieri*). A flexible nonossified midline opening in the plastron is also present in hard-shelled marine turtles and *Trionychidae*. The latter present additional features in the form of intermembranous sesamoid bones in addition to the regular plastral bones.

VetBooks.ir

FIG 70.4 Bony plastron of an 8-week-old *T. hermanni*. Growth of the bony plastron is starting at the periphery during late embryonic development. A fontanelle in the center of the plastron is still present at hatching. (Courtesy of Jean Meyer.)

In the leatherback turtle (*Dermochelys coriacea*) the plastron is vestigially reduced to a very narrow ossified ring structure. Ventral soft tissue windows are often present in the form of fontanels in juvenile specimens of most chelonians. Plastral reductions facilitate endoscopic or surgical approaches to the coelomic cavity.

PHYSIOLOGY

Scute Growth

The scutes are produced by the corneous epidermis covering the dermal bone. In the Hermann's tortoise (*Testudo hermanni*), scute growth mainly occurs in the hinge region where neighboring scutes adjoin each other forming a visible seam. During the growing season, beta-keratin–producing cells proliferate at the epidermal hinge region and form a thick new corneous layer, which becomes visible as a growth ring.[17,18] In *Chrysemys picta* the scute is growing along the whole surface, producing beta-keratin during the growing season and a thin layer of alpha-keratin in late fall, shortly before hibernation. When resuming growth in the following spring, new beta-keratin layers are produced underneath the alpha-keratin layer. The latter will serve as a scission layer, allowing shedding of the outer, older scute. It takes corneocytes 5 to 9 days to migrate from the base to the outer surface.[18] In *Graptemys* spp. the transition between epithelium and keratin is abrupt and lacks a discernable cornification zone.[23] In softshell turtles (*Trionychidae*) where dermal scutes are absent the body armor is guaranteed by a leathery dermis. The dermis consists of highly ordered plywood-like arrangements of collagen fiber bundles, which even find their reflection in the inner zone of the outer cortex of the underlying lamellar bone.[13] This plywood-like pattern of skin and bone reduces the weight of the shell and provides an outstanding biomedical stability and flexibility.

Scutes and Age Determination

The growth cycle of the keratinous scutes reflects metabolic conditions of the turtle. The resulting ring pattern, which is most obvious in species from temperate regions, may temptingly be used for age estimation. A literature survey[24] based on 145 publications dealing with this subject concludes that aging turtles by counting their rings is generally inaccurate but might be useful in some species, at some locations, up to a certain age. Scute surfaces are worn off superficially depending on environmental conditions, leading to erroneous results. In many aquatic species, an alpha-keratin layer is produced regularly between the normal beta-keratin layers. The superficial scute is shed along this scission layer, leaving a smooth outer surface.

Sexual Dimorphism

In general, females tend to grow larger than males and have a more vaulted carapace in order to host the produced clutch. In many chelonians, the concavity of the plastron is gender related, with males showing a greater concave curvature to accommodate the caudal aspect of the female's carapace during mating. Increased kinesis of the posterior end of the plastron aiding in oviposition is present in a number of species (e.g., *Rhinoclemmys, Testudo, Homopus, Leucocephalon* spp.). In male bowsprit tortoises (*Chersina angulata*) and African spurred tortoises (*Geochelone sulcata*) the epiplastron is impressively elongated cranially and aids in courtship fights. Fontanels may be retained for longer periods in female *Graptemys* spp. when compared with males.[20]

Role of the Shell in Anoxia Tolerance in Freshwater Turtles

During long-term submergence (hibernation), freshwater turtles are accumulating high concentrations of lactic acid. The shell acts as a buffer reserve by uptaking lactic acid in exchange with carbonates and bicarbonates. Interspecific anoxia tolerance differences exist with *Chrysemis picta* and *Chelydra serpentina* being more tolerant than *Stenotherus odoratus*, *Graptemys geographica*, and *Trachemys scripta*.[25] During submergence at 5°C, an alpha-adrenergic vasoactivity regulating the blood flow to shell and liver is evident.[26]

CLINICAL DISEASES

Scute Anomalies

Clinical Significance and Known Etiological Cause(s). These anomalies typically represent morphological variations without pathologic significance. The anomalies result from a developmental disruption of the embryonic arrangement of the placodes (see Embryonic Development of the Shell). The tessellation pattern of the keratinous scutes is well-conserved phylogenetically but is subject to significant individual variability.[27,28] The highly variable scutation in olive loggerhead sea turtles (*Lepidochelys olivacea*) opposes the determination of an exact number of scutes. A genetic determination of developmental anomalies could not be ascertained. The disruption of signaling pathways in early morphogenesis leads to a loss of the normal segmented distribution of scute primordia.[19] Environmental factors like high temperatures, desiccation,[29] and pollution[28] are hypothesized triggers to scute anomalies. The most frequent anomaly is the presence of supernumerary scutes. Their formation may be triggered by altered distances between placodes, resulting in vacant areas where supernumerary scutes form.[16]

Clinical Presentation, Treatment, and Prevention. Clinical presentations may include supernumerary scutes, missing scutes, or abnormal scute shapes due to the fusion of adjacent scutes. No therapy is indicated, but prevention includes the correction of unfavorable environmental conditions.

Ankylosis—Distorted Growth

Clinical Significance and Known Etiological Cause(s). Ankylosis is defined by the closure of bony sutures, thus impeding further growth. This may be generalized and physiological during the aging process in a number of species (e.g., *Terrapene*, *Cuora*, *Batagur*, *Callagur*, *Kachuga*,

VetBooks.ir

Dermatemys, and *Kinyxis*).[20] Irregular growth of bony plates is a common feature in chelonians. They mostly pose a cosmetic problem and may only lead to health concerns if the shape of the shell is substantially deformed, impairing organ function (especially breathing) and interfering with limb and neck movement or oviposition due to narrowing of the cranial or caudal shell.

Scoliosis, kyphosis, and lordosis or combinations thereof are rare conditions in chelonians and might reflect unfavorable conditions during incubation (humidity, dessication, temperature), or dietary and ambient inadequacies after hatching. Abnormalities in growth may be partly genetically based or a result of trauma in the pre- or post-hatching stage (see also Embryonic Development of the Shell). Severe scoliosis, kyphosis, and lordosis (impinging on spinal cord) can result in rear-limb paresis and chronic or acute prolapse of colon, cloaca, oviduct, and phallus. When ankylosis is confined to single suture areas of the growing shell, distortions of the carapace may result, as adjacent areas pursue their normal development. Trauma or developmental abnormalities may lead to premature ankylosis (see Chapter 113, Fig. 113.7b).

Clinical Presentation and Treatment. Irregular disproportionate growth, or distortions of carapace and plastron, are usually obvious. Surgical therapy is warranted if dystocia might result. In the early stages of deformation, dental expansion screws can be glued between the caudal carapace and plastron on either side of the cloaca to allow gradual widening of the caudal shell opening. Ovariectomy would also be an option to prevent dystocia.

Pyramiding

Clinical Significance and Known Etiological Cause(s). Pyramidal growth of the shell describes a condition characterized by the humped appearance of the carapace. This is physiological in the tent tortoise (*Psammobates tentorius*) but is pathological in most other tortoise species. The humps are the result of trabecular bone thickening between the inner and outer bone cortices of the shell. Scutes remain thin and just outline the dorsal shape of the bones. Pyramiding is usually a cosmetic problem if not accompanied by distorted growth (see Ankylosis—Distorted Growth) but does indicate captive mismanagement.

Many factors have been implicated in the cause of these changes: high dietary protein, inappropriate dietary calcium:phosphorus ratios, improper UV lighting, elevated temperature, low dietary fiber. or simple overfeeding. Research in African spurred tortoises (*Centrochelys [Geochelone] sulcata*) has indicated that low humidity appears to play a crucial role in the development of pyramidal growth. At higher humidity levels, the tortoises produced significantly smoother carapaces.[30] Dietary protein had only questionable influence when combined with dry ambient conditions. The underlying pathologic mechanisms remain hypothetical and abide their histologic elucidation. It is theorized that during dry seasons the intra- and intercellular pressure in growth zones is reduced by dehydration and that the tissues are ossified in this collapsed condition. In captive-raised leopard (*Stigmochelys pardalis*) and African spurred tortoises, the application of supplemental nocturnal heat can lead to increased growth rates and pyramiding.[31]

Clinical Presentation, Treatment, Prognosis, and Prevention. Clinically the carapace displays multiple humps or dorsal projections. Once formed, the deformed pyramid shaping is irreversible. Deficiencies in husbandry, especially low humidity, high nocturnal temperature, and diet should be corrected.

Softening of the Shell in Juvenile Herbivorous Tortoises

Clinical Significance and Known Etiological Cause(s). Described in juvenile *Testudo hermanni, T. graeca, T. marginata, Geochelone elegans, Geochelone pardalis*, pathology has been demonstrated in association with picornavirus infections, although adults may test PCR positive but appear healthy.[32] Cryptosporidiosis, *Balantidium*, and *Hexamita* spp infestations have also been reported in association with softening of the shell.[33,34] Picornavirus infections and *Hexamita* infection are often seen in conjunction with nephropathy leading to renal secondary hyperparathyroidism and osteodystrophy. Metabolic bone diseases of other origins must also be considered as differentials.

Clinical Presentation and Diagnostic Confirmation. Hatchlings thrive well up to the age of 6 to 8 weeks, when they start to present with signs of rhinitis, conjunctivitis, and anorexia, paired with translucency of the grayish plastron. The gallbladder may become visible as a dark spot on the right side, and there is progressive softening of the entire shell (Fig. 70.5). Pharyngeal swabs (for picornavirus PCR), fecal evaluations (for *Cryptosporidium* and *Balantidium*), and urinalysis (for *Hexamita*) are recommended. Postmortem examinations may permit picornavirus isolation from liver, lung, kidney, spleen, heart, brain, tongue, and intestine.

Treatment, Prognosis, and Prevention. Supportive care (fluid therapy, nutritional support) is the mainstay of therapy. In animals that present with distended bladders (that can cause ventilator compromise), catheterization and voiding the bladder can be beneficial. Prognosis is guarded. Quarantine and strict barrier nursing of affected animals are recommended.

Secondary Hyperparathyroidism (Metabolic Bone Disease)

Clinical Significance and Known Etiological Cause(s). Commonly seen in animals maintained indoors or in conjunction with improper dietary management (e.g., calcium deficient diets, unsuitable dietary Ca:P ratios, lack of UVB light exposure), or less commonly as a sequela to chronic liver and/or kidney failure.

Clinical Presentation and Diagnostic Confirmation. Softening of the shell and humped or distorted growth are common clinical presentations. (Fig. 70.6). Often there is collapse of the caudal carapace due to

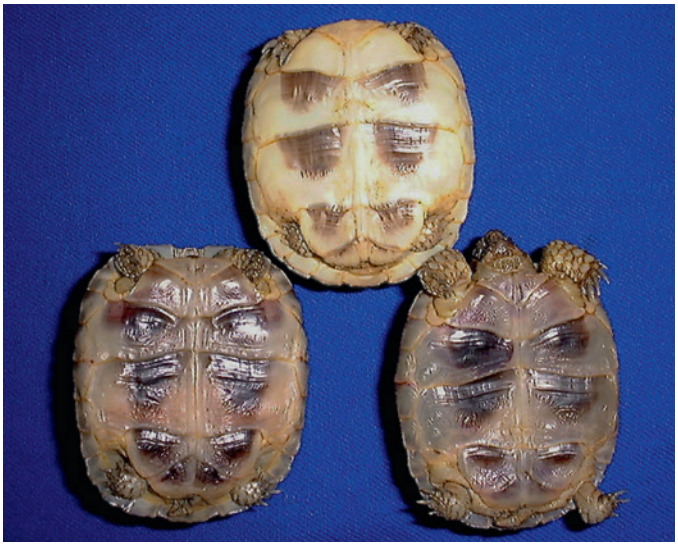

FIG 70.5 Softening of the shell of juvenile *Testudo graeca*, resulting from a picornavirus-induced nephropathy. Healthy clutch mate (*above*); affected animals with translucent shell (*below*) due to osteodystrophy. (Courtesy of Jean Meyer.)

FIG 70.6 Nutritional secondary hyperparathyroidism in a young *Testudo hermanni*. Note the pyramiding and the collapse of the caudal carapace. The nails are overgrown due to the abnormal gait. (Courtesy of Paolo Selleri.)

hind limb muscles pulling on their insertion points at the caudodorsal aspect of the carapace. These severe shell distortions may result in scoliosis, kyphosis, and lordosis (impinging on the spinal cord), causing rear limb paresis and chronic or acute prolapse of colon, cloaca, oviduct, and phallus. Additionally, dystocia may result. Survey radiographs typically reveal generalized reductions in skeletal opacification, consistent with demineralization. Total plasma calcium tends to only decrease late in disease progression, while ionized calcium tends to remain stable until the terminal stages. Elevations in phosphorus may also occur. Hypovitaminosis D_3 (25-hydroxy-cholecalciferol) assays are commercially available (Heartland Assays, Ames, IA) and decreases confirm UVB light deficiency.

Treatment, Prognosis, and Prevention. Therapy usually includes oral or parenteral calcium therapy, diuresis, and phosphate binders, but the mainstays are environmental and dietary improvements. (See Chapter 84 for more details.) Prognosis is good to poor depending on the stage of disease at which animals are presented and whether hepatic/renal failure is involved in the pathogenesis. Carapacial deformations are irreversible. Appropriate environment (especially UVB light and thermal provision) and diet are usually the best preventive measures.

Bacterial Shell Dermatitis/Osteomyelitis (Including Septicemic Cutaneous Ulcerative Disease)

Clinical Significance and Known Etiological Cause(s). Lesions of the carapace and the plastron have been historically termed "septicemic cutaneous ulcerative disease" (SCUD) or "shell rot" and are quite common in chelonians.[35] Although this condition is suspected of being of bacterial etiology,[36] few bacteria have been reported to be primary causative agents. In early reports of SCUD, the original causative agent was identified as *Escherichia freundii* (currently *Citrobacter freundii*); however, despite extensive clinical investigations, the primary cause of dermatitis and osteitis in chelonians often remains undetermined,[37–39] and currently SCUD is considered more as a syndrome associated with various bacteria, rather than a single obligate pathogen. In a study in which 19 bone biopsies were obtained from map turtles with shell lesions, six samples yielded aerobic isolates (*Chryseobacterium indologenes*, *Aeromonas hydrophila*, *Ralstonia pickettii*, and *Morganella morganii*), whereas 11 samples yielded various clostridial anerobes[23]; however, it was unclear if the bacteria were the cause of lesions.[23] In a zoologic collection, the gram-negative bacterium *Beneckea chitinivora* resulted in an outbreak of ulcerative shell disease in sliders, musk turtles, softshell turtles, side-neck turtles, and painted turtles.[40] *Serratia* may allow other bacteria (e.g., *Citrobacter freundii*) to invade tissues due to its lipolytic and proteolytic activity.[41] Generalized *Mycobacterium kansasii* infection may result in white carapacial lesions.[42]

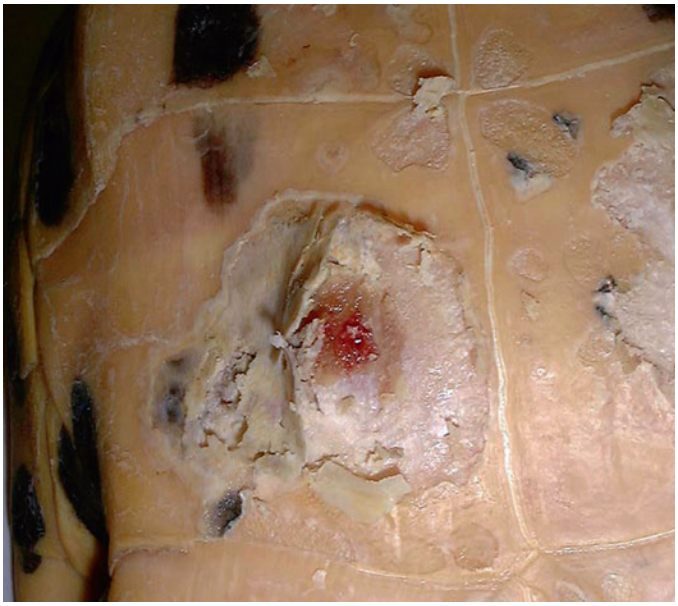

FIG 70.7 Deep ulcerative shell lesion on the plastron of a *Trachemys scripta*. *Aeromonas hydrophila* was cultured from freshly exposed tissue of the debrided lesions. (Courtesy of Jean Meyer.)

Clinical Presentation and Diagnostic Confirmation. Cutaneous lesions of the shell often penetrate through the keratin layer into the underlying bone, resulting in dermatitis and osteomyelitis (Fig. 70.7; Fig. 70.8a and b). Presumptive diagnosis is based on clinical appearance, but definitive diagnosis requires shell biopsy for microbiology (bacterial and fungal cultures) and histopathology.[23] Shell biopsies should be collected under general anesthesia using a bone trephine, preferably with fine teeth to reduce crushing artefacts of the biopsy samples. Dilute chlorhexidine may be used for mild antiseptic preparation of the biopsy site.[23] Obtained samples are to be submitted for microbiology and histology to evaluate the involvement of the cultured microorganisms in the shell pathology. The biopsy sites are closed with methylmethacrylate containing bone cement. As a more objective means to quantify shell lesions, a shell scoring system has been developed that divides the 54 scutes into six regions, with each region scored for lesion extent and severity and summated to produce a total shell disease score (TSDS).[23] The plastron is divided into three scutal regions, with the first including the gulars, humerals, and pectorals; the second being composed of the abdominals; and finally the third caudal region encompassing the femorals and anals. The carapacial regions are formed by a peripheral region containing all marginal scutes, the second region comprising the eight pleurals, and the third consisting of the vertebral scutes. A regional shell disease score is calculated by multiplying the regional score for the extent of the visible lesions (0 = absent, 1= minor [occupying <10% of the region], 2 = moderate [10%–50%], 3 = severe [>50%]), with a regional shell disease score for the severity of the lesions (0 = no lesion; 1 = superficial, only involving the keratin layer; 2 = intermediate, involving keratin and partial bone; 3 = deep, involving keratin and full thickness bone). The TSDS is calculated by adding all six regional scores.[23] The TSDS allows an objective evaluation of the extent and severity of shell lesions in relation to general body condition or other biometric data as hematology and biochemistry results.

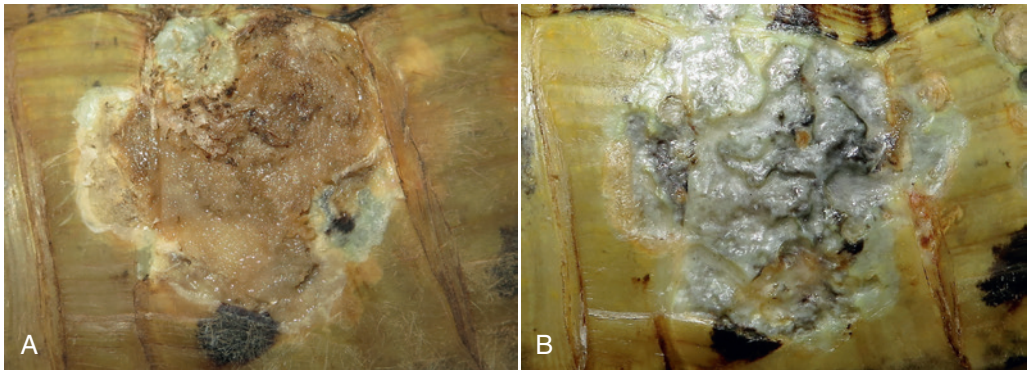

FIG 70.8 (A) Subscutal dermatitis and osteomyelitis (overlying scutes have been removed in the course of debridement). *Sphingobacterium mizutani, Brevundimonas diminuta, Corynebacterium* sp., and the fungus *Metarhizium anisopliae* were isolated from the necrotic bony material. (B) Progression was stopped by debridement followed by local antibiotic and antifungal treatment based on sensitivity testing. Beginning keratinization of the ingrowing epidermal surface is visible. The physiological color pattern of the scutes will not be restored. (Courtesy of Jean Meyer.)

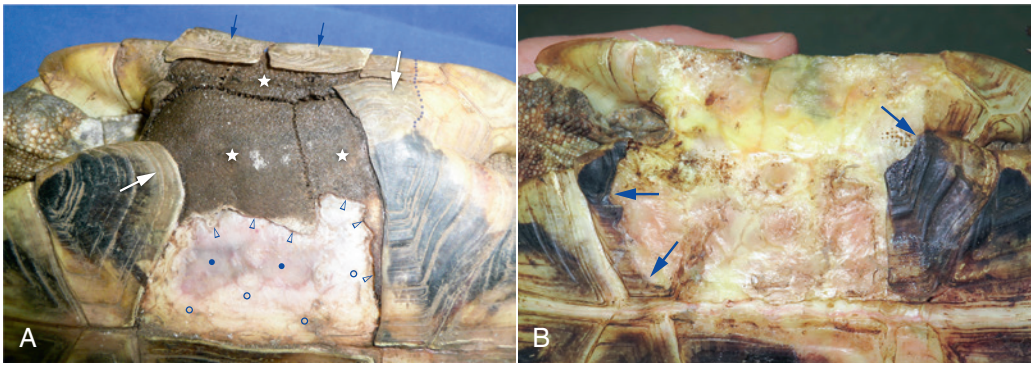

FIG 70.9 (A) Healing stages of a necrosis of the plastron in a tortoise. Detachment of the scutes (blue arrows). Subscutal bony necrosis visible through discoloration (white arrows). Scutes should be left in place and may be cut back to the dotted line. Bony necrosis (stars) and demarcation (blue arrowheads). Thickening of the semitranslucent soft coelomic membrane (blue dots). Fibrosis with subsequent calcification of the coelomic membrane (blue circles). (B) Same tortoise as in (A), but 1 year later. Well-calcified and keratinized solid scar tissue. Scutal definiton and colorization is lost. Old scutes were cut back to the level of intact contact with the epidermis (blue arrows). They should never be entirely removed if only margins detach from the epidermis. (Courtesy of Jean Meyer.)

Treatment. Treatment usually includes surgical debridement, dry docking aquatic species, bandages, and topical and systemic antimicrobials based on culture and sensitivity testing. Treatment of shell ulcerations using photopolymerizable nanohybrid composite appears to prevent relapses and allows faster return of aquatic turtles to their environment.[43] Low-level laser (photobiomodulation) therapy may also be used. We suggest two different approaches based on the severity of the disorder.

Fresh-contaminated wounds should be copiously flushed with antiseptic solutions (e.g., Nolvasan, Zoetis, Octenisept, Schülke & Mayr, Prontosan, Braun). Care must be taken that these solutions do not enter the body cavity through perforating bony lesions. Minor debridement can be achieved by the use of tooth brushes and wet-to-dry dressings. Fresh superficial wounds should be bandaged and changed daily. Silverdiazine cream or povidone-iodine containing ointments can be used on wounds. Exudative lesions benefit from absorptive dressings (e.g., Melolin, Smith & Nephew, UK). The wounds typically heal by second intention, and systemic antimicrobial therapy is seldom required.

Contaminated-infected wounds require more radical debridement, under general anesthesia with appropriate analgesia, using scalpel, dental units and descalers, bone burrs, or Dremel-type rotational hobby tools. The use of water-cooled systems prevent thermal damage and aid in flushing contaminated material. Swabs or tissue biopsies taken from freshly exposed, infected areas will give the most reliable culture results. Wet-to-dry dressings will help with further debridement. Filling the thoroughly debrided and disinfected areas with dental composite may promote healing in aquatic species.[43] Antibiotic treatment should be based on gram stains initially and subsequently culture and sensitivity testing. Metronidazole or ceftazidime should be considered where anaerobes are suspected or confirmed. The use of vacuum-assisted wound closure with silver impregnated bandaging materials promotes faster healing.[44] Deep-shell necrosis with substantial loss of bony shell will heal by metaplastic calcification of the coelomic membrane and subsequent keratinization of the ingrowing epidermal surface (Fig. 70.9A and B).

Prognosis and Prevention. Prognosis is dependent upon severity, nature of the pathogen(s) involved, and response to treatment. Prevention relies on proper management. Anecdotally, high humidity, low temperatures, poor nutrition, under-floor heaters, and traumatized skin or shell tend to be predisposing factors for the development of shell infections.[36]

Mycotic Shell Dermatitis/Osteomyelitis (Including White Spot Disease in Softshelled Turtles)

Clinical Significance and Known Etiological Cause(s). Fungal infections of the shell resulting in white or pale discoloration (e.g., "white-spot disease" in softshelled turtles) are not uncommon and are often secondarily infected with various bacteria.[45] Softshelled turtles artificially infected with the zoospores of *Aphanomyces sinensis* showed the typical whitish maculae on the carapace and high mortality.[45]

A ubiquitous saprophytic mold, *Purpureocillium lilacinum (Paecilomyces lilacinus)*, was the etiological agent of hyalohyphomycosis, characterized by white to gray spots on the carapace, plastron, and skin, diagnosed in Chinese softshelled turtles (*Pelodiscus sinensis*)[46] and Fly River turtles (*Carettochelys insculpta*).[47] In 1996 an *Aphanomyces* sp. infection was diagnosed as being responsible for white, cottonlike lesions in two juvenile softshelled turtles (*Pelodiscus sinensis*).[48] Mucormycosis has been described in softshelled turtles in Japan and in the United States.[49,50] White papular carapacial lesions could also be seen in conjunction with a generalized *Mycobacterium kansasii* infection and should be considered as differential.[42]

Clinical Presentation and Diagnostic Confirmation. Lesions are typically characterized as white to gray cottonlike spots or discolorations on the carapace, plastron, and skin. Diagnosis is confirmed by biopsy for fungal culture and histopathology, although secondary bacterial infections are common, and concurrent bacterial culture is also recommended (see Fig. 70.8A and B).

Treatment, Prognosis, and Prevention. Several antifungal treatments are reportedly effective. Hyalohyphomycosis has been successfully treated in Fly River turtles with 0.038% malachite green and 4.26% formaldehyde dips (Rid Ich+, Kordon, Hayward, CA), 0.15 mg/L for 15 minutes, twice a day, in combination with systemic itraconazole therapy at 10 mg/kg PO every 48 hrs for 20 days.[47]

Prognosis is generally guarded. In a mucormycosis outbreak affecting approximately 400 Florida softshell turtles showing circular gray integumentary lesions, death rate exceeded 50%.[50] However, timely treatment with topical and systemic therapy (i.e., described in the medical therapy previously), clinical resolution has been obtained.[47] Fungal overgrowth may develop as a consequence of indiscriminate, broad spectrum antibiotic use and may be favored by certain anatomic characteristics (e.g., the peculiar carapace of softshelled turtles (see previous discussion on scute growth) and by compromised immune functions due to inappropriate thermal provision, poor hygiene, or high population density.[45,46] Different species of fungus have different growth characteristics. The fungus *Aphanomyces* sp. found in two juvenile softshelled turtles had optimal growth at a temperature of 30°C, while the fungus *Aphanomyces sinensis* had maximal growth at 25° to 30°C and between pH 6–9, and mycelial growth declined and ceased at incubation temperatures of 35° and 40°C, respectively.[45,48]

Dyskeratosis in Tortoises

Clinical Significance and Known Etiological Cause(s). Shell dyskeratosis has been described worldwide in a number of species, including Texas tortoises (*Gopherus berlandieri*) and Mediterranean tortoises (*Testudo* sp.).[51,52] In Texas tortoises, *Fusarium semitectum* is responsible for characteristic lesions of the carapace and plastron.[52] The pathogenicity of *F. semitectum* was confirmed by isolation from affected individuals and cultivation in keratin-enhanced agar.[51] Hyalohyphomycosis by *Acremonium strictum* and *F. semitectum* caused whitish areas and fissures in the plastron and to a lesser extent on the plastrocarapacial bridges of nine privately owned Hermann's tortoises.[52] Cultures of soil samples from the garden where the animals lived also yielded *F. semitectum.* In an adult male Aldabra tortoise (*Aldabrachelys gigantea*), phaeohyphomycosis due to *Exophiala oligosperma* was responsible for a deep flaking area of the carapace.[53]

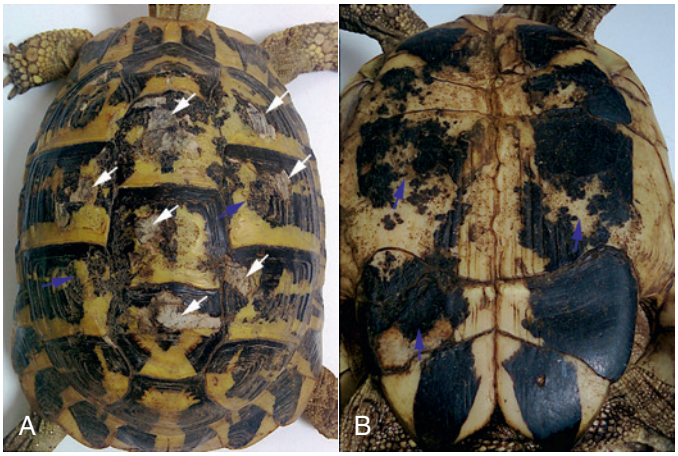

FIG 70.10 Dyskeratosis in an adult Hermann's tortoise (*Testudo hermanni*). Notice the different stages of alterations of several scutes on the carapace (A) and on the plastron (B) (loss of scute cover, white arrows; recornification, blue arrows). (Courtesy of Paolo Selleri.)

Clinical Presentation and Diagnostic Confirmation. Shell dyskeratosis lesions may be small, affecting a single scute, or extensive white blemishes affecting most scutes, in various stages of necrosis.[51] Fungal infections of the carapace typically result in corrosion of the epidermal lamellae of the scutes and scute sloughing (Fig. 70.10). Whitish blemishes may develop on the keratinaceous epidermal scutes (epidermal lamellae) that overlay the bones, such that the affected areas of the carapace appear whitish.[51]

Fungi may be diagnosed by culture or PCR. The degree of deep-bone involvement may be assessed through histological examination and nuclear scintigraphy bone scanning.[53]

Treatment, Prognosis, and Prevention. Treatment includes weekly debridement of the lesions and oral and topical antifungal agents with appropriate bandaging. In captive individuals, changes in management (e.g., improving substrate, sun exposure, and hygiene in the environment) and soil disinfection have been suggested.[52] Lesions typically resolve over several months.[53]

Dyskeratosis caused by *F. semitectum* is usually self-limiting although may result in corrosion of most of the carapacial scutes. Other fungal diseases (e.g., phaeohyphomycosis by *E. oligosperma*) may progress and spread to numerous sites on the carapace with severe deep-bone involvement. Systemic mycoses involving visceral structures have the worst prognosis. Because this disorder is caused by ubiquitous fungus, proper management of chelonians (e.g., avoiding excessive humidity, poor hygiene) may prevent the infection.[52]

Burns

Clinical Significance and Known Etiological Cause(s). Defective under-floor heaters and heating lamps might expose captive chelonians to hyperthermia, leading to various degrees of tissue damage of the plastron or carapace. Knocked over heating devices are prone to causing fire in shelters and entrapping the animals therein. In the case of blazes, free-ranging tortoises tend to seek shelter by digging into the ground and often incur carapacial burns.

Clinical Presentation and Diagnostic Confirmation. The keratinous scutes of the shell resist overheating or open fire to some extent, and

VetBooks.ir

affected tortoises might, at first glance, appear unharmed. As the heat destroys the underlying epidermis, scutes will start do detach at the thinner scutal seams days or weeks after the insult. Mild exudation may be initially seen at the scutal margins, which will dry up in the course of the disease process. Affected scutes should not be removed immediately as they often remain well attached in the center where the keratinous layer is thickest and heat damage to the underlying epidermis less pronounced. In chelonians exposed to open fires, smoke intoxication may result in respiratory distress with excessive salivation.

Treatment, Prognosis, and Prevention. Intensive supportive care with IV fluids, analgesics (e.g., Hydromorphone 0.5 mg/kg q 24 h) and nutritional support is vital. Radical debridement of loosening scutes is contraindicated, painful, and might result in substantial bleeding. In the course of the healing process, curved-up scute margins can be cut or debrided to prevent accumulation of devitalized tissue (Fig. 70.11). Infestation with fly larvae below the detached scutes must be prevented by bandaging the affected shell areas and/or by keeping the affected animals in pest-free environments. A combination of systemic and local antibiotic treatment is preferred, as systemic antibiotics alone might not reach peripheral sites with poor blood supply. Fungal overgrowth on necrotic tissues is a common sequel and must be treated with topical antifungals (e.g., Terbinafin ointment). Systemic antifungal drugs tend not to reach minimal therapeutic concentrations in the damaged tissues. Where scutes detach, granulation occurs and will subsequently keratinize. This tissue will not resemble a regular scute in contour or color. In deep burns, new bone will form below, and the necrotic tissue may take years to completely slough (see Fig. 70.9A and B).

Prognosis is good to poor depending on the degree and extension of burns and smoke intoxication. Financial implications of prolonged recovery and ongoing veterinary care should be considered. Fire detection devices should be installed in reptile areas with electrical heaters. Heating lamps and their installation must meet electrical and fire control regulations.

Frostbite

Clinical Significance and Known Etiological Cause(s). The exposure of parts of the body to freezing temperatures causes frost damage to the skin and peripheral tissues. This happens periodically when animals are hibernated under natural/outdoor conditions. Irregular stratification of the soil with interposed layers of stones and gravel might impede the digging efforts, causing hibernation too near the surface. At very low temperatures the dorsal carapace will undergo vascular and cellular injury.

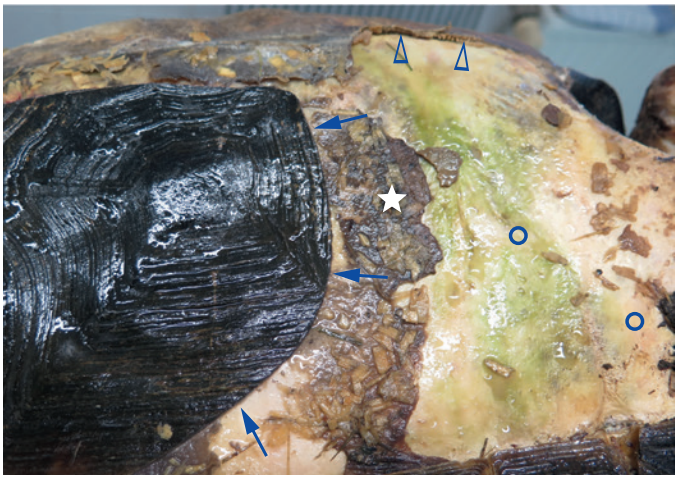

FIG 70.11 Deep burns on the plastron of an *Aldabrachelys gigantea*. The margins of the scutes detach as the underlying epidermis suffered a thermal necrosis (star). Scute margins are cut back (blue arrows). As necrotic bone is demarcated (arrowheads), scar tissue (circles) is formed underneath. The greenish tinge resulted from fecal material trapped below detached scute margins. (Courtesy of Jean Meyer.)

Clinical Presentation and Diagnostic Confirmation. Clinical signs of anorexia and ecchymosis of the shell, often paired with other nondermatologic presentations (e.g., pneumonia, rhinitis, cataracts, corneal opacities) are the main reasons for the owner to seek veterinary assistance. Because no specific diagnostic test for frostbite exists, the history of inadequate outdoor hibernation under long-lasting freezing weather conditions prompts the diagnosis of frostbite. Viral and bacterial infections with subsequent organ failure must be considered as differentials.

Treatment, Prognosis, and Prevention. Patients should be warmed up slowly to the species-specific preferred optimal temperature zone (POTZ) and provided with fluid therapy, analgesics, and nutritional support. In cases with concurrent lower respiratory tract disease, an antibiotic treatment is warranted. Subscutal ecchymosis will resolve. Scutes should be left in place even if exudation is present at the scutal seams. Local antimicrobial treatment may prevent secondary infection in these cases. If the damage to the capillary supply is irreversible, scutes will loosen, exposing necrotic epidermis and bone. In affected areas granulation tissue will grow and undergo subsequent keratinization.

The prognosis for the dermatologic conditions is good, but a concurrent pneumonia downgrades the prognosis for the patient. Frostbite can easily be prevented by providing monitored hibernation conditions at temperatures between 5° to 8°C. See Chapter 23 for detailed information.

Neoplasia of the Shell

Clinical Significance and Known Etiological Cause(s). Two cases of invasive, osteolytic, nonmetastatic squamous cell carcinomas (SCC) of the shell of *Testudo hermanni* have been described.[54]

Clinical Presentation and Diagnostic Confirmation. A 28-year-old and 55-year-old male *Testudo hermanni* presented with soft tissue swelling dorsal to the base of the tail and an ulceration of the caudal plastron, respectively. The extensive osteolysis of the caudal carapace of the first animal could only be detected by CT scan because the overlying scutes were still intact. The plastral SCC most likely originated from the shell, whereas the carapacial SCC originated from the skin at the dorsal base of the tail.

Full thickness biopsies or fine needle aspiration cytology are the diagnostic tests of choice for proliferative masses. Radiography and CT should be used for further evaluation of the extent of the bone and soft-tissue involvement.

Treatment, Prognosis, and Prevention. A surgical excision is the treatment of choice and may be combined with other modalities, such as cryosurgery, radiotherapy, and chemotherapy.[55–57] Squamous cell carcinomas have metastatic potential in chelonians,[58] which should be accounted for when the further therapeutical approach is to be elaborated. Furthermore, the prognosis is guarded to poor due to the highly invasive nature of SCCs.

Ophthalmology

Martin P.C. Lawton

Reptilian ophthalmology is still in its infancy, especially compared with the same subject in other taxa. However, it is slowly growing and becoming an established and appreciated discipline. Ensley et al.[1] stated that "The veterinary clinician does not routinely find himself examining the eyes of snakes"; a mere 5 years later, disease of the eye and the adnexal structures was considered commonly encountered in reptiles.[2] The difference in these statements probably has more to do with the lack of a routine and thorough ophthalmic examination as part of the standard clinical examination of all reptile cases than with a sudden advance in knowledge within such a short period of time.

The eye is a barometer that reflects the health of the animal, and therefore many systemic diseases can produce ocular signs even though they are not primary ocular diseases. The reptilian eye can also be an environmental barometer, as toxicity can affect many aspects of the eye. Organochlorine pesticides have been associated with ocular discharge, conjunctivitis, and blepharitis in eastern box turtles (*Terrapene carolina carolina*)[3] Always remember that the ocular responses to injury vary between different species and have a profound influence on the type of inflammatory responses and healing capabilities that may be expected.[4]

The eye is considered to clearly show how various species have modified their basic structures to current conditions and evolutionary opportunities.[5] The anatomy of the reptilian eye (with the exception of snakes) has many general anatomic similarities, with only minor variations between the groups.[2,6] In snakes, many structural differences (other than just spectacles, which some lizards also have) are seen in comparison with the rest of the reptiles and are covered separately.

ANATOMY AND PHYSIOLOGY

In considering the evolution, development, diversity, and function of the reptilian eye, there are two texts[6,7] that must be considered as the foundations of reptile ophthalmology and should be consulted before any other sources when studying this subject.

Parietal Eye

The parietal eye is also known as the third eye, median eye, or pineal accessory apparatus. It is found in two distinct groups of reptiles (order Squamata, suborder Sauria [Lacertillia], and order Rhynchocephalia) but is absent in crocodilians.[8] This is the remnant of the median eye of provertebrates, which was originally a paired visual organ on the roof of the head.[6] In reptiles, it still appears as an eyelike structure, on the top of the head, situated in a hole beneath the parietal bone (Fig. 71.1).[9] Some lizards have a superficial parietal eye, which is just below the skin in the parietal foramen at the junction between the parietal and frontal bones.[8] Supporting evidence has shown that dinosaurs had a pineal foramen that was thought to have contained a parietal eye.[10] The overlying scales show varying degrees of transparency (almost clear in the tuatara, *Sphenodon punctatus*) and are described as a cornea-like apparatus.[10] Lacertillia, which have a prominent parietal eye, include slow worms, monitors, lacertids, some iguanids, and skinks.[11]

Histologically, the parietal eye is variable in complexity and design but has been shown to always have a neurological input and to contain a primitive retina. In the tuatara (*Sphenodon punctatus*), *Anguis* spp., *Varanus* spp., and *Sceloporus* spp., the retina is cup-shaped and surrounded by a fibrous capsule with a lens-like structure above and attached to the retina on both sides.[6,11] The posterior space between the lens and the retina is filled with a material that resembles the vitreous of the lateral eyes. No irises, lids, or muscles are found.[11] The retina of the parietal eye, unlike that of the lateral eye, has fewer but larger ganglion cells, and the photoreceptoral processes protrude forward into the lumen.[10] The retinal innervation leads to the parietal nerve, which is a small nonmyelinated structure that may have two branches and a not entirely known distribution of the fibers.[10]

Although the true function of this organ remains a mystery,[12] a relationship and connection exists between the parietal eye, the pineal body,[10] the diencephalons of the forebrain, and especially the habenular nucleus.[6,11] In families with no parietal eye (gekkonids), the pineal body has been noted to be reduced in size.[10] The parietal eye is thought to play a role in both hormone production and thermoregulation[6,8] by acting as a dosimeter[9,11] with an ability to sense changes in intensity and wavelength of light then convert photic stimuli into neuroendocrine messages,[8] allowing optimal timing for reproduction and other activities.[10]

The parietal eye has also been shown to act as a "compass" for orientation and navigation within their home environment, a function that

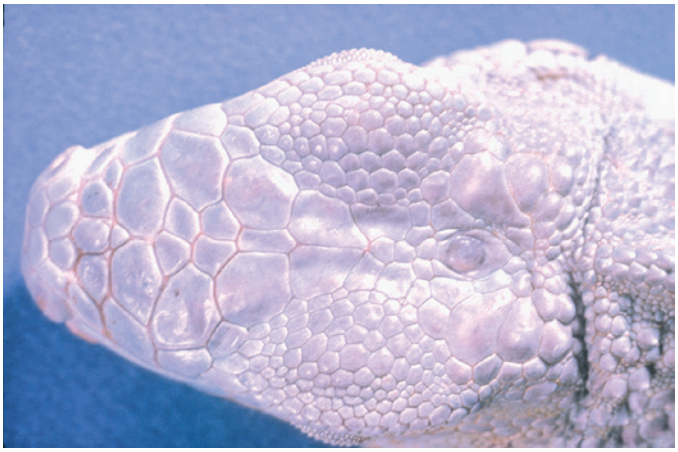

FIG 71.1 Parietal eye of an iguana. (Courtesy of Martin P.C. Lawton.)

VetBooks.ir

was lost on the organ being covered, temporarily, with nail varnish.[13] Electroretinographic (ERG) studies suggest that the parietal eye has a slower response (latency) to light than do lateral eyes and that this is irrespective of light wavelength.[10] The experimental effects of removal of the parietal eye in various lizards have shown changes in basking behavior and activity cycles[11] and a lower thermal tolerance.[10] This is probably because of the close physiological relationship between the parietal eye and the pineal body. The pineal body is responsible for producing melatonin and serotonin, both of which have marked effects on the sleep and awake cycles, and the parietal eye has been reported as having high levels of melatonin-forming enzymes (hydroxyindole O-methyltransferase).[10] This connection between the parietal eye acting as a dosimeter is further supported by the natural absence of the parietal eye in nocturnal lizards, although exceptions exist, such as in teiids and some geckos.[10]

Eyelids

Eyelids within the class Reptilia could well fill a chapter in themselves. Reptiles are divided into those with functional eyelids with a normal palpebral fissure; those with immobile and fused eyelids (spectacle) with no palpebral fissure; and all the possible variations in between.[14] Even within the group of reptiles with functional eyelids and normal palpebral fissures continued variation exists, and this group is further divided on the basis of various adaptations and changes that occur within the lower eyelid. Chelonia and Crocodilia all have functional eyelids with normal palpebral fissures, and the main variation to functionality of the eyelids and size of the palpebral fissure is mainly found in the squamates. Reptiles with spectacles are not dealt with in this section but have a separate heading of their own (Spectacles).

In most reptiles, the upper eyelid is the smaller and less mobile of the two,[1,9] with the lower eyelid moving up to cover the majority of the globe,[8] which is the reverse of the mammalian situation. The lizards are no exception, with the lower eyelid being the more moveable.[2] Most species have a third eyelid (Fig. 71.2). In Lacertidae, Teiidae, Scincidae, *Cordylosaurus, Lanthanotus*, and *Anolis*, some of the lower eyelid has become transparent,[2,7] with reduced or absent scales.[7] Some iguanids just have a few scales that are semitransparent when the eyelid is closed but are hidden within folds when the eyelid is open.[7] These are a protective mechanism to allow varying degrees of vision when the eyelids are closed, especially in adverse conditions, providing protection from sand or grit.[2,7]

Some lizards have a tarsal plate in the lower eyelid that offers support and is made of fibrous tissue.[7] *Ablepharus* and ground geckos often have fused eyelids that form a spectacle (discussed under the heading Spectacle). If any doubt exists as to the presence of true mobile eyelids or not, one should look for a nictitating membrane within the medial canthus, because whenever the eyelids are mobile, it is present.[7]

Similar to most lizards, the lower eyelid of chelonians is larger and more mobile than the upper eyelid.[7] The presence of a transparent window in the eyelid is rare in Chelonia and is only found in Chelodina or Emydidae.

The crocodilian eye is more of an exception in the reptile form as the upper eyelid is more mobile and, like humans, has a well-developed tarsal plate (tarsus),[7,15] which often becomes ossified with age.[16] The nictitating membrane (third eyelid) of crocodilians is well developed but semitransparent with a cartilaginous plate[7] (see Fig. 71.2). The presence of this third eyelid and the ability to close it across the globe even when the eyelids are open can make examination difficult but is a highly desirable protective feature. In aged alligators, calcium or other salt deposits can lead to an opacification of the normally clear third eyelid.[2]

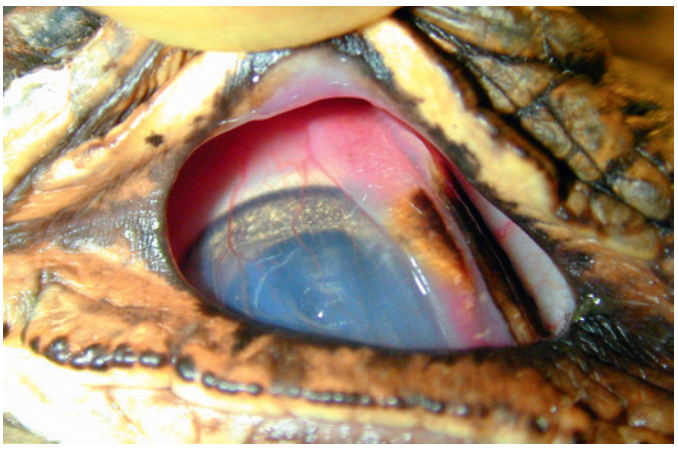

FIG 71.2 Semitransparent third eyelid in a caiman. (Courtesy of Martin P.C. Lawton.)

Spectacles

When the eyelids are fused, they form a transparent membrane over the globe, which is known by many terms, including spectacle, brille, eyecap, eye scale, watchglass, and goggle.[6,9,14] Spectacle is the term that will be used here. Three types of spectacles have been described[6]; the type found in squamates is the tertiary spectacle. Embryologically, a circular lid fold forms for all vertebrates, but in squamates that have spectacles this gradually closes over the globe, with the aperture moving dorsally and shrinking until it vanishes.[6,7] This dorsal movement of the aperture means that most of the squamate spectacle is composed of the lower eyelid. In the uropeltid snake (*Rhinophis* spp.) a small horizontal slitlike palpebral fissure is present in the newborn.[6,7]

All snakes, Amphisbaenidae, some geckos, some Lacertilia (*Ablepharus* sp., *Ophisops* sp., *Aniella* sp., Dibamidae, Anelytropidae, Euchirotidae), some Teiidae, *Uroplatus*, Pygopodidae, and Xantusiidae have fused eyelids with no palpebral fissure.[6] Although sometimes incorrectly reported as having spectacles, *Eublepharis* and *Coleonyx* geckos have normal eyelids, confirmed by the existence of their nictitating membranes.

The spectacle is composed of skin and therefore is a dry horny scale that is transparent. The spectacle has been referred to as a fixed window covered by the *stratum corneum* of the epidermis.[5] The surface of the spectacle is insensitive (compared to a cornea), as expected for hornified (cornified) skin. Lizards with spectacles are often seen cleaning this surface with their tongues.[9]

Microsilicone injection of the spectacle has shown it to be highly vascular,[2] and although in normal circumstances these vessels are not readily seen, they become apparent with inflammation.[14] The vascularity increases during ecdysis (Fig. 71.3B), and fluorescein studies[17] have showed that there is an increase permeability and leakage from these vessels. This transepidermal water loss causes the change in color of the spectacle prior to and aiding in the separation of the new and old layers of the epidermis. The permeability of the blood vessels is not found during the resting stage between cycles of ecdysis.[17] The spectacle becomes transparent again just before shedding.[2]

The most important point to remember is that the spectacle is not part of, nor is it attached to, the cornea.[14] There is always a space that separates the spectacle and the cornea—the subspectacular space (Fig. 71.4). This space has also been referred to as the intraconjuctival space.[6] The spectacle functions like a contact lens[7] under which the eye is fully mobile and independent. The subspectacular space is the equivalent of the conjunctival sac or space in mammals, except it is enclosed by the spectacle.[14] The space is filled with the secretions of the Harderian gland (see Lacrimal System), which provides lubrication

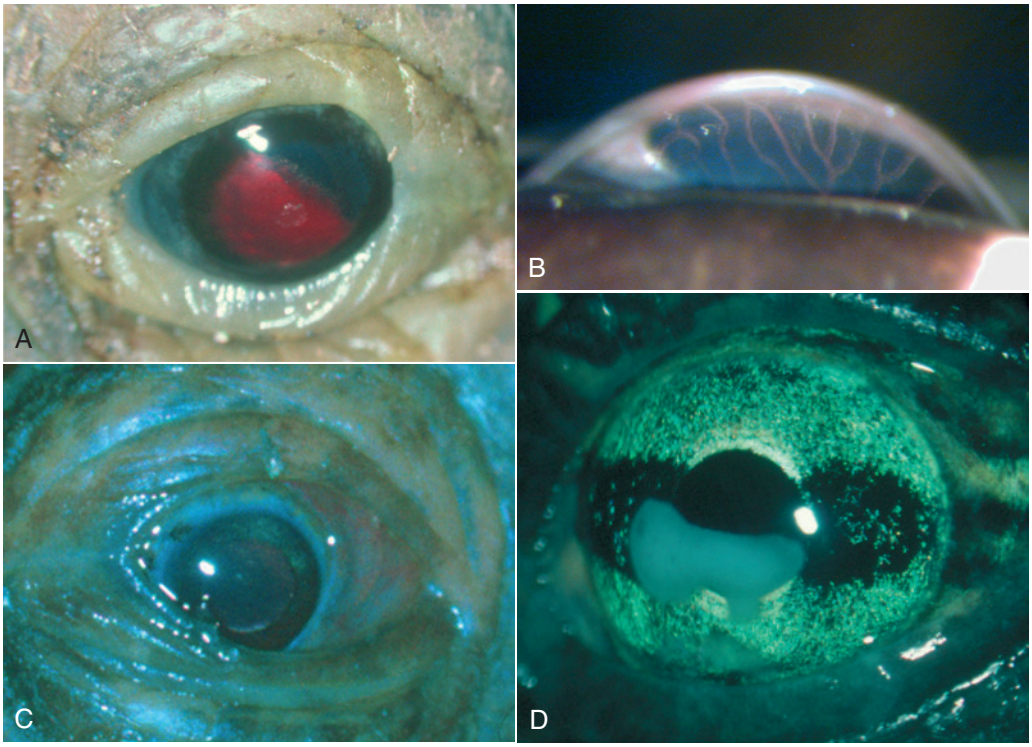

FIG 71.3 (A) Post-hibernation hyphema in a Mediterranean tortoise *(Testudo).* (B) Vascular structure of the spectacle. (C) *Arcus lipoides cornea* in a Mediterranean tortoise. and easy movement of the globe (although this is limited) beneath the spectacle. Despite this anatomic arrangement to allow movement, spontaneous movements of the globe are not frequently noted because the *bursalis* and *retractor bulbi* muscles are absent.[7] The thick, oily Harderian secretions do have a high reflective index and are thought to have some optical importance.[6]

Lacrimal System

The lacrimal (also cited as lachrymal or ophthalmic) glands are variable within the class Reptilia.[18] Most Sauria and Chelonia have a Harderian (Harder's) gland in the orbitonasal (medial) region[18,19] and a lacrimal gland in the orbitotemporal (lateral) region.[18] Conjunctival glands are also found and are mainly associated with the upper lid.[7]

The Harderian gland is firmly fixed in the medial part of the orbit, with the duct normally opening on the surface of the nictitating membrane (where present).[19] This is common to all groups of terrestrial vertebrates and was first described by Johan Harder in 1694, after whom the gland was named. Histologically, an enormous similarity is seen in reptiles between the lacrimal and Harderian glands that makes it difficult for them to be identified, even on histologic examination.[18] In Chelonia, confusion exists over which is the Harderian gland and which is the posterior lacrimal gland; the literature names both.[19] This has caused much doubt on claims such that the Harderian gland is absent in many geckos and chameleons.[2,7] In various Chelonia (*Testudo graeca*, *Trachemys scripta*, and *Chelonia mydas*), salt-secreting cells have been shown within the Harderian glands; these play a part in osmoregulation.[2] A large number of immunocompetent cells are also in the Harderian gland.[19]

VetBooks.ir

Snakes are generally accepted as having no lacrimal gland[2,5,6,9]; however, Williams[20] appears to be alone in considering that snakes have both lacrimal and Harderian glands, although this appears to be based on assumption rather than histologic studies. This lack of a lacrimal gland in snakes is an odd arrangement, because the lacrimal glands are usually associated with the upper and lower lids, and the Harderian gland is usually associated with the nictitating membrane,[19] which is absent in snakes. The Harderian gland is mainly posterior to the orbit and is large except in sea snakes, where it is reduced but still present.[2] The Harderian gland produces an oily secretion, and the lacrimal gland produces a watery secretion. The tear production in snakes is from the Harderian gland, which enters and fills the subspectacular space. The oily Harderian secretion is superior in lubrication properties to the watery lacrimal tears. Thus the retention of the Harderian gland and loss of the lacrimal gland is of advantage to the squamates with spectacles, where the globe may otherwise rub on the dorsal aspect of the spectacle. The duct of the Harderian gland opens directly into the lacrimal duct in *Natrix natrix*, but in more primitive snakes, it opens into the subspectacular space by several small ducts with a main duct opening into the lacrimal duct.[2] This oily secretion flows from the subspectacular space through the nasolacrimal duct first to the nose and then to the mouth.[6] In the family Dasypeltis (egg-eating snakes), the large Harderian gland's oily secretion contributes to the lubrication that is essential for swallowing eggs whole.[19] In chameleons there is a reverse movement of drinking water from the oral cavity through the nasolacrimal duct to flush the conjunctival sac.[21]

The nasolacrimal duct is absent in all Chelonia.[9] In crocodilians, the lacrimal ducts open in the front section of the nose, similar to mammals.[9]

Globe

The globe of most reptiles, unlike that of birds, is almost spherical. The scleral bones (scleral ossicles), when present, number between 6 to 17, with Mediterranean tortoises having 6 to 9, chameleons 11, and tuatara 16 or 17.[6] The bones are compactly placed and overlap their neighbors such that they form an almost immobile cup. In Chelonia, in addition to the scleral ossicles that may extend to the corneal rim,[6] a scleral cartilage is seen, up to 1 cm thick. In chameleons, the scleral cartilage is reduced to the foveal region, but in most other lizards it extends from the posterior pole of the globe to beyond the equator.[7] The scleral ossicles serve to maintain the convexity of the globe, allowing the ciliary body to be close to the lens and play a more important part in accommodation by changing the shape of the eye, therefore altering the distance between the cornea and fundus. Scleral ossicles are absent in crocodilians, but scleral cartilage extensions are found well into the *ora serrate*,[2,7] forming a cartilaginous cup.[6] The snake eye is totally different from all other reptiles in that it is slightly elongated along the visual axis.[7] The eye also has no scleral ossicles or cartilage but retains the spherical shape with the presence of tendinous connective tissue.[6] Pigmentary cells are found throughout the sclera.

Movement of the eye (except in chameleons) is limited because of the poor development of the rectus muscles, although, unlike birds, the *retractor bulbi* muscle is well developed. Chameleons have well-developed ocular muscles that allow a wide range of vision both monocular and binocular with 180 degrees in the horizontal plane and 90 degrees in the vertical plane.[9,21] Crocodilia have eyes situated dorsally so that even when they are in the water they can see above water level.[7] Land tortoises, crocodiles, and many diurnal lizards have narrow binocular vision of 25 degrees or less and thus rely on monocular vision.[9] Binocular vision is better in freshwater Chelonia (up to 30 degrees) and is most marked in the snapping turtle (*Chelydra serpentina*).[9]

The position of the eye in relation to the body has been shown[22] to affect intraocular pressure in juvenile loggerhead sea turtles (*Caretta caretta*). In dorsoventral and ventrodorsal positions the turtle has lower intraocular pressures compared with a head-down position; this is a response that is also seen in humans and is the result of venous pressure gradients within the eyes and the head. The normal intraocular pressure of reptiles is far lower than in mammals, with an average of about 6 mm Hg, whereas some land tortoises may have an average of 14 mm Hg.[22,23] A nonlinear negative relationship between body length and intraocular pressure was found in American alligators (*Alligator mississippiensis*).[24] The intraocular pressure was found to decrease as the body length increased, with a relationship to length and age; therefore a direct correlation may exist between the age and the intraocular pressure as has been found in some mammals.

The snake eye does not follow the normal reptilian format. Paleontologists and researchers generally agree that the snake evolved from the Varanidae. Because of evolutionary changing lifestyles to involve a nocturnal, burrowing, or subterrestrial existence, modification to the serpentine eye occurred. The changes involved were many, but of particular importance were the formation of the spectacle and development of a yellow lens and loss of the scleral ossicles. These changes in the eye occurred at the same time as the loss of limbs, parietal eye, and ears. The eye is considered to have degenerated to a vestigial organ, only to later evolve into its present structure as the snakes came back to the surface.[6] This certainly explains the major differences (not just in the spectacle) of the snake eye when compared with other reptilian species.

Cornea

The reptilian cornea is usually thin with no Bowman's membrane (layer). The crocodilian cornea is typically reptilian and thin.[7] In squamates with spectacles, the cornea is even thinner with only a single layer of corneal epithelium being found,[6,7] which is all that is necessary due to the protection provided by the presence of the spectacle. In lizards, the Descemet's membrane is present in all but a few geckos.[7] In land Chelonia, the cornea is thick with a prominent Descemet's membrane.[6]

The corneas of Chelonia have small radii of curvature and are therefore optically powerful in air, contributing dioptric power to the eye. In aquatic species, the cornea is optically ineffective when in water, but they are able to overcome this loss and still focus.[25] Freshwater turtles have exceptionally well-developed ciliary and iris musculature and a highly flexible lens that provides a wide dioptric range, giving high visual acuity in both air and water despite the loss of corneal refraction.[26] They are able to squeeze the lens (which is soft) through the pupil aperture,[6,7,25] which is similar to the accommodative changes seen in some diving birds. Two investigations have been undertaken of the visual acuity of the various Chelonia. The first was a retinoscope assessment of green sea turtles (*Chelonia mydas*), which were compared with a freshwater turtle (*Clemmys insulpta*) and a gopher tortoise (*Gopherus polyphemus*)[26]; the second study involved anatomic dissection, the use of a streak retinoscope, and schematic eye calculations in the red-eared slider (*Trachemys scripta elegans*) and marine turtles (*Chelonia mydas*, *Dermochelys cariacea*, and *Eretmochelys imbricata*).[25] Both studies came to the conclusion that the eyes of the marine turtles varied significantly compared with those of the freshwater turtles and land tortoises. The severe hyperopia of underwater is compensated by the accommodative changes of the lens.[25] The green sea turtle was found by Ehrenfeld and Kock to be emmetropic in water but extremely myopic when out of water.[26] Conversely, Northmore and Granda[25] considered marine turtles as emmetropic out of water as they were able to see

coastlines, which they could not if they were myopic out of water. The difference in opinion was considered by Northmore and Granda[25] to be due to the actively accommodating eye. The land tortoises were found to be similar to humans in that they are not able to overcome the loss of the corneal refraction in water.

As part of the normal aging process of *Testudo*, *arcus lipoides cornea*, seen as a white infiltration of cholesterol crystals into the peripheral cornea (see Fig. 71.3C),[27] is not unusual. Corneal cholesterol dystrophy can also occur in reptiles (such as terrapins) on a high polysaturated fat diet and is usually noted in the center of the cornea (see Fig. 71.3D).

Anterior Chamber and Uveal Tract

The reptilian iris has a well-developed sphincter of striated muscles that allows rapid control over papillary movement[2] and is resilient to the effects of mydriatics.

Naturally occurring miosis is sluggish.[8] Voluntary control of the iris is important where the sphincter iris is responsible for accommodation by deforming the lens, such as in Chelonia.[6] The voluntary control also means that there is no consensual pupillary light reflex.[8] A peculiar sexual dimorphism is shown in the color of the iris of most (but not all) *Terrepene* spp., where the male has a red iris and the female a brown iris.[7]

In lizards, differences in pupil shape are common, depending on whether a reptile is nocturnal (slit pupil) or diurnal (round pupils). *Heloderma spp*. are the exception as they have a round pupil.[7] In the Gekkonidae, often several tiny notches are paired off along the opposite margin of the iris.[6] In bright light, the pupil (normally a single slit) closes completely, leaving a series of pinholes (stenopeic openings)[7] that are very small oval pupils formed by these apposed notches. These stenopeic openings allow a sharp image to form on the retina, irrespective of distance, and it is a far sharper image than that of a single aperture.[6] Stenopeic openings are most obvious in the tokay gecko (*Gekko gecko*), in which its presence is considered to allow the formation of a clear image without any other accommodative adjustments.[7] The crocodilian iris, although more mobile and responsive than in lizards or chelonians, is also able to form a stenopeic slit in bright sunlight.[7]

The snake iris is generally a thick, heavily pigmented structure. It is highly mobile as, with the absence of eyelids, it plays a more important role in light protective function.[7] The East Indian long-nosed tree snake (*Dryophis mycterizans*) and the African bird snake (*Thelotornis kirtlandi*) have a horizontal keyhole-shaped pupil with the slot of the keyhole pointing forward beyond the rim of the lens. This is to position the slot of the keyhole (nasally) in line with the fovea (two of only three genera that have a fovea).[6] These two species are thought to have the sharpest sight and most accurate distance judgment of all snakes.[6]

Lens and Accommodation

Most reptiles have some sort of annular pad (ringwulst or annular ring), which is a thickened area of epithelial cells, usually at or near the equator, that allows the lens to connect directly to the ciliary body, usually by zonular fibers. The lizards have a thick equatorial annular pad formed by radial growth of the subcapsular epithelium that is largest in chameleons.[7] The ciliary body has a broad zone of firm contact with the lens in lizards.[6] Unlike lizards, chelonians have well-formed ciliary processes that attach to the lens,[7] although a small but weakly developed annular pad is found.[6,7] The crocodilians have ciliary processes that connect with the equator of the lens, where a small annular pad is found.[7] The snake has no equatorial annular pad,[6,7] but an anterior pad is formed from the subcapsular epithelial cells on the anterior surface.[7]

The reptile lens is flatter than that found in fish and amphibians.[28] The lenses of lizards are soft.[2] A larger lens is seen in nocturnal species.[7] In lizards, accommodation depends on the deformation of the lens.[7] Nocturnal and diurnal gekkonids differ in the biochemical composition of their lenses.[29] Nocturnal animals have colorless lenses, and yellow crystalline (water soluble protein) is found exclusively in lenses of diurnal geckos and gives their lenses a yellow coloration.[29]

The lens capsule is thin in chelonians, and the lenses are extremely soft and almost fluidlike in consistency.[6,7] The land tortoises have a flat lens that is less flat in the terrapins and more spherical in sea turtles.[6] Turtles are able to accommodate when submerged by squeezing the soft lens through the pupil aperture.[6,7,25]

The snake lens is pigmented yellow, spherical, and firmer than that of other reptilian lenses.[7] In snakes, the oil droplets in the rod cells of the retina do not have any color, so the yellow lenses take over this function of ultraviolet protection.[6] Accommodation in the snake is unique compared with other reptiles,[7] because it relies on the lens moving backward and forward in response to pressure changes within the vitreous and aqueous.[12] This is aided by the ciliary muscles that have migrated into the root of the iris, where they can apply pressure to the lens without altering its shape.[9]

Retina and Visual Tracts

Reptiles, like birds, have an anangiotic (avascular) retina (Fig. 71.5A). Nutrients are supplied and metabolic wastes removed by choroidal blood vessels or modified vessels protruding into the vitreous. All reptiles have a choriocapillaris and, during development, had a hyaloid vascular system.[30] The major differences found in the various reptile orders occurred as the hyaloid system regressed.

In chelonians there is total regression of both the hyaloid system and the choriocapillaris, with sole reliance on remaining choroidal blood vessels. An early avascular conus did develop above the optic disc in some turtles, but this regressed and is absent in all adults.[7]

In lizards, a structure similar to the avian pecten develops but is known as the *conus papillaris*. The *conus papillaris* usually protrudes into the vitreous from the optic disc[2] (Fig. 71.6), consisting of a vascularized glial tissue,[30] and is ectodermal in origin.[6] As in the avian pecten, the inner limiting membrane (vitreoretinal border) covers the *conus papillaris*.[31] It consists mainly of tiny blood vessels that are heavily pigmented.[6] The *conus papillaris* entirely obscures the fundoscopic view of the optic disc.[7] The conus is absent in Amphisbaenidae.[7]

In snakes, the conus has regressed in all but a few species and is replaced by a preretinal vascular meshwork derived from the hyaloid vessels known as the *membrana vasculosa retinae*,[30] which is mesodermal in origin.[6] This is a branching array of vessels derived from the choroid running into the posterior vitreous near and originating from the optic disc but just above the retina. In colubrids, the capillaries of the *membrana vasculosa retinae* penetrate the retina and become an intraretinal vessel.[7,30]

In adult crocodilians, the *conus papillaris* is functionless and is reduced to a glial pad consisting of one or two capillary loops that scarcely protrude into the vitreous and are on the optic nerve head.[2,6,7] In alligators, the conus has regressed even more into a layer of melanocytes found on the optic nerve head.[30]

The retina of reptiles, like other vertebrates, is composed of five primary cell types:

i. Photoreceptors,
ii. Outer segment,
iii. Inner segment,
iv. Nuclear and connecting fibers
v. Synaptic pedicles.

In the inner segment there are oil droplets with a high refractive indices that contribute to light collection in the visual cells and enhance retinal sensitivity as well as contrast and motion detection.[32] The reptile retina has rods and cones.[2,9] Many diurnal species have lost their rods,[8] for example, new world chameleons (*Chamaeleo* sp.) have a cone-rich retina.[33] In chelonians, cones predominate the retina.[7] In diurnal reptiles, yellow oil droplets are associated with the rod or certain cone cells (except for snakes), which act as ocular filters and are able to absorb ultraviolet and shortwave blue radiation to protect underlying cells[34] and reduce glare.[9] Where colored oil droplets are not found in the rod cells of the retina (such as in snakes) this function can be undertaken by yellow lenses.[6] Extra retinal photoreceptors allow circadian rhythms to be initiated and controlled, and the eyes have an inhibitory role.[5]

An *area centralis* is found in most species where the cones are smaller and more densely packed. Vision in all animals is improved by the presence of *areae centrales* or *foveae*. The *area centralis*, despite its name, is not always in the center of the fundus other than in humans (*macula lutea*). The *area centralis* is an area that has a marked increase in resolving power compared with the rest of the retina. A foveal depression in the retina is associated with a thinning of the retina and allows for a magnifying action and thus increased visual acuity; however, it is only present in a small number of reptiles.[6]

Fovea are present in *Amyda* spp. (the only turtles to have a fovea), *Sphenodon punctatus* (a medium, pure rod fovea), some diurnal skinks and varanids, and three genera of snakes (*Dryophis*, *Dryophiops*, and

Thelotornis). The fovea is absent in all crocodilians.[6] In nocturnal species of lizard, the fovea is absent (heloderms and most geckos) or reduced to the remnant of a foveal pit (*Xantusia*).[7] In diurnal species of lizards with a fovea, it has elongated cones that are closely packed, and some species (mainly arboreally diurnal) may have a second fovea temporally, as is also seen in some bifoveate birds.[7]

The crocodilian retinal epithelium has a tapetum formed by guanine crystals[6,7] that are hyperreflective at night when lights are shone into their eyes and is often used against them while being hunted. Rods greatly outnumber the cones in the periphery, with the cones resuming in the tapetal area. Near the ventral border of the tapetum, a horizontal oval *area centralis*, mainly of rods, exists.[7]

The optics and ocular physiology of *Trachemys scripta elegans* have been extensively studied.[25,35–37] They were found to have good vision; with the photoreceptors being 90% cones, they are able to see colors[36,38] and are particularly sensitive in the red region of the spectrum.[36] Although they have a high number of cones, they are thought to have a similar optic range to the duplex system of humans.[25]

The fibers within the optic chiasm do not completely cross in reptiles; however, most squamates and some turtles have ipsilateral projections providing good binocular vision.[39] There is nearly complete crossover of the optic nerves at the optic chiasm in *Trachemys scripta*.[35] This allows accurate panoramic vision and improved detection of movement, although only limited binocular vision is present and restricted to directly in front (25–30 degrees). The more lateral the eye, the more independent each eye, and greater panoramic field of vision. Optokinetic studies in *Trachemys scripta*[35] showed that transection of the tectal commissure caused no significant change in vision, suggesting that visual movement detection is a relatively independent function of the two eyes.

Many differences are seen in the neural pathways of reptiles. Blind snakes (which, despite their names, are sensitive to light and therefore not blind) of the families Typhlopidae and Leptotyphlopidae have a different retinal efferent system from that of higher snakes.[40] The blind snakes lack retinotectal connections, and the *nucleus rotundus* (the major thalamic nucleus receiving tectal efferens in reptiles and birds) is barely distinguishable.[40]

Boidae and Crotalinae (not Viperinae) have two electromagnetic radiation imaging systems, which although very similar, evolved independently.[41] The first is the lateral eyes, responsible for visible light, and the second are the pit organs, responsible for seeing infrared radiation.[42] These are the only animals known to image two distinct parts of the electromagnetic spectrum at the same time. Both the visual and infrared information obtained are probably involved in prey targeting. Experiments have shown that although vision is not necessary for accurate targeting (shown in experimentally blinded snakes), it is necessary for precise targeting in association with the infrared perception.[41] The infrared and visual information merge in the optic tectum where the individual neurons are found to be sensitive to both stimulation of the eyes (by visible light) and stimulation of the pit organs (by infrared radiation) from the same points in space.[41] A lateral descending nucleus of the medulla oblongata also is unique to infrared-imaging snakes. The combination of the electromagnetic radiation imaging system is important in triggering the guiding of the strike toward the prey by supplying accurate information on the position of the prey.[42] Accurate location of the prey requires the snake to move from a lateral to a rostral position and thus not only sensing the heat form of the prey but also the position and direction of any movement before striking.[42]

The pit organ in boidae is simple, consisting of a shallow depression in the labial scales (Fig. 71.7) in comparison to Viperidae, which have a concave membrane suspended within a cavity within a depression of the maxillary bone.[42] Both types of pit organs are innervated by a branch of the trigeminal nerve (ophthalmic, mandibular, and maxillary branches).[8,42] Electrophysiological studies demonstrate these organs are sensitive to temperature changes of 0.003°C, and the distance assessment is a basic trigonometrical surveying of the intensity profiles perceived by the various pits.[42] The pit organs may also be sensitive to microwave energy.[42]

OPHTHALMIC EXAMINATION

Reptilian ophthalmology requires an understanding of the normal state to recognize the abnormal. The veterinarian who desires to be proficient in reptilian medicine should perform a full ophthalmic examination in all cases, not only to gain the experience of the normal but also because systemic disease is often represented in lesions noted in the eyes and related structures.

The ophthalmic examination should be systematic, as for any other animal or any other part of the body. The examination should start with an assessment of the eyelids (fused or mobile), the tear film (where a spectacle is not present), the size and position of the globe, the cornea, anterior chamber, iris, lens, and finally the fundus. Both eyes, when present, should always be examined so that they can be compared and contrasted. If an obvious or suspected problem is seen with one eye, it is important to examine the other eye first as subtle changes or early lesions associated with a disease process may be more noticeable in the apparently normal eye than in the abnormal eye.

A brief examination with some form of focal illumination should be used (pen light, auroscope, etc). This allows a simple assessment of the clarity of the cornea and anterior chamber and highlights any adnexa or globe abnormalities. Any pupillary light response should be noted. Although the presence of striated muscles within the reptilian iris could prevent a pupillary light reflex, it is seldom absent unless substantial ocular disease exists[43]; indeed, a rapid direct light response is generally noted. Reptiles do not have a consensual light response, although they show a normal direct pupillary light response.[44]

A more detailed examination of the eye is not possible without some form of magnification (magnifying loupe, slit-lamp biomicroscope, or +10 to +15 diopter lens of the direct ophthalmoscope). The small size of the reptile eye leads to a high likelihood of subtle changes being missed if magnification is not employed. Magnification and slit-lamp use are essential to also aid the clinician in examination of snakes and lizards with spectacles, to distinguish between the anterior chamber and the subspectacular space, which is essential in reaching an accurate diagnosis of the site of any pathology (Fig. 71.8).[45,46] The use of a slit-lamp biomicroscope will allow an accurate placement of a lesion within the

VetBooks.ir

FIG 71.9 Tonometry in an (*Iguana iguana*). (Courtesy of Martin P.C. Lawton.)

anterior segment when an angled slit illumination is used to cut a "segment" of the area being examined.

Fundoscopy is often best achieved with indirect ophthalmoscopy and a 90-diopter lens or a panophthalmoscope (Welch Allen) that allows vision even through a small, often undilated pupil, as found in reptiles. The striated muscle in the iris allows voluntary control of the pupil size, which is unaffected by topical mydriatics routinely used in mammals.[2] Two ways of inducing mydriasis are with general anesthesia or with intracameral injection of neuromuscular blocking agents. Topical application of neuromuscular blocking agents has been shown to be ineffective in achieving mydriasis that may be related to a lack of corneal penetration of the drugs. The intracameral injection is performed under local anesthesia (proxymetacaine, applied topically to species without a spectacle) or with sedation (for those with spectacles). The technique requires a 27-gauge to 30-gauge needle to be advanced through the limbal conjunctivia and the cornea, into the anterior chamber where the neuromuscular blocking agent is administered in small volume. Reports of 0.05 to 0.1 mL of d-tubocurarine[15] or 0.1 mL of 20 mg/mL curare are effective.[2] The resulting mydriasis may last from 30 minutes to several hours for d-tubocurarine[15] to even days for curare.[2] In snakes and lizards that have a spectacle (as discussed later), an injection into the subspectacular space is ineffective and should not be confused with an intracameral injection (requiring the needle to first penetrate through the spectacle and then the cornea into the anterior chamber).[2]

Diagnostic Tests Specific to Ophthalmology

Ancillary ophthalmic aids, such as tonometry (Fig. 71.9), stains (see Fig. 71.5B), bacteriology, cytology, histopathology, electronmicroscopy, or ERG (electroretinography), all have application in evaluating the reptilian eye. Additionally as ophthalmic pathology often reflects systemic disease, ancillary diagnostics should be routinely utilized, including hematology, biochemistry, radiography, CT/MRI, and ultrasonography. Special mention should be made of the usefulness of ultrasonography (a minimum of 10 MHz is necessary) for the assessment of the globe or retro-orbital evaluation (see Fig. 71.6), which is easily performed, in most species, with manual restraint alone.[43,47]

Testing Patency of the Nasolacrimal System

The lacrimal system can be tested with fluorescein. In reptiles with a palpebral fissure, the stain is placed into the conjunctival fornix, and where it drains into the mouth is noted. In squamates with a spectacle, the patency of the lacrimal ducts can still be shown with injection of 0.05 mL of fluorescein through a 30-gauge needle into the subspectacular space.[15] The technique requires the needle to pass through the spectacle near the lateral canthus with visualization of the eye, with some form of magnification to prevent damage to the underlying (and very thin) cornea. The dorsal/maxillary mouth area just rostral to the Jacobson's organ should be evaluated for evidence of patency.[14] One must remember that tear-staining syndrome seen in tortoises is the result of the lack of a functional nasolacrimal system and is not indicative of an abnormality.[27] The tears of chelonians naturally spill over the eyelids and down the side of the face to eventually evaporate away, and any fluorescein placed into the eye does the same. Biopsy and cytology may be valuable[28] in determining disease etiology and assist in the treatment requirements.

CLINICAL DISEASES

Congenital and developmental ocular diseases are uncommon,[28] although microphthalmous (see Fig. 71.5C), anophthalmous, various colobomata, and failure of fusions can occur.

Eyelid Trauma

Trauma frequently affects the eyelids and may occur in any species. Trauma is particularly noted in red-eared sliders as a result of a feeding frenzy.[48] In most cases, traumatized lids need only topical antiseptic treatment (povidone-iodine) and cleaning to allow healing. More substantial lesions need surgical intervention (see Chapter 91).

Blepharoedema and Blepharitis

Swollen eyelids can be the result of a fluid edema (blepharoedema) or more solid swelling (blepharitis) (see Figs. 71.5D and 71.10A). Often one can lead to the other. A blepharospasm is often the presenting clinical sign of any irritation or abnormality of the eyelids (Fig. 71.11). Blepharospasm may be present in association with other ocular pathology or disease (as discussed later). Only primary blepharoedema and blepharitis are dealt with here. As always, samples should be taken for further investigation and to reach a definitive diagnosis and facilitate correct treatment.

Blepharoedema is a common finding in reptiles, especially freshwater chelonians,[18] and is often associated with hypovitaminosis A (see Fig. 71.5D). Hypovitaminosis A is the most common problem that affects the ocular adnexa.[2,18] The lack of vitamin A leads to squamous metaplasia

of the orbital glands and their ducts. This leads to replacement of mucus-secreting cells by flattened keratinized squamous epithelium, and the gland lamina become dilated and filled with keratinaceous and cellular debris.[49] Once the cells have undergone squamous metaplasia, they no longer perform their protective functions, and opportunistic bacterial infection is common. Lack of tears and metaplasia cause blepharoedema and a secondary blepharitis and conjunctivitis.[2,18] A good clinical history often allows the diagnosis to be suspected and response to treatment used for confirmation. Where treatment does not improve the condition, biopsies for histopathology prove useful. Treatment with vitamin A is dose related, and care must always be taken to prevent iatrogenic hypervitaminosis A. Swollen eyelids have also been documented in a colony of green anoles (*Anolis carolinensis*)[49] and are implicated in gecko retained eyecap syndrome. Blepharitis and closure of the eyelids associated with hypovitaminosis A is partly the result of the increase in bulk of the eyelids caused by enlargement of the ophthalmic glands.[18] Blepharitis (see Fig. 71.10A) can also be associated with a wide range of bacteria and can result in granulomata or abscess formation. Blepharitis may be caused by parasitic infestations, and five parasites (*Foleyella*) removed surgically from a newly imported Oustalet's chameleon (*Furcifer oustaleti*) have been described.[50] Eyelid scrapes for stained cytology should always be the first approach. Where bacteria are shown, samples for culture and sensitivity are advised. Where granuloma or abscess formation has occurred, surgical removal is necessary but with care to preserve the anatomic position of the eyelids. Sliding graft for eyelid reconstruction in reptiles is possible but is more involved than in mammals and is reason for referral.

Eyelid Neoplasia

Viral neoplasia of the eyelids has frequently been reported in a number of species. Although there are no published reports of non-viral-related neoplasia of the eyelids, these can occur. Viral neoplasias include fibropapilloma in green sea turtles, papillomata in green wall lizards (*Lacerta viridis*), and papillomata associated with poxvirus in the spectacled caiman (*Caiman crocodilus*).[2,15] Poxvirus in the caiman can be seen as focal raised papules anywhere on the skin, including the eyelids.[2]

VetBooks.ir

Herpesvirus infection of green sea turtles may cause severe ocular, cutaneous, and visceral disease.[51] Proliferative ulcerative lesions have been reported to affect the cornea, eyelids, periocular skin, and conjunctiva, and are typically pedunculated or polypoid with verrucous surface composed of hyperplastic epithelium overlying a collagenous stroma containing reactive fibroblasts.[2,51] This condition is often complicated by secondary bacterial infections, usually gram-negative organisms. Surgery may be attempted, although recurrence is common, and even recovered individuals are a potential source of infection for others in a colony. Diagnosis can often be made on the basis of gross appearance, but histopathologic examination is definitive.

Abrasions and Ulcers of the Spectacle

The spectacle is a physical barrier derived from the skin, and as such it is impervious to most topical medicaments,[2] making treatment of the underlying cornea or globe difficult, if not impossible, without a subspectacle injection or application.

Spectacles are protective in function, and therefore some trauma naturally occurs and is noted on routine examination of the spectacle but are often lost with subsequent ecdysis (see Fig. 71.10C). Damage to the spectacles of snakes may occur from a variety of causes. Factors that can lead to damage include the hazards of feeding live prey (especially to captive breed species), inappropriate environment, dysecdysis, and incorrect treatment of retained spectacles.[14] The spectacle is also subject to infectious or parasitic conditions. Only after a full ophthalmic examination, ideally with a slit-lamp biomicroscope can the degree of damage be assessed. Further investigations may also be necessary, including the use of scrapings for cytology or bacterial culture and sensitivity. In severe or chronic conditions, biopsy may be necessary for histopathologic examination.

In most circumstances, minor damage to the spectacle is normal and of little consequence, as the spectacle renews at every shed. Abrasions can normally be seen on the surface of the older spectacle (see Fig. 71.10C). Scratches and minor abrasions regularly occur without any discomfort and should never be misdiagnosed as a "corneal ulcer." If loss of transparency of the spectacle occurs, then the underlying cause should be assessed; causes include ecdysis, inflammatory deposits on the inner surface,[52] exposure to chemicals, or retention of spectacles and bacterial or fungal infection. The use of organophosphate insecticide or volatile polyurethane organic solvents for chemical fogging of the vivaria has been implicated in a thickening of the deeper cellular layers of the spectacle and a resulting loss of transparency in *Lampropeltis* sp.[53]

Deeper abrasions can, in some circumstances, be more correctly referred to as ulcers once the epidermis has been breached,[14] but they should more correctly be referred to as dermatologic ulcers to distinguish them from corneal ulcers. These more noticeable abrasions are always secondary to an underlying husbandry or disease problem, such as low humidity, parasites, or dysecdysis. Increased and often constant rubbing of the face against rocks, branches, or other objects in the vivaria results in abrasions to the spectacle. This appears as loss of clarity of the spectacle, with abrasions varying from superficial scratches to deep ulcers. The accumulation of substrate (particularly wood chips, fine sand, and walnut shell pieces) also may be forced under the superficial layers of the spectacle. Once the spectacle is damaged, associated vascularization or secondary infection may also be seen.

Providing the abrasions are not full thickness (see section, Loss of Spectacle), treatment is with topical antibiotics (ophthalmic or dermal), and correction of the underlying problem usually leads to no permanent damage. Steroidal combinations should be avoided because these could lead to delayed healing or predisposition to secondary infection, particularly fungal. Surgical debridement may be necessary with excessive roughness or pocketing or looseness of the edges of the skin or with accumulation of substrate under the surface layer of the spectacle (see Chapter 91). Rarely does damage or treatment of abrasions result in permanent opacity to the spectacle.

Loss of Spectacle

More substantial trauma to the spectacle usually involves avulsion, which is serious because it may result in corneal desiccation from a lack of continuity of the tear film and may ultimately result in loss of the eye, despite topical antibiotic therapy.[1,14] The spectacle is important for maintaining the tear film within the subspectacular space. The loss of a small part of the spectacle may have only minimal effects by increasing overflow (through the deficit) or evaporation of tears until regrowth occurs. If there is a total loss of the spectacle then this leads to the loss of the tear film and eventual desiccation of the cornea or panophthalmitis. The loss of the protective spectacle and the underlying fluid leads to damage of the single delicate layer of corneal epithelium (see Cornea section). The resulting damage to the cornea by drying leads to infection, ulceration, scarring, rupture, and permanent opacity with loss of vision (see Fig. 71.10D). In severe cases, shrinking of the globe (*phthisis bulbi*) occurs.

Loss of the spectacle can occur from a number of causes. The most common cause of the loss of the whole spectacle is associated with an inexperienced herpetologist (or veterinarian) attempting to remove a normal spectacle (wrongly diagnosed as a retained spectacle) with cellophane tape or forceps.[14] Other causes of loss include trauma (particularly as a sequel to long-term abrasion of the spectacle) or infection (as discussed later). Feeding of live prey (rodents) could also result in injury or penetration of the spectacle and should be avoided.

Treatment may be attempted with topical antibiotics and artificial tears, a cut-down soft contact lens, or transposition of an oral mucosa flap over the eye.[27,48] The use of a mucosal flap may save the eye but seldom allows normal vision, even though (like conjunctival grafts to the cornea in mammals) some long-term clearing may be seen (Fig. 71.12A). Some success has been achieved with a collagen graft material.

Infection of the Spectacle: Bacterial and Fungal

Although it is transparent, the spectacle is dermal, and this fact should not be forgotten at any stage of the assessment. Swabs, scrapes, and even biopsies can be performed to allow cytologic, histopathologic, bacterial, or fungal examinations, as indicated for any other dermal abnormality on the body.[14] Topical dyes routinely used for the examination of the cornea (such as Rose Bengal or fluorescein) have little advantage for assessment of the spectacle. For infection beneath the spectacle, see Subspectacular Abscess section.

Infections of the external surface of the skin are a common problem. Bacterial infections usually involve opportunistic gram-negative bacteria. In some cases, the epidermal layer may become infected with bacteria and result in an intraspectacular dermatitis.[20] In severe cases, such infections may be noted to spread beyond the margins of the spectacle.[14] This is often caused by retained spectacles or poor hygiene. Such an infection, in itself, could lead to spectacle retention or even loss of a spectacle or the eye. Treatment may require surgical incision to allow debridement and application of a suitable antibiotic agent. Where systemic spread is suspected, parenteral antibiotics may also be necessary.

Fungal infections are often encountered and are considered to be a reflection of poor management.[2] They are usually slower to develop, with the resulting infection causing more deformity of the spectacle, particularly thickening and pigmentary changes (see Fig. 71.12B).[14] The changes are seldom restricted to just the spectacle and often involve surrounding scales or even the whole head. Fungal infections need to

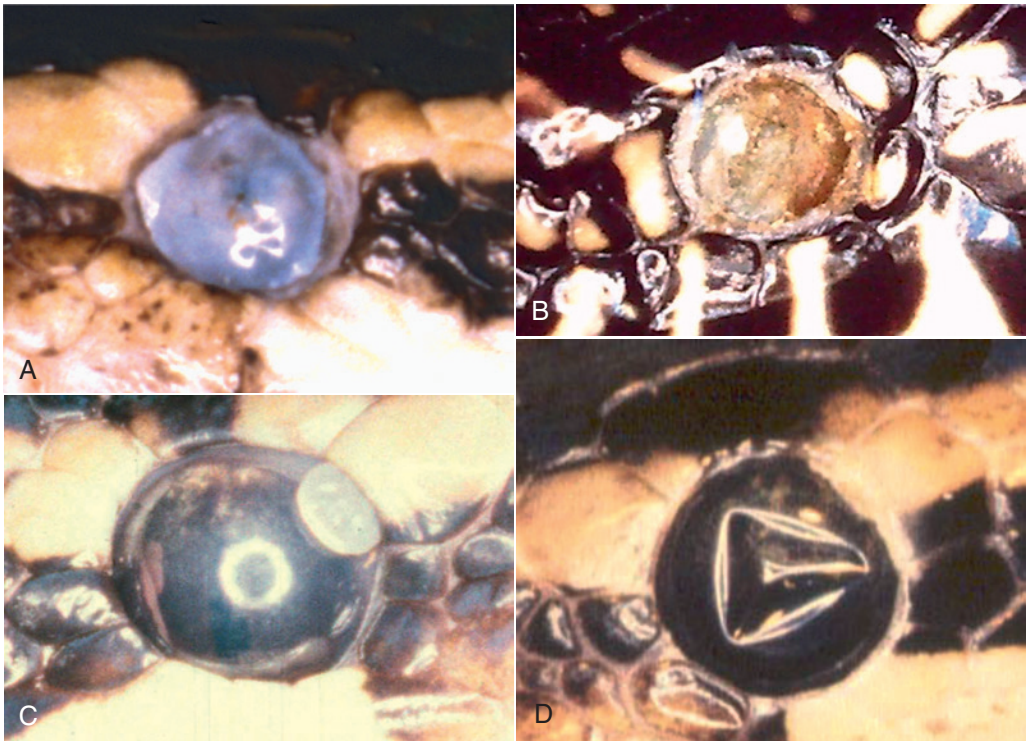

FIG 71.12 (A) Loss of spectacle after surgical and medical treatment in a ball python (*Python regius*). (B) Fungal infection of the spectacle in a king snake (*Lampropeltis* sp.). (C) Tick in the perispectacle sulcus of a ball python. (D) Indented spectacle associated with a retained spectacle in a ball python. (Courtesy of Martin P.C. Lawton.)

be identified and treated at an early stage or they may spread further. Diagnosis is based on cytology, culture, and sensitivity. These infections, if diagnosed early enough, can be treated with topical dermal antifungal creams, lotions, or ointments. A fungal infection from *Fusarium oxysporum* was reported[54] as penetrating the spectacle, and treatment required enucleation.

Subspectacular Abscess

Infection under the spectacle, involving the subspectacular space, is a common problem and can be due to one of four causes: (i) ascending infection from the oral cavity (via the nasolacrimal ducts), (ii) septicemia with hematogenous spread, (iii) penetrating trauma through the spectacle, or (iv) as a sequela to conjunctivitis.[2,15,28,52,55] In cases of primary infection or trauma, only one eye is affected, but with septicemic spread the infection is more often bilateral (Fig. 71.13).

The spectacle appears cloudy or white (leukoria) and may sometimes be distorted.[14] In cases of unilateral involvement, determining whether the infection is local or secondary to septicemia is important. White blood cell counts and blood cultures are necessary for differentiation. If the infection is secondary to septicemia, then locating and treating the primary infection at the same time as dealing with the subspectacular abscess is important.

Obtaining diagnostic material and effecting treatment requires making a surgical incision through the spectacle (see Chapter 91). Following the collection of diagnostic material, the subspectacular space should be flushed with balanced salt solution (or another suitable solution) often repeated until clear and an ophthalmic antibiotic solution such as gentamicin applied once or twice daily until infection is cleared. Depending on the culture and sensitivity results, systemic antibiotic treatment may also be necessary. In cases where severe disease of the oral cavity is involved, such as bacterial stomatitis, aggressive therapy to treat the underlying stomatitis must also be initiated. Gentle debridement and removal of caseous material in the oral cavity may be required. Additionally husbandry-related issues that have resulted in damage to the oral cavity and secondary bacterial stomatitis and subsequent

FIG 71.13 Established subspectacular abscess in right and developing subspectacular abscess in left eye of a ball python (*Python regius*). (Courtesy of Martin P.C. Lawton.)

VetBooks.ir

subspectacular abcessation must be addressed. A common example is mature boids housed in inappropriate caging with screen mesh tops or wide spacing in a rack system resulting in tauma to the rostrum as they attempt to "push out." This often occurs in the breeding season when male and female snakes are housed near each other and males are desperate to get out to breed females.

Parasites Affecting the Spectacle

Parasites, especially mites or ticks, are not uncommonly found around the adnexa.[56] Mites (*Ophionyssus* spp.) are commonly found between the thin skin in the area of the sulcus formed by the periorbital scales and the spectacle. Ticks (*Ixodidae*) are usually only found on newly imported species. Although ticks may be found anywhere on the body, they are more often found around the cloaca or head. They usually attach to the softer skin between scales or at the junction where the spectacle meets the scales of the head (see Fig. 71.12C).

Parasitic infestation can lead to retained spectacles and potential spread of bacterial or viral disease. Slit-lamp biomicroscopy is often necessary to detect mites, but even then visualization may prove difficult because they are often deep within the sulcus. Parasites may be physically removed (to thus confirm the diagnosis) by flushing with a suitable solution (such as balanced salt solution) via a fine 24-gauge cannula.[14] They may also be noted after the removal of a retained spectacle.

Direct-life cycle mites such as *Ophionyssus* are always an environmental problem and removal alone is insufficient. Any residual parasites or eggs must also be removed from the environment. Flushing with ivermectin (Ivomec, MSD Agvet) is a good method of physical removal of mites from the sulcus of the spectacle.[14] This technique requires the instillation of a small amount (0.2 mL) of undiluted ivermectin flushed around the sulcus, which, 2 minutes later, is followed by a thorough flushing with saline solution to remove the parasites. Although transdermal absorption is possible, the small volume of ivermectin and the thorough flushing appears sufficient to prevent any toxic effects.

Retained Spectacle

Retained spectacle is the most common ocular problem of snakes.[14,57,58] There is a syndrome in geckos referred to as retained eye caps.[28] However, this is a misnomer as it is often described in species without a spectacle. In these cases there is often underlying hypovitaminosis A with secondary bacterial infection and a resulting failure to shed the conjunctival lining underneath the eyelids, with the accumulation of cell debris within the palpebral fissure.[28]

The rest of this section concentrates only on the condition in snakes. Among multiple etiologies, environmental conditions are contributory if not the primary cause.[48] The condition arises because of a failure of the old spectacle to be shed during ecdysis.[14,48] The most common cause is a dry environment or dehydration (such as associated with systemic illness).[2] Other factors, such as inadequate nutrition or systemic disease, may also be contributory.[15] Scarring and the presence of mites may also lead to dysecdysis and retained spectacles. It is not unusual upon removal of a retained spectacle to find the mite (*Ophionyssus natricis*) still clinging to the spectacle or embedded within the sulcus formed from the spectacle and the protruding scales of the orbit ridge. Any cause of skin disease could also lead to the retention of spectacles,[14] including a suggestion of thyroid dysfunction.[46]

Temporary visual impairment may result from the retention of several spectacles. The retained spectacles may become secondarily infected, resulting in blindness. If not removed, subsequent shedding is also inhibited, and the spectacles build up to form a thickened mass of dead skin that affects the snake's vision and may affect its willingness or ability to feed.[14] The more retained layers, the easier the diagnosis of retained spectacle. A single retained spectacle may have only limited effects on the vision of the snake and is often missed by the owner, being picked up only during routine clinical examination at the time of presentation for other reasons. Often an associated creasing of the spectacle is seen as a dent in the surface when a spectacle has been retained. Ball (royal) pythons (*Python regius*) seem to be particularly prone to this phenomenon (see Fig. 71.12D). Although the absence of denting cannot be used to eliminate the possibility of a retained spectacle, the denting of a healthy spectacle (without a retained spectacle) is in itself pathognomonic of a previously retained spectacle. The denting decreases with time and usually disappears after the next slough, providing the spectacle is shed easily at that stage. This creasing or indenting of the new spectacle appears to have no effect on vision.

Diagnosis of a retained spectacle requires more than examining a slough and failing to find spectacles. Where dysecdysis is seen with retained skin still on the head and around, or leading to, the spectacle, the diagnosis is straightforward. Diagnosis is also easily made when multiple retained layers are found. The difficulty arises with the possibility of only one retained layer, when no indentation or opacification is seen. Examination with magnification (ideally with a slit-lamp illumination or biomicroscope) allows visualization of the increased thickness of the spectacle associated with extra layers.[14] Examination of the edges of the spectacle is useful because often tags of skin may be seen, especially if the head skin has been sloughed but only the spectacle is retained. Failure to confirm a retained spectacle before attempting treatment may lead to iatrogenic damage to the spectacle and corneal exposure (see previously). If any doubt exists as to whether or not a spectacle is retained, no treatment should be attempted but to wait until after the next shed and reexamine at that time.

Treatment involves soaking the retained spectacle to aid removal. This is best done with a wet cotton swab and rubbing from the medial and lateral canthi toward the center of the spectacle (Fig. 71.14). If the spectacle does not detach after gentle manipulation with a cotton swab, then artificial tears (hypromellose, Tears Naturale; Alcon or Ilube, Morfields) are applied several times daily for a few days to soften the spectacle before the technique is repeated. Although Frye[59] advised the use of forceps or other instruments to remove a retained spectacle, this author considers instrument use rarely indicated and should only be undertaken by an experienced veterinarian using magnification to reduce the risks of damage to, or even avulsion of, the underlying spectacle. The inadvertent removal of a new spectacle, as opposed to a retained spectacle, if unmanaged, leads to exposure keratitis[1,2] and eventual loss of the eye. If the retained spectacle cannot be removed easily, then waiting until the next shed to try again is best.

Pseudobuphthalmos

Blockage of the nasolacrimal system is more commonly encountered as a clinical problem in snakes and geckos.[2,44] Any fluid not draining down the nasolacrimal ducts is incapable of overflowing the sealed eyelid margins and accumulates in the subspectacular space. If fluid accumulation in the subspectacular space is due to a failure of nasolacrimal drainage, then the spectacle will bulge (see Chapter 91). This is correctly referred to as pseudobuphthalmos.[60] The resultant stretching of the spectacle has also been incorrectly referred to in the literature as a bullous spectaculopathy,[20,61] as it was considered similar to bullous keratopathy of mammals, where bullae or vesicles form within the epithelial cells of the cornea and can become large and even pendulous with the possibility of rupture.[62,63] The definition of a bulla is a cavitation, larger than a vesicle, within the epidermis.[64] The buildup of fluid within the subspectacular spaces cannot therefore be referred to as "bullous," nor indeed does it involve the spectacle per se. It should not therefore be referred to as bullous spectaculopathy but pseudobuphthalmos.

This condition was first incorrectly described[1] in an indigo snake (*Drycmarchon corais*) as "acute proptosis," but slit-lamp biomicroscopy confirms the accumulation of a clear, colorless fluid between the spectacle and the cornea, causing the spectacle to protrude with a noticeable enlargement in the subspectacular space biomicroscopy.[48] Pseudobuphthalmos is differentiated from subspectacular abscesses in that the fluid is clear and uninfected; if in doubt, stained cytology of aspirated fluid can be performed to document bacterial/inflammatory elements.

Investigation of nasolacrimal duct patency is possible with an injection of a small amount of fluorescein dye through the lateral canthus of the spectacle into the subspectacular space, as mentioned previously. However, when blockage is present, the increased pressure is likely to push fluid out through even the smallest hole in the spectacle. Chronic increase in pressure can eventually lead to damage of the cornea or even the globe itself.[14]

This condition may be only a temporary problem, and in one case, the eye returned to normal within 3 days without any therapy.[1] However, if it persists, then other causes, including masses in the maxillary region, may need to be ruled out by radiography or CT. Surgery may be required for persistent problems (see Chapter 91).

Keratoconjunctivitis Sicca (Dry Eye)

Keratoconjunctivitis sicca (dry eye) is seen in reptiles that do not have a spectacle (Fig. 71.15A). It is related to a reduction or failure of production of the aqueous phase of the tear film and is usually associated with changes in the lacrimal and Harderian glands associated with vitamin A deficiency.[18] The deficiency also causes conjunctival and corneal epithelial metaplasia and hyperkeratosis. Changes are reversible, but this is dependent on the length of time that the deficiency has existed. Often by the time the condition is presented to the veterinarian, permanent changes may have developed. Definitive diagnosis of the dry eye is made with cut down Schirmer tear test strips, phenol red thread, or the standardized endodontic absorbent paper point tear test placed into the conjunctival fossa to measure the aqueous phase of the tear film over a minute. Treatment of keratoconjunctivitis is similar to that

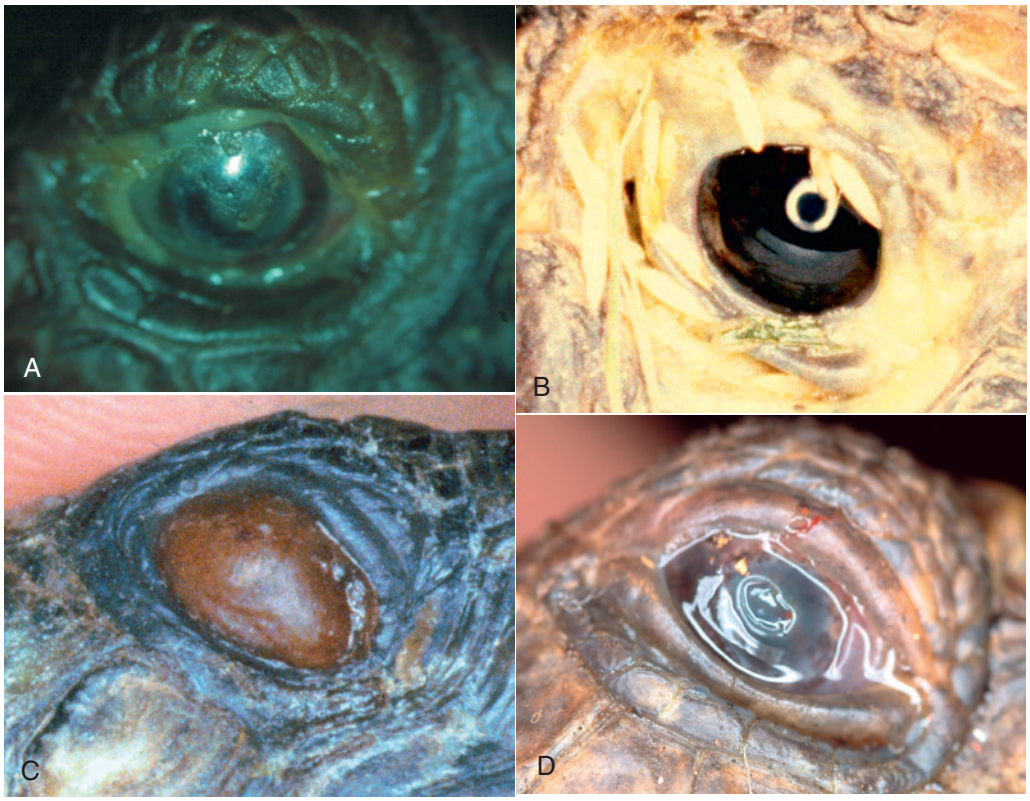

FIG 71.15 (A) Keratoconjuntivitis sicca (xerophthalmia) in a Mediterranean tortoise (*Testudo*). (B) Foreign body (seed) in eye of a Mediterranean tortoise. (C) Conjunctival swelling extending beyond the eyelid margins in a Mediterranean tortoise. (D) Corneal ulceration in a Mediterranean tortoise. (Courtesy of Martin P.C. Lawton.)

used in mammals, with artificial tear preparations, and when xerophthalmia (no tear production) is from vitamin A deficiency, administration of vitamin A and dietary correction is advised.[27,65]

Congenital Abnormalities of the Globe

Of the few congenital abnormalities described for the reptilian globe, microphthalmia is the most common disorder particularly in snakes,[2,16] although cyclopia and anophthalmia have been noted.[2] Five cases of bilateral and two of unilateral microphthalmia in a clutch of 16 eggs from 2 red-headed rat snakes (*Elaphe moellendorffi*) have been reported.[1] On histopathologic examination, normal structures were found within the small globes, with the only abnormalities being the absence of lenses.[1] Factors implicated in microphthalmia include genetics, nutrition, incubation temperatures and oxygen concentrations. Anophthalmia is rare but has been reported in several northern pine snakes (*Pituophis melanoleucus melanoleucus*).[2] The occurrence of true anophthalmia is rare, and a reptile that appears not to have eyes should always be considered as a case of microphthalmia unless histopathology confirms the absence of an eye (see Fig. 71.5C).[48]

Exophthalmos

Any retro-orbital mass or swelling can result in exophthalmia. Ultrasonographic examination with 10 to 20 MHz or greater probe is a useful tool to investigate, diagnose, and even allow guided biopsy for the collection of samples for cytology, histopathology, and culture. Abscessation is the most common cause of exophthalmos or periorbital swelling, and surgery is always indicated.[47] In chameleons, exophthalmos is often caused by periorbital swelling, which may be related to husbandry issues (reduced ventilation and humidity), irritants, vitamin A deficiency, and foreign bodies, as well as infection.[21]

An orbital varix (pathologic enlargement of one or more venous channels) has been described as a cause of an acute progressive swelling of one eye associated with an aneurysm of the retrobulbar vein in a green iguana (*Iguana iguana*), probably as a result of trauma.[43] Hypertension secondary to renal disease in iguanas, bearded dragons (*Pogona vitticeps*), and chameleons may also result in exophthalmia. This condition is often misdiagnosed in snakes and is really pseudobuphthalmos, with the subspectacular space being enlarged and causing enlargement of the globe.[1] A true unilateral congenital exophthalmia has been described, with histopathology demonstrating a cystlike structure with abundant eosinophils.[57]

Infection of the Globe

Bacterial infection can lead to a widespread degeneration within the globe and granulomatous response, often with the infection spreading beyond the globe itself.[66] Orbital infections can occur from hematogenous spread, penetrating injury, or foreign body.[67] The granulomatous response usually causes an enlargement of the globe, but as in other animals, severe trauma, inflammation, or infection can also lead to a shrinking of the eye (*phthisis bulbi*). A fungal infection in a rainbow boa (*Epicrates chenchria maurus*) has been reported as a cause of *phthisis bulbi*.[54]

Conjunctivitis

The examination of the conjunctivia should be routine in all reptiles with nonfused eyelids. Visual examination can still be performed (especially with magnification) in reptiles with a spectacle but is often limited because most of the conjunctiva is hidden from view. The frequent occurrence of foreign bodies within the conjunctival fornix is often linked to environmental conditions. In tortoises, ocular foreign bodies are a common finding in those that hibernate in hay (see Fig. 71.15B) or sand.[48] Lizards kept on peat or sand may occasionally get these materials into their eyes, resulting in blepharospasm.[48] Treatment is the removal of the foreign body by grasping it, often under topical local anesthesia with the aid of magnification and fine forceps or by physically flushing it out with a suitable solution (such as balanced salt or Hartmann's [lactated Ringer's] solution) via a soft fine-gauge intravenous cannula. Any ulceration or abrasion of the cornea should be treated with topical antibiotic.

A nonspecific inflammatory response due to a variety of ocular insults or disease can result in hyperemia, edema, and, it has been claimed, chemosis, but this is more subtle than in mammals and more associated with conjunctival swelling, extending beyond the eyelid margins (see Fig. 71.15C).[28]

Conjunctivitis is a common problem, although primary bacterial conjunctival infections are rare[2] and secondary opportunistic bacteria are more frequently encountered. In a survey of bacteria isolated from nondomesticated species with eye infections at a zoological collection, 5 of the 19 reported cases involved reptiles and included infections associated with *Aeromonas* spp., *Pasteurella* spp., and *Pseudomonas* spp.[68] In a laboratory colony of mixed lizards, an outbreak of conjunctivitis (with some developing respiratory disease) was associated with *Aeromona liquefaciens*.[69] A catarrhal conjunctivitis in a large group of Russian (Horsfield's) tortoises (*Agrionemys horsfieldii*) was secondary to debilitation and characterized by infection with *Proteus vulgaris*, *Citrobacter intermedium*, and a heavy infestation with oxyurids.[70]

Bacterial conjunctivitis in mammals is frequently suggested by mucopurulent discharge, but reptiles, like birds, lack granulocytic lysosomes, and therefore discharge is rarely seen. Infectious conjunctivitis usually results as caseous plaques, often retained within the conjunctival fornix but more commonly on the corneal surface (as discussed later).[48] Cases of keratoconjunctivitis (where both the cornea and conjunctiva are involved) are more likely to be associated with poor hygiene.[46] Ocular discharge and blepharospasm have been noted with bacterial infections of the conjunctiva in lizards.[69] Local extension of any infection could result in panophthalmitis and loss of the eye or even eventual septicemia and death.

The presence of plaques within the conjunctival fornix can cause a foreign body reaction. Any caseous material within the conjunctival fornix should be examined carefully with a microscope and, where indicated, submitted for culture and sensitivity. Occasions also exist where conjunctival biopsies should be taken for histopathologic or electron microscopic examination to differentiate between infection and metaplasia (vitamin A deficiency). Hypovitaminosis A causes displacement of the conjunctiva by desquamated cells that leads to the production of an amorphous mass or pseudoabscess and multiple retention cysts.[18] The material that accumulates in the conjunctival sac is a mixture of keratinous lamellae and eosinophil granulocytes.[18] One should always remember that this condition is a systemic disease.

Caseous conjunctivitis is part of the herpesvirus-related lung, eye, and trachea disease reported in green sea turtles.[71] An underlying secondary infection often involves gram-negative bacteria and a resultant keratoconjunctivitis. Affected turtles also have respiratory signs and may be unable to dive.[71]

Where conjunctivitis was noted in a survey of reptiles in a zoological collection, blepharitis (blepharoconjunctivitis), corneal disease, or other problems were found.[68] Any reptile (except those with spectacles) with blepharospasm warrants a careful examination of the conjunctival fornix with magnification and wetted endodontic paper points to remove any caseous plaques. Routine flushing with an appropriate solution, via a fine soft cannula (24-gauge), and antibiotics usually controls bacterial infections.[48] Conjunctivitis in snakes presents as a subspectacular abscess[14] and has been covered previously.

Certain plants (*Ficus, Pothos*) have been found to cause conjunctivitis in chameleons due to the oxalates in their leaves.[21] Viral infections, such

as fibropapilloma or herpesvirus infection of green sea turtles, may cause proliferative or ulcerative lesions of the conjunctiva.[2,51] Leeches (*Ozobrancus* sp.) have been found to parasitize the conjunctiva of green sea turtles.[2] Six species of *Neopolystoma* spp. were isolated from the conjunctival sac of freshwater chelonians, with a high prevalence rate (80% in one study) but low intensity (one to three worms per animal).[72]

Corneal Disease

Ulceration of the cornea may be associated with foreign bodies, prolonged infection, and trauma, as encountered in other taxa (see Fig. 71.15D). Corneal ulceration in snakes is rare because of the protective effects of the spectacle; generally only infection or severe trauma may cause this problem. Diagnosis of a corneal ulceration is made with the uptake of fluorescein dye into the stroma (see Fig. 71.5B). In reptiles with spectacles, topical fluorescein is not useful unless it is injected into the subspectacular space. Corneal lacerations are usually traumatic[73] and can be surgically repaired (see Chapter 91) but should always be treated prophylactically with topical ophthalmic antibiotics.

Keratitis

Excessive exposure to UV light may contribute to an induced photokeratoconjunctivitis and eventually lead to corneal ulceration.[74] In addition, care is required when using surgical or low-level therapeutic lasers.

Corneal inflammation/infection (keratitis) in tortoises may present as a white corneal mass (see Fig. 71.10B), is often associated with the immunosuppressive scenario of hibernation, and may be the result of infection with *Moraxella* spp., *Pseudomonas* spp., or *Aeromonas* spp.[27] Such keratitis is infectious and contagious and should be considered a herd problem. Treatment consists of removal of the plaque from the cornea (see Chapter 91) and topical therapy based on culture and sensitivity of the removed material. Severe keratitis can lead to scarring and pigmentation of the cornea, similar to that seen in mammals.

The presence of the spectacle in snakes does not preclude the development of corneal disease. A mycotic keratitis in a reticulated python has been described[75] where a firm mass was palpated under the spectacle and required enucleation together with the removal of some surrounding tissue. Histopathologic examination showed the corneal stroma to be infiltrated with spores and mycelia with branching filaments and septation. If fungal hyphae are seen on corneal scrapings, then treatment with topical miconazole is a possibility. Fungal keratitis, however, can cause a panophthalmitis,[44,54] which is only treatable with enucleation.[54] Topical corticosteroid therapy[44,54] and trauma[44] are possible underlying causes of fungal keratitis.

There are a number of viral infections that can cause keratitis, including herpesviral-induced proliferative or ulcerative lesions of the cornea of green sea turtles that can involve the entire cornea.[2,51,76] The lung-eye-trachea disease also causes changes to the cornea, usually involving a white plaque or opacification.[77]

Uveitis

Uveitis is infrequently reported and may be due to systemic disease, trauma, infection (bacteria, fungi, or virus), or neoplasia.[28] The clinical signs and treatment are similar to those noted in mammals. Hyphema and hypopyon are often present after exposure to freezing temperatures in chelonians (see Fig. 71.3A).[27,48] Hypopyon is a secondary feature of reptiles with an underlying systemic infection[2] such as a bacterial septicemia; *Klebsiella pneumoniae* has been associated as one possible cause.[45] All reptiles with hypopyon should have a thorough investigation for potential infectious causes. Where septicemia is confirmed, the prognosis is guarded.

Cataracts

As in all taxa, cataracts may occur for a variety of reasons, including senility. Cataracts in tortoises have been associated with freezing episodes.[27,48,78] They are hypothesized to be particularly prone to damage from low temperatures because of the soft and fluidlike nature of their lenses.[7] In some cases, these changes are reversible, although up to 18 months may be necessary for the lens to clear.[27,48] Cataract surgery in reptiles can be performed (see Chapter 91).

Retinal Disease

Our knowledge of retinal disease in reptiles is still very much in its infancy and sadly lacking when compared with that of mammalian and avian species. Often the effects are not noticed until the patient is totally blind, when medical intervention to restore vision is futile.[79] Retinal damage associated with vitamin A deficiency and freezing have been reported in tortoises.[78] In certain circumstances, early treatment with vitamin A may result in clinical improvement. Retinal degeneration has been reported in tokay geckos,[45,80] although it is thought to be a sporadic finding in most reptile families.[52]

Ocular Therapeutics

There are no specific medications licensed for ophthalmic use in reptiles, and therefore off-label treatments of human and other veterinary preparations are required. The range of antimicrobial ophthalmic preparations are often appropriate for the potential bacterial pathogens encountered and include several fluoroquinolones as well as gentamycin. The frequency used should mirror that for other species (usually three to four times per day). The size of the drop is appropriate for mammalian species (including humans), and owners should be warned that despite spillover from the small reptilian fornix, effectiveness is not reduced. Where the ocular presentation is part of a systemic infection, oral or injectable antibiotics are also indicated.

Vitamin supplements, especially vitamin A, can be used as an adjunctant therapy for a wide range of ocular conditions for which the case history is suggestive of nutritional deficiency. Overuse should be avoided to prevent possible toxic effects (e.g., hypervitaminosis A), and dietary correction is the mainstay of long-term treatment and prevention.

Inflammatory conditions, such as trauma and uveitis, should be treated with nonsteroidal anti-inflammatories (NSAIDs), either topically or systemically, or both. Topical drugs such as flubiprofen and bromfenac appear to be well tolerated. Corticosteroids should be avoided unless there is a real justification (e.g., unresponsive NSAID uveitis or corneal vascularization, immune-mediated disease).

For reptiles with spectacles, the potential penetration of topical medications may require a systemic treatment protocol or subspectacular injections in order to provide effective administration to the target area to be treated.

Lubricating drops (artificial tears) and N-acetylcystine may help to soften and dislodge retained spectacles.[28]

Otorhinolaryngology

Michelle Kischinovsky, Stephen J. Divers, Lori D. Wendland, and Mary B. Brown

The anatomy and physiology of reptiles differ greatly from avian and mammalian species but also between its orders, genera, and species. Knowledge of normal anatomical structures, their functions, physiological capabilities, and pathophysiology is essential in differentiation between the healthy and diseased.

Diseases affecting the ear, nose, and throat often follow similar disease patterns or have similar clinical signs, although different etiologies. Many are multifactorial, have nutritional, infectious or noninfectious causes or a combination thereof, as well as involving multiple areas of the body; therefore disease complexes or syndromes are often described in relation to these body systems. Although pathologies of the ear and nose involve key sensory organs, some reptiles appear to have great plasticity in thriving with sensory alteration, although welfare aspects should not be ignored. Disease differentiation can be difficult, time-consuming, and expensive. A systematic approach to the clinical examination combined with knowledge of the available and appropriate diagnostic tools will aid the investigatory process. With the threat of antibiotic resistance, emerging novel viruses and other infectious agents, as well as an increase in the incidence of zoonotic diseases, we should aim to treat a definitive diagnosis rather than a clinical manifestation.

ANATOMY AND PHYSIOLOGY

The structures of and within the laryngo-pharynx, aural, and nasal cavities vary greatly in size, shape, and function, between and even within orders. Taxanomic differences significant for disease identification will be highlighted, but unfortunately some generalizations will be made as detailed anatomical and physiological adaptations are beyond the scope of this chapter.

Ear

The reptilian ear is located caudoventral to the eye and is covered either by an enlarged cutaneous scale or a semitransparent tympanum of varying thickness. There are species-specific adaptations; however, the ear generally consists of three divisions (Fig. 72.1 and Fig. 72.2).

The external ear comprises the depression (external auditory meatus) extending from the lateral surface of the head to the tympanic membrane and collects sound waves from the environment. It is usually no more than a few millimeters deep, if present at all. The external ear is absent in chelonians, snakes, amphisbaenians, and tuataras, as well as some lizards.[1] In most species of gecko a meatal closure muscle is present, offering further protection to the tympanum.[2] In crocodilians a similar muscle is present in the dorsal of two skin folds (earflaps) overlaying and hiding the external meatus and tympanum.[3]

The middle ear transmits and amplifies sound waves from the tympanic membrane, creating vibrations transmitted through a chain of bony ossicles—the columella (an elongated version of the stapes)—and in some species also the cartilaginous extracolumella. The incus and malleus are absent in reptiles. The ossicles are suspended in the air-filled tympanic cavity and extend medially from the tympanic membrane to the oval window of the cochlea (Fig. 72.2 and Fig. 72.3). The tympanic cavity and structures vary widely in shape and size between orders, merely a narrow fissure in snakes and absent in amphisbaenians and tuatara. Snakes, lacking Eustachian tubes, have a quadrate bone connecting the mandible to the stapes and can receive low-frequency vibrations. In turtles, the large cavity extends caudally into a blind pouch within the squamosal bone. Crocodilians have an extensive channel system linking the right and left middle ears.[4]

In most lizards the differentiation between the tympanic cavity and pharyngeal space is indistinguishable, though in some chameleons this division is marked by a thin membrane with a small fenestration believed to correspond to the Eustachian tube.[1,5] The pharyngeal orifice of the Eustachian tube can be identified on the buccal oral mucosa just caudal to the angle of the jaw of the chelonian (Fig. 72.4).

The inner ear comprises the organs related to equilibrium/balance (the semicircular canals, utricle, and saccule) and auditory perception (cochlear duct). The vibrations received are transmitted via fluid oscillations to the cochlear hair cells. These movements are subsequently transmitted to the brain via the vestibulocochlear nerve (cranial nerve VIII) for interpretation. Species adaptations are extensive, and their individual anatomical and physiological descriptions are beyond the scope of this chapter.[1,6] In general, species with a well-developed

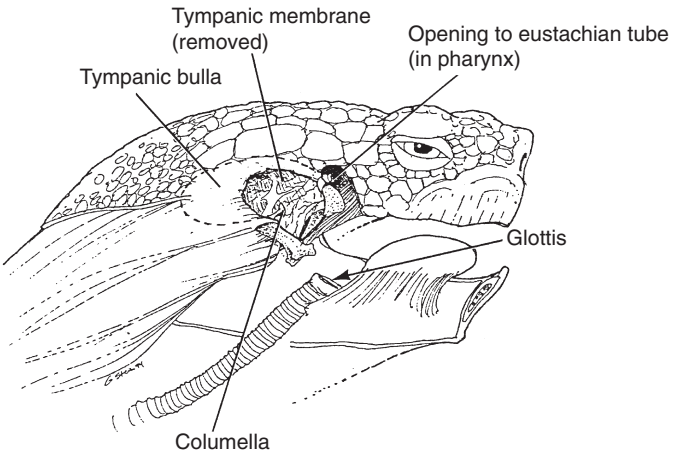

FIG 72.1 Head of a box turtle (*Terrapene* sp.) with the right lower jaw removed. Note the extent of the middle ear cavity demarcated by the *dashed line.* (Adapted from Boyer TH: Common problems of box turtles [*Terrapene* sp.] in captivity, *Bull ARAV.* 1992;2[1]:11.)

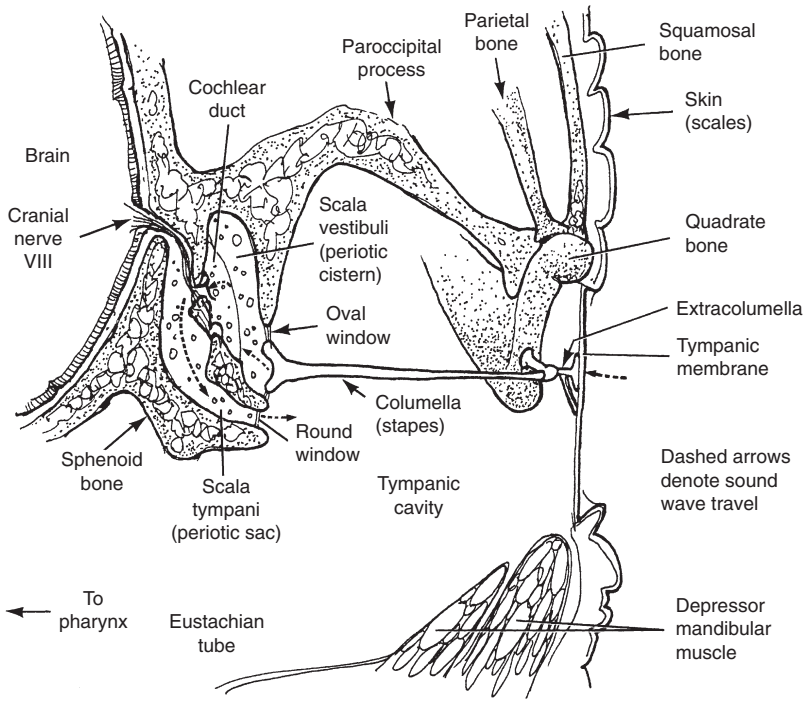

FIG 72.2 General relations of the middle and inner ear structures in the lizard *Scleroporus magister*. Coronal view of the right ear as viewed from behind. (Adapted from Wever EG: *The reptile ear,* Princeton, NJ: Princeton University Press; 1978.)

tympanum have a good sense of hearing, and atympanic species have hearing limited to low-frequency ranges of 150 to 600 Hz—generally the groundborne (somatic) or waterborne vibrations as opposed to airborne sound.[1,7] Furthermore, hearing does not seem dependent on the tympanic cavity size but more so on the conductive mechanism of the columella. It is supposed that reptilian ears are more important for balance than for hearing.[1]

Nasal Cavity

The upper respiratory tract consists of the rhinarium and the nasal cavity (Fig. 72.5). Within the nasal cavity are the external nares (Fig. 72.6), vestibulum nasi, cavum nasi proprium, conchae (turbinates), ductus nasopharyngeus, and the choanae (internal nares).[8–10] Furthermore, some species have a vomeronasal (Jacobson's organ) and nasal salt glands (Fig. 72.7). Reptiles typically breathe in air through the external nares with their mouth closed. Air enters the relatively short vestibulum and passes across the conchae in the nasal chamber then enters the pharynx via the choana(e), which is in close anatomical association with the larynx.

The tubular vestibulum nasi extends from the external nares to the cavum nasi proprium with the border often distinguishable by the difference in diameter and, in most, demarcated by a ridge in the lateral nasal wall. Turtles and many species of squamates, both aquatic and terrestrial, have erectile tissue in the vestibulum to close the opening during water or sand submersion.[11,12] In most reptiles and amphibians the cavum nasi proprium is the largest nasal structure and is usually subdivided into smaller cavities or parts by ridges, membranes, or cartilaginous septae. It is the portion that lies between the vestibulum and the nasopharyngeal duct and is partially covered by sensory epithelium. In chelonians the dorsal area is lined with multilayered olfactory epithelium and ventrally with nonsensory or respiratory epithelium.[11] The chonchae, projections from the lateral wall of the cavum nasi proprium, are present in varying degrees in crocodilians, tuataras, lizards, and most snakes, however, are lacking in chelonians.[11] The nasopharyngeal duct is a simple tubular connection between the cavum nasi proprium and the choana(e). The tuatara lack this structure; it is short in lizards and increasingly longer and more developed in snakes, turtles, and crocodilians, and even more so in aquatic species. It is lined by nonsensory epithelium.[11]

The vomeronasal organ, also referred to as Jacobson's organ, is generally located in the ventral nasal cavity (as opposed to the olfactory epithelium which generally lies dorsally). It is innervated by a branch of the olfactory nerve (cranial nerve I) and is rich in chemoreceptors. It is absent in crocodilians. In tuatara it remains in the nasal septum as a duct in the choanae connected with both the oral and nasal cavities, whereas it is associated with the mouth in squamates.[11,13] Turtles appear to have similar sensory cells scattered across the dorsal nasal epithelium and believed to be the homolog of the organ found in other reptiles. Semiaquatic turtles, crocodilians, and some lizards perform buccal oscillation (sometimes referred to as gular pumping), when air is passed over nasal epithelium by pharyngeal contractions. It is believed to serve an olfactory, rather than a respiratory, function, analogous to mammalian "sniffing."[14–16] In snakes and some lizards it is present just rostral to the choana(e) as a pair of pits in the roof of the mouth into which the tongue transfers chemical scents. The nasolacrimal ducts open either within (some snakes) or adjacent (some lizards) to the organ and drains from the medial canthus of the eye.[11]

Several nasal glands are present and vary greatly in shape, size, and function between species. The nasal salt glands are present in some desert-living, herbivorous, and marine lizards, such as the green iguana (*Iguana iguana*) and chuckwallas (*Sauromalus* sp.).[17,18] Excessive sodium, potassium, and chloride is excreted by these glands when plasma osmotic concentration is high and allows water conservation. The lizards can expel a clear fluid that dries into a fine white sodium-potassium salt powder, which can sometimes be seen deposited around the nares or on glass enclosures.

The choana(e) (palatine-like structure) divide the nasal, oral, and/or pharyngeal cavity. It is visible in the dorsal oropharynx and varies in shape and length from a narrow oval slit to a larger triangular opening.

Willis, University of Oklahoma. From Willis KL, Christensen-Dalsgard J, Ketten DR, et al. Middle ear cavity morphology is consistent with an aquatic origin for Testudines. *PLoS ONE*. 2013; 8[1]:e54086.)

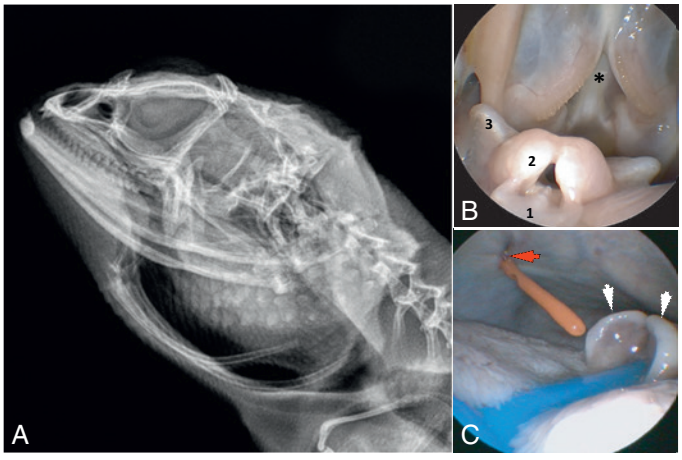

FIG 72.4 (A) Lateral radiograph of a conscious bearded dragon (*Pogona vitticeps*) illustrating the continuous airway from external nares to trachea thanks to the close approximation of the larynx and choana when the mouth is closed. (B) Endoscopic view of the iguanid larynx illustrating the epiglottis (1), paired arytenoid (2), and cricothyroid (3) cartilages. The dorsal choanal opening (*) is also visible. (C) Endoscopic view of the larynx and pharynx of a leopard tortoise (*Stigmochelys pardalis*). The blue Cole endotracheal tube has been retracted to provide a better view of the arytenoid cartilages (white arrows) and the right Eustachian opening (red arrow), which has been catheterized with a red catheter (as part of a surgical resolution for bacterial otitis). (Courtesy of Stephen J. Divers.)

It can be either a single opening or a paired structure. Most chelonians have ridges, flaps, or papillae along the lateral choanal margins.[11] Crocodilians have a unique structure visible in its place, the basihyal valve and velum palate, which isolate the oral cavity from the nasal cavity, pharynx, and larynx when partly submerged.

Pharynx/Larynx

The larynx is the section of the respiratory tract connecting the pharynx to the trachea. Its primary function is to protect the lower airways by closing upon mechanical stimulation. It allows reptiles to breathe while consuming food. There is a complex skeletal, muscular, ligamental, and neurological relation between the larynx, tongue, glottis, and palate that allow swallowing, inhalation, and vocalization, which is beyond the scope of this section.[19,20]

The larynx is situated on top of the hyoid bone, which is technically not part of the laryngeal structure, yet without it laryngeal motion would not be possible. Typically, the larynx is made up of several cartilaginous structures—often including the thyroid cartilage, cricoid cartilage, and paired arytenoid cartilages. In most reptiles, including chelonians and crocodilians, the thyroid and cricoid are fused to create the cartilago thyreocricoidea or cricothyroid cartilage (see Fig. 72.4B and C). As the larynx lies on the corpus of the hyoid apparatus, this part of the hyoid of turtles and crocodilians assumes the functions of the mammalian thyroid cartilage. Some reptiles have a membrane at the tongue-base equivalent to the epiglottis; others have a cartilaginous structure, which aids in vocalization sounds. Crocodilians lack an epiglottis. Snakes have one of the most specialized laryngeal structures, with a muscular hyoid-type attachment allowing forward movement of the upper trachea (glottal tube) pulling the larynx forward. This allows breathing during a lengthy prey-swallowing process.[21]

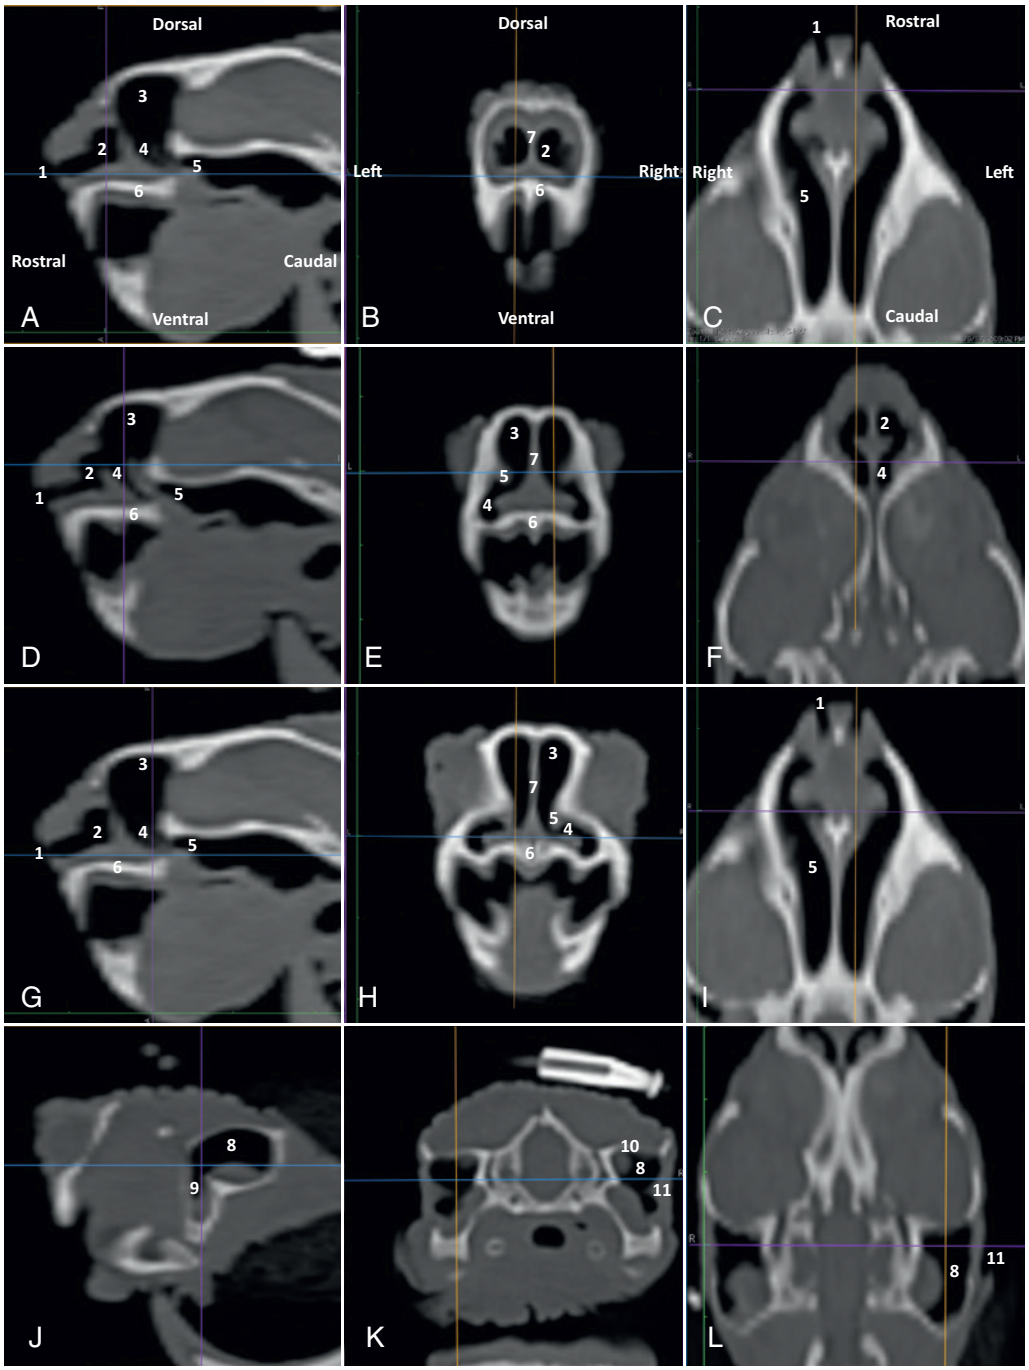

FIG 72.5 Skull CT of a desert tortoise (*Gopherus agassizii*, 0.6 mm slices, post-contrast bone algorithm, WW: +4000; WL: +400). Images A–C, D–F, and G–I represent corresponding sagittal (A, D, G), transverse (B, E, H) and coronal (C, F, I) planes through the skull. Yellow, purple, and blue lines indicate sagittal, transverse, and coronal planes, respectively; external nares (1), nasal vestibule (2), regio olfactoria (3), and regio intermedialis (4) make up the nasal cavity, choanal tube (5), palatine bone (6), and nasal septum (7). Images (J–L) represent corresponding sagittal (J), transverse (K), and coronal (L) at the level of the ear. Yellow, purple, and blue lines indicate sagittal, transverse, and coronal planes, respectively; also represented are the tympanic cavity (8), auditory or Eustachian tube (9), paraoccipital process (10), tympanic membrane (11). (Courtesy of Stephen J. Divers.)

GENERAL APPROACH TO CASE MANAGEMENT AND TREATMENT

The foundation for any successful case management is a thorough understanding of the clinical signs displayed. A detailed anamnesis will often identify anatomical areas that require further investigation, as well as understanding of the urgency and "aggressiveness" necessary in diagnostic and treatment planning. As many reptilian disease processes occur as a direct result of suboptimal husbandry, knowledge of individual species requirements is paramount, and detailed questioning into these conditions is necessary (e.g., temperature, humidity, ultraviolet lighting, daylight hours, air quality/draft, as well as feeding/dietary circumstances). See section 3 for further details.

During evaluation, care should be taken not to cause injury to the animal or the handler. Furthermore, many infectious agents are spread through the serous discharges produced in these body systems, hence appropriate protection and sanitation is necessary, especially when handling multiple specimens (see Chapter 42).

Clinical examination of the aural, nasal, and pharyngeal/laryngeal cavities should include inspection for symmetry and any pain response. All cavities should be free from lesions, discharges and swellings, parasites, and foreign objects. An oral inspection is necessary to evaluate the internal nares (choanae/choanal slit) as well as the pharyngeal space.

A complete blood count (biochemistry and hematology) may allow differentiation between an infectious and an inflammatory process as well as the overall function of vital organ systems. Such clinicopathologic data can be useful if general anesthesia or prolonged medical treatment is anticipated. Advanced diagnostic equipment has become available for aiding the investigation into these cavities, which are otherwise often difficult to impossible to evaluate antemortem.[22] Endoscopy, radiology, CT, and MRI facilitate visualization and sample collection for cytology, microbiology, or histopathology (see Fig. 72.6).

SPECIFIC DISEASES

Otitis

Generally, diseases of the reptilian ears are not extensive. Conditions that in other species would most certainly cause sequelae or noticeable behavioral changes caused by impaired hearing or balance do not appear to affect reptiles in a notable way. Congenital abnormalities have not been described.

Tympanic Protrusions. Aural polyps in the middle ear and aural-pharyngeal region of the green iguana (*Iguana iguana*) have been associated with cryptosporidial infections (Fig. 72.8B). The protozoan, commonly seen as a reptilian gastric pathogen, is not known to be part of the normal aural microflora in iguanas. Progressive protrusion of the tympanic membrane is typical, but anorexia and head swelling can occur. Histologically the masses consist of dense fibrous connective tissue with hyperplastic epithelium and mixed cells (heterophils, lymphocytes, and plasma cells), with scattered ducts, cysts, and glands.[23,24] The lesions resemble the inflammatory, nasopharyngeal polyps located in the tympanic cavity or auditory tube of cats.[25] Transmission electronmicroscopy has been used to identify cryptosporidial trophozoites. It is unknown whether *Cryptosporidium* was involved in inducing the polyp formation or a secondary invader.[24] Data surrounding best-practice treatment are deficient. Surgical removal has been attempted, but recurrence has been reported.

Aural Abscess

Clinical significance. Aural abscessation is a condition characterized by an accumulation of caseous material within the middle ear or tympanic cavity, resulting in a protrusion of the tympanum (Fig. 72.9). The condition exists in both free-ranging and captive reptilian populations and is most commonly seen in chelonians (tortoises and semiaquatic turtles) as well as occasionally in lizards.[26–32] It is commonly encountered in private practice and, although usually not an emergency, should be addressed with promptness. During an active infection/episode or postoperatively there appears to be no notable vestibular or hearing-related sequelae.

Known etiological cause(s). No known cause has been identified. Aural abscess formation appears to be multifactorial and a result of several predisposing factors. It is generally accepted that there exists a correlation between abscess formation and improper husbandry (e.g., suboptimal habitat temperatures, poor hygiene) leading to

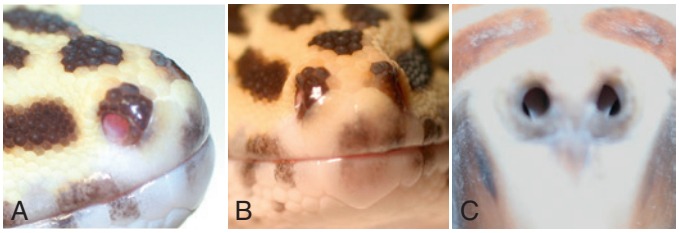

FIG 72.6 Normal external nares in a (A and B) leopard gecko (*Eublepharis macularius*) and (C) loggerhead sea turtle (*Caretta caretta*). (Courtesy of Stephen J. Divers.)

immunosuppression as well as inadequate nutrition resulting in vitamin A deficiency.[32] Hypovitaminosis A causes hyperplasia and squamous metaplasia of epithelial tissues, including those of the pharynx, trachea, middle ear, and Eustachian tube, leading to an accumulation of exfoliated squamous cells and keratin-like debris within the tympanic cavity, which eventually results in abscess formation.[27,32–34]

This assumed relationship is supported by free-ranging Eastern box turtles (*Terrapene carolina carolina*) with pathological aural changes in association with organochloride-containing pesticides known to cause vitamin A metabolism disruption in other species.[33–36] However, other studies have been unable to induce tympanic squamous metaplasia and therefore experimentally could not replicate the correlation between abscess formation and organochlorine compounds in vitamin A–deficient red-eared sliders (*Trachemys scripta elegans*).[37,38]

The Eustachian tubes, connecting the oropharynx to the middle ear, may provide a pathway for ascending pathogens into the tympanic cavity, which in an immunocompromised animal may contribute to abscess development (Fig. 72.10). However, no consistent bacterial pathogen has been isolated, and most (mainly aerobic gram-negatives) are believed to be opportunistic commensals from the oral cavity.[27,31,39] Though less likely, hematogenous spread and traumatic etiology are possible.

The anatomical differences between the chelonian ear and other reptilian taxa may also be a factor in the increased incidence of aural abscesses in chelonians, as this condition is rarely seen in lizards that lack Eustachian tubes and snakes where the tympanic cavity is reduced to a narrow fissure.[1] Aural abscesses have never been reported in species lacking a tympanic cavity.

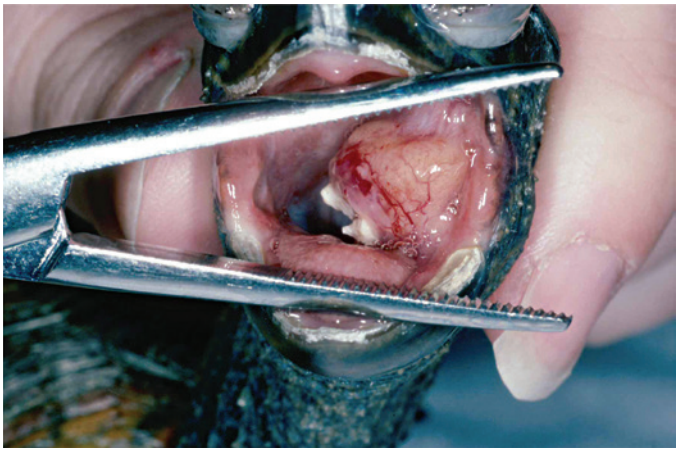

FIG 72.10 The Eustachian tube connects the middle ear to the oropharynx. Digital pressure on the tympanic membrane may force inflammatory debris through the passage into the pharynx. (Courtesy of Stephen Barten.)

The absence of lysosomes (within their granulocytic leukocytes) in reptiles results in a caseous, inspissated pus. Histologically, cases range from mild squamous metaplasia and hyperplasia to more severe cases involving pronounced inflammation and osteolysis.[27,33,39,40]

Clinical presentation and diagnostic confirmation. The tympanic swelling(s) may present as unilateral or bilateral, semifirm to firm, and cause protrusion of the tympanic membrane rather than rupture. Caseous debris may be seen entering the pharynx through the Eustachian openings. Obvious vestibular signs are generally lacking, though head tilt can occur (see Fig. 72.8A).

Diagnosis can often be made solely by visual assessment. Additional tests may add therapeutic or prognostic value and can include fine-needle aspiration cytology (to aid differentiation from neoplasia and cryptosporidiosis) as well as hematology and blood chemistry to evaluate systemic disease involvement. Radiography and computed tomography may aid in determination of severity and appropriate management.[40]

Specific therapy. Surgical intervention is required (see Chapter 92 for details on surgery of the ear). Due to the avascular and inspissated structure of the abscess, it is easily manipulated out of the tympanic cavity in its entirety. Vigorous cleaning with a curette is not advised, as it may damage the structures of the middle ear (columella) responsible for sound conduction.[41] The deficit is lavaged daily to twice daily and the tympanum is often left to heal by second intention, though reports of successful outcomes from sutured tympanums do exist. Placing an irrigation cannula can assist frequent flushing, especially in uncooperative tortoises (Fig. 72.11). Antibiotics, particularly systemic, are seldom necessary. Vitamin A supplementation as adjunct therapy has been suggested; however, no scientific evidence exists confirming that supplementation alone will add relief to the condition. Furthermore, a risk exists in development of iatrogenic hypervitaminosis A if given parenterally (see Chapter 84). It is difficult to reliably diagnose a deficiency of vitamin A as blood levels generally remain stable unless liver stores are severely depleted.[42]

Prognosis and prevention. Complete excavation of aural debris, appropriate wound management, and correction of any concurrent suboptimal husbandry conditions results in a good prognosis. Recurrence does occur and is typically due to inadequate surgical debridement or failure to address the underlying predisposing factors.[32] Education with regard to appropriate husbandry, sanitation, and nutrition is beneficial for prevention.

(A) The central ulcer is visible and an incision has been made around the tympanic membrane in preparation for surgical debridement. (B) Postoperative view demonstrating an irrigation cannula sutured in place to permit frequent flushing and topical therapy in this recalcitrant tortoise. (Courtesy of Stephen J. Divers.)

Rhinitis

Mycoplasmosis

Clinical significance. In general, respiratory mycoplasmosis in animal hosts is associated with chronic lower respiratory tract disease (pneumonia or pleuropneumonia) and can be accompanied by extrapulmonary manifestations, including synovitis/arthritis, otitis, and central nervous system sequelae.[43,44] In contrast, mycoplasmosis in turtles (also known as upper respiratory tract disease [URTD]) presents with clinical signs including nasal discharge, conjunctivitis, ocular discharge, and palpebral edema but not pneumonia.[45] Mycoplasmal infection can cause fulminant lethal sepsis and synovitis/arthritis in alligators and in experimentally infected caimans and synovitis/arthritis in crocodiles, and has been implicated in pneumonia in snakes.[7,46–51] *Mycoplasma* has been isolated from vertebral abscesses in green iguanas, but experimental infection studies were inconclusive as to the pathogenic potential.[52,53]

Mycoplasmosis is one of the most extensively characterized infectious diseases of free-ranging chelonians. Although a great deal of progress has been made to establish the etiology and distribution of the disease and the development of diagnostic assays, information is currently lacking with regards to the long-term effects of this disease within tortoise populations. Nearly catastrophic declines in desert tortoise (*Gopherus agassizii)* populations located in and around Kern County, California, that occurred in the late 1980s may have been associated with mycoplasmosis and contributed to the listing of desert tortoises north and west of the Colorado River as "threatened" by the federal government.[45,54] Similar morbidity and mortality events have been reported in gopher tortoise (*Gopherus polyphemus)* populations.[55–61] The extent to which mycoplasmosis is a contributing factor in these die-offs is presently unknown; however, many of these populations are the focus of extensive investigations attempting to determine the cause of increased tortoise mortality. Mycoplasmosis in virtually all animal species studied is typically characterized by chronic and life-long morbidity, with mortality observed during initial outbreaks or when stressors exacerbate the disease.[43,62,63] Therefore mortality events in wild populations are likely the result of synergism between the pathogen and external stressors such as drought and habitat degradation. Additional long-term studies evaluating mycoplasmal disease dynamics, influences on population demographics and individual tortoise survival, and anthropogenic influences on disease are critical for the development of sound, scientifically based management recommendations for free-ranging tortoises.

Known etiological cause(s). *Mycoplasma agassizii* and *M. testudineum* are recognized as distinct species and are the only confirmed, independent etiological agents of URTD in chelonians.[64–68] An unidentified but proposed third *Mycoplasma* sp. has been reported, in some cases in concert with clinical signs of URTD, in several members of the Emydidae family, most notably in *Terrapene* spp.[69–74] Mycoplasmas from the Emydidae family were not cultured and were identified only by partial 16S rRNA sequences that have 97% to 98% similarity to *M. agassizii*; however, based on the available GenBank sequences, Emydidae-specific signature mutations are present in the 16S rRNA gene.[70,72,73] Partial 16S rRNA sequences from members of the Geoemydidae also had 97% to 98% similarity to *M. agassizii.*[75,76] The PCR 16S rRNA sequence determined for members of the Emydidae and Geoemydidae ranged from only 15% to 66% of the gene with no clinical isolates obtained. Therefore it is unclear if these are new, but closely related, species or in fact *M. agassizii.* Clinical isolates will be required to fully address this issue.

Coinfections with herpesvirus and ranavirus have been reported.[70,77–79] Environmental stressors and concurrent infections with other bacterial and viral organisms may also be involved in the pathogenesis of this disease, as has been observed in mycoplasmal diseases affecting other host species.[62,80–83]

Although other microorganisms, including *Pasteurella testudinis,* iridovirus, herpesvirus and several fungal organisms have been isolated from tortoises with overlapping clinical signs; none have been demonstrated as independently resulting in URTD.[84–89]

Both *M. alligatoris* and *M. crocodylii* are confirmed as etiological agents of arthritis and pneumonia in Crocodylians; additionally, *M. alligatoris* is associated with multiorgan sepsis and mortality in alligators and caimans.[47,48,50,90–92] Although *Mycoplasma iguana* is generally considered pathogenic, the etiology has not been as rigorously confirmed.[52,53]

Experimental studies suggest that the primary route of transmission for mycoplasmas in both wild and captive tortoises is through direct contact, particularly when an animal is exhibiting a nasal discharge.[45,67,68,93,94] Vertical transmission occurs at a very low rate in mycoplasmal infections of poultry and is likely similar in chelonia.[94,95] It will be influenced by the time of infection in the female tortoise, the stage of oogenesis when the animal is clinically ill, and the virulence of the organism. In the wild, animals do not become seropositive until the age of sexual maturity.[61] Additional studies involving a large number of tortoises infected at different times during the reproductive cycle would be required to completely rule out vertical transmission in tortoises. Environmental transmission is unlikely in wild populations, since mycoplasmas lack a cell wall and are highly susceptible to desiccation in natural environments. In captive conditions, however, increased tortoise densities and higher loads of organic material could facilitate the persistence of the organism outside the host.

A *Mycoplasma* was isolated from a Burmese python.[49] Additionally, *Mycoplasma* sp. have been detected by 16S rRNA PCR and isolation from Boidae and Pythonidae snakes.[51] The clinical isolates appear to be new species, with only 90% reported similarity to *M. agassizii*; available GenBank sequences for Boidae and Pythonidae snakes were only 95% similar to both *M. agassizii* and *M. tesudineum* as well as to *Mycoplasma caviae,* a commensal of guinea pigs.[49,51] All cases presented as tracheitis and pneumonia; however, although these anecdotal reports are suggestive, the pathogenic potential and clinical significance remain unclear.[49,51]

Clinical presentation. URTD in tortoises is characterized by a rhinitis and conjunctivitis. Clinical signs, including nasal discharge, ocular discharge, palpebral and periocular edema, and conjunctival hyperemia and edema, may develop as early as 2 weeks postinfection (Fig. 72.12).[45,67,68,94] It is important to note that clinical signs may appear alone or in concert with other signs. The clinical presentation of URTD in tortoises is somewhat unusual in that tissue damage and disease

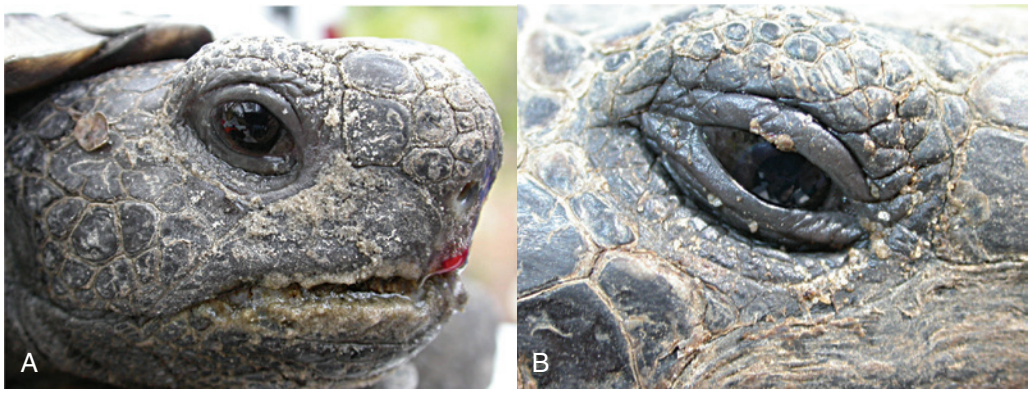

FIG 72.12 (A) A wild gopher tortoise (*Gopherus polyphemus*) with acute mycoplasmosis exhibiting a severe, hemorrhagic nasal discharge. (B) Gopher tortoise with conjunctivitis, ocular discharge, and palpebral edema due to mycoplasmosis.

appear localized to the upper respiratory tract. Mycoplasmal infections in other reptiles present primarily as pneumonia or arthritis.[47,48,52,91,92]

Experimental infection studies in gopher and desert tortoises suggest the following course of disease: (1) primary colonization of the upper respiratory tract with *Mycoplasma*; (2) host immune response to infection resulting in a reduction of *Mycoplasma* numbers and the development of clinical disease; and (3) progression to a chronic disease state where clinical signs and shedding of *Mycoplasma* occur intermittently. In chronically infected tortoises, it is typical for clinical signs to intensify and then abate cyclically.[45,75,94,96] Grooves extending ventrally from the nares, eroded nares, and depigmentation around the nares can be observed in tortoises that have repeatedly exhibited clinical signs (Fig. 72.13). Subclinical infections have also been documented; where the animal has a detectable serological response, histopathological lesions are present and *Mycoplasma* can sometimes be recovered on culture, but the tortoise does not exhibit overt disease.[45,85,94,96,97] Such tortoises could serve as a source of infection for naïve animals within the population or collection.

Decreased activity, irregular basking and burrowing behaviors, and reduced foraging have been documented in experimentally infected gopher and desert tortoises as well as a limited number of wild gopher tortoises.[58,98]

It is not certain which factors trigger the recrudescence of clinical signs in asymptomatic tortoises; however, environmental stressors have been shown to play a major role in mycoplasmal infections of other hosts.[44,63] Modeling of the impact of duration and time between recrudescent epizootic events suggested that the length of time between recrudescence events was a key component to minimizing adverse population impacts.[99] Anthropogenic factors such as habitat degradation, habitat destruction, and tortoise relocation, as well as climatic factors including drought or excessive rainfall, have all been suggested as potential influences that may result in increased morbidity and mortality in wild tortoises.[45,54,100] Increased tortoise densities, inappropriate temperature, and poor nutrition may all exacerbate mycoplasmosis in captive tortoises.

A specific antimycoplasmal antibody response develops and can be detected by 6 to 8 weeks after experimental infection.[67,68] The immune response generated may not be protective, however, and may in fact exacerbate the disease. In experimental studies, infected gopher tortoises that were challenged a second time with *M. agassizii* developed more severe clinical signs and had a more intense antibody response than from the initial infection.[45,94] This is consistent with the immunopathology associated with most mycoplasmal infections, where the host immune response is a key contributor to disease severity.[63] Studies evaluating the role of the immune response in the pathogenesis of this disease are difficult because very little is known about reptilian immunology and the reagents needed for such investigations are limited.

FIG 72.13 A wild gopher tortoise (*Gopherus polyphemus*) with severely eroded and depigmented nares. *Mycoplasma agassizii* was cultured from this individual.

Pathology. *Mycoplasma agassizii* adheres to the ciliated mucosal epithelium of the tortoise upper respiratory tract and causes severe disruption of the normal tissue architecture and function.[54,67,68,85,96] Gross, postmortem examination of infected animals may reveal no apparent clinical signs or a serous to mucopurulent nasal and ocular discharge, edematous and erythemic conjunctiva, and periocular and palpebral edema. Severely affected tortoises may have one or both nasal cavities completely obstructed with a thick, caseous discharge and varying degrees of nasal cavity erosion. Such animals may also have reduced coelomic fat or cachexia, thymus atrophy, hepatic hemosiderosis, and lymphocytic inflammation in the splenic sinusoids.[54,67,68,85,96] Histopathological lesions

VetBooks.ir

in the nasal cavity can also vary dramatically in severity and may include multifocal to focally extensive subepithelial lymphoid aggregates, a mixed inflammatory cell infiltrate consisting of heterophils, lymphocytes, plasma cells and macrophages, basal cell hyperplasia, mucous and olfactory epithelial metaplasia, and erosion of the ciliated epithelium.[54,67,68,85,96] Although *M. testudenium* can cause clinical signs of URTD, it does not appear to be as virulent as *M. agassizii* and the associated pathology and damage to the respiratory tract appears to be more focal and less severe.[45,101] In a study of 24 gopher tortoises, animals with URTD were more likely to have gram-negative bacteria isolated from their nasal cavity than tortoises without URTD, strongly suggesting that mycoplasmosis increases susceptibility to secondary infections.[96] This is consistent with other well-established mycoplasmal infections in mammalian and avian hosts.[63] Moribund tortoises with mycoplasmosis are often cachectic, have multisystemic disease, and death may be associated with secondary infectious, metabolic, or nutritional factors.[45,54,85,96]

For nonchelonian mycoplasmal infections of reptiles, pathology is primarily associated with the lower respiratory tract, joints, or sepsis-related multiorgan lesions. In naturally infected alligators, prominent findings included multifocal abscesses of the coccygeal and thoracic vertebrae, with degeneration of the spinal cord white matter, fibrosis, vertebral osteomalacia, and epaxial myofiber degeneration.[50,91] In lungs, airways, and small venules, a mixed inflammatory infiltrate of lymphocytes, plasma cells, and heterophils was present, typically extending into the adjacent connective tissue, which was often edematous with a similar inflammatory infiltrate. The bronchial epithelial lining was hyperplastic. Significant pericardial fluid and, in some cases, fibrinous adhesions of parietal and visceral pericardia were common, and the fibrin strands contained a mixed population of heterophils and lymphocytes.[91]

Although the etiological and clinical significance of mycoplasmosis has not been confirmed, tracheitis with concomitant pneumonia of suspected mycoplasma origin has been observed in snakes. Primary pathology attributed to *Mycoplasma* in snakes was proliferative lymphocytic tracheitis and pneumonia. Submucosal infiltrates consisted primarily of lymphocytes in the lungs and trachea, with heterophils seen in the trachea. Epithelial hyperplasia of airway mucosa with blunting or loss of cilia was observed in the respiratory tract, which is consistent with other respiratory mycoplasmal infections.[49,51]

Diagnostic testing and confirmation. Three diagnostic tests exist for the identification of *Mycoplasma* in reptiles: (1) direct mycoplasmal culture; (2) detection of mycoplasmal chromosomal DNA by polymerase chain reaction (PCR and qPCR); and (3) detection of antimycoplasma antibodies by enzyme-linked immunosorbent assay (ELISA). Each assay has strengths as well as limitations. The ELISA for tortoises has been extensively validated.[102] An ELISA is also available for *M. testudineum.*[101] ELISA tests for antibodies to other reptilian pathogens (*M. alligatoris*, *M. crocodylii*, *M. iguana*) have been developed, but these infections have not been widely studied so validation is limited.[46,103,104] Serological assays for other potential mycoplasmal pathogens of reptiles are not available. Therefore detailed information is provided here only for URTD diagnostics.

For URTD diagnosis, ELISA may not detect tortoises in the earliest stages of infection but is the most likely to detect clinically silent, intermittently shedding, and chronically infected animals. PCR/qPCR may detect animals in early stages of infection or those currently shedding *Mycoplasma*; however, false negative results can occur in chronically affected, intermittently shedding, or clinically asymptomatic animals or with inadequate sampling of nasal passages. Therefore optimal diagnostics include use of ELISA serology, culture, and PCR coupled with health assessment and observations for clinical signs, which may be intermittent or absent depending on the stage of infection.[45,102,105–107] These assays have been widely utilized for epidemiological surveys and for captive tortoise management; however, certain features of mycoplasmal infections in tortoises and other species create a diagnostic dilemma. For example, more than one *Mycoplasma* species can cause similar clinical disease, but exposure to these mycoplasmas is not necessarily detectable with the existing serological test. Further, individual strains of a given species may vary in virulence but have overlapping serology. Therefore diagnostic results must be interpreted cautiously and in the context of the clinical picture for each patient.

Either tortoise serum or plasma can be used for ELISA. Numerous sampling techniques can be used to collect specimens for PCR/culture, including swabs of choana(e) or nares, direct aspirates of a nasal discharge, or flushes of the nasal cavity. *Mycoplasma* preferentially colonizes the ventrolateral depression of the tortoise nasal cavity, and this area is difficult to access in a live animal. Nasal flushes can be performed with 0.5 to 5.0 mL sterile saline or sterile PBS (phosphate buffered saline) or using 0.5 to 1 mL sterile SP4 broth. If saline or PBS is used for the nasal flush, enrichment of the flush sample with 10% sterile bovine serum albumin, horse or fetal calf serum, SP4 medium, or glycerol before shipping is recommended. Unless the animal is exhibiting a significant nasal discharge, swabbing or even flushing the nasal cavity may be uninformative and result in false negative results. However, some recent studies have used oral swabs for PCR with similar to higher effectiveness than nasal lavages.[93,105,107] This method of collection may be less stressful and easier to perform, but the swab should be taken as close to the choanal opening as possible. It is important that swabs are protected in sterile transport medium, *Mycoplasma* SP4 medium, 10% sterile bovine serum albumin, or sterile glycerol before shipping, especially if cultural isolation is desired.

Elisa. Specific antibodies to *M. agassizii* in tortoise plasma are detected using an enzyme-linked immunosorbent assay, or ELISA with a sensitivity of 0.985 to 0.983, and a specificity of 0.999 to 1.0. A positive ELISA result has been positively correlated with the presence of histological lesions as well as the presence of clinical signs, especially a nasal discharge.[45,55,57,61,96,102,105,108] The ELISA was originally developed and validated for gopher and desert tortoises; however, there is evidence that the monoclonal antibodies utilized in the assay do recognize immunoglobulins from numerous other tortoise species. As with other serological assays, the ELISA can be performed on plasma or serum, and results are reported as a titer. A single positive result indicates that the animal has been exposed to *M. agassizii*, but it does not confirm that the animal was actively shedding at the time of sampling. Because it takes a minimum of 6 to 8 weeks postinfection for antibodies to reach a level that can be accurately detected by the assay, false negatives are more likely in the early stages of infection. The ELISA positive predictive value drops below 90% only at a seroprevalence of <9%, and the negative predictive value drops below 90% at a >85% seroprevalence, making the ELISA particularly useful for population studies.[109]

The current ELISA uses *M. agassizii* whole-cell lysate antigens in the analysis. The specificity of the assay is based on the affinity and avidity of antibodies produced by the tortoise in response to infection by *M. agassizii.* Because other *Mycoplasma* species have been documented to share immunogenic antigens, there is a potential for limited cross reactions to occur in any serological test. However, sera from >1000 wild gopher and desert tortoises with documented isolation of the two pathogens had relatively few serum samples that reacted to both *M. agassizii* and *M. testudineum.*[101,102,109] Importantly, those samples that did react with both *Mycoplasma* spp. were from tortoises in populations with documented presence of both pathogens supporting that cross reactions are unlikely. As new species of *Mycoplasma* are isolated from tortoises, validation and standardization of serological assays will be required. Therefore the current ELISA assays may miss infections by

VetBooks.ir

other *Mycoplasma* species. This demonstrates the importance of interpreting diagnostic results in the context of the individual patient. If a tortoise with clinical signs consistent with mycoplasmosis has a negative ELISA result but positive PCR, and the complete 16S rRNA gene is <97% identical to that of *M. agassizii,* then infection with other mycoplasmal species that do not cross-react with the current ELISA must be considered. The culture and PCR tests discussed below may help clarify the clinical picture in such an animal.

Western blots. Western blot banding patterns obtained using a single strain (*M. agassizii* PS6) have been interpreted as being able to distinguish between uninfected tortoises with natural antibodies and exposed tortoises with acquired antibodies.[100,110] However, studies in swine, poultry, and ruminants document extensive strain variability and the necessity to use multiple *Mycoplasma* strains as antigens in Western blots in order to avoid false negatives.[111–119] The importance for using multiple strains of *M. agassizii* in a Western blot was confirmed using sera from culture-positive gopher tortoises with histopathological evidence of URTD.[109] When using heterologous strains of *M. agassizii* as antigens in Western blot, approximately 25% of proven URTD-positive gopher tortoises had binding patterns similar to those reported by Hunter et al. as natural antibodies; [110] however, all sera had strong banding patterns when the homologous strain was used as antigen.[109,110] Thus, Western blot analysis using a single antigen (PS6) failed to detect gopher tortoises known to have URTD, whereas an ELISA using the PS6 strain as antigen was strain independent and reliably detected all infected tortoises. The need for multiple strains in Western blot analysis, but not in ELISA, is consistent with findings for other *Mycoplasma* species.[113,119] The concept of natural antibody must also be considered in light of new findings that identified immunobinding proteins in *Mycoplasma* species.[120,121] Similar to other well-known immunoglobulin-binding proteins such as Protein A, a new immunoglobulin-binding protein (Protein M) that binds with high affinity to all types of human and nonhuman immunoglobulins, has been identified in mycoplasmosis.[121] At least one other system has been described in which a *Mycoplasma* immunoglobulin-binding protein binds to IgG from a wide range of hosts and a second Ig protease then is able to cleave off the VH domain of the bound IgG.[120] Interestingly, an immunobinding/blocking protein homolog is present in *M. agassizii* (SMC19080.1, GI: 1174984488) and could confound interpretation of Western blots. Therefore Western blots are recommended only as a confirmatory test and only if either multiple strains or the homologous strain is used as antigen. Further, appropriate diluents should be added to the reagents to minimize nonspecific binding to the newly recognized immunoglobulin-binding proteins. A Western blot assay has been used to identify immunoreactive proteins of *M. crocodylii* but not for other mycoplasmas of reptile origin.[122]

Culture. *Mycoplasma* is extremely fastidious and require very specific medium and growth conditions. Therefore use of a laboratory with experience culturing this organism and established quality control procedures is essential. Tortoise mycoplasmas (*M. agassizii* and *M. testudineum)* must be cultivated at 30°C and grow slowly, requiring up to 6 weeks for primary isolation in many cases.[64–66] SP4 medium is used for culture and can be obtained from the laboratories that provide this service or large-scale manufacturers (Remel Laboratories, Lenexa, KS). Colonies on agar are small and can only be reliably seen by 50× magnification. There is a color change to broth medium, but caution should be taken if turbidity is observed, as this indicates bacterial or fungal contamination. In direct contrast, both *M. alligatoris* and *M. crocodylii* grow rapidly, producing visible colonies and color change to broth medium within 24 hours.[47,90] *Mycoplasma alligatoris* does not grow above 32°C, whereas *M. crocodlyii* has an optimal growth temperature of 37°C.[47,90] *Mycoplasma iguana* was first isolated on blood agar after 4 days but grows best on SP4 agar with an optimal growth at 37°C.[52]

PCR. Testing using PCR has many advantages for the diagnosis of mycoplasmosis, including high specificity and rapid detection. All current PCR assays target the 16S rRNA gene. A positive PCR provides direct proof of the presence of mycoplasmal genomic material at the time of sampling. Important considerations for diagnostic tests targeting the presence of the pathogen are that the microbial load may be decreased when clinical signs are absent and that inadequate sampling of the upper respiratory passages may lead to false-negative results. Although contamination of samples by other organisms will not generally interfere with the PCR test, swabs containing calcium alginate may inhibit the reaction and thus should not be used. The conventional PCR uses primers that amplify virtually the full ~1440 bp 16S rRNA gene.[61,64,102] Many reports suggest finding novel species based on sequence coverage of 15% to 60% of the gene; caution should be used unless the majority of the 16S rRNA gene sequence is obtained or a clinical isolate is available for confirmation of species differences. For *M. agassizii* and *M. testudineum,* restriction fragment length polymorphism (RFLP) analysis of the 1400 bp PCR product using AgeI and NciI yields a unique pattern for each species.[64] In the event that an aberrant pattern is observed, complete sequencing of both strands of the 16S rRNA gene using a minimum coverage of reads obtained from two primers is recommended. The nature of the qPCR assay targets shorter regions of genes. The qPCR protocols for tortoise *Mycoplasma* target specific regions of the 16S rRNA gene and have the advantage of providing a quantitative assessment of gene copies.[105,123] However, the amplicons cover only a small region of the gene and may not detect strains of the pathogen or closely related species that differ in genomic content in that target region; therefore specificity should be assessed stringently. For example, full sequence of the *M. agassizii* clinical isolate from an Indian star tortoise (*Geochelonia elegans;* GenBank KY212533) showed that virtually all of its sequence differences occurred in one variable region, which was included in the target for qPCR assays. Finally, molecular techniques do not provide clinical isolates for further testing, including determination of antimicrobial sensitivity. Combining either conventional or qPCR with culture would provide optimal pathogen detection.

Specific therapy. Although being one of the most extensively researched infectious chelonian diseases, antimicrobial treatment recommendations are largely empirically derived or based on information extrapolated from what is known about mycoplasmal infections in other species.[124–126] Limited studies are available to inform dosage and drug delivery in reptiles.[30,127–146] Further, all of the listed treatment protocols are considered extralabel use because none of these chemotherapeutic agents have been specifically licensed for reptiles.

Anecdotal reports of *Mycoplasma* clearance after treatment with various protocols exist; however, differentiation between clearance and subclinical infections can be exceedingly difficult and limitations of the diagnostic assays and sampling techniques add additional difficulty. In a recent study, even long-term oral therapy over 3 months failed to clear *Mycoplasma* from subclinical tortoises.[76] Chronically infected animals may remain asymptomatic for years before clinical signs recur. Further, antibody titers may decrease, and cultures may be negative because *Mycoplasma* numbers may be below the detectable limits of the assay or in such low numbers that they are difficult to recover by nasal flushing techniques. Captive tortoises as well as snakes with suspected mycoplasmosis should be isolated and treated with appropriate supportive care and antimicrobials to alleviate clinical signs and decrease the risk of disease transmission.

Mycoplasma lack a cell wall, and therefore antibiotics targeting cell wall development will be ineffective. Antibacterial classes typically used to treat mycoplasmal infections in numerous hosts include tetracyclines, fluoroquinolones, lincosamides, macrolides, and certain aminoglycosides.[125,147,148] Most pharmacokinetic studies have only been performed

VetBooks.ir

with a single-dose administration using intravenous, intramuscular, subcutaneous, rectal, or oral routes of administration. In chelonians, pharmacokinetics are available for enrofloxacin in gopher, Indian star, Hermann's (*Testudo hermanii*) tortoises, and loggerhead (*Caretta caretta*) sea turtles; for marbofloxacin and danafloxacin in loggerhead sea turtles; for clarithromycin and tulathromycin in desert tortoises; and for oxytetracycline in loggerhead sea turtles.[129,134–137,139,140,144,149,150] For nonchelonian reptiles, pharmacokinetic studies have been performed for azithromycin in ball pythons; for enroflaxacin in alligators, crocodiles, Burmese pythons, bearded dragons, and green iguanas; for marbofloxacin in ball pythons and crocodiles; and for tetracycline and oxytetracycline in alligators.[131,138,141,145,151–156] Although limited minimum inhibitory concentration data are available for mycoplasmas of reptile origin, minimum inhibitory concentrations are available for *Mycoplasma* originating from other species using macrolide, tetracycline, and quinolone classes of antibiotics.[125,126,143,157] Tetracyclines should be considered the first-line drug while pending sensitivity results. Advanced drugs like enrofloxacin and clarithromycin have frequently and inappropriately been advocated, and resistance is likely to become an increasing issue. In one study, oral clarithromycin treatment for 3 months failed to clear *Mycoplasma* from all but one subclinical animal.[76] The long-lasting macrolide tulathromycin may provide an additional treatment option.[134] New delivery methods such as the osmotic pump may provide an alternative route of antibiotic administration for long-term treatment.[158,159] Given the immunopathology associated with URTD, topical antibiotic-corticosteroid combinations are often used in conjunction with oral or parenteral antibiotics to minimize the local inflammatory response.[45,133,142,158,160,161] Providing necessary supportive care in terms of hydration and nutritional support, as well as maintaining the tortoise in the upper ranges of the preferred optimal temperature zone (POTZ) for that species, will all improve the animal's response to treatment.

Table 72.1 lists the various treatment regimens for antimicrobials with efficacy against mycoplasmas that have been reported in reptiles (see Chapter 127 for more details).[45,127,128,132,133,146,158,161] With minor clinical disease, oral medications are generally initially used and topical therapies are added as necessary. Animals with severe disease may have reduced enteric absorption of drugs and should be administered parenteral medications. Topical ophthalmic drops or ointments containing antibiotics such as tetracycline, oxytetracycline, gentamicin, or ciprofloxacin applied to the eyes may minimize ocular signs and provide more rapid relief. Therapeutic nasal flushes using gentamicin/betamethasone, gentamicin/DMSO/saline, and enrofloxacin/saline combinations or nebulization using an enrofloxacin/saline solution have all been described.[45,128,132,142,146,158] A retrograde flush technique has been reported in tortoises that involves placing the animal in dorsal recumbency, stabilizing the head, opening the beak by applying continuous pressure to the chin, and flooding the choanae with the gentamicin/betamethasone solution.[45,142] The tongue is then used to expel the fluid by applying digital pressure to the intermandibular area, forcing the tongue against the choanae. Chemical restraint may or may not be needed to perform this technique. Alternatively, the solution can be applied directly into the external nares. Some clinicians anecdotally report that the corticosteroid-antibiotic nasal flushes performed every 48 to 72 hours may reduce recurrence of clinical disease; however, long-term oral treatment with clarithromycin did not eliminate shedding of *Mycoplasma* from subclinical tortoises.[45,76]

Prognosis. Inadequate data on reptiles other than tortoises precludes rigorous prognoses, but observed clinical pneumonia in snakes suggests that if left untreated, adverse outcomes might be expected.[49,51] Acute mortality has been reported but is exceedingly rare except for alligators, where the septic disease was lethal.[91] Acute arthritis has been observed in farmed crocodiles, with 10% morbidity but low mortality.[48] Mortality was more commonly observed in chelonian hatchlings during the initial transmission studies.[94] Some tortoises may actually clear the infection, although this is not believed to occur very often.[68] Mycoplasmal infections involving other hosts usually are not cleared; however, numbers of *Mycoplasma* may be significantly reduced during chronic phases of infection when clinical signs are not exhibited.[44,63] Most tortoises develop chronic disease with intermittent expression of clinical signs. The bacteria persist in the nasal cavity and damage the mucosal tissue of the upper respiratory tract, resulting in increased susceptibility to secondary infections.[45,85,94,96] In cases of chronic mycoplasmosis, mortality is presumed to be due to severe debilitation and multisystemic disease.[45,85,94,96] Although not definitive, current data strongly suggest that the long-term effects of this disease may play a role in tortoise die-offs in selected populations, may shorten the longevity of individual tortoises, and may lower the reproductive potential of female tortoises, particularly if animals are sick during the reproductive season (Rostal et al Proc Desert Tortoise Council Symposium, 2001, pp 81–82, available at: https://deserttortoise.org/ocr_DTCdocs/2000-2001DTCProceedings-OCR.pdf).[94] This could result in profound impacts on the long-term survival of rare species.

The species or strain of *Mycoplasma* present in an individual or population is an important consideration when attempting to assess prognosis and develop appropriate management strategies. *Mycoplasma* in other hosts are known to vary in virulence, and preliminary evidence suggests that this occurs in reptiles as well.[67,94,162,163] Early transmission studies showed that different strains of *M. agassizii* differed in terms of the number of organisms required to colonize and cause disease.[67,94] Unfortunately, knowledge of the virulence potential is available for only a limited number of isolates. Therefore developing strategies to minimize risk from *Mycoplasma* in general is probably the safest approach. Actions taken will depend on the ultimate disposition of the animals and the risk to cohorts.

Prevention. Once a reptile has been diagnosed with mycoplasmosis, it is safest to consider that animal as persistently infected and a potential source of infection for other animals in the collection or population. In captivity, individual animals with confirmed mycoplasmosis should be housed independently from others, with efforts made to minimize the chance of cross-contamination using appropriate disinfection and sanitation protocols. Intermittent clinical disease can be treated periodically as discussed previously. Although the impact of this disease on overall longevity is unknown, many infected reptiles have continued to live and thrive for over a decade since their original exposure. However, the full impact of chronic disease in a long-lived species may take decades to become apparent.

Fomite transmission has been documented for other mycoplasmal infections.[164,165] Fomite transmission, particularly if equipment is contaminated with nasal exudates, should be considered possible in reptiles as well. Routine disinfection of all equipment using a 3% to 5% bleach solution or other appropriate commercial disinfectants will minimize the chance of cross-contamination.

Efforts should be made to separate eggs and hatchlings, as the hatchlings may be more likely to develop acute, fulminant disease. Further, keeping hatchlings separate may result in a noninfected group of animals. Managing a large group of infected reptiles will be significantly more challenging, as the presence of clinically ill animals within the same enclosure may exacerbate disease in the nonclinical animals, because those exhibiting a nasal discharge are more likely to transmit the organism. Empirical experience in the management of URTD outbreaks in group-housed tortoises, as well as standard infection control practices for other infectious diseases, suggest that the most effective management strategy is to separate the clinically ill animals for treatment. Isolation of ill reptiles for more intensive monitoring and treatment may help contain flare-ups. Ensuring adequate husbandry practices to minimize

VetBooks.ir

TABLE 72.1 Drugs Commonly Used to Treat Mycoplasmosis in Reptiles

Drug Class	Dosage[127,132,142,146,158,189]	Notes
Aminoglycosides (bacteriostatic)		Aminoglycosides are potentially nephrotoxic, maintain hydration
Gentamicin	10–20 mg/15 mL saline solution: nebulize for 30 min q12h[133,142]	Chelonians
	40 mg/1 mL DMSO/8 mL saline solution: use for nebulization[132,142]	
Gentamicin/betamethasone ophthalmic drops	1–2 drops to eyes, q12–24h[133]	Chelonians
	Drops applied to external nares q12–24h[133]	
	Reverse nasal flush q48–72h: Drops applied to choanae and flushed-out nares as described in text[45,133,142]	
Gentamicin	1.75 mg/kg IM q4d[189]	American alligator
	10 mg/kg IM q2d[189]	Painted turtle
	6 mg/kg IM q25d[189,190]	Red-eared terrapin
	2.5 mg/kg IM followed by 1.5 mg/kg q96h[191]	Python
Tobramycin	10 mg/kg IM q24–24h[189]	Chelonians
	2.5 mg/kg IM q24–72h[189]	Most species
Tylosin	5 mg/kg/day IM[189]	Most species
Fluoroquinolones (bacteriocidal)		
Danofloxacin	6 mg/kg IM/SC q48h	Loggerhead sea turtles[136]
Enrofloxacin: IM injection likely causes necrosis, so using a single IM followed by oral dosing should be considered[189]	5–10 mg/kg IM q12–48h[132,138,140,141,145,150,152,156,157,189,192]	Most species, including chelonians,[140,150,192] crocodylia,[138,152] bearded dragons,[141] iguanas,[193] and snakes
Enrofloxacin	Nasal flush: 50 mg per 250 mL sterile water, use 1–3 mL for nasal flush per nostril q24–48h	Use with oral or parenteral antibiotics until no nasal discharge[146,158,161]
Marbofloxacin	2–10 mg/kg PO/IM/IV q24–48h[135,137,151,154,194,195]	Loggerhead sea turtles[135,137]
		Chinese soft-shelled turtle[195]
		Ball pythons[151,194]
		Freshwater crocodiles[154]
Macrolides/Azalide (bacteriostatic)		
Azithromycin	10 mg/kg PO q5d[131,158,189,196]	Ball python[131,196]
Clarithromycin	15 mg/kg PO q48–72h[144,158,189]	Desert tortoises[133,144,189,197]
	20 mg/kg PO q48–72h for 90 days[76]	Forsten's tortoise, Sulawesi forest turtles[76]
Tylosin	5 mg/kg IM q24h for 10–60d[132,133,189]	
Tetracyclines (bacteriostatic)		
Oxytetracycline	5–10 mg/kg IM q24h[132,133]	Tortoises
Doxycycline	5–10 mg/kg q24h PO[189]	Most species
	25–50 mg/kg IM[142]	Most species
	50 mg/kg IM, then 25 mg/kg q72h[149,189]	Hermann's tortoises[149]

Please note that the routine use of broad-spectrum antimicrobials like fluoroquinolones should be avoided in favor of first-line drugs like tetracyclines.

stress within the colony may also help decrease the frequency of clinical disease expression.

Determining the disposition of seropositive or culture/PCR-positive wild tortoises, particularly those that end up in rehabilitation centers, is problematic. There is presently inadequate scientific data to provide definitive guidelines for such animals. In some cases, state and federal guidelines exist that specify protocols for rehabilitation and repatriation of these animals. Often tortoises in rehabilitation facilities are exposed to other chelonians either directly by combined housing or indirectly in common grazing areas. Such practices could potentially expose tortoises to a myriad of pathogens and parasites that these animals would not normally encounter in the wild. Although *Mycoplasma* does not survive long outside the host unless protected in organic material, there are numerous other pathogens, viruses in particular, that persist for extended periods in the environment. Rehabilitated animals that are exposed to such circumstances pose a serious threat to wild populations when they are released.

Potential options that have been considered for the repatriation of tortoises with mycoplasmosis include the release of tortoises back to the exact site of origin; relocation to recipient populations with high prevalence of infection; and with resident tortoises that already express clinical signs of URTD, admission into captive breeding programs, adoption as pets, or euthanasia for animals showing severe morbidity.[45,106] Unauthorized relocation of URTD-positive gopher tortoises into a naïve population with subsequent mortality events has been documented.[55,61] Each of these options has inherent problems and no single solution is applicable for every situation. The unique circumstances of each population should be considered. The ultimate disposition of the animal will

depend on the rarity of the species, the value of that animal to the population, the potential risk that animal poses to the population, and any existing regulations pertaining to that species. Certainly, decision making for such tortoises should be flexible and change as new scientific information becomes available.

Infectious Rhinitis (Excluding Mycoplasmosis). Discharges can range from clear serous discharge with bubbles to thick and mucoid (see Fig. 72.7A). Due to their position anterior to the oropharynx, stomatitis and pneumonia might also result in nasal discharge. It is important to distinguish nasal discharge from gastric reflux, as these have different causes and treatments. The long-nosed snakes (*Rhinocheilus* spp.) and dwarf boids (*Tropidophis* spp.) have been known to squirt blood from their nostrils as part of a defense mechanism (autohemorrhage); however, epistaxis is uncommon and should always be considered an abnormality that requires further investigation (Fig. 72.14A).[166] Metastatic mineralization of the nasal vasculature has been the cause of bleeds in green iguanas. Iatrogenic hypervitaminosis D_3 and hypercalcemia can result in mineralization of blood vessels, making them rigid and prone to rupture.

In addition to mycoplasmosis (mentioned previously), other agents identified in association with rhinitis include herpesviruses, ranaviruses, adenoviruses, reoviruses, intranuclear coccidiosis, *Pasteurella testudinis,* iridovirus, and chlamydiosis.[84–89]

Fungal infection and/or chronic upper respiratory tract disease may cause erosion or depigmentation of the nares (see Figs. 72.13 and 72.15C). Obstructive rhinitis usually occurs in conjunction with ulcerative stomatitis and/or bronchopneumonia and can be either uni- or bilateral, partial, or complete. The obstruction is most often caused by exudates, caseous material, and/or mucosal inflammation. This disease complex caused high mortality rates in hatchling and juvenile green turtles (*Chelonia mydas*) and loggerheads due to the inability to breathe and feed. The bacteria *Vibrio alginolyticus*, *Aeromonas hydrophila*, and *Flavobacterium* sp. were repeatedly isolated from cases of ulcerative stomatitis and obstructive rhinitis.[167]

Radiography and particularly CT can be useful for evaluating the nasal cavity, and sample collection for histopathology (or cytology) and microbiology cannot be overemphasized. Treatment should be based upon demonstration of a host pathological response and the causative agent. The routine use of advanced, broad-spectrum antimicrobials (e.g., fluoroquinolones, third- or fourth-generation cephalosporins) is not recommended.

Noninfectious Rhinitis. Noninfectious causes of nasal discharge include foreign bodies (e.g., grass awns or foxtails), congenital orofacial abnormalities (e.g., oronasal fistulae), or inhalant irritants. Some herbivorous, marine, varanid, and iguanid lizards can at times be seen with white, sometimes dried discharge surrounding their nostrils. This can be normal physiological excretion of sodium and potassium chloride crystals, produced by their nasal salt glands, but should, however, be differentiated from an upper respiratory or fungal infection.[17,18]

Complete or partial obstruction of the nare(s) can be attributed to various processes (Fig. 72.15B and D and Fig. 72.16C). Rhinoliths are seen infrequently, even in burrowing species where dirt could be an obvious nidus. However, on occasion, dysecdysis (retained shed) can occur within the nares, uni- or bilaterally (see Fig. 72.16B). This does not usually create a problem, unless allowed to accumulate over several sheds, causing obstructions. It is important to recognize that this may be an indication of an underlying condition and possibly caused by inappropriate husbandry. The retained shed usually dislodges on its own accord; however, it can be gently manipulated out, sometimes aided by moist cotton buds. If solidified within the cavity, a small hook

instrument or forceps can be used, but care should be taken not to traumatize the surrounding tissues. No further local treatment should be necessary.

Foreign bodies or discharge can easily lodge in the choanal slit (see Fig. 72.14B). Not infrequently will lizards present with abnormal mouth movements or mucoid discharge from mouth and/or nare(s). Bearded dragons appear overrepresented, and most often ingesta is the culprit and detected on clinical examination of the oral cavity. Among others, inflammation, petechiae, and icteric changes may also be noted on clinical examination of the choanal region (Fig. 72.17).

Sea turtles have been described with both a plastic straw and a fork occupying this space.[168,169] Removal was done in situ with pliers using forceful retraction and cleaned with a betadine solution before immediate release. It is believed that a fork was ingested, and thereafter regurgitation resulted in the fork entering the choana and lodging within the nasal turbinates. This highlights the importance of a thorough clinical examination and the use of appropriate imaging modalities (radiography, MRI, CT). It is also a site for fish-hook trauma in aquatic and semiaquatic species. Endoscopic evaluation and retrieval may be useful in larger reptiles. Rhinoscopy is invaluable in the investigation of the narrow nasal passage and cavity.

Rostral trauma, as a result of excessive rubbing or striking against enclosure sides, is not uncommon in captive amphibians and reptiles (see Fig. 72.16A). Fast-moving and fractious animals are at greater risk of injury, hence water dragons (*Physignathus* sp.), bearded dragons (*Pogona* sp.), and terrestrial snakes appear overrepresented. Mature male snakes housed near mature female snakes during the breeding season will commonly damage the rostral area by excessive attempts to "push out" of their enclosure, presumably in response to pheromones. Enclosure overcrowding, conspecific mismatch causing flight behavior, inappropriate caging, and inadequate furniture/enclosure design are primary causes.

The injuries span from superficial, self-limiting abrasions to damage so extensive that the external nares suffer long-term disfigurement and/or physiological consequences. Damage to the rostral area often leads to disruption of air movement through the nares, which results in open-mouth breathing. This results in drying of the oral mucosa, making it more susceptible to secondary infections, which may lead to nasal obstruction, stomatitis, and osteomyelitis, with loss of or even fractures of the maxillary bone.[170] Although challenging, due to the anatomical

restrictions surrounding the rhinarium, repairing the tissues to allow patency of the nares is critical to success (see Chapter 93). Inability to create nasal patency may result in the animal becoming an obligate mouth breather. Some affected animals may become anorectic, presumably due to interference with olfaction and may need nutritional support. Once lesions are established they should be treated immediately and aggressively. Daily to twice-daily flushing using topical antiseptics is essential (e.g., dilute chlorhexidine or betadine or saline-containing antimicrobials). Topical ointments may be considered (e.g., Manuka honey, silver sulfadiazine, antibiotic ointments) and if necessary adjunct systemic antibiotic therapy; however, these are no substitutes for accurate surgical debridement and reconstruction. Stress to the animal must be considered when determining the frequency of these treatments.

Prevention, or limitation, of rostral trauma can often be accomplished by husbandry changes, either directly, relating to the choice of specimens housed together (i.e., quantity, gender, age, size), or in enclosure design (i.e., adequate and species-appropriate furniture, removal of materials such as metal screens or "invisible" glass barriers). Although prohibited

in most countries, feeding live prey can also result in significant rostral trauma, as reptiles, snakes especially, will repeatedly strike hard/rough surfaces before apprehending prey.

Laryngitis and Pharyngitis

Laryngeal swelling and laryngitis are not uncommon; however, they usually occur in conjunction with other clinical signs (Fig. 72.18). A pharyngitis/laryngitis/conjunctivitis syndrome has recently been described in Australian farmed saltwater crocodiles (*Crocodylus porosus*), primarily hatchlings and juveniles.[171,172] In severe lesions there were frequently mixed gram-negative and -positive bacteria, as well as occasional hyphae in the necrotic exudates. PCR detected (a 55% prevalence of) *Chlamydia* spp. and (of these, 81% also harbored) a concurrent herpesvirus infection. There was a poor response to trialed treatments, with further research needed to identify the specific causative agent(s) and etiology. Crocodiles were prone to starvation and susceptible to laryngeal obstruction by fibrinous exudate due to their anatomical features (including the gular seal and their inability to cough). High mortality rates were common.[171]

Multifocal necrotizing ulcerative pharyngitis, with concurrent extensive tracheitis, pneumonia, and esophagitis, was seen in a gopher tortoise (*Gopherus polyphemus*). On transmission electron microscopy, intracytoplasmic viral particles were morphologically resembling an *Iridovirus.*[89] A similar respiratory syndrome involving pharyngitis, sinusitis, stomatitis, tracheitis, and a proliferative interstitial pneumonia with caseous material in the choana in ball pythons (*Python regius*) has been attributed to a novel *Nidovirus.*[173]

Rhabdias spp., nematode lungworms with a direct life cycle, are a common cause of respiratory infections in captive anurans. Eggs or first-stage larvae may sometimes be detected in oropharyngeal mucus. Several trematode species have been found in the oropharynx of frogs and toads, although clinical infections rarely arise from these infections.[174]

Myiasis is well known in wild amphibians (toads, frogs, salamanders) where the larva of two fly species, *Bufolucilia,* parasitize the nasal passages and cause extensive destruction of the mucosa, often leading to fatality.[175] Pharyngeal myiasis with the sarcophagid flesh fly larvae (Diptera) has been reported in two common ameivas (*Ameiva chrysolaema*).[176] And larval ascarids (presumed *Hexametra* sp.) has caused severe purulent, abscess-forming pharyngitis in the green-striped tree dragon (*Japalura splendida*) concurrently infected with multiple viruses.[177]

Pharyngeal and Submandibular Edema and Cellulitis

Swelling of the mandible can become so extensive, it interferes with normal breathing and swallowing mechanisms (Fig. 72.19A and B).

FIG 72.18 Laryngeal disease in two boa constrictors (*Boa constrictor*). (A) Laryngeal swelling and (B) bacterial laryngitis with generalized stomatitis. (Courtesy of Stephen J. Divers.)

Pharyngeal edema has been associated with renal disease in green iguanas. It is not uncommon due to hypoproteinemia, secondary to protein-losing nephropathy.[178] It is relevant to note that a presenting complaint may be dysphagia due to laryngeal/pharyngeal extra-luminal compression. Edema of the pharyngeal submucosa in combination with nasal mucosa ulceration, hepatic necrosis, and severe necrotizing inflammation was documented in green pythons (*Morelia* [*Chondropython*] *viridis*) as a result of ranavirus infection.[179]

Some Old World chameleons have an accessory lung lobe projecting from the anterior trachea. It can appear as a swelling of the ventral cervical region if it becomes filled with fluids, parasites, or inflammatory exudates. Its function is not fully understood.

Cervical Aneurysm

Dissecting aneurysms, or pseudoaneurysms, arising from the internal carotid artery or the aorta are not uncommon in adult bearded dragons but have also been reported in a green iguana and Burmese python (see Fig. 72.19C).[180] The clinical presentation in these cases was a large unilateral fluctuant to firm swelling on the dorsolateral neck or dorsal to the temporal muscles. Affected animals behave and forage normally unless the structure becomes a physical encumbrance. Aspiration yields whole blood and immediately refills after draining. In chronic cases, the blood may coagulate and cannot be aspirated. Doppler ultrasonography, radiography, CT, and MRI have been performed in preparation for surgical treatment.[181] Surgical removal is extremely challenging, but one successful surgical case has been anecdotally reported (Barten et al, Proc ARAV, 2006, pp 43–44). The etiology of the syndrome is unknown; trauma, hypertension, or genetic predisposition are possible.

Laryngeal Paralysis

A laryngeal paralysis-like condition was observed in a loggerhead sea turtle.[182] Stertorous upper airway sounds were caused by a partial airway obstruction due to unilateral laryngeal paralysis—similar to that seen in dogs. MRI, CT, and electromyography revealed abnormalities of the

VetBooks.ir

abductor arytenoideae or dilator laryngis muscle.[19,182,183] Hepatic and muscle biopsies were collected for histological and toxicological assessment, which showed unilateral myofiber atrophy as the predominant histological finding. The etiology was unknown, however, but suspected to be related to denervation atrophy. Iatrogenic cause from topical lidocaine to the glottis could not be excluded, though no other reports of this adverse effect exists (to the authors' knowledge).

Neoplasia

Primary neoplasms do not commonly originate from the ear, nose, or throat region of reptiles or amphibians. As with other swellings or growths, they should be systematically approached with aspiration cytology or, better still, biopsy histopathology before considering the most appropriate medical and/or surgical plan. Neoplasms are more frequently encountered in snakes, followed by lizards, chelonians, and crocodilians.[184,185] Lymphoma (with secondary infection) was diagnosed in the cranial cervical area of a green iguana and was diagnosed through histology and microbiology. Successful remission was achieved with a multimodal radiation and chemotherapy.[186] An incisional biopsy of a mass in the caudoventral pharyngeal region of a Madagascar ground boa (*Boa madagascariensis*) was confirmed as a squamous cell carcinoma. CT and MRI was performed to evaluate tumor invasion and planning for radiation therapy; however, therapy resistance was evident and the snake euthanized.[187] Thyroid adenoma in a green iguana presented as a ventral cervical mass and was successfully removed.[188]

Neoplasms originating from the nasal epithelium/mucosa are rare. One report of a well-differentiated esthesioneuroepithelioma of the olfactory epithelium (olfactory neuroblastoma) with involvement of the vomeronasal organ (Jacobson's organ) was diagnosed on histology in a blue-tongued skink (*Tiliqua scincoides*) (Zwart et al, Proc EAZWV and EWDA, 2002, pp 81–84). However, growths originating in adjacent organ systems can impede on the structures of the ear, nose (see Fig. 72.15D), and throat as seen with fibropapillomas in sea turtles (see Fig. 72.16C).
